Contrast agents are not used for most diagnostic ultrasound examinations. Because ultrasound relies on the detection of sound waves reflected from tissue interfaces, gases can create prominent acoustic interfaces near body tissues and can be adapted for use as contrast agents. Microbubbles containing air or other gases that are introduced into the bloodstream, act by increasing the ultrasound signal reflected from the vessel contents or from the structures fed by the vessels. Ultrasound contrast agents relying on microbubbles may be described as (a) encapsulated microbubbles, (b) gaseous liposomes, or (c) colloidal suspensions and emulsions. These agents allow visualization of small vessels, identification of tumor vascularity, improved contrast visualization of solid organs, and improved visualization of heart chambers and vascular grafts. Ultrasound contrast agents are generally very safe. They are designed so that no large bubbles form in the body (95% or more are $<10 \mu\text{m}$), and they have relatively short life spans before breaking down and dissipating. Microbubble decomposition occurs during passage through the heart and lungs and limits the time of beneficial imaging enhancement. Recent warnings regarding severe cardiopulmonary reactions have led to a change in the label for ultrasound microspheres.⁵¹

Perflutren (Protein-Type A Microspheres—Optison or Lipid Microspheres—Definity). Perflutren (also known as octafluoropropane) is a volatile gas that efficiently reflects sound waves. This gas is encapsulated as a protein or lipid microsphere that is generated when a solution of protein or lipids is agitated with the gas immediately prior to use. The milky white suspension of microspheres must be injected shortly after activation for maximal contrast enhancement. Protein shells consist primarily of human albumin associated with small amounts of *N*-acetyltryptophan and caprylic acid. Lipid shells consist of a phospholipid mixture, one of which is a polyethylene glycol phospholipid. Perflutren microspheres are indicated in suboptimal echocardiograms to improve the delineation of left ventricular borders.

Perflutren

REVIEW QUESTIONS

1. Describe two methods of radioactive decay that lack the production of charged nuclear particles. Why are such decay processes desirable for producing diagnostic images?
2. A physician requests a ventilation scan and a perfusion scan for a patient with a suspected pulmonary embolism. What radiopharmaceuticals will be used for this procedure and how do they localize in the region of interest?

3. What are the properties of the radioisotopes used in a dual isotope stress test?
4. A production lot of F-18 FDG is calibrated at 50 mCi/mL at 6 AM. What is the activity per milliliter by 10:30 AM later the same day?
5. What are the properties associated with x-ray, MRI, or ultrasound contrast agents that provide each class with the desirable characteristics for producing diagnostic images?

Central Nervous System Depressants

SHENQUAN LIU

CHAPTER OVERVIEW

Although the brain is undoubtedly the most wondrously complex organ, it is possible to distill the way it works into two opposing forces; excitation and inhibition (depressing). Central nervous system (CNS) depressants are drugs that can be used to slow down or “depress” the functions of the CNS. Although many agents have the capacity to depress the function of the CNS, CNS depressants discussed in this chapter include only anxiolytics, sedative–hypnotics, and antipsychotics.

There is some overlap between the first two groups. They often have several structural features in common and likewise often share at least one mode of action, positive modulation of the action of γ -aminobutyric acid (GABA) at GABA_A receptor complex. The list of anxiolytic, sedative, and hypnotic drugs is a short one—benzodiazepines, Z-drugs, barbiturates, and a miscellaneous group.

Antipsychotic drugs—previously known as *neuroleptic drugs*, *antischizophrenic drugs*, or *major tranquilizers*—are used in the symptomatic treatment of thought disorders (psychoses), most notably the schizophrenias. Antipsychotics are grouped into typical and atypical categories. Both categories share a common feature, a dopamine (DA)-like structure, often hydrophobically substituted. This feature can be related to the most commonly cited action of these agents, competitive antagonism of DA at D₂ or occasionally D₃ or D₄ receptors in the limbic system. The fundamental differences between typical and atypical antipsychotics are that the atypical agents are (a) less prone to produce extrapyramidal symptoms (EPS), because they are less able to block striatal D₂ receptors vis-à-vis limbic D₂ and D₃ receptors, and (b) more active against negative symptoms (social withdrawal, apathy, anhedonia).

ANXIOLYTIC, SEDATIVE, AND HYPNOTIC AGENTS

In addition to benzodiazepines, barbiturates, and a miscellaneous group, many drugs belonging to other pharmacological classes may possess one or more of the anxiolytic, sedative, and hypnotic activities. An arbitrary classification of these agents is as follows:

1. GABA_A receptor modulators

- Benzodiazepines are highly effective anxiolytic and hypnotic agents (e.g., diazepam, chlordiazepoxide, prazepam, clorazepate, oxazepam, alprazolam, flur-

azepam, lorazepam, triazolam, temazepam, estazolam, and quazepam). They bind to benzodiazepine-binding sites on GABA_A receptor (also known as benzodiazepine receptor [BzR]). They are sometimes called benzodiazepine receptor agonists (BzRAs).

- Nonbenzodiazepine hypnotics (Z-drugs): Imidazopyridine (zolpidem), pyrazolopyrimidine (zaleplon), and cyclopyrrolone (zopiclone and its [S]-[+]-enantiomer eszopiclone).
 - Barbiturates including amobarbital, aprobarbital, butobarbital, pentobarbital, phenobarbital, and secobarbital are largely obsolete and superseded by benzodiazepines. Their use is now confined to anesthesia and treatment of epilepsy.
 - General anesthetics and ethanol.
2. Melatonin-1 receptor (MT₁) agonists. A new drug in this area is ramelteon (Rozerem).¹ Currently, 10 Food and Drug Administration (FDA)-approved drugs for insomnia include nine BzRAs (five benzodiazepines, four nonbenzodiazepines) and ramelteon.
 3. Atypical azaspirodecanediones: Buspirone is a partial 5-HT_{1A} receptor agonist and an anxiolytic. It is less sedative and has less abuse potential.
 4. Miscellaneous drugs such as chloral hydrate, meprobamate, and glutethimide are no longer recommended, but occasionally used.
 5. Antipsychotics and anticonvulsants. It has been proposed that DA has a facilitative and active role in the sleep–wakefulness cycle. Waking appears to be a state maintained by D₂ receptor activation, whereas blocking D₂ receptor appears to cause sedation.
 6. Antidepressants: Many antidepressants cause sedation, of which trazodone, doxepin, and mirtazapine have been shown to be effective in the treatment of insomnia in patients with depression. Several selective serotonin reuptake inhibitors (SSRIs), including escitalopram, fluoxetine, fluvoxamine, paroxetine, and sertraline, became the first-line therapy for some anxiety disorders in 1990s because they are not as addictive as benzodiazepines.
 7. Sedative H₁-antihistamines: diphenhydramine and doxylamine:

Diphenhydramine is sometimes used as sleeping pills, particularly for wakeful children. It is proposed that histamine may have an involvement in wakefulness and rapid eye movement (REM) sleep. Histamine-related functions in the CNS are regulated at postsynaptic sites by both H₁ and H₂ receptors, whereas the H₃ receptors appear to be a presynaptic autoreceptor regulating the

- synthesis and release of histamine. The H₁ receptor agonists and the H₃ receptor antagonists increase wakefulness, whereas the H₁ receptor antagonists and H₃ receptor agonists have the opposite effect. Another example of H₁-antihistamines is doxylamine.
8. β -Adrenoceptor antagonists (e.g., propranolol) are sometimes used by actors and musicians to reduce the symptoms of stage fright, but their use by snooker players to minimize tremor is banned as unsportsmanlike.
 9. New areas explored for sleep-promoting agents:
 - Adenosine-2A receptor (A_{2A}) agonists (adenosine is a possible endogenous sleep-producing agent).
 - Linoleamide and 9,10-octadecenoamide are possible endogenous sleep-producing agents and are positive modulators of GABA_A receptors.²
 - Anandamide is an endogenous cannabinoid that might be used as a lead to search for new hypnotics.

The properties and side effects of FDA-approved hypnotics and commonly used but not FDA-approved hypnotics are reviewed.^{3,4} Older sedative-hypnotic drugs depress the CNS in a dose-dependent manner, progressively producing calming or drowsiness (sedation), sleep, unconsciousness, surgical anesthesia, coma, and eventually death from respiratory and cardiovascular depression. Although many factors influence the pharmacokinetic profile of sedatives and hypnotics, because most of them are in the nonionized form at physiological pH, their high lipophilicity is an important factor for following properties. (a) Most of them are absorbed well from the gastrointestinal (GI) tract, with good distribution to the brain. This property is responsible for the rapid onset of CNS effects of triazolam, thiopental, and newer hypnotics. (b) Many sedative-hypnotics cross the placental barrier during pregnancy. (c) They are also detectable in breast milk. (d) Some drugs with highest lipophilicity have short duration of action because of their redistribution. (e) Most drugs in this class are highly protein bound. (f) Metabolism to more water-soluble metabolites is necessary for their clearance from the body. Thus, the primary means of elimination of the benzodiazepines is metabolism, and most of them are extensively metabolized. Consequently, their duration of action depends mainly on the rate of metabolism and if their metabolites are active. Benzodiazepines are the most important drugs in both groups; therefore, the two groups are discussed together in the first section.

GABA_A Receptors, Benzodiazepines, and Related Compounds

GABA system (deficiency of GABA activity in CNS) is important in the pathophysiology of anxiety and insomnia. GABA is the most common and major inhibitory neurotransmitter (NT) in the brain and it exerts its rapid inhibitory action mostly through GABA receptors. It is known to activate two types of receptors, the ionotropic GABA_A and GABA_C receptors and the metabotropic GABA_B receptor. GABA_A receptor is the target for many anxiolytics and sedative-hypnotic agents including benzodiazepines, barbiturates, zolpidem, zaleplon, eszopiclone, steroids, anticonvulsive agents, and many other drugs that bind to different binding sites of the GABA_A receptors in neuronal membranes in the CNS.^{5,6} It is a ligand-gated chloride ion channel. Upon activation, Cl⁻ influx is increased and the membrane becomes hyperpolarized, resulting in neuronal inhibition.

GABA_A receptor exists as heteropentameric transmembrane subunits arranged around a central chloride ion (Cl⁻) channel. The five polypeptide subunits (each subunit has an extracellular N-terminal domain, four membrane-spanning domains, and an intracellular loop) that together make up the structure of GABA_A receptors come from the subunit families α , β , γ , δ , ϵ , π , ρ , and ξ . There are six isoforms of the α -polypeptide (α_1 - α_6), four of the β with two splice variants, and three of the γ with two variants. Most receptors consist of α , β , and γ combinations. Of these, α_1 , β_2 , and γ_2 are most common. The most common pentameric GABA receptor combination includes two α_1 , two β_2 , and one γ_2 subunit. Other highly expressed combinations are α_2 , β_2 , γ_2 and α_2 , β_3 , γ_2 .

The subunit composition of the receptors has great bearing on the response to benzodiazepines and other ligands. The multiplicity of subunits results in heterogeneity in GABA_A receptors and is responsible, at least in part, for the pharmacological diversity in benzodiazepine effects. For example, α , β , and γ subunits confer benzodiazepine sensitivity to the receptors, whereas α and β subunits confer barbiturates sensitivity to the receptors. The benzodiazepine recognition site is in the extracellular N-terminus of the α_1 , α_2 , α_3 , and α_5 subunits. Studies suggest that α_1 subunits are required for *hypnotic*, amnesic, and possibly anticonvulsant effects of benzodiazepines, whereas α_2 subunits are required for the *anxiolytic* and myorelaxant effects of benzodiazepines. The mutation to arginine of a histidine residue of the GABA_A receptor α_1 subunit render receptors containing that subunit insensitive to the enhancing hypnotic effects of diazepam. Whereas, if arginine replaces histidine in an α_2 subunit, the anxiolytic effect of benzodiazepines is lost.⁵ In addition, α_3 and α_5 subunits may be involved in other actions of benzodiazepines; α_4 or α_6 subunits do not respond to benzodiazepines.

Although the binding domain of the benzodiazepines is considered to be in the N-terminal domain of the α subunit, the benzodiazepines also require a γ_2 subunit for most positive allosteric effects. Amino acid residues in the α_1 subunit that have been identified as key binding sites within the benzodiazepine-binding site are His 101, Tyr 161, Thr 162, Gly 200, Ser 204, Thr 206, and Val 211. In the γ subunit, Phe 77 has been identified.^{2,5,7-12}

When benzodiazepines bind to a benzodiazepine recognition site, one of several allosteric sites that modulate the effect of GABA binding to GABA_A receptors located on GABA receptor complex, the benzodiazepines induce conformational (allosteric) changes in the GABA-binding site, thereby increasing the affinity of the receptor for GABA. As a result, the *frequency* of Cl⁻ channel openings is increased over that resulting from the binding of GABA alone, and the cell is further hyperpolarized, yielding a more pronounced decrease in cellular excitability. The benzodiazepines appear to have *no direct* effect on the GABA_A complex or ionophore.

Several newer agents that have structural characteristics broadly related to the benzodiazepines, including imidazopyridines (zolpidem), pyrazolopyrimidines (zaleplon), and cyclopyrrolone (eszopiclone), can act as positive modulators at the benzodiazepine α_1 recognition site selectively with fewer side effects.

Benzodiazepines and related compounds can act as agonists, antagonists, or inverse agonists at the benzodiazepine-

 β -Carboline

binding site on GABA_A receptor. Most classical benzodiazepines are positive modulators (*agonists*), many probably nonselectively for all the receptor subtypes that respond to benzodiazepines. Some have been claimed to be relatively selective as T-drugs and anticonvulsants. Some β -carbolines are negative modulators (*inverse agonists*) at benzodiazepine modulatory sites. Negative modulators diminish the positive effect of GABA on chloride flux. In whole animals, they appear to increase anxiety, produce panic attacks, and improve memory. There are also compounds that can occupy benzodiazepine modulatory sites, have no effect on chloride flux themselves, and block positive and negative modulators. They have been called variously *antagonists*, *zero modulators*, and *neutralizing allosteric modulators*. One such compound, flumazenil, is used clinically to counteract the sedative effect of benzodiazepines and benzodiazepine overdose.

In addition to benzodiazepine allosteric modulatory sites, there are other allosteric sites that recognize respectively, barbiturates, inhalation anesthetics, alcohols, propofol (separate sites), and neurosteroids. The convulsants picrotoxin and pentylene tetrazole have definite binding sites on GABA receptors.

The field of benzodiazepines was opened with the synthesis of chlordiazepoxide by Sternbach and the discovery of its unique pharmacological properties by Randall.¹³ Chlordiazepoxide (see the discussion on individual compounds) is a 2-amino benzodiazepine, and other amino compounds have been synthesized. When it was discovered that

Flumazenil (Romazicon)
An imidazobenzodiazepinone
A BZR antagonist

chlordiazepoxide is rapidly metabolized to a series of active benzodiazepine-2-ones (see the general scheme of metabolic relationships), however, emphasis shifted to the synthesis and testing of the latter group. Most benzodiazepines are 5-aryl-1,4-benzodiazepines and contain a carboxamide group in the seven-membered diazepine ring structure. Empirical structure-activity relationships (SARs) for anti-anxiety activity have been tabulated for this group (analogous statements apply for the older 2-amino group).^{13,14} The comparative quantitative SAR on nonbenzodiazepine compounds is also reviewed.¹⁵ The following general structure helps to visualize it (Fig. 12.1).

Aromatic or heteroaromatic ring A is required for the activity that may participate in π - π stacking with aromatic amino acid residues of the receptor. An electronegative substituent at position 7 is required for activity, and the more electronegative it is, the higher the activity. Positions 6, 8, and 9 should not be substituted. A phenyl ring C at position 5 promotes activity. If this phenyl group is *ortho* (2') or *diortho* (2',6') substituted with electron-withdrawing groups, activity is increased. On the other hand, *para* substitution decreases activity greatly. In diazepine ring B, saturation of the 4,5-double bond or a shift of it to the 3,4-position decreases activity. Alkyl substitution at the 3-position decreases activity; substitution with a 3-hydroxyl does not. The presence or absence of the 3-hydroxyl group is important pharmacokinetically. Compounds without the 3-hydroxyl group are nonpolar, 3-hydroxylated in liver slowly to active 3-hydroxyl metabolites, and have long overall half-lives. In

Figure 12.1 • General structure and SAR of benzodiazepines.

contrast, 3-hydroxyl compounds are much more polar, rapidly converted to inactive 3-glucuronides, which are excreted in urine and thus are short-lived (Fig. 12.1). The 2-carbonyl function is important for activity, as is the nitrogen atom at position 1. The N_1 -alkyl side chains are tolerated. A proton-accepting group at C2 is required and may interact with histidine residue (as a proton donor) in benzodiazepine-binding site of GABA_A receptor. Other triazole or imidazole rings capable of H-bonding can be fused on positions 1 and 2 and increase the activity.

Additional research yielded compounds with a fused triazolo ring, represented by triazolam and alprazolam. Midazolam, with a fused imidazolo ring, also followed. These compounds are short acting because they are metabolized rapidly by α -hydroxylation of the methyl substituent on the triazolo or imidazolo ring (analogous to benzylic oxidation). The resulting active α -hydroxylated metabolite is quickly inactivated by glucuronidation. The compounds are also metabolized by 3-hydroxylation of the benzodiazepine ring. Interestingly, an electron-attracting group at position 7 is not required for activity in some of these compounds.

The physicochemical and pharmacokinetic properties of the benzodiazepines greatly affect their clinical utility. Most benzodiazepines are lipophilic, in the nonionized form and thus well absorbed from the GI tract, whereas the more polar compounds (e.g., those with a 3-hydroxyl group) tend to be absorbed more slowly than the more lipophilic compounds.

These drugs tend to be highly bound to plasma proteins; in general, the more lipophilic the drug, the greater the binding. However, they do not compete with other protein-bound drugs. They are also very effectively distributed to the brain. Generally, the more lipophilic the compound, the greater is the distribution to the brain, at least initially. When diazepam is used as an anesthetic, it initially distributes to the brain and then redistributes to sites outside the brain. The benzodiazepines are extensively metabolized. The metabolism of benzodiazepines has received much study.^{16,17} Some of the major metabolic relationships are shown in Figure 12.2. Metabolites of some benzodiazepines are not only active but also have long half-lives, thus these drugs are long acting. Many benzodiazepines are metabo-

Figure 12.2 • Metabolism of benzodiazepines and their duration of action.

lized by cytochrome P450 (CYP) 3A4 and CYP2C19. CYP3A4 inhibitors (erythromycin, clarithromycin, ritonavir, itraconazole, ketoconazole, nefazodone, and grapefruit juice) can affect their metabolism. However, they do not induce the metabolism of other drugs. Therefore, the drugs have fewer drug interactions than barbiturates. In addition, they have lower abuse potential and a much greater margin of safety than the barbiturates.

BENZODIAZEPINES

Chlordiazepoxide Hydrochloride, United States Pharmacopeia (USP). Chlordiazepoxide hydrochloride, 7-chloro-2-(methylamino)-5-phenyl-3H-1,4-benzodiazepine 4-oxide monohydrochloride (Librium), is well absorbed after oral administration. Peak plasma levels are reached in 2 to 4 hours. The half-life of chlordiazepoxide is 6 to 30 hours. *N*-demethylation and hydrolysis of the condensed amidino group are rapid and extensive, producing demoxepam as a major metabolite. Demoxepam can undergo four different metabolic fates. It is converted principally to its active metabolite nordazepam, which is also a major active metabolite of diazepam, clorazepate, and prazepam. Nordazepam, in turn, is converted principally to active oxazepam (marketed separately), which conjugated to the excreted glucuronide. Because of the long half-life of parent drug and its active metabolites, this drug is long acting and self-tapering. As with diazepam (vide infra), repeated administration of chlordiazepoxide can result in accumulation of parent drug and its active metabolites, and thus cause excessive sedation.

Diazepam, USP. Diazepam, 7-chloro-1,3-dihydro-1-methyl-5-phenyl-2H-1,4-benzodiazepine-2-one (Valium), is prototypical and was the first member of the benzodiazepine-2-one group to be introduced. It is very lipophilic and is thus rapidly and completely absorbed after oral administration. Maximum peak blood concentration occurs in 2 hours and elimination is slow, with a half-life of about ~46 hours. As with chlordiazepoxide, diazepam is metabolized by *N*-demethylation to active nordazepam, which is 3-hydroxylated to active oxazepam (vide infra) and then metabolized according to the general scheme (Fig. 12.2). Like chlordiazepoxide, repeated administration of diazepam leads to accumulation of an active nordazepam,

Diazepam: Log P = 3.86, $t_{1/2}$ = ~46 h
Long-acting, Protein binding = 99%

which can be detected in the blood for more than 1 week after discontinuation of the drug. This drug is a long acting for the same reason. Diazepam is metabolized to nordazepam by CYP2C19 and CYP3A4. Cimetidine, by inhibiting CYP3A4, decreases the metabolism and clearance of diazepam. Thus, drugs that affect the activity of CYP2C19 or CYP3A4 may alter diazepam kinetics. Because diazepam clearance is decreased in the elderly and in patients with hepatic insufficiency, a dosage reduction may be warranted. It is widely used for several anxiety states and has an additional wide range of uses (e.g., as an anticonvulsant, a premedication in anesthesiology, and in various spastic disorders).

Prazepam, USP. Prazepam, 7-chloro-1-(cyclopropylmethyl)-1,3-dihydro-5-phenyl-2H-1,4-benzodiazepine-2-one (Verstran), has a long overall half-life. Extensive *N*-dealkylation occurs to yield active nordazepam. 3-Hydroxylation of both prazepam and nordazepam occurs.

Prazepam

Halazepam, USP. Halazepam, 7-chloro-1,3-dihydro-5-phenyl-1-(2,2,2-trifluoroethyl)-2H-1,4-benzodiazepine-2-one (Paxipam), is marketed as an anxiolytic and well absorbed. It is active and present in plasma, but much of its activity is caused by the major active metabolites nordazepam and oxazepam.

Halazepam

Flurazepam Hydrochloride, USP. Flurazepam hydrochloride, 7-chloro-1-[2-(diethylamino)ethyl]-5-(2-fluorophenyl)-1, 3-dihydro-2*H*-1, 4-benzodiazepine-2-one dihydrochloride (Dalmane), is notable as a benzodiazepine marketed almost exclusively for use in insomnia. Metabolism of the dialkylaminoalkyl side chain is extensive. A major metabolite is *N*¹-dealkyl flurazepam, which has a very long half-life and persists for several days after administration. Consequently, it produces cumulative clinical effects and side effects (e.g., excessive sedation) and residual pharmacologic activity, even after discontinuation.

Flurazepam hydrochloride
 $t_{1/2} = \sim 7$ h,
 $t_{1/2}$ of its active metabolite = 50 h
 long-acting

Quazepam. Quazepam (Doral) and its active metabolites reportedly are relatively selective for the benzodiazepine modulatory site on GABA_A receptors with α_1 subunit and are hypnotic agents. Quazepam is metabolized by

oxidation to the 2-oxo compound and then *N*-dealkylation. Both metabolites are active; the first reportedly is the more potent and selective. Thereafter, 3-hydroxylation and glucuronidation occur.

Quazepam
 $t_{1/2} = 39$
 long-acting

Clorazepate Dipotassium. Clorazepate dipotassium, 7-chloro-2,3-dihydro-2-oxo-5-phenyl-1*H*-1,4-benzodiazepine-3-carboxylic acid dipotassium salt monohydrate (Tranxene), can be considered a prodrug. Inactive itself, it undergoes rapid decarboxylation by the acidity of the stomach to nordazepam (a major active metabolite of diazepam), which has a long half-life and undergoes hepatic conversion to active oxazepam. Despite the polar character of the drug as administered, because it is quickly converted in the GI tract to an active nonpolar compound, it has a quick onset, overall long half-life, and shares similar clinical and pharmacokinetic properties to chlordiazepoxide and diazepam.

Oxazepam, USP. Oxazepam, 7-chloro-1,3-dihydro-3-hydroxy-5-phenyl-2*H*-1,4-benzodiazepin-2-one (Serax), is an active metabolite of both chlordiazepoxide and diazepam and can be considered a prototype for the 3-hydroxy benzo-

Oxazepam, Log P = 2.31

rapid glucuronidation
and excretion → $t_{1/2} = 4-8$ h

diazepines. For the stereochemistry of this and other 3-hydroxy compounds, see the chapter dealing with metabolism. It is much more polar than diazepam. Oxazepam is rapidly inactivated to glucuronidated metabolites that are excreted in the urine. Thus, the half-life of oxazepam is about 4 to 8 hours, and it is marketed as a short-acting anxiolytic. As a result, its cumulative effects with chronic therapy are much less than with long-acting benzodiazepine such as chlor-diazepoxide and diazepam.

Lorazepam, USP. Lorazepam, 7-chloro-5-(2-chlorophenyl)-3-dihydro-3-hydroxy-2*H*-1,4-benzodiazepine-2-one (Ativan), is the 2'-chloro derivative of oxazepam. In keeping with overall SARs, the 2'-chloro substituent increases activity. As with oxazepam, metabolism is relatively rapid and uncomplicated because of the 3-hydroxyl group in the compound. Thus, it also has short half-life (2–6 hours) and similar pharmacological activity.

Temazepam. Temazepam, 7-chloro-1,3-dihydro-3-hydroxy-1-methyl-5-phenyl-2*H*-1,4-benzodiazepine-2-one (Restoril), also occurs as a minor metabolite of diazepam. It can be visualized as *N*-methyl oxazepam, and indeed, a small amount of *N*-demethylation occurs slowly. However, metabolism proceeds mainly through glucuronidation of the 3-hydroxyl group, thus, it is intermediate acting and marketed as a hypnotic said to have little or no residual effect.

Lorazepam

rapid glucuronidation
and excretion → $t_{1/2} = 2-6$ h

TRIAZOLOBENZODIAZEPINES

Alprazolam, USP. Alprazolam, 8-chloro-1-methyl-6-phenyl-4*H*-*s*-triazolo[4,3-*a*][1,4]benzodiazepine (Xanax), is rapidly absorbed from the GI tract. Protein binding is lower (~70%) than with most benzodiazepines because of its lower lipophilicity. α -Hydroxylation of the methyl group to the methyl alcohol (a reaction analogous to benzylic hydroxylation) followed by conjugation is rapid; consequently, the duration of action is short. The drug is a highly potent anxiolytic on a milligram basis.

Triazolam, USP. Triazolam, 8-chloro-6-(*o*-chlorophenyl)-1-methyl-4*H*-*s*-triazolo[4,3-*a*][1,4] benzodiazepine (Halcion), has all of the characteristic benzodiazepine pharmacological actions. It is an ultra-short-acting hypnotic because it is rapidly α -hydroxylated to the 1-methyl alcohol, which is then rapidly conjugated and excreted. Consequently, it has gained popularity as sleep inducers, especially in elderly patients, because it causes less daytime sedation. It is metabolically inactivated primarily by hepatic and intestinal CYP3A4; therefore, coadministration with grapefruit juice increases its peak plasma concentration by 30%, leading to increased drowsiness.

Midazolam. This drug is used intravenously as a short-acting sedative-hypnotic and as an induction anesthetic because of its short half-life for the same reason. Further information can be found in the section on anesthetics.

NONBENZODIAZEPINE BzRAs

Zolpidem (Ambien, an imidazopyridine) and eszopiclone (Lunesta, a cyclopyrrolone) are nonbenzodiazepines and have been introduced as short- and moderate-acting hypnotics, respectively. Zolpidem exhibits a high selectivity for the α_1 subunit of benzodiazepine-binding site on GABA_A receptor complex, whereas eszopiclone is a “superagonist” at BzRs with the subunit composition $\alpha_1\beta_2\gamma_2$ and $\alpha_1\beta_2\gamma_3$. Zolpidem has a rapid onset of action of 1.6 hours and good bioavailability (72%), mainly because it is lipophilic and has no ionizable groups at physiological pH. Food can prolong the time to peak concentration without affecting the half-life probably for the same reason. It has short elimination half-life, because its aryl methyl groups is extensively α -hydroxylated to inactive metabolites by CYP3A4 followed by further oxidation by aldehyde dehydrogenase to the ionic carboxylic acid. The metabolites are inactive, short-lived, and eliminated in the urine. Its half-life in the elderly or the patients with liver disease is increased. Therefore, dosing should be modified in patients with hepatic insufficiency and the elderly. Because it has longer elimination half-life than zaleplon, it may be preferred for sleep maintenance. It was the most commonly prescribed drug for insomnia in 2001.

Zolpidem
Log P = 2.61
 $t_{1/2} = 2.5$
short-acting

Eszopiclone
 $t_{1/2} = 5-6$ h
moderate-acting

Zopiclone was originally marketed as a racemic mixture. Because its *S*-isomer is a primary active hypnotic, it is now marketed as eszopiclone in the United States. It is less selective for the α_1 subunit of GABA_A receptor, and it has relatively longer elimination half-life (~ 6 hours) than zolpidem and zaleplon. Consequently, it may be used for patients who tend to awaken during the night.

Zaleplon. Zaleplon (Sonata, a pyrazolopyrimidine) is another short-acting nonbenzodiazepine hypnotic. Pharmacologically and pharmacokinetically, zaleplon is similar to zolpidem; both are hypnotic agents with short half-lives. It also has selective high affinity for α_1 -subunit containing BzRs but produces effects at other BzR/GABA_A subtypes as well. Zaleplon is well absorbed following oral administration with an absolute bioavailability of approximately 30% because of significant presystemic metabolism. It exhibits a mean half-life of approximately 1 hour, with less than 1% of the dose excreted unchanged in urine. It is primarily metabolized by aldehyde oxidase to 5-oxo-zaleplon and is also metabolized to a lesser extent by CYP3A4. *N*-demethylation yields desethylzaleplon, which is quickly converted, presumably by aldehyde oxidase, to 5-oxo-desethylzaleplon. These oxidative metabolites are then converted to glucuronides and eliminated in urine. All of zaleplon's metabolites are pharmacologically inactive. It may have a more rapid onset (about 1 hour) and termination of action than zolpidem, and therefore, it is good to initiate sleep instead of keeping sleep.

Melatonin Receptor Agonist: Ramelteon

In the brain, three melatonin receptors (MT₁, MT₂, and MT₃) have been characterized. Activation of the MT₁ receptor results in sleepiness, whereas the MT₂ receptor may be related to the circadian rhythm. MT₃ receptors may be related to intraocular pressure. Their endogenous ligand, melatonin (*N*-acetyl-5-methoxytryptamine), at times referred to as “the hormone of darkness,” is *N*-acetylated and *O*-methylated product of serotonin found in the pineal gland and is biosynthesized and released at night and may play a role in the circadian rhythm of humans. It is promoted commercially as a sleep aid by the food supplement industry. However, it is a poor hypnotic drug because of its poor potency, poor absorption, poor oral bioavailability, rapid metabolism, and nonselective effects.

Ramelteon (Rozerem). The melatonin molecule was modified mainly by replacing the nitrogen of the indole ring with a carbon to give an indane ring and by incorporating 5-methoxyl group in the indole ring into a more rigid furan ring. The selectivity of the resulting ramelteon for MT_1 receptor is eight times more than that of MT_2 receptor. Unlike melatonin, it is more effective in initiating sleep (MT_1 activity) rather than to readjust the circadian rhythm (MT_2 activity). It appears to be distinctly more efficacious than melatonin but less efficacious than benzodiazepines as a hypnotic. Importantly, this drug has no addiction liability (it is not a controlled substance). As a result, it has recently been approved for the treatment of insomnia.

Barbiturates

The barbiturates were used extensively as sedative-hypnotic drugs. Except for a few specialized uses, they have been replaced largely by the much safer benzodiazepine. Barbiturates act throughout the CNS. However, they exert most of their characteristic CNS effects mainly by binding to an allosteric recognition site on $GABA_A$ receptors that

positively modulates the effect of the $GABA_A$ receptor—GABA binding. Unlike benzodiazepines, they bind at different binding sites and appear to increase the *duration* of the GABA-gated chloride channel openings. In addition, by binding to the barbiturate modulatory site, barbiturates can also increase chloride ion flux without GABA attaching to its receptor site on $GABA_A$. This has been termed a *GABA mimetic effect*. It is thought to be related to the profound CNS depression that barbiturates can produce.

The barbiturates are 5,5-disubstituted barbituric acids. Consideration of the structure of 5,5-disubstituted barbituric acids reveals their acidic character. Those without methyl substituents on the nitrogen have pK_a 's of about 7.6; those with a methyl substituent have pK_a 's of about 8.4. The free acids have poor water solubility and good lipid solubility (the latter largely a function of the two hydrocarbon substituents on the 5-position, although in the 2-thiobarbiturates, the sulfur atom increases lipid solubility).

Sodium salts of the barbiturates are readily prepared and are water soluble. Their aqueous solutions generate an alkaline pH. A classic incompatibility is the addition of an agent with an acidic pH in solution, which results in

Figure 12.3 • Structure–activity relationship of barbiturates.

formation and precipitation of the free water-insoluble disubstituted barbituric acid. Sodium salts of barbiturates in aqueous solution decompose at varying rates by base-catalyzed hydrolysis, generating ring-opened salts of carboxylic acids.

Structure–Activity Relationships

Extensive synthesis and testing of the barbiturates over a long time span have produced well-defined SARs (see Fig. 12.3), which have been summarized.¹⁸ The barbituric acid is 2,4,6-trioxohexahydropyrimidine, which lacks CNS depressant activity. However, the replacement of both hydrogens at position 5 with alkyl or aryl groups confers the activity. Both hydrogen atoms at the 5-position of barbituric acid must be replaced. This may be because if one hydrogen is available at position 5, tautomerization to a highly acidic trihydroxypyrimidine ($pK_a \sim 4$) can occur. Consequently, the compound is largely in the anionic form at physiological pH, with little nonionic lipid-soluble compound available to cross the blood-brain barrier.

In general, increasing lipophilicity increases hypnotic potency and the onset of action and decreases the duration of action. Thus, beginning with lower alkyls, there is an increase in onset and a decrease in duration of action with increasing hydrocarbon content up to about seven to nine total carbon atoms substituted on the 5-position. It is because that lipophilicity and an ability to penetrate the brain in the first case and an ability to penetrate liver microsomes in the second may be involved. In addition for more lipophilic compounds, partitioning out of the brain to other sites can be involved in the second instance. There is an inverse correlation between the total number of carbon atoms substituted on the 5-position and the duration of action, which is even better when the character of these substituents is taken into account, for example, the relatively

polar character of a phenyl substituent (approximates a three- to four-carbon aliphatic chain), branching of alkyls, presence of an isolated double or triple bond, and so on. Additionally, these groups can influence the ease of oxidative metabolism by effects on bond strengths as well as by influencing partitioning.

Absorption from the GI tract is good. Binding to blood proteins is substantial. Compounds with low lipophilicity may be excreted intact in the urine, whereas highly lipophilic compounds are excreted after metabolism to polar metabolites. Increasing the lipophilicity generally increases the rate of metabolism, except for compounds with an extremely high lipophilicity (e.g., thiopental), which tend to depotize and are thus relatively unavailable for metabolism. Metabolism generally follows an ultimate (ω) or penultimate ($\omega-1$) oxidation pattern. Ring-opening reactions are usually minor. *N*-methylation decreases duration of action, in large part, probably, by increasing the concentration of the lipid-soluble free barbituric acid. 2-Thiobarbiturates have a very short duration of action because its lipophilicity is extremely high, promoting depotization. Barbiturates find use as sedatives, as hypnotics, for induction of anesthesia, and as anticonvulsants.

Some of the more frequently used barbiturates are described briefly in the following sections. For the structures, the usual dosages required to produce sedation and hypnosis, the times of onset, and the duration of action, see Table 12.1.

BARBITURATES WITH A LONG DURATION OF ACTION (MORE THAN 6 HOURS)

Mephobarbital, USP. Mephobarbital, 3-methyl-5-ethyl-5-phenylbarbituric acid (metharbarital), is metabolically *N*-demethylated to phenobarbital, which many consider to account for almost all of the activity. Its principal use is as an anticonvulsant.

TABLE 12.1 Barbiturates Used as Sedatives and Hypnotics

General Structure

Generic Name Proprietary Name	R ₅	Substituents R' ₅	R ₁	Sedative Dose (mg)	Hypnotic Dose (mg)	Usual Onset of Action (min)
A. Long Duration of Action (more than 6 hours)						
Mephobarbital, <i>USP</i> <i>Mebaral</i>	C ₂ H ₅		CH ₃	30–100 ^a	100	30–60
Phenobarbital, <i>USP</i> <i>Luminal</i>	C ₂ H ₅		H	15–30 ^a	100	20–40
B. Intermediate Duration of Action (3–6 hours)						
Amobarbital, <i>USP</i> <i>Amytal</i>	CH ₃ CH ₂ —	(CH ₃) ₂ CHCH ₂ CH ₂ —	H	20–40	100	20–30
Butobarbital sodium, <i>USP</i> <i>Butisol Sodium</i>	CH ₃ CH ₂ —	CH ₃ CH ₂ CH— CH ₃	H	15–30	100	20–30
C. Short Duration of Action (less than 3 hours)						
Pentobarbital sodium, <i>USP</i> <i>Nembutal Sodium</i>	CH ₃ CH ₂ —	CH ₃ CH ₂ CH ₂ CH— CH ₃	H	30	100	20–30
Secobarbital, <i>USP</i> <i>Seconal</i>	CH ₂ =CHCH ₂ —	CH ₃ CH ₂ CH ₂ CH— CH ₃	H	15–30	100	20–30

^aDaytime sedative and anticonvulsant.

Phenobarbital, USP. Phenobarbital, 5-ethyl-5-phenylbarbituric acid (Luminal), is a long-acting sedative and hypnotic. It is also a valuable anticonvulsant, especially in generalized tonic-clonic and partial seizures (see the discussion on anticonvulsants). Metabolism to the *p*-hydroxyphenyl compound followed by glucuronidation accounts for about 90% of a dose.

BARBITURATES WITH AN INTERMEDIATE DURATION OF ACTION (3–6 HOURS)

Amobarbital
Log P = 2.10

Butobarbital
Log P = 1.56

Barbiturates with an intermediate duration of action are used principally as sedative-hypnotics. They include amobarbital, *USP*, 5-ethyl-5-isopentylbarbituric acid (Amytal), and its water-soluble sodium salt, amobarbital sodium, *USP*, 5-allyl-5-isopropylbarbituric acid (aprobarbital [Alurate]); butobarbital sodium, *USP*, the water-soluble sodium salt of 5-*sec*-butyl-5-ethylbarbituric acid (Butisol Sodium).

BARBITURATES WITH A SHORT DURATION OF ACTION (LESS THAN 3 HOURS)

Barbiturates that have substituents in the 5-position promoting more rapid metabolism (e.g., by increasing the lipophilicity) than the intermediate group include pentobarbital-sodium, *USP*, sodium 5-ethyl-5-(1-methylbutyl)barbiturate (Nembutal); secobarbital, *USP*, 5-allyl-5-(1-methylbutyl)barbituric acid (Seconal); and the sodium salt sodium secobarbital. Barbiturates with an ultrashort duration of action are discussed under anesthetic agents.

Miscellaneous Sedative-Hypnotics

A wide range of chemical structures (e.g., imides, amides, alcohols) can produce sedation and hypnosis resembling those produced by the barbiturates. Despite this apparent structural diversity, the compounds have generally similar structural characteristics and chemical properties: a nonpolar portion and a semipolar portion that can participate in

Pentobarbital
Log P = 2.10

Secobarbital
Log P = 2.33

H-bonding. In some cases, modes of action are undetermined. As a working hypothesis, most of the agents can be envisioned to act by mechanisms similar to those proposed for barbiturates and alcohols.

AMIDES AND IMIDES

Glutethimide, USP. Glutethimide, 2-ethyl-2-phenylglutarimide (Doriden), is one of the most active nonbarbiturate hypnotics that is structurally similar to the barbiturates, especially phenobarbital. Because of glutethimide's low aqueous solubility, its dissolution and absorption from the GI track is somewhat erratic. Consistent with its high lipophilicity, it undergoes extensive oxidative metabolism in the liver with a half-life of approximately 10 hours. Glutethimide is used as a racemic mixture with the (+) enantiomer being primarily metabolized on the glutarimide ring and the (−) enantiomer on the phenyl ring. The product of metabolic detoxification is excreted after conjugation with glucuronic acid at the hydroxyl group. The drug is an enzyme inducer. In the therapeutic dosage range, adverse effects tend to be infrequent. Toxic effects in overdose are as severe as, and possibly more troublesome than, those of the barbiturates.

Alcohols and Their Carbamate Derivatives

The very simple alcohol ethanol has a long history of use as a sedative and hypnotic. Its modes of action were described under the anesthetic heading and are said to apply to other alcohols. It is widely used in self-medication as a sedative-hypnotic. Because this use has so many hazards, it is seldom a preferred agent medically.

Phenobarbital, Log P = 1.71

As the homologous series of normal alcohols is ascended from ethanol, CNS depressant potency increases up to eight carbon atoms, with activity decreasing thereafter. Branching of the alkyl chain increases depressant activity and, in an isometric series, the order of potency is tertiary > secondary > primary. In part, this may be because tertiary and secondary alcohols are not metabolized by oxidation to the corresponding carboxylic acids. Replacement of a hydrogen atom in the alkyl group by a halogen increases the alkyl portion and, accordingly, for the lower-molecular weight compounds, increases potency. Carbamylation of alcohols generally increases depressant potency. Carbamate groups are generally much more resistant to metabolic inactivation than hydroxyl functions. Most of the alcohols and carbamates have been superseded as sedative-hypnotics. Several difunctional compounds (e.g., diol carbamates) have depressant action on the cord in addition to the brain and are retained principally for their skeletal muscle relaxant properties.

Ethchlorvynol, USP. Ethchlorvynol, 1-chloro-3-ethyl-1-penten-4-yn-3-ol (Placidyl), is a mild sedative-hypnotic with a quick onset and short duration of action ($t_{1/2} = 5.6$ hours). Because of its highly lipophilic character, it is extensively metabolized to its secondary alcohol (~90%) prior to its excretion. It reportedly induces microsomal hepatic enzymes. Acute overdose shares several features with barbiturate overdose.

Meprobamate, USP. Meprobamate, 2-methyl-2-propyltrimethylene dicarbamate, 2-methyl-2-propyl-1,3-propanediol dicarbamate (Equanil, Miltown), is officially indicated as an antianxiety agent. It is also a sedative-hypnotic agent. It has several overall pharmacological

Glutethimide, Log P = 2.70

Ethchlorvynol

properties resembling those of benzodiazepines and barbiturates. The mechanism of action underlying anxiolytic effects is unknown but may involve effects on conductivity in specific brain areas.¹⁹ It does not appear to act through effects on GABAergic systems. The drug is effective against absence seizures and may worsen generalized tonic-clonic seizures.

Meprobamate is also a centrally acting skeletal muscle relaxant. The agents in this group find use in several conditions, such as strains and sprains that may produce acute muscle spasm. They have interneuronal blocking properties at the level of the spinal cord, which are said to be partly responsible for skeletal muscle relaxation.¹⁹ Also, the general CNS depressant properties they possess may contribute to, or be mainly responsible for, the skeletal muscle relaxant activity. Dihydric compounds and their carbamate (urethane) derivatives, as described previously in the discussion of meprobamate, are prominent members of the group.

Meprobamate: R = H
Carisoprodol: R = CH(CH₃)₂

Carisoprodol, USP. Carisoprodol, *N*-isopropyl-2-methyl-2-propyl-1,3-propanediol dicarbamate, 2-methyl-2-propyl-1,3-propanediol carbamate isopropylcarbamate (Soma), is the mono-*N*-isopropyl-substituted relative of meprobamate. The structure is given in the discussion of meprobamate. It is indicated in acute skeletomuscular conditions characterized by pain, stiffness, and spasm. As can be expected, a major side effect of the drug is drowsiness.

Mephenesin

Chlorphenesin Carbamate

Chlorphenesin Carbamate. Chlorphenesin carbamate, 3-(*p*-chlorophenoxy)-1,2-propanediol 1-carbamate (Mao-late), is the *p*-chloro substituted and 1-carbamate derivative of the lead compound in the development of this group of agents, mephenesin. Mephenesin is weakly active and short-lived because of facile metabolism of the primary hydroxyl group. Carbamylation of this group increases activity. *p*-Chlorination increases the lipophilicity and seals off the *para* position from hydroxylation. Metabolism, still fairly rapid, involves glucuronidation of the secondary hydroxyl group. The biological half-life in humans is 3.5 hours.

Methocarbamol, USP. Methocarbamol, 3-(*o*-methoxyphenoxy)-1,2-propanediol 1-carbamate (Robaxin), is said to be more sustained in effect than mephenesin. Likely sites for metabolic attack include the secondary hydroxyl group and the two ring positions opposite the ether functions. The dihydric parent compound, guaifenesin, is used as an expectorant.

Guaifenesin: R = H
Methocarbamol: R = CONH₂

ALDEHYDES AND THEIR DERIVATIVES

For chemical reasons that are easily rationalized, few aldehydes are valuable hypnotic drugs. The aldehyde in use, chloral (as the hydrate), is thought to act principally through a metabolite, trichloroethanol. Acetaldehyde is used as the cyclic trimer derivative, paraldehyde, which could also be grouped as a cyclic polyether.

Chloral Hydrate, USP. Chloral hydrate, trichloroacetaldehyde monohydrate, CCl₃CH(OH)₂ (Noctec), is an aldehyde hydrate stable enough to be isolated. The relative stability of this *gem*-diol is largely a result of an unfavorable dipole-dipole repulsion between the trichloromethyl carbon and the carbonyl carbon present in the parent carbonyl compound.²⁰

Chloral hydrate is unstable in alkaline solutions, undergoing the last step of the haloform reaction to yield chloroform and formate ion. In hydroalcoholic solutions, it forms the hemiacetal with ethanol. Whether or not this compound is the basis for the notorious and potentially lethal effect of

Figure 12.4 • Reaction and metabolism of chloral.

the combination of ethanol and chloral hydrate (the “Mickey Finn”) is controversial. Synergism between two different CNS depressants also could be involved. Additionally, ethanol, by increasing the concentration of nicotinamide adenine dinucleotide (NADH), enhances the reduction of chloral to the more active metabolite trichloroethanol, and chloral can inhibit the metabolism of alcohol because it inhibits alcohol dehydrogenase. Chloral hydrate is a weak acid because its CCl_3 group is very strong electron withdrawing. A 10% aqueous solution of chloral hydrate has pH 3.5 to 4.4, which makes it irritating to mucous membranes in the stomach. As a result, GI upset commonly occurs for the drug if undiluted or taken on an empty stomach. Chloral hydrate as a capsule, syrup, or suppository is currently available. Although it is suggested that chloral hydrate per se may act as a hypnotic,²¹ chloral hydrate is very quickly converted to trichloroethanol, which is generally assumed to account for almost all of the hypnotic effect. The trichloroethanol is metabolized by oxidation to chloral and then to the inactive metabolite, trichloroacetic acid (see Fig. 12.4), which is also extensively metabolized to acylglucuronides via conjugation with glucuronic acid. It appears to have potent barbiturate-like binding to GABA_A receptors. Although an old drug, it still finds use as a sedative in non-operating room procedures for the pediatric patient.

Paraldehyde, USP. Paraldehyde, 2,4,6-trimethyl-s-trioxane, paracetaldehyde, is recognizable as the cyclic trimer of acetaldehyde. It is a liquid with a strong characteristic odor detectable in the expired air and an unpleasant taste. These properties limit its use almost exclusively to an institutional setting (e.g., in the treatment of delirium tremens). In the past, when containers were opened and air admitted and then reclosed and allowed to stand, fatalities occurred because of oxidation of paraldehyde to glacial acetic acid.

ANTIPSYCHOTICS

The psychoses affect approximately 1% of the population in all cultures. They are psychogenic mental disorders involving a loss of contact with reality. The psychotic disorders include schizophrenia, the manic phase of bipolar (manic-depressive) illness, acute idiopathic psychotic illness, and other conditions marked by severe agitation. The most common is schizophrenia, in which perception, thinking, communication, social functioning, and attention are altered.

Schizophrenia is a particular kind of psychosis characterized mainly by a clear sensorium but a marked thinking disturbance. Symptoms are called *positive* (e.g., delusions, hallucinations) or *negative* (e.g., flat affect, apathy); cognitive dysfunction may occur. In the schizophrenias, which have an extremely complex and multifactorial etiology,^{22,23} the fundamental lesion appears to be a defect in the brain's informational gating mechanism. Basically, the gating system has difficulty discriminating between relevant and irrelevant stimuli. The etiology of psychosis remains unknown, although genetic, neurodevelopmental and environmental causative factors have all been proposed. Psychoses can be

organic and related to a specific toxic chemical (e.g., delirium produced by central anticholinergic agents), an *N*-methyl *D*-aspartate (NMDA) receptor antagonist (e.g., phencyclidine [PCP]), a definite disease process (e.g., dementia), or they can be idiopathic.

Although the actual structural or anatomical lesions are not known, the basic defect appears to involve overactivity of dopaminergic neurons in the mesolimbic system. DA hypothesis for schizophrenia is the most fully developed of several hypotheses and is the basis for much of the rationale for drug therapy because (a) drugs that increase dopaminergic neurotransmission, such as levodopa (a DA precursor), amphetamines (a DA releaser), and apomorphine (a DA agonist), induce or exacerbate schizophrenia. Amphetamine-induced psychosis was determined to be caused by overactivation of mesolimbic D_2 receptors and judged to be the closest of the various chemically induced model psychoses to the schizophrenias; (b) DA receptor density is increased in certain brain regions of untreated schizophrenics; (c) many antipsychotic drugs strongly block postsynaptic D_2 receptors in CNS; and (d) successful treatment of schizophrenic patients has been reported to change the amount of homovanillic acid (HVA), a DA metabolite, in the cerebrospinal fluid, plasma, and urine. Consequently, the antipsychotic action is now thought to be produced (at least in part) by their ability to block DA receptors in the mesolimbic and mesofrontal systems. Moreover, extrapyramidal side effects of antipsychotic drugs correlate with their D_2 antagonism effect. The hyperprolactinemia that follows treatment with antipsychotics is caused by blockade of DA's tonic inhibitory effect on prolactin release from the pituitary. Nevertheless, the defects of DA hypothesis are significant, and it is now appreciated that schizophrenia is far more complex than originally supposed. Several classes of drugs are effective for symptomatic treatment.

Interest in DA, 5-HT, and Glu NTs led to most early drugs targeting the DA system, primarily as DA D_2 receptor. Typical antipsychotics (e.g., chlorpromazine, haloperidol) are better for treating positive signs than negative signs. For treating negative signs, the newer (atypical) antipsychotic drugs (e.g., clozapine, risperidone) target D_2 receptor and other receptors. The bases of the atypical group's activity against negative symptoms may be serotonin- 2_A receptor (5-HT $_{2A}$) block, block at receptors yet to be determined, and possibly decreased striatal D_2 block.²⁴ A classic competitive antagonism has been demonstrated at D_2 and D_3 receptors. Also, in recombinantly expressed receptors, inverse agonism has been demonstrated. Recent studies show that essentially all clinically used antipsychotic drugs are D_2 inverse agonists, suggesting that biochemical as well as clinical effects may not be explained by simple D_2 receptor blockade hypothesis.²⁵

Typical antipsychotics began with the serendipitous discovery of the antipsychotic activity of chlorpromazine. A clear association between the ability to block DA at mesolimbic D_2 receptors was established. The conventional typical antipsychotics (neuroleptics) are characterized by the production of EPS, roughly approximating the symptoms of Parkinson disease. These are reversible on discontinuing or decreasing the dose of the drug and are associated with blockade of DA at D_2 striatal receptors. After sustained high-dose therapy with antipsychotics, a late-appearing EPS, tardive dyskinesia, may occur. The overall

symptomatology resembles the symptoms of Huntington chorea. Atypical antipsychotics date from the discovery of clozapine, its antipsychotic properties, and its much lower production of EPS. Also contributing to the development of atypical antipsychotics was the introduction of risperidone. It has reduced EPS, has increased activity against negative symptoms, and, in addition to its DA-blocking ability, is a 5-HT $_{2A}$ antagonist. The view has been proposed that 5-HT $_{2A}$ receptors are involved in part (the negative symptoms) or wholly in schizophrenia. So far, the evidence appears to be that 5-HT $_{2A}$ blocking agents do not relieve positive effects of schizophrenia.²⁴ The view that 5-HT $_{2A}$ overactivity is the source of negative symptoms (part of the basis of psychosis) is not disproved at present, although some say it has been weakened.²⁴

One result of the development of atypical antipsychotics has been a renewed interest in models of psychosis other than the amphetamine model. In line with possible dual involvement of 5-HT and DA, the lysergic acid diethylamide (LSD, a 5-HT agonist) model has been cited as better fitting schizophrenias than the amphetamine model. However, this has been disputed. Interest in serotonergic involvement is still high and involves elucidating the roles of 5-HT $_6$ and 5-HT $_7$ receptors.

Interest remains in understanding the psychosis produced by several central anticholinergics. Muscarinic (M_1 and M_4) agonists appear to offer the best approach at this time.²⁶ The role of the M_5 receptor awaits synthesis of M_5 -specific drugs.²⁷

PCP (an NMDA antagonist)-induced psychosis has been proposed as a superior model for schizophrenia, because it presents both positive and negative symptoms.²⁴ It suggests that deficits in glutaminergic function occur in schizophrenia. Results of agonists of NMDA receptors, overall, have not been productive because of the excitatory and neurotoxic effects of the agents tested. Identification of susceptible receptor subtypes as targets, using glycine modulation or group II metabotropic receptor agonists to modulate NMDA receptors, has been proposed to circumvent the problems associated with the NMDA agonists.

The ionotropic glutamic acid α -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors are activated by brain-penetrating ampakines. There are suggestions that these agents exert some antipsychotic actions by increasing glutaminergic activity.

The individual antipsychotic agents are now considered. The substituted DA motif is useful as an organizational device. Antipsychotics can be classified into four groups (Table 12.2).

Phenothiazines

Several dozen phenothiazine antipsychotic drugs are chemically related agents used worldwide. Other phenothiazines are marketed primarily for their antiemetic, antihistaminic, or anticholinergic effect. The large body of information permits accurate statements about the structural features associated with activity (see Fig. 12.5). Many of the features were summarized and interpreted by Gordon et al.²⁸ Phenothiazines have a tricyclic structure (6-6-6 system) in which two benzene rings are linked by a sulfur and a nitrogen atom. The best position for substitution is the 2-position. Activity increases (with some exceptions) as

TABLE 12.2 Classification of Antipsychotics

Drug Groups	Structure Features	Examples	Comments
Phenothiazines	Aliphatic side chain Piperidine side chain Piperazine side chain	Chlorpromazine Thioridazine Fluphenazine	Least potent Least potent and ↓ EPS More potent and more EPS
Thioxanthenes	Double bond on C10	Thiothixene	Less potent than other phenothiazines
Butyrophenones	Aromatic butylpiperidines and diphenylbutylpiperidines	Haloperidol	More potent Fewer autonomic SEs Greater EPS
Newer drugs	Miscellaneous	Risperidone Clozapine Olanzapine	Less EPS Also good for negative symptoms

electron-withdrawing ability of the 2-substituent increases (e.g., chlorpromazine vs. promazine). Another possibly important structural feature in the more potent compounds is the presence of an unshared electron pair on an atom or atoms of the 2-substituent. Substitution at the 3-position can improve activity over unsubstituted compounds but not as significantly as substitution at the 2-position. Substitution at position 1 has a deleterious effect on antipsychotic activity, as does (to a lesser extent) substitution at the 4-position.

The significance of these substituent effects could be that the hydrogen atom of the protonated amino group of the side chain H-bonds with an electron pair of an atom of the 2-substituent to develop a DA-like arrangement.

Horn and Snyder,²⁹ from x-ray crystallography, proposed that the chlorine-substituted ring of chlorpromazine base could be superimposed on the aromatic ring of DA base, with the sulfur atom aligned with the *p*-hydroxyl group of DA and the aliphatic amino groups of the two compounds also aligned. The model used here is based on the interpretation of the SARs by Gordon et al.²⁸ and on the Horn and Snyder²⁹ proposal but involves the protonated species rather than the free base. The effect of the substituent at the 1-position might be to interfere with the side chain's ability to bring the protonated amino group in proximity with the 2-substituent. In the Horn and Snyder²⁹ scheme, the sulfur atom at position 5 is in a position analogous to the *p*-hydroxyl group of DA, and it was also assigned a receptor-binding function by Gordon et al.²⁸ A substituent at position 4 might interfere with receptor binding by the sulfur atom.

The three-carbon chain between position 10 and the aliphatic amino nitrogen is critical for neuroleptic activity. Shortening or lengthening the chain at this position drastically decreases the activity. The three-atom chain length

may be necessary to bring the protonated amino nitrogen in proximity with the 2-substituent. Shortening the chain to two carbons has the effect of amplifying the antihistaminic and anticholinergic activities. For example, promethazine is effective antihistamine, whereas the amino ethyl derivatives diethazine (anticholinergic) and ethopropazine (antimuscarinic) have proved useful in the treatment of Parkinson disease. The amine is always tertiary. *N*-dealkylation of the side chain or increasing the size of amino *N*-alkyl substituents reduces antidopaminergic and antipsychotic activity.

As expected, branching with large groups (e.g., phenyl) decreases activity, as does branching with polar groups. Methyl branching on the β -position has a variable effect on activity. More importantly, the antipsychotic potency of *levo* (the more active) and *dextro* isomers differs greatly. This has long been taken to suggest that a precise fit (i.e., receptor site occupancy) is involved in the action of these compounds.

Decreases in size from a dimethylamino group (e.g., going to a monomethylamino) greatly decrease activity, as do effective size increases, such as the one that occurs with *N,N*-diethylamino group. Once the fundamental requirement of an *effective* size of about that equivalent to a dimethylamino is maintained, as in fusing *N,N*-diethyl substituents to generate a conformationally restricted pyrrolidino group, activity can be enhanced with increasing chain length, as in *N*₂-substituted piperizino compounds.

The critical size of groups on the amino atom suggests the importance of the amino group (here protonated) for receptor attachment. The effect of the added chain length, once the critical size requirement is met, could be increased affinity. It appears to have been reasonably proved that the

3-atom chain between 2 Ns is optimal

protonated species of the phenothiazines can bind to DA receptors.³⁰

Several piperazine phenothiazines are esterified at a free hydroxyl with long-chain fatty acids to produce highly lipophilic and long-acting prodrugs. They tend to have large volumes of distribution, probably because they are sequestered in lipid compartments of the body and have very high affinity for selected NT receptors in the CNS. They generally have a much longer clinical duration of action than would be estimated from their plasma half-lives. This is paralleled by prolonged occupancy of DA D₂ receptors in brain. The decanoates of fluphenazine and haloperidol are used commonly in the United States; several others (including esters of pipotiazine and perphenazine) are available elsewhere.

Because of the high lipophilicity of most antipsychotic drugs, they are highly membrane and protein bound (92%–99%) mostly to albumin. They accumulate in the brain, lung, and other tissues with a rich blood supply and also enter the fetal circulation and breast milk.

Most phenothiazines undergo significant first-pass metabolism. Chlorpromazine and other phenothiazines are metabolized extensively by CYP2D6. Thus, oral doses of chlorpromazine and thioridazine have systemic availability of 25% to 35%, whereas parenteral (intramuscular) administration increases the bioavailability of active drug fourfold to tenfold. In contrast, haloperidol, which is less likely to be metabolized, has an average systemic availability of about 65%. Metabolism of the phenothiazines is complex in detail.

Diethazine (antimuscarinic)

Ethopropazine (antimuscarinic)

A major route is 7-hydroxylation of the tricyclic system. Because electron-withdrawing 2-Cl substituent blocks the hydroxylation on chlorophenyl ring, the hydroxylation occurs at 7-position rather than 2-position. Thus, the major initial metabolite is frequently the 7-hydroxy compound (active metabolite). This compound is further metabolized by conjugation with glucuronic acid, and the conjugate is excreted. Metabolites of chlorpromazine may be excreted in the urine weeks after the last dose of chronically administered drug. Full relapse may not occur until 6 weeks or more after discontinuation of many antipsychotics. Detailed reviews of the metabolites of phenothiazines (as well as SARs and pharmacokinetic factors) are available.³¹

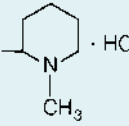

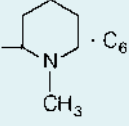

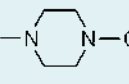

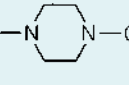

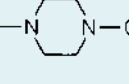

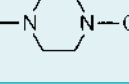

PRODUCTS

The structures of the phenothiazine derivatives described later are given in Table 12.3.

Chlorpromazine Hydrochloride, USP. Chlorpromazine hydrochloride, 2-chloro-10-[3-(dimethylamino)propyl]phe-

nothiazine monohydrochloride (Thorazine), was the first phenothiazine compound introduced into therapy. It is still useful as an antipsychotic. Other uses are in nausea, vomiting, and hiccough. Oral doses of chlorpromazine and thioridazine have systemic availability of 25% to 35% because of significant first-pass metabolism. Chlorpromazine and other phenothiazines are metabolized extensively by CYP2D6 (Fig. 12.6). In contrast, bioavailability of chlorpromazine may be increased up to 10-fold with injections, but the clinical dose usually is decreased by only threefold to fourfold. Chlorpromazine may weakly induce its own hepatic metabolism, because its concentration in blood is lower after several weeks of treatment at the same dosage. Alterations of GI motility also may contribute. The drug has significant sedative and hypotensive properties, possibly reflecting central histaminergic and peripheral α_1 -noradrenergic blocking activity, respectively. Effects of peripheral anticholinergic activity are common. As with the other phenothiazines, the effects of other CNS-depressant drugs, such as sedatives and anesthetics, can be potentiated.

Figure 12.6 • Some metabolic pathways for chlorpromazine.

Promazine. Promazine, 10-[3-(dimethylamino) propyl]-phenothiazine monohydrochloride (Sparine), was introduced into antipsychotic therapy after its 2-chloro-substituted relative. The 2H-substituent vis-à-vis the 2Cl substituent gives a milligram potency decrease as an antipsychotic, as encompassed in Gordon's rule. Tendency to EPS is also lessened, which may be significant, especially if it is decreased less than antipsychotic potency.

Triflupromazine Hydrochloride, USP. Triflupromazine hydrochloride, 10-[3-(dimethylamino)propyl]-2-(trifluoromethyl)phenothiazine monohydrochloride (Vesprin), has a greater milligram potency as an antipsychotic, higher EPS, but lower sedative and hypotensive effects than chlorpromazine. The 2- CF_3 versus the 2-Cl is associated with these changes. Overall, the drug has uses analogous to those of chlorpromazine.

Thioridazine Hydrochloride, USP. Thioridazine hydrochloride, 10-[2-(1-methyl-2-piperidyl)ethyl]-2-(methylthio)phenothiazine monohydrochloride (Mellaril), is a member of the piperidine subgroup of the phenothiazines. The drug has a relatively low tendency to produce EPS. The drug has high anticholinergic activity, and this activity in the striatum, counterbalancing a striatal DA block, may be responsible for the low EPS. It also has been suggested that there may be increased DA receptor selectivity, which may

be responsible. The drug has sedative and hypotensive activity in common with chlorpromazine and less antiemetic activity. At high doses, pigmentary retinopathy has been observed. Its major metabolites include *N*-demethylated, ring-hydroxylated, and *S*-oxidized products. Thioridazine is prominently converted to the active metabolite mesoridazine (discussed next), which probably contributes to the antipsychotic activity of thioridazine.

Mesoridazine Besylate, USP. Mesoridazine besylate, 10-[2-(methyl-2-piperidyl)ethyl]-2-(methylsulfinyl)phenothiazine monobenzenesulfonate (Serentil), shares many properties with thioridazine. However, no pigmentary retinopathy has been reported.

Prochlorperazine Maleate, USP. Prochlorperazine maleate, 2-chloro-10-[3-(4-methyl-1-piperazinyl)propyl]phenothiazine maleate (Compazine), is in the piperazine subgroup of the phenothiazines, characterized by high-milligram antipsychotic potency, a high prevalence of EPS, and low sedative and autonomic effects. Prochlorperazine is more potent on a milligram basis than its alkylamino counterpart, chlorpromazine. Because of the high prevalence of EPS, however, it is used mainly for its antiemetic effect, not for its antipsychotic effect.

Perphenazine, USP. Perphenazine, 4-[3-(2-chlorophenothiazine-10-yl)propyl]piperazineethanol; 2-chloro-10-[3-

[4-(2-hydroxyethyl)piperazinyl]propyl]phenothiazine (Trilafon), is an effective antipsychotic and antiemetic.

Fluphenazine Hydrochloride, USP. The member of the piperazine subgroup with a trifluoromethyl group at the 2-position of the phenothiazine system and the most potent antipsychotic phenothiazine on a milligram basis is fluphenazine hydrochloride, 4-[3-[2-(trifluoromethyl)phenazin-10-yl]propyl]-1-piperazineethanol dihydrochloride, 10[3-[4-(2-hydroxyethyl)piperazinyl]propyl]-2-trifluoromethylphenothiazine dihydrochloride (Permitil, Prolixin). It is also available as two lipid-soluble esters for depot intramuscular injection, the enanthate (heptanoic acid ester) and the decanoate ester. These long-acting preparations have use in treating psychotic patients who do not take their medication or are subject to frequent relapse.

Thiothixene, USP. The thioxanthene system differs from the phenothiazine system by replacement of the N-H moiety with a carbon atom doubly bonded to the propylidene side chain. With the substituent in the 2-position, *Z*- and *E*-isomers are produced. In accordance with the concept that the presently useful antipsychotics can be superimposed on DA, the *Z*-isomers are the more active antipsychotic isomers. The compounds of the group are very similar in pharmacological properties to the corresponding phenothiazines. Thus, thiothixene (*Z-N*-dimethyl-9-[3-(4-methyl-1-piperazinyl)propylidene]thioxanthene-2-sulfonamide (Navane), displays properties similar to those of the piperazine subgroup of the phenothiazines.

Ring Analogs of Phenothiazines: Benzazepines, Dibenzoxazepines, and Dibenzodiazepines

Additional tricyclic antipsychotic agents are the benzazepines, containing a seven-membered central ring (6-7-6 system). These newer atypical antipsychotics include diben-

zodiazepines (clozapine with 2-Cl), dibenzoxazepines (loxapine with 2-Cl), thienobenzodiazepines (olanzapine without 2-substituent), and dibenzothiazepines (quetiapine without 2-substituent). These ring analogs of phenothiazine antipsychotics; therefore, most of them share many clinical properties with the phenothiazines. However, they have some important differences, notably low production of EPS and reduction of negative symptoms. These benzazepines and other atypical antipsychotics including risperidone, ziprasidone, and aripiprazole block both D₂ and 5-HT_{2A} receptor, other DA and serotonin receptor subtypes, adrenergic, histamine, and muscarinic receptors. The low D₂ receptor affinity and the high 5-HT_{2A} receptor affinity of atypical antipsychotics including clozapine and olanzapine led to the proposal that 5-HT_{2A} antagonism accounts for their lower EPS.

PRODUCTS

Loxapine. A dibenzoxazepine derivative in use is *loxapine succinate*, 2-chloro-11-(4-methyl-1-piperazinyl)dibenz[*b, f*][1,4]oxazepine succinate (Daxolin). The structural relationship to the phenothiazine antipsychotics is apparent. Examples in this group are clothiapine, metiapine, zotepine, and others. They have electron-withdrawing groups at position 2, relatively close to the side-chain nitrogen atoms. Loxapine, an effective antipsychotic, blocks D₂-type receptors and has side effects similar to those reported for the phenothiazines. Its metabolism involves aromatic hydroxylation to give several phenolic metabolites that have higher affinity for D₂ receptors than the parent. It is also *N*-demethylated to yield amoxapine (an antidepressant drug), which inhibits norepinephrine (NE) neurotransporter to block neuronal NE reuptake.

Clozapine. The dibenzodiazepine derivative is *clozapine* (Clozaril). It is not a potent antipsychotic on a milligram basis (note the orientation of the *N*-methyl piperazine group relative to the chlorine atom). In addition to their moderate potencies at DA receptors (mainly D₄), clozapine interact with varying affinities at several other classes of receptors (α_1 and α_2 adrenergic, 5-HT_{1A}, 5-HT_{2A}, 5-HT_{2C}, muscarinic cholinergic, histamine H₁, and others). It is effective against both positive and negative symptoms of schizophrenia and has a low tendency to produce EPS. Clozapine has proved effective even in chronically ill patients who respond poorly to standard neuroleptics. However, there are legal restrictions on its use because of a relatively high frequency of agranulocytosis. As a rule, two other antipsychotics are tried before recourse to therapy with clozapine. Clozapine is metabolized

preferentially by CYP3A4 into demethylated, hydroxylated, and *N*-oxide derivatives that are excreted in urine and feces. Elimination half-life averages about 12 hours. Other clozapine-like atypical antipsychotics may lack a 2-Cl substituent on the aromatic ring (e.g., olanzapine and quetiapine).

Olanzapine and Quetiapine. Clozapine analogs, olanzapine (Zyprexa) and quetiapine (Seroquel) possess tricyclic systems with greater electron density than chlorpromazine. The drugs are atypical antipsychotics. Olanzapine is a more potent antagonist at D_2 and 5-HT_{2A} receptors than clozapine and is well absorbed, but about 40% of an oral dose is metabolized before reaching the systemic circulation. Plasma concentrations of olanzapine peak at about 6 hours after oral administration, and its elimination half-life ranges from 20 to 54 hours. Major readily excreted metabolites of olanzapine are the inactive 10-*N*-glucuronide and 4'-nor derivatives, formed mainly by the action of CYP1A2, with CYP2D6 as a minor alternative pathway. It may have even lower risk than risperidone and has achieved widespread use.

Overall, these two compounds should bind less strongly to D_2 receptors and permit more receptor selectivity among receptor subtypes than typical antipsychotics. This could

This keto group is important but can be replaced to *p*-F-phenyl group

This tertiary amino group attached to 4th carbon of the butyrophenone is important

Figure 12.7 • General structure and SAR of fluorobutyrophenones.

account for decreased striatal D₂-blocking activity (EPS). Quetiapine is highly metabolized by hepatic CYP3A4 to inactive and readily excreted sulfoxide and acidic derivatives.

Fluorobutyrophenones

The fluorobutyrophenones belong to a much-studied group of compounds, many of which possess high antipsychotic activity. The structural requirements for antipsychotic activity in the group are well worked out.³² General structure and SAR are expressed in the following structure (Fig. 12.7).

Attachment of a tertiary amino group to the fourth carbon of the butyrophenone skeleton is essential for neuroleptic activity; lengthening, shortening, or branching of the three-carbon propyl chain decreases neuroleptic potency. This aliphatic amino nitrogen is required, and highest activity is seen when it is incorporated into a cyclic form. A *p*-fluoro substituent aids activity. The C=O group gives optimal activity, although other groups, C(H)OH and C(H)aryl, also give good activity. The Y group can vary and assist activity, and an example is the hydroxyl group of haloperidol.

The empirical SARs could be construed to suggest that the 4-aryl piperidino moiety is superimposable on the

2-phenylethylamino moiety of DA and, accordingly, could promote affinity for D₂ and D₃ receptors. The long *N*-alkyl substituent could help promote receptor affinity and produce receptor antagonism activity and/or inverse agonism.

Some members of the class are D₂ and D₃ receptor antagonists and are extremely potent antipsychotic agents. EPS are extremely marked in some members of this class, which may, in part, be because of a potent DA block in the striatum and almost no compensatory striatal anticholinergic block. Most of the compounds do not have the structural features associated with effective anticholinergic activity.

Haloperidol, USP. Haloperidol, 4[4-(*p*-chlorophenyl)-4-hydroxypiperidone]-4'-*n*-fluorobutyrophenone (Haldol), the representative of several related classes of aromatic butylpiperidine derivatives, is a potent antipsychotic useful in schizophrenia and in psychoses associated with brain damage. It is frequently chosen as the agent to terminate mania and often used in therapy for Gilles de la Tourette syndrome. Haloperidol-induced dyskinesias may involve neurotoxicological metabolite similar to dopaminergic toxicant MPP⁺ (Fig. 12.8).

Figure 12.8 • Metabolism of haloperidol and its possible neurotoxic metabolites.

Droperidol

Droperidol, USP. Droperidol, 1-{1-[3-(*p*-fluorobenzoyl)propyl]-1,2,3,6-tetrahydro-4-pyridyl}-2-benzimidazolinone (Inapsine), may be used alone as a preanesthetic neuroleptic or as an antiemetic. Because of its very short-acting and highly sedating properties, its most frequent use is in combination (Innovar) with the narcotic agent fentanyl (Sublimaze) preanesthetically.

Risperidone. Risperidone (Risperdal, a benzisoxazole) has the structural features of a hybrid molecule between a butyrophenone antipsychotic and a trazodone-like antidepressant. Its superior side effects profile (compared with haloperidol) at dosage of 6 mg/d or less and the lower risk of tardive dyskinesia have contributed to its very widespread use. It benefited refractory psychotic patients, with parkinsonism controlled at one tenth the dose of antiparkinsonian drugs used with haloperidol.³³ Coexisting anxiety and depressive syndromes were also lessened. It is reported to decrease the negative (e.g., withdrawal, apathy) as well as the positive (e.g., delusions, hallucinations) symptoms of schizophrenia. This is reportedly a consequence of the compound's combination 5-HT₂-D₂ receptor antagonistic properties.³⁴ Overall, the reasons for the decreased EPS and

effectiveness against negative symptom are still under investigation. It is an important atypical antipsychotic. Risperidone is metabolized in the liver by CYP2D6 to an active metabolite, 9-hydroxyrisperidone. Because this metabolite and risperidone are nearly equipotent, the clinical efficacy of the drug reflects both compounds.

Figure 12.9 • Major metabolic pathway of ziprasidone.

Figure 12.10 • Major metabolic pathway for aripiprazole.

Ziprasidone. Ziprasidone (Geodon, a benzisothiazolpiperazinylindolone derivative) also has the structural features of a hybrid molecule between a butyrophenone antipsychotic and a trazodone-like antidepressant. It is highly metabolized to four major metabolites, only one of which, *S*-methylhydroziprasidone, likely contributes to its clinical activity (see Fig. 12.9). In humans, less than 5% of the dose is excreted unchanged. Reduction by aldehyde oxidase accounts for about 66% of ziprasidone metabolism; two oxidative pathways involving hepatic CYP3A4 account for the remainder.

Aripiprazole. Aripiprazole (Abilify). The newest, long-acting aripiprazole (an arylpiperazine quinolinone derivative), appears to be partial agonist of D_2 receptors (i.e., it stimulates certain D_2 receptors while blocking others depending on their locations in the brain and the concentration of drug). Bioavailability of aripiprazole is around 87%, with

peak plasma concentration attained at 3 to 5 hours after dosing. It is metabolized by dehydrogenation (see Fig. 12.10), oxidative hydroxylation, and *N*-dealkylation, largely mediated by hepatic CYPs 3A4 and 2D6.

The diphenylbutylpiperidine class can be considered a modification of the fluorobutyrophenone class. Because of their high lipophilicity, the compounds are inherently long acting. Pimozide has been approved for antipsychotic use, and penfluridol has undergone clinical trials in the United States. Overall, side effects for the two compounds resemble those produced by the fluorobutyrophenones.

β -AMINOKETONES

Several β -aminoketones have been examined as antipsychotics.³¹ They evolved out of research on the alkaloid lobeline. The overall structural features associated with activity

can be seen in the structure of molindone. In addition to the β -aminoketone group, there must be an aryl group positioned as in molindone. It might be conjectured that the proton on the protonated amino group in these compounds H-bonds with the electrons of the carbonyl oxygen atom. This would produce a cationic center, two-atom distance, and an aryl group that could be superimposed on the analogous features of protonated DA.

Molindone Hydrochloride. Molindone hydrochloride, 3-ethyl-6,7-dihydro-2-methyl-5-morpholinomethyl)indole-4(5*H*)-one monohydrochloride (Moban), is about as potent an antipsychotic as trifluoperazine. Overall, side effects resemble those of the phenothiazines.

Molindone Hydrochloride

BENZAMIDES

The benzamides evolved from observations that the gastroprokinetic and antiemetic agent, metoclopramide, has antipsychotic activity related to D_2 receptor block. It was hoped that the group might yield compounds with diminished EPS liability. This expectation appears to have been met. An H-bond between the amido H and the unshared electrons of the methoxyl group to generate a pseudo ring is considered important for antipsychotic activity in these compounds. Presumably, when the protonated amine is superimposed on that of protonated DA, this pseudo ring would superimpose on DA's aromatic ring.³⁴ These features can be seen in sulpiride and remoxipride.

Remoxipride (Roxiam). Remoxipride is a D_2 receptor blocker.³⁵ It is as effective as haloperidol with fewer EPS and autonomic side effects. Negative symptoms of schizophrenia are diminished. The drug is classed as an atypical antipsychotic. Life-threatening aplastic anemia was reported with its use, which prompted its withdrawal from the market.

With respect to the atypical antipsychotics, two events long in the past may shed some light on the events of today.

Metoclopramide
an gastroprokinetic & antiemetic agent
an 5-HT₄-partial agonists and D₂ antagonist

Sulpiride

Remoxipride

The field of reuptake-inhibiting antidepressants arose when only a very small structural change was made in an antipsychotic drug, and the new activity noted. (The antipsychotic activity remained.) Therefore, small changes in structure can produce antipsychotics that are active against depressive symptoms. Likewise, small changes in structure could provide selectivity among D_2 receptors.

Almost 40 years ago, it was noted that thioridazine was far less unpleasant for patients than its relatives.³⁶ Its tricyclic system is far more nucleophilic than that of most other drugs. The emphasis at the time, however, was to increase milligram potency by increasing D_2 receptor affinity by lowering tricyclic electron density. The experience of clozapine, with increased electron density of the receptor-binding rings and thus lower affinity, appears to validate the observation about thioridazine and appears to allow more selectivity among D_2 receptors. Lessening blocks on, for example, striatal D_2 receptors, and possibly mesocortical D_2 receptors could produce drugs that are much less unpleasant for the patient. Additionally, a less intense D_2 block could allow the effects of other blocks to make up more of the drug's total action (e.g., 5-HT transporter block). Several atypical antipsychotics have rings with enhanced nucleophilicity. Of course, other structural features could be influencing receptor selectivity, for example, increasing steric hindrance to receptor binding by the protonated amino group or to the ring binding.

Antimanic Agents

LITHIUM SALTS

The lithium salts used in the United States are the carbonate (tetrahydrate) and the citrate. Lithium chloride is not used because of its hygroscopic nature and because it is more irritating than the carbonate or citrate to the GI tract.

The active species in these salts is the lithium ion. The classic explanation for its antimanic activity is that it resembles the sodium ion (as well as potassium, magnesium, and calcium ions) and can occupy the sodium pump. Unlike the sodium ion, it cannot maintain membrane potentials. Accordingly, it might prevent excessive release of NTs (e.g., DA) that characterize the manic state. Many of the actions of lithium ion have been reviewed.³⁷ Despite considerable investigation, the mode of action of lithium remains unclear. The major possibility is that lithium reduces signal transduction through the phosphatidylinositol signaling pathway by uncompetitive inhibition of inositol phosphatase. As a result, the pool of inositol available for the

resynthesis of phosphatidylinositol-4,5-bisphosphate (PIP₂) is depleted, the cellular levels of PIP₂ is decreased, thereby, enzymatic formation of the second messengers is reduced.

The indications for lithium salts are acute mania (often with a potent neuroleptic agent for immediate control, because lithium is slow to take effect) and as a prophylactic to prevent occurrence of the mania of bipolar manic-depressive illness. Lithium salts are also used in severe recurrent unipolar depression. One effect of the drug that might be pertinent is an increase in the synthesis of presynaptic serotonin. Some have speculated that simply evening out transmission, preventing downward mood swing, for example, could be a basis for antidepressant action.

Because of its water solubility, the lithium ion is extensively distributed in body water. It tends to become involved in the many physiological processes involving sodium, potassium, calcium, and magnesium ions, hence, many side effects and potential drug interactions exist. The margin of safety is low; therefore, lithium should be used only when

plasma levels can be monitored routinely. In the desired dose range, side effects can be adequately controlled.

Because of the toxicity of lithium, there is substantial interest in design of safer compounds. As more is learned about lithium's specific actions, the likelihood of successful design of compounds designed to act on specific targets is increased. Actually, carbamazepine and valproic acid, which target sodium channels, are proving to be effective.³⁸ These two drugs are discussed in the anticonvulsant section.

Lithium Carbonate, USP, and Lithium Citrate. Lithium carbonate (Eskalith, Lithane) and lithium citrate (Cibalith-S) are the salts commercially available in the United States.

Central Dopaminergic Signaling Agents

A. MICHAEL CRIDER, MARCELO J. NIETO, AND KENNETH A. WITT

CHAPTER OVERVIEW

The understanding and development of dopamine (DA)-focused pharmacotherapy, with regard to central nervous system (CNS) disorders, requires the insight and integration of multiple disciplines. The structure–activity relationship (SAR) between drug and target, forming the foundation of medicinal chemistry, must be grounded by the ability to assess and discern the diseases under investigation. It is necessary to evaluate the drug with regard not only to the target, but also to the effects of the body on the drug, the nature of disease, subsequent actions of the target, and any potential “nontarget” actions. In this regard, DA-focused pharmacotherapy possesses numerous caveats owing to our lack of complete understanding of specific diseases and the overlapping action of the dopaminergic systems within the brain. Nevertheless, the respective drugs addressed in this chapter have proven to be effective in the symptomological management of Parkinson disease (PD) and schizophrenia, significantly enhancing the quality of life of individuals suffering from these disease states.

DOPAMINE

DA acts as a CNS neurotransmitter, controlling emotion, movement, and reward mechanisms, as well as serving as the metabolic precursor of norepinephrine and epinephrine. DA is classified as a catecholamine neurotransmitter based on its catechol nucleus and is derived from the amino acid tyrosine. Tyrosine is transported across the blood-brain barrier (BBB) into the brain, where it is then taken up by dopaminergic neurons. Conditions affecting tyrosine transport into the brain significantly impact DA formation. Once L-tyrosine enters the dopaminergic neuron, it is converted to L-dihydroxyphenylalanine (L-DOPA) by the enzyme tyrosine hydroxylase (TH), which is the rate-limiting step in DA synthesis. Subsequently, the enzyme L-aromatic amino acid decarboxylase (AADC) converts L-DOPA to DA (Fig. 13.1). The normally high levels of AADC in the brain will allow for the substantial increase in DA levels if levels of L-DOPA are increased. DA itself does not cross the BBB; however, L-DOPA crosses via the large neutral amino acid carrier.¹

Dopamine Storage and Release

DA is stored in neuronal presynaptic vesicles, with its release controlled by both nerve impulse and DA-autoreceptors

present on presynaptic neurons (Fig. 13.2). The nerve impulse (i.e., action potential) results in rapid depolarization causing calcium ion channels to open. Calcium then stimulates the transport of vesicles to the synaptic membrane; the vesicle and cell membrane fuse, which leads to the release of the DA. In general, the degree of DA release is dependent on the rate and pattern of the nerve impulse. The greater the speed and number of impulses, the more DA is released into the synaptic cleft—at least until the DA vesicle concentrations are depleted. The release process can also be modulated via DA-autoreceptors, which are present on presynaptic neurons. DA-autoreceptors act as a negative-feedback control mechanism that modifies both the release and synthesis of DA. In this regard, agonists with selectivity for presynaptic DA-autoreceptors (D₂-subtype) act to reduce DA levels and antagonists act to enhance DA levels.

Dopamine Receptors

Dopaminergic-mediated physiological effects are dependent on affinity and selectivity of a ligand (agonist or antagonist) for DA receptors. DA receptors fall into the larger class of metabotropic G-protein–coupled receptors that are prominent in the vertebrate CNS. Endogenous DA is the primary ligand for DA receptors. Once DA is released from presynaptic neurons, it acts at presynaptic DA-autoreceptors and postsynaptic receptors (Fig. 13.2). DA receptors are divided into five subtypes, D₁ to D₅. These five subtypes are grouped into two principal categories based on structure and signaling transduction mechanisms. D₁ and D₅ receptors are members of the “D1-family” of DA receptors; whereas the D₂, D₃, and D₄ receptors are members of the “D2-family.”² Activation of D1-family receptors stimulates the formation of cyclic adenosine monophosphate (cAMP) and phosphatidyl inositol hydrolysis. Increased cAMP in neurons is typically excitatory and can induce an action potential by modulating the activity of ion channels. Whereas, D2-family receptor activation inhibits cAMP synthesis, as well as suppresses Ca²⁺ currents and activates receptor-operated K⁺ currents. Decreased cAMP in neurons is typically inhibitory and reduces DA release. DA-autoreceptors are of the D2-family.

Although D1- and D2-family receptors have opposite effects with regard to cAMP, the physiological significance of their interactions is much more complex. DA receptors are widespread throughout the brain, but each subtype has a unique distribution. Additionally, postsynaptic DA receptors exist on multiple neuronal subtypes (e.g., gamma-aminobutyric acid [GABA]ergic, glutamatergic,

Figure 13.1 • Synthesis of DA.

and cholinergic neurons). Drugs that act as DA receptor agonists or antagonists often have differing affinity and selectivity for respective DA receptor subtypes. Thus, the net effect of any DA receptor agonist or antagonist on dopaminergic activity is dependent on both its presynaptic and postsynaptic effects. This complexity is further compounded by the receptor adaptations during disease states, such as PD and schizophrenia^{3,4}; as some DA receptor subtypes will upregulate (increased number of receptors), whereas other subtypes will downregulate (decreased number of receptors) dependent on stage of disease and time profile of drug treatment.

Dopamine Transporter

The dopamine transporter (DAT) is the primary mechanism by which DA is removed from the synaptic cleft. The DAT plays a critical role in the inactivation and recycling of DA by actively pumping the extracellular DA back into presynaptic nerve terminals. Regional brain distribution of DAT is found in areas with established dopaminergic circuitry (e.g., mesostriatal, mesolimbic, and mesocortical pathways). Its cellular localization at presynaptic terminals provides an

excellent marker of dopaminergic neurons that are damaged in PD.⁵ Additionally, the DAT has a well-established pharmacologic profile and is the principal target of psychostimulants (e.g., cocaine, amphetamine, and methylphenidate), which inhibit the reuptake of DA in the synaptic cleft resulting in locomotor stimulation.

Dopamine Metabolism

DA metabolism occurs through enzymatic action, via monoamine oxidase (MAO) or catechol-*O*-methyltransferase (COMT) (Fig. 13.3). There are two forms of MAO, MAO-A and MAO-B, both of which oxidize DA. DA is metabolized by intraneuronal MAO-A and by glial and astrocyte cells by MAO-A and MAO-B.⁶ Depending on the pathway, DA can be converted to either dihydroxyphenylacetic acid (DOPAC) or homovanillic acid (HVA). In humans, the major brain metabolite is HVA, followed by DOPAC. Accumulation of HVA in the cerebrospinal fluid (CSF) and brain can be used as a measure of the functional activity of dopaminergic neurons in the brain. Drugs that increase the turnover of DA (e.g., antipsychotics) also increase the amount of HVA in the brain and CSF.⁷

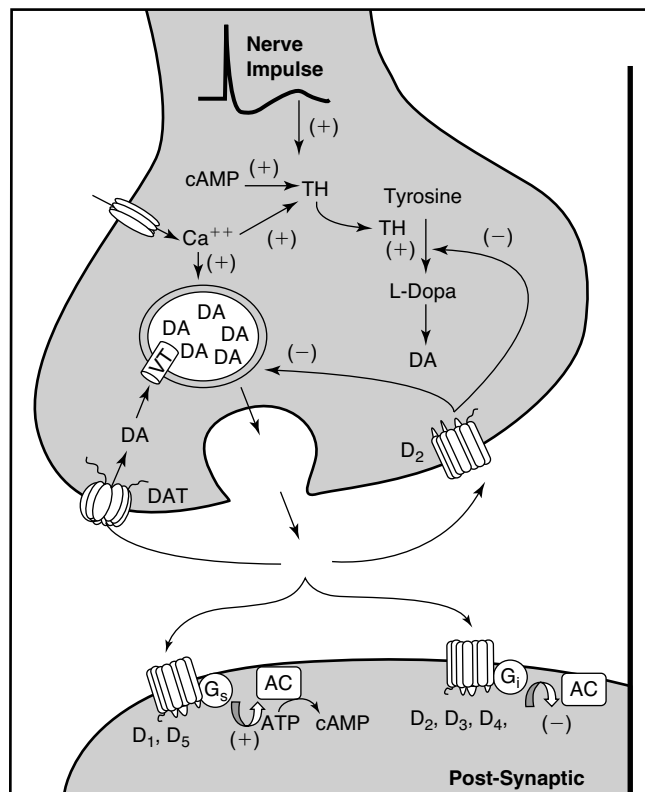

Figure 13.2 • Schematic model of mechanisms involved in DA synthesis, release, storage, reuptake, and receptor activity in presynaptic and postsynaptic neurons. (AC, adenylate cyclase; cAMP, cyclic adenosine monophosphate; VT, vesicular monoamine transporter.)

Dopaminergic Pathways

To understand the actions of DA-focused pharmacotherapy and the associated adverse effects, it is necessary to identify the principal dopaminergic pathways in the brain.^{3,4,7} The neurotransmission of DA can be divided into several major pathways: the nigrostriatal, mesocortical, mesolimbic, and tuberohypophyseal DA neuronal pathways (Fig. 13.4). The nigrostriatal pathway accounts for ~75% of the DA in the brain, consisting of cell bodies in the substantia nigra whose axons terminate in the striatum (principal connective nuclei of the basal ganglia). It is involved in the production of movement, as part of a system called the basal ganglia motor loop and is directly affected in PD. This system may also be involved in short-term side effects of antipsychotic medication (i.e., tremor and muscle rigidity), as well as long-term side effects of tardive dyskinesia. The mesocortical pathway originates in the ventral tegmental area and projects to the prefrontal cortex. It is essential to the normal cognitive function of the prefrontal cortex and is thought to be involved in motivation and emotional response. The mesolimbic pathway originates in cell bodies in the ventral tegmental area of the midbrain and project to the mesial components of the limbic system. Mesolimbic DA neurons are involved with pleasure and reward behavior and are heavily implicated in addiction. The tuberohypophyseal pathway emanates from the periventricular and arcuate nuclei of the hypothalamus, with projections to the pituitary gland and the median eminence of the hypothalamus (i.e., tuberoinfundibular DA tract). The tuberohypophyseal pathway is involved in the regulation of prolactin.

Figure 13.3 • Metabolic pathway of DA.

PARKINSON DISEASE

PD is a progressive neurodegenerative illness characterized by tremor, muscular rigidity, bradykinesia (slowness of movement), and postural imbalance.⁸ The incidence of PD is estimated to be about 1% in the general population older than 60 years of age.⁹ Although characterized as a neuromuscular disorder, dementia also occurs at a much greater rate in PD patients over the normal age-matched population.¹⁰ Although the etiology of PD remains unknown, several factors appear to play a role, including the aging process, environmental chemicals, oxidative stress, and genetic aspects.⁹ The discovery that drug addicts exposed to the pyridine derivative 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), a byproduct of “synthetic heroin,” developed a profound parkinsonian state led to intense study of the pathogenesis of PD.^{11,12} On the basis of investigations in the treatment of MPTP-treated primates, a working

understanding of neurochemical basis of PD has developed. The primary motor control-related symptoms have shown to be the result of dysregulation of the motor cortex via the nigrostriatal pathway. The dysregulation is caused by the depletion of DA-producing neurons within the pars compacta region of the substantia nigra that project to the striatum. This is often accompanied by Lewy bodies, which are abnormal aggregates of protein that develop inside nerve cells. In healthy individuals, stimulation of D₁ receptors within the striatum results in an increased excitatory outflow from the thalamus to the motor cortex and is known as the “direct pathway”; whereas stimulation of the D₂ receptors within the striatum results in a decreased excitatory outflow from the thalamus to the motor cortex and is known as the “indirect pathway.” However, under conditions of PD, the loss of dopaminergic input to the striatum leads to a decreased activity in the direct pathway and an increased activity in the indirect pathway (via D₁ and D₂ receptors, respectively). Both of these changes lead to

Figure 13.4 • Dopamine pathways in the brain (pathway projections not shown in their entirety). (Hp, hypothalamus; VTA, ventral tegmental area.)

decreased excitatory input to the motor cortex and the hypokinetic symptomatology associated with PD. Nevertheless, the symptoms of PD are not seen until about 80% of the dopaminergic neurons in the striatum have been destroyed. Thus, significant disease progression must occur before there is an observable reduction of motor movement and control.

Although DA loss within the striatum is the primary neurological factor associated with PD, other DA pathways and receptors have also been implicated. It has been postulated that dysregulation of mesolimbic and mesocortical dopaminergic pathways directly contributes to the depression states common with PD.¹³ Dementia with PD has been shown to correlate with a loss of response to dopaminergic drugs, which has been correlated with reduced D₃ receptors.¹⁴ DA D₃ receptors have also been postulated to play a role in motor control deficits associated with PD because they are often found colocalized with D₁ and D₂ and have shown to have a reduced expression in the basal ganglia of postmortem PD brains.^{14–16} However, the recognition of dopaminergic pathway and receptor changes has not led to any more effective treatment than levodopa, which remains the gold standard. Clinical trials on the D₁/D₂/D₃ agonist rotigotine have shown promise in alleviating symptoms of early PD.¹⁷ Yet, simply obtaining an optimal ratio of drug activity at these receptors will not slow the degeneration of dopaminergic neurons. Nevertheless, current PD pharmacotherapy is centered on replacement of dopaminergic activity within the striatum. Whether this is to enhance DA release from remaining neurons, increase DA synthesis, provide exogenous DA agonists, or reduce DA metabolism, none of these approaches or combinations therein have shown to provide successful long-term treatment of symptoms.

Levodopa/Carbidopa

The first significant breakthrough in the treatment of PD came about with the introduction of high-dose levodopa. Fahn¹⁸ referred to this as a revolutionary development in treating parkinsonian patients. The rationale for the use of levodopa for the treatment of PD was established in the early 1960s. Parkinsonian patients were shown to have decreased striatal levels of DA and reduced urinary excretion of DA. Since then, levodopa has shown to be remarkably effective for treating the symptoms of PD.¹⁹ Because of enzymatic action of MAO-A in the gastrointestinal (GI) tract and AADC in the periphery, only a small percentage (1%–2%) of levodopa is delivered into the CNS. Coadministration of levodopa with the AADC inhibitor, carbidopa, prevents decarboxylation of levodopa outside of the CNS. The combination of levodopa and carbidopa results in a substantial increase in DA delivery to the CNS with a decrease in peripheral side effects. Long-term therapy with levodopa leads to predictable motor complications. These include loss of efficacy before the next dose (“wearing off”), motor response fluctuations (“on/off”), and unwanted movements (dyskinesias).^{20,21} These effects are thought to be caused by the inability of levodopa therapy to restore normal DA levels in the CNS.²² As a result, the use of longer-acting DA agonists may benefit parkinsonian patients.

Levodopa, United States Pharmacopeia (USP).

Levodopa, (*S*)-2-amino-3-(3,4-dihydroxyphenyl) propanoic acid, is a white or almost white crystalline powder, slightly soluble in water, soluble in acidic and basic solutions, and practically insoluble in alcohol, chloroform, and ether. Aqueous solutions are neutral to slightly acidic (pK_a 's = 9.9 and 11.8).²³ Levodopa is rapidly absorbed from the small intestine by an active transport system for aromatic amino acids. It is widely distributed to most body tissues, but less to the CNS, and is bound to plasma proteins only to a minor extent (10%–30%). Levodopa is extensively decarboxylated by first-pass metabolism in the liver. A small amount is methylated to 3-*O*-methyl dopa (3OMD), which accumulates in the CNS because of its long half-life. Most of levodopa is converted to DA, small amounts of which in turn are metabolized to norepinephrine and epinephrine. At least 30 metabolites of levodopa have been identified. Metabolites of DA are rapidly excreted in the urine. The principal metabolites DOPAC and HVA (Fig. 13.3) account for up to 50% of the administered dose. After prolonged therapy with levodopa, the ratio of DOPAC and HVA excreted may increase, probably reflecting a depletion of methyl donors necessary for metabolism by COMT. Antipsychotic drugs, such as phenothiazines, butyrophenones, and reserpine interfere with the therapeutic effects of levodopa, and nonspecific MAO inhibitors interfere with inactivation of DA. Anticholinergic drugs (e.g., trihexyphenidyl, benztropine, and procyclidine) act synergistically with levodopa to improve certain symptoms of PD, especially tremor. However, large doses of anticholinergic drugs can slow gastric emptying sufficiently to cause a delay in reabsorption of levodopa by the small intestine. Sympathomimetic agents such as epinephrine or isoproterenol may also enhance the cardiac side effects of levodopa. In some patients, the coadministration of antacids may enhance the GI absorption of levodopa. Levodopa is essentially a prodrug; that is itself inactive, but after penetrating, the BBB is metabolized to DA. Levodopa is indicated for the treatment of idiopathic, postencephalitic, and symptomatic parkinsonism.

Carbidopa, USP. Carbidopa, (*S*)-3-(3,4-dihydroxyphenyl)-2-hydrazinyl-2-methylpropanoic acid, is a white crystalline powder, slightly soluble in water (pK_a = 7.8). Carbidopa is absorbed slower than levodopa and is 36% plasma protein bound.²³ Carbidopa is metabolized to two main metabolites (α -methyl-3-methoxy-4-hydroxyphenylpropionic acid and α -methyl-3,4-dihydroxyphenylpropionic acid). These two metabolites are primarily eliminated in the urine unchanged or as glucuronide conjugates. Unchanged carbidopa accounts for 30% of the total urinary excretion. No drug interactions have been described.

MAO-B Inhibitors

MAO inhibitors are utilized to prolong the plasma half-life of levodopa or block the striatal metabolism of DA. Initially, the

use of nonselective MAO inhibitors led to serious adverse effects caused by peripheral inhibition of monoamines. The use of selective MAO-B inhibitors decreases the risk of a hypertensive crisis that is associated with nonselective MAO inhibitors. The addition of a selective MAO-B inhibitor to levodopa therapy decreases both the metabolism of DA that is produced from levodopa and DA that is already present in the striatum.

Selegiline is an irreversible MAO-B inhibitor. Unlike compounds that inhibit MAO-A, selegiline does not produce the so-called cheese effect. This is a hypertensive crisis of the cardiovascular system caused by elevated levels of *p*-tyramine and other indirectly acting sympathomimetic amines that are found in certain foods (e.g., red wine, cheese, and herring).²⁴ Selegiline potentiates the effects of levodopa by blocking its metabolism by MAO. When administered with levodopa, selegiline allows for a reduction in the daily dosage and appears to improve the wearing-off effect of levodopa. However, whether selegiline is able to exert a neuroprotective effect in PD is inconclusive.²⁵ Selegiline is extensively first-pass metabolized to yield *N*-desmethylselegiline, 1-methamphetamine, and 1-amphetamine. These metabolites have been implicated in some of the psychomotor and cardiovascular adverse effects of selegiline.²⁶

Rasagiline is a selective irreversible inhibitor of MAO-B that is approximately five times more potent than selegiline. The *R*-isomer is the active enantiomer whereas the *S*-isomer demonstrates only weak inhibition of MAO-B. Similar to selegiline, rasagiline does not produce the characteristic cheese effect that is observed for nonselective MAO inhibitors.²⁷ The neuroprotective effect of rasagiline is inferred by the propargyl group. This effect is observed at drug concentrations well below those necessary to cause MAO-B inhibition. Several mechanisms have been proposed for the neuroprotective effect of rasagiline including (a) a decrease in proapoptotic proteins (Bax and Bad), (b) an increase in antiapoptotic proteins (Bcl-2 and Bcl-xL), and (c) stabilization of mitochondrial membrane potential, thus preventing subsequent release of proapoptotic proteins.^{28,29}

Selegiline Hydrochloride, USP. Selegiline hydrochloride, (*R*)-*N*-methyl-*N*-(1-phenylpropan-2-yl)prop-2-yn-1-amine hydrochloride (Eldepryl), is an off-white powder, freely soluble in water and methanol ($pK_a = 7.4$).³⁰ Selegiline is readily absorbed from the GI tract. It is well distributed in the body and it penetrates the CNS. Selegiline has a high apparent volume of distribution, short half-life, and a very high oral clearance, indicating an extensive metabolism not only in the liver but also through extrahepatic biotransformation. Transdermal delivery reduces the first-pass metabolism and provides higher and more prolonged plasma levels of unchanged selegiline and lower levels of metabolites compared with the oral administration.³¹ Selegiline transdermal system (EMSAM) has recently been approved for the treatment of depression.²³ Selegiline administered with fluoxetine may produce a “serotonin” syndrome (CNS irritability, increased

muscle tone, altered consciousness), and with meperidine could result in agitation, seizures, diaphoresis, and fever, which may progress to coma, apnea, and death. Drug reactions may occur several weeks following withdrawal of selegiline. The use of selegiline as monotherapy is limited to younger patients with early disease and without disabling symptoms.

Rasagiline Mesylate. Rasagiline mesylate, (*R*)-*N*-(prop-2-ynyl)-2,3-dihydro-1*H*-inden-1-amine methanesulfonate (Azilect), belongs to the propargylamine family and is a white to off-white powder, soluble in water or ethanol, slightly soluble in isopropanol. Rasagiline is rapidly absorbed. Plasma protein binding for rasagiline ranges from 88% to 94%, with specific binding to serum albumin being 61% to 63%. It undergoes complete biotransformation before excretion, mainly via *N*-dealkylation and hydroxylation, to yield three major metabolites: 1(*R*)-aminoindan, 3-hydroxy-*N*-propargyl-1-aminoindan, and 3-hydroxy-1-aminoindan. Both oxidative pathways are catalyzed by cytochrome P450 (CYP) enzymes, mainly the 1A2 isozyme. Rasagiline and its metabolites undergo glucuronide conjugation with subsequent urinary excretion.²⁹ Inhibitors of the CYP1A2 may increase plasma concentrations of rasagiline up to twofold.^{32,33} Because rasagiline is a selective and irreversible inhibitor of MAO-B, its duration of action is independent of the drug’s half-life and is instead determined by the regeneration rate of MAO-B. This characteristic is potentially beneficial in PD, where rasagiline’s prolonged effect may be able to limit the fluctuating responses that are characteristic of long-term drug treatment with levodopa.³⁴

Dopamine Agonists

The addition of DA agonists to levodopa therapy has gained widespread popularity in the treatment of PD.³⁵ DA agonists not only produce less dyskinesia, but also have been hypothesized to slow the progressive degeneration of DA neurons.³⁶ DA agonists are classified into ergot derivatives (pergolide, cabergoline, and bromocriptine) and nonergot derivatives (apomorphine, pramipexole, ropinirole, and rotigotine).

ERGOT DERIVATIVES

Pergolide binds with high affinity as an agonist at D_2 -type and $5-HT_{2B}$ receptors.³⁷ The compound also binds at D_1 receptors but with approximately 300-fold less affinity than at D_2 receptors. Pergolide is believed to induce valvular heart disease by acting on $5-HT_{2B}$ receptors.³⁸ Because of the potential for cardiac valve damage, pergolide has been recently withdrawn from the market.²³ Cabergoline exhibits high affinity at D_2 -like receptors with over 50-fold selectivity compared with D_1 -like receptors.³⁹ Additionally, cabergoline binds with high affinity at $5-HT_{2A}$ and $5-HT_{2B}$ receptors.³⁷ The compound is approved in the United States only for hyperprolactinemia but is used in other countries for the treatment of PD. At the low dose used in the treatment of hyperprolactinemia, cabergoline does not appear to increase the risk of cardiac valve complications.²³ Bromocriptine acts as an agonist at D_2 -like receptors and an antagonist at D_1 -like receptors.⁴⁰ Additionally, it exhibits high affinity at $5-HT_{2A}$ and $5-HT_{2B}$ receptors. Although bromocriptine acts as an agonist at $5-HT_{2A}$ receptors, it shows partial agonism at $5-HT_{2B}$

receptors.⁴¹ Compared with cabergoline, bromocriptine exhibits less dyskinesia, which may be related to its D₁-antagonist activity.³⁷

Bromocriptine Mesylate, USP. Bromocriptine mesylate, (6*aR*,9*R*)-5-bromo-*N*-((2*R*,5*S*,10*aS*,10*bS*)-10*b*-hydroxy-5-isobutyl-2-isopropyl-3,6-dioxooctahydro-2*H*-oxazolo[3,2-*a*]pyrrolo[2,1-*c*]pyrazin-2-yl)-7-methyl-4,6,6*a*,7,8,9-hexahydroindolo[4,3-*fg*]quinoline-9-carboxamide methanesulfonate (Parlodel), is a white solid soluble in ethanol and slightly soluble in water (pK_a 's = 6.6 and 15). Bromocriptine is rapidly absorbed after oral administration and it has low systemic bioavailability because of its extensive first-pass metabolism. Bromocriptine enters the brain quickly with a half-life for uptake into the brain of approximately 0.3 hours; 8% of the drug crosses the BBB.²³ The metabolites are excreted primarily in the bile and feces. The high first-pass hepatic metabolism implies an increased risk of drug interactions. Concomitant administration with the DA antagonists, metoclopramide, or domperidone may aggravate parkinsonian symptoms and induce extrapyramidal side effects (EPS). Other drugs that may interact with bromocriptine are highly plasma protein-bound drugs (e.g., warfarin, increased dyskinesia caused by bromocriptine); macrolides antibacterials (enhanced dopaminergic effects); and caffeine (elevation in plasma bromocriptine concentrations). The combination of levodopa/AADC inhibitors with bromocriptine permits a reduction of the dose of levodopa. Thus, the side effects of levodopa are decreased, resulting in a more continuous stimulation of DA receptors.

Cabergoline. Cabergoline, (6*aR*,9*R*,10*aR*)-7-allyl-*N*-(3-(dimethylamino)propyl)-*N*-(ethylcarbamoyl)-4,6,6*a*,7,8,9,10,10*a*-octahydroindolo[4,3-*fg*]quinoline-9-carboxamide (Dostinex), is a white powder soluble in alcohol, chloroform, and *N,N*-dimethylformamide; slightly soluble in acidic solutions and in *n*-hexane; and insoluble in water. Following oral administration, peak plasma concentrations are reached within 2 to 3 hours. Cabergoline is moderately bound to plasma proteins in a concentration-independent manner. The absolute bioavailability of cabergoline is unknown. Cabergoline is extensively metabolized by the liver, predominantly via hydrolysis of the acylurea bond of the urea moiety. CYP450 metabolism appears to be minimal. The major metabolites identified thus far do not

contribute to the therapeutic effect of cabergoline. Less than 4% is excreted unchanged in the urine. Fecal excretion represents the main route of cabergoline elimination. There are no reports of interactions of cabergoline with other antiparkinsonian agents. Clarithromycin may elevate the plasma concentration of cabergoline by the inhibition of both CYP3A4 and P-glycoprotein.⁴² Cabergoline is a potent D₂ receptor agonist and is indicated for the treatment of hyperprolactinemic disorders, either idiopathic or caused by pituitary adenomas.

NONERGOT DERIVATIVES

Pramipexole acts as an agonist at D₂ and D₃ receptors with greater affinity for D₃ than D₂ receptors. The compound has no appreciable affinity for D₁, D₅, 5-HT_{2A}, and 5-HT_{2B} receptors.³⁷ The reduced dyskinesia associated with pramipexole compared with cabergoline may be related to its low affinity for the D₁ receptor. Ropinirole has about 20-fold selectivity for cloned human D₃ receptors compared with D₂ receptors. Additionally, ropinirole has low affinity for 5-HT_{2A}, 5-HT_{2B}, and D₁-like receptors.³⁷ A recent study suggests that D₃-agonists may be able to restore DA neurons and exert a neuroprotective effect.⁴³ These developments could offer exciting new therapeutic options for parkinsonian patients.

Apomorphine Hydrochloride, USP. Apomorphine hydrochloride, (6*aR*)-6-methyl-5,6,6*a*,7-tetrahydro-4*H*-dibenzo[de,g]quinolone-10,11-diol hydrochloride (Apokyn), is a white or off-white powder or crystal soluble in hot water (pK_a = 8.92). Apomorphine is an aporphine alkaloid of the benzoquinoline class. Oral apomorphine is poorly absorbed and has a bioavailability of less than 4%. Upon subcutaneous administration, apomorphine is completely absorbed. Within 10 to 20 minutes, the maximum concentration of the drug is distributed from the blood plasma to the CSF. Other potential routes of administration include continuous subcutaneous infusion, intravenous infusion, intranasal spray application, sublingual, and rectal administration.²³ The agent is highly lipophilic in nature, allowing for rapid diffusion across the BBB after injection. Apomorphine has a short plasma half-life; however, clinical effects may last from 60 to 90 minutes. Apomorphine displays a significant degree of interpatient variability in its pharmacokinetic profile. Studies of both intravenous and subcutaneous injection routes found this

variation was not attributable to body weight, age, gender, and duration of PD or L-DOPA dose/duration alone. Apomorphine is extensively metabolized. Hypothesized routes include sulfation, *N*-demethylation, glucuronidation, and oxidation. Subcutaneous injections of apomorphine are renally and hepatically cleared, with the majority appearing to be renally cleared. Dosage adjustments are needed in both liver and renal impairment. The activity of apomorphine is believed to be caused by stimulation of postsynaptic D₁- and D₂-type receptors within the caudate/putamen in the brain. Apomorphine is indicated for the acute, intermittent treatment of hypomobility, “off” episodes (“end-of-dose wearing off” and unpredictable on/off episodes) associated with advanced PD.²³

Pramipexole Dihydrochloride. Pramipexole dihydrochloride, (*S*)-2-amino-6-propylamino-dihydrochloride (Mirapex), is a white to off-white powder soluble in water, slightly soluble in methanol and ethanol, and practically insoluble in dichloromethane. Following oral administration, pramipexole is readily absorbed. Pharmacokinetic properties differ between men and women, with area under the curve (AUC) for each dose level being 35% to 43% greater in women, mainly because of a 24% to 27% lower oral clearance. The drug undergoes minimal hepatic biotransformation and is excreted virtually unchanged in the urine by the renal tubular secretion. Pramipexole interacts with drugs excreted by renal tubular secretion (H₂-antagonists, diuretics, verapamil, quinidine, quinine), which leads to a decreased clearance of pramipexole.^{44,45} Pramipexole is indicated for treatment of the signs and symptoms of idiopathic PD, alone or in combination with levodopa. It is also indicated for symptomatic treatment of moderate to severe idiopathic restless legs syndrome (RLS).

Ropinirole Hydrochloride. Ropinirole hydrochloride, 4-(2-(dipropylamino)ethyl)indolin-2-one hydrochloride (Requip), is a white to pale greenish yellow powder that is very soluble in water. Ropinirole is rapidly absorbed after oral administration with maximal plasma concentrations generally reached after about 1.5 hours, and the elimination half-life appears to be approximately 3 hours. Ropinirole is also rapidly and extensively distributed from the vascular compartment and shows low plasma protein binding that is independent of its plasma concentration. This drug is cleared by metabolism in the liver, with only 10% being excreted unchanged. The main metabolite of ropinirole is the *N*-despropyl metabolite. The glucuronide of this metabolite and the carboxylic acid metabolite, 4-carboxymethylindolin-2-one, account only for 10% of the administered dose. None of the metabolites is pharmacologically active, and the excretion of ropinirole-derived products is mainly via the urine. The main CYP450 isozyme involved in the metabolism of ropinirole is CYP1A2. Inhibitors or inducers of this enzyme have been shown to alter the clearance of ropinirole.^{46,47} Ropinirole is believed to act as an agonist at postsynaptic D₂ receptors. Ropinirole is indicated for the treatment of the signs and symptoms of idiopathic PD and moderate to severe primary RLS.

Rotigotine. Rotigotine, (6*S*)-6-{propyl[2-(2-thienyl)ethyl]amino}-5,6,7,8-tetrahydro-1-naphthalenol (Neupro), is a nonergoline that is available as a silicone-based, self-adhesive matrix, transdermal system for continuous delivery

over a 24-hour period. Approximately 45% of the drug is released within 24 hours. The terminal half-life of rotigotine is 5 to 7 hours after removal of the patch. Rotigotine is 90% bound to plasma proteins. The compound undergoes extensive metabolism and has low bioavailability by the oral route. The major metabolites of rotigotine are the glucuronide and sulfate conjugates of rotigotine and sulfate conjugates of *N*-despropylrotigotine and *N*-desthienylethyl rotigotine. Rotigotine is excreted in the urine (71%) and feces (11%).²³ Studies using human liver microsomes did not find any interactions with CYP1A2, CYP2C9, CYP2C19, CYP2D6, and CYP3A4 substrates.⁴⁸ Rotigotine transdermal system contains sodium metabisulfite, and individuals sensitive to sulfite could be at risk for allergic reactions. Additionally, somnolence is a common adverse reaction with individuals on rotigotine, and patients should be closely monitored during therapy.²³ In transfected Chinese hamster ovary (CHO) cells, rotigotine binds with high affinity at D₃ and D_{2L} receptors (variants in the D₂ receptor subtype are caused by insertion of the 29 amino acids into the third loop to give D_{2s} and D_{2L}).⁴⁹ Using rat CHO cells, rotigotine shows over 30-fold selectivity at D₃ versus D₂ receptors.⁴⁸ Rotigotine was approved in May 2007 for the treatment of early-stage PD.

COMT Inhibitors

When administered with an AADC inhibitor, circulating levodopa is mainly metabolized by COMT. In the presence of a COMT inhibitor, the peripheral metabolism of levodopa is therefore decreased.

Tolcapone is a selective and reversible inhibitor of COMT in the CNS and periphery. Inhibition of COMT in the periphery reduces the formation of 3OMD in tissues that have significant COMT activity. It has been speculated that 3OMD may compete with the uptake of levodopa into the CNS and thereby contributes to the wearing-off effect of levodopa. Administration of levodopa in combination with a dopa decarboxylase inhibitor (carbidopa) and a COMT inhibitor (tolcapone) increases CNS delivery of levodopa. Therefore, more continuous levels of levodopa and DA are maintained.⁵⁰ Unlike tolcapone, entacapone does not penetrate the BBB to any extent. Thus, the compound only inhibits peripheral COMT. When combined with levodopa and carbidopa, entacapone provides less motor fluctuations in parkinsonian patients. Another advantage of entacapone over tolcapone is its lack of hepatotoxicity.⁵¹

Tolcapone. Tolcapone, 3,4-dihydroxy-4'-methyl-5-nitrobenzophenone (Tasmar), is a yellow, odorless, nonhygroscopic, crystalline compound (pK_a = 4.78). Tolcapone is rapidly absorbed after oral administration. Tolcapone is highly bound to plasma albumin (>98%), and its distribution is therefore restricted. Tolcapone has low first-pass metabolism. It is almost completely metabolized in the liver before

excretion, and 60% is excreted by the kidney. The major metabolite of tolcapone is an inactive glucuronide conjugate. COMT inhibitors increase chronotropic and arrhythmogenic effects of epinephrine.^{52,53} Tolcapone is indicated as an adjunct to levodopa/carbidopa for the management of signs and symptoms of PD.

Entacapone. Entacapone, (*E*)-2-cyano-3-(3,4-dihydroxy-5-nitrophenyl)-*N,N*-diethyl-2-propenamide (Comtan), is a nitrocatechol that is practically insoluble in water ($pK_a = 4.50$). Entacapone is rapidly absorbed after oral administration and does not cross the BBB. Entacapone does not distribute widely into tissues because of its high plasma protein binding and it is completely metabolized before excretion. The main metabolic pathway is by isomerization to the *cis*-isomer followed by direct glucuronidation of the parent and the *cis*-isomer. The glucuronide conjugates are inactive. Entacapone is eliminated in the feces (90%) and urine (10%). Entacapone is indicated as an adjunct to levodopa/carbidopa to treat patients with idiopathic PD who experience the signs and symptoms of end-of-dose wearing off.

Carbidopa/Levodopa/Entacapone. Levodopa, carbidopa, and entacapone (Stalevo) are formulated together to take advantage of each compound's mechanism of action. When entacapone is coadministered with levodopa and carbidopa, plasma levels of levodopa are greater and more sustained.²³ For absorption, distribution, metabolism, and excretion (ADME) properties and drug interactions, refer to the preceding monograph.

Other Antiparkinsonian Drugs

Anticholinergic agents have been used in the early stages of PD, frequently with amantadine and selegiline. The most commonly employed anticholinergics are benztrapine, trihexyphenidyl, orphenadrine, and procyclidine. These compounds are most useful for treating the tremor aspect of PD. Because most individuals with PD are elderly, anticholinergics may impair cognitive function. Additionally, anticholinergics may produce various side effects through blockade of peripheral muscarinic receptors.^{21,26}

Amantadine has demonstrated beneficial effects in the treatment of PD, especially in attenuating dyskinesias.²⁶ Although amantadine has DA-releasing properties, other pharmacological mechanisms appear to be involved in its antiparkinsonian effect. The compound is a weak noncompetitive *N*-methyl *D*-aspartate (NMDA) antagonist, yet it differs in its action from the NMDA antagonist MK-801 in a rodent model of PD.⁵⁴ Additionally, amantadine potently inhibits nicotinic acetylcholine function in the hippocampus.⁵⁵

ANTIPSYCHOTIC DRUGS

Psychotic illness is a compilation of multiple disorders, including schizophrenia, the manic phase of bipolar syndrome, acute idiopathic psychosis, and other conditions marked by severe agitation,⁵⁶ yet the term “psychosis” is most often associated with schizophrenia. Schizophrenia affects approximately 1% of the U.S. population,⁵⁷ with both genetic⁵⁸ and neurodevelopmental⁵⁹ implications. Schizophrenia is characterized by delusions, abnormal behaviors, hallucinations, and thought disorders (i.e., positive symptoms), as well as loss of normal emotions, abilities, and motivation (i.e., negative symptoms). Although the etiology of schizophrenia is unknown, the principal neurochemical theories focus on DA⁶⁰ and, more recently, on glutamate and serotonin.^{61,62} Much of our current knowledge of the mechanisms involved in schizophrenia has come from analyzing effects of antipsychotic drugs.

The DA hypothesis of schizophrenia (DHS) has been the principal neurochemical theory of schizophrenia for more than 30 years. The basis of the DHS lies in the capacity of antipsychotic drugs to block DA receptors (D_2 receptor subtype) positively correlated to their clinical potency in alleviating the symptoms of schizophrenia.^{60,63} Nevertheless, the observed inactivity of D_2 -antagonists in some individuals with schizophrenia and the pharmacological independence of positive and negative symptoms indicate further level of complexity. Other variants of the DHS suggest an imbalance between dopaminergic pathways, which may be phasic in nature.^{64,65} With regard to symptomatology, it is thought that a dysregulation in the mesocortical DA pathway contributes to negative symptoms.^{66,67} Positron emission tomography (PET) studies suggest that individuals with schizophrenia may have decreased densities of D_1 receptors in the prefrontal cortex.⁶⁸ Presynaptic D_1 receptors within the prefrontal cortex are believed to modulate glutamatergic activity, directly effecting working memory in individuals with schizophrenia.⁶⁹ The positive symptoms are believed to be derived from D_2 receptor hyperactivity or upregulation within the mesolimbic pathway.^{66,70} Although it remains uncertain as to exactly how the different dopaminergic pathways and DA receptor subtype activities mediate the positive and negative symptoms of schizophrenia, it is clear that DA is a critical mediator. Yet, other transmitters have also been implicated. Glutamate NMDA receptor antagonists (e.g., phencyclidine, ketamine) produce psychotic symptoms in humans. A combined glutamate and DA dysregulation has also been implicated with schizophrenia.⁷¹ Likewise, serotonin has modulatory effects on DA pathways in the brain and has been implicated in the reduction of side effects induced by D_2 receptor antagonists.

Typical Antipsychotic Agents

Typical antipsychotics (also known as first-generation or conventional antipsychotics, classical neuroleptics, or major tranquilizers) are a class of antipsychotic drugs first developed in the 1950s and used to treat psychosis (in particular, schizophrenia). Typical antipsychotics include phenothiazines, thioxanthenes, butyrophenones, diphenylbutylpiperidines, and the dihydroindolones (e.g., molindone, not commercially available in the United States). The conventional antipsychotic drugs can be classified as high (haloperidol and fluphenazine) or low potency

(chlorpromazine) based on their affinity for DA D₂ receptors and the average therapeutic dose.⁷² This group of antipsychotics is also associated with a significant degree of EPS. Some EPS are defined as acute dystonias (i.e., involuntary movements: muscle spasms, protruding tongue), which tend to occur within the first few weeks of treatment and decline over time. However, the EPS that is most widely associated with these drugs is tardive dyskinesia (i.e., impairment of voluntary movements, often in the face and tongue), which develops over months to years and is often irreversible. High-potency typical antipsychotics tend to be associated with more EPS and less histaminic (sedation), alpha adrenergic (orthostasis), and anticholinergic (dry mouth) side effects. Low-potency typical antipsychotics are associated with less EPS but more H₁, α₁, and muscarinic side effects. Currently, the only patients in which the typical antipsychotic agents are preferred are those for whom there is a clear indication for short- or long-acting injectable preparations, and/or a tolerance to the side effects.

Phenothiazines and Thioxanthenes

The phenothiazine nucleus was first synthesized in 1876 (methylene blue) by Badische Anilin und Soda Fabrik (BASF) chemist H. Caro and elucidated by A. Bernstein in 1883 (thiodiphenylamine). It was not until 1950 that chlorpromazine (Table 13.1) was synthesized to explore its antihistaminic properties. The observations on the side effects of chlorpromazine prompted French psychiatrists Delay, Denicker, and Harl to use it in schizophrenic patients, publishing their seminal paper in 1952.⁷³ In 1958, Petersen et al.^{74,75} synthesized the first thioxanthene. The structural difference with the phenothiazines is the bioisosteric replacement of the N at the 10-position for a carbon atom in the thioxanthenes. The side chain (R10) in the thioxanthenes is attached by a double bond to the tricyclic system. This portion of the molecule is not involved in the interaction with the receptor, but it serves to position correctly the other elements of the molecule. Thioxanthenes that have a double bond in the side chain can be either *cis*- or *trans*-isomers (Fig. 13.5).^{76,77} The active form is the *cis*-isomer, which can be perfectly superimposed with the phenothiazine and the DA molecules, meaning that the *Z*-configuration is the preferred one for optimal receptor affinity. In general, thioxanthenes are more potent than the structurally related phenothiazines.

STRUCTURE–ACTIVITY RELATIONSHIPS

The SAR of phenothiazines is relatively simple because only position 2 (ring A) and the side chain afford active antipsychotic molecules. Conformational studies on chlorpromazine reveal that tilting of the side chain toward ring A allows favorable van der Waals interactions of the side chain with the chlorine substituent.⁷⁸ The resulting conformation permits the superimposition of DA. Substitution at the 1-position sterically hinders the ability of the side chain to approach ring A. On the other hand, a substituent at the 3-position will be too far from the side chain to provide van der Waals attractions. A trifluoromethyl group will give more van der Waals contacts with the side chain than a chloro substituent and, in fact, triflupromazine is more potent than chlorpromazine (Table 13.1). As a general rule, electron-withdrawing groups at the 2-position increase the antipsychotic efficacy (chlorpromazine vs. promazine).

In the thioxanthenes, the substituent at the 2-position does not govern the side chain in the same way as with the phenothiazines to assume a DA-like conformation.⁷⁹ The *cis* or *trans* conformation of unsubstituted thioxanthenes does not show any differential potency. For thioxanthenes, the 2-substituent of the *cis* form provides a closer approximation of the side chain toward ring A, enabling the substituent to enter into the van der Waals attractive forces with the side chain.^{78,80,81}

A major requirement for the antipsychotic activity of phenothiazines is that the basic amino group be separated by three carbon atoms from the parent ring system. Molecular models indicate that a shorter or a branched side chain prohibits the assumption of the DA-like conformation caused by van der Waals repulsive forces between the side chain and the phenothiazine ring. The nature of the substituent on the side chain amine may also influence the conformation of the phenothiazine side chain. A piperazine ring affords more van der Waals contacts with the 2-substituent than does an alkylamino side chain. Piperazinyl phenothiazines are more potent in their antischizophrenic effects, their ability to elicit EPS, and their affinity for the DA-sensitive adenylate cyclase than alkylamino phenothiazines.^{78,82}

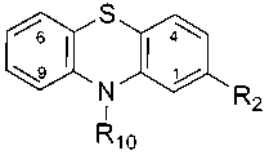

PHARMACOKINETIC PROPERTIES

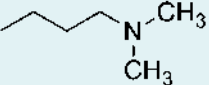

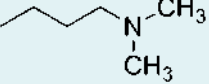

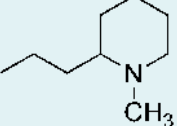

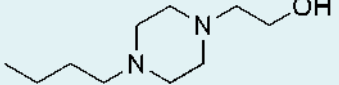

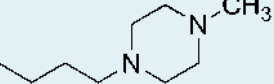

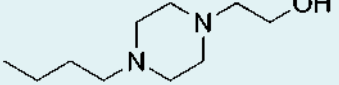

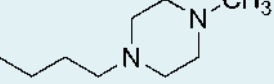

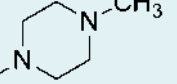

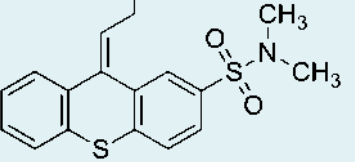

In general, these classes of drugs are rapidly absorbed from the GI tract (Table 13.1), but there is considerable individual patient variation in peak plasma concentrations.⁸³ Chlorpromazine has been the most widely studied phenothiazine, and it is believed that thioxanthenes and phenothiazines are metabolized following a very similar pathway. Compared with the phenothiazines, the thioxanthenes are less likely to form phenolic metabolites.⁸⁴ Chlorpromazine undergoes extensive first-pass metabolism yielding numerous metabolites. Numerous sites of attack by microsomal CYP450 system (especially CYP2D6) are possible, and most of these reactions happen to various degrees.^{85,86} Several metabolites have been isolated and characterized. Phase I reactions include oxidative *N*-demethylation to give primary and secondary amines, aromatic hydroxylation that yields phenols, side chain tertiary amine oxidation that affords *N*-oxide metabolites, *S*-oxidation to give sulfoxide and sulfones, oxidative deamination that yields side chain carboxylic acids, and *N*-10 dealkylation to give chlorphenothiazine. Most of these metabolites are subject of further reactions similar to those already mentioned. From the 168 proposed metabolites, only 45 have been isolated, and the 7-hydroxy-chlorpromazine metabolite has been evaluated and found to be effective in schizophrenia. More recently, the sulfoxide metabolite was found to have a diminished therapeutic response.^{87,88} Excretion is primarily via the kidneys with less than 1% of a dose excreted unchanged in the urine and 20% to 70% as conjugated or unconjugated metabolites. Approximately 5% of a dose is excreted in feces via biliary elimination. Some metabolites can still be detected up to 18 months after discontinuation of long-term therapy.

SPECIFIC AGENTS

Chlorpromazine Hydrochloride, USP. Chlorpromazine hydrochloride, 2-chloro-10-[3-(dimethylamino)propyl]phenothiazine (Thorazine), is a white to slightly creamy white, odorless, bitter tasting, crystalline powder (pK_a = 9.43). The

drug has significant sedative and hypotensive properties, possibly reflecting central and peripheral α_1 -adrenergic blocking activity, respectively. As with the other phenothiazines, the effects of the other CNS-depressant drugs, such as sedatives and anesthetics, can be potentiated.⁹⁰ Chlorpromazine is a minor substrate of CYP1A2 and 3A4 and a major substrate

of CYP2D6.⁹¹ Chlorpromazine also is a strong inhibitor of CYP2D6 and a weak inhibitor of CYP2E1. Inhibitors of the CYP2D6 enzyme may increase the levels/effects of chlorpromazine and chlorpromazine may increase the levels/effects of CYP2D6 substrates. Chlorpromazine may also decrease the bioactivation of CYP2D6 prodrug substrates.⁹¹

Figure 13.5 • *Trans*-(A) versus *cis*-(B) isomers in the thiothixenes.

Chlorpromazine has strong anticholinergic and sedative effects and is a potent antiemetic. It is considered a low-potency neuroleptic agent and therefore the associated incidence of EPS is low. The incidence of sedative, anticholinergic, and cardiovascular side effects is high, however. It is indicated for the symptomatic relief of nausea, vomiting, hiccups, and porphyria; for preoperative sedation; and for the treatment of psychotic disorders.

Thioridazine Hydrochloride, USP. Thioridazine hydrochloride, 10-[2-(1-methyl-2-piperidyl)ethyl]-2-(methylthio)phenothiazine (Mellaril), is a member of the piperidine subgroup of the phenothiazines. Thioridazine occurs as a white or slightly yellow, crystalline or micronized powder, which is odorless or has a faint odor and is practically insoluble in water and freely soluble in dehydrated alcohol ($pK_a = 9.66$). Thioridazine has relatively low tendency to produce EPS. The drug has sedative and hypotensive activity in common with chlorpromazine and less antiemetic activity. At high doses, pigmentary retinopathy has been observed. Thioridazine has similar activity toward the CYP450 family of enzymes as chlorpromazine. Thioridazine is indicated for the treatment of schizophrenic patients who fail to respond adequately to treatment with other antipsychotic drugs.

Perphenazine, USP. Perphenazine, 2-[4-[3-(2-chloro-10*H*-phenothiazin-10-yl)propyl]piperazin-1-yl]ethanol. Perphenazine is a minor substrate of CYP1A2, 2C9, 2C19, and 3A4 and a major substrate for 2D6. Perphenazine is indicated for use in the management of the manifestations of psychotic disorders and for the control of severe nausea and vomiting in adults.

Trifluoperazine Hydrochloride, USP. Trifluoperazine hydrochloride, 10-[3-(4-Methyl-1-piperazinyl)propyl]-[2-(trifluoromethyl)phenothiazine dihydrochloride (Stelazine). The absorption of trifluoperazine is erratic and variable and it is widely distributed into tissues. The excretion of trifluoperazine occurs 50% via kidneys and the other 50% is through enterohepatic circulation. The metabolism and drug interactions of trifluoperazine are the same as with the other phenothiazines. Trifluoperazine does not show any specific drug interactions. Trifluoperazine is indicated for the management of schizophrenia and short-term treatment of nonpsychotic anxiety.

Thiothixene, USP. Thiothixene, *N,N*-dimethyl-9-[3-(4-methyl-1-piperazinyl)propylidene]thioxanthene-2-sulfonamide (Navane). The absorption of thiothixene is erratic because of its high lipophilicity. Thiothixene is

widely distributed into tissues and it is more than 90% bound to plasma proteins. Thiothixene has a similar metabolic pathway as the phenothiazines. Thiothixene is a major substrate of CYP1A2, and CYP1A2 inducers may decrease the levels/effects of thiothixene, whereas CYP1A2 inhibitors may increase the levels/effects of thiothixene. Thiothixene is also a weak inhibitor of CYP2D6. As with other antipsychotic agents, some patients who are resistant to previous medications have responded favorably to thiothixene. Thioxanthenes may also be of value in the management of withdrawn, apathetic schizophrenic patients.

BUTYROPHENONES AND RELATED STRUCTURES

Haloperidol was discovered by Janssen Laboratories (1958) as a byproduct while they were investigating analgesics structurally related to meperidine.⁷³ The behavioral profile of haloperidol was found to be very similar to that of chlorpromazine, but the required dose was about 50-fold less to exert the same behavioral effect. It was rapidly studied and pursued as a new drug. Soon after, Janssen Laboratories discovered and developed droperidol, another butyrophenone analog. Conformationally, the butyrophenones can assume a conformation resembling portions of the phenothiazine molecule. The three-carbon side chain of the phenothiazines may be analogous to the three-carbon bridge that separates the amino function from the carbonyl moiety of haloperidol. Moreover, the piperidine ring would correspond to the side chain amine or piperazine of the phenothiazines. After the introduction of haloperidol and droperidol, a great number of SAR studies were carried out.⁹² As for the pharmacophore of the butyrophenones (Fig. 13.6), it is known that a tertiary amino group at the fourth carbon as well as the *para*-substituted (F is preferred) phenyl ring at the 1-position are required for D₂ affinity.^{93,94} Possible variations on the butyrophenone group are at the piperidine moiety, in particular at the 4-position of the ring. Modifications by lengthening, shortening, or branching of the three-carbon propyl chain decrease neuroleptic activity. Replacement of the keto group also decreases D₂ affinity. The tertiary amino group is usually part of an *N*-containing heterocycles, preferably a piperidine ring. Replacement of the six-member basic ring by smaller or larger heterocyclic rings or by noncyclic amines decreases DA affinity.

Conformationally restricted butyrophenones also possess high D₂ affinity. Haloperidol and droperidol are the only butyrophenones currently commercially available in the United States. Replacement of the keto group for a di-4-fluorophenylmethane moiety produced diphenylbutylpiperidines, another class of neuroleptics. Pimozide, the prototype of this group of drugs, is structurally related to droperidol and is the only member commercially available within the diphenylbutylpiperidines class.

Figure 13.6 • Pharmacophore of the butyrophenones.

PHARMACOKINETIC PROPERTIES

Haloperidol is the prototype of the butyrophenones and the one that has been studied the most. Haloperidol and droperidol, the two butyrophenones available in the United States, are well absorbed from the GI tract.⁸³ First-pass metabolism in the liver reduces the bioavailability of haloperidol to approximately 60%. Haloperidol undergoes extensive metabolism including *N*-dealkylation, reduction, oxidation, and *N*-oxidation. Most of the metabolites of haloperidol are inactive. Hydroxyhaloperidol, the reduced (ketone) metabolite of haloperidol, is the only active metabolite and it is also subject to extensive hepatic metabolism (Fig. 13.7).^{83,95}

SPECIFIC AGENTS

Haloperidol, USP. Haloperidol, 4-[4-(*p*-chlorophenyl)-4-hydroxypiperidino]-4-fluorobutyrophenone (Haldol), is an odorless white to yellow crystalline powder. Haloperidol is well and rapidly absorbed and has a high bioavailability. It is more than 90% bound to plasma proteins. Haloperidol is excreted slowly in the urine and feces. About 30% of a dose is excreted in urine and about 20% of a dose in feces via biliary elimination,⁹⁶ and only 1% of a dose is excreted as unchanged drug in the urine.⁹⁷ Haloperidol is a minor substrate of

CYP1A2 and a major substrate of CYP2D6 and CYP3A4. CYP2D6 inhibitors may increase the levels/effects of haloperidol.⁹¹ Haloperidol may increase the levels/effects of CYP2D6 substrates⁹⁸ and it may decrease the bioactivation of CYP2D6 prodrugs substrates. Haloperidol also is a moderate inhibitor of CYP2D6 and CYP3A4. CYP3A4 inducers may decrease the levels/effects of haloperidol, whereas CYP3A4 inhibitors may increase the levels/effects of haloperidol. Centrally acting acetylcholinesterase inhibitors may increase the risk of antipsychotic-related EPS. The precise mechanism of antipsychotic action is unclear but is considered to be associated with the potent DA D₂ receptor-blocking activity in the mesolimbic system and the resulting adaptive changes in the brain. Haloperidol is used primarily for the long-term treatment of psychosis and is especially useful in patients who are noncompliant with their drug treatment.

Haloperidol Decanoate. Haloperidol decanoate, 4-[4-(4-chlorophenyl)-4-hydroxypiperidino]-4-fluorobutyrophenone decanoate (Haldol Decanoate), is the decanoate ester (prodrug) of haloperidol. Peak plasma concentrations occur within 3 to 9 days and then decrease slowly. Haloperidol decanoate has no intrinsic activity. Haloperidol decanoate

Figure 13.7 • Metabolic pathway for haloperidol.

undergoes hydrolysis by plasma and/or tissue esterases to form haloperidol and decanoic acid, subsequently; haloperidol is metabolized in the liver. The pharmacological effects are those of haloperidol, which is released by bioconversion. Haloperidol decanoate is indicated for the treatment of long-term maintenance in schizophrenia, psychoses especially paranoid, and other mental and behavioral problems.

Droperidol, USP. Droperidol, 1-1-[3-(*p*-fluorobenzoyl)propyl]-1,2,[3,6-tetrahydro-4-pyridyl]-2-benzimidazolinone (Inapsine). Centrally acting acetylcholinesterase inhibitors may increase the risk of antipsychotic-related EPS. CNS depressants may produce additive sedative effects (benzodiazepines, barbiturates, antipsychotics, ethanol, opiates, and other sedative medications). Droperidol in combination with certain forms of inhalation anesthetics may produce peripheral vasodilatation and hypotension. Metoclopramide may increase the risk of EPS produced by droperidol.

Pimozide, USP. Pimozide, 1-[1-[4,4-*bis*(*p*-fluorophenyl)butyl]-4-piperidyl]-2-benzimidazolinone (Orap), is a white to creamy white solid ($pK_a = 9.42$). Pimozide is 50% absorbed after oral administration. It is metabolized by CYP450 enzymes, in particular the CYP3A4 and CYP1A2 isozymes, to inactive metabolites. Pimozide is excreted in the urine and to a lesser extent in the feces. Toxic effects may be produced with pimozide in the presence of inducers or inhibitors of CYP3A4 and CYP1A2. Pimozide is also a strong inhibitor of CYP2D6 without appearing to be an important substrate of this isoform.⁹⁹ The use of pimozide in the United States is small, but it is a critical drug for many patients with Gilles de la Tourette disorder who cannot tolerate haloperidol.

Atypical Antipsychotic Agents

Atypical antipsychotics (also known as second-generations) include drugs such as clozapine, olanzapine, quetiapine, risperidone, aripiprazole, and ziprasidone. With the development of the first atypical antipsychotic, clozapine, a clear division in treatment outcomes was observed. Atypical antipsychotics have generally shown to provide a greater reduction in both the positive and negative symptoms of schizophrenia, as well as an improvement in cognitive function. Thus, atypical antipsychotics are currently considered to be the first line of treatment for individuals with schizo-

phrenia. Affinity for 5-HT_{2A} receptors is a feature of several of the recently developed atypical antipsychotics. Many researchers believe that D₂ receptor antagonism, coupled with 5-HT_{2A} receptor antagonism, is responsible for the differentiation of effects observed with atypical antipsychotics. Inhibitory 5-HT neurons terminate on presynaptic DA neurons in the striatum. Thus, antagonism of presynaptic 5-HT_{2A} receptors leads to an increase in DA release. This increase in DA release is thought to attenuate D₂ blockade caused by antipsychotics. The decreased EPS associated with some of the atypical antipsychotics has also been suggested to be caused by 5-HT_{2A} receptor blockade.¹⁰⁰ Nevertheless, high 5-HT_{2A} receptor occupancy does not ensure that an antipsychotic will exhibit an atypical profile. Even at 80% to 90% 5-HT_{2A} receptor occupancy, no antipsychotic effect is observed unless D₂ receptor occupancy exceeds the 65% threshold.^{101,102}

Other theories regarding the mechanisms of action of atypical antipsychotics have also been suggested. Kapur and Seeman¹⁰¹ proposed that a low occupancy of D₂ receptors is sufficient to account for an atypical action. These investigators have suggested that a fast dissociation rate from D₂ receptors allows for DA neurotransmission that is more physiological. Yet, this theory has been questioned because several typical antipsychotics dissociate at similar rates as atypical agents.¹⁰³ The atypical profile of clozapine was initially suggested to be related to its high affinity for D₄ receptors; however, classical antipsychotics such as chlorpromazine and haloperidol also bind with high affinity at the D₄ receptor (Table 13.2). Additionally, the atypical antipsychotic, quetiapine, has no appreciable affinity for the D₄ receptor. Thus, it seems that antagonism at the D₄ receptor cannot explain the unique profile of atypical antipsychotics.^{104,105} In the end, no single theory to date has been able to globally define and/or differentiate the actions of antipsychotics. This is as much caused by the complexity of the disease and interpretation of respective drug-mediated behavioral effects, as it is to determining the actual mechanism of action of any individual drug.

SPECIFIC AGENTS

Clozapine. Clozapine, 8-chloro-11-(4-methyl-1-piperazinyl) 5*H*-dibenzo[*b,e*] [1,4] diazepine (Clozaril), is a yellow crystalline powder that is only slightly soluble in water. With the introduction of clozapine, a different pharmacological

Receptor binding profiles were generously provided by the National Institute of Mental Health's Psychoactive Drug Screening Program, Contract # NO1MH32004 (NIMH PDSP). The NIMH PDSP is directed by Bryan L. Roth MD, PhD at the University of North Carolina at Chapel Hill and Project Officer Jamie Driscoll at NIMH, Bethesda MD, USA.

*Hot ligand: 3*H*-Spiperone.

#Hot ligand: 3*H*-8-OH-DPAT.

profile was observed compared with the classical antipsychotics.¹⁰⁶ Unlike typical antipsychotics, clozapine is largely devoid of EPS. The lack of EPS with this compound was postulated to be caused by its preferential binding to mesolimbic rather than striatal DA receptors.¹⁰⁷ Furthermore, clozapine was shown to exhibit potent affinity for 5-HT_{2A} receptors.¹⁰⁸ When administered at a dose of 100 mg twice a day (bid [*L. bis in die*]), an average steady state plasma concentration of 319 ng/mL resulted at an average of 2.5 hours after administration. Because food does not apparently affect absorption, clozapine may be given with or without food. The compound is 97% bound to plasma proteins; however, interactions with other drugs have not been fully investigated.²³ Clozapine is extensively metabolized after absorption with 50% of an administered dose excreted in the urine and 30% in the feces. Clozapine is metabolized to two major metabolites by *N*-oxidation and *N*-demethylation. Clozapine *N*-oxide (CZNO) is thought to be formed by the action of CYP3A4 and flavin monooxygenase 3 (FMO3), whereas *N*-desmethylclozapine (DMCZ) appears to result by the action of CYP3A4 and CYP1A2 (Fig. 13.8).¹⁰⁹ Clozapine also binds with high affinity at M₁ and M₄ muscarinic receptors in the limbic area of the brain.¹⁰⁴ Whether affinity for muscarinic receptors contributes to the atypical profile for clozapine has not been established.¹⁰³

DMCZ shows partial agonism at D₂ and D₃ receptors and exhibits a distinctly different pharmacological profile compared with clozapine and other atypical antipsychotics. Unlike clozapine, which is a potent M₁ muscarinic antagonist, DMCZ is a potent M₁ agonist. Agonism at muscarinic receptors has been proposed to be useful for impaired cognition in schizophrenia. Burnstein et al.¹¹⁰ found that DMCZ acted as a partial agonist at DA D₂ and D₃ receptors. These investigators suggested that the low incidence of EPS associated with clozapine may be caused by the partial agonism of DMCZ at D₂ and D₃ receptors. Thus, DMCZ may be of interest as an atypical antipsychotic with an improved side effect profile compared with clozapine.

Although clozapine demonstrates a favorable pharmacological profile compared with typical antipsychotics, its use is restricted by a relatively high incidence of agranulocytosis. The exact mechanism for the cause of agranulocytosis has not been confirmed, but a highly reactive nitrenium ion that is formed by the action of hepatic enzymes appears to be involved.¹¹¹ The mean elimination half-life of clozapine

following a single 75-mg dose is 8 hours. Because of several adverse effects, clozapine is only used in refractory cases of schizophrenia. Individuals with a history of seizures or predisposed to seizures should be cautioned when taking clozapine. Similar to other atypical antipsychotic agents, clozapine causes an increased risk of mortality in elderly individuals with dementia-related psychoses.²³

Olanzapine. Olanzapine, 2-methyl-4-(4-methyl-1-piperazinyl)-10*H*-thieno[2,3-*b*][1,5] benzodiazepine (Zyprexa), is a yellow crystalline solid that is essentially insoluble in water. Olanzapine orally disintegrating tablets (Zyprexa Zydis) is a solid dosage form that immediately disintegrates when exposed to saliva. This product is useful for elderly patients who have difficulty in swallowing. An injectable form, olanzapine for injection (Zyprexa IM), is indicated for agitation associated with schizophrenia or bipolar I mania. Olanzapine is combined with fluoxetine (Symbyax) for use in depression that is associated with bipolar I disorder. Peak concentrations of oral olanzapine are reached at 6 hours after oral administration, and absorption of the compound is not affected by food.²³ Olanzapine is 93% bound to plasma proteins, and its mean half-life is 27 hours.^{112,113} Olanzapine undergoes extensive first-pass metabolism, and about 40% of an oral dose is metabolized prior to reaching the systemic circulation. The major metabolite of olanzapine in human subjects is the 10-*N*-glucuronide. Other human metabolites that have identified include the *N*-desmethyl, the *N*-oxide, and the 2-hydroxymethyl metabolites (Fig. 13.9). The *N*-desmethyl and the 2-hydroxymethyl metabolites are products of CYP1A2 and CYP2D6 action, respectively.^{112,113}

Olanzapine binds with high affinity at DA D₂, 5-HT_{2A}, 5-HT_{2C}, 5-HT₆, α₁, and H₁ histamine receptors. The effects of olanzapine for the treatment of schizophrenia are presumably mediated through antagonism at D₂ and 5-HT_{2A} receptors.^{23,112,113} The use of olanzapine in acute mania that is associated with bipolar I disorder is thought to be mediated by antagonism at D₂ and other monamine receptors. Additionally, olanzapine is postulated to produce its mood stabilizing and antidepressant effects through 5-HT_{2A} receptor blockade and increased cortical DA and NE concentrations.¹¹⁴ Several studies have investigated the effect of olanzapine-induced weight gain and new-onset type 2 diabetes.^{115,116} In a comparison study with risperidone, olanzapine was shown to have a greater risk of producing dyslipidemia and type 2 diabetes.^{105,116}

Quetiapine. Quetiapine, 2-[2-(4-dibenzo[*b,f*][1,4]thiazepin-11-yl-1-piperazinyl)ethoxy]-ethanol fumarate (2:1, salt) (Seroquel), is a white to off-white crystalline powder that is moderately water soluble. Quetiapine is rapidly absorbed, and peak plasma levels occur 1 to 2 hours after administration. Food does not appreciably affect the absorption of quetiapine. The compound is 83% bound to plasma proteins and it has a mean elimination half-life of 7 hours. Administration of a single dose of ¹⁴C-quetiapine showed that only 1% of the drug was excreted unchanged, with 73% excreted into the urine and approximately 30% excreted in the feces.²³ Numerous metabolites of quetiapine are known, and the sulfoxide metabolite represents the major metabolite present in plasma (Fig. 13.10). This metabolite is pharmacologically inactive. The remaining metabolites represent only 5% of the total radioactivity found in plasma. The 7-hydroxy and the 7-hydroxy-*N*-desalkyl are active metabolites, but

Figure 13.8 • Metabolic pathway of clozapine.

Figure 13.9 • Metabolic pathway of olanzapine.

because of their low concentrations in plasma are not thought to contribute to the overall effects of quetiapine.^{107,117}

In human liver microsomes, four primary metabolites of quetiapine are formed. These include quetiapine sulfoxide, 7-hydroxyquetiapine, and the *N*- and *O*-desalkylated metabolites (Fig. 13.10). This study showed that CYP3A4 is the major isoform of P450 responsible for quetiapine metabolism. CYP3A4 inducers (carbamazepine) or CYP3A4 inhibitors (ketoconazole) can either decrease or increase plasma levels of quetiapine.¹¹⁸

Common side effects associated with quetiapine therapy are orthostatic hypotension and somnolence. These effects are

presumably caused by α -adrenergic and histamine H_1 receptor blockade, respectively. As with other atypical antipsychotics, patients treated with quetiapine should be monitored for hyperglycemic symptoms. Also, children and adolescents with major depressive disorder may experience an increase in their depression or suicidal tendencies.^{23,107} Quetiapine binds with high affinity at α_1 , α_2 , H_1 , and 5-HT_{2A} receptors but has much lower affinity for D₂ and 5-HT_{1A} receptors. The action of quetiapine at D₂ and 5-HT_{2A} receptors is that of an antagonist, whereas it shows agonist effects at 5-HT_{1A} receptors.^{119,120} Quetiapine dissociates rapidly from D₂ receptors, and this leads to lower D₂ receptor occupancy compared with

Figure 13.10 • Metabolic pathway of quetiapine.

Figure 13.11 • Metabolic pathway of risperidone.

typical antipsychotics such as chlorpromazine.¹²¹ This finding may explain the lack of EPS associated with quetiapine.¹⁰⁷

Risperidone. Risperidone, 3-[2-[4-(6-fluoro-1,2-benzisoxazol-3-yl)-1-piperidinyl]ethyl]-6,7,8,9-tetrahydro-2-methyl-4*H*-pyrido[1,2-*b*]pyrimidin-4-one (Risperdal), is a white to slightly beige powder that is essentially insoluble in water. Risperidone is also available as a 1-mg/mL oral solution and as orally disintegrating tablets (Risperdal M-Tab). Risperidone is well absorbed, and peak levels occur about 1 hour after administration. The absorption of risperidone is not affected by food. Risperidone is about 90% bound to albumin and α_1 -acid glycoprotein, whereas its metabolite 9-hydroxyrisperidone is bound about 77%.²³ Risperidone is primarily metabolized in humans to the active metabolite 9-hydroxyrisperidone (Fig. 13.11). Although CYP2D6 was thought to be the major P450 isoform in the formation of the 9-hydroxy metabolite, a recent report suggests that CYP3A4 is involved.¹²¹ The potent CYP3A4 inducer, rifampin, was shown to significantly reduce plasma concentrations of risperidone,¹²² whereas ketoconazole, a CYP3A4 inhibitor, decreased the formation of the 9-hydroxy metabolite.¹²³ The metabolism of risperidone appears to be stereoselective. In human microsomes, the CYP2D6 inhibitor, quinidine, strongly inhibited the formation of (+)-9-hydroxyrisperidone, whereas the CYP3A4 inhibitor, ketoconazole, inhibited the formation of (–)-9-hydroxyrisperidone.¹²⁴ Individuals concurrently on risperidone and other medications should be carefully monitored because impaired CYP2D6 activity could increase the risk for drug interactions.^{125,126} Renal excretion is the main route of elimination for risperidone and its metabolites. The mean half-life of risperidone is 3 hours in extensive metabolizers and 21 hours in poor metabolizers, respectively. The elimination half-life for the 9-hydroxy metabolite is similar to risperidone in extensive and poor metabolizers, with an overall elimination half-life of about 20 hours.²³ The major side effects associated with risperidone therapy are orthostatic hypotension, dose-related hyperprolactinemia, mild weight gain, EPS, and insomnia.¹²⁷ At higher doses (6 mg/day), risperidone is the atypical antipsychotic that most closely resembles conventional agents. A PET study in a group of individuals with schizophrenia showed that D_2 receptor occupancy was dose dependent. If the dose was increased such that D_2 receptor occupancy was 79% to 85%, the majority of patients developed EPS.¹²⁶ Risperidone is associated with increased mortality in elderly patients with dementia-related psychosis and is not recommended for these individuals.²³ Risperidone binds with high affinity at 5-HT_{2A}, 5-HT₇, D_2 , α_1 , α_2 , and H_1 receptors. The antipsychotic action of risperidone has been proposed to be the result of D_2 and 5-HT_{2A} antagonism.^{23,107} Risperidone is effective in treating the positive and negative symptoms of schizophrenia and as adjunct therapy in bipolar mania.¹²⁷ The U.S. Food and Drug Administration (FDA) granted ap-

proval of risperidone orally disintegrating tablets in October 2006 for the treatment of irritability in autistic children and adolescents.²³

Paliperidone. Paliperidone, (\pm)-3-[2-[4-(6-fluoro-1,2-benzisoxazol-3-yl)-1-piperidinyl]ethyl]-6,7,8,9-tetrahydro-9-hydroxy-2-methyl-4*H*-pyrido[1,2-*a*]pyrimidin-4-one (Invega), is essentially insoluble in water and is available as extended-release tablets. Paliperidone is delivered at a constant rate using an osmotic drug release device (Osmotic Release Oral Systems [OROS]). The absolute bioavailability of paliperidone is 28%, and studies in healthy subjects on a high-fat, high-calorie meal showed an increase in AUC. Paliperidone is 74% bound to plasma proteins. After a single, 1-mg dose of ¹⁴C-paliperidone, 59% of the dose was excreted in the urine as unchanged drug, and 32% of the dose was recovered as metabolites. Most of the drug (80%) is excreted by the kidneys. Paliperidone is metabolized by dealkylation, hydroxylation, dehydrogenation, and scission of the benzoxazole ring. None of these metabolic pathways account for more than 10% of the dose. The terminal elimination half-life of paliperidone is 23 hours.²³

Aripiprazole. Aripiprazole, (7-[4-[4-(2,3-dichlorophenyl)-1-piperazinyl]butoxy]-3,4-dihydro-2(1*H*)-quinolone, is an atypical antipsychotic that is available in tablets (Abilify), orally disintegrating tablets (Abilify Discmelt), and a 1-mg/mL oral solution. Unlike the other atypical antipsychotics, aripiprazole exhibits partial agonist activity at D_2 , D_3 , D_4 , and 5-HT_{1A} receptors, and antagonist action at 5-HT_{2A} receptors. Although aripiprazole exhibits a low incidence of EPS, the compound occupies about 95% of striatal D_2 receptors at therapeutic doses. Additionally, aripiprazole does not have a fast rate of dissociation from D_2 receptors. Although the mechanism of action of this compound remains to be elucidated, the atypical profile for aripiprazole may be related to its action at other monoamine receptors.^{105,128} The compound is well absorbed with peak plasma levels occurring 3 to 5 hours after oral administration. Food does not affect absorption of aripiprazole. Aripiprazole is extensively metabolized in the liver by the action of CYP2D6 and CYP3A4. The primary metabolite in humans is dehydroaripiprazole (Fig. 13.12). This metabolite represents about 40% of aripiprazole at steady state.²³ In the presence of CYP3A4 and CYP2D6 inhibitors or inducers, dosage adjustments of aripiprazole may be required. The mean elimination half-lives in extensive and poor metabolizers are 75 hours and 146 hours, respectively.²³ The major adverse effects of aripiprazole are headache, anxiety, and insomnia.¹²⁹ Similar to other atypical antipsychotics, aripiprazole shows an increased risk in mortality in elderly patients with dementia-related psychosis.²³ Aripiprazole demonstrates a different pharmacological profile from all other atypical antipsychotics. The compound exhibits partial agonist activity at 5-HT_{1A} receptors and antagonist action at 5-HT_{2A} receptors. The partial agonism at 5-HT_{1A} may

Figure 13.12 • Metabolic pathway of aripiprazole.

contribute to the effects of aripiprazole against the negative symptoms of schizophrenia.¹³⁰ Unlike other antipsychotics, aripiprazole acts as a partial agonist at D₂ receptors. Additionally, the major metabolite, dehydroaripiprazole, shows similar pharmacological properties as aripiprazole, and it also acts as a partial agonist at D₂ receptors.¹³¹ It has been suggested that a partial D₂ agonist will exhibit functional agonist activity in areas of the brain (mesocortical pathway) that have low DA levels, whereas a D₂ partial agonist can function as an antagonist in areas of the brain (mesolimbic pathway) where DA levels are high. Thus, positive symptoms of schizophrenia are reduced without significant EPS.¹³² Aripiprazole is indicated for schizophrenia and for acute mania that is associated with bipolar I disorder.²³

Ziprasidone. Ziprasidone, 5-[2-[4-(1,2-benzisothiazol-3-yl)-1-piperazinyl]ethyl]-6-chloro-1,3-dihydro-2H-indol-2-one, is available as the hydrochloride monohydrate for oral

administration (Geodon) and as the mesylate trihydrate salt for intramuscular (IM) injection. The compound is well absorbed with peak plasma levels occurring at 6 to 8 hours after oral administration. The oral absorption is enhanced approximately twofold in the presence of food. Ziprasidone is bound about 99% to plasma proteins, primarily to albumin and α_1 -acid glycoprotein. Ziprasidone is not displaced in the presence of two highly protein bound drugs, warfarin and propranolol. Ziprasidone is extensively metabolized with only about 5% of the drug excreted unchanged.²³ In humans, two major pathways are responsible for the metabolism of ziprasidone: (a) oxidation by CYP3A4 (one third) and (b) reduction by aldehyde oxidase (two thirds).^{133,134} The combined action of these metabolic pathways leads to four major circulating metabolites: benisothiazole piperazine sulfoxide (BITP-sulfoxide), benisothiazole piperazine sulfone (BITP-sulfone), ziprasidone sulfoxide, and S-methyldihydroziprasidone (Fig. 13.13).

Figure 13.13 • Metabolic pathway of ziprasidone.^{133,134}

Multidrug therapy involving ziprasidone does not appear to be a serious concern, because the reductive activity of aldehyde oxidase is not affected by other drugs.¹³⁴ The elimination half-life of ziprasidone is 4 hours with about 20% of the drug excreted in urine and 66% eliminated in the feces.^{23,107} Ziprasidone has a low incidence of sedation, EPS, and postural hypotension. Unlike other atypical antipsychotics, ziprasidone does not cause weight gain or elevated glucose levels. Ziprasidone has been shown to cause a mild-to-moderate increase in the QTc interval.¹³⁴ Prolongation of the QTc interval in some other drugs is associated with potentially life-threatening ventricular arrhythmias and sudden death. As with other atypical antipsychotic agents, ziprasidone can increase the risk of mortality in elderly patients with dementia-related psychosis and is not indicated in these individuals.²³ Ziprasidone binds with high affinity at D₂, D₃, 5-HT_{1A}, 5-HT_{1D}, 5-HT_{2A}, 5-HT_{2C}, and α_1 -receptors. The compound acts as an agonist at 5-HT_{1A} receptors and as an antagonist at D₂ and 5-HT_{2A} receptors. Ziprasidone also inhibits synaptic uptake of serotonin and norepinephrine. Thus, it has been postulated that ziprasidone has potential use as an anxiolytic and an antidepressant.^{107,135} Ziprasidone is indicated for schizophrenia and acute mania that is associated with bipolar disorder, whereas the injectable form of ziprasidone is indicated for the treatment of acute agitation in schizophrenic patients.²³

FUTURE DIRECTIONS

DA has long been linked with PD and schizophrenia in a unique and multifaceted relationship. Although this close

association ensures that DA and the dopaminergic systems will remain a primary focus for the treatment of both PD and schizophrenia, other avenues of therapy are on the horizon. A focus on neuroprotective agents for the treatment of PD may provide a more efficacious approach than DA symptomology-based therapies. Such treatments would target the mechanisms involved in the pathogenesis of the disease. A promising antioxidant, coenzyme Q₁₀ (ubiquinone), has been proposed to slow down functional decline.¹³⁶ Based on findings that mitochondrial dysregulation and oxidative damage may play a role in the loss of nigral neurons, it is hypothesized that coenzyme Q₁₀ could be an effective neuroprotectant.^{136,137} Inhibitors of glutamate, anti-inflammatory, and antiapoptotic drugs have also been proposed as PD neuroprotectants,^{138,139} although currently there is a lack of clinical verification. Yet, another approach is the use of gene therapy, using a glial cell line-derived neurotrophic factor to slow neurodegeneration in PD.^{18,140,141} New approaches are also being explored in terms of schizophrenia treatment. Over the past decade, a dysfunction of glutaminergic neurons has been suggested to contribute to the pathophysiology of schizophrenia. This theory is supported by the fact that a noncompetitive inhibitor at NMDA receptors (a subtype of glutamate receptors) produces positive and negative symptoms of schizophrenia in normal subjects. Compounds that target the NMDA receptor may offer an alternative treatment for schizophrenia.¹⁴² Ultimately, future strategies for the pharmacological treatment of PD and schizophrenia will likely evolve into a combination DA and non-DA approaches, appropriately tailored to each patient's needs.

REVIEW QUESTIONS

1. Using chlorpromazine as the prototype, discuss the SAR of the phenothiazine antipsychotics.

2. Ropinirole and rotigotine act as agonists at D₃ receptors. Compare the structures of these two compounds with that of DA. Clearly specify the pharmacophoric groups in ropinirole and rotigotine that impart D₃ agonist activity.

3. Shown below is the structure of the typical antipsychotic trifluoperazine. Give the structure of five likely metabolites for this compound.

4. Explain the rationale for the combination product levodopa/carbidopa/entacapone in the treatment of PD.

5. Shown on the next column are the structures of the atypical antipsychotics olanzapine and clozapine. Describe the pharmacological action of these compounds at the D₂ and 5-HT_{2A} receptors. What is the relationship between the circled phenyl ring in clozapine and the 2-methylthiophene ring in olanzapine?

Anticonvulsants

MATTHIAS C. LU

CHAPTER OVERVIEW

The terms *anticonvulsant* and *antiepileptic drug* (AED) are used interchangeably in the literature to describe a diverse group of medications used clinically to provide seizure control in patients with epilepsies. However, because some anticonvulsants described in this chapter are used to treat neuropathic pains and/or to control severe mood changes in patients with mania and other mood disorders, the term AED will be used only when discussing the therapeutic usage of these drugs in the context of epilepsy treatment.

Epilepsy is the most prevalent neurological disorder affecting more than 0.5% of the world's population.¹ It is characterized by recurrent seizures, unprovoked by any identifiable causes. The etiology of epilepsy is largely unknown even though recent evidence suggests that it may have a genetic component associated with its disease development.^{2,3} Seizures, on the other hand, are symptoms of disturbed electrical activity in the brain characterized by episodes of abnormal, excessive, and synchronous discharge of a group of neurons within the brain that cause involuntary movement, sensation, or thought.⁴ It is generally agreed that seizures may result from primary or acquired neurological disturbances of brain function as a result of an imbalance between excitatory and inhibitory processes in the brain. There are many possible causes of seizures including brain tumors or infections, head trauma, neurological diseases, systemic or metabolic disorders, alcohol abuse, drug overdose, or toxicities.

In North America, the incidence of newly diagnosed epilepsy (~50–100 cases/100,000 per year) is highest among children younger than 5 years of age and the elderly older than 65 years of age.^{1,5} Most of these newly diagnosed seizure disorders can be effectively controlled initially with the use of AEDs such as valproic acid (VPA), carbamazepine (CBZ), ethosuximide, and phenytoin to prevent recurrence of seizure activity.⁶ However, the success of pharmacotherapy of epilepsy with these conventional AEDs is often hampered by the loss of effectiveness after prolonged drug exposure (~1/3 of the newly diagnosed patients become resistant to current pharmacotherapy).⁷ The reason for this refractory to an AED may be a result of the coexistence of factors related to the epileptogenesis of the disease state or to the development of pharmacodynamic or pharmacokinetic tolerances.⁸ In addition, the usage of these AEDs as first-line treatment options is associated with a wide range of clinical problems including drug interactions, idiosyncratic reactions, hepatotoxicity, and AED-induced teratogenesis.^{6,9,10} These intolerable adverse

events can negatively influence patient compliance and significantly diminish quality of life in patients with epilepsies.⁶ Furthermore, even with recent market introduction of at least 10 newer AEDs with much improved side effects and toxicities profile, only less than 5% of patients with refractory epilepsy have their seizures effectively controlled with these newer AEDs.¹¹

Thus, the goal of this chapter is to provide the readers with a basic understanding of how each of the drug molecules works, how they are metabolized, and the role these metabolite(s) might play in the development of idiosyncratic reactions or toxicities. Some of the basic concepts presented in this chapter will allow clinicians to assess potential drug–drug/food interactions and to provide optimal treatment plan for their patients. The inclusion of the structure–activity relationships (SARs) within each drug or structure type in this chapter should also provide readers with a much needed tool to evaluate future drug development in this area.

DISEASE STATES REQUIRING ANTICONVULSANT THERAPY

The diagnosis of a first epileptic seizure or epilepsy, at primary care facilities, is often subjective and prone to error because it is usually based on eyewitness accounts of the episodes.^{6,12} An incorrect diagnosis, especially of the seizure type, however, can have far-reaching negative consequences for the patient, including loss of work and driving privileges, potential toxic or ineffective medication given, and other socioeconomic consequences.¹³

Classification of Epileptic Seizures and Recommended Initial Drug Therapy

The 1981 classification of the epileptic seizure types¹⁴ and the 1989 classification of epileptic syndromes and epilepsies¹⁵ are still widely accepted and workable because their accuracy facilitates diagnosis, drug selection, and precise discussion of seizure disorders.^{6,16} Seizures are classified, based on their initial signs and symptoms and the pattern seen on the electroencephalogram (EEG), into two broad categories as generalized seizures or as partial seizures.¹³

Each of the epilepsy types is characterized by an abnormal pattern in the EEG. The EEG indicates sudden, excessive electrical activity in the brain. Most of the currently available AEDs work by preventing, stopping, or lessening this electrical activity. The precise causes of these abnormal changes is still unknown; however, it has been hypothesized

that there is a site or focus of damaged or abnormal hyperexcitable neurons in the brain. These neurons can fire excessively and sometimes recruit adjacent neurons that in turn induce other neurons to fire. Thus, the location and the extent of the abnormal firing is essential for the determination of the epilepsy types.¹⁶

PRIMARY GENERALIZED SEIZURES

Two major types of generalized seizures are the primarily generalized tonic-clonic seizures (grand mal) and the absence (petit mal) seizures. The typical primarily generalized tonic-clonic seizure is often preceded by a series of bilateral muscular jerks followed by loss of consciousness, which in turn is followed by a series of tonic and then clonic spasms. The typical absence seizure (classic petit mal) consists of a sudden brief loss of consciousness (~10 seconds), sometimes with no motor activity, although often some minor clonic motor activity exists. Based on a recent evidence-based metaanalysis of AED efficacy and effectiveness, the recommended initial monotherapy for patients with generalized seizures are CBZ, oxcarbazepine (OXC), lamotrigine, VPA, phenytoin, and topiramate (TPM), whereas children with absence seizures are best treated with lamotrigine, VPA, or ethosuximide.^{6,13}

PARTIAL SEIZURES

Major types of partial seizure are simple partial seizures (focal) and complex partial seizures (temporal lobe or psychomotor). Partial seizures are the most common seizure types experienced by approximately 60% to 70% of the adult patients. A prototypic simple partial seizure is Jacksonian motor epilepsy in which the Jacksonian march may be seen. As the abnormal discharge proceeds over the cortical site involved, the visible seizure progresses over the area of the body controlled by the cortical site. Partial seizures, if not controlled, may progress to another seizure type known as the secondarily generalized partial seizures (tonic-clonic or grand mal). The first-line treatment for patients with newly diagnosed or untreated simple partial seizures are CBZ or phenytoin for adults, lamotrigine or gabapentin for elderly adults, and OXC for children.^{6,13}

The complex partial seizure is represented by the psychomotor or temporal lobe seizure. There is an aura, then a confused or bizarre but seemingly purposeful behavior lasting 2 to 3 minutes, often with no memory of the event. The seizure may be misdiagnosed as a psychotic episode. Although the initial treatment is the same, it is much harder to control complex partial seizures.

Anticonvulsants Used in Neuropathic Pain

Neuropathic pain, despite its heterogeneity in etiology and anatomical locations, is characterized by a neuronal hyperexcitability in damaged areas of the nerves. This neuronal hyperexcitability and many of the corresponding cellular changes is quite similar to that of epilepsy. Thus, it is not surprising that anticonvulsants such as CBZ, gabapentin, and more recently its close analog, pregabalin were approved for relieving pains associated with diabetic neuropathy, trigeminal neuralgia, and other neuropathic pains.¹⁷ Both gabapentin and pregabalin have become an

important treatment option in neuropathic pain because of their lack of potential drug interactions and minimal side effect profiles.

MECHANISMS OF ACTION OF ANTICONVULSANTS

At the cellular level, three basic mechanisms are believed to contribute to the antiepileptic action of the currently marketed anticonvulsants.^{18,19} These are (a) modulation of voltage-gated ion channels (Na^+ , Ca^{2+} , and K^+), (b) enhancement of γ -aminobutyric acid (GABA)-mediated inhibitory neurotransmission, and (c) attenuation of excitatory (particularly glutamate-mediated) neurotransmission in the brain. Many of AEDs, especially the newer drugs, work by more than one of the above mechanisms of actions, therefore possessing a broader spectrum of antiepileptic action.

Voltage-Gated Ion Channels as Targets for Anticonvulsants

VOLTAGE-GATED SODIUM CHANNELS

Voltage-gated sodium channels (VGSCs) in the presynaptic nerve terminal of the excitatory glutamate receptors are the molecular target for phenytoin, CBZ, and lamotrigine as well as some of the newer AEDs, such as OXC, felbamate (FBM), and zonisamide.¹⁸ These aromatic AEDs inhibit excessive neuronal firing by binding to a site near the inactivation gate, thereby prolonging inactivation of VGSCs.²⁰ Figure 14.1 illustrates how phenytoin interacts with the hypothetical *inactivation gate* receptor according to a pharmacophore model suggested by Unverferth et al.²¹ as a result of molecular simulations with these aromatic AEDs. This model includes an aromatic binding site and two separate hydrogen bonding sites for interacting with potent AEDs such as phenytoin and lamotrigine.

VOLTAGE-GATED CALCIUM CHANNELS

The voltage-gated calcium channels (VGCCs) are essential in regulating Ca^{2+} signaling, which is associated with many important cellular events such as the release of excitatory glutamate neurotransmitters, the plasticity changes

Figure 14.1 • Binding of phenytoin to the hypothetical “inactivation gate” receptor on the voltage-gated sodium channels.

of long-term potentiation in learning and memory, and the maintenance of homeostasis of nerve cells. It has been suggested that excessive influx of Ca^{2+} plays a critical role in the induction and progression of epileptic seizures.^{22,23} There are distinct classes of VGCCs. The high-threshold L-type Ca^{2+} channels in the presynaptic glutaminergic receptors require strong depolarization for activation and are the primary molecular targets of gabapentin and pregabalin, both of which are effective in refractory partial seizures.^{22,24} On the other hand, the low-threshold T-type Ca^{2+} channels require only weak depolarization for activation and are the molecular targets of AEDs such as ethosuximide and zonisamide.^{18,25}

VOLTAGE-GATED POTASSIUM CHANNELS

Potentiation of the voltage-gated K^+ channels is another attractive target for designing of newer AEDs, because they are intimately associated with the membrane repolarization processes.²⁰ Levetiracetam (LEV), a novel AED recently marketed for the adjunctive therapy of refractory partial seizures in adults, has been suggested to work by reducing the voltage-operated A-type potassium currents as one of its mechanism of actions.^{26,27}

GABA_A Receptors as Targets for Anticonvulsants

It is now well recognized that cellular excitability leading to convulsive seizures can be attenuated by GABAergic stimulation in the brain.¹⁹ The GABA_A receptor is one of two ligand-gated ion channels responsible for mediating the effects of GABA, the major inhibitory neurotransmitter in the brain.^{18,19} Activation of the GABA_A/benzodiazepine (BZD) receptors/chloride channel complex allows increased chloride conductance, thereby preventing the spread of neuronal excitations.^{28,29}

The potential targets for AED's action on the GABAergic inhibitory synapses include (a) drugs that enhance the biosynthesis of GABA (gabapentin, pregabalin, and VPA), (b) drugs that inhibit GABA degradation (vigabatrin), (c) drugs that inhibit the reuptake of GABA (tiagabine), and (d) drugs that bind to an allosteric site on the postsynaptic GABA_A receptor complex that increase chloride conductance (barbiturates, BZDs, neurosteroids, FBM, TPM).¹⁹

DRUGS THAT ENHANCE THE BIOSYNTHESIS OF GABA

GABA, the major inhibitory neurotransmitter in the brain, is biosynthesized at the GABAergic neurons by the decarboxylation of the amino acid, L-glutamic acid (itself an excitatory amino acid neurotransmitter in the brain). The rate-limiting enzyme that catalyzes this conversion is L-glutamic acid decarboxylase (GAD). The essential cofactor for this enzymatic reaction is pyridoxal phosphate (vitamin B₆) (see Fig. 14.2). GABA, after its release from the synaptic nerve terminal, is degraded by another pyridoxal-dependent enzyme, the GABA transaminase (GABA-T), which transfers an amino group from GABA to α -ketoglutarate producing L-glutamic acid and succinic acid semialdehyde (SSA). As shown in Figure 14.2, SSA is further oxidized by the action of the enzyme succinic semialdehyde dehydrogenase (SSADH, an aldehyde dehydrogenase) to succinic acid that can enter the TCA cycle for the production of additional α -ketoglutarate or be further reduced by SSA reductase (an alcohol dehydrogenase that catalyzes the interconversion of SSA and 4-hydroxybutyric acid).³⁰

Being a 3-substituted GABA, gabapentin and especially pregabalin, may have the ability to activate GAD,³¹ in addition to their major anticonvulsant action at the high-threshold L-type Ca^{2+} channels in the presynaptic glutaminergic receptors.²⁴ Both of these drugs are weak activators of GAD; however, their pharmacological actions on the GAD can not be discounted because gabapentin was able to elevate brain GABA levels (~75%–100%) in patients with epilepsy within hour after the first dosing.³²

Similar to gabapentin and pregabalin, VPA, also elevates brain levels of GABA in patients with epilepsy.³⁰ It is generally agreed that VPA inhibits SSADH, the enzyme responsible for conversion of SSA to succinic acid. The exact mechanism of action of how this inhibition enhances GABA levels in the brain is still the subject of much debate (i.e., from an indirect stimulation of GAD to an inhibition of GABA-T). However, if we take into account that GABA also inhibits SSA reductase, an enzyme that reduces SSA to γ -hydroxybutyric acid, an epitogenic metabolite of GABA. Thus, it is reasonable to propose that VPA elevates GABA levels by reversing the transamination reaction mediated by GABA-T because of the accumulation of its product, SSA at the enzyme active site of GABA-T (Fig 14.2).

Figure 14.2 • Biosynthesis and metabolism of GABA.

DRUGS THAT INHIBIT GABA DEGRADATION

Vigabatrin (γ -vinyl-GABA) is an irreversible inhibitor of GABA-T, rationally designed based on the biochemical mechanism of transamination reaction.^{19,33} Briefly, vigabatrin, because of its structural similarity, competes with GABA for binding to GABA-T and forms a Schiff base intermediate with the cofactor, pyridoxal phosphate similar to GABA. However, unlike its substrate GABA, during the process of transferring the amino group to the pyridoxal phosphate, a reactive intermediate is formed with vigabatrin that immediately attaches itself to the active site of the enzyme, thereby irreversibly inhibiting GABA-T and increasing GABA levels in the brain.

DRUGS THAT INHIBIT REUPTAKE OF GABA

Released GABA is actively taken back into the GABAergic neurons or glial cells in the brain by GABA transporters (GATs).^{28,34} Tiagabine, structurally related to nipepetic acid, is a selective inhibitor of the neuronal and glial GAT1 at the GABAergic neurons and an effective drug for the treatment of patients with refractory epilepsy.³⁴ Addition of two lipophilic heterocyclic rings to the nicopetic acid moiety did not interfere with its ability to bind GAT1 but actually allows tiagabine to cross into the brain freely and also more selectively than nicopetic acid toward GAT1.³⁴

DRUGS THAT BIND TO THE GABA_A RECEPTOR COMPLEX AND MODULATE CHLORIDE INFLUX

Many clinically useful anxiolytic hypnotic-sedatives and some AED drugs such as BZDs, and barbiturates (e.g., phenobarbital) exert their pharmacological actions by interacting with a discrete neuronal site on the GABA_A-BZD receptor-chloride channel complex.³⁵ The GABA_A-chloride ionophore is a glycoprotein pentamer that contains two α , two β , and one γ subunit and is present throughout the mammalian brain.^{28,35} It has been hypothesized that binding of BZD agonists such as clonazepam to its receptor enhances GABA-mediated inhibitory neurotransmission by increasing the frequency of chloride channel openings. TPM, a broad-spectrum AED, also binds and increases the frequency of chloride channel opening but at a different site than the BZDs.¹⁸ Barbiturates, on the other hand, bind to a third binding site on the GABA_A receptor complex and increases the duration of chloride channel openings.³⁵ It has been hypothesized that the binding of these drugs to their respective binding sites induces conformational changes, thereby allowing GABA to work more efficiently to modulate chloride channel openings.

Excitatory Glutamate-Mediated Receptors as Target for Anticonvulsants

The acidic amino acids, L-glutamate and L-aspartate, are the most important excitatory neurotransmitters in the brain acting through two distinct families of glutamate receptors, the ligand-gated, ionotropic receptors and the G-protein-coupled metabotropic receptors.³⁶ The ligand-gated glutamate receptors such as *N*-methyl-D-aspartic acid (NMDA)/ α -amino-3-hydroxyl-5-methyl-4-isoxazole propionic acid (AMPA) receptors modulate sodium and calcium influx and are involved in mediating excitatory synaptic transmission including the initiation and spread of seizure activity. Activation of these

receptors is responsible for important functions in the brain including long-term potentiation in memory acquisition, learning, and some neurodegenerative disorders.^{22,37} These receptors are potential therapeutic targets for epilepsy and other neurodegenerative disorders such as stroke and head injury, Alzheimer, and other chronic debilitating disorders. However, efforts in finding effective and safe NMDA antagonists have failed because of their toxicities and intolerable side effects.³⁸ Thus, with the exception of TPM, which deriving some of its antiepileptic action by modulating the AMPA receptor and FBM, which appears to bind to the glycine binding site on the NMDA receptor, none of the current AEDs has any direct action at the postsynaptic glutamate receptors.¹⁹ Metabotropic glutamate receptors, on the other hand, modulate the release of glutamic acid, GABA, and other important neurotransmitters in the brain. Thus, these receptors are exciting new therapeutic targets for designing medications for pain, addiction, Parkinson disease, schizophrenia, and other neurodegenerative disorders.²⁸

CLINICALLY IMPORTANT ANTICONVULSANTS

There is very little SAR among the clinically useful anticonvulsants except within each structure type, primarily affecting their side effects and toxicities. Thus, these aspects of medicinal chemistry will be covered under each structure type or under the individual drug monographs covered in this section.

Valproic Acid (Depakote, Depakene, Depacon)

VPA is an established AED with a simple chemical structure but an unusually broad spectrum of action. It is generally well tolerated, but its use is limited by two rare but significant toxic side effects (hepatotoxicity and teratogenicity) that can be dose-dependent or idiosyncratic in nature.^{9,39,40} These drawbacks are apparently shared by its equipotent active metabolite, (E)-2-propyl-2-pentenoic acid (2-ene-VPA) (Fig. 14.3).

VPA is also an important inhibitor of the cytochrome P450 isozymes, mainly of CYP2C9 and also of uridine diphosphate (UDP)-glucuronyl transferase and epoxide hydrolase.¹⁰ This inhibition is competitive and dose-dependent, and its effect is observed when sufficient concentrations of VPA is achieved (usually within 24 hours). Thus, an increase in the plasma concentrations of other AEDs such as lamotrigine is to be expected after dosing with VPA.

Metabolism of VPA is very complex and is the result of hepatic mitochondrial β -oxidation and microsomal oxidations, catalyzed by CYP2C9, CYP2C19, and CYP2E1 and possibly CYP3A4, and glucuronidations.^{39,40} At least 10 metabolites have been identified. The major urinary inactive metabolite is 2-propyl-3-keto-pentanoic acid (3-keto-VPA) and an equipotent active metabolite, (E)-2-ene-VPA. Other minor metabolites identified are their hydroxylated or dehydrated products, and 2-propylglutaric acid (see Fig. 14.3 for their structures). All of these metabolites are excreted as O-glucuronides.

The hepatotoxicity of VPA is most likely associated with 2, 4-diene-VPA and/or 4-epoxy-VPA rather than the 4-ene-VPA originally suggested because its closely related

Figure 14.3 • Metabolic pathways of valproic acid.

analogs, α -fluoro-4-ene-VPA and α -fluoro-VPA, were not found to have any liver toxicity.⁴¹ These toxic or reactive metabolites are normally detoxified as a cysteine conjugate via the GSH/glutathione transferase metabolic pathway.⁴¹ Alternatively, the 4-epoxy-VPA can also be deactivated by epoxy hydrolase to form the corresponding inactive VPA-4,5-diol (Fig. 14.3). It should be pointed out that these toxic metabolites may also react with the sulfhydryl group or other nucleophiles on the cellular proteins, thereby forming covalently bonded haptens. These drug-modified proteins then elicit and become the target of an immune response, thereby producing the observed idiosyncratic allergic reactions in clinically susceptible patients.

Valroceamide (valproyl glycinamide, VLR) and DP-VPA (SPD-421) are two novel VPA analogs currently in phase II clinical trials^{42,43} (Fig. 14.4). The anticonvulsant properties of VLR were found to be a result of the parent molecule and not because of its metabolic biotransformation to VPA or glycine (i.e., itself an inhibitory neurotransmitter in the brain). The major *in vivo* inactive metabolite is valproyl glycine, which is formed via the normal metabolic inactivation of peptide drugs.⁴² SPD-421, on the other

hand, is a phosphatidylcholine derivative of VPA. The phospholipid part of the molecule significantly increases its lipid solubility and facilitates its transport into the brain. Furthermore, SPD-421 was found to be minimally metabolized in the liver with most of the drug renally eliminated. However, upon entry into the brain, SPD-421 is specifically cleaved by the enzyme, phospholipase A₂ (PLA₂), at the site of seizure to release VPA (there is evidence that the activity of PLA₂ is significantly increased in neurons associated with epileptiform activity prior to seizure attack).⁴³ Thus, unlike VPA, both of these drugs are said to have low drug-interaction potentials.

Phenytoin (Dilantin, Kapseals, Phenytek) and Fosphenytoin (Cerebyx)

Phenytoin, 5,5-diphenylhydantoin (Dilantin), is a prime example of an effective anticonvulsant acting through its action at the VGSC.¹⁸ Phenytoin is structurally very similar to phenobarbital but lacks the dependence liability (see the discussion of barbiturate-type anxiolytic hypnotic-sedative drugs under “CNS Depressants” in this

Figure 14.4 • Novel valproic acid analogs in phase II trials.

Figure 14.5 • Biotransformation of fosphenytoin to phenytoin.

text). Phenytoin is very effective against all seizure types except absence; however, the drug may be incompletely or erratically absorbed from sites of administration because of its very low water solubility. For this reason, fosphenytoin, a prodrug of phenytoin, was developed and marketed to avoid complications such as vein irritation, tissue damage, and muscle necrosis associated with parenteral phenytoin administration. Fosphenytoin is rapidly absorbed either by intravenous or intramuscular administration.⁴³ It is converted into phenytoin through phosphatase

catalyzed hydrolysis of the phosphate ester as shown in Figure 14.5.

METABOLISM OF PHENYTOIN

The principal metabolic pathway of phenytoin in humans is aromatic hydroxylation, catalyzed by the cytochrome P450 isozymes (CYP2C9 and CYP2C19).^{10,44} The metabolic biotransformations and its *in vivo* detoxification pathways are depicted in Figure 14.6. The major metabolites of phenytoin

Figure 14.6 • Metabolic pathways of phenytoin.

are the 5-(4-hydroxyphenyl)-5-phenyl hydantoin (*p*-HPPH) and dihydrodiol. Both of these inactive metabolites are excreted as the corresponding *O*-glucuronides. Further oxidation of *p*-HPPH leads to a catechol metabolite, which appears in the urine as a methyl conjugate by the action of catechol-*O*-methyltransferase (COMT).

HYPERSENSITIVITY REACTION OF PHENYTOIN

Hypersensitivity reactions (idiosyncratic toxicity) to phenytoin and other aromatic AEDs in susceptible individuals are believed to stem from the reactions of these reactive intermediates (i.e., arene oxide, catechol, or *o*-quinone) with hepatic enzymes or other cellular proteins forming covalently bonded haptens.⁴⁵ The reactive intermediate, arene oxide, is deactivated by either epoxide hydrolase to dihydrodiol (a major urinary metabolite) or by the action of GSH and glutathione transferase. It has also been suspected that these reactive arene oxides or epoxides mediate the teratogenicity of phenytoin and other AEDs. Recent studies indicate that epoxide hydrolase might be useful as a biomarker for prenatal determination of risk of fetal hydantoin syndrome.^{46,47} Again, glutathione and epoxide hydrolase are important for detoxification of these reactive metabolites. Furthermore, a normal level of COMT in the liver or kidneys also greatly reduces the amount of catechol, which can be easily oxidized to the reactive *o*-quinone. Thus, COMT and the NADPH-dependent quinone oxidoreductase may play a protective role in phenytoin-induced toxicities.⁴⁸

Both phenytoin and phenobarbital are potent liver enzyme inducers. Both of these drugs induce cytochrome P450 isozymes CYP1A2, CYP2C9/19, and CYP3A4, as well as epoxide hydrolase and UDP-glucuronyl transferase (phase II enzyme responsible for glucuronide formation).¹⁰ Thus, for patients who are using multiple drugs, their plasma concentrations for drugs metabolized by these enzymes will be greatly affected.

Phenobarbital and Primidone (Mysoline)

Although sedative-hypnotic barbiturates commonly display anticonvulsant properties, only phenobarbital display enough anticonvulsant selectivity for use as antiepileptics. Primidone (Mysoline) is metabolized by CYP2C9/19 to phenobarbital and phenylethylmalonamide (PEMA) as shown in Figure 14.7. Both of these metabolites have anticonvulsant activities. However, it is generally believed that the pharmacological action of primidone is mainly a result of the minor metabolite, phenobarbital. Thus, primidone is much less potent/toxic than phenobarbital, because most of the drug is rapidly degraded to the less potent metabolite, PEMA.⁴⁹

Carbamazepine (Tegretol) and Oxcarbazepine (Trileptal)

CBZ, 5H dibenz[b,f]lazepine 5 carboxamide is an iminostilbene derivative of tricyclic antidepressants.⁵⁰ The two phenyls substituted on the urea nitrogen fit the pharmacophore pattern suggested for binding to the VGSC²¹ (Fig. 14.1). Like phenytoin, CBZ is useful in generalized tonic-clonic and partial seizures.

The major metabolic pathway of CBZ is the formation of a stable metabolite, 10,11-CBZ epoxide by cytochrome P450 isozyme CYP3A4. This reactive metabolite is further deactivated by the action of epoxide hydrolase to give inactive 10,11-CBZ-diol that is excreted as the corresponding glucuronides⁵⁰ (Fig. 14.8). The epoxide is a suspect in the idiosyncratic reactions CBZ may produce (e.g., aplastic anemia).⁴⁸ OXC is a newer AED with a similar mechanism of action to CBZ except for its metabolic inactivation pathway. It is also not a liver enzyme inducer like CBZ and phenytoin.^{43,50} With the presence of a carbonyl function at the C-10 carbon, OXC is reduced to the corresponding CBZ-10-ol by the action of alcohol dehydrogenase that is excreted as its

Figure 14.7 • Metabolic biotransformation of primidone.

Figure 14.8 • Metabolism of carbamazepine and oxcarbazepine.

O-glucuronide or can be further oxidized to the 10,11-CBZ-diol as an inactive metabolite (Fig. 14.8). Thus, OXC is said to have much fewer hepatic and idiosyncratic side effects associated with CBZ.²³ Although OXC does not induce its own metabolism, it is a weak inducer of CYP3A4 and UDP-glucuronyl transferase and also inhibits CYP2C19. Thus, severe drug–drug interactions with medications metabolized by these enzymes are to be expected.⁴³

Gabapentin (Neurontin) and Pregabalin (Lyrica)

Gabapentin and its closely related analog pregabalin, (S)-3-isobutyl-GABA (Fig. 14.9), are broad-spectrum anti-convulsants with multiple mechanisms of action.^{24,51} In addition to modulating calcium influx and stimulate GABA biosynthesis as discussed earlier, they also compete for the biosynthesis of L-glutamic acid because of their structural similarity to L-leucine.⁵¹ Gabapentin and pregabalin have very little liability for causing metabolic-based drug–drug interactions, particularly when used in combination with other AEDs because they are not metabolized in humans. More than 95% of the drug is excreted unchanged through the kidneys. However, there are some differences in their bioavailability. Unlike gabapentin, which exhibits 60% bioavailability when given in low doses because of intestinal uptake by a saturable small neutral L-amino acid transporter, the absorption of pregabalin is almost complete (98%) and exhibits an ideal linear

pharmacokinetic profile.²⁴ This high bioavailability of pregabalin can be attributed to its closer structure similarity to the essential amino acid, L-leucine.

FELBAMATE (FELBATOL) AND FLUROFELBAMATE

FBM, another potent and effective AED with a broad spectrum of action, is a carbamate ester of 2-phenyl-1, 3-propanediol, structurally similar to the anxiolytic drug meprobamate.⁴³ The carbamate ester is stable to esterases and therefore provides good oral bioavailability. However, the FBM therapy was found to be associated with rare but severe side effects such as aplastic anemia, idiosyncratic reactions, and hepatic failures within 6 months of its market introduction.^{52,53} Extensive clinical metabolic studies with FBM have been able to link the formation of reactive metabolite(s) and the clinically observed toxicities.⁵² FBM undergoes hepatic cytochrome P450-mediated hydroxylations (i.e., catalyzed by hepatic isozymes, CYP3A4, and CYP2E1) to give 2-hydroxyfelbamate (2-OH-FBM) and *p*-hydroxyfelbamate (*p*OH-FBM) that are excreted as their corresponding glucuronides (Fig. 14.10).

However, FBM also undergoes esterase-catalyzed hydrolysis to give two minor metabolites, 2-phenyl-1, 3-propanediol monocarbamate (MCF) and 3-carbamoyl-2-phenylpropionic acid (CPPA). It has been suggested that during the oxidative degradation of MCF to CPPA, the intermediate, 3-carbamoyl-2-phenylpropionaldehyde could be converted to a potentially toxic reactive metabolite, 2-

Figure 14.9 • Gabapentin, pregabalin, and L-leucine.

Figure 14.10 • Metabolic biotransformation of felbamate.

phenylpropanal (atropaldehyde) that is normally deactivated as a cysteine conjugate via the GSH/glutathione transferase pathway discussed earlier under the metabolism of VPA.³⁹ Isolation of 4-hydroxy-5-phenyl-1,3-oxazaperhydroin-2-one (i.e., a precursor for 2-phenylpropionaldehyde in human urine) provided further evidence linking this toxic metabolite to the observed clinical toxicities.⁵³ Similar to VPA discussed earlier, placement of a fluorine atom at the C-2 position of FBM resulted in a very potent anticonvulsant, 2-fluorofelbamate that lacks the idiosyncratic properties of FBM. Fluorofelbamate is currently under phase II clinical trials.⁵⁴

It should be pointed out that although FBM has no effect on CYP2C9, it is an inhibitor of CYP2C19 and also inhibits the mitochondrial enzymes responsible for β -oxidation. Thus, drug interactions between FBM and VPA are to be expected.⁵⁵

Novel Broad-Spectrum Anticonvulsants

Chemical structures of these newer broad-spectrum anticonvulsants are shown in Figure 14.11. All of these drugs have unique mechanisms of action and will be discussed in individual drug monographs.

Figure 14.11 • Newer broad-spectrum anticonvulsants.

LAMOTRIGINE (LAMICTAL)

Lamotrigine, an AED of the phenyltriazine class, has been found effective against refractory partial seizures. Like phenytoin and CBZ, its main mechanism of action appears to be blockade of sodium channels that is both voltage- and use-dependent. It also inhibits the high-threshold calcium channel, possibly through inhibition of presynaptic N-type calcium channels and also blocks glutamate release.^{18,19} Lamotrigine is metabolized predominantly by glucuronidation. The major inactive urinary metabolites isolated are 2-*N*-glucuronide (76%) and 5-*N*-glucuronide (10%) because the aromatic ring is somewhat deactivated by the presence of chlorine atoms toward arene oxide formation.⁵⁶ Coadministration of lamotrigine with valproate, however, greatly increases the incidence of its idiosyncratic reactions.⁵⁶ It is conceivable that in the presence of VPA, an inhibitor of UDP-glucuronyl transferase, the concentration of the reactive arene oxide intermediate may be increased because of the reduced capacity of UDP-glucuronyl transferase to metabolize lamotrigine via normal glucuronidation pathways.

TOPIRAMATE (TOPAMAX)

TPM is a sulphamate-substituted monosaccharide, a derivative of the naturally occurring sugar D-fructose that exhibits broad and potent AED actions at both glutamate and GABA receptors.¹⁹ It has good oral bioavailability of 85% to 95%, most likely resulting from its structural similarity to D-glucose. Thus, it may be actively transported into the brain by the D-glucose transporter. (Recall that D-fructose and D-glucose have identical stereochemistry at many of their chiral centers.) Only about 20% of the drug is eliminated by hepatic metabolism (CYP2C19), the remaining drug is excreted unchanged by the kidneys.⁵⁷ The sulphamate ester is hydrolyzed by sulfatases to the corresponding primary alcohol, which is further oxidized to the corresponding carboxylic acid. Even though there are no reports of significant interactions between TPM and other AEDs, TPM is said to have a weak carbonic anhydrase inhibitory activity because of the presence of the sulphamate moiety. Thus, concomitant use of TPM with other carbonic anhydrase inhibitors should be avoided.⁵⁷ The exact mechanism of actions are still unknown, but TPM appears to block glutamate release, antagonize glutamate kainic acid/AMPA receptors, and increase GABAergic transmission by binding to a site distinct from BZDs or barbiturates on the GABA_A receptor complex.¹⁹

ZONISAMIDE (ZONEGRAN, EXCEGRAN)

Zonisamide, a sulfonamide-type anticonvulsant was recently approved for adjunctive therapy in the treatment of partial seizures in adults with epilepsy.⁴³ Zonisamide is primarily metabolized by reductive ring cleavage of the 1,2-benzisoxazole ring to 2-sulfamoyl-acetyl-phenol (Fig. 14.11). This biotransformation is mainly carried out by the intestinal bacteria rather than the mammalian cytosolic aldehyde oxidase suggested earlier.⁵⁸ Again, because of the presence of a sulfonamide moiety in zonisamide molecule, precaution should be given to patients who have a history of hypersensitivity reactions toward sulfonamide drugs and concomitant use of zonisamide with other carbonic anhydrase inhibitors should also be avoided.⁵⁹

LEVETIRACETAM (KEPPRA)

LEV is an analog of the nootropic agent, piracetam. Only the *S*-isomer shown in Figure 14.11 has any anticonvulsant activity. Unlike piracetam, LEV does not have any affinity for the AMPA receptor thereby has no nootropic activity for the treatment of Alzheimer disease. LEV also has no affinity for GABA receptors, BZD receptors, the various excitatory amino acid related receptors, or the voltage-gated ion channels.^{43,60} For this reason, its mechanism of anticonvulsant action remains unclear, but it appears to exert its antiepileptic action by modulating kainite/AMPA-induced excitatory synaptic currents, thus decreasing membrane conductance.⁶⁰ Furthermore, the anticonvulsant activity of this drug appears to be mediated by the parent molecule rather than by its inactive metabolite, (*S*)- α -ethyl-2-oxo-1-pyrrolidineacetic acid (i.e., via the hydrolysis of amide group).⁶¹ Like gabapentin, LEV has few drug interactions with other AEDs thereby can be used in combination to treat refractory epilepsy.^{10,56}

Anticonvulsants Acts on a Selective Molecular Target**TIAGABINE (GABITRIL)**

A glance at tiagabine's structure (Fig. 14.12) suggests an uptake inhibitor. Reportedly, it blocks GABA reuptake as a major mode of its anticonvulsant activity. Its use is against partial seizures. Inhibitors of GABA transporter-1 (GAT-1 inhibitors) increase extracellular GABA concentration in the hippocampus, striatum, and cortex, thereby prolonging the inhibitory action of GABA released synaptically. Nipecotic acid is a potent inhibitor of GABA reuptake into synaptosomal membranes, neurons, and glial cells. However, nipecotic acid fails to cross the blood-brain barrier following systemic administration because of its high degree of ionization. Tiagabine, marketed as the single R(-)-enantiomer, a potent GAT-1 inhibitor structurally related to nipecotic acid, has an improved ability to cross the blood-brain barrier, and it has recently received Food and Drug Administration (FDA) approval as an AED.⁴³ It is well absorbed and readily metabolized by CYP3A4 to an inactive metabolite, 5-oxo-tiagabine (oxidation of the thiophen ring) or eliminated as glucuronide of the parent molecule.

Over 90% of tiagabine is metabolized by CYP3A4 isozymes.⁶² The primary site of metabolic attack is the oxidation of the thiophen rings leading to 5-oxo-tiagabine that lacks anticonvulsant activity and the glucuronidation via the carboxylic function. Thus, the plasma concentrations of tiagabine would be greatly effected by any compound that induces or inhibits CYP3A4.

ETHOSUXIMIDE (ZARONTIN) AND METHSUXIMIDE (CELONTIN)

Ethosuximide is considered the prototypical anticonvulsant needed for treating patients with absence seizures.^{6,19,25} Ethosuximide and the *N*-dealkylated active metabolite of methsuximide (Fig. 14.12) work by blocking the low-threshold T-type calcium channels, thereby reducing the hyperexcitability of thalamic neurons that is specifically associated with absence seizure.²⁰

Figure 14.12 • Anticonvulsants acts on a selective molecular target.

VIGABATRIN (SABRIL)

Vigabatrin, a 4-vinyl analog of GABA, produces its pharmacological action by irreversibly blocking GABA catabolism catalyzed by GABA-T as discussed earlier. It is marketed in Europe and Canada as an adjunctive treatment of patients with partial seizures, but it has yet to gain FDA approval in the United States even after extensive clinical trials.⁵⁶ The main concern with this drug is its ability to cause a reversible visual field defect associated with retinal function in the eyes.⁶³

BENZODIAZEPINES

For details of the chemistry and SARs of the BZDs, see the discussion of anxiolytic sedative–hypnotic drugs. Among the current clinically useful drugs, the structural features associated with anticonvulsant activity are identical with those associated with anxiolytic sedative–hypnotic activity.

Clonazepam (Klonopin)

Clonazepam is useful in absence seizures and in myoclonic seizures. Tolerance to the anticonvulsant effect of the clonazepam often developed rather quickly, and it is a common problem with the BZDs. Metabolism involves hydroxylation of the C-3 position, followed by glucuronidation and nitro group reduction, followed by acetylation.

Diazepam (Valium, Diastat)

Diazepam is given orally (Valium) or rectally (Diastat) as an adjunctive treatment in patients with generalized tonic–clonic status epilepticus (i.e., an acute and potentially fatal seizure) or in patients with refractory epilepsy in combination with other AEDs.⁴ For details on diazepam (Valium), see its discussion under anxiolytics and sedative–hypnotic agents.

FUTURE DEVELOPMENT OF ANTIEPILEPTIC DRUGS

As stated earlier, even with the recent introduction of newer AEDs, greater than a third of newly diagnosed patients with epilepsy are still in need of an effective AED to control their seizures.^{3,11,20} Furthermore, all current AEDs work only as prophylaxis against the symptoms of epilepsy, they do not prevent disease progression into refractory epilepsy. Future directions in the development of AEDs must come from either a better understanding of the epileptogenesis, especially the genetic mechanisms that underlie disease progression or the development of resistance after prolonged pharmacotherapy,³ or from an innovative design strategy that produce new AEDs with unique mechanisms of action.¹¹ Several of these agents are currently undergoing different phases of clinical trials. The readers are to consult recent reviews for further details of these agents.^{64–66}

REVIEW QUESTIONS

1. Provide a biochemical reason why pregabalin has better bioavailability than gabapentin.
2. SSADH deficiency, a rare inborn error of human metabolism, disrupts the normal metabolism of the inhibitory neurotransmitter GABA. Explain why these individuals are more susceptible to seizure activity.
3. Explain chemically/biochemically why 2-fluoro-VPA, a synthetic analog of VPA currently in clinical trials, may not possess similar hepatotoxic/teratogenic side effects as VPA.
4. Provide a biochemical rationale why valproic acid, a VPA analog, lacks epoxide hydrolase inhibitory activity and teratogenicity of VPA at clinically relevant concentrations.

5. Explain why coadministering valproate with phenytoin will increase its idiosyncratic toxicities. Identify at least two possible reactive metabolites of phenytoin that may be responsible for this observation.
6. Explain why there are cross-sensitivities among phenytoin, phenobarbital, fosphenytoin and primidone.
7. What will be the expected metabolic profile of CBZ if a specific inhibitor of CYP3A4 such as ketoconazole, an antifungal drug or the flavones present in grapefruit is taken concurrently?
8. Explain why lamotrigine is eliminated more rapidly in patients who have been taking CBZ or phenytoin.
9. Provide a possible rationale for why CYP3A4 inducers can increase the clearance of FBM, yet CYP3A4 inhibitors have little or no effect on its pharmacokinetic profile.
10. Explain why some dose adjustment of VPA may be required if FBM is added to a regimen of VPA.

Central Nervous System Stimulants

JOHN M. BEALE, JR.

CHAPTER OVERVIEW

This chapter discusses a broad range of agents that stimulate the central nervous system (CNS). The *analeptics* classically are a group of agents with a limited range of use because of the general nature of their effects. The *methylxanthines* have potent stimulatory properties, mainly cortical at low doses but with more general effects as the dose is increased. The *central sympathomimetic agents* amphetamine and close relatives have alerting and antidepressant properties but are medically used more often as anorexigants. The *antidepressant drugs* are used most frequently in depressive disorders and can be broadly grouped into the monoamine oxidase inhibitors (MAOIs), the monoamine reuptake inhibitors, and agents acting on autoreceptors. A small group of miscellaneous acting drugs, which includes several hallucinogens, cocaine, and cannabinoids, concludes the chapter.

ANALEPTICS

The traditional analeptics are a group of potent and relatively nonselective CNS stimulants. The convulsive dose lies near their analeptic dose. They can be illustrated by picrotoxinin and pentylenetetrazole. Both are obsolete as drugs but remain valuable research tools in determining how drugs act. Newer agents, modafinil and doxapram, are more selective and have use in narcolepsy and as respiratory stimulants.

Picrotoxin

Picrotoxinin, the active ingredient of picrotoxin, has the following structure:

According to Jarboe et al.,¹ the hydroxylactonyl moiety is mandatory for activity, with the 2-propenyl group assisting. Picrotoxinin exerts its effects by interfering with the inhibitory effects of γ -aminobutyric acid (GABA) at the level of the GABA_A receptor's chloride channel. The drug is obsolete medically. Pharmacologically, it has been

useful in determining mechanisms of action of sedative-hypnotics and anticonvulsants. Butyrolactones bind to the picrotoxinin site.

Pentylenetetrazole

Pentylenetetrazole, 6,7,8,9-tetrahydro-5H-tetrazolo[1,5-a]azepine, 1,5-pentamethylenetetrazole (Metrazol), has been used in conjunction with the electroencephalograph to help locate epileptic foci. It is used as a laboratory tool in determining potencies of potential anticonvulsant drugs in experimental animals. The drug acts as a convulsant by interfering with chloride conductance.² It binds to an allosteric site on the GABA_A receptor and acts as a negative modulator. Overall, it appears to share similar effects on chloride conductance with several other convulsive drugs, including picrotoxinin.

Modafinil

Modafinil (Provigil) has overall wakefulness-promoting properties similar to those of central sympathomimetics. It is considered an atypical α_1 -norepinephrine (NE) receptor stimulant and is used to treat daytime sleepiness in narcolepsy patients. Adverse reactions at therapeutic doses are reportedly not severe and may include nervousness, anxiety, and insomnia. Modafinil is used by oral administration.

Doxapram Hydrochloride

Doxapram, 1-ethyl-4-(2-morpholinoethyl)-3,3-diphenyl-2-pyrrolidinone hydrochloride hydrate (Dopram), has an obscure molecular mechanism of action. Overall, it stimulates respiration by action on peripheral carotid chemoreceptors. It has use as a respiratory stimulant postanesthetically, after CNS depressant drug overdose, in chronic obstructive pulmonary diseases, and in the apneas. Dopram is administered exclusively by intravenous injection. Because of the benzyl alcohol content of the injectable formulation, Dopram must never be given to neonates.

METHYLYXANTHINES

The naturally occurring methylxanthines are caffeine, theophylline, and theobromine. See Table 15.1 for their structures and occurrence and Table 15.2 for their relative potencies.

Caffeine is a widely used CNS stimulant. Theophylline has some medical use as a CNS stimulant, but its CNS-stimulant properties are encountered more often as sometimes severe, and potentially life-threatening, side effects of its use in bronchial asthma therapy. Theobromine has very little CNS activity (probably because of poor physicochemical properties for distribution to the CNS).

Caffeine is often used as it occurs in brewed coffee, brewed tea, and cola beverages. In most subjects, a dosage of 85 to 250 mg of caffeine acts as a cortical stimulant and facilitates clear thinking and wakefulness, promotes an ability to concentrate on the task at hand, and lessens fatigue. As the dose is increased, side effects indicating excessive stimulation (e.g., restlessness, anxiety, nervousness, tremulousness) become more marked. (They may be present in varying degrees at lower-dose levels.) With further increases in dosage, convulsions can occur. A review of the actions of caffeine in the brain with special reference to factors that contribute to its widespread use appears to be definitive.³

The CNS effects of theophylline at low-dose levels have been little studied. At high doses, the tendency to produce convulsions is greater for theophylline than for caffeine. In addition to being cortical stimulants, theophylline and caffeine are medullary stimulants, and both are used as such. Caffeine may be used in treating poisoning from CNS-depressant drugs, although it is not a preferred drug.

The important use of theophylline and its preparations in bronchial asthma is discussed elsewhere. Caffeine also is reported to have valuable bronchodilating properties in asthma. Finally, because of central vasoconstrictive effects, caffeine has value in treating migraine and tension headaches and may have actual analgesic properties in the latter use.

The CNS-stimulating effects of the methylxanthines were once attributed to their phosphodiesterase-inhibiting ability. This action is probably irrelevant at therapeutic doses. Evidence indicates that the overall CNS-stimulant ac-

Theobromine	H	CH ₃	CH ₃	Cocoa

tion is related more to the ability of these compounds to antagonize adenosine at A₁ and A_{2A} receptors.³⁻⁶ All of the roles of these receptors are still under study. The adenosine receptor subtypes and their pharmacology have been reviewed.^{3,7-9} Problems with the present compounds, such as caffeine and theophylline, are lack of receptor selectivity and the ubiquitous nature of the various receptor subtypes.

Caffeine and theophylline have pharmaceutically important chemical properties. Both are weak Brønsted-Lowry bases. The reported pK_a values are 0.8 and 0.6 for caffeine and 0.7 for theophylline. These values represent the basicity of the imino nitrogen at position 9. As acids, caffeine has a pK_a above 14, and theophylline, a pK_a of 8.8. In theophylline, a proton can be donated from position 7 (i.e., it can act as a Brønsted acid). Caffeine cannot donate a proton from position 7 and does not act as a Brønsted acid at pH values less than 14. Caffeine does have electrophilic sites at positions 1, 3, and 7. In addition to its Brønsted acid site at 7, theophylline has electrophilic sites at 1 and 3. In condensed terms, both compounds are electron-pair donors, but only theophylline is a proton donor in most pharmaceutical systems.

Although both compounds are quite soluble in hot water (e.g., caffeine 1:6 at 80°C), neither is very soluble in water at room temperature (caffeine about 1:40, theophylline about 1:120). Consequently, various mixtures or complexes designed to increase solubility are available (e.g., citrated caffeine, caffeine and sodium benzoate, theophylline-ethylenediamine compound [aminophylline]).

Caffeine in blood is not highly protein bound; theophylline is about 50% bound. Differences in the substituent at the 7-position may be involved. Additionally, caffeine is

TABLE 15.2 Relative Pharmacological Potencies of the Xanthine Alkaloids

Theobromine	3	3	2	2	2	3

^a1, most potent

more lipophilic than theophylline and reputedly achieves higher brain concentrations. The half-life of caffeine is 5 to 8 hours, and that of theophylline, about 3.5 hours. About 1% of each compound is excreted unchanged. The compounds are metabolized in the liver. The major metabolite of caffeine is 1-methyluric acid, and that of theophylline, 1,3-dimethyluric acid.¹⁰ Neither compound is metabolized to uric acid, and they are not contraindicated in gout.

CENTRAL SYMPATHOMIMETIC AGENTS (PSYCHOMOTOR STIMULANTS)

Sympathomimetic agents, whose effects are manifested mainly in the periphery, are discussed in Chapter 16. A few simple structural changes in these peripheral agents produce compounds that are more resistant to metabolism, more non-polar, and better able to cross the blood-brain barrier. These effects increase the ratio of central to peripheral activity, and the agents are designated, somewhat arbitrarily, as *central sympathomimetic agents*.

In addition to CNS-stimulating effects, manifested as excitation and increased wakefulness, many central sympathomimetics exert an anorexiant effect. Central sympathomimetic (noradrenergic) action is often the basis for these effects. Other central effects, notably dopaminergic and serotonergic effects, can be operative, however.¹¹ In some agents, the ratio of excitation and increased wakefulness to anorexiant effects is decreased, and the agents are marketed as anorexiant. Representative structures of this group of compounds are given in Table 15.3. The structures of the anorexiant phendimetrazine and sibutramine and the alerting agents methylphenidate and pemoline, useful in attention-deficient disorders, are given in the text.

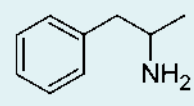

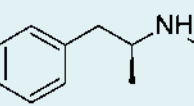

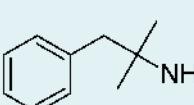

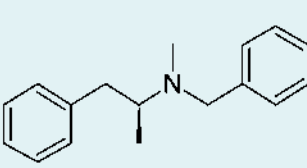

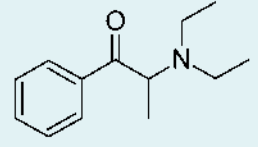

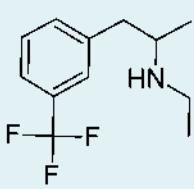

Structural features for many of the agents can be visualized easily by considering that within their structure, they contain a β -phenethylamine moiety, and this grouping can give some selectivity for presynaptic or postsynaptic noradrenergic systems. β -Phenethylamine, given peripherally, lacks central activity. Facile metabolic inactivation by monoamine oxidases (MAOs) is held responsible. Branching with lower alkyl groups on the carbon atom adjacent (α) to the amino nitrogen increases CNS rather than peripheral activity (e.g., amphetamine, presumably by retarding metabolism). The α branching generates a chiral center. The *dextro(S)*-isomer of amphetamine is up to 10 times as potent as the *levo(R)*-isomer for alerting activity and about twice as active as a psychotomimetic agent. Hydroxylation of the ring or hydroxylation on the β -carbon (to the nitrogen) decreases activity, largely by decreasing the ability to cross the blood-brain barrier. For example, phenylpropanolamine, with a β -hydroxyl (OH), has about 1/100th the ability to cross the blood-brain barrier of its deoxy congener, amphetamine.

Halogenation (F, Cl, Br) of the aromatic ring decreases sympathomimetic activity. Other activities may increase. *p*-Chloroamphetamine has strong central serotonergic activity (and is a neurotoxin, destroying serotonergic neurons in experimental animals).^{12,13}

Methoxyl or methylenedioxy substitution on the ring tends to produce psychotomimetic agents, suggesting tropism for dopaminergic (D₂) receptors.

N-methylation increases activity (e.g., compare methamphetamine with dextroamphetamine). Di-*N*-methylation de-

	Fenfluramine

creases activity. Mono-*N* substituents larger than methyl decrease excitatory properties, but many compounds retain anorexiant properties. Consequently, some of these agents are used as anorexiant, reportedly with less abuse potential than amphetamine.

There can be some departure from the basic β -phenethylamine structure when compounds act by indirect noradrenergic mechanisms. A β -phenethylamine-like structure, however, can be visualized in such compounds.

The abuse potential of the more euphoriant and stimulatory of the amphetamines and amphetamine-like drugs is well documented. They produce an exceedingly destructive addiction. Apparently, both a euphoric "high" (possibly related to effects on hedonistic D₂ receptors) and a post-euphoric depression (especially among amine-depleting drugs) contribute to compulsive use of these agents. Abuse of these drugs (especially methamphetamine) in recent years has reached disastrous proportions.

Recognized medical indications for dextroamphetamine and some very close congeners include narcolepsy, Parkinson disease, attention-deficient disorders, and, although not the preferred agents for obesity, appetite suppression. In some conditions, such as Parkinson disease, for which its main use

is to decrease rigidity, the antidepressant effects of dextroamphetamine can be beneficial. It is also reportedly an effective antidepressant in terminal malignancies. In almost all cases of depression, and especially in major depressive disorders of the unipolar type, however, dextroamphetamine has long been superseded by other agents, notably the MAOIs and the monoamine reuptake-inhibiting antidepressants.

The compounds and their metabolites can have complex, multiple actions. In a fundamental sense, the structural basis for action is quite simple. The compounds and their metabolites resemble NE and can participate in the various neuronal and postsynaptic processes involving NE, such as synthesis, release, reuptake, and presynaptic and postsynaptic receptor activation. Also, because dopamine (DA) and, to a lesser extent, serotonin (5-hydroxytryptamine [5-HT]) bear a structural resemblance to NE, processes in DA- and 5-HT-activated systems can be affected. To illustrate the potential complexity, the receptor activations that can be associated with just one parameter, reduction in food intake, reportedly are α_1 , β_1 , β_2 , 5-HT_{1B}, 5-HT_{2A}, 5-HT_{2C}, D₁, and D₂.

PRODUCTS

Amphetamine Sulfate

Amphetamine, (\pm)-1-phenyl-2-aminopropane (Benzedrine), as the racemic mixture has a higher proportion of cardiovascular effects than the *dextro* isomer. For most medical uses, the dextrorotatory isomer is preferred.

Dextroamphetamine Sulfate and Dextroamphetamine Phosphate

Dextroamphetamine, (+)-(*S*)-methylphenethylamine, forms salts with sulfuric acid (Dexedrine) and with phosphoric acids. The phosphate is the more water-soluble salt and is preferred if parenteral administration is required. The dextrorotatory isomer has the (*S*) configuration and fewer cardiovascular effects than the levorotatory (*R*)-isomer. Additionally, it may be up to 10 times as potent as the (*R*)-isomer as an alerting agent and about twice as potent a psychotomimetic agent. Although it is a more potent psychotomimetic agent than the (*R*)-isomer, it has a better ratio of alerting to psychotomimetic effects.

The major mode of action of dextroamphetamine is release of NE from the mobile pool of the nerve terminal. Other mechanisms, such as inhibition of uptake, may make a small contribution to the overall effects. The alerting actions relate to increased NE available to interact with postsynaptic receptors (α_1). Central β -receptor activation has classically been considered the basis for most of the anorexic effect.

The psychotomimetic effects are linked to release of DA and activation of postsynaptic receptors. D₂ and mesolimbic D₃ receptors would be involved. Effects on 5-HT systems also have been linked to some behavioral effects of dextroamphetamine. Effects via 5-HT receptors would include 5-HT_{1A} receptors and, theoretically, all additional receptors through 5-HT₇.

Dextroamphetamine is a strongly basic amine, with values from 9.77 to 9.94 reported. Absorption from the gastrointestinal tract occurs as the lipid-soluble amine. The drug is not extensively protein bound. Varying amounts of the drug are excreted intact under ordinary conditions. The amount is insignificant under conditions of alkaline urine. Under conditions producing systemic acidosis, 60% to 70% of the drug can be excreted unchanged. This fact can be used to advantage in treating drug overdose.

The α -methyl group retards, but does not terminate, metabolism by MAO. Under most conditions, the bulk of a dose of dextroamphetamine is metabolized by *N*-dealkylation to phenylacetone and ammonia. Phenylacetone is degraded further to benzoic acid.

In experimental animals, about 5% of a dose accumulates in the brain, especially the cerebral cortex, the thalamus, and the corpus callosum. It is first *p*-hydroxylated and then β -hydroxylated to produce *p*-hydroxynorephedrine, which has been reported to be the major active metabolite involved in NE and DA release.¹⁴

Methamphetamine Hydrochloride

Methamphetamine, (+)-1-phenyl-2-methylaminopropane hydrochloride desoxyephedrine hydrochloride (Desoxyn), is the *N*-methyl analog of dextroamphetamine. It has more marked central and less peripheral action than dextroamphetamine. It has a very high abuse potential, and by the intravenous route, its salts are known as "speed." The overall abuse problem presented by the drug is a national disaster. Medicinally acceptable uses of methamphetamine are analogous to those of dextroamphetamine.

Phentermine Ion-Exchange Resin and Phentermine Hydrochloride

The free base is α,α -dimethylphenethylamine, 1-phenyl-2-methylaminopropane. In the resin preparation (Ionamin), the base is bound with an ion-exchange resin to yield a slow-release product; the hydrochloride (Wilpowr) is a water-soluble salt.

Phentermine has a quaternary carbon atom with one methyl oriented like the methyl of (*S*)-amphetamine and one methyl oriented like the methyl of (*R*)-amphetamine, and it reportedly has pharmacological properties of both the (*R*)- and (*S*)-isomers of amphetamine. The compound is used as an appetite suppressant and is a Schedule IV agent, indicating less abuse potential than dextroamphetamine.

Benzphetamine Hydrochloride

Benzphetamine hydrochloride, (+)-*N*-benzyl-*N*, α -dimethylphenethylamine hydrochloride, (+)-1-phenyl-2-(*N*-methyl-*N*-benzylamine)propane hydrochloride (Didrex), is *N*-benzyl-substituted methamphetamine. The large (benzyl) *N*-substituent decreases excitatory properties, in keeping with the general structure-activity relationship (SAR) for the group. Anorexiant properties are retained. Classically, amphetamine-like drugs with larger than *N*-methyl substituents are cited as anorexiant through central β -agonism. No claims for selectivity among β -receptor subtypes have been made in such citations. The compound shares mechanism-of-action characteristics with methylphenidate. Overall, it is said to reduce appetite with fewer CNS excitatory effects than dextroamphetamine.

Diethylpropion Hydrochloride

Because it has two large (relative to H or methyl) *N*-alkyl substituents, diethylpropion hydrochloride, 1-phenyl-2-diethylaminopropan-1-one hydrochloride (Tenuate, Tepanil), has fewer sympathomimetic, cardiovascular, and CNS-stimulatory effects than amphetamine. It is reportedly an anorexiant agent that can be used for the treatment of obesity in patients with hypertension and cardiovascular disease. According to the generalization long used for this group of drugs, increasing *N*-alkyl size reduces central α_1 effects and increases β effects, even though the effects are likely mediated principally by indirect NE release.

Fenfluramine Hydrochloride

Fenfluramine hydrochloride, (\pm)-*N*-ethyl- α -methyl-*m*-(trifluoromethyl)phenethylamine hydrochloride (Pondimin), is unique in this group of drugs, in that it tends to produce sedation rather than excitation. Effects are said to be mediated principally by central serotonergic, rather than central noradrenergic, mechanisms. In large doses in experimental animals, the drug is a serotonin neurotoxin.¹⁵ It was withdrawn from human use after reports of heart valve damage and pulmonary hypertension. From its structure, more apolar or hydrophobic character than amphetamine, tropism for serotonergic neurons would be expected. Likewise, the structure suggests an indirect mechanism. If an indirect mechanism were operative, then all postsynaptic 5-HT re-

ceptors could be activated. Evidence from several studies indicates that the 5-HT_{1B} and the 5-HT_{2C} receptors are most responsible for the satiety effects of 5-HT. 5-HT may also influence the type of food selected (e.g., lower-fat food intake).¹¹ The (+) isomer, dexfenfluramine (Redux), has a greater tropism for 5-HT systems than the racemic mixture. It, too, was withdrawn because of toxicity.

Phendimetrazine Tartrate

The optically pure compound phendimetrazine tartrate, (2*S*,3*S*)-3,4-dimethyl-2-phenylmorpholine-*L*-(+)-tartrate (Plegine), is considered an effective anorexiant that is less abuse prone than amphetamine. The stereochemistry of (+)phendimetrazine is as shown.¹⁶

Sibutramine

Sibutramine (Meridia) is said to be an uptake inhibitor of NE and 5-HT. These mechanisms fit its structure. It is reportedly an antidepressant and an anorexiant drug. This mechanism implies that activation of all presynaptic and postsynaptic receptors in NE and 5-HT systems is possible. The data are not completely clear, but studies to date indicate that the receptors principally involved are α_1 , β_1 , and 5-HT_{2C}.¹¹

Methylphenidate Hydrochloride

Because methylphenidate (Ritalin) has two asymmetric centers, there are four possible isomers. The *threo* racemate is the marketed compound and is about 400 times as potent as the *erythro* racemate.¹⁷ The absolute configuration of each of the *threo*-methylphenidate isomers has been determined.¹⁸ Considering that the structure is fairly complex (relative to amphetamine), it is likely that one of the two components of the *threo* racemate contains most of the activity. Evidence indicates that the (+) -(2*R*,2'*R*)*threo* isomer is involved principally in the behavioral and pressor effects of the racemate.¹⁹ As is likely with many

central psychomotor stimulants, there are multiple modes of action.

Methylphenidate, probably largely via its *p*-hydroxy metabolite, blocks NE reuptake, acts as a postsynaptic agonist, depletes the same NE pools as reserpine, and has effects on dopaminergic systems, such as blocking DA reuptake.

Methylphenidate is an ester drug with interesting pharmacokinetic properties arising from its structure. The pK_a values are 8.5 and 8.8. The protonated form in the stomach reportedly resists ester hydrolysis. Absorption of the intact drug is very good. After absorption from the gastrointestinal tract, however, 80% to 90% of the drug is hydrolyzed rapidly to inactive ritalinic acid.²⁰ (The extent of hydrolysis may be about five times that for (+) versus (-).²¹) Another 2% to 5% of the racemate is oxidized by liver microsomes to the inactive cyclic amide. About 4% of a dose of the racemate reportedly reaches the brain in experimental animals and there is *p*-hydroxylated to yield the putative active metabolite.

Methylphenidate is a potent CNS stimulant. Indications include narcolepsy and attention-deficit disorder. The structure of the (2*R*,2'*R*) isomer of the *threo* racemic mixture is shown.

Pemoline

Pemoline, 2-amino-5-phenyl-4(5*H*)-oxazolone (Cylert), has a unique structure.

The compound is described as having an overall effect on the CNS like that of methylphenidate. Pemoline requires 3 to 4 weeks of administration, however, to take effect. A partial explanation for the delayed effect may be that one of the actions of the agent, as observed in rats, is to increase the rate of synthesis of DA.

ANTIDEPRESSANTS

Monoamine Oxidase Inhibitors

Antidepressant therapy usually implies therapy directed against major depressive disorders of the unipolar type and is centered on three groups of chemical agents: the MAOIs, the monoamine reuptake inhibitors, and autoreceptor desensitizers and antagonists. Electroshock therapy is another option. The highest cure or remission rate is achieved with electroshock therapy. In some patients, especially those who

are suicidal, this may be the preferred therapy. MAOIs and monoamine reuptake inhibitors have about the same response rate (60%–70%). In the United States, the latter group is usually chosen over MAOIs for antidepressant therapy. A key prescribing tenet is that if a member of the patient's family has been successfully treated with an antidepressant drug, then the patient will likely respond to that same drug.

A severe problem associated with the MAOIs that has been a major factor in relegating them to second-line drug status is that the original compounds inhibit liver MAOs irreversibly in addition to brain MAOs, thereby allowing dietary pressor amines that normally would be inactivated to exert their effects systemically. Several severe hypertensive responses, some fatal, have followed ingestion of foods high in pressor amines. It was hoped that the development of agents such as selegiline that presumably spare liver MAO might solve this problem. The approach of using MAO selectivity did solve the hypertensive problem, but the compound was not an antidepressant (it is useful in Parkinson disease). Another approach using a reversible MAOI has yielded antidepressants that lacked the hypertensive "cheese" effect. Another prominent side effect of MAOIs is orthostatic hypotension, said to arise from a block of NE released in the periphery. Actually, one MAOI, pargyline, was used clinically for its hypotensive action. Finally, some of the first compounds produced serious hepatotoxicity. Compounds available today reportedly are safer in this regard but suffer the stigma of association with the older compounds.

The history of MAOI development illustrates the role of serendipity. Isoniazid is an effective antitubercular agent but is a very polar compound. To gain better penetration into the *Mycobacterium tuberculosis* organism, a more hydrophobic compound, isoniazid substituted with an isopropyl group on the basic nitrogen (iproniazid), was designed and synthesized. It was introduced into clinical practice as an effective antitubercular agent. CNS stimulation was noted, however, and the drug was withdrawn. Later, it was determined in experimental animals and in vitro experiments with a purified MAO that MAO inhibition, resulting in higher synaptic levels of NE and 5-HT, could account for the CNS effects. The compound was then reintroduced into therapy as an antidepressant agent. It stimulated an intense interest in hydrazines and hydrazides as antidepressants and inaugurated effective drug treatment of depression.²² It continued to be used in therapy for several years but eventually was withdrawn because of hepatotoxicity.

The present clinically useful irreversible inactivators can be considered mechanism-based inhibitors of MAO.²³ They are converted by MAO to agents that inhibit the enzyme. They can form reactants that bond covalently with the enzyme or its cofactor. A consequence of irreversible inactivation is that the action of the agents may continue for up to 2 weeks after administration is discontinued. The delay is caused by the necessity of synthesizing new, active MAO to replace the covalently inactivated enzyme. Consequently, many drugs degraded by MAO or drugs that elevate levels of MAO substrates cannot be administered during that time.

For a long time, because the agents that opened the field and then dominated it were irreversible inactivator, MAO

inhibition was almost always regarded as irreversible. From the beginning, however, it was known that it was possible to have agents that act exclusively by competitive enzyme inhibition. For example, it has long been known that the harmala alkaloids harmine and harmaline act as CNS stimulants by competitive inhibition of MAO. Reversible (competitive) inhibitors selective for each of the two major MAO subtypes (A and B) are reportedly forthcoming.

Moclobemide has received considerable attention abroad. A reversible inhibitor of MAO-A, it is considered an effective antidepressant and permits metabolism of dietary tyramine.²⁴ Metabolites of the drug are implicated in the activity. Reversible inhibitors of MAO-A (RIMAs) reportedly are antidepressant without producing hypertensive crises. Reversible inhibitors of MAO-B have also been studied. Presently, selective MAO-B inhibition has failed to correlate positively with antidepressant activity; selegiline, however, has value in treating Parkinson disease. A transdermal patch (Emsam) is useful in the treatment of depression.

The clinically useful MAOI antidepressants are nonselective between inhibiting metabolism of NE and 5-HT. Agents selective for a MAO that degrades 5-HT have been under study for some time. The structures of phenelzine and tranylcypromine are given in Table 15.4.

Phenelzine Sulfate

Phenelzine sulfate, 2-(phenylethyl)hydrazine sulfate (Nardil), is an effective antidepressant agent. A mechanism-based inactivator, it irreversibly inactivates the enzyme or its cofactor, presumably after oxidation to the diazine, which can then break up into molecular nitrogen, a hydro-

gen atom, and a phenethyl free radical. The latter would be the active species in irreversible inhibition.²⁵

Tranylcypromine Sulfate

Tranylcypromine sulfate, (\pm)-*trans*-2-phenylcyclopropylamine sulfate (Parnate), was synthesized to be an amphetamine analog (visualize the α -methyl of amphetamine condensed onto the β -carbon atom).²⁶ It does have some amphetamine-like properties, which may be why it has more immediate CNS-stimulant effects than agents that act by MAO inhibition alone. For MAO inhibition, there may be two components to the action of this agent. One is thought to arise because tranylcypromine has structural features (the basic nitrogen and the quasi- π character of the α - and β -cyclopropane carbon atoms) that approximate the transition state in a route of metabolism of β -arylamines.^{27,28} As α - and β -hydrogen atoms are removed from the normal substrate of the enzyme, the quasi- π character develops over the α, β -carbon system. Duplication of the transition state permits extremely strong, but reversible, attachment to the enzyme. Additionally, tranylcypromine is a mechanism-based inactivator. It is metabolized by MAO, with one electron of the nitrogen pair lost to flavin. This, in turn, produces homolytic fission of a carbon-carbon bond of cyclopropane, with one electron from the fission pairing with the remaining lone nitrogen electron to generate an imine (protonated) and with the other residing on a methylene carbon. Thus, a free radical is formed that reacts to form a covalent bond with the enzyme or with reduced flavin to inactivate the enzyme.²⁹

Monoamine Reuptake Inhibitors

Originally, the monoamine reuptake inhibitors were a group of closely related agents, the tricyclic antidepressants (TCAs), but now they are quite diverse chemically. Almost all of the agents block neuronal reuptake of NE or 5-HT or both (i.e., are selective).

Reuptake inhibition by these agents is at the level of the respective monoamine transporter via competitive inhibition of binding of the monoamine to the substrate-binding compartment. Probably the same site on the protein is involved for inhibitor and monoamine, but this has not yet been proved. The mechanism of reuptake by monoamine transporters has been reviewed.³⁰

The net effect of the drug is to increase the level of the monoamine in the synapse. Sustained high synaptic levels of 5-HT, NE, or both appear to be the basis for the antidepressant effect of these agents. There is a time lag of 2 or more

TABLE 15.4 Structures of Monoamine Oxidase Inhibitors

Generic Name Proprietary Name	Structure
Phenelzine Sulfate Nardil	
Tranylcypromine Sulfate Parnate	

weeks before antidepressant action develops. It is considered that (in the case of 5-HT) 5-HT_{1A} receptors and (in the case of NE) α_2 receptors undergo desensitization and transmitter release is maintained. Of course, activation of postsynaptic receptors and sustained transmission is the ultimate result of sustained synaptic levels of neurotransmitter.³¹

Tricyclic Antidepressants

The SARs for the TCAs are compiled in detail in the eighth edition of this text.³² The interested reader is referred to this compilation. In summary, there is a large, bulky group encompassing two aromatic rings, preferably held in a skewed arrangement by a third central ring, and a three- or, sometimes, two-atom chain to an aliphatic amino group that is monomethyl or dimethyl substituted. The features can be visualized by consulting the structures of imipramine and desipramine as examples. The overall arrangement has features that approximate a fully extended *trans* conformation of the β -arylamines. To relate these features to the mechanism of action, reuptake block, visualize that the basic arrangement is the same as that found in the β -arylamines, plus an extra aryl bulky group that enhances affinity for the substrate-binding compartment of the transporter. The overall concept of a β -arylamine-like system with added structural bulk, usually an aryl group, appears to be applicable to many newer compounds—selective serotonin reuptake inhibitors (SSRIs), selective norepinephrine reuptake inhibitors (SNERIs)—that do not have a tricyclic grouping.

The TCAs are structurally related to each other and, consequently, possess related biological properties that can be summarized as characteristic of the group. The dimethyl-amino compounds tend to be sedative, whereas the monomethyl relatives tend to be stimulatory. The dimethyl compounds tend toward higher 5-HT to NE reuptake block ratios: in the monomethyl compounds, the proportion of NE uptake block tends to be higher and, in some cases, is considered selective NE reuptake. The compounds have anticholinergic properties, usually higher in the dimethylamino compounds. When treatment is begun with a dimethyl compound, a significant accumulation of the monomethyl compound develops as *N*-demethylation proceeds.

The TCAs are extremely lipophilic and, accordingly, very highly tissue bound outside the CNS. Because they have anticholinergic and noradrenergic effects, both central and peripheral side effects are often unpleasant and sometimes dangerous. In overdose, the combination of effects, as well as a quinidine-like cardiac depressant effect, can be lethal. Overdose is complicated because the agents are so highly protein bound that dialysis is ineffective.

PRODUCTS

Imipramine Hydrochloride

Imipramine hydrochloride, 5-[3-(dimethylamino)propyl]-10,11-dihydro-5*H*-dibenz[*b,f*]azepine monohydrochloride (Tofranil), is the lead compound of the TCAs. It is also a close relative of the antipsychotic phenothiazines (replace the 10–11 bridge with sulfur, and the compound is the antipsychotic agent promazine). It has weaker D₂ postsynaptic blocking activity than promazine and mainly affects amines (5-HT, NE, and DA) via the transporters. As is typical of dimethyl-amino compounds, anticholinergic and sedative (central H₁ block) effects tend to be marked. The compound per se has a

tendency toward a high 5-HT-to-NE uptake block ratio and probably can be called a *serotonin transport inhibitor* (SERTI). Metabolic inactivation proceeds mainly by oxidative hydroxylation in the 2-position, followed by conjugation with glucuronic acid of the conjugate. Urinary excretion predominates (about 75%), but some biliary excretion (up to 25%) can occur, probably because of the large nonpolar grouping. Oxidative hydroxylation is not as rapid or complete as that of the more nucleophilic ring phenothiazine antipsychotics; consequently, appreciable *N*-demethylation occurs, with a buildup of norimipramine (or desimipramine).

The demethylated metabolite is less anticholinergic, less sedative, and more stimulatory and is a SNERI.³¹ Consequently, a patient treated with imipramine has two compounds that contribute to activity. Overall, the effect is nonselective 5-HT versus NE reuptake. The activity of desimipramine or norimipramine is terminated by 2-hydroxylation, followed by conjugation and excretion. A second *N*-demethylation can occur, which in turn is followed by 2-hydroxylation, conjugation, and excretion.

Desipramine Hydrochloride

The structure and salient properties of desipramine hydrochloride, 10,11-dihydro-*N*-methyl-5*H*-dibenz[*b,f*]azepine-5-propanamine monohydrochloride, 5-(3-methylamino-propyl)-10,11-dihydro-5*H*-dibenz[*b,f*]azepine hydrochloride (Norpramin, Pertofrane), are discussed under the heading, Imipramine. Among tricyclics, desipramine would be considered when few anticholinergic effects or a low level of sedation are important. It is a SNERI.³¹

Clomipramine Hydrochloride

Clomipramine (Anafranil) is up to 50 times as potent as imipramine in some bioassays. This does not imply clinical superiority, but it might be informative about tricyclic and, possibly, other reuptake inhibitors. The chloro replacing the H-substituent could increase potency by increasing distribution to the CNS, but it is unlikely that this would give the potency magnitude seen. It might be conjectured that an H-bond between the protonated amino group (as in vivo) and the unshared electrons of the chloro substituent

might stabilize a β -arylamine-like shape and give more efficient competition for the transporter. The drug is an antidepressant. It is used in obsessive-compulsive disorder, an anxiety disorder that may have an element of depression.

Amitriptyline Hydrochloride

Amitriptyline, 3-(10,11-dihydro-5*H*-dibenzo[*a,d*]cyclohepten-5-ylidene)-*N,N*-dimethyl-1-propanamine hydrochloride, 5-(3-(dimethylaminopropylidene)-10,11-dihydro-5*H*-dibenzo[*a,d*]cycloheptene hydrochloride (Elavil), is one of the most anticholinergic and sedative of the TCAs. Because it lacks the ring-electron-enriching nitrogen atom of imipramine, metabolic inactivation mainly proceeds not at the analogous 2-position but at the benzylic 10-position (i.e., toluene-like metabolism predominates). Because of the 5-exocyclic double bond, *E*- and *Z*-hydroxy isomers are produced by oxidation metabolism. Conjugation produces excretable metabolites. As is typical of the dimethyl compounds, *N*-demethylation occurs, and nortriptyline is produced, which has a less anticholinergic, less sedative, and more stimulant action than amitriptyline. Nortriptyline is a SNER³¹; the composite action of drug and metabolite is nonselective.

Nortriptyline Hydrochloride

Pertinent biological and chemical properties for nortriptyline, 3-(10,11-dihydro-5*H*-dibenzo[*a,d*]cyclohepten-5-ylidene)-*N*-methyl-1-propanamine hydrochloride, 5-(3-(methylamino)propylidene)-10,11-dihydro-5*H*-dibenzo[*a,d*]cycloheptene hydrochloride (Aventyl, Pamelor), are given previously in the discussion of amitriptyline. Metabolic inactivation and elimination are like those of amitriptyline. Nortriptyline is a selective NE transporter (NET) inhibitor.³¹

Protriptyline Hydrochloride

Protriptyline hydrochloride, *N*-methyl-5*H*-dibenzo[*a,d*]cycloheptene-5-propylamine hydrochloride, 5-(3-methylaminopropyl)-5*H*-dibenzo[*a,d*]cycloheptene hydrochloride (Vivactil), like the other compounds under consideration, is an effective antidepressant. The basis for its chemical naming can be seen by consulting the naming and the structure of imipramine. Protriptyline is a structural isomer of nortriptyline. Inactivation can be expected to involve the relatively localized double bond. Because it is a monomethyl compound, its sedative potential is low.

Trimipramine Maleate

For details of chemical nomenclature, consult the description of imipramine. Replacement of hydrogen with an α -methyl substituent produces a chiral carbon, and trimipramine (Surmontil) is used as the racemic mixture. Biological properties reportedly resemble those of imipramine.

Doxepin Hydrochloride

Doxepin, 3-dibenz[*b,e*]oxepin-11(6*H*)ylidene-*N,N*-dimethyl-1-propanamine hydrochloride, *N,N*-dimethyl-3-(dibenz[*b,e*]oxepin-11(6*H*)-ylidene)propylamine (Sinequan, Adapin), is an oxa congener of amitriptyline, as can be seen from its structure.

The oxygen is interestingly placed and should influence oxidative metabolism as well as postsynaptic and presynaptic binding affinities. The (*Z*)-isomer is the more active, although the drug is marketed as the mixture of isomers. The drug overall is a NE and 5-HT reuptake blocker with significant anticholinergic and sedative properties. It can be anticipated that the nor- or des- metabolite will contribute to the overall activity pattern.

Maprotiline Hydrochloride

Maprotiline hydrochloride, *N*-methyl-9,10-ethanoanthracene-9(10*H*)-propanamine hydrochloride (Ludiomil), is sometimes described as a tetracyclic rather than a tricyclic antidepressant. The description is chemically accurate, but the compound, nonetheless, conforms to the overall TCA pharmacophore. It is a dibenzobicyclooctadiene and can be viewed as a TCA with an ethylene-bridged central ring. The compound is not strongly anticholinergic and has stimulant properties. It can have effects on the cardiovascular system. It is a SNERI.³¹

Amoxapine

Consideration of the structure of amoxapine, 2-chloro-11-(1-piperazinyl)dibenz-*[b,f]* [1,4]oxazepine (Asendin), reinforces the fact that many antidepressants are very closely related to antipsychotics. Indeed, some, including amoxapine, have significant effects at D₂ receptors. The *N*-methyl-substituted relative of amoxapine is the antipsychotic loxapine (Loxitane). The 8-hydroxy metabolite of amoxapine is reportedly active as an antidepressant and as a D₂ receptor blocker.

Selective Serotonin Reuptake Inhibitors

Structurally, the SSRIs differ from the tricyclics, in that the tricyclic system has been taken apart in the center. (This abolishes the center ring, and one ring is moved slightly forward from the tricyclic “all-in-a-row” arrangement.) The net effect is that the β -arylamine-like grouping is present, as in the tricyclics, and the compounds can compete for the substrate-binding site of the serotonin transporter protein (SERT). As in the tricyclics, the extra aryl group can add extra affinity and give favorable competition with the substrate, serotonin.

Many of the dimethylamino tricyclics are, in fact, SSRIs. Because they are extensively *N*-demethylated in vivo to nor-compounds, which are usually SNERIs, however, the overall effect is not selective. Breaking up the tricyclic system breaks up an anticholinergic pharmacophoric group and gives compounds with diminished anticholinergic effects. Overall, this diminishes unpleasant CNS effects and increases cardiovascular safety. Instead, side effects related to serotonin predominate.

Fluoxetine

In fluoxetine (Prozac), protonated in vivo, the protonated amino group can H-bond to the ether oxygen electrons, which can generate the β -arylamino-like group, with the other aryl serving as the characteristic “extra” aryl. The *S*-isomer is much more selective for SERT than for NET. The major metabolite is the *N*-demethyl compound, which is as potent as the parent and more selective (SERT versus NET).

Therapy for 2 or more weeks is required for the antidepressant effect. Somatodendritic 5-HT_{1A} autoreceptor desensitization with chronic exposure to high levels of 5-HT is the accepted explanation for the delayed effect for this and other serotonin reuptake inhibitors.

To illustrate a difference between selectivity for a SERT and a NET, if the *para* substituent is moved to the *ortho* position (and is less hydrophobic, typically), a NET is obtained. This and other SERTs have anxiolytic activity. One of several possible mechanisms would be agonism of 5-HT_{1A} receptors, diminishing synaptic 5-HT. Presumably, synaptic levels of 5-HT might be high in an anxious state.

Paroxetine

In the structure of paroxetine (Paxil), an amino group, protonated in vivo could H-bond with the $-CH_2O-$ unshared electrons. A β -arylamine-like structure with an extra aryl group results. The compound is a very highly selective SERT. As expected, it is an effective antidepressant and anxiolytic.

Sertraline

Inspection of sertraline (Zoloft) (1*S*,4*S*) reveals the pharmacophore for SERT inhibition. The Cl substituents also predict tropism for a 5-HT system. The depicted stereochemistry is important for activity.

Fluvoxamine

The *E*-isomer of fluvoxamine (Luvox) (shown) can fold after protonation to the β -arylamine-like grouping. Here, the "extra" hydrophobic group is aliphatic.

**Citalopram**

Citalopram (Celexa) is a racemic mixture and is very SERT selective. The *N*-monodemethylated compound is slightly less potent but is as selective. The aryl substituents are important for activity. The ether function is important and probably interacts with the protonated amino group to give a suitable shape for SERT binding.

**Selective Norepinephrine Reuptake Inhibitors**

The discussion of fluoxetine opened the subject of SNERIs. That is, movement of a *para* substituent of fluoxetine (and relatives) to an *ortho* position produces a SNERI.

Nisoxetine

Nisoxetine is a SNERI and is an antidepressant. Most activity resides in the β -isomer.

**Reboxetine**

Most of the activity of reboxetine resides in the *S,S*-isomer (The marketed compound is *RR* and *SS*.) It is claimed to be superior to fluoxetine in severe depression. It is marketed in Europe. At least three tricyclic compounds, desipramine, nortriptyline, and the technically tetracyclic maprotiline are SNERIs. They, of course, have typical characteristic TCA side effects but lower anticholinergic and H_1 -antihistaminic (sedative) effects than dimethyl compounds. SNERIs are clinically effective antidepressants.

It would be expected that in the case of SNERIs, α_2 presynaptic receptors would be desensitized, after which sustained NE transmission would be via one or more postsynaptic receptors; α_1 , β_1 , and β_2 receptors are possibilities.

**Newer (Nontricyclic) Nonselective 5-HT And NE Reuptake Inhibitors**

Presently, one such compound is clinically used in the United States.

Venlafaxine

The structure and activity of venlafaxine (Effexor) are in accord with the general SARs for the group. As expected, it is an effective antidepressant. Venlafaxine is a serotonin-norepinephrine reuptake inhibitor (SNRI).

**Selective Serotonergic Reuptake Inhibitors and 5-HT_{2A} Antagonists**

The SSRIs and 5-HT_{2A} antagonists are represented by trazodone (Desyrel) and nefazodone (Serzone).

The structures of these two compounds derive from those of the fluorobutyrophenone antipsychotics. They have β -arylamine-like structures that permit binding to the SERT and inhibit 5-HT reuptake. In these compounds, the additional hydrophobic substituent can be viewed as being attached to the nitrogen of the β -arylamine-like group. Additionally, they are 5-HT_{2A} antagonists. That antagonism may or may not afford antipsychotic effectiveness is discussed under antipsychotics. 5-HT_{2A} antagonists appear to have antidepressant and anxiolytic activities. They may act, at least in part, by enhancing 5-HT_{1A} activities.³³ Also, some of the effects may be mediated through 5-HT_{2C} agonism

(perhaps generally so for 5-HT-acting antidepressants). Some of the side effects of SSRIs are considered to be mediated through 5-HT_{2A} receptors, so a 5-HT_{2A} blocker would reduce them.³³ The two compounds yield the same compound on *N*-dealkylation. It is a serotonin reuptake inhibitor.

The most common use of trazodone is not as an antidepressant. A 100-mg dose can be used as a sedative-hypnotic. Despite this use, it has been shown that nefazodone produces better sleep hygiene than does trazodone, which is a rapid eye movement (REM)-suppressing compound.

5-HT_{1A} Agonists and Partial Agonists

Buspirone

The initial compound in this series, buspirone (BuSpar), has anxiolytic and antidepressant activities and is a partial 5-HT_{1A} agonist. Its anxiolytic activity is reportedly caused by its ability to diminish 5-HT release (via 5-HT_{1A} agonism). High short-term synaptic levels of 5-HT are characteristic of anxiety. Also, because it is a partial agonist, it can stimulate postsynaptic receptors when 5-HT levels are low in the synapse, as is the case in depression. Several other spirones are in development as anxiolytics and antidepressants.³⁴

α₂ Antagonists

Mirtazapine

Mirtazapine (Remeron) was recently introduced for clinical use in the United States; its parent mianserin (pyridyl N replaced with C-H) was long known to be an antidepressant. It is reported to be faster acting and more potent than certain SSRIs. The mode of action gives increased NE release via α₂-NE receptor antagonism and increased 5-HT release via antagonism of NE α₂ heteroreceptors located on serotonergic neurons.^{33,34}

Miscellaneous Antidepressants

Bupropion

The mechanism of action of bupropion (Wellbutrin) is considered complex and reportedly involves a block of DA reuptake via the dopamine transporter (DAT), but the overall antidepressant action is noradrenergic. A metabolite that contributes to the overall action and its formation can be easily rationalized. Oxidation of one of the methyl groups on the *t*-butyl substituent yields hydroxybupropion, an active metabolite. Reduction of the keto group also occurs, yielding threohydrobupropion and erythrohydrobupropion. Both of these metabolites are also active.

Hydroxybupropion is half as potent as the parent bupropion, and the hydrobupropion isomers are five times less potent. The presence of these metabolites, especially hydroxybupropion which is formed by cytochrome P450 2D6 (CYP2D6), suggests that there will be a myriad of drug interactions with bupropion.

Duloxetine (Cymbalta)

Duloxetine (Cymbalta) is a newer antidepressant. It is largely like venlafaxine, which is an SNRI (selective norepinephrine reuptake inhibitor).

MISCELLANEOUS CNS-ACTING DRUGS

This section deals with a collection of drugs that do not fit easily under other topic headings in this chapter or the chapter on CNS depressants (Chapter 12). All of the drugs are drugs of abuse and could be organized under that heading.

The β-arylamino hallucinogens arose because of interest in the naturally occurring hallucinogens psilocin and mescaline and in modifying the amphetamines, which were popular drugs at the time. Lysergic acid diethylamide (LSD) was accidentally discovered during research on ergot alkaloids. It is of scientific interest because it serves as one model for clinical psychosis. Phencyclidine (PCP) is scientifically interesting because it gives information about the ionotropic *N*-methyl-D-aspartate glutamic acid receptor, and its CNS effects serve as a model for schizophrenia.

Cocaine as a CNS stimulant is a pernicious drug of abuse. Research on why it is so strongly addictive and on drug measures that might mitigate its effects has been intense in the past 2 decades.

Δ¹-Tetrahydrocannabinol and its relatives were studied for many years to determine the SARs. The field was given stimulus with the discovery of the endogenous cannabinoid receptors. Presently, the endogenous cannabinoid system is under investigation.

1 β -Arylamino Hallucinogens

A property of the 1 β -arylamino hallucinogens is alteration of the perception of stimuli. Reality is distorted, and the user may undergo depersonalization. Literally, the effects are those of a psychosis. Additionally, the drugs can produce anxiety, fear, panic, frank hallucinations, and additional symptoms that may be found in a psychosis. Accordingly, they are classed as hallucinogens and psychotomimetics.

This group can be subgrouped into those that possess an indolethylamine moiety, those that possess a phenylethylamine moiety, and those with both. In the first group, there is a structural resemblance to the central neurotransmitter 5-HT, and in the second, there is a structural resemblance to NE and DA. This resemblance is suggestive, and there may be some selectivity of effects on the respective transmitter systems. With structures of the complexity found in many of these agents, however, a given structure may possibly affect not just the closest structurally related neurotransmitter systems but other systems as well. Thus, a phenethylamine system could affect not only NE and DA systems but also 5-HT systems, and an indolethylamine system could affect not only 5-HT but also NE and DA systems.

INDOLETHYLAMINES

Dimethyltryptamine

Dimethyltryptamine is a very weak hallucinogen, active only by inhalation or injection, with a short duration of action. It possesses pronounced sympathomimetic (NE) side effects.

Psilocybin and Psilocin

Psilocybin is the phosphoric acid ester of psilocin and appears to be converted to psilocin as the active species in vivo. It occurs in a mushroom, *Psilocybe mexicana*. Both drugs are active orally, with a short duration of action.

Synthetic α -methyl-substituted relatives have a much longer duration of action and enhanced oral potency.³⁵ This suggests that psilocin is metabolized by MAOs.

2-PHENYLETHYLAMINES

Mescaline

Mescaline, 3,4,5-trimethoxyphenethylamine, is a much-studied hallucinogen with many complex effects on the CNS. It occurs in the peyote cactus. The oral dose required for its hallucinogenic effects is very high, as much as 500 mg of the sulfate salt. The low oral potency probably results from facile metabolism by MAO. α -Methylation increases CNS activity. Synthetic α -methyl-substituted relatives are more potent.^{35,36} The drugs 2,5-dimethoxy-4-methylamphetamine (DOM), 3,4-methylenedioxyamphetamine (MDA), and 2,5-dimethyl-dicyanoquinonediimine (DMDA; ecstasy) are extremely potent and are dangerous drugs of abuse.

Mescaline

1-(2,5-Dimethoxy-4-methylphenyl)-2-aminopropane (DOM, STP)

3,4-Methylenedioxyamphetamine (MDA)

DMDA (ecstasy)

The presence of methoxyl or dioxymethylene (methylenedioxy) substituents on a 2-phenethylamine system is a characteristic of many psychotomimetic compounds and strongly suggests DA involvement.

AN AGENT POSSESSING BOTH AN INDOLETHYLAMINE AND A PHENYLETHYLAMINE MOIETY

(+)-Lysergic Acid Diethylamide

Both an indolethylamine group and a phenylethylamine group can be seen in the structure of the extraordinarily

potent hallucinogen LSD. The stereochemistry is exceedingly important. Chirality, as shown, must be maintained or activity is lost; likewise, the location of the double bond, as shown, is required.³⁷ Experimentally, LSD has marked effects on serotonergic and dopaminergic neurons. The bases for all of its complex CNS actions are not completely understood, however. Recently, its actions have been suggested as being more typical of schizophrenic psychotic reactions than the model based on amphetamine. For more on this, see the discussion of atypical antipsychotics (Chapter 12).

Dissociative Agents

Phencyclidine

Phencyclidine was introduced as a dissociative anesthetic for animals. Its close structural relative ketamine is still so used and may be used in humans (Chapter 22). In humans, PCP produces a sense of intoxication, hallucinogenic experiences not unlike those produced by the anticholinergic hallucinogens, and often, amnesia.

The drug affects many systems, including those of NE, DA, and 5-HT. It has been proposed that PCP (and certain other psychotomimetics) produces a unique pattern of activation of ventral tegmental area dopaminergic neurons.³⁸ It blocks glutaminergic *N*-methyl-D-aspartate receptors.³⁹ This action is the basis for many of its CNS effects. PCP itself appears to be the active agent. The psychotic state produced by this drug is also cited as a better model than amphetamine psychosis for the psychotic state of schizophrenia.⁴⁰

Euphoriant-Stimulant

Cocaine

Cocaine as a euphoriant-stimulant, psychotomimetic, and drug of abuse could as well be discussed with amphetamine and methamphetamine, with which it shares many biological properties. At low doses, it produces feelings of well-being, decreased fatigue, and increased alertness. Cocaine tends to produce compulsive drug-seeking behavior, and a full-blown toxic psychosis may emerge. Many of these effects appear to be related to the effects of increased availability of DA for interaction with postsynaptic receptors (D_2 and D_3 receptors are pertinent). Cocaine is a potent DA reuptake blocker, acting by competitive inhibition of the DAT. A phenethylamine moiety

with added steric bulk may suffice for this action. An interaction between a hydrogen atom on the nitrogen of the protonated form of cocaine and an oxygen of the benzoyl ester group, or alternatively, an interaction between the unshared electron pair of the freebase nitrogen and the carbonyl of the benzoyl ester group, could approximate this moiety.

Considerable research on drugs affecting the DAT has been published in recent years. A review of pharmacotherapeutic agents for cocaine abuse is available.⁴¹

Depressant-Intoxicant

Δ^1 -Tetrahydrocannabinol or Δ^9 -THC

There are two conventions for numbering THC: that arising from terpenoid chemistry produces Δ^1 -THC and that based on the dibenzopyran system results in a Δ^9 -THC designation. The terpenoid convention is used here.

Tetrahydrocannabinoid is a depressant with apparent stimulant sensations arising from depression of higher centers. Many effects, reputedly subjectively construed as pleasant, are evident at low doses. The interested reader may consult a pharmacology text for a detailed account. At higher doses, psychotomimetic actions, including dysphoria, hallucinations, and paranoia, can be marked. Structural features associated with activity among cannabis-derived compounds have been reviewed.⁴² Notably, the phenolic OH is required for activity. Certain SARs (especially separation of potency between enantiomers) for cannabinoids suggested action at receptors.⁴³ Two receptors for THC have been discovered. The relevant receptor for CNS actions is CB_1 .⁴⁴ CB_2 occurs in immune tissues. The first natural ligand found for the receptor is the amide derivative of arachidonic acid, anandamide.⁴⁵ Other natural cannabinoids are arachidonic acid 2-glycerol ester and 2-arachidonyl glycerol ether.⁴⁶ The endogenous cannabinoid system appears to function as a retrograde messenger system at both stimulatory synapses and depressant synapses. The synaptic transmitter causes postsynaptic syntheses of endocannabinoids that are then transported to CB_1 receptors located presynaptically where they fine-tune both excitatory and inhibitory neurons.⁴⁷⁻⁵¹ Because CB_1 receptors appear to be present in all brain areas and affect both excitatory and inhibitory systems, the prospect of developing selective cannabinoid drugs acting at receptors is considered not good. Designing drugs to affect the transporter is considered the most promising research route.

Endocannabinoids, as regulated by leptin, are also involved in maintaining food intake and in other behaviors.^{52,53}

Adrenergic Agents

SHENQUAN LIU

CHAPTER OVERVIEW

Adrenergic drugs exert their principal pharmacological and therapeutic effects by either enhancing or reducing the activity of the various components of the sympathetic division of the autonomic nervous system. In general, substances that produce effects similar to stimulation of sympathetic nervous activity are known as *sympathomimetics* or *adrenergic stimulants*. Those that decrease sympathetic activity are referred to as *sympatholytics*, *antiadrenergics*, or *adrenergic-blocking agents*.

Adrenergic agents act on adrenergic receptors (adrenoceptors, ARs) or affect the life cycle of adrenergic neurotransmitters (NTs), including norepinephrine (NE, noradrenaline), epinephrine (E, adrenaline), and dopamine (DA). These NTs modulate many vital functions, such as the rate and force of cardiac contraction, constriction, and dilation of blood vessels and bronchioles, the release of insulin, and the breakdown of fat. Therefore, adrenergic drugs constitute a broad class of agents, including albuterol (a bronchodilator), atenolol (an antihypertensive), and many common over-the-counter (OTC) cold remedies (Table 16.1). This chapter examines the biochemical basis for adrenergic action, adrenoceptors and then discusses the agents that affect the synthesis, storage, uptake, metabolism, or release of the adrenergic NTs and especially those that act directly on the various types of adrenoceptors.

ADRENERGIC NEUROTRANSMITTERS

Structure and Physicochemical Properties

NE, E, and DA are chemically catecholamines (CAs), which refer generally to all organic compounds that contain a catechol nucleus (ortho-dihydroxybenzene) and an ethylamine group (Fig. 16.1). In a physiological context, the term usually means DA and its metabolites NE and E. E contains one secondary amino group and three hydroxyl groups. Using the polyfunctional solubilizing potential and calculated log P (-0.63) of E, one would expect the molecule is polar and soluble in water, and, indeed, this turns out to be the case.

E is a weak base ($pK_a = 9.9$) because of its aliphatic amino group. It is also a weak acid ($pK_a = 8.7$) because of its phenolic hydroxyl group. It can be predicted that ionized species (the cation form) of E at physiological pH is predominant ($\log D$ at pH 7 = -2.75). This largely accounts for the high water solubility of this compound as well as other CAs. Because log P with a value of 0 to 3 is an optimal window

for absorption, we can predict that E has poor absorption and poor central nervous system (CNS) penetration.

Like most phenols, the catechol functional groups in CAs are highly susceptible to facile oxidation. E and NE undergo oxidation in the presence of oxygen (air) or other oxidizing agents to produce a quinone analog, which undergoes further reactions to give mixtures of colored products, one of which is adrenochrome (Fig. 16.2). Hence, solutions of these drugs often are stabilized by the addition of an antioxidant (reducing agent) such as ascorbic acid or sodium bisulfite.

E and NE each possess a chiral carbon atom; thus, each can exist as an enantiomeric pair of isomers. The enantiomer with the (*R*) configuration is biosynthesized by the body and possesses the biological activity. This (*R*) configuration of many other adrenergic agents also contributes to their high affinity to the corresponding adrenoceptors.

Biosynthesis

The CA biosynthesis and physiological regulation in neuroendocrine cells has been reviewed.¹ A summary view of the events and life cycle of NE are given in Figure 16.3.

CAs in neuroendocrine cells are in a state of constant flux. They are continuously being synthesized, released, and metabolized, yet they maintain a remarkable constant level in tissues. CAs are widely distributed in mammals, and their levels and physiological functions are regulated at many sites. The biosynthesis involves a sequence of enzymatic reactions.² The steps in the biosynthesis of CAs and related enzyme inhibitors are shown in Figure 16.4.

The first step in CA biosynthesis is the 3'-hydroxylation of the amino acid L-tyrosine to form L-dihydroxyphenylalanine (L-DOPA). L-Tyrosine is normally present in the circulation and transported actively into the adrenergic neuron, where it is 3'-hydroxylated by tyrosine hydroxylase (TH, tyrosine-3-monooxygenase). TH is stereospecific and requires molecular O_2 , Fe^{2+} , and a tetrahydropteridine cofactor. As usual for the first enzyme in a biosynthetic pathway, TH hydroxylation is the rate-limiting step in the biosynthesis of NE. Further proof that this step is rate limiting in CA biosynthesis is that inhibitors of TH markedly reduce endogenous NE and DA in the brain and NE in the heart, spleen, and other sympathetically innervated tissues. This enzyme plays a key role in the regulation of CA biosynthesis and is, therefore, the logical biological target of some drugs.

Some effective TH inhibitors include α -methyl-*p*-tyrosine, α -methyl-3'-iodotyrosine, and α -methyl-5-hydroxytryptophan. In general, α -methyl analogs are more potent than the unmethylated analogs. Most of the agents in this category act

(text continues on page 522)

TABLE 16.1 Most Commonly Used Adrenergic Prescription Drugs

Mechanism of Action	Drug	Major Indications
α_1 -Agonists	Naphazoline (Privine)	Nasal & ophthalmic congestion
α_2 -Agonists	Clonidine (Catapres)*	Hypertension
	Methyldopa (Aldomet)	Hypertension
α_1 -Blockers	Prazosin (Minipress)	Hypertension & benign prostatic hyperplasia (BPH)
	Terazosin (Hytrin)*	Hypertension & BPH
	Doxazosin (Cardura)*	Hypertension & BPH
	Tamsulosin (Flomax)	BPH & hypertension
β_2 -Agonists	Albuterol (Ventolin)*	Asthma
α_1 -, β_1 -, & β_2 -Blockers	Labetalol (Normodyne)*	Hypertension
	Carvedilol (Coreg)	Hypertension & heart failure
β_1 - & β_2 -Blockers	Propranolol (Inderal)*	Hypertension, arrhythmias, & angina
	Nadolol (Corgard)*	Hypertension, angina, & hyperthyroidism
	Timolol (Timoptic)*	Glaucoma & hypertension
	Sotalol (Betapace)*	Arrhythmias
	Levobunolol (Betagan)	Glaucoma
β_1 -Blockers	Acebutolol (Sectral)	Hypertension, angina, & hyperthyroidism
	Atenolol (Tenormin)*	Hypertension, angina, & hyperthyroidism
	Metoprolol (Lopressor)*	Hypertension
	Bisoprolol (Zebeta)*	Hypertension

as competitive inhibitors of TH. α -Methyl-*p*-tyrosine (metyrosine, Demser, Fig. 16.4) and its methyl ester have been the TH inhibitors most widely used to demonstrate the effects of exercise, stress, and various drugs on the turnover of CAs and to lower NE formation in patients with pheochromocytoma and malignant hypertension.

TH is a specific phenotypic marker of CA-producing cells in the CNS and peripheral nervous system (PNS). The activity of TH is carefully controlled. For example, adrenergic nerve stimulation leads to activation of a protein kinase that phosphorylates TH, thereby increasing its activity.³ In addition, through end-product inhibition, NE markedly reduces TH activity. The basis of this feedback inhibition is believed to be a competition between the CA product and the pterin cofactor.

The second step in CA biosynthesis is the decarboxylation of L-DOPA to give DA, which is an important NT and a drug in its own right discussed in Chapter 13. The enzyme involved is DOPA decarboxylase. Although originally believed to remove carboxyl groups only from L-DOPA, a study of purified enzyme preparations and specific inhibitors demonstrated that DOPA decarboxylase acts on all naturally occurring aromatic L-amino acids, including L-histidine (precursor in the biosynthesis of histamine), L-tyrosine, L-tryptophan (precursor in the biosynthesis of 5-HT), and L-phenylalanine in addition to both L-DOPA and L-5-hydroxytryptophan. Therefore, this enzyme is more appropriately referred to as *L-aromatic amino acid decarboxylase* (AADC). In addition to being found in catecholaminergic neurons, AADC is found in high concentrations in many other tissues, including the liver and kidneys.

In simplest term, parkinsonism can be characterized as a DA deficiency in the brain. Thus, increasing brain levels of DA should ameliorate the symptoms. Unfortunately, direct parenteral DA administration is useless because the compound does not penetrate the blood-brain barrier (BBB). However, oral dosing with L-DOPA (levodopa, Dopar) could act as a prodrug because it entered the brain (on a specific carrier) and then was decarboxylated to DA there. L-DOPA is effective and decrease tremor and rigidity. Unfortunately, many adverse systemic effects were the result of the high doses needed to achieve the desired results. The main reason is the relatively higher concentration of AADC in peripheral system than in the brain. Inhibition of peripheral AADC activity by coadministration of at peripheral decarboxylase inhibitor such as carbidopa (charged at physiological pH), can markedly increase the proportion of levodopa that crosses the BBB. (see Chapter 13).

The third step in CA biosynthesis is side-chain β -hydroxylation of DA to give NE. DA formed in the cytoplasm of the neuron is actively transported into storage vesicles by a 12-helix membrane-spanning proton antiporter called the vesicular monoamine transporter (VMAT) and is then hydroxylated stereospecifically at the β -carbon to NE inside the vesicle by dopamine β -hydroxylase (DBH, dopamine β -monooxygenase). The NE formed is stored in the vesicles until depolarization of the neuron initiates the process of vesicle fusion with the plasma membrane and extrusion of NE into the synaptic cleft. DBH has rather low substrate specificity and acts in vitro on various substrates besides DA, hydroxylating almost any phenylethylamine to its corresponding phenylethanolamine (e.g., tyramine to octopamine, α -methyldopamine to α -methylnorepinephrine).

A number of the resultant structurally analogous metabolites can replace NE at the noradrenergic nerve endings and function as "false" NTs.

The last step in CA biosynthesis is the *N*-methylation of NE to give E in the adrenal medulla. The reaction is catalyzed by the enzyme phenylethanolamine-*N*-methyltransferase (PNMT). PNMT is a cytosolic enzyme and the methyl donor *S*-adenosyl methionine (SAM) is required for the *N*-methylation of NE. The adrenal medullary enzyme has rather low substrate specificity and transfers methyl groups to the nitrogen atom on various β -phenylethanolamines. The reaction occurs in the cell cytoplasm, and the E formed is transported into the storage granules of the chromaffin cells. Although PNMT is mostly found in the adrenal medulla, low levels of activity exist in heart and mammalian brain. Regulation of this enzyme in the brain has not been extensively studied, but glucocorticoids are known to regulate the activity of PNMT in the adrenal gland.

Storage, Release, Uptake, and Metabolism

Storage and Release. A large percentage of the NE present is located within highly specialized subcellular particles (later shown to be synaptic vesicles but colloquially referred to as *granules*) in sympathetic nerve endings and chromaffin cells. Much of the NE in CNS is also located within similar vesicles. The concentration in the vesicles is maintained also by the VMAT.

Following its biosynthesis and storage in granules, the entrance of Ca^{2+} into these cells results in the extrusion of NE by exocytosis of the granules. Ca^{2+} -triggered secretion involves interaction of highly conserved molecular scaffolding proteins leading to docking of granules at the plasma membrane and then NE is released from sympathetic nerve endings into the synaptic cleft, where it interacts with specific presynaptic and postsynaptic adrenoceptors, on the effector cell, triggering a biochemical cascade that results in a physiologic response by the effector cell. Indirectly acting and mixed sympathomimetics (e.g., tyramine, amphetamines, and ephedrine) are capable of releasing stored transmitter from noradrenergic nerve endings by a calcium-independent process. These drugs are poor agonists (some are inactive) at adrenoceptors, but they are excellent substrates for VMAT. They are avidly taken up into noradrenergic nerve endings by NE reuptake transporter (NET) responsible for NE reuptake into the nerve terminal. In the nerve ending, they are then transported by VMAT into the vesicles, displacing NE, which is subsequently expelled into the synaptic space by reverse transport via NET. Their action does not require vesicle exocytosis.

Uptake. Once NE has exerted its effect at adrenergic receptors, there must be mechanisms for removing the NE from the synapse and terminating its action at the receptors. These mechanisms include (a) reuptake of NE into the presynaptic neuron (recycling, major mechanism) by NET and into extraneuronal tissues, (b) conversion of NE to an inactive metabolite, and (c) diffusion of the NE away from the synapse. The first two of these mechanisms require specific transport proteins or enzymes, and therefore are targets for pharmacologic intervention. By far, the most important of these mechanisms is recycling the NE. This process is termed *uptake-1* and involves a Na^+/Cl^- -dependent

transmembrane (TM) NET that has a high affinity for NE.⁴ This reuptake system also transports certain amines other than NE into the nerve terminal, and can be blocked by such drugs as cocaine and some of the tricyclic antidepressants (see Chapter 15). Similar transporters, dopamine transporter (DAT) and serotonin transporter (SERT) are responsible for the reuptake of DA and 5-HT (serotonin), respectively, into the neurons that release these transmitters. Some of the NE that reenters the sympathetic neuron is transported from the cytoplasm into the storage granules carried out by an H⁺-dependent TM VMAT.⁵ There, it is held in a stable complex with adenosine triphosphate (ATP) and proteins until sympathetic nerve activity or some other stimulus causes it to be released into the synaptic cleft. Certain drugs, such as reserpine, block this transport, preventing the refilling of synaptic vesicles with NE and eventually cause nerve terminals to become depleted of their NE stores. By this mechanism, reserpine inhibits neurotransmission at adrenergic synapses.

In addition to the neuronal uptake of NE, there exists an extraneuronal uptake process, called *uptake-2* with relatively low affinity for NE. Although its physiological significance is unknown, it may play a role in the disposition of circulating CAs, because CAs that are taken up into extraneuronal tissues are metabolized quite rapidly.

Metabolism. The second mechanism of CA removal is metabolism. The major mammalian enzymes of importance in the CA metabolism are monoamine oxidase (MAO) and catechol-*O*-methyltransferase (COMT).^{6,7} The comparison of the two enzymes is shown in Table 16.2.

Both E and NE are orally inactive and have short durations of action because of their high hydrophilicity, ionization, and extensive first-pass metabolic deactivation by COMT and MAO. The lack of substrate specificity of COMT and MAO is manifested in the metabolism of NE and E, shown in Figure 16.5. Not only do both MAO and COMT use NE and E as substrates, but each also acts on the metabolites produced by the other. Drugs that are catechols are subject to metabolism by COMT, whereas drugs with unsubstituted or secondary *N*-methyl-amino amino groups are often substrates for MAO.

The first enzyme of importance in the metabolism of CAs in the adrenergic neurons of human brain and peripheral tissues is MAO. MAOs oxidatively deaminate CAs to their corresponding aldehydes, which are rapidly oxidized to the corresponding acid by the enzyme aldehyde dehydrogenase (AD). In some circumstances, the aldehyde is reduced to the glycol by aldehyde reductase (AR). For

example, NE is deaminated oxidatively by MAO to give 3',4'-dihydroxyphenylglycolaldehyde (DOPGA), which then is reduced by AR to 3',4'-dihydroxyphenylethylene glycol. It is primarily this glycol metabolite that is released into the circulation, where it undergoes methylation by the COMT that it encounters in nonneuronal tissues. The product of methylation, 3'-methoxy-4'-hydroxyphenylethylene glycol, is oxidized by alcohol dehydrogenase and AD to give 3'-methoxy-4'-hydroxymandelic acid. This metabolite commonly is referred to as *vanillylmandelic acid* (VMA), and is the major end product of several pathways of NE metabolism. An estimate of CA turnover can be obtained from laboratory analysis of total metabolites (sometimes referred to as *VMA and metanephrines*) in 24-hour urine sample. In the oxidative deamination of NE and E at extraneuronal sites such as the liver, the aldehyde formed is oxidized usually by AD to give 3,4-dihydroxymandelic acid (DOMA). MAO inhibitors (MAOIs) prevent MAO-catalyzed deamination of NE, DA, and 5-HT following their reuptake into the nerve terminal from the synaptic cleft. As a result, higher concentration of the NTs will be stored in the vesicles and become available for release from the presynaptic terminals on demand. Antidepressants such as phenelzine (Nardil), isocarboxazid (Marplan), and tranylcypromine (Parnate) are MAOIs.

There are two types of MAOs, and these exhibit different substrate selectivity.⁸ MAO-B primarily metabolizes DA and thus MAO-B inhibitors would tend to preserve brain DA and be effective by themselves and/or potentiate levodopa. Selegiline (Eldepryl) is a specific type MAO-B inhibitor and does extend the duration and increase the efficacy of levodopa. The drug is promising, probably as an adjunct to levodopa or in levodopa refractory patients.

The understanding of CAs metabolism can be important in the management of certain drug therapies and may even aid in diagnosis. For example, changes resulting from drugs may indicate the success of a treatment. The cerebrospinal fluid (CSF) levels of methylhydroxyphenylglycolaldehyde (MOPEG) are indicative of NE levels. Just as they can be related to the intensity of depression, the degree of improvement expected with antidepressants can be monitored in the weeks it may take before the clinical symptoms improve. A CSF level of homovanillic acid (HVA, the major metabolite of brain DA, which is a counterpart of end metabolite of NE) is understandably low in parkinsonism.

The second enzyme of importance in the metabolism of CAs is COMT that *O*-methylates 3'-OH group of CAs and renders them inactive. Methylation by COMT occurs almost

TABLE 16.2 Comparison of MAO and COMT

	MAO	COMT

Figure 16.5 • Metabolism of norepinephrine and epinephrine by MAO and COMT.

exclusively on the *meta*-OH group of the catechol, regardless of whether the catechol is NE, E, or one of the metabolic products. For example, the action of COMT on NE and E gives normetanephrine and metanephrine, respectively. A converging pattern of the metabolism of NE and E in which 3'-methoxy-4'-hydroxymandelic acid (VMA) and 3'-methoxy-4'-hydroxyphenylethylene glycol are common end products thus occurs, regardless of whether the first metabolic step is oxidation by MAO or *O*-methylation by COMT. In patients with tumors of chromaffin tissue that secrete these amines (a rare cause of high blood pressure), the urinary excretion of VMA is markedly increased and is used as a diagnostic test for this condition.

Under normal circumstances, VMA is the principal urinary metabolite of NE, although substantial amounts of 3'-methoxy-4'-hydroxyphenylethylene glycol are excreted along with varying quantities of other metabolites, both in the free form and as sulfate or glucuronide conjugates (not shown in the schemes). Endogenous E is excreted primarily as metanephrine and VMA. These pathways of metabolism are also important to drugs that are structural analogs of NE. Tolcapone (Tasmar) and entacapone (Comtan) are COMT inhibitors presently available.

CAs released from either noradrenergic nerve terminals or the adrenal medulla are recognized by and bind to specific receptor molecules on the plasma membrane of the neuroeffector cells. These receptor ligand interactions produce a physiological response. Many cells possess these

receptors, and the binding of an agonist will generally cause the organism to respond in a fight-or-flight manner. For instance, the heart rate will increase and the pupils will dilate, energy will be mobilized, and blood flow will be diverted from other organs to skeletal muscle.

ADRENERGIC RECEPTORS

Adrenergic Receptor Subtypes

Membrane receptors transfer information from the environment to the cell's interior. A few nonpolar signal molecules such as estrogens and other steroid hormones are able to diffuse through the cell membranes and, hence, enter the cell. However, most signaling molecules such as CAs are too polar to pass through the membrane, and no appropriate transport systems are available. Thus, the information that they present must be transmitted across the cell membrane without the molecules themselves entering the cell. A membrane-associated receptor protein such as adrenergic receptors often performs the function of information transfer across the membrane.

In 1948, Ahlquist⁹ proposed and designated α - and β -adrenoceptors based on their apparent drug sensitivity. The diverse physiological responses of CAs are mediated via α_1 -, α_2 -, and β -adrenoceptors, which are further divided into α_{1A} , α_{1B} , α_{1D} , α_{2A} , α_{2B} , α_{2C} , β_1 , β_2 , and β_3 . They all belong

TABLE 16.3 Distribution and Effects of Adrenoceptors and Main Uses of the Adrenergic Drugs

Organ or Tissue	Predominant Adrenoceptors	Effect of Activation	Physiological Effect	Drugs	Therapeutic Uses
Blood vessels and skin	α_1	Vasoconstriction	↑ Blood pressure	α_1 -Agonists	Shock, hypotension
Mucous membranes	α_1	Vasoconstriction		α_1 -Agonists	Nasal congestion
Prostatic gland muscle	α_{1A}	Contraction	Prostatic hyperplasia	α_1 -Antagonists	Hypertension
CNS	α_2	↓ NE release	↓ Blood pressure	α_{1A} -Antagonists	BPH
Heart muscle	β_1 (minor β_2, β_3)	Muscle contraction	↑ Heart rate & force	α_2 -Agonists	Hypertension
Bronchial smooth muscle	α_1	Smooth muscle contraction	Closes airways	β_1 -Antagonists	Arrhythmias
	β_2 (Bronchodilation)	Smooth muscle relaxation	Dilates & opens airways	β_2 -Agonists	Asthma and COPD

	β_2	Smooth muscle relaxation	(-) Uterine contractions		
Kidney	β_1	Increases rennin secretion	↑ Blood pressure		

to the superfamily of guanine nucleotide (G)-regulatory proteins (G-protein)-coupled receptors (GPCR), which have seven-transmembrane (7TM) helical regions. Elucidation of the characteristics of these receptors and the biochemical and physiological pathways they regulate has increased our understanding of the seemingly contradictory and variable effects of CAs on various organ systems. Although structurally related, different receptors regulate distinct physiological process by controlling the synthesis or release of various second messengers. An important factor in the response of any cell or organ to adrenergic drugs is the density and proportion of α - and β -adrenoceptors. For example, NE has relatively little capacity to increase bronchial airflow, because the receptors in bronchial smooth muscle are largely of the β_2 -subtype. In contrast, isoproterenol (ISO) and E are potent bronchodilators.

The various adrenoceptor types and subtypes are not uniformly distributed with certain tissues containing more of one type than another. Table 16.3 describes various tissues they predominate, types of adrenoceptors, the result of activating these receptors, and the principal therapeutic uses of adrenergic agonists and antagonists. The clinical use of receptors-selective drugs becomes obvious when one considers the adrenoceptor subtypes and their locations.

α_1 -Agonists as Vasoconstrictors and Nasal Decongestants. In blood vessels, the principal effect is vasoconstriction. Blood vessels with α_1 -receptors are present in skin and during the fight-or-flight response, vasoconstriction results in the decreased blood flow to this organ. This accounts for an individual's skin appearing pale when frightened. Agonists acting selectively on α_1 -receptors cause vasoconstriction and thus can be used alongside local anesthetics in dentistry to localize and prolong the effect on the anesthetic at the site of injection. They are also used as nasal decongestants (vasoconstriction of mucous membranes) and for raising blood pressure (vasoconstriction of blood vessels) in shock.

α_1 -Antagonists for Treatment of Hypertension. Because α_1 -agonists are vasoconstrictor and hypertensive, α_1 -antagonists would be expected to be vasodilators and

hypotensive with clear implications of treating hypertension. Similarly, they should block α_{1A} -receptor in prostate smooth muscle and relax the muscle with implication of treating benign prostatic hyperplasia (BPH).

α_2 -Agonists for Treatment of Hypertension. α_2 -Agonists (e.g., clonidine) act at CNS sites to decrease sympathetic outflow to the periphery, resulting in decreased NE release at sympathetic nerve terminal and, therefore, relaxed vascular smooth muscle.

β_1 -Blockers for Treatment of Hypertension, Angina, and Certain Cardiac Arrhythmias. Activation of the β_1 -receptors in heart causes an increase in rate and force of contraction and β_1 -blockers should be expected to slow the heart rate and decrease the force of contraction. They are used in treating hypertension, angina, and certain cardiac arrhythmias.

β_2 -Agonists for Treatment of Asthma and Premature Labor. A major clinical use for adrenergic agonists is in treatment of asthma. Activation of β_2 -receptors relaxes the smooth muscles in the bronchi, thus dilating and opening airways. Similarly, activation of β_2 -receptors in the uterus relaxes the muscle, and some β_2 -agonists are thus used to inhibit uterine contractions.

α -Adrenergic Receptors

The subtypes of adrenoceptor and their effector systems are summarized in Table 16.4. In the early 1970s, the discovery that certain adrenergic agonists and antagonists exhibited various degrees of selectivity for presynaptic and postsynaptic α -receptors led to the proposal that postsynaptic α -receptors be designated α_1 and that presynaptic α -receptors be referred to as α_2 .¹⁰ Later, a functional classification of the α -receptors was proposed wherein α_1 -receptors were designated as those that were excitatory, while α_2 -receptors purportedly mediated inhibitory responses.¹¹ Further developments revealed, however, that both α_1 - and α_2 -receptors could be either presynaptic or postsynaptic and either excitatory or inhibitory in their responses. However, the physiologic significance of postsynaptic α_2 -receptors is less well understood.¹²

TABLE 16.4 Subtypes of Adrenoceptors and Their Effector Systems

Receptor	Agonists	Antagonists	G Protein	Main Biochemical Effectors
α_1	E \geq NE \gg ISO Phenylephrine Methoxamine	Prazosin Corynanthine	G _q	(+) PLC \rightarrow \uparrow IP ₃ & DAG \uparrow Ca ²⁺
α_2	E \geq NE \gg ISO Clonidine	Yohimbine	G _i G _i ($\beta\gamma$ subunits)	(-) AC \rightarrow \downarrow cAMP \uparrow K ⁺ channels

β_2	ISO > E > NE Terbutaline	Butoxamine	G _s	(+) AC \rightarrow \uparrow cAMP

G_s, the s in subscript indicates the subunit's stimulatory role; G_i, the i in subscript indicates the subunit's inhibitory role; G_q, the q in subscript indicates the protein coupling receptors to phospholipase C.

Pharmacological and molecular biological methods have shown that it is possible to subdivide the α_1 - and α_2 -receptors into additional subtypes. The α_1 - and α_2 -receptors each have been divided into at least three subtypes, which have been designated α_{1A} , α_{1B} , α_{1D} and α_{2A} , α_{2B} , α_{2C} , respectively.^{13–15}

Both receptor subtypes belong to a superfamily of membrane receptors whose general structure consists of 7TM α -helical segments. The interaction of adrenergic drugs and the receptors alters the tertiary or quaternary structure of the receptor, including the intracellular domain. These structural changes are not sufficient to yield an appropriate response, because they are restricted to a small number of receptor molecules in the cell membrane. The information embodied by CAs or drugs, which act as primary messengers, must be transduced into downstream activity that can alter the biochemistry of the cell. The signal-transduction mechanisms involve coupling to G proteins. Each G protein is a heterotrimer consisting of α -, β -, and γ -subunit and is classified based on their distinctive α subunits. G proteins of particular importance for adrenoceptor function include G_s, the stimulatory G protein of adenylyl cyclase (AC); G_i, the inhibitory G protein of AC; and G_q, the protein coupling receptors to phospholipase C (PLC).

The α - and β -receptors differ from each other in their structures, functions, and in the second-messenger system that is affected.^{16,17} Stimulation of α_1 -receptors results in the regulation of multiple effector systems. A primary mode of signal transduction involves (a) activation of the G_q-PLC-IP₃-Ca²⁺ pathway and (b) the activation of other Ca²⁺ and calmodulin-sensitive pathway such as CaM kinases. The α_1 -receptor subtype is coupled to the enzyme PLC via a G_q. When stimulated by activation of the α_1 -receptor, PLC hydrolyzes phosphatidylinositol-4,5-bisphosphate (PIP₂) to give the second messengers inositol-1,4,5-triphosphate (IP₃) and 1,2-diacylglycerol (DAG). In smooth muscle, IP₃ stimulates the release of Ca²⁺ from the sarcoplasmic reticulum, resulting in an increase in free intracellular calcium levels. Increased free intracellular calcium is correlated with smooth muscle contraction, whereas DAG activates protein kinase C (PKC), which phosphorylates proteins, and may induce slowly developing contractions of vascular smooth muscle (Fig. 16.6).

Vasoconstriction is commonly initiated by the opening of voltage-gated L-type Ca²⁺ channels in the sarcolemma during plasma membrane depolarization, which mediates Ca²⁺ flux into the cytoplasm. Ca²⁺ entry into the cell

activates calmodulin (CaM). The Ca²⁺-CaM complex activates myosin light chain kinase (MLCK) to phosphorylate myosin light chain (myosin-LC). The phosphorylated myosin-LC interacts with actin to form actin-myosin cross-bridges, a process that initiates vascular smooth muscle cell contraction. The vascular constriction thus causes an increase in blood pressure. In contrast, relaxation is a coordinated series of steps that act to dephosphorylate and hence inactivate myosin-LC.

Activation of α_2 -receptors leads to a reduction in the catalytic activity of AC, which in turn results in a lowering of intracellular levels of cyclic adenosine monophosphate (cAMP) (Fig. 16.7). The α_2 -receptor-mediated inhibition of AC is regulated by the G_i.

α -Receptors of the CNS and in peripheral tissues perform a number of important physiological functions.¹⁶ In particular, α -receptors are involved in control of the cardiovascular system. For example, constriction of vascular smooth muscle is mediated by both postjunctional α_1 - and α_2 -receptors, though the predominant receptor mediating this effect is α_1 .¹⁸ In the heart, activation of α_1 -receptors results in a selective inotropic response with little or no change in heart rate.¹⁹ This is in contrast to the β_1 -receptor, which is the predominant postjunctional receptor in the heart, mediating both inotropic and chronotropic effects. In the brain, activation of postjunctional α_2 -receptors reduces sympathetic outflow from the CNS, which in turn causes a lowering of blood pressure.²⁰ The prototypical α_2 -receptor is the presynaptic α -receptor found on the terminal sympathetic neuron.^{10,11,21} Interaction of this receptor with agonists such as NE and E results in inhibition of NE release from the neuron. The α_2 -receptors not only play a role in the regulation of NE release but also regulate the release of other NTs, such as acetylcholine and serotonin. Both α_1 - and α_2 -receptors also play an important role in the regulation of several metabolic processes, such as insulin secretion and glycogenolysis.²²

β -Adrenergic Receptors

Three β -receptor subtypes have been cloned, including β_1 , β_2 , and β_3 . In 1967, Lands et al.²³ suggested that β -receptors could be subdivided into β_1 and β_2 types. Seventeen years later, Arch et al.²⁴ identified a third subtype of β -receptor in brown adipose tissue designated as the β_3 subtype.¹³ All clinically relevant α_1 -, β_1 -, β_2 -, and β_3 -receptors are postsynaptic

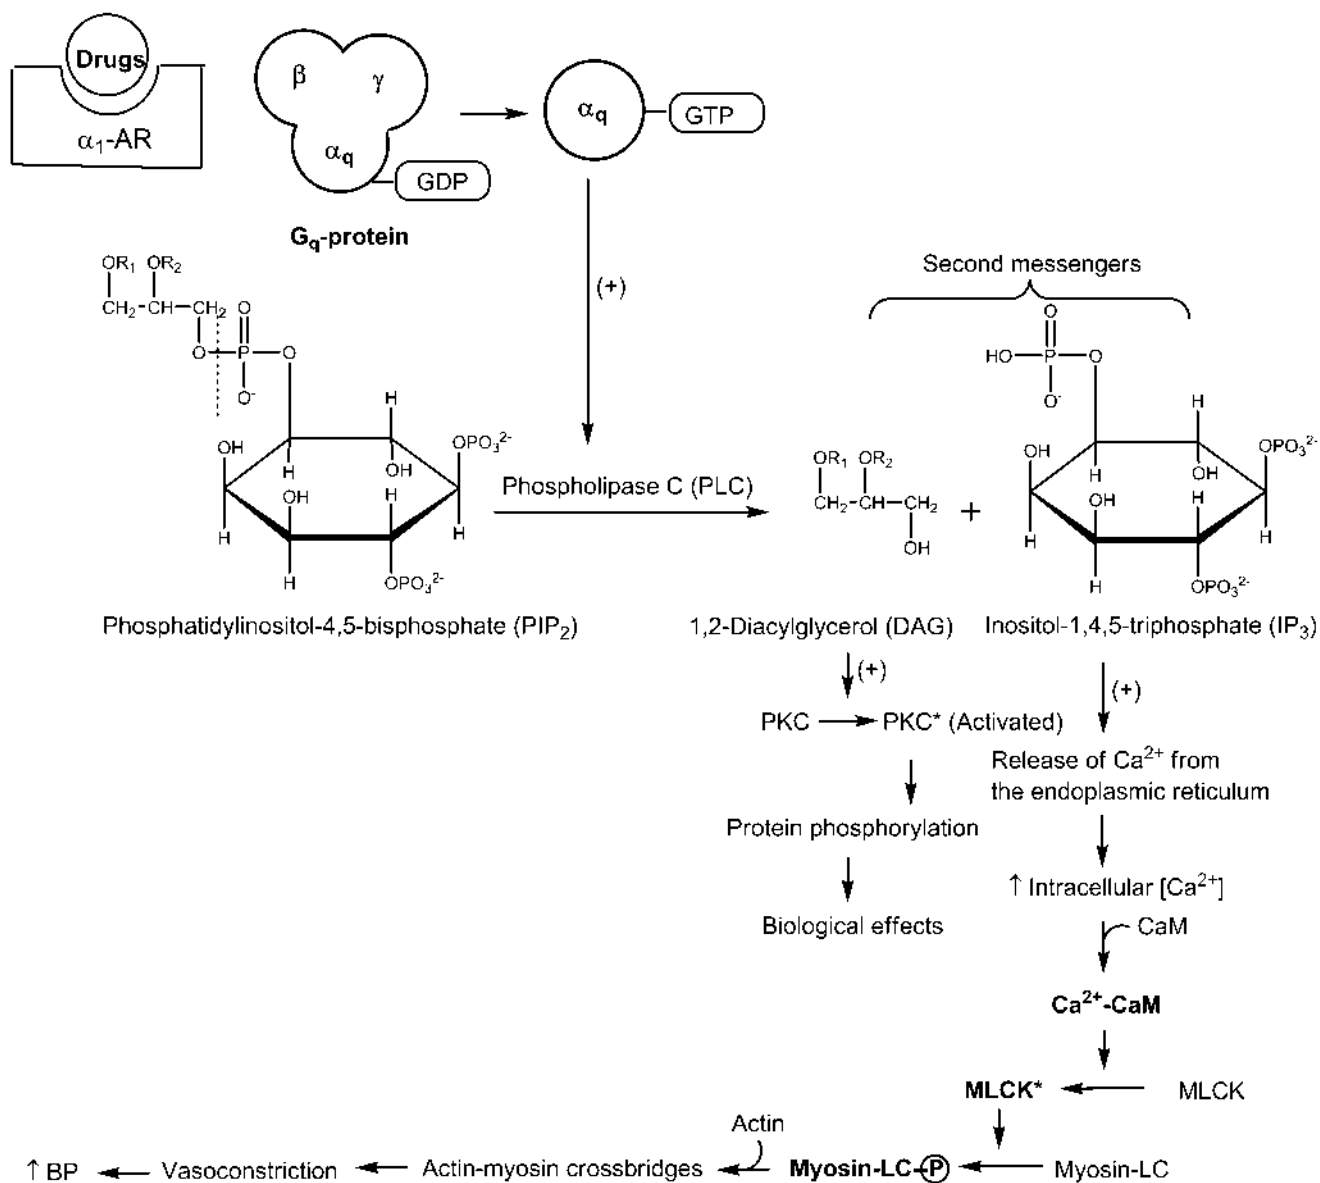

Figure 16.6 • Mechanism of α_1 -receptor-mediated signal transduction.

receptors that are linked to stimulation of biochemical processes in the postsynaptic cell. The function of presynaptic β -receptors is, however, unclear. The β -adrenoceptor subtypes also differ in terms of the rank order of potency of the adrenergic receptor agonists NE, E, and ISO (Table 16.4).

The use of β_2 -agonists as bronchodilators and β_1 - or β_1/β_2 -blockers as antihypertensives is well established. The β_1 -receptors are located mainly in the heart, where they mediate the positive inotropic and chronotropic effects of the CAs. They are also found on the juxtaglomerular cells of the kidney, where they are involved in increasing renin secretion. The β_2 -receptors are located on smooth muscle throughout the body, where they are involved in relaxation of the smooth muscle, producing such effects as bronchodilation and vasodilation. They are also found in the liver, where they promote glycogenolysis. The β_3 -receptor is located on brown adipose tissue and is involved in the stimulation of lipolysis.

All three β -receptors are coupled to AC, which catalyzes the conversion of ATP to cAMP (Fig. 16.7). This coupling

is via the G-protein G_s .^{25,26} In the absence of an agonist, guanosine diphosphate (GDP) is bound reversibly to the G_s protein. Interaction of the agonist with the receptor causes a conformational change in the receptor, which decreases the affinity of the G_s protein for GDP and a concomitantly increases the affinity for guanosine triphosphate (GTP). The α_s -subunit of G_s -protein complex dissociates from the receptor-G protein tertiary complex and then binds to and activates AC.

The intracellular function of the second-messenger cAMP is activation of protein kinases, which phosphorylate specific proteins, thereby altering their function.²⁷ The action of cAMP is terminated by a class of enzymes known as phosphodiesterase (PDE) that catalyzes the hydrolysis of cAMP to AMP (Fig. 16.7) and is related to the mechanism of action of caffeine and theophylline.

Cloning of the gene and complementary DNA (cDNA) for the mammalian β -receptor has made it possible to explore the structure-function relationships of the receptor.²⁸ Through such studies of single point mutations, it has

Figure 16.7 • Mechanism of β_2 -receptor-mediated signal transduction.

been proposed that the adrenergic agonist-binding site is within the TM-spanning regions, whereas the cytoplasmic regions of the receptor interact with the G_s protein. Specifically, aspartic acid residue 113 in transmembrane region III (TM-III) acts as the counterion to the cationic amino group of the adrenergic agonist. This aspartic acid residue is found not only in a comparable position in all the other adrenoceptors but also in other known GPCRs that bind substrates having positively charged nitrogens in their structure. Two serine residues, at positions 204 and 207 in TM-V, form H-bonds with the catechol OH groups of the adrenergic agonists. The β -OH group of adrenergic agonists is thought to form an H-bond with the side chain of asparagine 293 in TM-VI, whereas the phenylalanine residue at position 290 in the same TM-VI is believed to interact with the catechol ring (Fig. 16.8). Because the serine is in the fifth membrane-spanning region and the aspartic acid is in the third, it is likely that CAs bind parallel to the plane of the membrane, forming a bridge between the two TM-spanning regions.

Molecular biological techniques have shown the existence of adrenergic receptor polymorphism for both the α - and β -receptors. It is postulated that such polymorphisms may be an important factor behind individual differences in responses to drugs acting at these receptors. In addition, there

may be an association between the polymorphisms of adrenergic receptor genes and disease states.²⁹

DRUGS AFFECTING ADRENERGIC NEUROTRANSMISSION

Drugs Affecting Catecholamine Biosynthesis

Metyrosine (α -Methyl-L-tyrosine, Demser). Although inhibition of any of the three enzymes involved in CA biosynthesis should decrease CAs, inhibitors of the first and the rate-limiting enzyme TH would be the most effective. As such, metyrosine is a much more effective competitive inhibitor of E and NE production than agents that inhibit any of the other enzymes involved in CA biosynthesis. It is often possible to “fool” the enzymes into accepting a structurally similar and unnatural substrate such as metyrosine. Metyrosine differs structurally from tyrosine only in the presence of an α -methyl group (Fig. 16.9). It is one example of a CA-biosynthesis inhibitor in clinical use.³⁰ Although metyrosine is used as a racemic mixture, it is the (–) isomer that possesses the inhibitory activity. Metyrosine, which is given orally in dosages ranging from

Figure 16.8 • Model of β_2 -AR binding sites: Illustration of the Easson-Stedman hypothesis representing the interaction of three critical pharmacophoric groups of norepinephrine with the complementary binding areas on the adrenergic receptor as suggested by site-directed mutagenesis studies.

Figure 16.9 • Mechanism of action of metyrosine.

Figure 16.10 • Metabolic activation of α -methyl-*m*-tyrosine to metaraminol.

1 to 4 g/day, is used principally for the preoperative management of pheochromocytoma, chromaffin cell tumors that produce large amounts of NE and E. Although these adrenal medullary tumors are often benign, patients frequently suffer hypertensive episodes. Metyrosine reduces the frequency and severity of these episodes by significantly lowering CA production (35%–80%). The drug is polar ($\log P = 0.73$) and excreted mainly unchanged in the urine. Because of its limited solubility in water caused by intramolecular bonding of the zwitterions, crystalluria is a potential serious side effect. It can be minimized by maintaining a daily urine volume of more than 2 L. Inhibitors of CA synthesis have limited clinical utility because such agents nonspecifically inhibit the formation of all CAs and result in many side effects. Sedation is the most common side effect of this drug.

A similar example is the use of α -methyl-*m*-tyrosine in the treatment of shock. It differs structurally from metyrosine only in the presence of *m*-OH instead of *p*-OH in metyrosine. This unnatural amino acid is accepted by the enzymes of the biosynthetic pathway and converted to metaraminol (an α -agonist) as shown (Fig. 16.10).

Inhibitors of AADC (e.g., carbidopa) have proven to be clinically useful, but not as modulators of peripheral adrenergic transmission. Rather these agents are used to inhibit the metabolism of drug L-DOPA administered in the treatment of Parkinson disease (Chapter 13).

Drugs Affecting Catecholamine Storage and Release

Reserpine (an NT Depletor). Reserpine, a prototypical and historically important drug, is an indole alkaloid obtained from the root of *Rauwolfia serpentina* found in India.

As is typical of many indole alkaloids, reserpine is susceptible to decomposition by light and oxidation. Reserpine is extensively metabolized through hydrolysis of the ester function at position 18 and yields methyl reserpate and 3,4,5-trimethoxybenzoic acid. It not only depletes the vesicle storage of NE in sympathetic neurons in PNS, neurons of the CNS, and E in the adrenal medulla, but also depletes the storage of serotonin and DA in their respective neurons in the brain. Reserpine binds extremely tightly with and blocks VMAT that transports NE and other biogenic amines from the cytoplasm into the storage vesicles.³¹ Thus in sympathetic neurons, NE, which normally is transported into the storage vesicles, is instead metabolized by mitochondrial MAO in the cytoplasm. In addition, there is a gradual loss of vesicle-stored NE as it is used up by release resulting from sympathetic nerve activity so that the storage vesicles eventually become dysfunctional. The end result is a depletion of NE in the sympathetic neuron. Analogous effects are seen in the adrenal medulla with E and with 5-HT in serotonergic neurons.

When reserpine is given orally, its maximum effect is seen after a couple of weeks. A sustained effect up to several weeks is seen after the last dose has been given. This is because the tight binding of reserpine to storage vesicles continues for a prolonged time, and recovery of sympathetic function requires synthesis of new vesicles over a period of days to weeks after discontinuation of the drug. Most adverse effects of reserpine ($\log P = 4.37$) are caused by CNS effects because it readily enters the CNS. Sedation and inability to concentrate or perform complex tasks are the most common adverse effects. More serious is the occasional psychotic depression that can lead to suicide, which support monoamine theory of pathology of depression. Agents with fewer side effects have largely replaced reserpine in clinical use.

Reserpine ($\log P = 4.37$, $\log D = 3.93$)

Guanethidine
pK_a = 13.43
No CNS activity

Guanadrel
pK_a = 12.76
No CNS activity

Guanethidine (Ismelin) and guanadrel (Hylorel) are seldom used orally active antihypertensives. Drugs of this type enter the adrenergic neuron by way of the uptake-1 process and accumulate within the neuronal storage vesicles. There they bind to the storage vesicles and stabilize the neuronal storage vesicle membranes, making them less responsive to nerve impulses. The ability of the vesicles to fuse with the neuronal membrane is also diminished, resulting in inhibition of NE release into the synaptic cleft in response to a neuronal impulse and generalized decrease in sympathetic tone. Long-term administration of some of these agents also can produce a depletion of NE stores in sympathetic neurons.

Both neuronal blocking drugs possess a guanidino moiety [CNHC(=NH)NH₂], which is attached to either a hexahydroazocinyl ring linked by an ethyl group as in guanethidine, or a dioxaspirodecyl ring linked by a methyl group as in guanadrel. The presence of the more basic guanidino group (pK_a >12) than the ordinary amino group in these drugs means that at physiological pH, they are essentially completely protonated. Thus, these agents do not get into the CNS. As a result, this drug has none of the central effects seen with many of the other antihypertensive agents described in this chapter. Guanethidine contains two basic nitrogen atoms with pK_a values of 9.0 and 13.43, and can therefore form guanethidine monosulfate (C₁₀H₂₂N₄ · H₂SO₄) or guanethidine sulfate [(C₁₀H₂₂N₄)₂ · H₂SO₄].

Although guanethidine and guanadrel have virtually the same mechanism of action on sympathetic neurons, they differ in their pharmacokinetic properties. For example, although guanethidine is absorbed incompletely after oral administration (3%–50%), guanadrel is well absorbed, with a bioavailability of 85%.³² These two agents also differ in terms of half-life: Guanethidine has a half-life of about 5 days, whereas guanadrel has a half-life of 12 hours. Both agents are partially metabolized (~50%) by the liver, and both are used to treat moderate-to-severe hypertension, either alone or in combination with another antihypertensive agent.

SYMPATHOMIMETIC AGENTS

Sympathomimetic agents produce effects resembling those produced by stimulation of the sympathetic nervous system. They may be classified as agents that produce effects by a direct, indirect, or mixed mechanism of action. Direct-acting agents elicit a sympathomimetic response by interacting directly with adrenergic receptors. Indirect-acting agents produce effects primarily by causing the release of NE from

adrenergic nerve terminals; the NE that is released by the indirect-acting agent activates the receptors to produce the response. Compounds with a mixed mechanism of action interact directly with adrenergic receptors and indirectly cause the release of NE. As described later, the mechanism by which an agent produces its sympathomimetic effect is related intimately to its chemical structure.

Direct-Acting Sympathomimetics

STRUCTURE–ACTIVITY RELATIONSHIPS

The structure–activity relationships (SARs) summary is shown in Figure 16.11. Comprehensive reviews of the SARs of α - and β -agonists and antagonists^{33–35} covered their developments in the late 1980s. The parent structure with the features in common for many of the adrenergic drugs is β -phenylethylamine. The manner in which β -phenylethylamine is substituted on the *meta*- and *para*-positions of the aromatic ring, on the amino (R₁), and on α -, (R₂)-, and β -positions of the ethylamine side chain influences not only their mechanism of action, the receptor selectivity, but also their absorption, oral activity, metabolism, degradation, and thus duration of action (DOA). For the direct-acting sympathomimetic amines, maximal activity is seen in β -phenylethylamine derivatives containing (a) a catechol and (b) a (1*R*)-OH group on the ethylamine portion of the molecule. Such structural features are seen in the prototypical direct-acting compounds NE, E, and ISO. The SARs are supported by the model of β -AR binding studies (Fig. 16.8).

Optical Isomerism. A critical factor in the interaction of adrenergic agonists with their receptors is stereoselectivity. Substitution on either carbon-1 or carbon-2 yields optical isomers. (1*R*,2*S*) isomers seem correct configuration for direct-acting activity. For CAs, the more potent enantiomer has the (1*R*) configuration. This enantiomer is typically several 100-fold more potent than the enantiomer with the (1*S*) configuration. It appears that for all direct-acting, phenylethylamine-derived agonists that are structurally similar to NE, the more potent enantiomer is capable of assuming a conformation that results in the arrangement in space of the catechol group, the amino group, and the (1*R*)-OH group in a fashion resembling that of (1*R*)-NE. This explanation of stereoselectivity is based on the presumed interaction of these three critical pharmacophoric groups with three complementary binding areas on the receptor and is known as the Easson-Stedman hypothesis.^{17,36} This three-point interaction is supported by site-directed mutagenesis studies²⁸ on the adrenergic receptor and is illustrated in Figure 16.8.

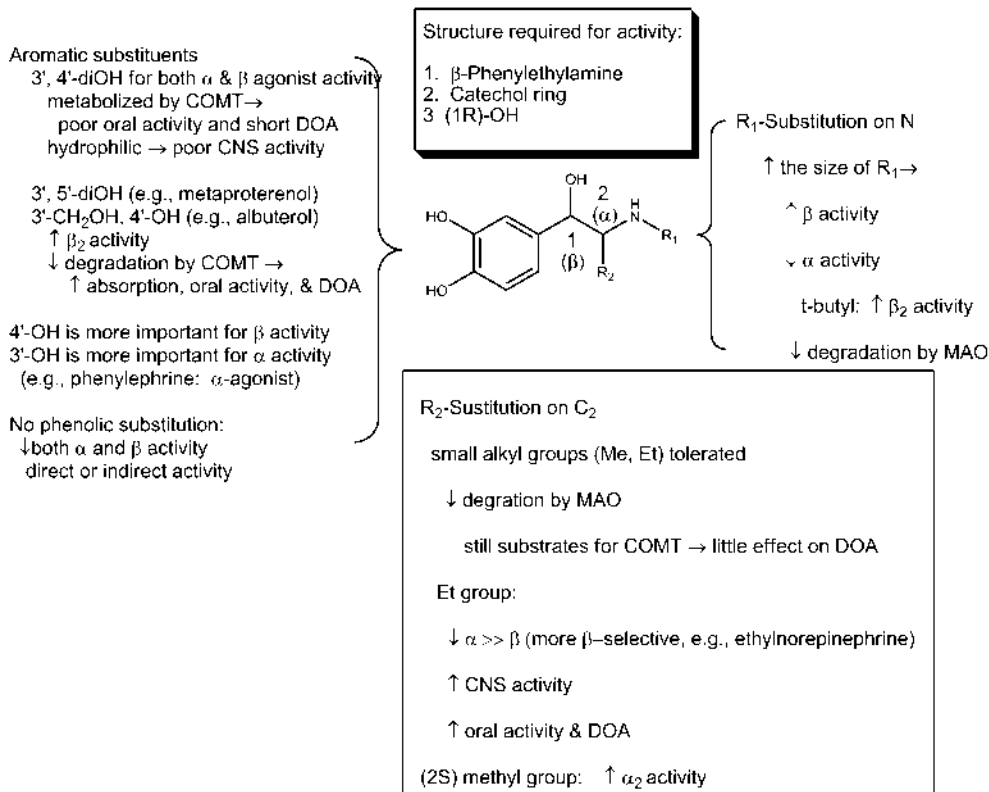

Figure 16.11 • Structure–activity relationship of adrenergic phenylethylamine agonists.

Separation of Aromatic Ring and Amino Group.

By far, the greatest adrenergic activity occurs when two carbon atoms separate the aromatic ring from the amino group. This rule applies with few exceptions to all types of activities.

R₁, Substitution on the Amino Nitrogen Determines α - or β -Receptor Selectivity. The amine is normally ionized at physiological pH. This is important for direct agonist activity, because replacing nitrogen with carbon results in a large decline in activity. The activity is also affected

by the number of substituents on the nitrogen. Primary and secondary amines have good adrenergic activity, whereas tertiary amines and quaternary ammonium salts do not. The nature of the amino substituent also dramatically affects the receptor selectivity of the compound. As the size of the nitrogen substituent increases, α -receptor agonist activity generally decreases and β -receptor agonist activity increases. Thus, NE has more α -activity than β -activity and E is a potent agonist at α -, β_1 -, and β_2 -receptors. ISO, however, is a potent β_1 - and β_2 -agonist but has little affinity for α -receptors.

Norepinephrine (NE)
 $\alpha > \beta$ agonist
 α agonist

Epinephrine (E)
 α , β_1 and β_2 agonist
nonselective α and β agonist

Isoproterenol (ISO)
 β_1 and β_2 agonists
nonselective β agonist

N-t-Butylnorepinephrine (Colterol)
selective β_2 agonist

Ephedrine (Log P = 1.05)
more α and β activity
less lipophilic \rightarrow less CNS activity

Methamphetamine (Log P = 1.97)
less α and β activity
more lipophilic \rightarrow more CNS activity

(1R, 2S)- α -Methylnorepinephrine
active isomer
selective α_2 agonist

The nature of the substituents can also affect β_1 - and β_2 -receptor selectivity. In several instances, it has been shown that a β_2 -directing *N-tert*-butyl group enhances β_2 -selectivity. For example, *N-tert*-butylnorepinephrine (Colterol) is 9 to 10 times more potent as an agonist at tracheal β_2 -receptors than at cardiac β_1 -receptors. These results indicate that the β -receptor has a larger lipophilic binding pocket adjacent to the amine-binding aspartic acid residue than do the α -receptors. Increasing the length of the alkyl chain offers no advantage, but if a polar functional group is placed at the end of the alkyl group, the situation changes. In particular, adding a phenol group to the end of a C2 alkyl chain results in a dramatic rise in activity, indicating that an extra polar-binding region has been accessed, which can take part in H-bonding. Experiments have shown the activity of the extension analog is thereby increased by a factor of 800. As R₁ becomes larger than butyl group, it can provide compounds with α_1 -blocking activity (e.g., tamsulosin and labetalol). Large substituents on the amino group also protect the amino group from undergoing oxidative deamination by MAO.

R₂, Substitution on the α -Carbon (Carbon-2). Substitution by small alkyl group (e.g., CH₃- or C₂H₅-) slows metabolism by MAO but has little overall effect on DOA of catechols because they remain substrates for COMT. However, the resistance to MAO activity is more important in noncatechol indirect-acting phenylethylamines. The DOA of drugs such as ephedrine or amphetamine is thus measured in hours rather than in minutes. Because addition of small alkyl group increases the resistance to metabolism and lipophilicity, such compounds often exhibit enhanced oral effectiveness and greater CNS activity than their counterparts that do not contain an α -alkyl group. In addition, compounds with an α -methyl substituent persist in the nerve terminals and are more likely to release NE from storage sites. For example, metaraminol is an α -agonist and also exhibits a greater degree of indirect sympathomimetic activity.

Phenylephrine
less α and β activity than NE
selective α_1 agonist
almost no β activity

Metaproterenol

not metabolized by COMT \rightarrow
better oral bioavailability

Resorcinol

Methyl or ethyl substitution on the α -carbon of the ethylamine side chain reduces direct agonist activity at both α - and β -receptors. α -Substitution also significantly affects receptor selectivity. An ethyl group in this position diminishes α -activity far more than β -activity, affording compounds with β -selectivity (e.g., ethylnorepinephrine and isoetharine). In the case of β -receptors, for example, α -methyl or ethyl substitution results in compounds toward the β_2 -selectivity, whereas in the case of α -receptors, α -methyl substitution gives compounds toward the α_2 -selectivity. Another effect of α -substitution is the introduction of a chiral center, which has pronounced effects on the stereochemical requirements for activity. For example, with α -methylnorepinephrine, it is the *erythro* (1R,2S) isomer that possesses significant activity at α_2 -receptors.

OH substitution on the β -carbon (carbon-1) generally decreases CNS activity largely because it lowers lipid solubility. However, such substitution greatly enhances agonist activity at both α - and β -receptors. For example, ephedrine is less potent than methamphetamine as a central stimulant, but it is more powerful in dilating bronchioles and increasing blood pressure and heart rate. Compounds lacking the β -OH group (e.g. DA) have a greatly reduced adrenergic receptor activity. Some of the activity is retained, indicating that the OH group is important but not essential. The R-enantiomer of NE is more active than the S-enantiomer, indicating that the secondary alcohol is involved in an H-bonding interaction.

Substitution on the Aromatic Ring. Maximal α - and β -activity also depends on the presence of 3' and 4' OH groups. Tyramine, which lacks two OH groups, has no affinity for adrenoceptors, indicating the importance of the OH groups. Studies of β -adrenoceptor structure suggest that the OH groups on serine residues 204 and 207 probably form H-bonds with the catechol OH groups at positions 3' and 4', respectively.

Although the catechol moiety is an important structural feature in terms of yielding compounds with maximal agonist activity at adrenoceptors, it can be replaced with other substituted phenyl moieties to provide selective adrenergic agonists. This approach has been used in particular in the design of selective β_2 -agonists. For example, replacement of the catechol function of ISO with the resorcinol structure gives a selective β_2 -agonist, metaproterenol. Furthermore, because the resorcinol ring is not a substrate for COMT, β -agonists that contain this ring structure tend to have better absorption characteristics and a longer DOA than their catechol-containing counterparts. In another approach, replacement of the *meta*-OH of the catechol structure with a hydroxymethyl group gives agents, such as albuterol, which show selectivity to the β_2 -receptor. Because they are not catechols, these agents are not metabolized by COMT and thus show improved oral bioavailability and longer DOA.

Modification of the catechol ring can also bring about selectivity at α -receptors as it appears that the catechol moiety is more important for α_2 -activity than for α_1 -activity. For example, removal of the *p*-OH group from E gives phenylephrine, which, in contrast to E, is selective for the α_1 -receptor. Phenylephrine is less potent than E at both α - and β -receptors, with β_2 -activity almost completely absent. However, the OH group can be replaced by other groups capable of interacting with the binding site by H-bonding. This is particularly true for the *meta*-OH group, which can be replaced by CH_2OH , NHMe , NHCOR , NMe_2 , or NHSO_2R group.

CAs without OH Groups. Phenylethylamines that lack OH groups on the ring and the β -OH group on the side chain act almost exclusively by causing the release of NE from sympathetic nerve terminals and thus results in a loss of direct sympathomimetic activity. Because substitution of OH groups on the phenylethylamine structure makes the resultant compounds less lipophilic, unsubstituted or alkyl-substituted compounds cross the BBB more readily and have more central activity. Thus, amphetamine and methamphetamine exhibit considerable CNS activity.

CAs per oral have only a brief DOA and are almost inactive, because they are rapidly inactivated in the intestinal mucosa and in the liver before reaching the systemic circulation. In contrast, compounds without one or both phenolic OH substituents are, however, not metabolized by COMT, and they are orally active and have longer DOA.

Imidazolines and α -Adrenergic Agonists. Although nearly all β -agonists are β -phenylethanolamine derivatives, it is α -adrenoceptors that exhibit a far more diverse assortment of structures. A second chemical class of α -agonists, the

X = usually CH_2 (α_1 agonists) or NH (α_2 agonists)

Figure 16.12 • General structural features of the imidazoline α -adrenergic receptor agonists.

imidazolines, which give rise to α -agonists and are thus vasoconstrictors. These imidazolines can be nonselective, or they can be selective for either α_1 - or α_2 -receptors. Structurally, most imidazolines have their heterocyclic imidazoline nucleus linked to a substituted aromatic moiety via some type of bridging unit (Fig. 16.12).³⁴ The optimum bridging unit (X) is usually a single methylene group or amino group. Although modification of the imidazoline ring generally results in compounds with significantly reduced agonist activity, there are examples of so-called open-ring imidazolines that are highly active. The nature of the aromatic moiety, as well as how it is substituted, is quite flexible. However, agonist activity is enhanced when the aromatic ring is substituted with halogen substituents like chlorine (Cl) or small alkyl groups like methyl group, particularly when they are placed in the two *ortho* positions. Because the SARs of the imidazolines are quite different from those of the β -phenylethylamines, it has been postulated that the imidazolines interact with α -receptors differently from the way the β -phenylethylamines do, particularly with regard to the aromatic moiety.³⁷

ENDOGENOUS CATECHOLAMINES

The three naturally occurring catecholamines DA, NE, and E are used as therapeutic agents.

Dopamine. (DA, 3',4'-dihydroxyphenylethylamine) differs from NE in lacking of 1-OH group. It is the immediate precursor of NE and is a central NT particularly important in the regulation of movement (see Chapter 13). As a catechol and primary amine, DA is rapidly metabolized by COMT and MAO and has a short DOA with no oral activity. It is used intravenously in treatment of shock. In contrast with the NE and E, DA increases blood flow to the kidney in doses that have no chronotropic effect on the heart or that cause no increase in blood pressure. The increased blood flow to the kidneys enhances glomerular filtration rate, Na^+ excretion, and, in turn, urinary output. The dilation of renal blood vessels produced by DA is the result of its agonist action on the D_1 -DA receptor.

Dopamine (DA, Log P = 0.12)

NE (Log P = -0.63)

E (Log P = 0.28)

All are polar and metabolized by both MAO and COMT → orally inactive and short duration of action

In doses slightly higher than those required to increase renal blood flow, DA stimulates the β_1 -receptors of the heart to increase cardiac output. Some of the effects of DA on the heart are also caused by NE release. Infusion at a rate greater than $10 \mu\text{g}/\text{kg}$ per minute results in stimulation of α_1 -receptors, leading to vasoconstriction and an increase in arterial blood pressure. DA should be avoided or used at a much reduced dosage (one tenth or less) if the patient has received an MAO inhibitor. Careful adjustment of dosage also is necessary in patients who are taking tricyclic antidepressants.

Norepinephrine (NE, Levophed) differs from DA only by addition of a 1-OH substituent (β -OH-DA) and from E only by lacking the *N*-methyl group. Like DA, it is polar and rapidly metabolized by both COMT and MAO, resulting in poor oral bioavailability and short DOA (1 or 2 minutes even when given intravenously). It is a stimulant of α_1 -, α_2 -, and β_1 -adrenoceptors (notice that lacking the *N*-methyl group results in lacking β_2 - and β_3 -activity). It is used to counteract various hypotensive crises, because its α -activity raises blood pressure and as an adjunct treatment in cardiac arrest because its β -activity stimulates the heart. It has limited clinical application caused by the nonselective nature of its activities.

Epinephrine (E, Adrenalin) differs from NE only by the addition of an *N*-methyl group. Like the other CAs, E is light sensitive and easily oxidized on exposure to air because of the catechol ring system. The development of a pink-to-brown color indicates oxidative breakdown. To minimize oxidation, solutions of the drug are stabilized by the addition of reducing agents such as sodium bisulfite. E is also destroyed readily in alkaline solutions and by metals (e.g., Cu, Fe, Zn) and weak oxidizing agents. It is used in aqueous solution for inhalation as the free amine. Like other amines, it forms salts with acids, hydrochloride, and the bitartrate being the most common.

Like NE, it lacks oral activity and has short DOA. However, it is much more widely used clinically than NE. E is a potent stimulant of all α_1 -, α_2 -, β_1 -, β_2 -, and β_3 -adrenoceptors, and thus it switches on all possible adrenergic receptors, leading to a whole range of desired and side effects. Particularly prominent are the actions on the heart and on vascular and other smooth muscle. It is a very potent vasoconstrictor and cardiac stimulant. NE has, in general, greater β -activity caused by an additional *N*-methyl group. Therefore, E is used to stimulate the heart in cardiac arrest. Although intravenous infusion of E has pronounced effects on the cardiovascular system, its use in the treatment of

heart block or circulatory collapse is limited because of its tendency to induce cardiac arrhythmias.

The ability of epinephrine to stimulate β_2 -receptors has led to its use by injection and by inhalation to relax bronchial smooth muscle in asthma and in anaphylactic reactions. Several OTC preparations (e.g., Primatene, Bronkaid) used for treating bronchial asthma use E. It is also used in inhibiting uterine contraction. Because of its α -activity, E is used to treat hypotensive crises and nasal congestion, to enhance the activity of local anesthetics, and as a constrictor in hemorrhage.

In addition, E is used in the treatment of open-angle glaucoma, where it apparently reduces intraocular pressure by increasing the rate of outflow of aqueous humor from the anterior chamber of the eye. The irritation often experienced on instillation of E into the eye has led to the development of other preparations of the drug that potentially are not as irritating. One such example is dipivefrin.

Dipivefrin (Propine, Dipivalyl Epinephrine). To overcome several of the pharmacokinetic and pharmaceutical shortcomings of E as an ophthalmic agent, the prodrug approach has been successfully applied. Dipivefrin is a prodrug of E that is formed by the esterification of the catechol OH groups of E with pivalic acid. Most of the advantages of this prodrug over E stem from improved bioavailability. The greatly increased lipophilicity allows much greater penetrability into the eye through the corneal epithelial and endothelial layer. The stroma in between requires hydrophilicity for penetration. Dipivefrin has that, too, due to the 1-OH group and cationic nitrogen (the eyedrops contain the hydrochloride [HCl] salt). This dual solubility permits much greater penetrability into the eye than the very hydrophilic E hydrochloride. Increased DOA is also achieved because the drug is resistant to the metabolism by COMT. In addition to its increased *in vivo* stability, it is also less easily oxidized by air due to the protection of the catechol OH groups. This high bioavailability and *in vivo* and *in vitro* stability translate into increased potency such that the 0.1% ophthalmic solution is approximately equivalent to a 2% E solution. After its absorption, it is converted to E by esterases slowly in the cornea and anterior chamber. Dipivefrin also offers the advantage of being less irritating to the eye than E.

α -ADRENERGIC RECEPTOR AGONISTS

All selective α_1 -agonists have therapeutic activity as vasoconstrictors. Structurally, they include (a) phenylethanolamines

Epinephrine (E)
catechol: easily oxidized
less lipophilic than dipivefrin
poor absorption and poor penetration of the eye
irritating to eyes when used in treatment of glaucoma

Dipivefrin: Ester and prodrug of E
Noncatechol: less easily oxidized
more lipophilic than E
better absorption and penetration of the eye
less irritating to the eye than E

Epinephrine (E)

Phenylephrine

Metaraminol

such as phenylephrine, metaraminol, and methoxamine and (b) 2-arylimidazolines such as xylometazoline, oxymetazoline, tetrahydrozoline, and naphazoline.

Phenylephrine. (Neo-Synephrine, a prototypical selective direct-acting α_1 -agonist) differs from E only in lacking a *p*-OH group. It is orally active, and its DOA is about twice that of E because it lacks the catechol moiety and thus is not metabolized by COMT. However, its oral bioavailability is less than 10% because of its hydrophilic properties ($\log P = -0.3$), intestinal 3'-*O*-glucuronidation/sulfation and metabolism by MAO. Lacking the *p*-OH group, it is less potent than E and NE but it is a selective α_1 -agonist and thus a potent vasoconstrictor. It is used similarly to metaraminol and methoxamine for hypotension. Another use is in the treatment of severe hypotension resulting from either shock or drug administration. It also has widespread use as a nonprescription nasal decongestant in both oral and topical preparations. When applied to mucous membranes, it reduces congestion and swelling by constricting the blood vessels of the membranes. In the eye, it is used to dilate the pupil and to treat open-angle glaucoma. In addition, it is used in spinal anesthesia to prolong the anesthesia and to prevent a drop in blood pressure during the procedure. It is relatively nontoxic and produces little CNS stimulation. Metaraminol is just another example.

Methoxamine (Vasoxyl) is another α_1 -agonist and par-enteral vasopressor used therapeutically and so have few cardiac stimulatory properties. It is bioactivated by *O*-demethylation to an active *m*-phenolic metabolite. In fact, it tends to slow the ventricular rate because of activation of the carotid sinus reflex. It is less potent than phenylephrine as a vasoconstrictor. Methoxamine is used primarily during surgery to maintain adequate arterial blood pressure, especially in conjunction with spinal anesthesia. It does not stimulate the CNS. Because it is not a substrate for COMT, its DOA is significantly longer than NE.

Midodrine (ProAmatine) is the *N*-glycyl prodrug of the selective α_1 -agonist desglymidodrine. Removal of the *N*-glycyl moiety from midodrine occurs readily in the liver as well as throughout the body, presumably by amidases. Midodrine is orally active and represents another example of a dimethoxy- β -phenylethylamine derivative that is used therapeutically for its vasoconstrictor properties. Specifically, it is used in the treatment of symptomatic orthostatic hypotension.

Midodrine: *N*-glycyl prodrug of desglymidodrine

ProdrugAn active *m*-phenolic metabolite
 α_1 agonist and vasoconstrictor

Naphazoline (Privine), tetrahydrozoline (Tyzine, Visine), xylometazoline (Otrivin), and oxymetazoline (Afrin) are 2-arylimidazolines α_1 -agonists. These agents are used for their vasoconstrictive effects as nasal and ophthalmic decongestants. Although nearly all β -agonists are phenylethanolamine derivatives, α -receptors accommodate more diverse chemical structures. All 2-arylimidazoline α_1 -agonists contain a one-carbon bridge between C-2 of the imidazoline ring and a phenyl ring, and thus a phenylethylamine structure feature is there. *Ortho*-lipophilic groups on the phenyl ring are important for α -activity. However, *meta*- or *para*-bulky lipophilic substituents on the phenyl ring may be important for the α_1 -selectivity. They have limited access to the CNS, because they essentially exist in an ionized form at physiological pH caused by the very basic nature of the imidazoline ring ($pK_a = 10-11$). Xylometazoline and oxymetazoline have been used as topical nasal decongestants because of their ability to promote constriction of the nasal mucosa. When taken in large doses, oxymetazoline

may cause hypotension, presumably because of a central clonidine-like effect. Oxymetazoline also has significant affinity for α_{2A} -receptors.

Clonidine (Catapres) differs from 2-arylimidazoline α_1 -agonists mainly by the presence of *o*-chlorine groups and a NH bridge. The *o*-chlorine groups afford better activity than *o*-methyl groups at α_2 sites. Importantly, clonidine contains a NH bridge (aminoimidazolines) instead of CH₂ bridge in 2-arylimidazoline. The uncharged form of clonidine exists as a pair of tautomers as shown next. Clonidine is an example of a (phenylimino) imidazolidine derivative that possesses central α_2 -selectivity. The $\alpha_1:\alpha_2$ ratio is 300:1. Under certain conditions, such as intravenous infusion, clonidine can briefly exhibit vasoconstrictive activity as a result of stimulation of peripheral α -receptors. However, this hypertensive effect, if it occurs, is followed by a much longer-lasting hypotensive effect as a result of the ability of clonidine to enter into the CNS and stimulate

Imidazoline moiety
pKa 9-10
Limited access to the CNS

Clonidine (pK_a = 8.0) : R = H some passage into the CNS

4-Hydroxyclonidine : R = OH no passage into the CNS

Apraclonidine (pK_a = 9.22) : R = NH₂ no passage into the CNS

α_2 -receptors located in regions of the brain such as the nucleus tractus solitarius. Stimulation of these α_2 -receptors brings about a decrease in sympathetic outflow from the CNS, which in turn leads to decreases in peripheral vascular resistance and blood pressure.^{20,38} Bradycardia is also produced by clonidine as a result of a centrally induced facilitation of the vagus nerve and stimulation of cardiac prejunctional α_2 -receptors.³⁹ These pharmacological actions have made clonidine quite useful in the treatment of hypertension.

The ability of clonidine and its analogs to exert an antihypertensive effect depends on the ability of these compounds not only to interact with the α_2 -receptor in the brain but also to gain entry into the CNS. For example, in the case of clonidine, the basicity of the guanidine group (typically pK_a = 13.6) is decreased to 8.0 (the pK_a of clonidine) because of the inductive and resonance effects of the dichlorophenyl ring. Thus, at physiological pH, clonidine will exist to a significant extent in the nonionized form required for passage into the CNS. It has an oral bioavailability of more than 90%.

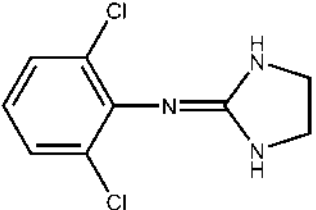

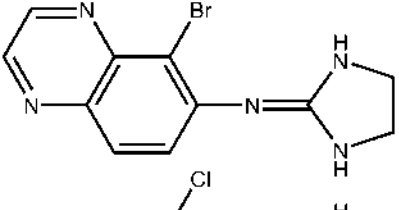

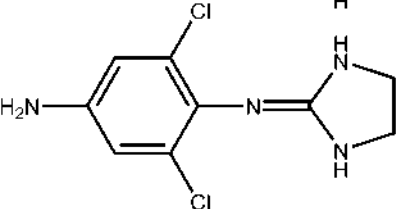

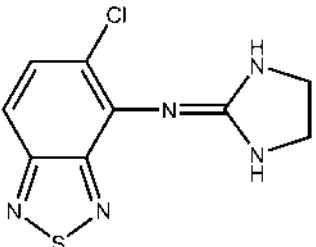

Although various halogen and alkyl substitutions can be placed at the two ortho positions of the (phenylimino)imidazolidine nucleus without affecting the affinity of the derivatives for α_2 -receptors, methyl analogs are much more readily metabolized to the corresponding acids (inactive) and thus have short DOA. Halogen substituents such as chlorine seem to provide the optimal characteristics in this regard.⁴⁰ One of the metabolites of clonidine, 4-hydroxyclonidine, has good affinity for α_2 -receptors, but because it is too polar to get into the CNS, it is not an effective antihypertensive agent.

In addition to binding to the α_2 -adrenergic receptor, clonidine, as well as some other imidazolines, shows high affinity for what has been termed the *imidazoline* receptor.^{41,42} Through the use of imidazoline and α_2 -antagonists, specific nonadrenergic imidazoline binding sites (I₁-IBS) have recently been characterized in CNS control of blood pressure, which are GPCR, with agmatine (decarboxylated arginine) being the endogenous ligand for IBS.^{43,44} However, other studies involving both site-directed mutagenesis of the α_{2A} -receptor subtype and genetically engineered knockout mice deficient in either the α_{2A} - or α_{2B} -receptor subtypes provide evidence that the hypotensive response of the α_2 -receptor agonists such as clonidine primarily involves the α_{2A} -receptor

subtype.^{45,46} Thus, the central hypotensive activity for clonidine and other 2-aminoimidazolines need both α_2 -receptors and I₁-IBS to produce their central sympatholytic response. Clonidine appears to be more selective for α_2 -receptors than for I₁-IBS.

Apraclonidine (Iopidine) and Brimonidine (Alpha-gan). In addition to its therapeutic use as an antihypertensive agent, clonidine has been found to provide beneficial effects in several other situations,⁴⁷ including glaucoma, spasticity, migraine prophylaxis, opiate withdrawal syndrome, and anesthesia. This has prompted the development of analogs of clonidine for specific use in some of the mentioned areas. Two of such examples are apraclonidine and brimonidine. Apraclonidine does not cross the BBB. However, brimonidine can cross the BBB and hence can produce hypotension and sedation, although these CNS effects are slight compared with those of clonidine. CNS effects of these drugs are correlated well to their log P, pK_a, and thus log D value. Both apraclonidine and brimonidine are selective α_2 -agonists with α_1 : α_2 ratios of 30:1 and 1,000:1, respectively. Brimonidine is a much more selective α_2 -agonist than clonidine or apraclonidine and is a first-line agent for treating glaucoma. Apraclonidine's primary mechanism of action may be related to a reduction of aqueous formation, whereas brimonidine lowers intraocular pressure by reducing aqueous humor production and increasing uveoscleral outflow. Apraclonidine is used specifically to control elevations in intraocular pressure that can occur during laser surgery on the eye. Another example is tizanidine (Zanaflex), which finds use in treating spasticity associated with multiple sclerosis or spinal cord injury. By stimulating α_2 -adrenergic receptors, it is believed to decrease the release of excitatory amino acid NTs from spinal cord interneurons.⁴⁸

Guanabenz (Wytensin) and Guanfacine (Tenex) (Open-Ring Imidazolidines). Studies on SAR of central α_2 -agonists showed that the imidazoline ring was not necessary for α_2 -activity. Two clonidine analogs, guanabenz (pK_a = 8.1) and guanfacine (pK_a = 7), which are closely related chemically and pharmacologically, are also used as antihypertensive drugs. In these compounds, the 2,6-dichlorophenyl moiety found in clonidine is connected to a guanidino group by a two-atom bridge. In the case of

	Drugs	Log P	pKa	Log D at pH 7	CNS activity
	Clonidine	1.6	8.3	0.8	++
	Brimonidine	0.9	9.63	-1.34	+
	Apraclonidine	0.3	9.22	-1.91	--
	Tizanidine	0.65	9.18	-1.47	+

guanabenz, this bridge is a $-\text{CH}=\text{N}-$ group, whereas for guanfacine, it is a $-\text{CH}_2\text{CO}-$ moiety. For both compounds, conjugation of the guanidino moiety with the bridging moiety helps to decrease the pK_a of the basic group, so that at physiological pH a significant portion of each drug exists in its nonionized form. This accounts for their CNS penetration and high oral bioavailability (70%–80% for guanabenz and >80% for guanfacine).

Guanfacine is more selective for α_2 -receptors than is clonidine. Their mechanism of action is the same as that of clonidine. Differences between clonidine and its two analogs are seen in their elimination half-life values and in their metabolism and urinary excretion patterns. The elimination half-life of clonidine ranges from 20 to 25 hours, whereas that for guanfacine is about 17 hours. Guanabenz has the shortest DOA of these three agents, with a half-life of about 6 hours. Clonidine and guanfacine are excreted unchanged in the urine to the extent of 60% and 50%,

respectively. Very little of guanabenz is excreted unchanged in the urine.

Methyldopa (*L*- α -methyldopa, Aldomet) differs structurally from L-DOPA only in the presence of a α -methyl group. Originally synthesized as an AADC inhibitor, methyldopa ultimately decreases the concentration of DA, NE, E, and serotonin in the CNS and periphery. However, its mechanism of action is not caused by its inhibition of AADC but, rather, by its metabolism in the CNS to its active metabolite (α -methylnorepinephrine). Methyldopa is transported actively into CNS via an aromatic amino acid transporter, where it is decarboxylated by AADC in the brain to (1*R*,2*S*)- α -methyldopamine. This intermediate, in turn, is stereospecifically β -hydroxylated by DBH to give the (1*R*,2*S*)- α -methylnorepinephrine. This active metabolite is a selective α_2 -agonist because it has correct (1*R*,2*S*) configuration (Fig. 16.13). It is currently postulated

that α -methylnorepinephrine acts on α_2 -receptors in the CNS in the same manner as clonidine, to decrease sympathetic outflow and lower blood pressure.

Absorption can range from 8% to 62% and appears to involve an amino acid transporter. Absorption is thus affected by food, and about 40% of that absorbed is converted to methyl dopa-*O*-sulfate by the intestinal mucosal cells. Methyl dopa is used only by oral administration because its zwitterionic character limits its solubility. The ester hydrochloride salt of methyl dopa, methyl dopate (Aldomet), was developed as a highly water-soluble derivative that could be used to make parenteral preparations. It is converted to methyl dopa in the body through the action of esterases (Fig. 16.13).

DUAL α - AND β -AGONISTS/ANTAGONISTS

Dobutamine (Dobutrex) is a positive inotropic agent administered intravenously for congestive heart failure. It resembles DA structurally but possesses a bulky 1-(methyl)-3-(4-hydroxyphenyl)propyl group on the amino group. It possesses a center of asymmetry, and both enantiomeric forms are present in the racemic mixture used clinically. The (–) isomer of dobutamine is a potent α_1 -agonist, which is capable of causing marked pressor responses. In contrast, (+)-dobutamine is a potent α_1 -antagonist, which can block the effects of (–)-dobutamine. Importantly, the effects of these two isomers are mediated via β_1 -receptors. Both isomers appear to be full agonists, but the (+) isomer is a more potent β_1 -agonist than the (–) isomer (approximately tenfold).^{49,50}

Dobutamine
oxidized slightly by air
COMT metabolism and conjugation \rightarrow
orally inactive and short DOA

Dobutamine contains a catechol group and is orally inactive and thus is given by intravenous infusion. Solutions of the drug can exhibit a slight pink color because of oxidation of the catechol function. It has a plasma half-life of about 2 minutes because it is metabolized by COMT and by conjugation, although not by MAO.

β -ADRENERGIC RECEPTOR AGONISTS

Isoproterenol (Isuprel) is a nonselective and prototypical β -agonist ($\beta_2/\beta_1 = 1$). After oral administration, the absorption of ISO is rather erratic and undependable. The principal reason for its poor absorption characteristics and relatively short DOA is its facile metabolism by sulfate and glucuronide conjugation of the phenolic OH groups and *o*-methylation by COMT. Because it is a catechol, it is sensitive to light and air. Aqueous solutions become pink on standing. Unlike E and NE, ISO does not appear to

undergo oxidative deamination by MAO. The drug has DOA of 1 to 3 hours after inhalation.

Because of an isopropyl substitution on the nitrogen atom, it has virtually no α -activity. However, it does act on both β_1 - and β_2 -receptors. It thus can produce an increase in cardiac output by stimulating cardiac β_1 -receptors and can bring about bronchodilation through stimulation of β_2 -receptors in the respiratory tract. In fact, it is one of the most potent bronchodilators available and is available for use by inhalation and injection. Cardiac stimulation is an occasionally dangerous adverse effect. This effect of ISO on the heart is sometimes used in the treatment of heart block.

The cardiac stimulation caused by its β_1 -activity and its lack of oral activity have led to its diminished use in favor of more selective β -agonists. The problems have been overcome at least partially by the design and development of several noncatechol selective β_2 -agonists. These agents relax smooth muscle of the bronchi, uterus, and skeletal muscle vascular supply. They find their primary use as bronchodilators in the treatment of acute and chronic bronchial asthma and other obstructive pulmonary diseases.

Metaproterenol (Alupent), terbutaline (Bricanyl, Brethine), and fenoterol (an investigational drug) belong to the structural class of resorcinol bronchodilators that have 3',5'-diOH groups of the phenyl ring (rather than 3',4'-diOH groups as in catechols). 3',5'-diOH groups confer β_2 -receptor selectivity on compounds with large amino substituents. For example, metaproterenol (a resorcinol analog of ISO), terbutaline (an *N*-*t*-butyl analog of metaproterenol), and other similar compounds are resorcinol β_2 -selective agonists. They relax the bronchial musculature in patients with asthma but cause less direct cardiac stimulation than do the nonselective β -agonists. Because metaproterenol has a β -directing *N*-isopropyl group and it is less β_2 selective than either terbutaline or albuterol (both

have β_2 -directing *t*-butyl groups), and hence is more prone to cause cardiac stimulation. Although these agents are more selective for β_2 -receptors, they have a lower affinity for β_2 -receptors than ISO. However, they are much more effective when given orally, and they have a longer DOA. This is because they are resistant to the metabolism by either COMT or MAO. Instead, their metabolism primarily involves glucuronide conjugation. Although both metaproterenol and terbutaline exhibit significant β_2 -receptor selectivity, the common cardiovascular effects associated with other adrenergic agents can also be seen with these drugs when high doses are used.

Albuterol (Proventil, Ventolin), pirbuterol (Maxair), and salmeterol (Serevent) are examples of selective β_2 -agonists whose selectivity results from replacement of the *meta*-OH group of the aromatic ring with a hydroxymethyl moiety. Pirbuterol is closely related structurally to albuterol ($\beta_2/\beta_1 = 60$); the only difference between the two is that pirbuterol contains a pyridine ring instead of a benzene ring. As in the case of metaproterenol and terbutaline, these drugs are not metabolized by either COMT or MAO. Instead, they are conjugated with sulfate. They are thus orally active, and exhibit a longer DOA than ISO. The DOA of terbutaline, albuterol, and pirbuterol is in the range of 3 to 6 hours. (*S*)-albuterol enhances bronchial muscle contraction, and this undesirable effect is completely avoided by using the pure (*R*)-albuterol, levalbuterol (Xopenex). Therefore, the efficacy is achieved at one-fourth dose of racemic albuterol with markedly reduced adverse effects.

Salmeterol has an *N*-phenylbutoxyhexyl substituent in combination with a β -OH group and a salicyl phenyl ring for optimal direct-acting β_2 -receptor selectivity and potency. It has a potency similar to that of ISO. This drug associates with the β_2 -receptor slowly resulting in slow onset of action and dissociates from the receptor at an even slower rate.⁵¹ It

Albuterol

Pirbuterol

Salmeterol

is resistant to both MAO and COMT and highly lipophilic (log P = 3.88). It is thus very long acting (12 hours), an effect also attributed to the highly lipophilic phenylalkyl substituent on the nitrogen atom, which is believed to interact with a site outside but adjacent to the active site.

Formoterol and Levalbuterol. Formoterol (Foradil) is also a lipophilic (log P = 1.6) and long-acting β_2 -agonist. It has 3'-formylamino (β -directing) and 4'-OH groups on one phenyl ring and a lipophilic β -directing *N*-isopropyl-*p*-methoxyphenyl group on the nitrogen atom. Its long DOA (12 hours), which is comparable to that of salmeterol, has been suggested to result from its association with the membrane lipid bilayer,⁵² from which it gradually diffuses to provide prolonged stimulation of β_2 receptors and its resistance to MAO and COMT. Formoterol has a much faster onset of action than does salmeterol as result of its lower lipophilicity. Both of these long-acting drugs are used by inhalation and are recommended for maintenance treatment of asthma, usually in conjunction with an inhaled corticosteroid.

Formoterol (Log p = 1.6)

All of the previously mentioned β_2 -agonists possess at least one chiral center and are used as racemic mixtures. Formoterol possesses two chiral centers and is used as the racemic mixture of the (R,R) and (S,S) enantiomers. As mentioned previously, it is the (*R*) isomer of the

Isoetharine

phenylethanolamines that possesses the pharmacological activity. There is no clinical advantage for using (*R,R*)-formoterol as bronchodilators compared with the racemic mixture because of its high potency and low dose. However, concerns have been raised about the use of racemic mixtures under the belief that the inactive isomer may be responsible for some of the adverse effects. Levalbuterol (Xopenex), the pure (*R*) isomer of racemic albuterol, represents the first attempt to address this issue as mentioned earlier.

Isoetharine. (α -ethyl ISO) was the first β_2 -selective drug widely used for the treatment of airway obstruction. However, its degree of selectivity and activity for β_2 -receptors may not approach that of some of the other agents such as terbutaline, albuterol, or even ISO. Because of the presence of the β_2 -directing α -ethyl group and β -directing isopropyl group, isoetharine is a β_2 -agonist and is resistant to MAO. However, because it contains the catechol ring system, it is metabolized by COMT and *O*-sulfated quite effectively. Consequently, it has a short DOA similar to that of ISO and is used only by inhalation for the treatment of acute episodes of bronchoconstriction.

Bitolterol (Tornalate, a Prodrug). Colterol (active metabolite of bitolterol) differs from ISO by replacing the β -directing *N*-isopropyl to β_2 -directing *N*-*tert*-butyl group, which results in the increased β_2 -selectivity. Bitolterol (Tornalate) is a prodrug of colterol (a β_2 -selective agonist) in which the catechol OH groups have been converted to di-*p*-toluate esters, providing increased lipid solubility caused by the presence of the two lipophilic di-*p*-toluate esters in bitolterol. The presence of the bulky di-ester and bulky *N*-*tert*-butyl groups also prolong the DOA (8 hours) because it is resistant to COMT and MAO metabolism. Bitolterol is administered by inhalation for bronchial asthma and reversible bronchospasm. The highly bulky *p*-toluoyl groups apparently inhibit the efficiency of the esterases. After absorption, it is hydrolyzed by esterases slowly enough in the

Bitolterol (a prodrug of Colterol)

esterases in the lung
and other tissues

lung and other tissues to produce the active agent (colterol) affording sustained bronchodilation. The DOA of a single dose of the prodrug bitolterol is twice that of a single dose of colterol, permitting less frequent administration and greater convenience to the patient. Colterol is then metabolized after pharmacological action by COMT and conjugation.

Ritodrine (Yutopar) is a selective β_2 -agonist that was developed specifically for use as a uterine relaxant. Its uterine inhibitory effects are more sustained than its effects on the cardiovascular system, which are minimal compared with those caused by nonselective β -agonists. The cardiovascular effects usually associated with its administration are mild tachycardia and slight diastolic pressure decrease. Usually, it is administered initially by intravenous infusion to stop premature labor and subsequently it may be given orally.

Ritodrine

β_3 -Adrenergic Receptor Agonists. The β_3 -receptor has been shown to mediate various pharmacological effects such as lipolysis, thermogenesis, and relaxation of the urinary bladder. Activation of the β_3 -receptor is thought to be a possible approach for the treatment of obesity, type 2 diabetes mellitus, and frequent urination. Therefore, it is recognized as an attractive target for drug discovery. Selective β_3 -agonists have been developed, but they have not been approved for therapeutic

use. Continuing clinical studies will clarify the physiologic effects mediated by β_3 -receptors and elucidate the potential therapeutic uses of its agonists in humans.⁵³

Indirect-Acting Sympathomimetics

Indirect-acting sympathomimetics act by releasing endogenous NE. They also enter the nerve ending by way of the active-uptake process and displace NE from its storage granules. As with the direct-acting agents, the presence of the catechol OH groups enhances the potency of indirect-acting phenylethylamines. However, the indirect-acting drugs that are used therapeutically are not catechol derivatives and, in most cases, do not even contain an OH moiety. In contrast with the direct-acting agents, the presence of a β -hydroxyl group decreases, and an α -methyl group increases, the effectiveness of indirect-acting agents. The presence of nitrogen substituents decreases indirect activity, with substituents larger than methyl groups rendering the compound virtually inactive. Phenylethylamines that contain a tertiary amino group are also ineffective as NE-releasing agents. Given the foregoing structure-activity considerations, it is easy to understand why amphetamine and *p*-tyramine are often cited as prototypical indirect-acting sympathomimetics. Because amphetamine-type drugs exert their primary effects on the CNS, they are discussed in more detail in Chapter 15. This chapter discusses those agents that exert their effects primarily on the periphery.

Amphetamine
Log P = 2.81*p*-Tyramine

Hydroxyamphetamine (Paredrine) is an effective, indirect-acting sympathomimetic drug. It differs from amphetamine in the presence of *p*-OH group and so it has little or no CNS-stimulating action. It is used to dilate the pupil for diagnostic eye examinations and for surgical procedures on the eye. It is sometimes used with cholinergic blocking drugs like atropine to produce a mydriatic effect, which is more pronounced than that produced by either drug alone.

Hydroxyamphetamine
Log P = 1.07
pKa = 10.71

Propylhexedrine (Benzedrex) is another analog of amphetamine in which the aromatic ring has been replaced with a cyclohexane ring. This drug produces vasoconstriction and a decongestant effect on the nasal membranes, but it has only about one half the pressor effect of amphetamine and produces decidedly fewer effects on the CNS. Its major use is for a local vasoconstrictive effect on nasal mucosa in the symptomatic relief of nasal congestion caused by the common cold, allergic rhinitis, or sinusitis.

Propylhexedrine

L-(+)-Pseudoephedrine. (Sudafed, Afrinol, Drixoral) is the (*S,S*) diastereoisomer of ephedrine. Whereas ephedrine has a mixed mechanism of action, L-(+)-pseudoephedrine acts mostly by an indirect mechanism and has virtually no direct activity. The structural basis for this difference in mechanism is the stereochemistry of the carbon atom possessing the β -OH group. In pseudoephedrine, this carbon atom possesses the (*S*) configuration, the wrong stereochemistry at this center for a direct-acting effect at adrenoceptors. Although it crosses the BBB (log P = 1.05, pKa = 9.38), L-(+)-pseudoephedrine's lack of direct activity affords fewer CNS effects than does ephedrine. It is a naturally occurring alkaloid from the *Ephedra* species. This agent is found in many OTC nasal decongestant and cold medications. Although it is less prone to increase blood pressure than ephedrine, it should be used with caution in hypertensive individuals, and it should not be used in combination with MAO inhibitors.

Sympathomimetics with a Mixed Mechanism of Action

Those phenylethylamines considered to have a mixed mechanism of action usually have no hydroxyls on the aromatic ring but do have a β -hydroxyl group.

D-(-)-Ephedrine. The pharmacological activity of (1*R*,2*S*)-D-(-)-ephedrine resembles that of E. The drug acts on both α - and β -receptors. Its ability to activate β -receptors probably accounted for its earlier use in asthma. It is the classic example of a sympathomimetic with a mixed mechanism of action.

Lacking H-bonding phenolic OH groups, ephedrine is less polar (log P = 1.05, pKa = 9.6) and, thus, crosses the BBB far better than do other CAs. Therefore, ephedrine has been used as a CNS stimulant and exhibits side effects related to its action in the brain. It causes more pronounced stimulation of the CNS than E. The drug is not metabolized

by either MAO or COMT and therefore has more oral activity and longer DOA than E. Like many other phenylisopropylamines, a significant fraction of the drug is excreted unchanged in the urine although it can be *p*-hydroxylated and *N*-demethylated by cytochrome P450 mixed-function oxidases. Because it is a weak base, its excretion can be accelerated by acidification of the urine.

Ephedrine has two asymmetric carbon atoms; thereby creating four optically active isomers. The *erythro* racemate is called *ephedrine*, and the *threo* racemate is known as *pseudoephedrine* (ψ -ephedrine). Natural ephedrine is the D (-) isomer, and it is the most active of the four isomers as a pressor amine. This is largely because of the fact that this isomer has the correct (1R,2S) configuration for optimal direct action at adrenergic receptors.

Ephedrine decomposes gradually and darkens when exposed to light. The free alkaloid is a base, and an aqueous solution of the free alkaloid has a pH above 10. The salt form has a pK_a of 9.6. Ephedrine and its salts are used orally, intravenously, intramuscularly, and topically for various conditions, such as allergic disorders, colds, hypotensive conditions, and narcolepsy. It is used locally to constrict the nasal mucosa and cause decongestion and to dilate the pupil or the bronchi. Systemically, it is effective for asthma, hay fever, and urticaria.

This drug is an alkaloid that can be obtained from the stems of various species of *Ephedra*. Ma huang, the plant containing ephedrine, was known to the Chinese in 2000 BC, but the active principle, ephedrine, was not isolated until 1885. In recent years, various companies have begun marketing extracts of *Ephedra* shrubs for such purposes as weight loss and enhancement of athletic performance. Herbalists also market them as “alternative medicines” for cold and cough relief. It has been estimated that nearly one third of young, obese women have used a weight-loss supplement containing *Ephedra*.⁵⁴ Pharmacists must be aware that some patients may be taking such ma huang

containing herbal remedies or dietary supplements in addition to regulated drugs that could lead to serious adverse reactions.

Phenylpropanolamine (Propadrine) is the *N*-desmethyl analog of ephedrine and thus has many similar properties. Lacking the *N*-methyl group, phenylpropanolamine is slightly more polar, and therefore does not enter the CNS as well as ephedrine. This modification gives an agent that has slightly higher vasopressive action and lower central stimulatory action than ephedrine. Its action as a nasal decongestant is more prolonged than that of ephedrine. It is orally active. Phenylpropanolamine was a common active component in OTC appetite suppressants and cough and cold medications until 2001 when the Food and Drug Administration (FDA) recommended its removal from such medications, because studies showed an increased risk of hemorrhagic stroke in young women who took the drug.

Metaraminol (Aramine) is the *N*-desmethyl- α -methyl analog of phenylephrine. It possesses a mixed mechanism of action, with its direct-acting effects mainly on α_1 -receptors. It is used parenterally as a vasopressor in the treatment and prevention of the acute hypotensive state occurring with spinal anesthesia. It also has been used to treat severe hypotension brought on by other traumas that induce shock.

ADRENERGIC RECEPTOR ANTAGONISTS (BLOCKERS)

α -Blockers

Because α -agonists cause vasoconstriction and raise blood pressure, α -blockers should be therapeutically used as antihypertensive agents. Unlike the β -blockers, which bear clear structural similarities to the adrenergic agonists NE,

Phenylephrine

Metaraminol

E, and ISO, the α -blockers consist of several compounds of diverse chemical structure that bear little obvious resemblance to the α -agonists.³⁴

NONSELECTIVE α -BLOCKERS

Tolazoline (Priscoline) and phentolamine (Regitine) are imidazoline competitive α -blockers, and primarily of historical interest. The structure of tolazoline are similar to the imidazoline α_1 -agonists, but does not have the lipophilic substituents required for agonist activity. The type of group attached to the imidazoline ring thus dictates whether an imidazoline is an agonist or a blocker. Phentolamine is the more effective α -blocker, but neither drug is useful in treating essential hypertension for following reasons. (a) Tolazoline and phentolamine have both α_1 - and α_2 -blocking activity and produce tachycardia. Presumably, the blocking actions of these agents at presynaptic α_2 -receptors contribute to their cardiac stimulatory effects by enhancing the release of NE. Both agents also have a direct vasodilatory action on vascular smooth muscle that may be more prominent than their α -blocking effects. (b) The blocking action of tolazoline is relatively weak, but its histamine-like and acetylcholine-like agonistic actions probably contribute to its vasodilatory activity. Its histamine-like effects include stimulation of gastric acid secretion, rendering it inappropriate for administration to patients who have gastric or peptic ulcers.

It has been used to treat Raynaud syndrome and other conditions involving peripheral vasospasm. Tolazoline is available in an injectable form and is indicated for use in persistent pulmonary hypertension of the newborn when supportive measures are not successful. Phentolamine is

Tolazoline

Phentolamine

used to prevent or control hypertensive episodes that occur in patients with pheochromocytoma. It also has been used in combination with papaverine to treat impotence.

IRREVERSIBLE α -BLOCKERS

Agents in this class, when given in adequate doses, produce a slowly developing, prolonged adrenergic blockade that is not overcome by E. They are irreversible α -blockers, because β -haloalkylamines in the molecules alkylate α -receptors (recall that β -haloalkylamines are present in nitrogen mustard anticancer agents and are highly reactive alkylating agents). Although dibenamine is the prototypical agent in this class, it is phenoxybenzamine that is used therapeutically today.

The mechanism whereby β -haloalkylamines produce a long-lasting, irreversible α -receptor blockade is depicted in Figure 16.14. The initial step involves the formation of an intermediate aziridinium ion (ethylene iminium ion). The positively charged aziridinium ion electrophile then reacts with a nucleophilic group on the α -receptor (if this occurs in the vicinity of the α -receptor), resulting in the formation of a covalent bond between the drug and the receptor. Unfortunately, these nonselective drugs alkylate not only α -receptors but also other biomolecules, leading to their toxicity. It is thus used only to relieve the sympathetic effects of pheochromocytoma.

Phenoxybenzamine (Dibenzyline) an old but powerful α -blocker, is a haloalkylamine that blocks α_1 - and α_2 -receptors irreversibly. Phenoxybenzamine administration has been described as producing a "chemical sympathectomy" because of its selective blockade of the excitatory

Figure 16.14 • Mechanism of inactivation of α -adrenergic receptors by β -haloalkylamines.

responses of smooth muscle and of the heart muscle. Although phenoxybenzamine is capable of blocking acetylcholine, histamine, and serotonin receptors, its primary pharmacological effects, especially that of vasodilation, may be attributed to its α -adrenergic blocking capability. As would be expected of a drug that produces such a profound α -blockade, administration is frequently associated with reflex tachycardia, increased cardiac output, and postural hypotension. There is also evidence indicating that blockade of presynaptic α_2 -receptors contribute to the increased heart rate produced by phenoxybenzamine.

The onset of action of phenoxybenzamine is slow, but the effects of a single dose of drug may last 3 to 4 days, because essentially new receptors must be made to replace those that have been inhibited irreversibly. The principal peripheral effects following its administration are an increase in systemic blood flow, an increase in skin temperature, and a lowering of blood pressure. It has no effect on the parasympathetic system and little effect on the gastrointestinal tract. The most common side effects are miosis, tachycardia, nasal stuffiness, and postural hypotension,

all of which are related to the production of adrenergic blockade.

Oral phenoxybenzamine is used for the preoperative management of patients with pheochromocytoma and in the chronic management of patients whose tumors are not amenable to surgery. Only about 20% to 30% of an oral dose is absorbed.

SELECTIVE α_1 -BLOCKERS

Prazosin (Minipress), terazosin (Hytrin), and doxazosin (Cardura) are quinazoline α_1 -blockers. As a result, in part, of its greater α_1 -receptor selectivity, the quinazoline class of α -blockers exhibits greater clinical utility and has largely replaced the nonselective haloalkylamine and imidazoline α -blockers. Structurally, these agents consist of three components: the quinazoline ring, the piperazine ring, and the acyl moiety. The 4-amino group on the quinazoline ring is very important for α_1 -receptor affinity. Although they possess a piperazine moiety attached to the quinazoline ring, this group can be replaced with other heterocyclic moieties (e.g., piperidine moiety) without loss of affinity. The nature

of the acyl group has a significant effect on the pharmacokinetic properties.⁵⁵

These drugs dilate both arterioles and veins and are thus used in the treatment of hypertension. They offer distinct advantages over the other α -blockers, because they produce peripheral vasodilation without an increase in heart rate or cardiac output. This advantage is attributed, at least in part, to the fact that prazosin blocks postjunctional α_1 -receptors selectively without blocking presynaptic α_2 -receptors. Contraction of the smooth muscle of prostate gland, prostatic urethra, and bladder neck is also mediated by α_1 -adrenoceptors, with α_{1A} being predominant, and blockade of these receptors relaxes the tissue. For this reason, these agents are also used in the treatment of BPH, where they help improve urination flow rates.

Although the adverse effects of these drugs are usually minimal, the most frequent one, known as the *first-dose phenomenon*, is sometimes severe. This is a dose-dependent effect characterized by marked excessive postural hypotension and syncope, and can be minimized by giving an initial low dose at bedtime.

The main difference between prazosin, terazosin, and doxazosin lies in their pharmacokinetic properties. As mentioned previously, these differences are dictated by the nature of the acyl moiety attached to the piperazine ring. These drugs are metabolized extensively with the metabolites excreted in the bile. The fact that a single α_{1A} -adrenoceptor subtype is found in the prostatic and urethral smooth muscle cells led to the design of drugs with uroselectivity for this receptor subtype. Thus, alfuzosin and tamsulosin are uroselective α_1 -blockers and first-line drugs for treatment of BPH without utility in treating hypertension.

Alfuzosin (Uroxatral) is also a quinazolinone α_1 -blocker but differs from terazosin in replacing the piperazine ring in terazosin with an open piperazine ring (a rotatable propylenediamine group). Alfuzosin is more selective for the subtype of α_{1A} -receptor in the prostate gland than those in vascular tissue. Thus, it has been used extensively in treating BPH as a first-line drug with fewer cardiovascular side effects than terazosin and doxazosin.

Tamsulosin (Flomax), a nonquinazolinone benzenesulfonamide, is the first in the class of subtype selective α_{1A} -blocker. It is many folds more selective for α_{1A} -receptors than for the other α_1 -receptors. This selectivity may favor blockade of α_{1A} -receptors found in the prostate gland over those found in vascular tissue. Tamsulosin is efficacious in the treatment of BPH with little effect on blood pressure. Orthostatic hypotension is not as great with this agent as with the nonselective quinazolinones.

SELECTIVE α_2 -BLOCKERS

Yohimbine and Corynanthine. Yohimbine (Yocon) is a competitive and selective α_2 -blocker. The compound is an indolealkylamine alkaloid and is found in the bark of the tree *Pausinystalia yohimbe* and in *Rauwolfia* root; its structure resembles that of reserpine. These isomeric indole alkaloids known as the yohimbanes exhibit different degrees of selectivity toward the α_1 - and α_2 -receptors, depending on their stereochemistry. For example, yohimbine is a

Tamsulosin

selective α_2 -blocker, whereas corynanthine is a selective α_1 -blocker. The only difference between these two compounds is the relative stereochemistry of the carbon containing the carbomethoxy substituent. In yohimbine, this group lies in the plane of the alkaloid ring system, whereas in corynanthine, it lies in an axial position and thus is out of the plane of the rings.⁵⁶

Yohimbine

Corynanthine

Yohimbine increases heart rate and blood pressure as a result of its blockade of α_2 -receptors in the CNS. It has been used experimentally to treat male erectile impotence.

Mirtazapine (Remeron) is another example of tetracyclic α_2 -blockers that shows selectivity for α_2 -receptors versus α_1 -receptors.⁵⁷ Blockade of central α_2 -receptors results in an increased release of NE and serotonin. This has prompted its use as an antidepressant. This agent also has activity at nonadrenergic receptors. It is a potent blocker of 5-HT₂ and 5-HT₃ serotonin receptors and at histamine H₁-receptors.

Mirtazapine (Log D = 1.38)

β -Blockers

STRUCTURE–ACTIVITY RELATIONSHIPS

β -Blockers are among the most widely employed antihypertensives and are also considered the first-line treatment for glaucoma. Most of β -blockers are in the chemical class of aryloxypropanolamines. The first β -blocker, dichloroisoproterenol (DCI), was reported in 1958 by Powell and Slater.⁵⁸ DCI differs structurally from ISO in that the agonist directing 3'4'-di-OH groups have been replaced by two chloro groups. This simple structural modification, involving the replacement of the aromatic OH groups, has provided the basis for nearly all of the approaches used in subsequent efforts to design and synthesize therapeutically useful β -blockers.³⁵ Unfortunately, DCI is not a pure antagonist but a partial agonist. The substantial direct sympathomimetic action of DCI precluded its development as a clinically useful drug.

Pronethalol was the next important β -blocker developed. Although it had much less intrinsic sympathomimetic activity (ISA) than DCI, it was withdrawn from clinical testing because of reports that it caused thymic tumors in mice. Within 2 years of this report, however, Black and Stephenson⁵⁹ described the β -blocking actions of propranolol, a close structural relative of pronethalol. Propranolol has become one of the most thoroughly studied and widely used drugs in the therapeutic armamentarium. It is the standard against which all other β -blockers are compared.

Propranolol belongs to the group of β -blockers known as *aryloxypropanolamines*. This term reflects the fact that an $-\text{OCH}_2-$ group has been incorporated into the molecule between the aromatic ring and the ethylamino side chain. Because this structural feature is frequently found in β -blockers, the assumption is made that the $-\text{OCH}_2-$ group is responsible for the antagonistic properties of the molecules. However, this is not true; in fact,

Dichloroisoproterenol (DCI, a partial β agonist)Pronethalol (a β blocker with toxicity)Propranolol (a prototype of β blockers)Practolol (a prototype of β_1 blockers)

the $-\text{OCH}_2-$ group is present in several compounds that are potent β -agonists.⁶⁰ This latter fact again leads to the conclusion that it is the nature of the aromatic ring and its substituents that is the primary determinant of β -antagonistic activity. The aryl group also affects the absorption, excretion, and metabolism of the β -blockers.⁶¹ Note that the side chain has been moved from C2' to the C1' position from the naphthyl ring.

The nature of the aromatic ring is also a determinant in their β_1 -selectivity. One common structural feature of many cardioselective β -blockers is the presence of a *para*-substituent of sufficient size on the aromatic ring along with the absence of *meta*-substituents. Practolol is the prototypical example of a β_1 -blocker of this structural type. It was the first cardioselective β_1 -blocker to be used extensively in humans. Because it produced several toxic effects, however, it is no longer in general use in most countries.

Like β -agonists, β -directing *tert*-butyl and isopropyl groups, are normally found on the amino function of the aryl-oxopropanolamine β -blockers. It must be a secondary amine for optimal activity.

For aryloxypropanolamine adrenergic agonists, the β -OH-substituted carbon must be in the *R* absolute configuration for maximal direct activity. However, for β -blockers, the β -OH-substituted carbon must be in the *S* absolute configuration for maximal β -blocking activity. Because of the insertion of an oxygen atom in the side chain of the aryl-oxopropanolamines, the Cahn-Ingold Prelog priority of the substituents around the asymmetric carbon differs from the agonists. This is effect of the nomenclature rules. The pharmacologically more active enantiomer of β -blockers interacts with the receptor recognition site in same manner as that of the agonists. In spite of the fact that nearly all of the β -blocking activity resides in one enantiomer, propranolol and most other β -blockers are used clinically as racemic mixtures. The only exceptions are levobunolol, timolol, and penbutolol, with which the (*S*) enantiomer is used.

Propranolol ($\log P = 3.10$) is the most lipophilic drug among the available β -blockers, and thus it enters the CNS much better than the less lipophilic drug such as atenolol ($\log P = 0.10$) or nadolol ($\log P = 1.29$). The use of lipophilic β -blockers such as propranolol has been associated with more CNS side effects, such as dizziness, confusion, or depression. These side effects can be avoided, however, with the use of hydrophilic drugs, such as atenolol or nadolol. The more lipophilic drugs are primarily cleared by the liver, and so their doses need to be adjusted in patients with liver disease. In contrast, the less lipophilic drugs are cleared by the kidney and so their doses need to be adjusted in patients with impaired renal function.

NONSELECTIVE β -BLOCKERS (FIRST GENERATION)

Propranolol (Inderal, others) is the prototypical and nonselective β -blocker. It blocks the β_1 - and β_2 -receptors with equal affinity, lacks ISA, and does not block α -receptors. Propranolol, like the other β -blockers discussed, is a competitive blocker whose receptor-blocking actions can be reversed with sufficient concentrations of β -agonists. Currently, propranolol is approved for use in the United States for hypertension, cardiac arrhythmias, angina pectoris, postmyocardial infarction, hypertrophic cardiomyopathy, pheochromocytoma, migraine prophylaxis, and essential tremor. In addition, because of its high lipophilicity ($\log P = 3.10$) and thus its ability to penetrate the CNS, propranolol has found use in treating anxiety and is under investigation for the treatment of a variety of other conditions, including schizophrenia, alcohol withdrawal syndrome, and aggressive behavior.

Some of the most prominent effects of propranolol are on the cardiovascular system. By blocking the β -receptors of the heart, propranolol slows the heart, reduces the force of contraction, and reduces cardiac output. Because of reflex sympathetic activity and blockade of vascular β_2 -receptors, administration may result in increased peripheral resistance. The antihypertensive action, at least in part, may be attributed to its ability to reduce cardiac output, as well as to its suppression of renin release from the kidney. Because it exhibits no selectivity for β_1 -receptors, it is contraindicated in the presence of conditions such as asthma and bronchitis.

A facet of the pharmacological action of propranolol is its so-called membrane-stabilizing activity. This is a nonspecific effect (i.e., not mediated by a specific receptor), which

is also referred to as a *local anesthetic effect*. Both enantiomers possess membrane-stabilizing activity. Because the concentrations required to produce this effect far exceed those obtained with normal therapeutic doses of propranolol and related β -blockers, it is unlikely that the nonspecific membrane-stabilizing activity plays significant role in the clinical efficacy of β -blockers.

Propranolol is well absorbed after oral administration, but it undergoes extensive first-pass metabolism before it reaches the systemic circulation. Lower doses are extracted more efficiently than higher doses, indicating that the extraction process may become saturated at higher doses. In addition, the active enantiomer is cleared more slowly than the inactive enantiomer.⁶²

One of the major metabolites after a single oral dose is naphthoxylic acid. It is formed by a series of metabolic reactions involving *N*-dealkylation, deamination, and oxidation of the resultant aldehyde. Another metabolite of particular interest is 4-hydroxypropranolol, which is a potent β -blocker that has some ISA. It is not known what contribution, if any, 4-hydroxypropranolol makes to the pharmacological effects seen after administration of propranolol. The half-life of propranolol after a single oral dose is 3 to 4 hours, which increases to 4 to 6 hours after long-term therapy.

Other Nonselective β -Blockers. Several other clinically used nonselective β -blockers include *nadolol* (Corgard), *pindolol* (Visken), *penbutolol* (Levatol), *carteolol* (Cartrol, Ocupress), *timolol* (Blocadren, Timoptic), *levobunolol* (Betagan), *sotalolol* (Betapace), and *metipranolol* (OptiPranolol). Structures of these compounds are shown in Figure 16.15. The first five of these blockers are used to treat hypertension. Nadolol is also used in the long-term management of angina pectoris, whereas timolol finds use in the prophylaxis of migraine headaches and in the therapy following myocardial infarction. Sotalolol is used as an antiarrhythmic in treating ventricular arrhythmias and atrial fibrillation because in addition to its β -adrenergic

blocking activity, this agent blocks the inward K^+ current that delays cardiac repolarization.

Carteolol, timolol, levobunolol, and metipranolol are used topically to treat open-angle glaucoma. These agents lower intraocular pressure with virtually no effect on pupil size or accommodation. They thus offer an advantage over many of the other drugs used in the treatment of glaucoma. Although the precise mechanism whereby β -blockers lower intraocular pressure is not known with certainty, it is believed that they may reduce the production of aqueous humor. Even though these agents are administered into the eye, systemic absorption can occur, producing such adverse effects as bradycardia and acute bronchospasm in patients with bronchospastic disease.

Pindolol possesses modest membrane-stabilizing activity and significant intrinsic β -agonistic activity. Penbutolol and carteolol also have partial agonistic activity but not to the degree that pindolol does. The β -blockers with partial agonistic activity cause less slowing of the resting heart rate than do agents without this capability. The partial agonistic activity may be beneficial in patients who are likely to exhibit severe bradycardia or who have little cardiac reserve.

Timolol, pindolol, penbutolol, and carteolol have half-life values in the same range as propranolol. Nadolol undergoes very little hepatic metabolism and most of this drug is excreted unchanged in the urine. As a result, the half-life of nadolol is about 20 hours, making it one of the longest-acting β -blockers. Timolol undergoes first-pass metabolism but not to the same extent that propranolol does. Timolol and penbutolol are metabolized extensively such that little or no unchanged drug excreted in the urine. Pindolol is metabolized by the liver to the extent of 60%, with the remaining 40% being excreted in the urine unchanged.

β_1 -SELECTIVE BLOCKERS (SECOND GENERATION)

The discovery that β -blockers are useful in the treatment of cardiovascular disease, such as hypertension, stimulated a search for cardioselective β -blockers. Cardioselective

Figure 16.15 • Nonselective β -blockers.

β_1 -blockers are drugs that have a greater affinity for the β_1 -receptors of the heart than for β_2 -receptors in other tissues. Such cardioselective agents should provide two important therapeutic advantages. The first advantage should be the lack of a blocking effect on the β_2 -receptors in the bronchi. Theoretically, this would make β_1 -blockers safe for use in patients who have bronchitis or bronchial asthma. The second advantage should be the absence of blockade of the vascular β_2 -receptors, which mediate vasodilation. This would be expected to reduce or eliminate the increase in peripheral resistance that sometimes occurs after the administration of nonselective β -blockers. Unfortunately, cardioselectivity is usually observed with β_1 -blockers at only relatively low doses. At normal therapeutic doses, much of the selectivity is lost.

At present, the following β_1 -selective blockers are used therapeutically: *acebutolol* (Sectral), *atenolol* (Tenormin), *betaxolol* (Kerlone, Betoptic), *bisoprolol* (Zebeta), *esmolol* (Brevibloc), and *metoprolol* (Lopressor). Structures of these agents are depicted in Figure 16.16. All of these agents except esmolol are indicated for the treatment of hypertension. Atenolol and metoprolol are also approved for use in treating angina pectoris and in therapy following myocardial infarction. Betaxolol is the only β_1 -selective blocker indicated for the treatment of glaucoma.

Esmolol was designed specifically to possess a very short DOA; it has an elimination half-life of 9 minutes. Its effects disappear within 20 to 30 minutes after the infusion is discontinued. Esmolol must be diluted with an injection

Figure 16.16 • β_1 -Selective blockers.

solution before administration; it is incompatible with sodium bicarbonate. The short DOA of esmolol is the result of rapid hydrolysis of its ester functionality by esterases present in erythrocytes (Fig. 16.17). The resultant carboxylic acid is an extremely weak β -blocker that does not appear to exhibit clinically significant effects. The acid metabolite has an elimination half-life of 3 to 4 hours and is excreted primarily by the kidneys. This agent is administered by continuous intravenous infusion for control of ventricular rate in patients with atrial flutter, atrial fibrillation, or sinus tachycardia. Its rapid onset and short DOA render it useful during surgery, after an operation, or during emergencies for short-term control of heart rates. Esmolol and acebutolol are also indicated for treating certain cardiac arrhythmias.

In the class of β_1 -selective blockers, only acebutolol possesses ISA. However, this activity is very weak. Acebutolol and betaxolol possess membrane-stabilizing activity, but the activity is much weaker than that seen with propranolol.

The half-life values of acebutolol and metoprolol are comparable to that seen with propranolol, and those of atenolol and bisoprolol are about twice that of propranolol. Betaxolol, with a half-life ranging between 14 and 22 hours, has the longest DOA of the β_1 -selective blockers. Like pro-

pranolol, metoprolol has low bioavailability because of significant first-pass metabolism. Although the bioavailability of betaxolol is very high, it is metabolized extensively by the liver, with very little unchanged drug excreted in the urine. Atenolol ($\log P = 0.10$), like nadolol ($\log P = 1.29$), has low lipid solubility and does not readily cross the BBB. It is absorbed incompletely from the gastrointestinal tract, the oral bioavailability being approximately 50%. Little of the absorbed portion of the dose is metabolized; most of it is excreted unchanged in the urine. In the case of bisoprolol, about 50% of a dose undergoes hepatic metabolism, whereas the remaining 50% is excreted in the urine unchanged.

Acebutolol is one of the very few β -blockers whose metabolite plays a significant role in its pharmacological actions. This drug is absorbed well from the gastrointestinal tract, but it undergoes extensive first-pass metabolic conversion to diacetolol by hydrolytic conversion of the amide group to the amine, followed by acetylation of the amine (Fig. 16.18). After oral administration, plasma levels of diacetolol are higher than those of acebutolol. Diacetolol is also a selective β_1 -blocker with partial agonistic activity; it has little membrane-stabilizing activity. It has a longer half-life (8–12 hours) than the parent drug and is excreted by the kidneys.

Figure 16.17 • Metabolism of esmolol.

β -BLOCKERS WITH α_1 -ANTAGONIST ACTIVITY (THIRD GENERATION)

Several drugs have been developed that possess both β - and α -receptor-blocking activities within the same molecule. Two examples of such molecules are labetalol (Normodyne) and carvedilol (Coreg). As in the case of dobutamine, the arylalkyl group with nearby methyl group in these molecules is responsible for its α_1 -blocking activity. The bulky *N*-substituents and another substituted aromatic ring are responsible for its β -blocking activity.

Labetalol (Normodyne, Trandate, others), a phenylethanolamine derivative, is representative of a class of drugs that act as competitive blockers at α_1 -, β_1 -, and β_2 -receptors. It is a more potent β -blocker than α -blocker. Because it has two asymmetric carbon atoms (1 and 1'), it exists as a mixture of four isomers. It is this mixture that is used clinically in treating hypertension. The different isomers, however, possess different α - and β -blocking activities. The β -blocking activity resides solely in the (1*R*,1'*R*) isomer, whereas the α_1 -blocking activity is seen in the (1*S*,1'*R*) and (1*S*,1'*S*) isomers, with the (1*S*,1'*R*) isomer possessing the greater therapeutic activity.⁶³ Labetalol is a clinically useful antihypertensive agent. The rationale for its use in the management of hypertension is that its α -receptor-blocking effects produce vasodilation and its β -receptor-blocking effects prevent the reflex tachycardia usually associated with vasodilation. Although labetalol is very well absorbed, it undergoes extensive first-pass metabolism.

Figure 16.18 • Metabolism of acebutolol.

Carvedilol. Carvedilol (Coreg) is a β -blocker that has a unique pharmacological profile. Like labetalol, it is a β -blocker that possesses α_1 -blocking activity. Only the (*S*) enantiomer possesses the β -blocking activity, although both enantiomers are blockers of the α_1 -receptor.⁶⁴ Overall, its β -blocking activity is 10- to 100-fold of its α -blocking activity. This drug is also unique in that it possesses antioxidant activity and an antiproliferative effect on vascular smooth muscle cells. It thus has a neuroprotective effect and the ability to provide major cardiovascular organ protection.⁶⁵ It is used in treating hypertension and congestive heart failure.

ACKNOWLEDGMENT

The author wishes to express his gratitude to Dr. Paul Goldsmith for proofreading. Portions of this text were taken from Dr. Rodney L. Johnson's chapter in the 11th edition of this book.

REVIEW QUESTIONS

- What functional group interactions between the catecholamines and adrenoceptors are most likely? Which functional groups are considered pharmacophores of catecholamines?
- Which of the following drugs would be resistant to metabolism by COMT and why?
- Which of the drug(s) shown would be the least orally active and have the shortest duration of action and why?

4. Which of the following drugs is the most likely to be selective β_2 -agonist?

5. Which of the following drugs is considered to be a pro-drug?

Cholinergic Drugs and Related Agents

STEPHEN J. CUTLER

CHAPTER OVERVIEW

This chapter describes the role that the autonomic nervous system plays in regulating the mammalian system. This chapter supports the fact that acetylcholine (ACh) plays a critical role in the mechanisms of regulation of human physiology. This, in turn, not only serves in the development of agents that mimic the effect of ACh, but also those that block its effects as therapeutic agents. Through these developments, scientists are gaining a better understanding of how to treat diseases such as Alzheimer disease, Parkinson disease, and, most recently, overactive bladder. For pharmacists to be good practitioners, it is necessary that they understand how the autonomic nervous system influences normal physiological function as well as to how they can be used in manipulating diseases.

Few systems, if any, have been studied as extensively as those innervated by neurons that release ACh at their endings. Since the classic studies of Dale,¹ who described the actions of the esters and ethers of choline on isolated organs and their relationship to muscarine, pharmacologists, physiologists, chemists, and biochemists have applied their knowledge to understand the actions of the cholinergic nerve and its neurotransmitter. Advances in the applications of biotechnology and chemistry have developed probes that have uncovered the complexity of the action of ACh on cholinergic neurons and receptors, unknown when ACh was first demonstrated in the frog heart in 1921 by Loewi as the substance released by vagus nerve stimulation.²

This chapter includes the drugs and chemicals that act on cholinergic nerves or the tissues they innervate to either mimic or block the action of ACh. Drugs that mimic the action of ACh do so either by acting directly on the cholinergic receptors in the tissue or by inhibiting acetylcholinesterase (AChE), the enzyme that inactivates ACh at the nerve terminal. Chemicals that bind or compete with ACh for binding to the receptor may block cholinergic neurotransmission.

Cholinergic nerves are found in the peripheral nervous system and central nervous system (CNS) of humans. Its

presence in the CNS is currently receiving the most attention, as researchers are beginning to unlock the mysteries surrounding cognitive impairment and, most particularly, Alzheimer disease. Synaptic terminals in the cerebral cortex, corpus striatum, hippocampus, and several other regions in the CNS are rich in ACh and in the enzymes that synthesize and hydrolyze this neurotransmitter. Many experiments show that agonists and antagonists of cholinergic receptors can modify the output of neurotransmitters, including ACh, from brain preparations. Although the function of ACh in the brain and brainstem is not clear, it has been implicated in memory and behavioral activity in humans.³ The *peripheral nervous system* consists of those nerves outside the cerebrospinal axis and includes the somatic nerves and the autonomic nervous system. The *somatic nerves* are made up of a sensory (afferent) nerve and a motor (efferent) nerve. The *motor nerves* arise from the spinal cord and project uninterrupted throughout the body to all skeletal muscle. ACh mediates transmission of impulses from the motor nerve to skeletal muscle (i.e., neuromuscular junction).

The *autonomic nervous system* is composed of two divisions: *sympathetic* and *parasympathetic*. ACh serves as a neurotransmitter at both sympathetic and parasympathetic preganglionic nerve endings, postganglionic nerve fibers in the parasympathetic division, and some postganglionic fibers (e.g., salivary and sweat glands) in the sympathetic division of the autonomic nervous system. The autonomic nervous system regulates the activities of smooth muscle and glandular secretions. These, as a rule, function below the level of consciousness (e.g., respiration, circulation, digestion, body temperature, metabolism). The two divisions have contrasting effects on the internal environment of the body. The sympathetic division frequently discharges as a unit, especially during conditions of rage or fright, and expends energy. The parasympathetic division is organized for discrete and localized discharge and stores and conserves energy.

Drugs and chemicals that cause the parasympathetic division to react are termed *parasympathomimetic*, whereas those blocking the actions are called *parasympatholytic*. Agents that mimic the sympathetic division are *sympathomimetic*, and those that block the actions are *sympatholytic*. Another classification used to describe drugs and chemicals acting on the nervous system or the structures that the fibers innervate are based on the neurotransmitter released at the nerve ending. Drugs acting on the autonomic nervous system are divided into *adrenergic*, for those postganglionic sympathetic fibers that release norepinephrine and epinephrine,

and *cholinergic*, for the remaining fibers in the autonomic nervous system and the motor fibers of the somatic nerves that release ACh.

CHOLINERGIC RECEPTORS

There are two distinct receptor types for ACh that differ in composition, location, and pharmacological function and have specific agonists and antagonists. Cholinergic receptors have been characterized as *nicotinic* and *muscarinic* on the basis of their ability to be bound by the naturally occurring alkaloids nicotine and muscarine, respectively. Receptor subtypes that differ in location and specificity to agonists and antagonists have been identified for both the nicotinic and muscarinic receptors.

Nicotinic Receptors

Nicotinic receptors are coupled directly to ion channels and, when activated by ACh, mediate very rapid responses. Ion channels are responsible for the electrical excitability of nerve and muscle cells and for the sensitivity of sensory cells. The channels are pores that open or close in an all-or-nothing fashion on time scales ranging from 0.1 to 10 milliseconds to provide aqueous pathways through the plasma membrane that ions can transverse. Factors affecting selectivity of ion pores include both the charge and size of the ion. Ions in aqueous solution are hydrated. The water around the ion is characterized by the presence of two distinct water structures: a tightly bound, highly ordered layer immediately surrounding the ion and a second, less structured layer⁴ (Fig. 17.1). Ion transport through a channel requires some denuding of the surrounding water shell. The degree of organization of the water structure determines the energy required to remove the hydration

Figure 17.1 • Hydrated cation showing a highly structured shell of water around the cation (A), a less structured layer surrounding the inner water shell (B), and water in a “normal” state (C). (With permission from the author and the Royal Society of Chemistry.)

TABLE 17.1 Radii of Alkali and Alkali Earth Cations

Ion	Ionic Radius (Å)	Effective Hydrated Radius (Å)
Li ⁺	0.60	4.5
Na ⁺	0.95	3.4
K ⁺	1.33	2.2

shell and is a factor in the selectivity of that ion channel.⁵ Table 17.1 lists the effective radii of alkali and alkaline earth cations.

The nicotinic ACh receptor was the first neurotransmitter isolated and purified in an active form.⁶ It is a glycoprotein embedded into the polysynaptic membrane that can be obtained from the electric organs of the marine ray, *Torpedo californica* and the electric eel, *Electrophorus electricus*. The receptor is pictured as a cylindrical protein of about 250,000 Da and consists of five-subunit polypeptide chains, of which two appear to be identical.^{7,8} The subunit stoichiometry of the polypeptide units from the *Torpedo* receptor is $\alpha_2\beta\gamma\delta$.⁹ The peptide chains of the receptor are arranged to form an opening in the center, which is the ion channel. Each α chain contains a negatively charged binding site for the quaternary ammonium group of ACh. The receptor appears to exist as a dimer of the two five-subunit polypeptide chain monomers linked through a disulfide bond between δ chains. A structural protein of molecular weight 43,000 binds the nicotinic receptor to the membrane (Fig. 17.2). With so many variables in the subunits, many combinations of nicotinic subtype receptors are available.

When the neurotransmitter ACh binds to the nicotinic receptor, it causes a change in the permeability of the membrane to allow passage of small cations Ca²⁺, Na⁺, and K⁺. The physiological effect is to temporarily depolarize the end plate. This depolarization results in muscular contraction at a neuromuscular junction or, as occurs in autonomic ganglia, continuation of the nerve impulse. Neuromuscular nicotinic ACh receptors are of interest as targets for autoimmune antibodies in myasthenia gravis and for muscle relaxants used during the course of surgical procedures. Nicotinic receptors in autonomic ganglia, when blocked by drugs, can play a role in the control of hypertension.

NICOTINIC RECEPTOR SUBTYPES

Nicotinic receptors located in the neuromuscular junction differ from those on neurons, such as those in the CNS and autonomic ganglia, in that they have different ligand specificities. Nicotinic receptors at the neuromuscular junction (N₁) are blocked by succinylcholine, *d*-tubocurarine, and decamethonium and stimulated by phenyltrimethylammonium. N₂-nicotinic receptors are found in autonomic ganglia. They are blocked by hexamethonium and trimethaphan but stimulated by tetramethylammonium and dimethyl-4-phenylpiperazinium (DMPP). Nicotinic receptor subtypes

Figure 17.2 • Model of the nicotinic receptor consisting of five protein subunits embedded in a cell membrane, based on electron microscopy and neutron scattering data. Jagged lines represent oligosaccharide chains on the upper part of the receptor. A 43K protein is bound to the receptor on the cytosolic side of the cell membrane. The ACh-binding sites are shown on the two-subunit proteins. (Reprinted with permission from Lindstrom, J. M., et al.: Cold Spring Harbor Symp. Quant. Biol. 48:93, 1983.)

have also been identified in many regions of the CNS; however, their pharmacological function is not yet fully understood.¹⁰ Even so, great attempts are being made to understand the role of so many receptor subtypes, particularly those found in the CNS.^{11,12}

Muscarinic Receptors

Muscarinic receptors play an essential role in regulating the functions of organs innervated by the autonomic nervous system to maintain homeostasis of the organism. The action of ACh on muscarinic receptors can result in stimulation or inhibition of the organ system affected. ACh stimulates secretions from salivary and sweat glands, secretions and contraction of the gut, and constriction of the airways of the respiratory tract. It inhibits contraction of the heart and relaxes smooth muscle of blood vessels.

As early as 1980, it became apparent that a single muscarinic receptor type could not mediate the actions of ACh. Research on cholinergic receptors has increased since the 1980s, as these receptors represent potential targets for useful drugs for disease states that are becoming more prevalent because of our increasing population of aged persons. The outcome of these studies has been the discovery of several muscarinic receptor subtypes.

Muscarinic receptors mediate their effects by activating guanosine triphosphate (GTP)-binding proteins (G proteins). These receptors have seven protein helices that transcend the plasma membrane, creating four extracellular domains and four intracellular domains (Fig. 17.3). The extracellular domain of the receptor contains the binding site for ACh. The intracellular domain couples with G proteins to initiate biochemical changes that result in pharmacological action from receptor activation.

MUSCARINIC RECEPTOR SUBTYPES

Evidence from both pharmacological and biochemical studies shows that subtypes of muscarinic receptors are located in the CNS and peripheral nervous system.^{13,14} Molecular cloning studies have revealed the existence of five different molecular mammalian muscarinic receptor proteins. The cloned receptors have been identified as m_1 to m_5 . In another

Figure 17.3 • Hypothetical model of a muscarinic receptor showing the location of the transmembrane helical protein domains and the extracellular and intracellular domains connecting the seven α -helical proteins in the membrane. (Reprinted from Goyal, R. K.: *N. Engl. J. Med.* 321:1024, 1989, with permission from the author and the Massachusetts Medical Society.)

method of identification, muscarinic receptor subtypes have been defined on the basis of their affinity for selective agonists and antagonists and the pharmacological effects they cause. These receptors are designated with capital letters and subscript numbers as M_1 to M_5 . The nomenclature convention adopted for these receptors is that the pharmacologically defined subtypes M_1 , M_2 , and M_3 correspond to the genetically defined subtypes m_1 , m_2 , and m_3 . The m_4 gene-derived protein is referred to as the M_4 subtype and has many pharmacological properties similar to those of the M_2 subtype. The m_5 receptor gene product does not have an equivalent pharmacological profile.

M_1 Receptors. Even though molecules do not have exclusive selectivity on muscarinic receptor subtypes, M_1 receptors have been defined as those with high affinity for pirenzepine and low affinity for compounds such as AF-DX 116. They have been termed *neural* because of their distribution within particular brain structures. In addition to the CNS, M_1 receptors are located in exocrine glands and autonomic ganglia. In humans, these receptors seem to affect arousal attention, rapid eye movement (REM) sleep, emotional responses, affective disorders including depression, and modulation of stress. They are believed to participate in higher brain functions, such as memory and learning. Alzheimer disease research has implicated cholinergic neurons and receptors, but evidence does not show conclusively that these are the primary causes of the disease. M_1 receptors have been identified in submucosal glands and some smooth muscle. They are located in parietal cells in the gastrointestinal (GI) tract and in peripheral autonomic ganglia,

such as the intramural ganglia of the stomach wall. When stimulated, M_1 receptors cause gastric secretion.¹⁵ Although McN-A343 is a selective agonist, pirenzepine hydrochloride (HCl) acts as an antagonist and has been used outside the United States for the treatment of peptic ulcer disease.

M_2 Receptors. M_2 receptors are identified by their high affinity for methoctramine, a polyamine, and by their low affinity for pirenzepine. M_2 receptors are also called *cardiac* muscarinic receptors because they are located in the atria and conducting tissue of the heart. Their stimulation causes a decrease in the strength and rate of cardiac muscle contraction. These effects may be produced by affecting intracellular K^+ and Ca^{2+} levels in heart tissue. M_2 receptors activate K^+ channels to cause hyperpolarization of cardiac cells, resulting in bradycardia. These receptors may also act through an inhibitory G protein (G_i) to reduce adenylate cyclase activity and lower cyclic 3',5'-adenosine monophosphate (cAMP) levels in cardiac cells. Lower cAMP levels decrease the amount of free Ca^{2+} in cardiac cells and slow down the heart rate.¹⁶ M_2 receptors can also serve as autoreceptors on presynaptic terminals of postganglionic cholinergic nerves to inhibit ACh release. The balance of the effects of multiple muscarinic receptor subtypes determines the size of the airway of the smooth muscle in the bronchioles. Contraction is primarily the result of the action of ACh on M_3 receptors (see on next page) following stimulation of the vagus. At the same time, ACh stimulates inhibitor M_2 autoreceptors located on nerve endings to limit release of ACh. In asthmatics, neuronal M_2 receptors in the lungs do not function normally.¹⁷

M₃ Receptors. M₃ receptors, referred to as *glandular* muscarinic receptors, are located in exocrine glands and smooth muscle. Their effect on these organ systems is mostly stimulatory. Glandular secretions from lacrimal, salivary, bronchial, pancreatic, and mucosal cells in the GI tract are characteristic of M₃ receptor activation. Contraction of visceral smooth muscle is also a result of M₃ receptor stimulation. These stimulant effects are mediated through G protein activation of phospholipase C (PLC) to form the second-messenger inositol triphosphate (IP₃) and diacylglycerol (DAG). Discoveries in the past decade have revealed that the endothelium can control the tone of vascular smooth muscle by the synthesis of a potent relaxant, endothelium-derived relaxing factor (EDRF), now identified as nitric oxide (NO), and a vasoconstrictor substance, endothelium-derived contracting factor (EDCF). The synthesis and release of these substances contribute to the tone of the vascular epithelium. M₃ receptors, when activated in endothelial cells, cause the release of EDRF and contribute to vasodilation.¹⁸

M₄ Receptors. M₄ receptors, like M₂ receptors, act through G_i protein to inhibit adenylate cyclase. They also function by a direct regulatory action on K⁺ and Ca²⁺ ion channels. M₄ receptors in tracheal smooth muscle, when stimulated, inhibit the release of ACh¹⁹ in the same manner that M₂ receptors do.

M₅ Receptors. A great deal of research remains to be performed on the M₅ subclass of receptors. Because the M₅ receptor messenger RNA (mRNA) is found in the substantia nigra, it has been suggested that M₅ receptors may regulate dopamine release at terminals within the striatum.

BIOCHEMICAL EFFECTS OF MUSCARINIC RECEPTOR STIMULATION

Transmission at the synapse involving second messengers is much slower, about 100 ms, compared with the few milliseconds at synapses where ion channels are activated directly. The delayed reaction to receptor stimulation is caused by a cascade of biochemical events that must occur to cause the pharmacological response (Fig. 17.4). The sequence of events in these second-messenger systems begins with activation of the receptors by an agonist and involves the activation of G proteins that are bound to a portion of the intracellular domain of the muscarinic receptor.²⁰ G proteins are so called because of their interaction with the guanine nucleotides GTP and guanosine diphosphate (GDP). They translate drug–receptor interactions at the surface of the cell to components inside the cell to create the biological response. G proteins consist of three subunits, α , β , and γ . When the receptor is occupied, the α subunit, which has enzymatic activity, catalyzes the conversion of GTP to GDP. The α subunit bound with GTP is the active form of the G protein that can associate with various enzymes (i.e., PLC and adenylate cyclase) and ion channels (K⁺ and Ca²⁺). G proteins are varied, and the α subunit may cause activation (G_s) or inactivation (G_i) of the enzymes or channels. Recent studies suggest that β and γ subunits also contribute to pharmacological effects.²¹

A single drug–receptor complex can activate several G protein molecules, and each in turn can remain associated with a target molecule (e.g., an enzyme) and cause the production of many molecules, amplifying the result of the

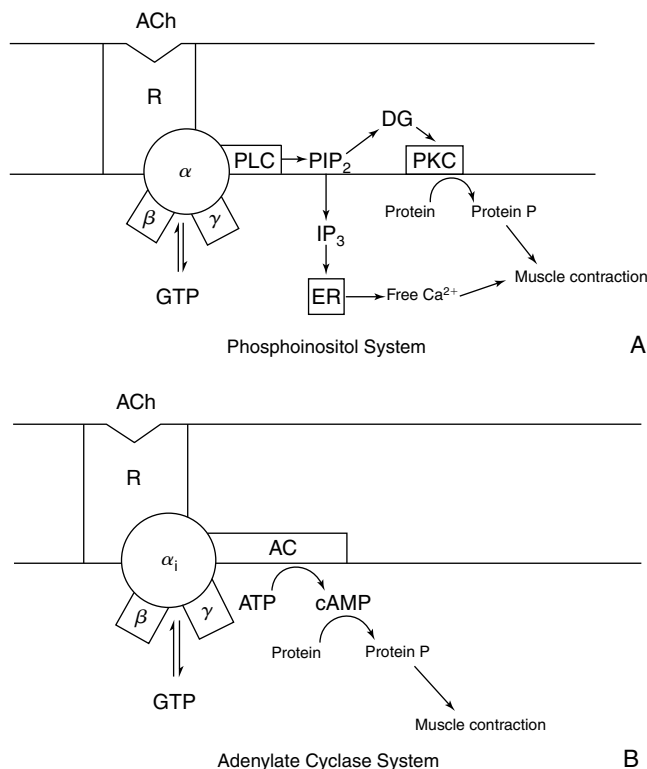

Figure 17.4 • Proposed biochemical mechanisms of cholinergic receptor action. **A.** ACh activates a G protein (α , β , γ) in the phospholipase system to activate the membrane enzyme phospholipase C (PLC), enhancing muscle contraction. **B.** Inhibition of adenylate cyclase system through an inhibitory G protein (α_1) to cause muscle relaxation.

initial drug–receptor combination. M₁, M₃, and M₅ receptors activate PLC, causing the release of IP₃ and DAG, which in turn release intracellular Ca²⁺ and activate protein kinases, respectively. M₂ and M₄ receptors produce inhibition of adenylate cyclase.

Phosphoinositol System. The phosphoinositol system requires the breakdown of membrane-bound phosphatidylinositol 4,5-diphosphate (PIP₂) by PLC to IP₃ and DAG, which serve as second messengers in the cell. IP₃ mobilizes Ca²⁺ from intracellular stores in the endoplasmic reticulum to elevate cytosolic free Ca²⁺. The Ca²⁺ activates Ca²⁺-dependent kinases (e.g., troponin C in muscle) directly or binds to the Ca²⁺-binding protein calmodulin, which activates calmodulin-dependent kinases. These kinases phosphorylate cell-specific enzymes to cause muscle contraction. DAG is lipidlike and acts in the plane of the membrane through activation of protein kinase C to cause the phosphorylation of cellular proteins, also leading to muscle contraction (Fig. 17.4).^{22,23}

Adenylate Cyclase. Adenylate cyclase, a membrane enzyme, is another target of muscarinic receptor activation. The second-messenger cAMP is synthesized within the cell from adenosine triphosphate (ATP) by the action of adenylate cyclase. The regulatory effects of cAMP are many, as it can activate various protein kinases. Protein kinases catalyze the phosphorylation of enzymes and ion channels, altering the amount of calcium entering the cell and thus affecting

muscle contraction. Muscarinic receptor activation causes lower levels of cAMP, reducing cAMP protein-dependent kinase activity, and a relaxation of muscle contraction. Some have suggested that a GTP-inhibitory protein (G_i) reduces the activity of adenylate cyclase, causing smooth muscle relaxation (Fig. 17.4).^{20,24}

Ion Channels. In addition to the action of protein kinases that phosphorylate ion channels and modify ion conductance, G proteins are coupled directly to ion channels to regulate their action.²⁴ The Ca^{2+} channel on the cell membrane is activated by G proteins without the need of a second messenger to allow Ca^{2+} to enter the cell. The α subunit of the G protein in heart tissue acts directly to open the K^+ channel, producing hyperpolarization of the membrane and slowing the heart rate.

CHOLINERGIC NEUROCHEMISTRY

Cholinergic neurons synthesize, store, and release ACh (Fig. 17.5). The neurons also form choline acetyltransferase (ChAT) and AChE. These enzymes are synthesized in the

soma of the neuron and distributed throughout the neuron by axoplasmic flow. AChE is also located outside the neuron and is associated with the neuroglial cells in the synaptic cleft. ACh is prepared in the nerve ending by the transfer of an acetyl group from acetyl-coenzyme A (CoA) to choline. The reaction is catalyzed by ChAT. Cell fractionation studies show that much of the ACh is contained in synaptic vesicles in the nerve ending but that some is also free in the cytosol. Choline is the limiting substrate for the synthesis of ACh. Most choline for ACh synthesis comes from the hydrolysis of ACh in the synapse. Choline is recaptured by the presynaptic terminal as part of a high-affinity uptake system under the influence of sodium ions²⁵ to synthesize ACh.

Several quaternary ammonium bases act as competitive inhibitors of choline uptake. Hemicholinium (HC-3), a bisquaternary cyclic hemiacetal, and the triethyl analog of choline, 2-hydroxyethyltriethylammonium, act at the presynaptic membrane to inhibit the high-affinity uptake of choline into the neuron. These compounds cause a delayed paralysis at repetitively activated cholinergic synapses and can produce respiratory paralysis in test animals. The delayed block is caused by the depletion of stored ACh, which may be

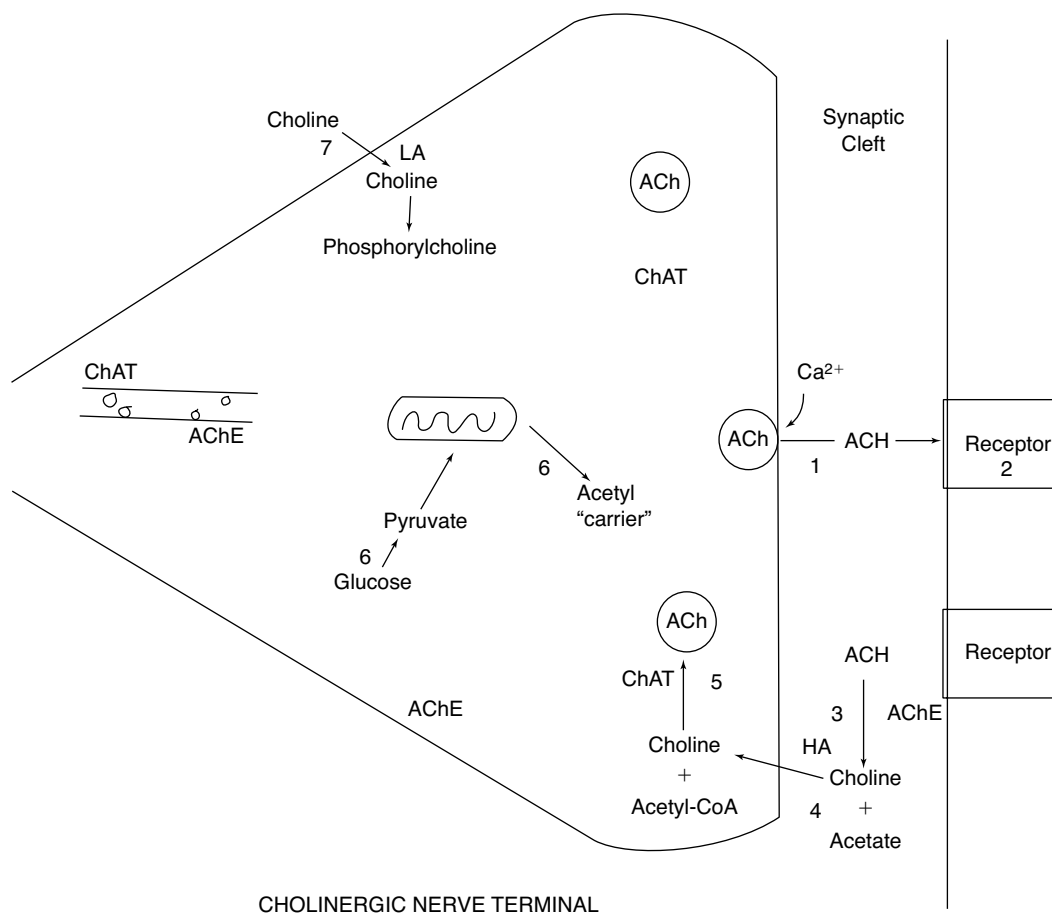

Figure 17.5 • Hypothetical model of synthesis, storage, and release of ACh. 1. ACh is released from storage granules under the influence of the nerve action potential and Ca^{2+} . 2. ACh acts on postsynaptic cholinergic receptors. 3. Hydrolysis of ACh by AChE occurs in the synaptic cleft. 4. A high-affinity uptake system returns choline to the cytosol. 5. ChAT synthesizes ACh in the cytosol, and the ACh is stored in granules. 6. Glucose is converted to pyruvate, which is converted to acetyl-CoA in the mitochondria. Acetyl-CoA is released from the mitochondria by an acetyl carrier. 7. Choline is also taken up into the neuron by a low-affinity uptake system and converted partly to phosphorylcholine.

reversed by choline. The acetyl group used for the synthesis of ACh is obtained by conversion of glucose to pyruvate in the cytosol of the neuron and eventual formation of acetyl-CoA. Because of the impermeability of the mitochondrial membrane to acetyl-CoA, this substrate is brought into the cytosol by the aid of an acetyl "carrier."

The synthesis of ACh from choline and acetyl-CoA is catalyzed by ChAT. Transfer of the acetyl group from acetyl-CoA to choline may be by a random or an ordered reaction of the Theorell-Chance type. In the ordered sequence, acetyl-CoA first binds to the enzyme, forming a complex (EA) that then binds to choline. The acetyl group is transferred, and the ACh formed dissociates from the enzyme active site. The CoA is then released from the enzyme complex, EQ, to regenerate the free enzyme. The scheme is diagrammed in Figure 17.6. ChAT is inhibited *in vitro* by *trans-N*-methyl-4-(1-naphthylvinyl)pyridinium iodide²⁶; however, its inhibitory activity in whole animals is unreliable.²⁷

Newly formed ACh is released from the presynaptic membrane when a nerve action potential invades a presynaptic nerve terminal.²⁸ The release of ACh results from depolarization of the nerve terminal by the action potential, which alters membrane permeability to Ca^{2+} . Calcium enters the nerve terminal and causes release of the contents of several synaptic vesicles containing ACh into the synaptic cleft. This burst, or quantal release, of ACh causes depolarization of the postsynaptic membrane. The number of quanta of ACh released may be as high as several hundred at a neuromuscular junction, with each quantum containing between 12,000 and 60,000 molecules. ACh is also released spontaneously in small amounts from presynaptic membranes. This small amount of neurotransmitter maintains

muscle tone by acting on the cholinergic receptors on the postsynaptic membrane.

After ACh has been released into the synaptic cleft, its concentration decreases rapidly. It is generally accepted that there is enough AChE at nerve endings to hydrolyze into choline and acetate any ACh that has been liberated. For example, there is sufficient AChE in the nerve junction of rat intercostal muscle to hydrolyze about 2.7×10^8 ACh molecules in 1 ms; this far exceeds the 3×10^6 molecules released by one nerve impulse.²⁹

CHOLINERGIC AGONISTS

Cholinergic Stereochemistry

Three techniques have been used to study the conformational properties of ACh and other cholinergic chemicals: x-ray crystallography, nuclear magnetic resonance (NMR), and molecular modeling by computation. Each of these methods may report the spatial distribution of atoms in a molecule in terms of torsion angles. A *torsion angle* is defined as the angle formed between two planes, for example, by the O1—C5—C4—N atoms in ACh. The angle between the oxygen and nitrogen atoms is best depicted by means of Newman projections (Fig. 17.7). A torsion angle has a positive sign when the bond of the front atom is rotated to the right to eclipse the bond of the rear atom. The spatial orientation of ACh is described by four torsion angles (Fig. 17.8).

The conformation of the choline moiety of ACh has drawn the most attention in studies relating structure and

Figure 17.6 • Ordered synthesis of acetylcholine (ACh) by choline acetyltransferase (ChAT).

Figure 17.7 • Spatial orientation of O1—C5—C4—N atoms in ACh.

pharmacological activity. The torsion angle (τ_2) determines the spatial orientation of the cationic head of ACh to the ester group. X-ray diffraction studies have shown that the torsion angle (τ_2) on ACh has a value of $+77^\circ$. Many compounds that are muscarinic receptor agonists containing a choline component (e.g., $\text{O}-\text{C}-\text{C}-\text{N}^+[\text{CH}_3]_3$) have a preferred synclinal (gauche) conformation, with τ_2 values ranging from 68° to 89° (Table 17.2). Intermolecular packing forces in the crystal as well as electrostatic interactions between the charged nitrogen group and the ether oxygen of the ester group are probably the two dominant factors that lead to a preference for the synclinal conformation in the crystal state. Some choline esters display an antiperiplanar (*trans*) conformation between the onium and ester groups. For example, carbamoyl choline chloride (τ_2 , $+178^\circ$) is stabilized in this *trans* conformation by several hydrogen bonds. Acetylthiocholine iodide (τ_2 , $+171^\circ$) is in this conformation because of the presence of the bulkier and less electronegative sulfur atom, and (+) *trans*-(1*S*,2*S*)-acetoxy-cyclopropyltrimethylammonium iodide (τ_2 , $+137^\circ$) is fixed in this conformation by the rigidity of the cyclopropyl ring.

NMR spectroscopy of cholinergic molecules in solution is more limited than crystallography in delineating the conformation of compounds and is restricted to determining the torsion angle O1—C5—C4—N. Most NMR data are in agreement with the results of x-ray diffraction studies. NMR studies indicate that ACh and methacholine apparently are not in their most stable *trans* conformation but exist in one of two gauche conformers³⁰ (Fig. 17.9). This may result from strong intramolecular interactions that stabilize the conformation of these molecules in solution.³¹

Molecular orbital calculations based on the principles of quantum mechanics may be used to determine energy minima of rotating bonds and to predict preferred conformations for the molecule. By means of molecular mechanics, theoretical conformational analysis has found that ACh has an energy minimum for the τ_2 torsion angle at about 84° and that the preferred conformation of ACh corresponds closely in aqueous solution to that found in the crystal state.

The study of interactions between bimolecules and small molecules is of great interest and importance toward the understanding of drug action. These studies are challenging

From Shefter, E.: Structural variations in cholinergic legends. In Triggle, D. J., Moran, J. F., and Barnard, E. A. (eds.). *Cholinergic Ligand Interactions*. New York, Academic Press, 1971, pp. 87–89.

because of the large size of at least one molecule. For the first time, the conformation of a neurotransmitter has been determined for a molecule in the bound state. ACh is transformed from the gauche conformation in the free state to a nearly *trans* conformation when bound to the nicotinic receptor.³² The active conformation of muscarinic agonists on their receptor has a dihedral angle of τ_2 between 110° and 117° .³³

The parasympathomimetic effects of muscarine were first reported in 1869,³⁴ but its structure was not elucidated until 1957.³⁵ Muscarine has four geometric isomers: muscarine, epimuscarine, allomuscarine, and epiallomuscarine (Fig. 17.10). None has a center or plane of symmetry. Each geometric isomer can exist as an enantiomeric pair. The activity of muscarine, a nonselective muscarinic receptor agonist, resides primarily in the naturally occurring (+)-muscarine enantiomer.

It is essentially free of nicotinic activity and apparently has the optimal stereochemistry to act on the muscarinic receptor subtypes. Synthetic molecules with a substituent on the carbon atom that corresponds to the β carbon of ACh also show great differences in muscarinic activity between their isomers. Acetyl-(+)-(*S*)- β -methylcholine, (+)-*cis*-(2*S*)-methyl-(4*R*)-trimethylammonium-1,3-dioxolane, (+)-*trans*-(1*S*,2*S*)-acetoxy-cyclopropyltrimethylammonium, and naturally occurring (+)-2*S*,3*R*,5*S*-muscarine are more potent than their enantiomers and have very high ratios of activity between the (*S*)- and (*R*)-isomer (Table 17.3). A similar observation may be made of (+)-acetyl-(*S*)- β -methylcholine, (+)-*cis*-(2*S*)-methyl-(4*R*)-trimethylammonium-1,3-dioxolane, and (+)-*trans*-(1*S*,2*S*)-acetoxy-cyclopropyltrimethylammonium, all of

which have an (*S*) configuration at the carbon atom that corresponds to the β carbon of ACh. Each of these active muscarinic molecules may be deployed on the receptor in the same manner as ACh and (+)-muscarine. Their (*S*)/(*R*) ratios (Table 17.3) show the greatest stereoselectivity of the muscarinic receptor in guinea pig ileum for the configuration at the carbon adjacent to the ester group. In contrast, the nicotinic receptors are not considered as highly stereoselective as their muscarinic counterparts.

Structure–Activity Relationships

Although muscarinic receptors have been cloned and the amino acid sequences are known, their three-dimensional structures remain unresolved. Thus, it is not possible to use this information alone to design specific drug molecules. Scientists still use pharmacological and biochemical tests to determine optimal structural requirements for activity. ACh is a relatively simple molecule. The chemistry and ease of testing for ACh biological activity have allowed numerous chemical derivatives to be made and studied. Alterations on the molecule may be divided into three categories: the onium group, the ester function, and the choline moiety.

The onium group is essential for intrinsic activity and contributes to the affinity of the molecule for the receptors, partially through the binding energy and partially because of its action as a detecting and directing group. Molecular modeling data show the binding site to be a negatively charged aspartic acid residue in the third of the seven transmembrane helices of the muscarinic receptor.³⁶ Hydrophobic pockets are located in helices 4, 5, 6, and 7 of the muscarinic receptor (Fig. 17.11).³⁷ The trimethylammonium group is the optimal functional moiety for activity, although some significant exceptions are known (e.g., pilocarpine, arecoline, nicotine, and oxotremorine). Phosphonium, sulfonium, arsenonium isosteres, or substituents larger than methyl on the nitrogen increase the size of the onium moiety, produce diffusion of the positive charge, and interfere sterically with proper drug–receptor interaction, resulting in decreased activity (Table 17.4).

The ester group in ACh contributes to the binding of the compound to the muscarinic receptor because of hydrogen bond formation with threonine and asparagine residues at

^aReduces effect of acetylcholine.

the receptor site. A comparison of the cholinergic activity of a series of alkyltrimethylammonium compounds [R-N⁺(CH₃), R = C₁–C₉] shows *n*-amyltrimethylammonium,³⁸ which may be considered to have a size and mass similar to those of ACh and to be one magnitude weaker as a muscarinic agonist. The presence of the acetyl group in ACh is not as critical as the size of the molecule. Studying a series of *n*-alkyltrimethylammonium salts revealed³⁹ that for maximal muscarinic activity, the quaternary ammonium group should be followed by a chain of five atoms; this has been referred to as the *five-atom rule*.

Shortening or lengthening the chain of atoms that separates the ester group from the onium moiety reduces muscarinic activity. An α substitution on the choline moiety decreases both nicotinic and muscarinic activity, but muscarinic activity is decreased to a greater extent. Nicotinic activity is decreased to a greater degree by substitution on the β carbon. Therefore, acetyl α -methylcholine, although less potent than ACh, has more nicotinic than muscarinic activity, whereas acetyl- β -methylcholine (methacholine) exhibits more muscarinic than nicotinic activity. Hydrolysis by AChE is more affected by substitutions on the β than the α carbon. The hydrolysis rate of racemic acetyl β -methylacetylcholine is about 50% of that of ACh; racemic acetyl α -ACh is hydrolyzed about 90% as fast.

Oxotremorine. Oxotremorine [1-(*pyrrolidino*)-4-pyrrolidino-2-butyne] has been regarded as a CNS muscarinic stimulant. Its action on the brain produces tremors in experimental animals. It increases ACh brain levels in rats up to 40% and has been studied as a drug in the treatment of Alzheimer disease. Although earlier studies suggested that

Figure 17.12 • Comparison of the geometries of oxotremorine and muscarine.

this approach of elevating levels of ACh to treat Alzheimer disease is useful, this belief was highly disputed by many researchers. Nevertheless, oxotremorine, as a cholinergic agonist, facilitates memory storage.⁴⁰ These findings have served as important leads in the development of agents useful in treating Alzheimer disease. Although it possesses groups that do not occur in other highly active muscarinic agents, oxotremorine's *trans* conformation shows that distances between possible active centers correspond with (+)-muscarine (Fig. 17.12).⁴¹

Arecoline. Arecoline is an alkaloid obtained from the seeds of the betel nut (*Areca catechu*). For many years, natives of the East Indies have consumed the betel nut as a source of a euphoria-creating substance.

CHOLINERGIC RECEPTOR ANTAGONISTS

Characterization of muscarinic receptors can now be extended beyond the pharmacological observations on organ systems (e.g., smooth muscle, heart) to determine structure–activity relationships. Dissociation constants of antagonists from radioligand-binding experiments on the various muscarinic receptors have played a major role in identifying these receptors and the selectivity of antagonists to the five muscarinic receptor subtypes. Antagonists with high affinity for one receptor and a low affinity for the other four receptor types are very few, however, and many antagonists bind to several subtypes with equal affinity. M₁ receptors have been identified as those with high affinity for pirenzepine and low affinity for a compound such as AF-DX 116. Pirenzepine can distinguish between M₁ and M₂, M₃, or M₅ but has significant affinity for M₄ receptors. Himbacine can distinguish between M₁ and M₄ receptors. Methoctramine, a polymethylenetetramine, not only discriminates between M₁ and M₂ receptors but also has good selectivity for M₂ muscarinic receptors. M₂ receptors bind to AF-DX 116 and gallamine, a neuromuscular blocking agent. M₃ receptors have a high affinity for 4-diphenylacetoxy-*N*-methylpiperidine (4-DAMP) and hexahydrosiladifenidol (HHSiD) but

Figure 17.13 • Chemical structures of partially selective muscarinic antagonists.

also exhibit affinity for M_1 and M_2 receptors.²¹ Tropicamide has been reported to be a putative M_4 receptor antagonist. Figure 17.13 includes structures of some receptor subtype antagonists.

Products

Acetylcholine Chloride. ACh chloride exerts a powerful stimulant effect on the parasympathetic nervous system. Attempts have been made to use it as a cholinergic agent, but its duration of action is too short for sustained effects, because of rapid hydrolysis by esterases and lack of specificity when administered for systemic effects. It is a cardiac depressant and an effective vasodilator. Stimulation of the vagus and the parasympathetic nervous system produces a tonic action on smooth muscle and induces a flow from the salivary and lacrimal glands. Its cardiac-depressant effect results from (a) a negative chronotropic effect that causes a decrease in heart rate and (b) a negative inotropic action on heart muscle that produces a decrease in the force of myocardial contractions. The vasodilatory action of ACh is primarily on the arteries and the arterioles, with distinct effect on the peripheral vascular system. Bronchial constriction is a characteristic side effect when the drug is given systemically.

One of the most effective antagonists to the action of ACh is atropine, a nonselective muscarinic antagonist. Atropine blocks the depressant effect of ACh on cardiac muscle and its production of peripheral vasodilation (i.e., muscarinic effects) but does not affect the skeletal muscle contraction (i.e., nicotinic effect) produced.

ACh chloride is a hygroscopic powder that is available in an admixture with mannitol to be dissolved in sterile water for injection shortly before use. It is a short-acting miotic when introduced into the anterior chamber of the eye and is especially useful after cataract surgery during the placement of sutures. When applied topically to the eye, it has little therapeutic value because of poor corneal penetration and rapid hydrolysis by AChE.

Methacholine Chloride, United States Pharmacopeia (USP). Methacholine chloride, acetyl- β -methylcholine

chloride or (2-hydroxypropyl)trimethylammonium chloride acetate, is the acetyl ester of β -methylcholine. Unlike ACh, methacholine has sufficient stability in the body to give sustained parasympathetic stimulation. This action is accompanied by little (1/1,000 that of ACh) or no nicotinic effect.

Methacholine can exist as (*S*) and (*R*) enantiomers. Although the chemical is used as the racemic mixture, its muscarinic activity resides principally in the (*S*)-isomer. The (*S*)/(*R*) ratio of muscarinic potency for these enantiomers is 240:1.

(+)-Acetyl-(*S*)- β -methylcholine is hydrolyzed by AChE, whereas the (*R*)(-)-isomer is not. (-)-Acetyl-(*R*)- β -methylcholine is a weak competitive inhibitor (K_i , 4×10^{-4} M) of AChE obtained from the electric organ of the eel (*E. electricus*). The hydrolysis rate of the (*S*)(+)-isomer is about 54% that of ACh. This rate probably compensates for any decreased association (affinity) owing to the β -methyl group with the muscarinic receptor site and may account for the fact that ACh and (+)-acetyl- β -methylcholine have equimolar muscarinic potencies in vivo. (-)-Acetyl-(*R*)- β -methylcholine weakly inhibits AChE and slightly reinforces the muscarinic activity of the (*S*)(+)-isomer in the racemic mixture of acetyl- β -methylcholine.

In the hydrolysis of the acetyl α - and β -methylcholines, the greatest stereochemical inhibitory effects occur when the choline is substituted in the β -position. This also appears to be true of organophosphorous inhibitors. The (*R*)(-)- and (*S*)(+)-isomers of acetyl- α -methylcholine are hydrolyzed at 78% and 97% of the rate of ACh, respectively.

Methacholine chloride occurs as colorless or white crystals or as a white crystalline powder. It is odorless or has a slight odor and is very deliquescent. It is freely soluble in water, alcohol, or chloroform, and its aqueous solution is neutral to litmus and bitter. It is hydrolyzed rapidly in alkaline solutions. Solutions are relatively stable to heat and will keep for at least 2 or 3 weeks when refrigerated to delay growth of molds.

Carbachol. Choline chloride carbamate is nonspecific in its action on muscarinic receptor subtypes. The pharmacological activity of carbachol is similar to that of ACh. It is an ester of choline and thus possesses both muscarinic and nicotinic properties by cholinergic receptor stimulation. It can also act indirectly by promoting release of ACh and by its weak anticholinesterase activity. Carbachol forms a carbamyl ester in the active site of AChE, which is hydrolyzed more slowly than an acetyl ester. This slower hydrolysis rate reduces the amount of free enzyme and prolongs the duration of ACh in the synapse. Carbachol also stimulates the autonomic ganglia and causes contraction of skeletal muscle but differs from a true muscarinic agent in that it does not have cardiovascular activity despite the fact that it seems to affect M_2 receptors.⁴²

Carbachol is a miotic and has been used to reduce the intraocular tension of glaucoma when a response cannot be obtained with pilocarpine or neostigmine. Penetration of the cornea is poor but can be enhanced by the use of a wetting agent in the ophthalmic solution. In addition to its topical use for glaucoma, carbachol is used during ocular surgery, when a more prolonged miosis is required than can be obtained with ACh chloride.

Carbachol Chloride

Carbachol differs chemically from ACh in its stability to hydrolysis. The carbamyl group of carbachol decreases the electrophilicity of the carbonyl and, thus, can form resonance structures more easily than ACh can. The result is that carbachol is less susceptible to hydrolysis and, therefore, more stable in aqueous solutions.

Bethanechol Chloride, USP. Bethanechol, β -methylcholine chloride carbamate, (2-hydroxypropyl)trimethylammonium chloride carbamate, carbamylmethylcholine chloride (Urecholine), is nonspecific in its action on muscarinic receptor subtypes but appears to be more effective at eliciting pharmacological action of M_3 receptors.⁴³ It has pharmacological properties similar to those of methacholine. Both are esters of β -methylcholine and have feeble nicotinic activity. Bethanechol is inactivated more slowly by AChE in vivo than is methacholine. It is a carbamyl ester and is expected to have stability in aqueous solutions similar to that of carbachol.

The main use of bethanechol chloride is in the relief of urinary retention and abdominal distention after surgery. The drug is used orally and by subcutaneous injection. It must never be administered by intramuscular or intravenous injection because of the danger from cholinergic overstimulation and loss of selective action. Proper administration of the drug is associated with low toxicity and no serious side effects. Bethanechol chloride should be used with caution in asthmatic patients; when used for glaucoma, it produces frontal headaches from the constriction of the sphincter muscle in the eye and from ciliary muscle spasms. Its duration of action is 1 hour.

Bethanechol Chloride

Pilocarpine Hydrochloride, USP. Pilocarpine monohydrochloride is the hydrochloride of an alkaloid obtained from the dried leaflets of *Pilocarpus jaborandi* or *P. microphyllus*, in which it occurs to the extent of about 0.5% together with other alkaloids.

Pilocarpine Hydrochloride

It occurs as colorless, translucent, odorless, faintly bitter crystals that are soluble in water (1:0.3), alcohol (1:3), and chloroform (1:360). (In this chapter, a solubility expressed as 1:360 indicates that 1 g is soluble in 360 mL of the solvent at 25°C. Solubilities at other temperatures are so indicated.) It is hygroscopic and affected by light; its solutions are acid to litmus and may be sterilized by autoclaving. Alkalies saponify the lactone group to give the pharmacologically inactive hydroxy acid (pilocarpic acid). Base-catalyzed epimerization at the ethyl group position occurs to an appreciable extent and is another major pathway of degradation.⁴⁴ Both routes result in loss of pharmacological activity.

Pilocarpine is a nonselective agonist on the muscarinic receptors. Despite this, it reportedly acts on M₃ receptors in smooth muscle to cause contractions in the gut, trachea, and eye.^{45,46} In the eye, it produces pupillary constriction (miosis) and a spasm of accommodation. These effects are valuable in the treatment of glaucoma. The pupil constriction and spasm of the ciliary muscle reduce intraocular tension by establishing better drainage of ocular fluid through the canal of Schlemm, located near the corner of the iris and cornea. Pilocarpine is used as a 0.5% to 0.6% solution (i.e., of the salts) in treating glaucoma. Systemic effects include copious sweating, salivation, and gastric secretion.

Pilocarpine Nitrate, USP. Pilocarpine mononitrate occurs as shining white crystals that are not hygroscopic but are light sensitive. It is soluble in water (1:4) and alcohol (1:75) but insoluble in chloroform and ether. Aqueous solutions are slightly acid to litmus and may be sterilized in the autoclave. The alkaloid is incompatible with alkalies, iodides, silver nitrate, and reagents that precipitate alkaloids.

Cevimeline Hydrochloride. Cevimeline (Evoxac) is *cis*-2'-methylspiro {1-azabicyclo [2.2.2] octane-3, 5' -[1,3] oxathiolane} hydrochloride, hydrate (2:1). Cevimeline has a molecular weight of 244.79 and is a white to off white crystalline powder. It is freely soluble in alcohol, chloroform, and water. Cevimeline is a cholinergic agonist which binds to the M₃ muscarinic receptor subtype, which results in an increase secretion of exocrine glands, such as salivary and sweat glands. Because of these effects, it was approved for use in the treatment of dry mouth associated with Sjögren syndrome. By stimulating the salivary muscarinic receptors cevimeline promotes secretion thereby alleviating dry-mouth in these patients. Cevimeline is metabolized by the isozymes CYP2D6 and CYP3A3 and CYP3A4. It has a half-life of 5 hours.⁴⁷

Cholinesterase Inhibitors

There are two types of cholinesterases in humans, AChE and butyrylcholinesterase (BuChE). The cholinesterases differ in their location in the body and their substrate specificity. AChE is associated with the outside surface of glial cells in the synapse and catalyzes the hydrolysis of ACh to choline and acetic acid. Inhibition of AChE prolongs the duration of the neurotransmitter in the junction and produces pharmacological effects similar to those observed when ACh is administered. These inhibitors are indirect-acting cholinergic agonists. AChE inhibitors have been used in the treatment of myasthenia gravis, atony in the GI tract, and glaucoma. They have also been used as agricultural insecticides and nerve gases. More recently, they have received attention as symptomatic drug treatments in patients suffering from Alzheimer disease.⁴⁸

BuChE (pseudocholinesterase) is located in human plasma. Although its biological function is not clear, it has catalytic properties similar to those of AChE. The substrate specificity is broader (Table 17.5), and it may hydrolyze dietary esters and drug molecules in the blood.

Three different chemical groupings, acetyl, carbamyl, and phosphoryl, may react with the esteratic site of AChE. Although the chemical reactions are similar, the kinetic parameters for each type of substrate differ and result in differences between toxicity and usefulness.

The initial step in the hydrolysis of ACh by AChE is a reversible enzyme-substrate complex formation. The association rate (k_{+1}) and dissociation rate (k_{-1}) are relatively large. The enzyme-substrate complex, E_A-ACh, may also

TABLE 17.5 Hydrolysis of Various Substrates by AChE and BuChE

^aRelative rates at approximately optimal substrate concentration; rate with acetylcholine = 100.

where CX = carbamylating substrate

form an acetyl-enzyme intermediate at a rate (k_2) that is slower than either the association or dissociation rates. Choline is released from this complex with the formation of the acetyl-enzyme intermediate, EA. This intermediate is then hydrolyzed to regenerate the free enzyme and acetic acid. The acetylation rate, k_2 , is the slowest step in this sequence and is rate-limiting (see discussion that follow).

Kinetic studies with different substrates and inhibitors suggest that the active center of AChE consists of several major domains: an anionic site, to which the trimethylammonium group binds; an esteratic site, which causes hydrolysis of the ester portion of ACh; and hydrophobic sites, which bind aryl substrates, other uncharged ligands, and the alkyl portion of the acyl moiety of ACh. There is also a peripheral anionic site, removed by at least 20 Å from this active center, which allosterically regulates activity at the esteratic site.⁴⁹ The anionic site was believed to have been formed by the γ -carboxylate group of a glutamic acid residue,⁵⁰ but more recent studies suggest that the aromatic moieties of tryptophan and phenylalanine residues bind the quaternary ammonium group of ACh in the anionic site through cation- π interactions.⁵¹ The location and spatial organization in the esteratic site by serine, histidine, and glutamic acid residues constitute the esteratic site. The triad of these amino acid residues contributes to the high catalytic efficiency of AChE (Fig. 17.14).⁵²

AChE attacks the ester substrate through a serine hydroxyl, forming a covalent acyl-enzyme complex. The serine is activated as a nucleophile by the glutamic acid and histidine residues that serve as the proton sink to attack the carbonyl carbon of ACh. Choline is released, leaving the acetylated serine residue on the enzyme. The acetyl-enzyme

intermediate is cleaved by a general base catalysis mechanism to regenerate the free enzyme. The rate of the deacetylation step is indicated by k_3 .

Carbamates such as carbachol are also able to serve as substrates for AChE, forming a carbamylated enzyme intermediate (E-C). The rate of carbamylation (k_2) is slower than the rate of acetylation. Hydrolysis (k_3 , decarbamylation) of the carbamyl-enzyme intermediate is 10^7 times slower than that of its acetyl counterpart. The slower hydrolysis rate limits the optimal functional capacity of AChE, allowing carbamate substrates to be semireversible inhibitors of AChE.

In the mechanism above, k_3 is rate-limiting. The rate k_2 depends not only on the nature of the

alcohol moiety of the ester but also on the type of carbamyl ester. Esters of carbamic acid are better

carbamylating agents of AChE than the methylcarbamyl

and dimethylcarbamyl analogs.⁵³

where PX = phosphorylating substrate

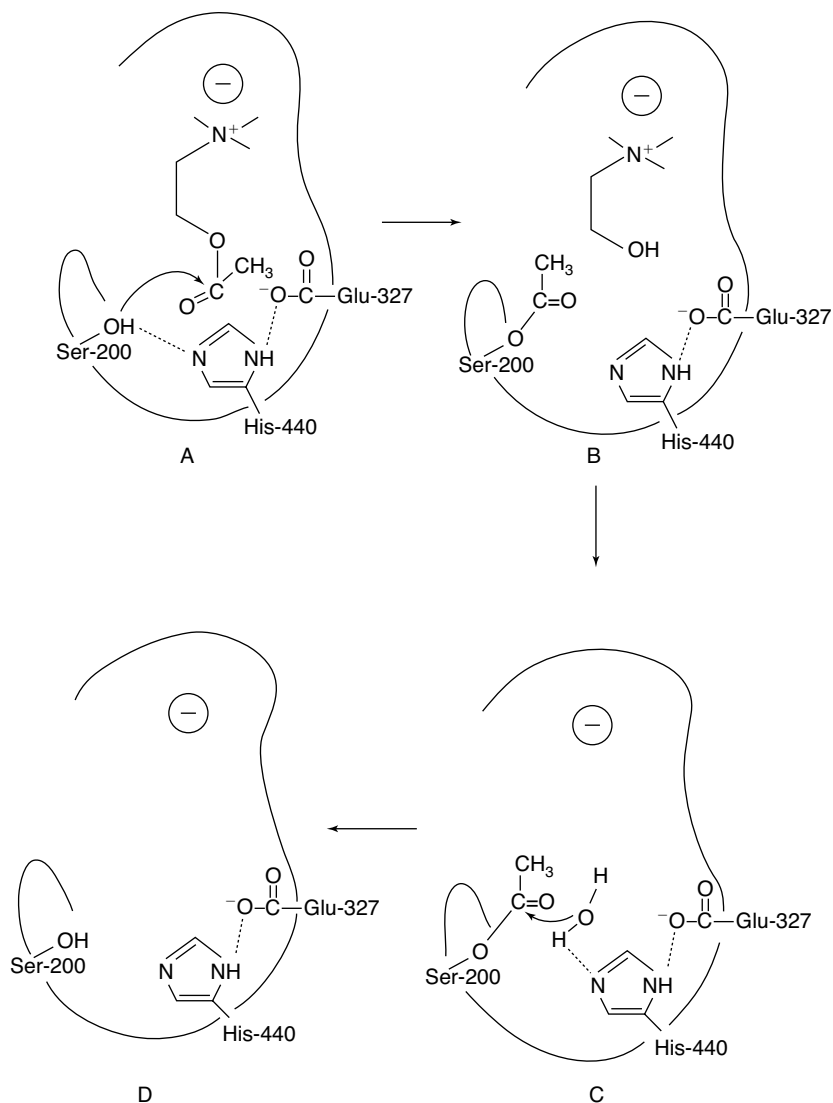

Figure 17.14 • Mechanism of hydrolysis of ACh by AChE. **A.** ACh–AChE reversible complex. **B.** Acetylation of esteratic site. **C.** General base-catalyzed hydrolysis of acetylated enzyme. **D.** Free enzyme.

Organophosphate esters of selected compounds can also esterify the serine residue in the active site of AChE. The hydrolysis rate (k_3) of the phosphorylated serine is extremely slow, and hydrolysis to the free enzyme and phosphoric acid derivative is so limited that the inhibition is

considered irreversible. These organophosphorous compounds are used in the treatment of glaucoma, as agricultural insecticides, and, at times, as nerve gases in warfare and bioterrorism. Finally, some have either been or are currently being evaluated for use against Alzheimer disease. Table 17.6 shows the relative potencies of several AChE inhibitors.

Reversible Inhibitors

Physostigmine, USP. Physostigmine is an alkaloid obtained from the dried ripe seed of *Physostigma venenosum*. It occurs as a white, odorless, microcrystalline powder that is slightly soluble in water and freely soluble in alcohol, chloroform, and the fixed oils. The alkaloid, as the free base, is quite sensitive to heat, light, moisture, and bases, undergoing rapid decomposition. In solution, it is hydrolyzed to methyl carbamic acid and eseroline, neither of which inhibits AChE. Eseroline is oxidized to a red compound, rubreserine,⁵⁴ and then further decomposed to eserine blue and eserine brown. Addition of sulfite or ascorbic acid prevents oxidation of the phenol, eseroline, to rubreserine. Hydrolysis does take place, however, and the physostigmine is inactivated. Solutions are most stable at pH 6 and should never be sterilized by heat.

Physostigmine is a relatively poor carbamylating agent of AChE and is often considered a reversible inhibitor of the enzyme. Its cholinesterase-inhibiting properties vary with the pH of the medium (Fig. 17.15). The conjugate acid of physostigmine has a pK_a of about 8, and as the pH of the solution is lowered, more is present in the protonated form. Inhibition of cholinesterase is greater in acid media, suggesting that the protonated form makes a contribution to the inhibitory activity well as its carbamylation of the enzyme.

Physostigmine was used first as a topical application in the treatment of glaucoma. Its lipid solubility properties permit adequate absorption from ointment bases. It is used systemically as an antidote for atropine poisoning and other anticholinergic drugs by increasing the duration of action of ACh at cholinergic sites through inhibition of AChE. Physostigmine, along with other cholinomimetic drugs acting in the CNS, has been studied for use in the treatment of Alzheimer disease.⁵⁵ Cholinomimetics that are currently used or which have been recently evaluated in the treatment of Alzheimer disease include donepezil, galantamine, metrifonate, rivastigmine, and tacrine.⁴⁸ It is anticipated that this list will continue to grow as the etiology of this disease becomes better understood.

Physostigmine Salicylate, USP. The salicylate of physostigmine (eserine salicylate) may be prepared by neutralizing an ethereal solution of the alkaloid with an ethereal solution of salicylic acid. Excess salicylic acid is removed from the precipitated product by washing it with ether. The salicylate is less deliquescent than the sulfate.

Physostigmine salicylate occurs as a white, shining, odorless crystal or white powder that is soluble in water (1:75), alcohol (1:16), or chloroform (1:6) but much less soluble in ether (1:250). On prolonged exposure to air and light, the crystals turn red. The red may be removed by washing the crystals with alcohol, although this causes loss of the compound as well. Aqueous solutions are neutral or slightly acidic and take on a red coloration after a period. The coloration may be taken as an index of the loss of activity of physostigmine solutions.

Figure 17.15 • Effect of pH on inhibition of cholinesterase by physostigmine and neostigmine.

Neostigmine Bromide

Solutions of physostigmine salicylate are incompatible with the usual reagents that precipitate alkaloids (alkalies) and with iron salts. Incompatibility also occurs with benzalkonium chloride and related wetting agents because of the salicylate ion.

Physostigmine Sulfate, USP. Physostigmine sulfate occurs as a white, odorless, microcrystalline powder that is deliquescent in moist air. It is soluble in water (1:4), alcohol (1:0.4), and ether (1:1,200). It has the advantage over the salicylate salt of being compatible in solution with benzalkonium chloride and related compounds.

Neostigmine Bromide. Neostigmine bromide, (*m*-hydroxyphenyl)trimethylammonium bromide dimethylcarbamate or the dimethylcarbamate ester of 3-hydroxyphenyltrimethylammonium bromide (Prostigmin bromide), is used as an antidote to nondepolarizing neuromuscular blocking drugs and in the treatment of myasthenia gravis. It occurs as a bitter, odorless, white, crystalline powder. It is soluble in water and alcohol. The crystals are much less hygroscopic than those of neostigmine methylsulfate and thus may be used in tablets. Solutions are stable and may be sterilized by boiling. Aqueous solutions are neutral to litmus.

Neostigmine Methylsulfate

Use of physostigmine, as a prototype of an indirect-acting parasympathomimetic drug, facilitated the development of stigmine, in which a trimethylamine group was placed *para* to a dimethylcarbamate group in benzene. Better inhibition of cholinesterase was observed when these groups were placed *meta* to each other as in neostigmine, a more active and useful agent. Although physostigmine contains a methylcarbamate functional group, greater chemical stability toward hydrolysis was obtained with the dimethylcarbamyl group in neostigmine.⁵⁶

Neostigmine has a half-life of about 50 minutes after oral or intravenous administration. About 80% of a single intramuscular dose is excreted in the urine within 24 hours; approximately 40% is excreted unchanged, and the remainder is excreted as metabolites. Of the neostigmine that reaches the liver, 98% is metabolized in 10 minutes to 3-hydroxyphenyltrimethyl ammonium, which has activity similar to, but weaker than, neostigmine. Its transfer from plasma to liver cells and then to bile is probably passive. Because cellular membranes permit the passage of plasma proteins synthesized in the liver into the bloodstream through capillary walls or lymphatic vessels, they may not present a barrier to the diffusion of quaternary amines such as neostigmine. The rapid hepatic metabolism of neostigmine may provide a downhill gradient for the continual diffusion of this compound.⁵⁷ A certain amount is hydrolyzed slowly by plasma cholinesterase.

Neostigmine has a mechanism of action quite similar to that of physostigmine. It effectively inhibits cholinesterase at about 10^{-6} M concentration. Its activity does not vary with pH, and at all ranges it exhibits similar cationic properties (Fig. 17.15). Skeletal muscle is also stimulated by neostigmine, a property that physostigmine does not have.

The uses of neostigmine are similar to those of physostigmine but differ in exhibiting greater miotic activity, fewer and less unpleasant local and systemic manifestations, and greater chemical stability. The most frequent application of neostigmine is to prevent atony of the intestinal, skeletal, and bladder musculature. An important use is in the treatment of myasthenia gravis, a condition caused by an autoimmune mechanism that requires an increase in ACh concentration in the neuromuscular junction to sustain normal muscular activity.

Neostigmine Methylsulfate. Neostigmine methylsulfate, (*m*-hydroxyphenyl)trimethylammonium methylsulfate dimethylcarbamate or the dimethylcarbamate ester of 3-hydroxyphenyltrimethylammonium methylsulfate (Prostigmin methylsulfate), is a bitter, odorless, white, crystalline powder. It is very soluble in water and soluble in alcohol. Solutions are stable and can be sterilized by boiling. The compound is too hygroscopic for use in a solid form and thus is always used as an injection. Aqueous solutions are neutral to litmus.

Pyridostigmine Bromide

The methylsulfate salt is used postoperatively as a urinary stimulant and in the diagnosis and treatment of myasthenia gravis.

Pyridostigmine Bromide, USP. Pyridostigmine bromide, 3-hydroxy-1-methylpyridinium bromide dimethylcarbamate or pyridostigmine bromide (Mestinon), occurs as a white, hygroscopic, crystalline powder with an agreeable, characteristic odor. It is freely soluble in water, alcohol, and chloroform.

Ambenonium Chloride

Pyridostigmine bromide is about one fifth as toxic as neostigmine. It appears to function in a manner similar to that of neostigmine and is the most widely used anticholinesterase agent for treating myasthenia gravis. The liver enzymes and plasma cholinesterase metabolize the drug. The principal metabolite is 3-hydroxy-*N*-methylpyridinium. Orally administered pyridostigmine has a half-life of 90 minutes and a duration of action of between 3 and 6 hours.

Ambenonium Chloride. Ambenonium chloride, [oxalylbis(iminoethylene)]bis[*o*-chlorobenzyl]diethylammonium] dichloride (Mytelase chloride), is a white, odorless powder, soluble in water and alcohol, slightly soluble in chloroform, and practically insoluble in ether and acetone. Ambenonium chloride is used for the treatment of myasthenia gravis in patients who do not respond satisfactorily to neostigmine or pyridostigmine.

This drug acts by suppressing the activity of AChE. It possesses a relatively prolonged duration of action and causes fewer side effects in the GI tract than the other anticholinesterase agents. The dosage requirements vary considerably, and the dosage must be individualized according to the response and tolerance of the patient. Because of its quaternary ammonium structure, ambenonium chloride is absorbed poorly from the GI tract. In moderate doses, the drug does not cross the blood-brain barrier. Ambenonium chloride is not hydrolyzed by cholinesterases.

Demecarium Bromide, USP. Demecarium bromide, (*m*-hydroxyphenyl)trimethylammonium bromide, decamethylenebis[methylcarbamate] (Humorsol), is the diester of (*m*-hydroxyphenyl)trimethylammonium bromide with decamethylene-bis-(methylcarbamic acid) and thus is comparable to a bis-prostigmine molecule.

Edrophonium Chloride

It occurs as a slightly hygroscopic powder that is freely soluble in water or alcohol. Ophthalmic solutions of the drug have a pH of 5 to 7.5. Aqueous solutions are stable and may be sterilized by heat. Its efficacy and toxicity are comparable to those of other potent anticholinesterase inhibitor drugs. It is a long-acting miotic used to treat wide-angle glaucoma and accommodative esotropia. Maximal effect occurs hours after administration, and the effect may persist for days.

Demecarium Bromide

Donepezil

Donepezil. Donepezil, (\pm)-2,3-dihydro-5,6-dimethoxy-2-[[1-(phenylmethyl)-4-piperidinyl]methyl]-1*H*-inden-1-one (Aricept), commonly referred to in the literature as E2020, is a reversible inhibitor of AChE. It is indicated for the treatment of symptoms of mild-to-moderate Alzheimer disease. Donepezil is approximately 96% bound to plasma proteins, with an elimination half-life of 70 hours. It is metabolized principally by the 2D6 and 3A4 isozymes of the P450 system.

Edrophonium Chloride, USP. Edrophonium chloride, ethyl(*m*-hydroxyphenyl)dimethylammonium chloride (Tensilon), is a reversible anticholinesterase agent. It is bitter and very soluble in water and alcohol. Edrophonium chloride injection has a pH of 5.2 to 5.5. On parenteral administration, edrophonium has a more rapid onset and shorter duration of action than neostigmine, pyridostigmine, or ambenonium. It is a specific anticholinesterase agent and acts within 1 minute to alleviate overdose of *d*-tubocurarine, dimethyl *d*-tubocurarine, or gallamine triethiodide. The drug is also used to terminate the action of any one of these drugs when the physician so desires. It is of no value, however, in terminating the action of the depolarizing (i.e., noncompetitive) blocking agents, such as decamethonium and succinylcholine. In addition to inhibiting AChE, edrophonium chloride has a direct cholinomimetic effect on skeletal muscle, which is greater than that of most other anticholinesterase drugs.

Edrophonium chloride is structurally related to neostigmine methylsulfate and has been used as a potential diagnostic agent for myasthenia gravis. This is the only degenerative neuromuscular disease that can be temporarily improved by administration of an anticholinesterase agent. Edrophonium chloride brings about a rapid increase in muscle strength without significant side effects.

Galantamine. Galantamine, 4a,5,9,10,11,12-hexahydro-3-methoxy-11-methyl-6*H*-benzofuro-[3a,3,2,ef][2]-benzazepin-6-ol (Nivalin, Reminyl), is an alkaloid extracted from the tuberous plant *Leucojum aestivum* (L.) belonging to the Amaryllidaceae family and from the bulbs of the daffodil, *Narcissus pseudonarcissus*. It is a reversible cholinesterase inhibitor that appears to have no effect on butyrylcholinesterase. In addition, it acts at allosteric nicotinic sites, further enhancing its cholinergic activity. Galantamine undergoes slow and minor biotransformation with approximately 5% to 6% undergoing demethylation. It is primarily excreted in the urine.

Rivastigmine

Metrifonate. Metrifonate is an organophosphate that was originally developed to treat schistosomiasis under the trade name Bilarcil. It is an irreversible cholinesterase inhibitor with some selectivity for BuChE over AChE. It achieves sustained cholinesterase inhibition by its nonenzymatic metabolite dichlorvos (DDVP), a long-acting organophosphate. Its use in mild-to-moderate Alzheimer disease was suspended recently because of adverse effects experienced by several patients during the clinical evaluation of this product. Toxicity at the neuromuscular junction is probably attributable to the inhibition by the drug of neurotoxic esterase, a common feature of organophosphates.

Rivastigmine. Rivastigmine (Exelon, EA 713) is a pseudoirreversible noncompetitive carbamate inhibitor of AChE. Although the half-life is approximately 2 hours, the inhibitory properties of this agent last for 10 hours because of the slow dissociation of the drug from the enzyme. The Food and Drug Administration (FDA) approved its use in mild-to-moderate Alzheimer disease in April 2000. In July 2007, rivastigmine was granted approval for use in managing mild-to-moderate dementia associated with Parkinson disease.

Tacrine Hydrochloride

Tacrine Hydrochloride. Tacrine hydrochloride, 1,2,3,4-tetrahydro-9-aminoacridine hydrochloride (THA, Cognex), is a reversible cholinesterase inhibitor that has been used in the treatment of Alzheimer disease for several years. The drug has been used to increase the levels of ACh in these patients on the basis of observations from autopsies that concentrations of ChAT and AChE are markedly reduced in the brain, whereas the number of muscarinic receptors is almost normal. The use of the drug is not without controversy, as conflicting results on efficacy have been reported.^{58,59} The drug has been used in mild-to-moderate Alzheimer dementia.

Irreversible Inhibitors

Both AChE and BuChE are inhibited irreversibly by a group of phosphate esters that are highly toxic (LD_{50} for humans is 0.1–0.001 mg/kg). These chemicals are nerve poisons and have been used in warfare, in bioterrorism, and as agricultural insecticides. They permit ACh to accumulate at nerve endings and exacerbate ACh-like actions. The compounds belong to a class of organophosphorous esters. A general formula for such compounds follows:

Sarín

A is usually oxygen or sulfur but may also be selenium. When A is other than oxygen, biological activation is required before the compound becomes effective as an inhibitor of cholinesterases. Phosphorothionates [$R_1R_2P(S)X$] have much poorer electrophilic character than their oxygen

analogues and are much weaker hydrogen bond-forming molecules because of the sulfur atom.⁶⁰ Their anticholinesterase activity is 10^5 -fold weaker than their oxygen analogues. X is the leaving group when the molecule reacts with the enzyme. Typical leaving groups include fluoride, nitrile, and *p*-nitrophenoxy. The R groups may be alkyl, alkoxy, aryl, aryloxy, or amino. The R moiety imparts lipophilicity to the molecule and contributes to its absorption through the skin. Inhibition of AChE by organophosphorous compounds takes place in two steps, association of enzyme and inhibitor and the phosphorylation step, completely analogous to acylation by the substrate (Fig. 17.16). Stereospecificity is mainly caused by interactions of enzyme and inhibitor at the esteratic site.

The serine residue at the esteratic site forms a stable phosphoryl ester with the organophosphorous inhibitors. This stability permits labeling studies⁶¹ to be carried out on this and other enzymes (e.g., trypsin, chymotrypsin) that have the serine hydroxyl as part of their active site.

Although insecticides and nerve gases are irreversible inhibitors of cholinesterases by forming a phosphorylated serine at the esteratic site of the enzyme, it is possible to reactivate the enzyme if action is taken soon after exposure to

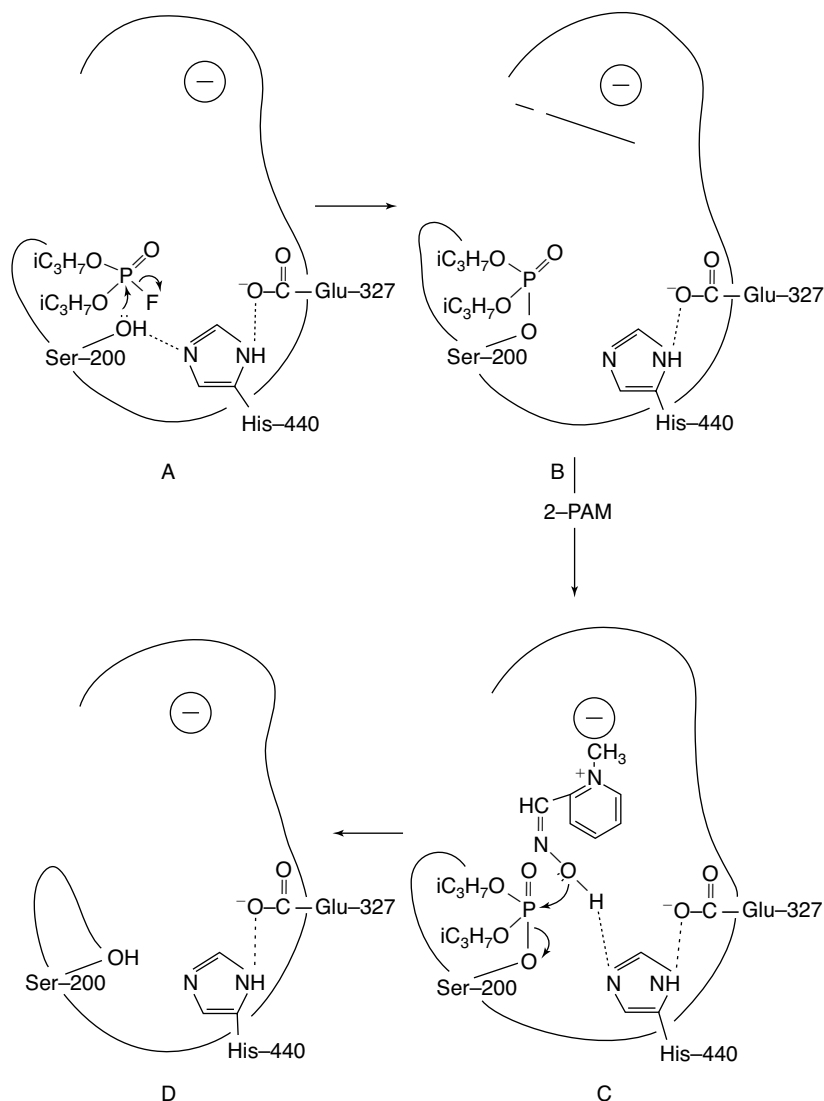

Figure 17.16 • Phosphorylation and reactivation of cholinesterase. **A.** Phosphorylation of serine by isofluorophosphate. **B.** Phosphorylated serine at the esteratic site. **C.** Nucleophilic attack on phosphorylated residue by 2-PAM. **D.** Free enzyme.

Figure 17.17 • Aging of phosphorylated enzyme.

these poisons. Several compounds can provide a nucleophilic attack on the phosphorylated enzyme and cause regeneration of the free enzyme. Substances such as choline, hydroxylamine, and hydroxamic acid have led to the development of more effective cholinesterase reactivators, such as nicotinic hydroxamic acid and pyridine-2-aldoxime methiodide (2-PAM). A proposed mode of action for the reactivation of cholinesterase that has been inactivated by isofluorophate by 2-PAM is shown in Figure 17.16.

Cholinesterases that have been exposed to phosphorylating agents (e.g., sarin) become refractory to reactivation by cholinesterase reactivators. The process is called *aging* and occurs both in vivo and in vitro with AChE and BuChE. Aging occurs by partial hydrolysis of the phosphorylated moiety that is attached to the serine residue at the esteratic site of the enzyme (Fig. 17.17).

Phosphate esters used as insecticidal agents are toxic and must be handled with extreme caution. Symptoms of toxicity are nausea, vomiting, excessive sweating, salivation, miosis, bradycardia, low blood pressure, and respiratory difficulty, which is the usual cause of death.

The organophosphate insecticides of low toxicity, such as malathion, generally cause poisoning only by ingestion of relatively large doses. Parathion or methylparathion, however, cause poisoning by inhalation or dermal absorption. Because these compounds are so long acting, cumulative and serious toxic manifestations may result after several small exposures.

Isofluorophate

Products

Isofluorophate, USP. Isofluorophate, diisopropylphosphorofluoridate (Floropryl), is a colorless liquid soluble in water to the extent of 1.54% at 25°C, which decomposes to give a pH of 2.5. It is soluble in alcohol and to some extent in peanut oil. It is stable in peanut oil for a period of 1 year but decomposes in water in a few days. Solutions in peanut oil can be sterilized by autoclaving. The compound should be stored in hard glass containers. Continued contact with soft glass is said to hasten decomposition, as evidenced by discoloration.

Echothiophate Iodide

Isofluorophate must be handled with extreme caution. Contact with eyes, nose, mouth, and even skin should be avoided because it can be absorbed readily through intact epidermis and more so through mucous tissues.

Because isofluorophate irreversibly⁶² inhibits cholinesterase, its activity lasts for days or even weeks. During this period, new cholinesterase may be synthesized in plasma, erythrocytes, and other cells.

A combination of atropine sulfate and magnesium sulfate protects rabbits against the toxic effects of isofluorophate. Atropine sulfate counteracts the muscarinic effect, and magnesium sulfate counteracts the nicotinic effect of the drug.⁶³ Isofluorophate has been used in the treatment of glaucoma.

Echothiophate Iodide, USP. Echothiophate iodide, (2-mercaptoethyl)trimethylammonium iodide, *S*-ester with *O,O*-diethylphosphorothioate (Phospholine Iodide), occurs as a white, crystalline, hygroscopic solid that has a slight mercaptan-like odor. It is soluble in water (1:1) and dehydrated alcohol (1:25); aqueous solutions have a pH of about 4 and are stable at room temperature for about 1 month.

Tetraethylpyrophosphate

Echothiophate iodide is a long-lasting cholinesterase inhibitor of the irreversible type, as is isofluorophate. Unlike the latter, however, it is a quaternary salt, and when applied locally, its distribution in tissues is limited, which can be very desirable. It is used as a long-acting anticholinesterase agent in the treatment of glaucoma.

Hexaethyltetraphosphate (HETP) and Tetraethylpyrophosphate (TEPP). HETP and TEPP are compounds that also show anticholinesterase activity. HETP was developed by the Germans during World War II and is used as an insecticide against aphids. When used as insecticides, these compounds have the advantage of being hydrolyzed rapidly to the relatively nontoxic, water-soluble compounds phosphoric acid and ethyl alcohol. Fruit trees or vegetables sprayed with this type of compound retain no harmful residue after a period of a few days or weeks, depending on the weather conditions. Workers spraying with these agents should use extreme caution so that the vapors are not breathed and none of the vapor or liquid comes in contact with the eyes or skin.

Malathion. Malathion, 2-[(dimethoxyphosphinothioyl)thio]butanedioic acid diethyl ester, is a water-insoluble phosphodithioate ester that has been used as an agricultural insecticide. Malathion is a poor inhibitor of cholinesterases. Its effectiveness as a safe insecticide is a result of the different rates at which humans and insects metabolize the chemical. Microsomal oxidation, which causes desulfuration, occurs slowly to form the phosphothioate (malaoxon), which is 10,000 times more active than the phosphodithioate (malathion) as a cholinesterase inhibitor. Insects detoxify the phosphothioate by a phosphatase, forming dimethyl phosphorothioate, which is inactive as an inhibitor. Humans, however, can rapidly hydrolyze malathion by a

carboxylesterase enzyme, yielding malathion acid, a still poorer inhibitor of AChE. Phosphatases and carboxylesterases further metabolize malathion acid to dimethylphosphothioate. The metabolic reactions are shown in Figure 17.18.

Parathion. Parathion, *O,O*-diethyl *O-p*-nitrophenyl phosphorothioate (Thiophos), is a yellow liquid that is freely soluble in aromatic hydrocarbons, ethers, ketones, esters, and alcohols but practically insoluble in water, petroleum ether, kerosene, and the usual spray oils. It is decomposed at a pH above 7.5. Parathion is used as an agricultural insecticide. It is a relatively weak inhibitor of cholinesterase;

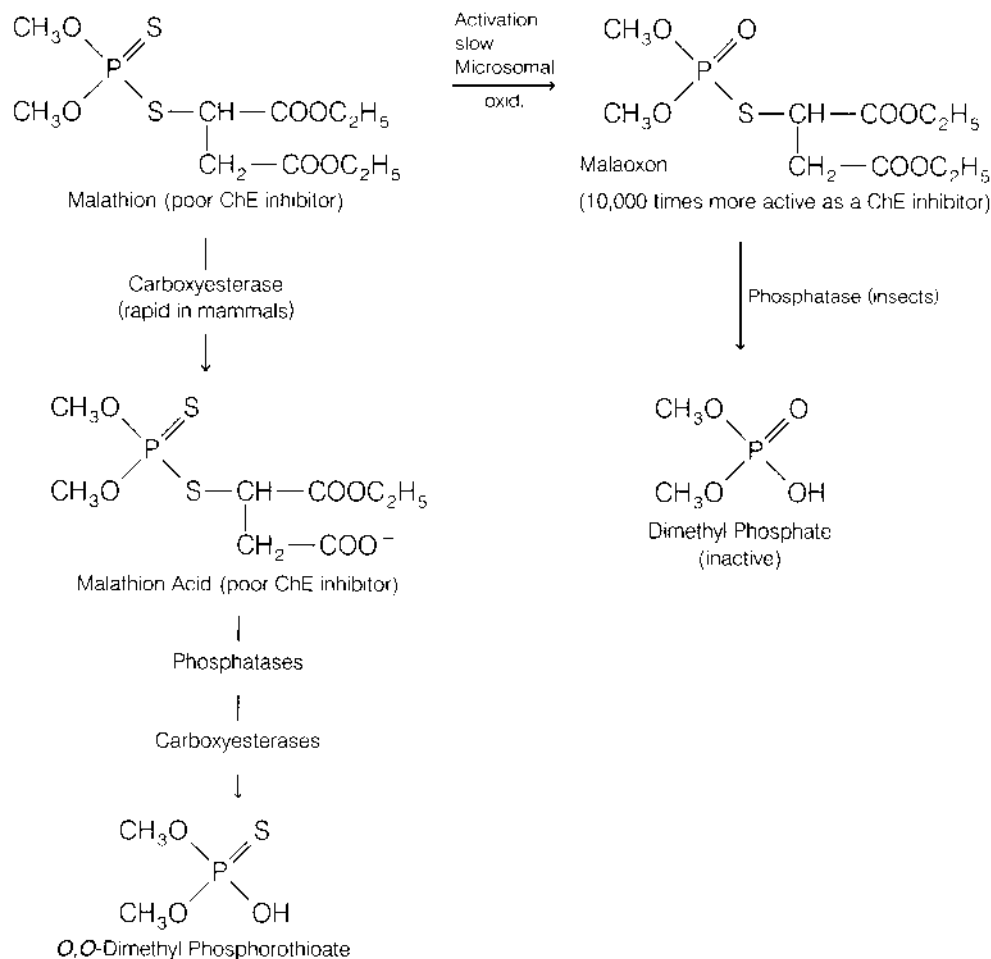

Figure 17.18 • Comparison of metabolism of malathion by mammals and insects.

however, enzymes present in liver microsomes and insect tissues convert parathion ($pI_{50} < 4$) to paraoxon, a more potent inhibitor of cholinesterase ($pI_{50} > 8$).⁶⁴ Parathion is also metabolized by liver microsomes to yield *p*-nitrophenol and diethylphosphate; the latter is inactive as an irreversible cholinesterase inhibitor.⁶⁵

Schradan. Schradan, octamethyl pyrophosphoramidate (OMPA), *bis*[bisdimethylaminophosphonous] anhydride (Pestox III), is a viscous liquid that is miscible with water and soluble in most organic solvents. It is not hydrolyzed by alkalis or water but is hydrolyzed by acids. Schradan is used as a systemic insecticide for plants, being absorbed by the plants without appreciable injury. Insects feeding on the plant are incapacitated.

Schradan is a weak inhibitor of cholinesterases *in vitro*. *In vivo*, it is metabolized to the very strong inhibitor hydroxymethyl OMPA. Hydroxymethyl OMPA is not stable and is metabolized further to the *N*-methoxide, which is a weak inhibitor of cholinesterase.⁶⁶

Pralidoxime Chloride, USP. Pralidoxime chloride, 2-formyl-1-methylpyridinium chloride oxime, 2-PAM chloride, or 2-pyridine aldoxime methyl chloride (Protopam chloride), is a white, nonhygroscopic, crystalline powder that is soluble in water, 1 g in less than 1 mL.

Pralidoxime chloride is used as an antidote for poisoning by parathion and related pesticides. It may be effective

against some phosphates that have a quaternary nitrogen. It is also an effective antagonist for some carbamates, such as neostigmine methylsulfate and pyridostigmine bromide. The mode of action of pralidoxime chloride is described in Figure 17.16.

Pralidoxime Chloride

The biological half-life of pralidoxime chloride in humans is about 2 hours, and its effectiveness is a function of

its concentration in plasma, which reaches a maximum 2 to 3 hours after oral administration.

Pralidoxime chloride, a quaternary ammonium compound, is most effective by intramuscular, subcutaneous, or intravenous administration. Treatment of poisoning by an anticholinesterase will be most effective if given within a few hours. Little will be accomplished if the drug is used more than 36 hours after parathion poisoning has occurred.

CHOLINERGIC BLOCKING AGENTS

A wide variety of tissues respond to ACh released by the neuron or exogenously administered chemicals to mimic this neurotransmitter's action. Peripheral cholinergic receptors are located at parasympathetic postganglionic nerve endings in smooth muscle, sympathetic and parasympathetic ganglia, and neuromuscular junctions in skeletal muscle. Although ACh activates these receptors, there are antagonists that are selective for each. Atropine is an effective blocking agent at parasympathetic postganglionic terminals. Like most classic blocking agents, it acts on all muscarinic receptor subtypes. *d*-Tubocurarine blocks the effect of ACh on skeletal muscle, which is activated by N₁ nicotinic receptors. Hexamethonium blocks transition at N₂ nicotinic receptors located in autonomic ganglia.

Anticholinergic action by drugs and chemicals apparently depends on their ability to reduce the number of free receptors that can interact with ACh. The theories of Stephenson⁶⁷ and Ariens⁶⁸ have explained the relationship between drug–receptor interactions and the observed biological response (see Chapter 2). These theories indicate that the amount of drug–receptor complex formed at a given time depends on the affinity of the drug for the receptor and that a drug that acts as an agonist must also possess another property, called *efficacy* or *intrinsic activity*. Another explanation of drug–receptor interactions, the Paton rate theory,⁶⁹ defines a biological stimulus as proportional to the rate of drug–receptor interactions (see Chapter 2). Both of these theories are compatible with the concept that a blocking agent that has high affinity for the receptor may decrease the number of available free receptors and the efficiency of the endogenous neurotransmitter.

Structure–Activity Relationships

A wide variety of compounds possess anticholinergic activity. The development of such compounds has been largely empiric and based principally on atropine as the prototype. Nevertheless, structural permutations have resulted in compounds that do not have obvious relationships to the parent molecule. The following classification delineates the major chemical types encountered:

- Solanaceous alkaloids and synthetic analogs
- Synthetic aminoalcohol esters
- Aminoalcohol ethers
- Aminoalcohols
- Aminoamides
- Miscellaneous
- Papaveraceous

The chemical classification of anticholinergics acting on parasympathetic postganglionic nerve endings is complicated somewhat because some agents, especially the quaternary ammonium derivatives, act on the ganglia that have a muscarinic component to their stimulation pattern and, at high doses, at the neuromuscular junction in skeletal muscle.

There are several ways in which the structure–activity relationship could be considered, but in this discussion we follow, in general, the considerations of Long et al.,⁷⁰ who based their postulations on the 1-hyoscyamine molecule being one of the most active anticholinergics and, therefore, having an optimal arrangement of groups.

Anticholinergic compounds may be considered chemicals that have some similarity to ACh but contain additional substituents that enhance their binding to the cholinergic receptor.

Benzilylcarbocholine

As depicted above, an anticholinergic agent may contain a quaternary ammonium function or a tertiary amine that is protonated in the biophase to form a cationic species. The nitrogen is separated from a pivotal carbon atom by a chain that may include an ester, ether, or hydrocarbon moiety. The substituent groups *A* and *B* contain at least one aromatic moiety capable of van der Waals interactions to the receptor surface and one cycloaliphatic or other hydrocarbon moiety for hydrophobic bonding interactions. *C* may be hydroxyl or carboxamide to undergo hydrogen bonding with the receptor.

THE CATIONIC HEAD

It is generally considered that the anticholinergic molecules have a primary point of attachment to cholinergic sites through the *cationic head* (i.e., the positively charged nitrogen). For quaternary ammonium compounds, there is no question of what is implied, but for tertiary amines, one assumes, with good reason, that the cationic head is achieved by protonation of the amine at physiological pH. The nature of the substituents on this cationic head is critical insofar as a parasympathomimetic response is concerned. Steric factors that cause diffusion of the onium charge or produce a less-than-optimal drug–receptor interaction result in a decrease of parasympathomimetic properties and allow the drug to act as an antagonist because of other bonding interactions. Ariens⁶⁸ has shown that carbocholines (e.g., benzilylcarbocholine) engage in a typical competitive action with ACh, although they are less effective than the corresponding compounds possessing a cationic head, suggesting

that hydrophobic bonding may play an important role in these drug-receptor interactions.

THE HYDROXYL GROUP

Although not requisite for activity, a suitably placed alcoholic hydroxyl group enhances antimuscarinic activity over that of a similar compound without the hydroxyl group. The position of the hydroxyl group relative to the nitrogen appears to be fairly critical, with the diameter of the receptive area estimated to be about 2 to 3 Å. It is assumed that the hydroxyl group contributes to the strength of binding, probably by hydrogen bonding to an electron-rich portion of the receptor surface.

THE ESTERIC GROUP

Many of the highly potent antimuscarinic compounds possess an ester grouping, and this may be a contributing feature for effective binding. This is reasonable because the agonist (i.e., ACh) possesses a similar function for binding to the same site. An esteric function is not necessary for activity, because several types of compounds do not possess such a group (e.g., ethers, aminoalcohols).

CYCLIC SUBSTITUTION

Examination of the active compounds discussed in the following sections reveals that at least one cyclic substituent

(phenyl, thienyl, or other) is a common feature in almost all anticholinergic molecules. Aromatic substitution is often used in connection with the acidic moiety of the ester function. Virtually all acids used, however, are of the aryl-substituted acetic acid variety. Use of aromatic acids leads to low activity of these compounds as anticholinergics but potential activity as local anesthetics.

In connection with the apparent need for a cyclic group, Ariens⁶⁸ points out that the “mimetic” molecules, richly endowed with polar groups, undoubtedly require a complementary polar receptor area for effective binding. As a consequence, it is implied that a relatively nonpolar area surrounds such sites. Thus, increasing the binding of the molecule in this peripheral area by introducing flat, nonpolar groups (e.g., aromatic rings) should achieve compounds with excellent affinity but without intrinsic activity. This postulate is consistent with most antimuscarinic drugs, whether they possess an ester group or not.

PARASYMPATHETIC POSTGANGLIONIC BLOCKING AGENTS

Parasympathetic postganglionic blocking agents are also known as antimuscarinic, anticholinergic, parasympatholytic, or cholinolytic drugs. Antimuscarinic drugs act by competitive antagonism of ACh binding to muscarinic receptors. Endogenous neurotransmitters, including ACh, are relatively small molecules. Ariens⁶⁸ noted that competitive reversible antagonists generally are larger molecules capable of additional binding to the receptor surface. The most potent anticholinergic drugs are derived from muscarinic agonists that contain one or sometimes two large or bulky groups. Ariens⁶⁸ suggested that molecules that act as competitive reversible antagonists generally are capable of binding to the active site of the receptor but have an additional binding interaction that increases receptor affinity but does not contribute to the intrinsic activity (efficacy) of the drug. Several three-dimensional models of G-protein-coupled receptors, including the muscarinic receptor, have been reported. Despite knowledge of their amino acid sequences, it is not yet possible to provide an unambiguous description of the docking of molecules to these receptors. The concepts of Ariens⁶⁸ and others, however, appear consistent with the binding site models proposed. Bebbington and Brimblecombe⁴¹ proposed in 1965 that there is a relatively large area lying outside the agonist–receptor binding site, where van der Waals interactions can take place between the agonist and the receptor area. This, too, is not inconsistent with contemporary theories on cholinergic receptor interaction with small molecules.

Therapeutic Actions

Organs controlled by the autonomic nervous system usually are innervated by both the sympathetic and the parasympathetic systems. There is a continual state of dynamic balance between the two systems. Theoretically, one should achieve the same end result by either stimulation of one of the systems or blockade of the other. Unfortunately, there is usually a limitation to this type of generalization. There are, however, three predictable and

clinically useful results from blocking the muscarinic effects of ACh.

1. *Mydriatic effect*: dilation of the pupil of the eye; and *cycloplegia*, a paralysis of the ciliary structure of the eye, resulting in a paralysis of accommodation for near vision
2. *Antispasmodic effect*: lowered tone and motility of the GI tract and the genitourinary tract
3. *Antisecretory effect*: reduced salivation (*antisialagogue*), reduced perspiration (*anhidrotic*), and reduced acid and gastric secretion

These three general effects of parasympatholytics can be expected in some degree from any of the known drugs, although, occasionally, one must administer rather heroic doses to demonstrate the effect. The mydriatic and cycloplegic effects, when produced by topical application, are not subject to any greatly undesirable side effects because of limited systemic absorption. This is not true for the systemic antispasmodic effects obtained by oral or parenteral administration. Drugs with effective blocking action on the GI tract are seldom free of adverse effects on the other organs. The same is probably true of drugs used for their antisecretory effects. Perhaps the most common side effects experienced from the oral use of these drugs, under ordinary conditions, are dryness of the mouth, mydriasis, and urinary retention. The latter effects have been exploited in the development of agents used to manage overactive bladder with symptoms of the urge of urinary incontinence, urgency, and frequency.

Mydriatic and cycloplegic drugs are generally prescribed or used in the office by ophthalmologists. Their principal use is for refraction studies in the process of fitting lenses. This permits the physician to examine the eye retina for possible abnormalities and diseases and provides controlled conditions for the proper fitting of glasses. Because of the inability of the iris to contract under the influence of these drugs, there is a definite danger to the patient’s eyes during the period of drug activity unless they are protected from strong light by the use of dark glasses. These drugs also are used to treat inflammation of the cornea (keratitis), inflammation of the iris and the ciliary organs (iritis and iridocyclitis), and inflammation of the choroid (choroiditis). A dark-colored iris appears to be more difficult to dilate than a light-colored one and may require more concentrated solutions. Caution in the use of mydriatics is advisable because of their demonstrated effect in raising the intraocular pressure. Pupil dilation tends to cause the iris to restrict drainage of fluid through the canal of Schlemm by crowding the angular space, thereby leading to increased intraocular pressure. This is particularly true for patients with glaucomatous conditions.

Atropine is used widely as an antispasmodic because of its marked depressant effect on parasympathetically innervated smooth muscle. It appears to block all muscarinic receptor subtypes. Atropine is, however, the standard by which other similar drugs are measured. Also, atropine has a blocking action on the transmission of the nerve impulse, rather than a depressant effect directly on the musculature. This action is termed *neurotropic*, in contrast with the action of an antispasmodic such as papaverine, which appears to act by depression of the muscle cells and is termed *musculotropic*.

Papaverine is the standard for comparison of muscurotropic antispasmodics and, although not strictly a parasympatholytic, is treated together with its synthetic analogs later in this chapter. The synthetic antispasmodics appear to combine neurotropic and musculotropic effects in greater or lesser measure, together with a certain amount of ganglion-blocking activity for the quaternary derivatives.

Anticholinergic drugs have a minor role in the management of peptic ulcer disease.⁷¹ For the present, the most rational therapy involving anticholinergic drugs seems to be a combination of a nonirritating diet to reduce acid secretion, antacid therapy, and reduction of emotional stress. Most of the anticholinergic drugs are offered either as the chemical alone, or in combination with a CNS depressant such as phenobarbital, or with a neuroleptic drug to reduce the CNS contribution to parasympathetic hyperactivity. In addition to the antisecretory effects of anticholinergics on hydrochloric acid and gastric acid secretion, there have been some efforts to use them as antisialagogues and anhidrotics.

Paralysis agitans or parkinsonism (Parkinson disease), first described by the English physician James Parkinson in 1817, is another condition that is often treated with anticholinergic drugs. It is characterized by tremor, "pill rolling," cogwheel rigidity, festinating gait, sialorrhea, and masklike facies. Fundamentally, it represents a malfunction of the extrapyramidal system. Parkinsonism is characterized by progressive and selective degeneration of dopaminergic neurons, which originate in the substantia nigra of the midbrain and terminate in the basal ganglia (i.e., caudate nucleus, putamen, and pallidum). Skeletal muscle movement is controlled to a great degree by patterns of excitation and inhibition resulting from the feedback of information to the cortex and mediated through the pyramidal and extrapyramidal pathways. The basal ganglia structures, such as the pallidum, corpus striatum, and substantia nigra, serve as data processors for the pyramidal pathways and the structures through which the extrapyramidal pathways pass on their way from the spinal cord to the cortex. Lesions of the pyramidal pathways lead to a persistent increase in muscle tone, resulting in an excess of spontaneous involuntary movements, along with changes in the reflexes. Thus, the basal ganglia are functional in maintaining normal motor control. In parkinsonism, there is degeneration of the substantia nigra and corpus striatum, which are involved with controlled integration of muscle movement. The neurons in the substantia nigra and basal ganglia use the neurotransmitter dopamine and interact with short cholinergic interneurons. When dopamine neurons degenerate, the balance between them is altered. The inhibitory influence of dopamine is reduced, and the activity of cholinergic neurons is increased. The principal goal of anticholinergic drugs in the treatment of parkinsonism is to decrease the activity of cholinergic neurons in the basal ganglia.

The usefulness of the belladonna group of alkaloids for the treatment of parkinsonism was an empiric discovery. Since then, chemists have prepared many synthetic analogs of atropine in an effort to retain the useful antitremor and antirigidity effects of the belladonna alkaloid while reducing the adverse effects. In this process, it was discovered that antihistamine drugs (e.g., diphenhydramine) reduced tremor and rigidity. The antiparkinsonian-like activity of

antihistamines has been attributed to their anticholinergic properties. The activity of these drugs is confined to those that can pass through the blood-brain barrier.

SOLANACEOUS ALKALOIDS AND ANALOGS

The solanaceous alkaloids, represented by (–)-hyoscyamine, atropine [(–)-hyoscyamine], and scopolamine (hyoscine), are the forerunners of the class of antimuscarinic drugs. These alkaloids are found principally in henbane (*Hyoscyamus niger*), deadly nightshade (*Atropa belladonna*), and jimson weed (*Datura stramonium*). There are other alkaloids that are members of the solanaceous group (e.g., apatropine, noratropine, belladonnine, tigloidine, meteloidine) but lack sufficient therapeutic value to be considered in this text.

Crude drugs containing these alkaloids have been used since early times for their marked medicinal properties, which largely depend on inhibition of the parasympathetic nervous system and stimulation of the higher nervous centers. Belladonna, probably as a consequence of the weak local anesthetic activity of atropine, has been used topically for its analgesic effect on hemorrhoids, certain skin infections, and various itching dermatoses. Application of sufficient amounts of belladonna or its alkaloids results in mydriasis. Internally, the drug causes diminution of secretions, increases the heart rate (by depression of the vagus nerve), depresses the motility of the GI tract, and acts as an antispasmodic on various smooth muscles (ureter, bladder, and biliary tract). In addition, it directly stimulates the respiratory center. The multiplicity of actions exerted by the drug is looked on with some disfavor, because the physician seeking one type of response unavoidably also obtains the others. The action of scopolamine-containing drugs differs from those containing hyoscyamine and atropine in having no CNS stimulation; rather, a narcotic or sedative effect predominates. The use of this group of drugs is accompanied by a fairly high incidence of reactions because of individual idiosyncrasies; death from overdosage usually results from respiratory failure. A complete treatment of the pharmacology and uses of these drugs is not within the scope of this text. The introductory pages of this chapter briefly review some of the more pertinent points in connection with the major activities of these drug types.

Structural Considerations

All of the solanaceous alkaloids are esters of the bicyclic aminoalcohol 3-hydroxytropine or of related aminoalcohols. The structural formulas that follow show the piperidine ring system in the commonly accepted chair conformation because this form has the lowest energy requirement. The alternate boat form can exist under certain conditions, however, because the energy barrier is not great. Inspection of the 3-hydroxytropine formula also indicates that even though there is no optical activity because of the plane of symmetry, two stereoisomeric forms (tropine and pseudotropine) can exist because of the rigidity imparted to the molecule through the ethylene chain across the 1,5 positions.

In tropine, the axially oriented hydroxyl group, *trans* to the nitrogen bridge, is designated α , and the alternate *cis* equatorially oriented hydroxyl group is designated β .

The aminoalcohol derived from scopolamine, namely scopine, has the axial orientation of the 3-hydroxyl group but, in addition, a β -oriented epoxy group bridged across the 6,7 positions, as shown. Of the several different solanaceous alkaloids known, it has been indicated that (–)-hyoscyamine, atropine, and scopolamine are the most important. Their structures are shown, but antimuscarinic activity is associated with all of the solanaceous alkaloids that possess the tropinelike axial orientation of the esterified hydroxyl group. Studying the formulas reveals that in each case tropic acid is the esterifying acid. Tropic acid contains an easily racemized asymmetric carbon atom, the moiety accounting for optical activity in these compounds in the absence of racemization. The proper enantiomorph is necessary for high-antimuscarinic activity, as illustrated by the potent (–)-hyoscyamine in comparison with the weakly active (+)-hyoscyamine. The racemate, atropine, has intermediate activity. The marked difference in antimuscarinic potency of the optical enantiomorphs apparently does not extend to the action on the CNS, inasmuch as both seem to have the same degree of activity.⁷²

The solanaceous alkaloids have been modified by preparing other esters of 3- α -tropanol or making a quaternary of the nitrogen in tropanol or scopine with a methyl halide. These compounds represent some of the initial attempts to separate the varied actions of atropine and scopolamine. Few aminoalcohols have been found that impart the same degree of neurotropic activity as that exhibited by the ester formed by combination of tropine with tropic acid. Similarly, the tropic acid portion is highly specific for the anticholinergic action, and substitution by other acids decreases neurotropic potency, although the musculotropic action may increase. The earliest attempts to modify the atropine molecule retained the tropine portion and substituted various acids for tropic acid.

Besides changing the acid residue, other changes have been directed toward the quaternization of the nitrogen. Examples of this type of compound are methscopolamine bromide, homatropine methylbromide, and anisotropine methylbromide. Quaternization of the tertiary amine produces variable effects in terms of increasing potency. Decreases in activity are apparent in comparing atropine with methylatropine (no longer used) and scopolamine with methscopolamine. Ariens et al.⁷³ ascribed decreased activity, especially when the groups attached to nitrogen are larger than methyl, to a possible decrease in affinity for the anionic site on the cholinergic receptor. They attributed this decreased affinity to a combination of greater electron repulsion by such groups and greater steric interference to the approach of the cationic head to the anionic site. In general, quaternization reduces parasympathomimetic action much more than parasympatholytic action. This may be partially a result of the additional blocking at the parasympathetic ganglion induced by quaternization, which could offset the decreased affinity at the postganglionic site. However, quaternization increases the curariform activity of these alkaloids and aminoesters, a usual consequence of quaternizing alkaloids. Another disadvantage in converting an alkaloidal base to the quaternary form is that the quaternized base is absorbed more poorly through the intestinal wall, so that the activity becomes erratic and, in some instances, unpredictable. Bases (such as alkaloids) are absorbed through the lipoidal gut wall only in the dissociated form, which can

be expected to exist for a tertiary base, in the small intestine. Quaternary nitrogen bases cannot revert to an undissociated form, even in basic media and, presumably, may have difficulty passing through the gut wall. Since quaternary compounds can be absorbed, other less efficient mechanisms for absorption probably prevail. Quaternary ammonium compounds combine reversibly with endogenous substances in the gut, such as mucin, to form neutral ion-pair complexes. These complexes penetrate the lipid membrane by passive diffusion.

Products

Atropine, USP. Atropine is the tropine ester of racemic tropic acid and is optically inactive. It possibly occurs naturally in various Solanaceae, although some claim, with justification, that whatever atropine is isolated from natural sources results from racemization of (–)-hyoscyamine during the isolation process. Conventional methods of alkaloid isolation are used to obtain a crude mixture of atropine and hyoscyamine from the plant material. This crude mixture is racemized to atropine by refluxing in chloroform or by treatment with cold dilute alkali. Because the racemization process makes atropine, an official limit is set on the hyoscyamine content by restricting atropine to a maximum levorotation under specified conditions.

Homatropine Hydrobromide

Atropine occurs in the form of optically inactive, white, odorless crystals possessing a bitter taste. It is not very soluble in water (1:460, 1:90 at 80°C) but is more soluble in alcohol (1:2, 1:1.2 at 60°C). It is soluble in glycerin (1:27), in chloroform (1:1), and in ether (1:25). Saturated aqueous solutions are alkaline in reaction (pH ~9.5). The free base is useful when nonaqueous solutions are to be made, such as in oily vehicles and ointment bases. Atropine has a plasma half-life of about 2 to 3 hours. It is metabolized in the liver to several products, including tropic acid and tropine.

Atropine Sulfate, USP. Atropine sulfate (Atropisol) is prepared by neutralizing atropine in acetone or ether solution with an alcoholic solution of sulfuric acid, with care used to prevent hydrolysis. The salt occurs as colorless crystals or as a white, crystalline powder. It is efflorescent in dry air and should be protected from light to prevent decomposition.

Atropine sulfate is freely soluble in water (1:0.5), in alcohol (1:5, 1:2.5 at boiling point), and in glycerin (1:2.5). Aqueous solutions are not very stable, although solutions may be sterilized at 120°C (15 lb pressure) in an autoclave

if the pH is kept below 6. Sterilization probably is best effected by the use of aseptic techniques and a bacteriological filter. It has been suggested that no more than a 30-day supply of an aqueous solution should be made and that for small quantities the best procedure is to use hypodermic tablets and sterile distilled water.⁷³ Kondritzer and Zvirblis⁷⁴ have studied the kinetics of alkaline and proton-catalyzed hydrolyses of atropine in aqueous solution. The region of maximal stability lies between pH 3 and approximately 5. They have also proposed an equation to predict the half-life of atropine undergoing hydrolysis at constant pH and temperature.

The action of atropine or its salts is the same. It produces a mydriatic effect by paralyzing the iris and the ciliary muscles and, for this reason, is used by the oculist in iritis and corneal inflammations and lesions. Its use is rational in these conditions because one of the first rules in the treatment of inflammation is rest, which, of course, is accomplished by the paralysis of muscular motion. Its use in the eye (0.5%–1% solutions or gelatin disks) for fitting glasses is widespread. Atropine is administered in small doses before general anesthesia to lessen oral and air passage secretions and, when administered with morphine, to lessen the respiratory depression induced by morphine.

Atropine causes restlessness, prolonged pupillary dilation, and loss of visual accommodation and, furthermore, gives rise to arrhythmias such as atrioventricular dissociation, ventricular extrasystoles, and even ventricular fibrillation. Even though ether has been gradually replaced by other anesthetics, thereby eliminating problems with respiratory secretions caused by ether and thus requiring atropine, surgeons and anesthesiologists today continue to use it as an anesthetic premedicant to reduce excessive salivary and airway secretions and to prevent vagal reflexes.

Its ability to dry secretions has also been used in the so-called rhinitis tablets for symptomatic relief in colds. In cathartic preparations, atropine or belladonna has been used as an antispasmodic to lessen the smooth muscle spasm (gripping) often associated with catharsis.

Atropine may be used to treat some types of arrhythmias. It increases the heart rate by blocking the effects of ACh on the vagus. In this context, it is used to treat certain reversible bradyarrhythmias that may accompany acute myocardial infarction. It is also used as an adjunct to anesthesia to protect against bradycardia, hypotension, and even cardiac arrest induced by the skeletal muscle relaxant succinylcholine chloride.

Another use for atropine sulfate emerged following the development of the organophosphates, which are potent inhibitors of AChE. Atropine is a specific antidote to prevent the muscarinic effects of ACh accumulation, such as vomiting, abdominal cramps, diarrhea, salivation, sweating, bronchoconstriction, and excessive bronchial secretions. It is used intravenously but does not protect against respiratory failure caused by depression of the respiratory center and the muscles of respiration.

Hyoscyamine, USP. Hyoscyamine is a levorotatory alkaloid obtained from various solanaceous species. One of the commercial sources is Egyptian henbane (*Hyoscyamus muticus*), in which it occurs to the extent of about 0.5%. Usually, it is prepared from the crude drug in a manner similar to that used for atropine and is purified as the oxalate. The free base is obtained easily from this salt.

It occurs as white needles that are sparingly soluble in water (1:281), more soluble in ether (1:69) or benzene (1:150), very soluble in chloroform (1:1), and freely soluble in alcohol. It is used as the sulfate and hydrobromide. The principal reason for the popularity of the hydrobromide has been its nondeliquescent nature. The salts have the advantage over the free base in being quite water soluble.

Hyoscyamine is the *levo* form of the racemic mixture known as atropine. The *dextro* form does not exist naturally but has been synthesized. Cushny⁷⁵ compared the activities of (–)-hyoscyamine, (+)-hyoscyamine, and the racemate (atropine) in 1904 and found greater peripheral potency for the (–) isomer and twice the potency of the racemate. All later studies have essentially confirmed that the (+) isomer is only weakly active and that the (–) isomer is, in effect, the active portion of atropine. Inspection of the relative doses of atropine sulfate and hyoscyamine sulfate illustrates the differences very nicely. The principal criticism offered against the use of hyoscyamine sulfate exclusively is that it tends to racemize to atropine sulfate rather easily in solution, so that atropine sulfate then becomes the more stable of the two. All of the isomers behave very much the same in the CNS.

Hyoscyamine is used to treat disorders of the urinary tract more so than any other antispasmodic, although there is no evidence that it has any advantages over the other belladonna preparations and the synthetic anticholinergics. It is used to treat spasms of the bladder and, in this manner, serves as a urinary stimulant. It is used together with a narcotic to counteract the spasm produced by the narcotic when the latter is used to relieve the pain of urethral colic. Hyoscyamine preparations are also used as antispasmodics in the therapy of peptic ulcers.

Hyoscyamine Sulfate, USP. Hyoscyamine sulfate (Levsin sulfate) is a white, odorless, crystalline compound of a deliquescent nature that also is affected by light. It is soluble in water (1:0.5) and alcohol (1:5) but almost insoluble in ether. Solutions of hyoscyamine sulfate are acidic to litmus.

This drug is used as an anticholinergic in the same manner and for the same indications as atropine and hyoscyamine, but it possesses the disadvantage of being deliquescent.

Scopolamine. Scopolamine (hyoscine) is found in various members of the Solanaceae (e.g., *H. niger*, *Duboisia myoporoides*, *Scopolia* spp., and *Datura metel*). Scopolamine usually is isolated from the mother liquor remaining from the isolation of hyoscyamine.

Hyoscine is the older name for this alkaloid, although *scopolamine* is the accepted name in the United States. Scopolamine is the *levo* component of the racemic mixture that is known as *atrosine*. The alkaloid is racemized readily in the presence of dilute alkali.

The alkaloid occurs in the form of a levorotatory, viscous liquid that is only slightly soluble in water but very soluble in alcohol, chloroform, or ether. It forms crystalline salts with most acids, with the hydrobromide being the most stable and the most popularly accepted. An aqueous solution of the hydrobromide containing 10% mannitol is said to be less prone to decomposition than unprotected solutions. The commercially available transdermal system of scopolamine comprises an outer layer of polymer film and a drug reservoir containing scopolamine, polyisobutylene, and mineral

oil, which is interfaced with a microporous membrane to control diffusion of the drug. In this dosage form, scopolamine is effective in preventing motion sickness. The action is believed to be on the cortex or the vestibular apparatus. Whereas atropine stimulates the CNS, causing restlessness and talkativeness, scopolamine usually acts as a CNS depressant.

Scopolamine Hydrobromide, USP. Scopolamine hydrobromide (hyoscine hydrobromide) occurs as white or colorless crystals or as a white, granular powder. It is odorless and tends to effloresce in dry air. It is freely soluble in water (1:1.5), soluble in alcohol (1:20), only slightly soluble in chloroform, and insoluble in ether.

Scopolamine is a competitive blocking agent of the parasympathetic nervous system as is atropine, but it differs markedly from atropine in its action on the higher nerve centers. Both drugs readily cross the blood-brain barrier and, even at therapeutic doses, cause confusion, particularly in the elderly.

A sufficiently large dose of scopolamine will cause an individual to sink into a restful, dreamless sleep for about 8 hours, followed by a period of approximately the same length in which the patient is in a semiconscious state. During this time, the patient does not remember events that take place. When scopolamine is administered with morphine, this temporary amnesia is termed *twilight sleep*.

Homatropine Hydrobromide, USP. Homatropine hydrobromide, 1 α H,5 α H-tropan-3 α -ol mandelate (ester) hydrobromide (Homatrocel), occurs as white crystals or as a white, crystalline powder that is affected by light. It is soluble in water (1:6) and alcohol (1:40), less soluble in chloroform (1:420), and insoluble in ether.

Solutions are incompatible with alkaline substances, which precipitate the free base, and with the common reagents that precipitate alkaloids. As with atropine, solutions are sterilized best by filtration through a bacteriological filter.

Homatropine Methylbromide

Homatropine hydrobromide is used topically to paralyze the ciliary structure of the eye (cycloplegia) and to effect mydriasis. It behaves very much like atropine but is weaker and less toxic. In the eye, it acts more rapidly but less persistently than atropine. Dilation of the pupil takes place in about 15 to 20 minutes, and the action subsides in about 24 hours. By using a miotic, such as physostigmine, it is possible to restore the pupil to normality in a few hours.

Homatropine Methylbromide, USP. Homatropine methylbromide, 3 α -hydroxy-8-methyl-1 α H,5 α H-tropanium bromide mandelate (Novatropine, Mesopin), occurs as a bitter, white, odorless powder and is affected by light. The compound is readily soluble in water and alcohol but insoluble in ether. The pH of a 1% solution is 5.9 and that of a 10% solution is 4.5. Although a solution of the compound yields a precipitate with alkaloidal reagents, such as mercuric potassium iodide test solution, addition of alkali hydroxides or carbonates does not cause the precipitate that occurs with nonquaternary nitrogen salts (e.g., atropine, homatropine).

Ipratropium Bromide

Homatropine methylbromide is transported poorly across the blood-brain barrier because of its quaternary ammonium group and, therefore, has far fewer stimulant properties than atropine. It does have all the characteristic peripheral parasympathetic depressant properties of atropine and is used to reduce oversecretion and to relieve GI spasms.

Ipratropium Bromide. Ipratropium bromide, 3-(3-hydroxy-1-oxo-2-phenylpropoxy)-8-methyl-8-(1-methylethyl)-8-azoniabicyclo[3.2.1]octane bromide (Atrovent), is a quaternary ammonium derivative of atropine. It is freely soluble in water and ethanol but insoluble in chloroform and ether. The salt is stable in neutral and acidic solutions but rapidly hydrolyzed in alkaline solutions.

Tropic Acid Tropine

Ipratropium bromide is used in inhalation therapy to produce dilation of bronchial smooth muscle for acute asthmatic attacks. The drug produces bronchodilation by competitive inhibition of cholinergic receptors bound to smooth

muscle of the bronchioles. Ipratropium may also act on the surface of mast cells to inhibit ACh-enhanced release of chemical mediators. The drug has a slow onset of action, within 5 to 15 minutes after being administered by inhalation, and should not be used alone for acute asthmatic attacks. The peak therapeutic effect from one dose is observed between 1 and 2 hours. The effects of the drug last for about 6 hours. It has a half-life of 3.5 hours.

Tiotropium Bromide. Tiotropium bromide, ($1\alpha,2\beta,4\beta,7\beta$)-7-[(hydroxidi-2-thienylacetyl)oxy]-9,9-dimethyl-3-oxa-9-azoniatricyclo[3.3.1.0^{2,4}]nonane, (Spiriva) is an antimuscarinic agent that is used in an inhalation device to deliver the drug into the lungs. It is indicated in the treatment of chronic obstructive pulmonary disease (COPD), including chronic bronchitis and emphysema. The standard once-daily dose is 18 μg of tiotropium.

Clidinium Bromide

SYNTHETIC CHOLINERGIC BLOCKING AGENTS

Aminoalcohol Esters

The solanaceous alkaloids are generally agreed to be potent parasympatholytics, but they have the undesirable property of producing a wide range of effects through their nonspecific blockade of autonomic functions. Efforts to use the antispasmodic effect of the alkaloids most often result in side effects such as dryness of the mouth and fluctuations in pulse rate. Therefore, synthesis of compounds possessing specific cholinolytic actions has been a very desirable field of study. Few prototypical drugs were as avidly dissected in the minds of researchers as atropine in attempts to modify its structure to separate the numerous useful activities (i.e., antispasmodic, antisecretory, mydriatic, and cycloplegic). Most early research was carried out in the pre- and post-World War II era before muscarinic receptor subtypes were known.

Efforts at synthesis started with rather minor deviations from the atropine molecule, but a review of the commonly used drugs today indicates a marked departure from the rigid tropane aminoalcohols and tropic acid residues. Examination of the structures of antispasmodics shows that the acid portion has been designed to provide a large hydrophobic moiety rather than the stereospecific requirement of (*S*)-tropic acid in (*-*)-hyoscyamine that was once considered important. One of the major developments in the field of aminoalcohol esters was the successful introduction of the quaternary ammonium derivatives as contrasted with

the tertiary amine-type esters synthesized originally. Although some effective tertiary amine esters are in use today, the quaternaries, as a group, represent the more popular type and appear to be slightly more potent than their tertiary amine counterparts.

The accompanying formula shows the portion of the atropine molecule (enclosed in the curved dotted line) believed to be responsible for its major activity. This is sometimes called the *spasmophoric* group and compares with the *anesthesiophoric* group obtained by similar dissection of the cocaine molecule. The validity of this conclusion has been amply borne out by the many active compounds having only a simple diethylaminoethyl residue replacing the tropine portion.

Cyclopentolate Hydrochloride

The aminoalcohol portion of eucatropine may be considered a simplification of the atropine molecule. In eucatropine, the bicyclic tropine has been replaced by a monocyclic aminoalcohol and mandelic acid replaces tropic acid (see under "Products").

Although simplification of the aminoalcohol portion of the atropine prototype has been a guiding principle in most research, many of the anticholinergics now used still include a cyclic aminoalcohol moiety. The aminoalcohol ester anticholinergics are used primarily as antispasmodics or mydriatics, and cholinolytic compounds classed as aminoalcohol or aminoalcohol ether analogs of atropine are, with few exceptions, used as antiparkinsonian drugs.

Another important feature in many of the synthetic anticholinergics used as antispasmodics is that they contain a quaternary nitrogen, presumably to enhance activity. The initial synthetic quaternary compound methantheline bromide has served as a forerunner for many others. These compounds combine anticholinergic activity of the antimuscarinic type with some ganglionic blockade to reinforce the parasympathetic blockade. Formation of a quaternary ammonium moiety, however, introduces the possibility of blockade of voluntary synapses (curariform activity); this can become evident with sufficiently high doses.

Products

The antimuscarinic compounds now in use are described in the following monographs.

Clidinium Bromide, USP. Clidinium bromide, 3-hydroxy-1-methylquinuclidinium bromide benzilate (Quarzan), is a white or nearly white, almost odorless, crystalline powder that is optically inactive. It is soluble in water and alcohol but only very slightly soluble in ether and benzene.

Dicyclomine Hydrochloride

This anticholinergic agent is marketed alone and in combination with the minor tranquilizer chlordiazepoxide (Librium) in a product known as Librax. The rationale of the combination for the treatment of GI complaints is the use of an anxiety-reducing agent together with an anticholinergic agent, based on the recognized contribution of anxiety to the development of the diseased condition. It is suggested for peptic ulcer, hyperchlorhydria, ulcerative or spastic colon, anxiety states with GI manifestations, nervous stomach, irritable or spastic colon, and others. Clidinium bromide is contraindicated in glaucoma and other conditions that may be aggravated by the parasympatholytic action, such as prostatic hypertrophy in elderly men, which could lead to urinary retention.

Cyclopentolate Hydrochloride, USP. Cyclopentolate hydrochloride, 2-dimethylaminoethyl 1-hydroxy- α -phenylcyclopentaneacetate hydrochloride (Cyclogyl), is a crystalline, white, odorless solid that is very soluble in water, easily soluble in alcohol, and only slightly soluble in ether. A 1% solution has a pH of 5.0 to 5.4.

Eucatropine Hydrochloride

It is used only for its effects on the eye, where it acts as a parasympatholytic. When placed in the eye, it quickly produces cycloplegia and mydriasis. Its primary field of usefulness is in refraction studies. Cyclopentolate hydrochloride can be used, however, as a mydriatic in the management of iritis, iridocyclitis, keratitis, and choroiditis. Although it does not seem to affect intraocular tension significantly, it is best to be very cautious with patients with high intraocular pressure and with elderly patients with possible unrecognized glaucomatous changes.

Cyclopentolate hydrochloride has one half of the antispasmodic activity of atropine and is nonirritating when instilled repeatedly into the eye. If not neutralized after the refraction studies, its effect dissipates within 24 hours. Neutralization with a few drops of pilocarpine nitrate solution, 1% to 2%, often results in complete recovery in 6 hours. It is supplied as a ready-made ophthalmic solution in concentrations of either 0.5% or 2%.

Dicyclomine Hydrochloride, USP. Dicyclomine hydrochloride, 2-(diethylamino)ethyl bicyclohexyl-1-carboxyl-

ate hydrochloride (Bentyl), has some muscarinic receptor subtype selectivity. It binds more firmly to M_1 and M_3 than to M_2 and M_4 receptors.⁷⁶

Glycopyrrolate

Dicyclomine hydrochloride has one eighth of the neurotropic activity of atropine and approximately twice the musculotropic activity of papaverine. This preparation, first introduced in 1950, has minimized the adverse effects associated with the atropine-type compounds. It is used for its spasmolytic effect on various smooth muscle spasms, particularly those associated with the GI tract. It is also useful in dysmenorrhea, pylorospasm, and biliary dysfunction.

Eucatropine Hydrochloride, USP. Eucatropine hydrochloride, euphthalmine hydrochloride or 1,2,2,6-tetramethyl-4-piperidyl mandelate hydrochloride, possesses the aminoalcohol moiety characteristic of one of the early local anesthetics (e.g., β -eucaine) but differs in the acidic portion of the ester by being a mandelate instead of a benzoate. The salt is an odorless, white, granular powder, providing solutions that are neutral to litmus. It is very soluble in water, freely soluble in alcohol and chloroform, but almost insoluble in ether.

Mepenzolate Bromide

The action of eucatropine hydrochloride closely parallels that of atropine, although it is much less potent than the latter. It is used topically in a 0.1 mL dose as a mydriatic in 2% solution or in the form of small tablets. Use of concentrations from 5% to 10% is, however, not uncommon. Dilation, with little impairment of accommodation, takes place in about 30 minutes, and the eye returns to normal in 2 to 3 hours.

Glycopyrrolate, USP. Glycopyrrolate, 3-hydroxy-1,1-dimethylpyrrolidinium bromide α -cyclopentylmandelate (Robinul), occurs as a white, crystalline powder that is soluble in water or alcohol but practically insoluble in chloroform or ether.

Methantheline Bromide

Propantheline Bromide

Glycopyrrolate is a typical anticholinergic and possesses, at adequate dosage levels, the atropine-like effects characteristic of this class of drugs. It has a spasmolytic effect on the musculature of the GI tract as well as the genitourinary tract. It diminishes gastric and pancreatic secretions and the quantity of perspiration and saliva. Its side effects are also typically atropine-like (i.e., dryness of the mouth, urinary retention, blurred vision, constipation). Glycopyrrolate is a more potent antagonist on M_1 than on M_2 and M_3 receptors. The low affinity of M_2 receptors may, in part, explain the low incidence of tachycardia during use of this drug as an antispasmodic.⁷⁷ Because of its quaternary ammonium character, glycopyrrolate rarely causes CNS disturbances, although in sufficiently high dosage, it can bring about ganglionic and myoneural junction block.

The drug is used as an adjunct in the management of peptic ulcer and other GI ailments associated with hyperacidity, hypermotility, and spasm. In common with other anticholinergics, its use does not preclude dietary restrictions or use of antacids and sedatives if these are indicated.

Mepenzolate Bromide. Mepenzolate bromide, 3-hydroxy-1,1-dimethylpiperidinium bromide benzilate (Cantil), has an activity about one half that of atropine in reducing ACh-induced spasms of the guinea pig ileum. The selective action on colonic hypermotility is said to relieve pain, cramps, and bloating and to help curb diarrhea.

Oxyphencyclimine Hydrochloride

Methantheline Bromide, USP. Methantheline bromide, diethyl(2-hydroxyethyl)methylammonium bromide xanthene-9-carboxylate (Banthine Bromide), is a white, slightly hygroscopic, crystalline salt that is soluble in water to produce solutions with a pH of about 5. Aqueous solutions are not stable and hydrolyze in a few days. The bromide form is preferable to the very hygroscopic chloride.

This drug, introduced in 1950, is a potent anticholinergic agent and acts at the nicotinic cholinergic receptors of the sympathetic and parasympathetic systems, as well as at the myoneural junction of the postganglionic cholinergic fibers. Like other quaternary ammonium drugs, methantheline bromide is absorbed incompletely from the GI tract.

Among the conditions for which methantheline bromide is indicated are gastritis, intestinal hypermotility, bladder irritability, cholinergic spasm, pancreatitis, hyperhidrosis, and peptic ulcer, all of which are manifestations of parasympathotonia.

Side reactions are atropine-like (mydriasis, cycloplegia, dryness of mouth). The drug is contraindicated in glaucoma. Toxic doses may bring about a curare-like action, a not too surprising fact when it is considered that ACh is the mediating factor for neural transmission at the somatic myoneural junction. This side effect can be counteracted with neostigmine methylsulfate.

Oxyphencyclimine Hydrochloride. Oxyphencyclimine hydrochloride, 1,4,5,6-tetrahydro-1-methyl-2-pyrimidinyl methyl α -phenylcyclohexanecarboxylate monohydrochloride (Daricon, Vistrax), was introduced in 1958 and promoted as a peripheral anticholinergic-antisecretory agent, with little or no curare-like activity and little or no ganglionic blocking activity. These activities are probably absent because of the tertiary character of the molecule. This activity is in contrast with that of compounds that couple antimuscarinic action with ganglionic blocking action. The tertiary character of the nitrogen promotes intestinal absorption of the molecule. Perhaps the most significant activity of this compound is its marked ability to reduce both the volume and the acid content of the gastric juices, a desirable action in view of the more recent hypotheses pertaining to peptic ulcer therapy. Another important feature of this compound is its low toxicity in comparison with many of the other available anticholinergics. Oxyphencyclimine hydrochloride is hydrolyzed in the presence of excessive moisture and heat. It is absorbed from the GI tract and has a duration of action of up to 12 hours.

Diphenhydramine

Oxyphencyclimine hydrochloride is suggested for use in peptic ulcer, pylorospasm, and functional bowel syndrome. It is contraindicated, as are other anticholinergics, in patients with prostatic hypertrophy and glaucoma.

Propantheline Bromide, USP. Propantheline bromide, 2-hydroxy-ethyl)diisopropylmethylammonium bromide xanthen-9-carboxylate (Pro-Banthine), is prepared in a manner exactly analogous to that used for methantheline bromide. It is a white, water-soluble, crystalline substance, with properties quite similar to those of methantheline bromide. Its chief difference from methantheline bromide is in its potency, which has been estimated variously to be 2 to 5 times as great.

Benztropine Mesylate

Oxybutynin. Oxybutynin, 4-Diethylaminobut-2-ynyl-2-cyclohexyl-2-hydroxy-2-phenyl-ethanoate, (Oxytrol) was one of the first agents specifically developed to exploit the effects that cholinergic blocking agents have on the bladder. By competitively blocking the muscarinic receptors, it has direct spasmolytic effects on bladder smooth muscle. This reduction in smooth muscle tone allows for greater volumes of urine to be stored in the bladder, which results in less urinary incontinence, urgency, and frequency. Oxybutynin acts as a competitive antagonist on M_1 , M_2 , and M_3 receptor subtypes.⁷⁸

Orphenadrine Citrate

Trospium Chloride. Trospium chloride, 3 α -benzoyloxynortropane-8-spiro-1'-pyrrolidinium chloride, (Sanctura) was available in Europe for almost 20 years before gaining approval in the United States in May 2004. Much like oxybutynin, it too is a competitive antagonist for muscarinic receptors and is used to manage overactive bladder. The quaternary amine reduces the likelihood that this agent will cross the blood-brain barrier. In addition, it has a limited

metabolic profile, largely a result of its highly water-soluble characteristics.⁷⁹

Biperiden

Solifenacin Succinate. Solifenacin succinate (Vesicare), (+)-(1S, 3'R)-quinuclidin-3'-yl 1-phenyl-1,2,3,4-tetrahydroisoquinoline-2-carboxylate, is a competitive antagonist for M_1 , M_2 , and M_3 receptor subtypes. One of the issues surrounding the use of such antagonists is the selectivity for the bladder over other tissue such as the salivary glands. It is reported that the selectivity of solifenacin for bladder muscarinic receptors over salivary receptors is superior to the effects observed with oxybutynin.⁸⁰

Procyclidine Hydrochloride

Aminoalcohol Ethers

The aminoalcohol ethers thus far introduced have been used as antiparkinsonian drugs rather than as conventional anticholinergics (i.e., as spasmolytics or mydriatics). In general, they may be considered closely related to the antihistaminics and, indeed, do possess substantial antihistaminic properties. In turn, the antihistaminics possess anticholinergic activity and have been used as antiparkinsonian agents. Comparison of chlorphenoxamine and orphenadrine with the antihistaminic diphenhydramine illustrates the close similarity of structure. The use of diphenhydramine in parkinsonism has been cited previously. Benztropine may also be considered a structural relative of diphenhydramine, although the aminoalcohol portion is tropine and, therefore, more distantly related than chlorphenoxamine and orphenadrine. In the structure of benztropine, a three-carbon chain intervenes between the nitrogen and oxygen functions, whereas the others evince a two-carbon chain. However, the rigid ring structure possibly orients the nitrogen and oxygen functions into more nearly the two-carbon chain interprosthetic distance than is apparent at first glance. This, combined with the flexibility

of the alicyclic chain, would help to minimize the distance discrepancy.

Tridihexethyl Chloride

Benztropine Mesylate, USP. Benztropine mesylate, 3α -(diphenylmethoxy)- $1\alpha H,5\alpha H$ -tropane methanesulfonate (Cogentin), has anticholinergic, antihistaminic, and local anesthetic properties. Its anticholinergic effect makes it applicable as an antiparkinsonian agent. It is about as potent an anticholinergic as atropine and shares some of the side effects of this drug, such as mydriasis and dryness of mouth. Importantly, however, it does not produce central stimulation but instead exerts the characteristic sedative effect of the antihistamines.

The tremor and rigidity characteristic of parkinsonism are relieved by benztropine mesylate, and it is particularly valuable for those patients who cannot tolerate central excitation (e.g., aged patients). It may also have a useful effect in minimizing drooling, sialorrhea, masklike facies, oculogyric crises, and muscular cramps.

The usual caution exercised with any anticholinergic in glaucoma and prostatic hypertrophy is observed with this drug.

Orphenadrine Citrate. Orphenadrine citrate, N,N -dimethyl-2-(*o*-methyl- α -phenylbenzyloxy)ethylamine citrate (1:1) (Norflex), introduced in 1957, is closely related to diphenhydramine structurally but has much lower antihistaminic activity and much higher anticholinergic action. Likewise, it lacks the sedative effects characteristic of diphenhydramine. Pharmacological testing indicates that it is not primarily a peripherally acting anticholinergic because it has only weak effects on smooth muscle, on the eye, and on secretory glands. It does reduce voluntary muscle spasm, however, by a central inhibitory action on cerebral motor areas, a central effect similar to that of atropine.

Trihexyphenidyl Hydrochloride

This drug is used for the symptomatic treatment of Parkinson disease. It relieves rigidity better than it does tremor, and in certain cases, it may accentuate the latter. The

drug combats mental sluggishness, akinesia, adynamia, and lack of mobility, but this effect seems to diminish rather rapidly with prolonged use. It is best used as an adjunct to the other agents, such as benztropine, procyclidine, cycrimine, and trihexyphenidyl, in the treatment of paralysis agitans. Orphenadrine citrate is also used as an adjunct to rest, physiotherapy, and other measures to relieve pain of local muscle spasm (e.g., nocturnal leg cramps).

The drug has a low incidence of the usual side effects for this group, namely, dryness of mouth, nausea, and mild excitation.

Aminoalcohols

The development of aminoalcohols as parasympatholytics took place in the 1940s. It was soon established, however, that these antispasmodics were equally efficacious in parkinsonism.

Several of the drugs in this class of antimuscarinic agents possess bulky groups in the vicinity of hydroxyl and cyclic amino functional groups. These compounds are similar to the classic aminoester anticholinergic compounds derived from atropine. The presence of the alcohol group seems to substitute adequately as a prosthetic group for the carboxyl function in creating an effective parasympathetic blocking agent. The aminoester group, per se, is not a necessary adjunct to cholinolytic activity, provided that other polar groupings, such as the hydroxyl, can substitute as a prosthetic group for the carboxyl function. Another structural feature common to all aminoalcohol anticholinergics is the γ -aminopropanol arrangement, with three carbons intervening between the hydroxyl and amino functions. All of the aminoalcohols used for paralysis agitans are tertiary amines. Because the desired locus of action is central, formation of a quaternary ammonium moiety destroys the antiparkinsonian properties. These aminoalcohols have been quaternized, however, to enhance the anticholinergic activity to produce an antispasmodic and antisecretory compound, such as tridihexethyl chloride.

Biperiden, USP. Biperiden, α -5-norbornen-2-yl- α -phenyl-1-piperidinepropanol (Akineton), introduced in 1959, has a relatively weak visceral anticholinergic, but a strong nicotinic, action in terms of its ability to block nicotine-induced convulsions. Therefore, its neurotropic action is rather low on intestinal musculature and blood vessels. It has a relatively strong musculotropic action, which is about equal to that of papaverine, in comparison with most synthetic anticholinergic drugs. Its action on the eye, although mydriatic, is much lower than that of atropine. These weak anticholinergic effects add to its usefulness in Parkinson syndrome by minimizing side effects.

Isopropamide Iodide

The drug is used in all types of Parkinson disease (postencephalitic, idiopathic, arteriosclerotic) and helps to eliminate akinesia, rigidity, and tremor. It is also used in drug-induced extrapyramidal disorders to eliminate symptoms and permit continued use of tranquilizers. Biperiden is also of value in spastic disorders not related to parkinsonism, such as multiple sclerosis, spinal cord injury, and cerebral palsy. It is contraindicated in all forms of epilepsy.

Biperiden Hydrochloride, USP. Biperiden hydrochloride, α -5-norbornen-2-yl- α -phenyl-1-piperidinepropanol hydrochloride (Akineton hydrochloride), is a white, optically inactive, crystalline, odorless powder that is slightly soluble in water, ether, alcohol, and chloroform and sparingly soluble in methanol.

Biperiden hydrochloride has all of the actions described for biperiden. The hydrochloride is used for tablets because it is better suited to this dosage form than is the lactate salt. As with the free base and the lactate salt, xerostomia (dryness of the mouth) and blurred vision may occur.

Procyclidine Hydrochloride, USP. Procyclidine hydrochloride, α -cyclohexyl- α -phenyl-1-pyrrolidinepropanol hydrochloride (Kemadrin), was introduced in 1956. Although it is an effective peripheral anticholinergic and, indeed, has been used for peripheral effects similar to its methochloride (i.e., tricyclamol chloride), its clinical usefulness lies in its ability to relieve voluntary muscle spasticity by its central action. Therefore, it has been used with success in the treatment of Parkinson syndrome. It is said to be as effective as trihexyphenidyl and is used to reduce muscle rigidity in postencephalitic, arteriosclerotic, and idiopathic types of the disease. Its effect on tremor is not predictable and probably should be supplemented by combination with other similar drugs.

Tropicamide

The toxicity of the drug is low, but when the dosage of the drug is high, side effects are noticeable. At therapeutic dosage levels, dry mouth is the most common side effect. The same care should be exercised with this drug as with all other anticholinergics when it is administered to patients with glaucoma, tachycardia, or prostatic hypertrophy.

Tridihexethyl Chloride, USP. Tridihexethyl chloride, 3-cyclohexyl-3-hydroxy-3-phenylpropyltriethylammonium chloride (Pathilon), is a white, bitter, crystalline powder with a characteristic odor. The compound is freely soluble in water and alcohol, with aqueous solutions being nearly neutral in reaction.

Diphepanil Methylsulfate

Although this drug, introduced in 1958, has ganglion-blocking activity, its peripheral atropine-like activity predominates; therefore, its therapeutic application has been based on the latter activity. It possesses the antispasmodic and the antisecretory activities characteristic of this group, but because of its quaternary character, it is valueless in relieving Parkinson syndrome.

The drug is useful for adjunctive therapy in a wide variety of GI diseases, such as peptic ulcer, gastric hyperacidity, and hypermotility and spastic conditions, such as spastic colon, functional diarrhea, pylorospasm, and other related conditions. Because its action is predominantly antisecretory, it is more effective in gastric hypersecretion than in hypermotility and spasm. It is best administered intravenously for the latter conditions.

The side effects usually found with effective anticholinergic therapy occur with the use of this drug. These are dryness of mouth, mydriasis, and such. As with other anticholinergics, care should be exercised when administering the drug to patients with glaucomatous conditions, cardiac decompensation, and coronary insufficiency. It is contraindicated in patients with obstruction at the bladder neck, prostatic hypertrophy, stenosing gastric and duodenal ulcers, or pyloric or duodenal obstruction.

Trihexyphenidyl Hydrochloride, USP. Trihexyphenidyl hydrochloride, α -cyclohexyl- α -phenyl-1-piperidinepropanol hydrochloride (Artane, Tremin, Pipanol), introduced in 1949, is approximately half as active as atropine as an antispasmodic but is claimed to have milder side effects, such as mydriasis, drying of secretions, and cardioacceleration. It has a good margin of safety, although it is about as toxic as atropine. It has found a place in the treatment of parkinsonism and is claimed to provide some measure of relief from the mental depression often associated with this condition. It

Ethopropazine Hydrochloride

does, however, exhibit some of the side effects typical of the parasympatholytic-type preparation, although adjusting the dose carefully may often eliminate these.

Tolterodine. Tolterodine (Detrol), 2-[3-[bis(1-methyl-ethyl)amino]-1-phenyl-propyl]-4-methyl-phenol, is an antimuscarinic agent that acts on M_2 and M_3 muscarinic subtype receptors. By competitively blocking of the muscarinic receptors results in a reduction of the smooth muscle tone, allowing for greater volume of urine to be stored in the bladder. This results in less urinary incontinence, urgency, and frequency.⁸¹

Papaverine Hydrochloride

Aminoamides

From a structural standpoint, the aminoamide type of anticholinergic represents the same type of molecule as the aminoalcohol group, with the important exception that the polar amide group replaces the corresponding polar hydroxyl group. Aminoamides retain the same bulky structural features found at one end of the molecule or the other in all of the active anticholinergics. Isopropamide iodide is the only drug of this class currently in use.

Another amide-type structure is that of tropicamide, formerly known as bis-tropamide, a compound with some of the atropine features.

Isopropamide iodide, USP. Isopropamide iodide, 3-carbamoyl-3,3-diphenylpropyl)diisopropylmethylammonium iodide (Darbid), occurs as a bitter, white to pale yellow, crystalline powder that is only sparingly soluble in water but freely soluble in chloroform and alcohol.

Nicotine

This drug, introduced in 1957, is a potent anticholinergic, producing atropine-like effects peripherally. Even with its

quaternary nature, it does not cause sympathetic blockade at the ganglionic level except at high dosages. Its principal distinguishing feature is its long duration of action. A single dose can provide antispasmodic and antisecretory effects for as long as 12 hours.

It is used as adjunctive therapy in the treatment of peptic ulcer and other conditions of the GI tract associated with hypermotility and hyperacidity. It has the usual side effects of anticholinergics (dryness of mouth, mydriasis, difficult urination) and is contraindicated in glaucoma, prostatic hypertrophy, etc.

Tropicamide, USP. Tropicamide, *N*-ethyl-2-phenyl-*N*-(4-pyridylmethyl)hydracrylamide (Mydriacyl), is an effective anticholinergic for ophthalmic use when mydriasis is produced by relaxation of the sphincter muscle of the iris, allowing adrenergic innervation of the radial muscle to dilate the pupil. Its maximum effect is achieved in about 20 to 25 minutes and lasts for about 20 minutes, with complete recovery in about 6 hours. Its action is more rapid in onset and wears off more rapidly than that of most other mydriatics. To achieve mydriasis, either 0.5% or 1.0% concentration may be used, although cycloplegia is achieved only with the stronger solution. Its uses are much the same as those described above for mydriatics in general, but opinions differ on whether the drug is as effective as homatropine, for example, in achieving cycloplegia. For mydriatic use, however, in examination of the fundus and treatment of acute iritis, iridocyclitis, and keratitis, it is quite adequate; and because of its shorter duration of action, it is less prone to initiate a rise in intraocular pressure than the more potent, longer-lasting drugs. As with other mydriatics, however, pupil dilation can lead to increased intraocular pressure. In common with other mydriatics, it is contraindicated in patients with glaucoma, either known or suspected, and should not be used in the presence of a shallow anterior chamber. Thus far, no allergic reactions or ocular damage has been observed with this drug. The ability to clone the various muscarinic receptor subtypes has allowed the observation that tropicamide has modest selectivity for the M_4 receptor.⁸²

Darifenacin Hydrobromide. Darifenacin (Enablex), (s)-2-{1-[2-(2,3-dihydrobenzofuran-5-yl)ethyl]-3-pyrrolidinyl}-2,2-diphenylacetamide, is an antimuscarinic agent that has selectivity for the M_3 muscarinic subtype receptor. By competitively blocking of the muscarinic receptors results in a reduction of the smooth muscle tone, allowing for greater volume of urine to be stored in the bladder. This results in less urinary incontinence, urgency, and frequency. It is a white to almost white, crystalline powder, with a molecular weight of 507.5. Darifenacin is metabolized by the isozymes CYP2D6 and CYP3A4 with the primary metabolic routes being monohydroxylation of the dihydrobenzofuran ring,

opening of the dihydrobenzofuran ring, and *N*-dealkylation of the pyrrolidine nitrogen.⁸³

Trimethaphan Camsylate

Miscellaneous

Further structural modification of classic antimuscarinic agents can be found in the drugs described next. Each of them has the typical bulky group characteristic of the usual anticholinergic molecule. One modification is represented by the diphenylmethylene moiety (e.g., diphemanil); a second, by a phenothiazine (e.g., ethopropazine); and a third, by a thioxanthene structure (e.g., methixene).

Diphemanil Methylsulfate, USP. Diphemanil methylsulfate, 4-(diphenylmethylene)-1,1-dimethylpiperidinium methylsulfate (Prantal), or diphemanil methylsulfate is a potent cholinergic blocking agent. In the usual dosage range, it acts as an effective parasympatholytic by blocking nerve impulses at the parasympathetic ganglia, but it does not invoke a sympathetic ganglionic blockade. It is claimed to be highly specific in its action on those innervations that activate gastric secretion and GI motility. Although this drug can produce atropine-like side effects, they rarely occur at recommended doses. The highly specific nature of its action on gastric functions makes the drug useful in the treatment of peptic ulcer, and its lack of atropine-like effects makes its use much less distressing than other antispasmodic drugs. In addition to its action in decreasing gastric hypermotility, diphemanil methylsulfate is valuable in hyperhidrosis in low doses (50 mg twice daily) or topically. The drug is not well absorbed from the GI tract, particularly in the presence of food, and should be administered between meals. The methylsulfate salt was chosen as the best, because the chloride is hygroscopic and the bromide and iodide ions have exhibited toxic manifestations in clinical use.

Mecamylamine Hydrochloride

Ethopropazine Hydrochloride, USP. Ethopropazine hydrochloride, 10-[2-(diethylamino)propyl]phenothiazine monohydrochloride (Parsidol), introduced to therapy in 1954, has antimuscarinic activity and is especially useful in the symptomatic treatment of parkinsonism. In this capacity, it has value in controlling rigidity, and it also has a favorable effect on tremor, sialorrhea, and oculogyric crises. It is often used in conjunction with other antiparkinsonian drugs for complementary activity.

Side effects are common with this drug but are usually not severe. Drowsiness and dizziness are the most common side effects at ordinary dosage levels, and as the dose increases, xerostomia, mydriasis, and others become evident. It is contraindicated in conditions such as glaucoma because of its mydriatic effect.

Papaverine Hydrochloride, USP. Papaverine hydrochloride, 6,7-dimethoxy-1-veratrylisoquinoline hydrochloride, was isolated by Merck in 1848 from opium, in which it occurs to the extent of about 1%. Although its natural origin is closely related to morphine, the pharmacological actions of papaverine hydrochloride are unlike those of morphine. Its main effect is as a spasmolytic on smooth muscle, acting as a direct, nonspecific relaxant on vascular, cardiac, and other smooth muscle. Because of its broad antispasmodic action on ACh muscarinic receptors, it is often called a *nonspecific antagonist*. Papaverine hydrochloride has been used in the treatment of peripheral vascular disorders, but its use is limited by lack of potency.

Papaverine hydrochloride interferes with the mechanism of muscle contraction by inhibiting the cyclic nucleotide phosphodiesterases in smooth muscle cells responsible for converting cAMP and cyclic guanosine monophosphate (cGMP) to 5'-AMP and 5'-GMP, respectively. The increased levels of cAMP and cGMP are associated with

Atracurium Besylate

muscle relaxation through their phosphorylation of myosin light-chain kinase.

GANGLIONIC BLOCKING AGENTS

Autonomic ganglia have been the subject of interest for many years in the study of interactions between drugs and nervous tissues. The first important account⁸⁴ was given by Langley and described the stimulating and blocking actions of nicotine on sympathetic ganglia. It was found that small amounts of nicotine stimulated ganglia and then produced a blockade of ganglionic transmission because of persistent depolarization. From these experiments, Langley was able to outline the general pattern of innervation of organs by the autonomic nervous system. *Parasympathetic* ganglia usually are located near the organ they innervate and have preganglionic fibers that stem from the cervical and thoracic regions of the spinal cord. *Sympathetic* ganglia consist of 22 pairs that lie on either side of the vertebral column to form lateral chains. These ganglia are connected both to each other by nerve trunks and to the lumbar or sacral regions of the spinal cord.

Using the sympathetic cervical ganglion as a model revealed that transmission in the autonomic ganglion is more complex than formerly believed. Traditionally, stimulation of autonomic ganglia by ACh was considered to be the nicotinic action of the neurotransmitter. It is now understood that stimulation by ACh produces a triphasic response in sympathetic ganglia. Impulse transmission through the ganglion occurs when ACh is released from preganglionic fibers and activates the N_2 nicotinic receptors of the neuronal membrane. This triggers an increase in sodium and potassium conductances of a subsynaptic membrane, resulting in an initial excitatory postsynaptic potential (EPSP) with a latency of 1 ms, followed by an inhibitory postsynaptic potential (IPSP) with a latency of 35 ms, and, finally, a slowly generating EPSP with a latency of several hundred milliseconds. The ACh released by preganglionic fibers also activates M_1 muscarinic receptors of the ganglion and probably of the small-intensity fluorescent (SIF) cell. This results in the appearance of a slow IPSP and a slow EPSP in the neurons of the ganglion.⁸⁵ The initial EPSP is blocked by conventional competitive nondepolarizing ganglionic blocking agents, such as hexamethonium, and is considered the primary

Doxacurium Chloride

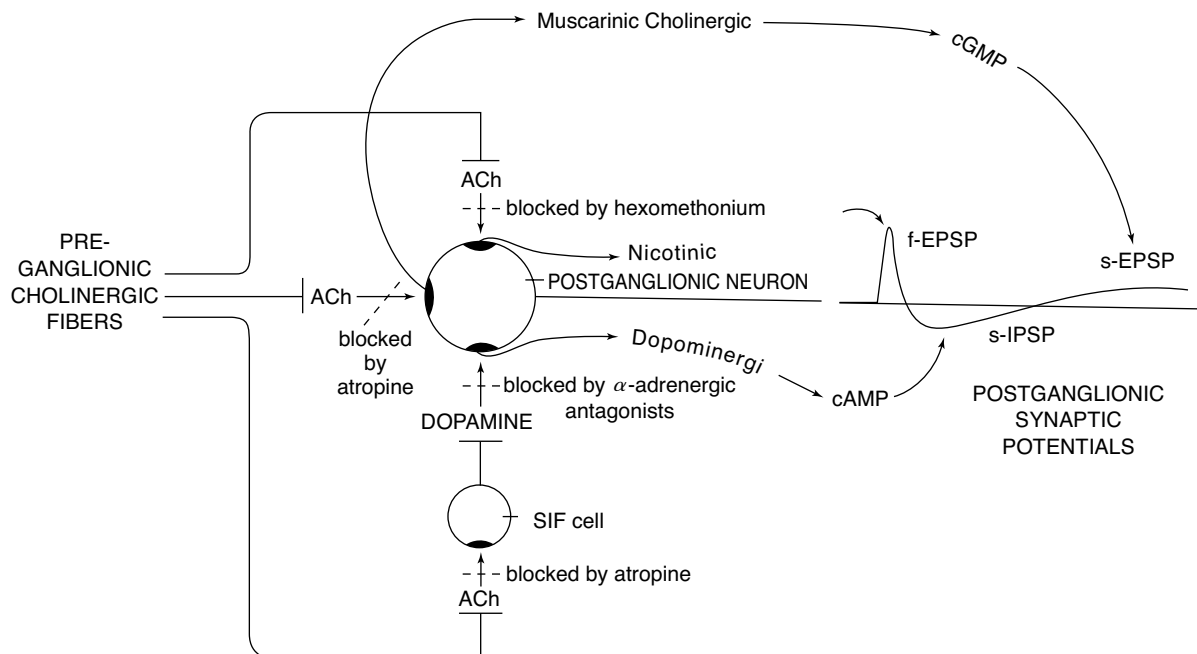

Figure 17.19 • Neurotransmission at the sympathetic cervical ganglion.

pathway for ganglionic transmission.⁸⁶ The slowly generating or late EPSP is blocked by atropine but not by the traditional ganglionic blocking agents. This receptor has muscarinic properties because methacholine causes generation of the late EPSP without causing the initial spike characteristic of ACh. Atropine also blocks the late EPSP produced by methacholine. There may be more than one type of muscarinic receptor in sympathetic ganglia. Atropine blocks both high-affinity (M_1) and low-affinity (M_2) muscarinic receptors in the ganglion.⁸⁷ In addition to the cholinergic pathways, the cervical sympathetic ganglion has a neuron that contains a catecholamine.⁸⁸ These neuronal cells, identified initially by fluorescence histochemical studies and shown to be smaller than the postganglionic neurons, are now referred to as SIF cells. Dopamine has been identified as the fluorescent catecholamine in the SIF cells that are common to many other sympathetic ganglia. Dopamine apparently mediates an increase in cAMP, which causes hyperpolarization of postganglionic neurons (Fig. 17.19). The IPSP phase of the transmission of sympathetic ganglia following ACh administration can be blocked by both atropine and α -adrenergic blocking agents.⁸⁵

If a similar nontraditional type of ganglionic transmission occurs in the parasympathetic ganglia, it has not yet become evident. With the anatomical and physiological differences between sympathetic and parasympathetic ganglia, it should be no surprise that ganglionic agents may show some selectivity between the two types of ganglia. Although we do not have drug classifications such as “parasympathetic ganglionic blockers” and “sympathetic ganglionic blockers,” we do find that certain ganglia have a predominant effect over certain organs and tissues and that a nondiscriminant blockade of autonomic ganglia results in a change in the effect of the autonomic nervous system on that organ (Table 17.7).

None of the commonly known ganglionic blockers has yet been identified as a selective blocker of parasympathetic ganglia.

Van Rossum^{89,90} has reviewed the mechanisms of ganglionic synaptic transmission, the mode of action of ganglionic stimulants, and the mode of action of ganglionic blocking agents. They have been classified as blocking agents in the following manner.

Depolarizing Ganglionic Blocking Agents

Depolarizing blocking agents are actually ganglionic stimulants. Thus, for nicotine, small doses give an action similar to that of the natural neuroeffector ACh, an action

TABLE 17.7 Results of Ganglionic Blockers on Organs

Organ	Predominant System	Results of Ganglionic Blockade
Cardiovascular system		
Heart	Parasympathetic	Tachycardia
Arterioles	Sympathetic	Vasodilation
Veins	Sympathetic	Dilation
Eye		
Iris	Parasympathetic	Mydriasis
Ciliary muscle	Parasympathetic	Cycloplegia
GI tract	Parasympathetic	Relaxation
Urinary bladder	Parasympathetic	Urinary retention
Salivary glands	Parasympathetic	Dry mouth
Sweat glands	Sympathetic ^a	Anhidrosis

^aNeurotransmitter is ACh.

known as the "nicotinic effect of ACh." Larger amounts of nicotine, however, bring about a ganglionic block characterized initially by depolarization, followed by a typical competitive antagonism. To conduct nerve impulses, the cell must be able to carry out a polarization and depolarization process, and if the depolarized condition is maintained without repolarization, obviously no conduction occurs. ACh itself, in high concentration, will bring about an autoinhibition. Chemicals that cause this type of ganglionic block are not of therapeutic significance. The classes of ganglionic blocking agents that are described are therapeutically useful.

Nondepolarizing Competitive Ganglionic Blocking Agents

Compounds in the class of nondepolarizing competitive ganglionic blocking agents possess the necessary affinity to attach to the nicotinic receptor sites that are specific for ACh, but they lack the intrinsic activity necessary for impulse transmission (i.e., they cannot effect depolarization of the cell). Under experimental conditions, in the presence of a fixed concentration of blocking agent of this type, a large enough concentration of ACh can offset the blocking action by competing successfully for the specific receptors. When such a concentration of ACh is administered to a ganglion preparation, it appears that the intrinsic activity of the ACh is as great as it was when no antagonist was present, the only difference being in the larger concentration of ACh required. It is evident, then, that such blocking agents are "competitive" with ACh for the specific receptors involved and that either the agonist or the antagonist, if present in sufficient concentration, can displace the other. Drugs falling into this class are tetraethylammonium salts, hexamethonium, and trimethaphan. Mecamylamine possesses a competitive component in its action but is also noncompetitive, a so-called dual antagonist.

Nondepolarizing Noncompetitive Ganglionic Blocking Agents

Nondepolarizing noncompetitive ganglionic blocking agents produce their effect not at the specific ACh receptor site but at some point farther along the chain of events that is necessary for transmission of the nerve impulse. When the block has been imposed, increasing the concentration of ACh has no effect; thus, apparently, ACh does not act competitively with the blocking agent at the same receptors. Theoretically, a pure noncompetitive blocker should have a high-specific affinity for the noncompetitive receptors in the ganglia and a very low affinity for other cholinergic synapses, together with no intrinsic activity. Mecamylamine, as mentioned above, has a noncompetitive component but is also a competitive blocking agent.

The first ganglionic blocking agents used in therapy were tetraethylammonium chloride and bromide. Although one might assume that curariform activity would be a deterrent to their use, the curariform activity of the tetraethyl compound is less than 1% of that of the corresponding tetramethylammonium compound. A few years after the introduction of the tetraethylammonium compounds, Paton and Zaimis⁹¹

investigated the usefulness of the bis-trimethylammonium polymethylene salts:

Gallamine Triethiodide

As shown, their findings indicate that there is a critical distance of about five to six carbon atoms between the onium centers for good ganglionic blocking action. Interestingly, the pentamethylene and hexamethylene compounds are effective antidotes against the curare effect of the decamethylene compound. Hexamethonium bromide and hexamethonium chloride emerged from this research as clinically useful products.

Trimethaphan camphorsulfonate, a monosulfonium compound, bears some similarity to the quaternary ammonium types because it, too, is a completely ionic compound. Although it produces a prompt ganglion-blocking action on parenteral injection, its action is short, and it is used only for controlled hypotension during surgery. Almost simultaneously with the introduction of chlorisondamine (now long removed from the market), announcement was made of the powerful ganglionic blocking action of mecamlamine, a secondary amine *without* quaternary ammonium character. As expected, the latter compound showed uniform and predictable absorption from the GI tract as well as a longer duration of action. Its action was similar to that of hexamethonium.

Drugs of this class have limited usefulness as diagnostic and therapeutic agents in the management of peripheral vascular diseases (e.g., thromboangiitis obliterans, Raynaud disease, diabetic gangrene). The principal therapeutic application has been in the treatment of hypertension through blockade of the sympathetic pathways. Unfortunately, the action is non-specific, and the parasympathetic ganglia, unavoidably, are blocked simultaneously to a greater or lesser extent, causing visual disturbances, dryness of the mouth, impotence, urinary retention, and constipation. Constipation, in particular, probably caused by unabsorbed drug in the intestine (poor absorption), has been a drawback because the condition can proceed to a paralytic ileus if extreme care is not exercised. For this reason, cathartics or a parasympathomimetic (e.g., pilocarpine nitrate) is frequently administered simultaneously. Another adverse effect is the production of orthostatic (postural) hypotension (i.e., dizziness when the patient stands up in an erect position). Prolonged administration of the ganglionic blocking agents results in diminished effectiveness because of a buildup of tolerance, although some are more prone to this than others. Because of the many serious side effects, more effective hypotensive agents have replaced this group of drugs.

In addition to these adverse effects, there are several limitations to the use of these drugs. For instance, they are contraindicated in disorders characterized by severe reduction of blood flow to a vital organ (e.g., severe coronary insufficiency, recent myocardial infarction, retinal and cerebral

thrombosis) as well as situations in which there have been large reductions in blood volume. In the latter, the contraindication exists because the drugs block the normal vasoconstrictor compensatory mechanisms necessary for homeostasis. A potentially serious complication, especially in older men with prostatic hypertrophy, is urinary retention. These drugs should be used with care or not at all in the presence of renal insufficiency, glaucoma, uremia, and organic pyloric stenosis.

Trimethaphan Camsylate, USP. Trimethaphan camsylate, (+)-1,3-dibenzyldecahydro-2-oxoimidazo[4,5-*c*]thieno[1,2- α]-thiolium 2-oxo-10-bornanesulfonate (1:1) (Arfonad), consists of white crystals or a crystalline powder with a bitter taste and a slight odor. It is soluble in water and alcohol but only slightly soluble in acetone and ether. The pH of a 1% aqueous solution is 5.0 to 6.0.

This ganglionic blocking agent is short acting and is used for certain neurosurgical procedures in which excessive bleeding obscures the operative field. Certain craniotomies are included among these operations. The action of the drug is direct vasodilation, and because of its transient action, it is subject to minute-by-minute control. This fleeting action, however, makes it useless for hypertensive control. The drug is ineffective when given orally. The usual route of administration is intravenous. Trimethaphan camsylate is indicated in the treatment of hypertensive emergencies to reduce blood pressure rapidly. These emergencies may include pulmonary hypertension associated with systemic hypertension and acute dissecting aneurysm.

Mecamylamine Hydrochloride. The secondary amine mecamylamine hydrochloride, *N*,2,3,3-tetramethyl-2-norbornanamine hydrochloride (Inversine), has a powerful ganglionic blocking effect that is almost identical to that of hexamethonium. It has an advantage over most of the ganglionic blocking agents in being absorbed readily and smoothly from the GI tract. It is rarely used, however, for the treatment of moderate-to-severe hypertension because severe orthostatic hypotension occurs when the drug blocks sympathetic ganglia.

NEUROMUSCULAR BLOCKING AGENTS

Agents that block the transmission of ACh at the motor end plate are called *neuromuscular blocking agents*. The therapeutic use of these compounds is primarily as adjuvants in surgical anesthesia to obtain relaxation of skeletal muscle. They also are used in various orthopedic procedures, such as alignment of fractures and correction of dislocations.

The therapeutically useful compounds in this group sometimes are referred to as possessing *curariform* or *curarimimetic* activity in reference to the original representatives of the class, which were obtained from curare. Since then, synthetic compounds have been prepared with similar activity. Although all of the compounds falling into this category, natural and synthetic alike, bring about substantially the same end result (i.e., voluntary-muscle relaxation), there are some significant differences in mechanisms.

The possible existence of a junction between muscle and nerve was suggested as early as 1856, when Claude Bernard observed that the site of action of curare was neither the nerve nor the muscle. Since that time, it has been agreed that ACh mediates transmission at the neuromuscular junction by a sequence of events described previously in this chapter. The neuromuscular junction consists of the axon impinging onto a specialized area of the muscle known as the muscle end plate. The axon is covered with a myelin sheath, containing the nodes of Ranvier, but is bare at the ending. The nerve terminal is separated from the end plate by a gap of 200 Å. The subsynaptic membrane of the end plate contains the cholinergic receptor, the ion-conducting channels (which are opened under the influence of ACh), and AChE.

One of the anatomical differences between the neuromuscular junction and other ACh-responsive sites is the absence in the former of a membrane barrier or sheath that envelopes the ganglia or constitutes the blood-brain barrier. This is important in the accessibility of the site of action to drugs, particularly quaternary ammonium compounds, because they pass through living membranes with considerably greater difficulty and selectivity than do compounds that can exist in a nonionized species. The essentially bare nature (i.e., lack of lipophilic barriers) of the myoneural junction permits ready access by quaternary ammonium compounds. In addition, compounds with considerable molecular dimensions are accessible to the receptors in the myoneural junction. As a result of this property, variations in the chemical structure of quaternaries have little influence on the potential ability of the molecule to reach the cholinergic receptor in the neuromuscular junction. Thus, the following types of neuromuscular junction blockers have been noted.

Nondepolarizing Blocking Agents

Traditionally, *nondepolarizing blocking agents* is a term applied to categorize drugs that compete with ACh for the recognition site on the nicotinic receptor by preventing depolarization of the end plate by the neurotransmitter. Thus, by decreasing the effective ACh–receptor combinations, the end plate potential becomes too small to initiate the propagated action potential. This results in paralysis of neuromuscular transmission. The action of these drugs is quite analogous to that of atropine at the muscarinic receptor sites of ACh. Many experiments suggest that the agonist (ACh) and the antagonist compete on a one-to-one basis for the end plate receptors. Drugs in this class are tubocurarine, dimethyltubocurarine, pancuronium, and gallamine.

Depolarizing Blocking Agents

Drugs in the category of depolarizing blocking agents depolarize the membrane of the muscle end plate. This depolarization is quite similar to that produced by ACh itself at ganglia and neuromuscular junctions (i.e., its so-called nicotinic effect), with the result that the drug, if in sufficient concentration, eventually will produce a block. Either smooth or voluntary muscle, when challenged repeatedly with a depolarizing agent, eventually becomes insensitive.

This phenomenon is known as *tachyphylaxis*, or *desensitization*, and is demonstrated convincingly under suitable experimental conditions with repeated applications of ACh itself, the results indicating that within a few minutes the end plate becomes insensitive to ACh. These statements may imply that a blocking action of this type is clear-cut, but under experimental conditions, it is not quite so unambiguous, because a block that begins with depolarization may regain the polarized state even before the block. Furthermore, depolarization induced by increasing the potassium ion concentration does not prevent impulse transmission. For these and other reasons, it is probably best to consider the blocking action a desensitization until a clearer picture emerges. Drugs falling in this class are decamethonium and succinylcholine.

Curare and Curare Alkaloids

Originally *curare* was a term used to describe collectively the very potent arrow poisons used since early times by the South American Indians. The arrow poisons were prepared from numerous botanic sources and often were mixtures of several different plant extracts. Some were poisonous by virtue of a convulsant action and others by a paralyzant action. Only the latter type is of value in therapeutics and is spoken of ordinarily as curare.

Chemical investigations of the curares were not especially successful because of difficulties in obtaining authentic samples with definite botanic origin. Not until 1935 was a pure crystalline alkaloid, *d*-tubocurarine chloride, possessing in great measure the paralyzing action of the original curare, isolated from a plant. Wintersteiner and Dutcher,⁹² in 1943, isolated the same alkaloid. They showed, however, that the botanic source was *Chondodendron tomentosum* (Menispermaceae) and, thus, provided a known source of the drug.

Following the development of quantitative bioassay methods for determining the potency of curare extracts, a purified and standardized curare was developed and marketed under the trade name Intocostin (purified *C. tomentosum* extract), the solid content of which consisted of almost one-half (+)-tubocurarine solids. Following these essentially pioneering developments, (+)-tubocurarine chloride and dimethyltubocurarine iodide appeared on the market as pure entities.

Tubocurarine Chloride, USP. Tubocurarine chloride, (+)-tubocurarine chloride hydrochloride pentahydrate, is prepared from crude curare by a process of purification and crystallization. Tubocurarine chloride occurs as a white or yellowish white to grayish white, odorless, crystalline powder that is soluble in water. Aqueous solutions of it are stable to heat sterilization.

The structural formula for (+)-tubocurarine was long thought to be that of Ia (see structure diagram). Through the work of Everett et al.,⁹³ the structure is now known to be that of Ib. The monoquaternary nature of Ib thus revealed has caused some reassessment of thinking concerning the theoretical basis for the blocking action, because all had previously assumed a diquaternary structure (i.e., Ia). Nevertheless, this does not negate the earlier conclusions that a diquaternary nature of the molecule

provides better blocking action than does a monoquaternary nature (e.g., Ib is approximately fourfold less potent than dimethyl tubocurarine iodide). Further, (+)-isotubocurarine chloride (Ic) has twice the activity of Ib in the particular test used.

Tubocurarine is a nondepolarizing blocking agent used for its paralyzing action on voluntary muscles, the site of action being the neuromuscular junction. Its action is inhibited or reversed by the administration of AChE inhibitors, such as neostigmine, or by edrophonium chloride (Tensilon). Such inhibition of its action is necessitated in respiratory embarrassment caused by overdose. Additionally, in somewhat higher concentrations, *d*-tubocurarine may enter the open ion channel and add a noncompetitive blockade. Cholinesterase inhibitors do not restore this latter action easily or fully. Often, adjunctive artificial respiration is needed until the maximal curare action has passed. The drug is inactive orally because of inadequate absorption through lipoidal membranes in the GI tract, and when used therapeutically, it usually is injected intravenously.

d-Tubocurarine binds for only 1 ms to the receptor, yet its pharmacological effect of muscle paralysis, produced by administration of the drug intravenously during surgery, lasts for up to 2 hours. The basis of this action is the pharmacokinetics of the drug. *d*-Tubocurarine is given intravenously, and although 30% to 77% is bound to plasma proteins, the drug is distributed rapidly to central body compartments, including neuromuscular junctions. About 45% of *d*-tubocurarine is eliminated unchanged by the kidneys. Its half-life is 89 minutes.

Tubocurarine, in the form of a purified extract, was used first in 1943 as a muscle relaxant in shock therapy for mental disorders. Its use markedly reduced the incidence of bone and spine fractures and dislocations from convulsions because of shock. Following this, it was used as an adjunct in general anesthesia to obtain complete muscle relaxation, a use that persists to this day. Before its use began, satisfactory muscle relaxation in various surgical procedures (e.g., abdominal operations) was obtainable only with “deep” anesthesia with the ordinary general anesthetics. Tubocurarine permits a lighter plane of anesthesia, with no sacrifice in the muscle relaxation so important to the surgeon. A reduced dose of tubocurarine is administered with ether because ether itself has curare-like action.

Metocurine Iodide, USP. Metocurine iodide, (+)-*O,O'*-dimethylchondrocurarine diiodide (Metubine iodide), is prepared from natural crude curare by extracting the curare with methanolic potassium hydroxide. When the extract is treated with an excess of methyl iodide, the (+)-tubocurarine is converted to the diquaternary dimethyl ether and crystallizes out as the iodide (see “Tubocurarine Chloride”). Other ethers besides the dimethyl ether have been made and tested. For example, the dibenzyl ether was one third as active as tubocurarine chloride, and the diisopropyl compound had only one half the activity. For comparison, the dimethyl ether has approximately 4 times the activity of tubocurarine chloride.

The pharmacological action of this compound is the same as that of tubocurarine chloride, namely, a nondepolarizing competitive blocking effect on the motor end plate of skeletal muscles. It is considerably more potent than *d*-tubocurarine, however, and has the added advantage of exerting much less effect on respiration. The effect on respiration is not a significant factor in therapeutic doses. Accidental overdose is counteracted best by forced respiration.

Synthetic Compounds with Curariform Activity

Curare, until relatively recent times, remained the only useful curarizing agent; and it, too, suffered from a lack of standardization. The original pronouncement in 1935 of the structure of (+)-tubocurarine chloride, unchallenged for 35 years, led other workers to hope for activity in synthetic substances of less complexity. The quaternary ammonium character of the curare alkaloids coupled with the known activity of the various simple onium compounds hardly seemed to be coincidental, and it was natural for research to follow along these lines. One of the synthetic compounds discovered was marketed in 1951 as Flaxedil (gallamine triethiodide). Other various neuromuscular blocking agents have followed.

Atracurium Besylate. Atracurium besylate, 2-(2-carboxyethyl)-1,2,3,4-tetrahydro-6,7-dimethoxy-2-methyl-1-veratrylisoquinolinium benzenesulfonate pentamethylene ester (Tracrium), is a nondepolarizing neuromuscular blocking agent that is approximately 2.5 times more potent than *d*-tubocurarine. Its duration of action (half-life, 0.33 hours) is much shorter than that of *d*-tubocurarine. The drug is

Figure 17.20 • Hoffman elimination and hydrolysis reactions of atracurium.

metabolized rapidly and nonenzymatically to yield laudanosine and a smaller quaternary compound (Fig. 17.20), which do not have neuromuscular blocking activity. In vitro experiments show that atracurium besylate breaks down at pH 7.4 and 37°C by a Hoffman elimination reaction.⁹⁴ Atracurium besylate undergoes enzymatic decomposition of its ester function to yield an inactive quaternary alcohol and quaternary acid. AChE inhibitors such as neostigmine, edrophonium, and pyridostigmine antagonize paralysis by atracurium besylate.

Doxacurium Chloride. The molecular structure of doxacurium chloride, 1,2,3,4-tetrahydro-2-(3-hydroxypropyl)-6,7,8-trimethoxy-2-methyl-1-(3,4,5-trimethoxybenzyl) isoquinolinium chloride succinate (Nuromax), provides the possibility for 10 stereoisomers: 4 *d,l* pairs and two *meso*

forms. Of the 10 stereoisomers, 3 are all-*trans* configuration, and these are the only active ones.⁹⁵ Doxacurium chloride is a long-acting nondepolarizing blocking agent. The drug differs from drugs such as gallium and pancuronium in that it has no vagolytic activity. It is used as a skeletal muscle relaxant in surgical procedures expected to last longer than 90 minutes.

Gallamine Triethiodide, USP. Gallamine triethiodide, [*v*-phenenyl-tris(oxyethylene)]tris[triethylammonium] triiodide (Flaxedil), is a skeletal muscle relaxant that works by blocking neuromuscular transmission in a manner similar to that of *d*-tubocurarine (i.e., a nondepolarizing blocking agent). It does have some differences, however. It has a strong vagolytic effect and a persistent decrease in neuromuscular function after successive doses that cannot be

Vecoronium Bromide

overcome by cholinesterase inhibitors. Gallamine triethiodide also has muscarinic antagonistic properties and binds with greater affinity to the M_2 receptors than to the M_1 receptor. This latter characteristic may cause its strong vagolytic action.^{95, 96}

The drug is contraindicated in patients with myasthenia gravis, and one should remember that its action is cumulative, as with curare. The antidote for gallamine triethiodide is neostigmine.

Mivacurium Chloride. Mivacurium chloride, 1,2,3,4-tetrahydro-2-(3-hydroxypropyl)-6,7-dimethoxy-2-methyl-1-(3,4,5-trimethoxybenzyl)isoquinolinium chloride, (E)-4-octandioate (Mivacron), is a mixture of three stereoisomers, the *trans-trans*, *cis-trans*, and *cis-cis* diesters, each of which has neuromuscular blocking properties. The *cis-cis* isomer is about one tenth as potent as the other isomers. Mivacurium chloride is a short-acting nondepolarizing drug

used as an adjunct to anesthesia to relax skeletal muscle. The drug is hydrolyzed by plasma esterases, and it is likely that anticholinesterase agents used as antidotes could prolong rather than reverse the effects of the drug.

Pancuronium Bromide. Although pancuronium bromide, 2 β ,16 β -dipiperidino-5 α -androstandi-3 α ,17 β -diol diacetate dimethobromide (Pavulon), is a synthetic product, it is based on the naturally occurring alkaloid malouetine, found in arrow poisons used by primitive Africans. Pancuronium bromide acts on the nicotinic receptor and in the ion channel, inhibiting normal ion fluxes.

This blocking agent is soluble in water and is marketed in concentrations of 1 or 2 mg/mL for intravenous administration. It is a typical nondepolarizing blocker, with a potency approximately 5 times that of (+)-tubocurarine chloride and a duration of action approximately equal to the latter. Studies indicate that it has little or no histamine-releasing potential or ganglion-blocking activity and that it has little effect on the circulatory system, except for causing a slight rise in the pulse rate. As one might expect, ACh, anticholinesterases, and potassium ion competitively antagonize it, whereas its action is increased by inhalation anesthetics such as ether, halothane, enflurane, and methoxyflurane. The latter enhancement in activity is especially important to the anesthetist because the drug is frequently administered as an adjunct to the anesthetic procedure to relax the skeletal muscle. Perhaps the most frequent adverse reaction to this agent is occasional prolongation of the neuromuscular block beyond the usual time course, a situation that can usually be controlled with neostigmine or by manual or mechanical

ventilation, since respiratory difficulty is a prominent manifestation of the prolonged blocking action.

As indicated, the principal use of pancuronium bromide is as an adjunct to anesthesia, to induce relaxation of skeletal muscle, but it is also used to facilitate the management of patients undergoing mechanical ventilation. Only experienced clinicians equipped with facilities for applying artificial respiration should administer it, and the dosage should be adjusted and controlled carefully.

Pipecurium Bromide. Pipecurium bromide, 4,4'-(3 α , 17 β -dihydroxy-5 α -androstan-2 β , 16 β -ylene)bis(1,1-dimethylpiperazinium)dibromide diacetate (Arduan), is a nondepolarizing muscle relaxant similar, both chemically and clinically, to pancuronium bromide. It is a long-acting

drug indicated as an adjunct to anesthesia and in patients undergoing mechanical ventilation.

Vecuronium Bromide. Vecuronium bromide, 1-(3 α , 17 β -dihydroxy-2 β -piperidino-5 α -androstan-16 β -yl)-1-methylpiperidinium bromide diacetate (Norcuron), is the monoquaternary analog of pancuronium bromide. It belongs to the class of nondepolarizing neuromuscular blocking agents and produces effects similar to those of drugs in this class. It is unstable in the presence of acids and undergoes gradual hydrolysis of its ester functions in aqueous solution. Aqueous solutions have a pH of about 4.0. This drug is used mainly to produce skeletal muscle relaxation during surgery and to assist in controlled respiration after general anesthesia has been induced.

Pancuronium Bromide

Pipecurium Bromide

Vecuronium Bromide

Succinylcholine Chloride, USP. Succinylcholine chloride, choline chloride succinate (2:1) (Anectine, Sucostrin), is a white, odorless, crystalline substance that is freely soluble in water to give solutions with a pH of about 4. It is stable in acidic solutions but unstable in alkali. Aqueous solutions should be refrigerated to ensure stability.

Succinylcholine chloride is characterized by a very short duration of action and a quick recovery because of its rapid hydrolysis after injection. It brings about the typical muscular paralysis caused by blocking nervous transmission at the myoneural junction. Large doses may cause temporary respiratory depression, as with similar agents. Its action, in contrast with that of (1)-tubocurarine, is not antagonized by neostigmine, physostigmine, or edrophonium chloride. These anticholinesterase drugs actually prolong the action of

succinylcholine chloride, which suggests that the drug is probably hydrolyzed by cholinesterases. The brief duration of action of this curare-like agent is said to render an antidote unnecessary if the proper supportive measures are available. Succinylcholine chloride has a disadvantage, however, in that the usual antidotes cannot terminate its action promptly.

It is used as a muscle relaxant for the same indications as other curare agents. It may be used for either short or long periods of relaxation, depending on whether one or several injections are given. In addition, it is suitable for continuous intravenous drip administration.

Succinylcholine chloride should not be used with thiopental sodium because of the high alkalinity of the latter. If used together, they should be administered immediately after mixing; however, separate injection is preferable.

REVIEW QUESTIONS

- When discussing the structure–activity relationship of acetylcholine what will alkyl substitutions on the beta carbon cause to the molecule?
 - decrease rate of hydrolysis by esterases
 - decrease nicotinic action
 - increase muscarinic action
 - All of the above are correct.
 - Only a and c are correct.
- The therapeutic usefulness of the agent represented below is:

- incontinence
- glaucoma
- myasthenia gravis
- insecticidal agent
- irritable bowel syndrome

- The therapeutic usefulness of the agent represented below is in treating Alzheimer disease. Please describe why this agent has usefulness in treating this disease.

- Describe the reason cholinergics can be used in myasthenia gravis.

Drugs Acting on the Renal System

STEPHEN J. CUTLER

CHAPTER OVERVIEW

Drugs acting on the renal system describes the role renin–angiotensin system plays in regulating the cardiovascular system. This chapter supports the fact that this system plays a critical role in the mechanisms of hypertension and heart failure (formally recognized as congestive heart failure [CHF]). This, in turn, serves in the development of therapeutic agents that act on the various enzymes and receptors associated with the renin–angiotensin system. For pharmacists to be good practitioners, it is necessary that they understand how the renin–angiotensin system influences normal physiological functions as well as how components of the system, such as renin, angiotensin I and II, and angiotensin-converting enzyme, can be used in manipulating specific cardiovascular diseases.

The Renin–Angiotensin System and Hypertension

The renin–angiotensin system is a hormonal system that plays a central role in the control of sodium excretion and body fluid volume. It interacts closely with the sympathetic nervous system and aldosterone secretion in the regulation of blood pressure. Figure 18.1 shows the relationship of the component parts of the renin–angiotensin system and their main physiological effects.

The relationship between the renin–angiotensin system and blood pressure in humans has been known since before the beginning of the 20th century. Tigerstedt and Bergman¹ demonstrated in 1898 that, when injected in a host, kidney extract produced a potent vasopressor response. The substance was named *renin*. Many years later, this substance was shown to require a cofactor to produce vasoconstriction.² Eventually, in 1939, this hypertensive substance was isolated, identified as a decapeptide, and later called *angiotensin*. This cofactor existed as an inactive precursor, angiotensinogen. Later studies revealed that angiotensin existed in two forms, the biologically inactive decapeptide angiotensin I and the active octapeptide angiotensin II.³

The precursor of angiotensin, angiotensinogen, is a glycoprotein of molecular weight (MW) 58,000 to 61,000, synthesized primarily in the liver and brought into the circulatory system. Renin, an aspartyl protease (MW 35,000–40,000), whose primary source is the kidney, cleaves the Leu-Val bond from the aspartic acid end of the angiotensinogen polypeptide molecule to release the decapeptide angiotensin I (Fig. 18.2). The biochemical conversion continues with the cleavage of a dipeptide (His-Leu)

from the carboxyl terminal of angiotensin I by angiotensin-converting enzyme (ACE) to form the octapeptide angiotensin II, a potent vasoconstrictor. Angiotensin III is formed by removal of the *N*-terminal aspartate residue of angiotensin II, a reaction catalyzed by glutamyl aminopeptidase. In contrast to angiotensin II, angiotensin III has a less potent but significant regulatory effect on sodium excretion by the renal tubules. This is primarily resulting from the effect angiotensin III has in stimulating aldosterone secretion, a potent mineralocorticoid.

The vasoconstrictive effects of angiotensin II are a result of many factors. In the kidneys, it constricts glomerular arterioles. The effects are greater on efferent arterioles than afferent ones. Constriction of afferent arterioles results in increased arteriolar resistance, which raises systemic arterial blood pressure. In addition, angiotensin II stimulates the release of vasopressin from the hypothalamus. Vasopressin is also known as the *antidiuretic hormone* (ADH), because this peptidic hormone is typically released to conserve water when the body is dehydrated. In the kidneys, it increases the permeability to water of the distal convoluted tubules and collecting tubules in the nephrons. This, in turn, results in concentrating the urine and reducing urine volume. By inducing moderate vasoconstriction, this peptide results in an increase in blood pressure. Additionally, angiotensin II has been shown to stimulate the production of endothelin, a 21 amino acid peptide that is produced in the vascular endothelium and which plays a role in the regulation of smooth muscle contraction and which contributes to blood pressure regulation (see Chapter 19).⁴ Lastly, angiotensin II plays a primary role in regulating aldosterone secretion. Upon stimulation by the renin–angiotensin system, aldosterone is secreted by the adrenal cortex and elicits its effects at various sites, including the nephrons. It is responsible for the reabsorption of sodium into the bloodstream. This results in increased levels of sodium in the plasma, which in turn result in increased blood volume and vascular resistance.⁵ If aldosterone levels in the body become too high, then symptoms such as elevated blood pressure or heart failure (formally classified as CHF) can occur.

The regulatory action of the renin–angiotensin system in controlling sodium and potassium balance and arterial blood pressure is modified by vasodilators called kinins. Proteolytic enzymes that circulate in the plasma form *kinins*. Kallikrein is activated in plasma by noxious influences to act on a kinin, callidin, which is converted to bradykinin by tissue enzymes. Bradykinin enhances release of the prostaglandins PGE₂ and PGI₂ within certain tissues to produce a vasodilatory effect (Fig. 18.3). Bradykinin is converted to inactive products by

Figure 18.1 • Renin–angiotensin system of blood pressure control.

ACE and other carboxypeptidases.⁶ Although ACE causes activation of angiotensin and inactivation of bradykinin, actions that appear to be opposite, the balance of the system seems to favor vasoconstriction.

ACE is a membrane-bound enzyme anchored to the cell membrane through a single transmembrane domain located near the carboxy-terminal extremity. The enzyme is a zinc-containing glycoprotein with an MW about 130,000. It is a nonspecific peptidyl dipeptide hydrolase, widely distributed in mammalian tissues, that cleaves dipeptides from the car-

boxy terminus of several endogenous peptides. The minimum structural requirement for binding and cleavage of a substrate by ACE is that it is a tripeptide with a free carboxylate group. A general exception is that this enzyme does not cleave peptides with a penultimate prolyl residue.⁷ This accounts for the biological stability of angiotensin II.⁷ The important binding points at the active site of ACE are a cationic site to attract a carboxylate ion and a zinc ion that can polarize a carbonyl group of an amide function to make it more susceptible to hydrolysis. In the active site, there is

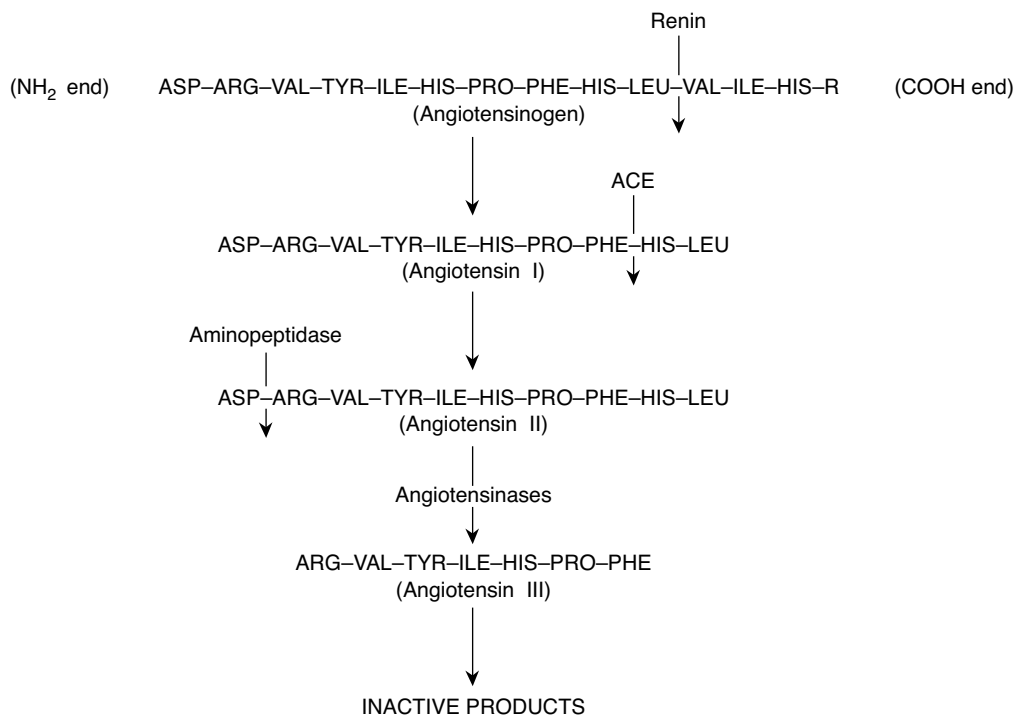

Figure 18.2 • Biochemistry of the renin–angiotensin system: formation of angiotensins from angiotensinogen.

Figure 18.3 • Bradykinin formation and action.

a nucleophilic attack of the amide carbonyl by the γ -carbonyl group of a glutamic acid residue to cause hydrolysis of the peptide. Figure 18.4 shows a hypothetical model of the hydrolysis of angiotensin I by the active site of ACE. ACE exists in more than one form. Somatic ACE that regulates blood pressure, found in most tissues, differs from the isoenzyme ACE found in the testis. Somatic ACE, in contrast to testicular ACE, contains two binding domains. The principal active site for hydrolysis is the domain located in the C-terminal half of somatic ACE.⁸

Because the renin-angiotensin system plays such an important role in regulating kidney function,⁹ aldosterone release,¹⁰ electrolyte balance, and blood volume, it is easy to recognize why targeting this pathway is beneficial in the management of high blood pressure and heart failure. Inhibitors of angiotensin-converting enzyme (ACE in-

hibitors) are often used to reduce the formation of the more potent angiotensin II. In addition, angiotensin receptor blockers (ARBs) can be used to prevent angiotensin II from acting on angiotensin receptors.¹¹

Recently, there have been several agents investigated for their ability to inhibit renin, which in turn results in less angiotensin II being produced.¹²

RENIN-ANGIOTENSIN SYSTEM INHIBITORS

Angiotensin-Converting Enzyme Inhibitors

PRODUCTS

Captopril. Captopril, 1-[(2*S*)-3-mercapto-2-methyl-1-oxopropionyl]proline (Capoten), blocks the conversion of angiotensin I to angiotensin II by inhibiting the converting enzyme. The rational development of captopril as an inhibitor of ACE was based on the hypothesis that ACE and carboxypeptidase A functioned by similar mechanisms. It was noted that *d*-2-benzylsuccinic acid⁷ was a potent inhibitor of carboxypeptidase A, but not ACE. By use of this small

Figure 18.4 • Model showing cleavage of the histidine-phenylalanine residue of angiotensin I by ACE to form the octapeptide antiotensin II and the dipeptide residue of histidine and leucine.

Figure 18.5 • Accommodation of captopril to the active site of ACE.

molecule as a prototype, captopril was designed with a carboxyl group on a proline and a thiol group was introduced to enhance the binding to the zinc ion of ACE. The important binding points at the active site of ACE are thought to be an arginine residue, which provides a cationic site that attracts a carboxylate ion, and a zinc ion, which can polarize a carbonyl group of an amide function to make it more susceptible to hydrolysis. Hydrophobic pockets lie between these groups in the active site, as does a functional group that forms a hydrogen bond with an amide carbonyl. Figure 18.5 shows the hypothetical binding of captopril in the active site of ACE.

Captopril
(Capoten)

Lisinopril. Lisinopril, 1-[N²-[S-1-carboxy-3-phenylpropyl]-L-lysyl]-L-proline dihydrate (Prinivil, Zestril), is a lysine derivative of enalaprilat, the active metabolite of enalapril. Like all ACE inhibitors, it is an active site-directed inhibitor of the enzyme, with the zinc ion used in an effective binding interaction at a stoichiometric ratio of 1:1. The pharmacological effects of lisinopril are similar to those of captopril and enalapril.

Lisinopril

(Zestril)

ACE-INHIBITOR PRODRUGS

Many new ACE inhibitors became available for the treatment of hypertension following the clinical effectiveness of enalapril. Enalapril is a non-thiol-containing ACE inhibitor devoid of the side effects of rash and loss of the sense of taste characteristic of the thiol-containing compound captopril. With the exception of the phosphorus-containing fosinopril, these antihypertensive agents have a 2-(S)-aminophenylbutyric acid ethyl ester moiety differing only in the substituents on the amino group. They have the common property of acting as prodrugs, being converted to the active enzyme inhibitor following absorption and metabolism by liver and intestinal enzymes. These drugs (Fig. 18.6), like the prototypical drug captopril, are used in the treatment of mild-to-moderate hypertension, either alone or in conjunction with diuretics or calcium channel blockers. Table 18.1 compares some of their properties.

PRODUCTS

Enalapril Maleate. Enalapril maleate, 1-[N[(S)-1-carboxy-3-phenylpropyl]-L-alanyl]-L-proline 1'-ethyl ester maleate (Vasotec), is a long-acting ACE inhibitor. It requires activation by hydrolysis of its ethyl ester to form the diacid enalaprilat. Enalapril is devoid of the side effects of rash and loss of taste seen with captopril. These side effects are similar to those of the mercapto-containing drug penicillamine. The absence of the thiol group in enalapril maleate may free it from these side effects. The half-life is 11 hours.

Enalapril
(Vasotec)

Figure 18.6 • ACE-inhibitor prodrugs.

Benzapril Hydrochloride. Benzapril hydrochloride, (3*S*)-3-[[*(1S)*-1-carboethoxy-3-phenylpropyl]amino]-2,3,4,5-tetrahydro-2-oxo-1*H*-1-benzazepine-1-acetic acid 3-ethyl ester hydrochloride (Lotensin), is metabolized rapidly to the active diacid benzaprilat. As with the ACE prodrugs, no mutagenicity has been found, even though these drugs cross the placenta.

Quinapril Hydrochloride. Quinapril hydrochloride, (*S*)-[*(S)*-*N*-[*(S)*21-carboxy-3-phenylpropyl]alanyl]-1,2,3,4-tetrahydro-3-isoquinolinecarboxylic acid 1-ethyl ester hydrochloride (Acuretic), forms the diacid quinaprilate in the

body. It is more potent than captopril and equipotent to the active form of enalapril.

Ramipril. Ramipril, (2*S*, 3*aS*, 6*aS*)-1-[(*S*)-*N*-[*(S)*-1-carboxy-3-phenylpropyl]alanyl]octahydrocyclopenta[*b*]pyrrole-2-carboxylic acid 1-ethyl ester (Altace), is hydrolyzed to ramiprilat, its active diacid form, faster than enalapril is hydrolyzed to its active diacid form. Peak serum concentrations from a single oral dose are achieved between 1.5 and 3 hours. The ramiprilate formed completely

TABLE 18.1 Comparison of Properties of ACE-Inhibitor Prodrugs

Prodrug	Metabolite	Metabolite Protein Binding (%)	Metabolite Plasma $t_{1/2}$ (hours)	Mode of Excretion
Benazepril	Benazeprilat	95	10–11	Renal
Enalapril	Enalaprilat	50–60	11.0	Renal
Fosinopril	Fosinoprilat	97	11.5	Renal/fecal
Quinapril	Quinaprilat	97	3.0	Renal/fecal
Ramipril	Ramiprilat	56	13–17	Renal/fecal

suppresses ACE activity for up to 12 hours, with 80% inhibition of the enzyme still observed after 24 hours.

Fosinopril Sodium. Fosinopril sodium, (4*S*)-4-cyclohexyl-1-[[[(*RS*)-1-hydroxy-2-methylpropoxy](4-phenylbutyl)phosphinyl]acetyl]-L-proline sodium salt (Monopril), is a phosphorus-containing ACE inhibitor. It is inactive but serves as a prodrug, being completely hydrolyzed by intestinal and liver enzymes to the active diacid fosinoprilat.

Trandolapril. Trandolapril, 1-[2-(1-ethoxycarbonyl-3-phenylpropylamino)propionyl]octahydroindole-2-carboxylic acid (Mavik), is an indole-containing ACE inhibitor that is structurally related to most of the preceding agents discussed. Enalapril is very similar to trandolapril, with the primary difference occurring in the heterocyclic systems. The pyrrolidine of enalapril has been replaced with an octahydroindole system. Much like enalaprilate, trandolapril must be hydrolyzed to tranolaprilate, which is the bioactive species.

ANGIOTENSIN ANTAGONISTS

There are four different subtypes of angiotensin II receptor subclasses identified to date and include AT₁, AT₂, AT₃, and AT₄. These belong to the class of G-protein-coupled receptors and are responsible for the signal transduction of the hormone. Although there is some understanding of the role AT₂ plays in development of a fetus or neonate, there is very little known about the role of AT₂ and AT₃ in the human body. However, it is the AT₁ receptors that are of particular interest in managing specific cardiovascular diseases. Studies have demonstrated that stimulation of AT₁ receptors by angiotensin II result in vasoconstriction, aldosterone synthesis and secretion, increased vasopressin secretion, decreased renal blood flow, renal tubular sodium reuptake, and several other physiological events.

Administration of a competitive antagonist that inhibits angiotensin II at the AT₁ receptor will produce a vasodilatory effect. Because the substrate for this receptor is an octapeptide, much of the earlier work was performed by using various peptide systems. One such agent, saralasin, is an octapeptide that differs from angiotensin by two amino acids. This agent's use was limited because it had some partial agonistic properties. Nevertheless, it served as a lead in the development of other agents that are useful in antagonizing the angiotensin II receptor. The most significant lead in the development of this class came from a series of imidazole-5-acetic acid derivatives that attenuated pressor response to angiotensin II in test animals. Molecular modeling revealed that the imidazole-5-acetic acid could be exploited to mimic more closely the pharmacophore of angiotensin II. The first successful agent to be developed through this method is losartan. Later, four other agents were introduced into the U.S. market. These tend to be biphenylmethyl derivatives that possess certain acidic moieties, which can interact with various positions on the receptor, much like the substrate, angiotensin II.

ANGIOTENSIN II BLOCKERS

PRODUCTS

Losartan. Losartan, 2-butyl-4-chloro-1-[*p*-(*o*-1*H*-tetrazol-5-yl-phenyl)benzyl]imidazole-5-methanol monopotassium salt (Cozarr), was the first nonpeptide imidazole to be introduced as an orally active angiotensin II antagonist with high specificity for AT₁. When administered to patients, it undergoes extensive first-pass metabolism, with the 5-methanol being oxidized to a carboxylic acid. This metabolism is mediated by CYP 2C9 and 3A4 isozymes. The 5-methanol metabolite is approximately 15 times more potent than the parent hydroxyl compound. Because the parent hydroxyl compound has affinity for the AT₁ receptor, strictly speaking, it is not a prodrug.¹³

Candesartan. Candesartan, (+)-1-[[[(cyclohexyloxy)carbonyl]oxy]ethyl 2-ethoxy-1-[[2'-(1*H*-tetrazol-5-yl)[1,1'-biphenyl]-4-yl]methyl]-1*H*-benzimidazole-7-carboxylate (Atacand), like losartan, possesses the acidic tetrazole system, which most likely plays a role in binding to the angiotensin II receptor similarly to the acidic groups of angiotensin II. Also, the imidazole system has been replaced with a benzimidazole possessing an ester at position 7. This ester must be hydrolyzed to the free acid. Fortunately, this conversion takes place fairly easily because of the carbonate in the ester side chain. This facilitates hydrolysis of the ester so much that conversion to the free acid takes place during absorption from the gastrointestinal tract.

Irbesartan. Irbesartan, 2-butyl-3-[[29-(1*H*-tetrazol-5-yl)[1,19-biphenyl]-4-yl]methyl]1,3-diazaspiro[4,4]non-1-en-4-one (Avapro), like losartan, possesses the acidic tetrazole system, which most likely plays a role, similar to the acidic groups of angiotensin II, in binding to the angiotensin II receptor. In addition, the biphenyl system that serves to separate the tetrazole from the aliphatic nitrogen is still present. A major difference in this agent is that it does not possess the acidic side chain. Even so, irbesartan has good affinity for the angiotensin II receptor because of hydrogen bonding with the carbonyl moiety of the amide system. Also, this particular agent does not require metabolic activation as candesartan does.

Telmisartan. Telmisartan, 4'-[(1,4'-dimethyl-2'-propyl[2,6'-bi-1*H*-benzimidazol]-1'-yl)methyl]-[1,1'-biphenyl]-2-carboxylic acid (Micardis), does not appear to bear any structural relationship to this class, but there is actually a great deal of overlap in the chemical architecture with other agents. The first, and most significant, difference is the replacement of the acidic tetrazole system with a simple carboxylic acid. This acid, like the tetrazole, plays a role in receptor binding. The second difference is the lack of a carboxylic acid near the imidazole nitrogen that also contributes to receptor binding.¹⁴ As with irbesartan, however, there is not a need for this group to be acidic but, rather, to be one that participates in receptor binding. The second imidazole ring, much like a purine base in deoxyribonucleic acid (DNA), can hydrogen bond with the angiotensin II receptor.

Olmesartan. Olmesartan medoxomil, (5-methyl-2-oxo-1,3-dioxol-4-yl)methyl-5-(2-hydroxypropan-2-yl)-2-

Olmesartan medoxomil

propyl-3-[[4-[2-(2H-tetrazol-5-yl)phenyl]phenyl]methyl]imidazole-4-carboxylate (Benicar, Olmetec) uses the tetrazole ring system as its acidic system, which participates in receptor binding.¹⁴ When administered to a patient, the drug is rapidly and completely bioactivated by ester hydrolysis of the medoxomil during absorption from the gastrointestinal tract. Once the prodrug is converted to the active form, virtually no further metabolism occurs. In September 2007, the Food and Drug Administration (FDA) approved its use as a combination product with the calcium channel blocker amlodipine for the management of hypertension. This combination product is sold under the tradename of Azor.

Valsartan. Valsartan, *N*-(1-oxopentyl)-*N*-[[2'-(1*H*-tetrazol-5-yl)[1,1'-biphenyl]-4-yl]methyl]-*L*-valine (Diovan), like losartan, possesses the acidic tetrazole system, which most likely plays a role, similar to that of the acidic groups of angiotensin II, in binding to the angiotensin II receptor. In addition, the biphenyl system that serves to separate the tetrazole from the aliphatic nitrogen is still present. In addition, there is a carboxylic acid side chain in the valine moiety that also serves to bind to the angiotensin II receptor.¹⁵

RENIN INHIBITORS

Renin is a circulating enzyme that is secreted by the kidneys in response to decreases in glomerular filtration rate, which is typically a result of low blood volume. It is a 340-amino acid protein that participates in the renin-angiotensin system. It is responsible for cleaving angiotensinogen, which is produced in the liver, to angiotensin I. As indicated previously in this chapter, angiotensin I is converted to angiotensin II, which plays an important role in regulating blood pressure, among other physiological events. Inhibitors of renin have usefulness in managing cardiovascular diseases such as hypertension and heart failure because of their ability in reducing the influence on the renin-angiotensin system through reduced biosynthesis of angiotensin II and other bioactive intermediates.¹⁶

Although this drug target has been investigated for more than 30 years, it represents the first new class of orally active antihypertensive agents and joins at least seven other classes of antihypertensive drugs. The other classes, as described in Chapter 19, include diuretics, α -blockers, β -blockers, calcium channel blockers, as well as those discussed in this chapter and include ACE inhibitors, ARBs, and aldosterone receptor antagonists.

PRODUCTS

Aliskiren. Aliskiren, (2*S*,4*S*,5*S*,7*S*)-5-amino-*N*-(2-carbamoyl-2-methyl-propyl)-4-hydroxy-7-[[4-methoxy-3-(3-methoxypropoxy)phenyl]methyl]-8-methyl-2-propan-2-yl-nonanamide (Tekturna), is the first renin inhibitor introduced into the U. S. market.¹⁷ It was approved by the FDA in 2007 for the management of hypertension. The trade name for aliskiren in the United Kingdom is Rasilez.

Aliskiren

ALDOSTERONE ANTAGONISTS

Aldosterone antagonists are, as the name implies, receptor antagonists at the mineralocorticoid receptor. Antagonism of these receptors inhibits sodium resorption in the distal tubule of the nephron, which in turn, interferes with sodium/potas-

sium exchange, reducing urinary potassium excretion. Overall, this results in a weak diuretic effect and decreases cardiac workload. Agents that block aldosterone may be used in the management of hypertension or heart failure. The two agents approved for use in the United States are spironolactone (Aldactone) and eplerenone (Inspra) and are discussed in greater detail in the diuretic chapter of this textbook.

REVIEW QUESTIONS

- The renin-angiotensin system plays an important role in regulation of blood pressure. For that reason, this pathway encompasses the conversion of an approximately 400 amino acid sequence to a decapeptide, then to the biologically active octapeptide, and is an excellent target for drug therapy to manage hypertension. Describe the starting protein and its conversion to the biologically active metabolite. Be sure to include the enzymes involved in the conversion of the protein and peptides.
- The therapeutic usefulness of the agent represented below (candesartan [Atacand]) is:
 - angiotensin-converting enzyme inhibitor
 - angiotensin II receptor blocker
 - renin inhibitor
 - aldosterone antagonist
 - More than one answer is correct.
- Although the agent represented below (losartan [Cozaar]) has some pharmacological effects, one of its metabolites is reported to be more potent. Identify the metabolite and describe its production.

- angiotensin-converting enzyme inhibitor
- angiotensin II receptor blocker

CHAPTER 19

Cardiovascular Agents

STEPHEN J. CUTLER

CHAPTER OVERVIEW

Proteins, cardiovascular agents, describe the role various chemical entities play in controlling cardiovascular diseases. This chapter describes the agents used in the treatment of angina, cardiac arrhythmias, hypertension, erectile dysfunction, hyperlipidemias, and disorders of blood coagulation. For pharmacists to be good practitioners, it is necessary that they understand the pathophysiology of cardiovascular diseases and the agents used to treat these syndromes.

The treatment and therapy of cardiovascular disease have undergone dramatic changes since the 1950s. Data show that since 1968 and continuing through the 1990s, there has been a noticeable decline in mortality from cardiovascular disease. The bases for advances in the control of heart disease have been (a) a better understanding of the disease state, (b) the development of effective therapeutic agents, and (c) innovative medical intervention techniques to treat problems of the cardiovascular system.

The drugs discussed in this chapter are used for their action on the heart or other parts of the vascular system, to modify the total output of the heart or the distribution of blood to the circulatory system. These drugs are used in the treatment of angina, cardiac arrhythmias, hypertension, hyperlipidemias, and disorders of blood coagulation. This chapter also includes a discussion of hypoglycemic agents, thyroid hormones, and antithyroid drugs.

ANTIANGINAL AGENTS AND VASODILATORS

Most coronary artery disease conditions are caused by deposits of atheromas in the intima of large and medium-sized arteries serving the heart. The process is characterized by an insidious onset of episodes of cardiac discomfort caused by ischemia from inadequate blood supply to the tissues. Angina pectoris (angina), the principal symptom of ischemic heart disease, is characterized by a severe constricting pain in the chest, often radiating from the precordium to the left shoulder and down the arm. The syndrome has been described since 1772, but not until 1867 was amyl nitrite introduced for the symptomatic relief of angina pectoris.¹ It was believed at that time that anginal pain was precipitated by an increase in blood pressure and that the use of amyl nitrite reduced both blood pressure and, concomitantly, the work required of the heart. Later, it was generally accepted that nitrites relieved angina pectoris by dilating the coronary arteries and that changes in the work of the heart were of

only secondary importance. We now know that the coronary blood vessels in the atherosclerotic heart already are dilated, and that ordinary doses of dilator drugs do not significantly increase blood supply to the heart; instead, anginal pain is relieved by a reduction of cardiac consumption of oxygen.²

Although vasodilators are used in the treatment of angina, a more sophisticated understanding of the hemodynamic response to these agents has broadened their clinical usefulness to other cardiovascular conditions. Because of their ability to reduce peripheral vascular resistance, vasodilators, including organonitrates, angiotensin-converting enzyme (ACE) inhibitors, and angiotensin receptor–blocking agents, are used to improve cardiac output in some patients with congestive heart failure (CHF).

The coronary circulation supplies blood to the myocardial tissues to maintain cardiac function. It can react to the changing demands of the heart by dilating its blood vessels to provide sufficient oxygen and other nutrients and to remove metabolites. Myocardial metabolism is almost exclusively aerobic, which makes blood flow critical to the support of metabolic processes of the heart. This demand is met effectively by the normal heart, because it extracts a relatively large proportion of the oxygen delivered to it by the coronary circulation. The coronary blood flow depends strongly on myocardial metabolism, which in turn is affected by work done by the heart and the efficiency of the heart. The coronary system normally has a reserve capacity that allows it to respond by vasodilation to satisfy the needs of the heart during strenuous activity by the body.

Coronary atherosclerosis, one of the more prevalent cardiovascular diseases, develops with increasing age and may lead to a reduction of the reserve capacity of the coronary system. It most often results in multiple stenosis and makes it difficult for the coronary system to meet adequately the oxygen needs of the heart that occur during physical exercise or emotional duress. Insufficient coronary blood flow (*myocardial ischemia*) in the face of increased oxygen demand produces angina pectoris.

The principal goal in the prevention and relief of angina is to limit the oxygen requirement of the heart, so that the amount of blood supplied by the stenosed arteries is adequate. Nitrate esters, such as nitroglycerin, lower arterial blood pressure and, in turn, reduce the work of the left ventricle. This action is produced by the powerful vasodilating effect of the nitrates on the arterial system and, to an even greater extent, on the venous system. The result is reduced cardiac filling pressure and ventricular size. This reduces the work required of the ventricle and decreases the oxygen requirements, allowing the coronary system to satisfy the oxygen demands of myocardial tissue and relieve anginal pain.

Intermediary Myocardial Metabolism

Energy metabolism by heart tissue provides an adequate supply of high-energy phosphate compounds to replace the adenosine triphosphate (ATP) that is continually being consumed in contraction, ion exchange across membranes, and other energy-demanding processes. Because of the high turnover rate of ATP in heart muscle, a correspondingly high rate of ATP production in the mitochondria is required.

Normal myocardial metabolism is aerobic, and the rate of oxygen use parallels the amount of ATP synthesized by the cells.³ Free fatty acids (FFAs) are the principal fuel for myocardial tissue, but lactate, acetate, acetoacetate, and glucose are also oxidized to carbon dioxide and water. A large volume of the myocardial cell consists of mitochondria in which two-carbon fragments from FFA breakdown are metabolized through the Krebs cycle. The reduced flavin and nicotinamide dinucleotides formed by this metabolism are reoxidized by the electron-transport chain because of the presence of oxygen (Fig. 19.1). In the hypoxic or ischemic heart, the lack of oxygen inhibits the electron-transport chain function and causes an accumulation of reduced flavin and nicotinamide coenzymes. As a result, fatty acids are converted to lipids rather than being oxidized. To compensate for this, glucose use and glycogenolysis increase, but the resulting pyruvate cannot be oxidized; instead, it is converted to lactate. A great loss of efficiency occurs as a result of the change of myocardial metabolism from aerobic to anaerobic pathways. Normally, 36 mol of ATP are formed from the oxidation of 1 mol of glucose, but only 2 mol are formed from its glycolysis. This great loss of high-energy stores during hypoxia thus limits the functional capacity of

the heart during stressful conditions and is reflected by the production of anginal pain.

Nitrovasodilators

SMOOTH MUSCLE RELAXATION

The contractile activity of all types of muscle (smooth, skeletal) is regulated primarily by the reversible phosphorylation of myosin. Myosin of smooth muscle consists of two heavy chains (molecular weight [MW] 200,000 each) that are coiled to produce a filamentous tail. Each heavy chain is associated with two pairs of light chains (MW 20,000 and 16,000) that serve as substrates for calcium- and calmodulin-dependent protein kinases in the contraction process. Together with actin (MW 43,000), they participate in a cascade of biochemical events that are part of the processes of muscle contraction and relaxation (Fig. 19.2).

Cyclic nucleotides, cyclic adenosine monophosphate (cAMP), and, especially, cyclic guanosine monophosphate (cGMP) play important roles in the regulation of smooth muscle tension. cAMP is the mediator associated with the smooth muscle relaxant properties of drugs such as β -adrenergic agonists. It activates the protein kinases that phosphorylate myosin light-chain kinase (MLCK). Phosphorylation of MLCK inactivates this kinase and prevents its action with Ca^{2+} and calmodulin to phosphorylate myosin, which interacts with actin to cause contraction of smooth muscle (Fig. 19.2).

The activity of cGMP in smooth muscle relaxation is affected by exogenous and endogenous agents. It is suggested⁴ that nitrovasodilators undergo metabolic transformation in

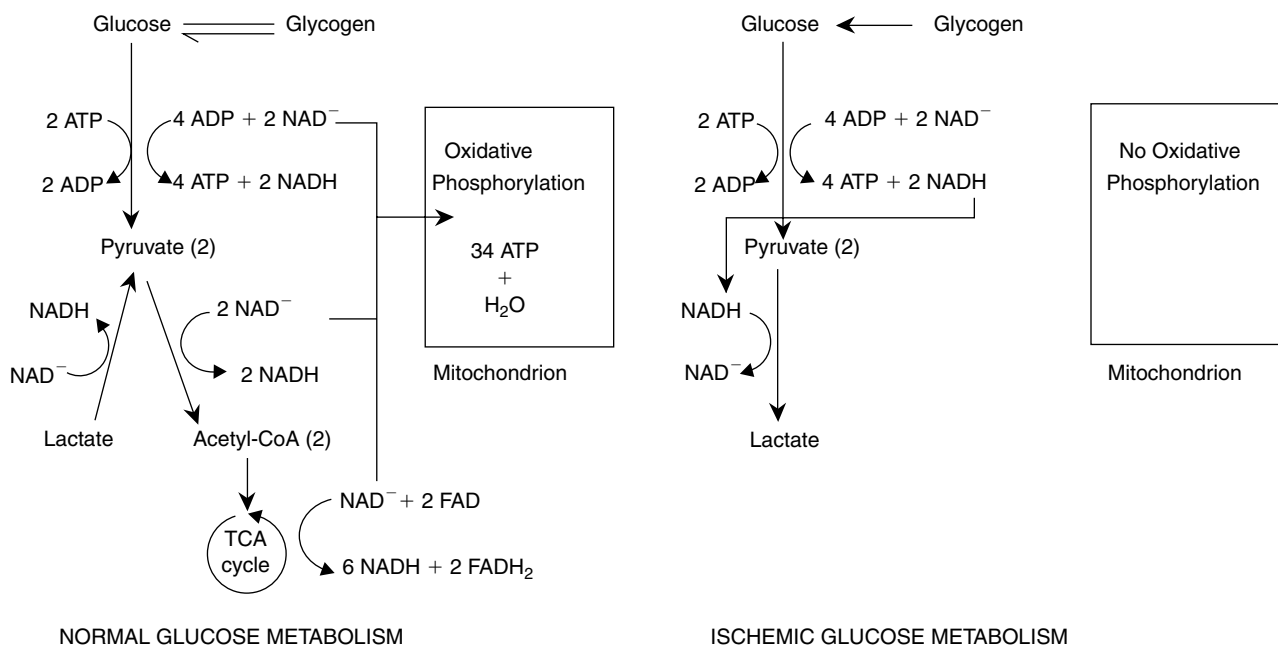

Figure 19.1 • Normal and ischemic myocardial metabolism of glucose. A total production of 36 mol of ATP results from the aerobic catabolism of 1 mol of glucose and use of NADH and FADH₂ in the oxidative phosphorylation process in mitochondria. When oxygen is not available, NADH and FADH₂ levels rise and shut off the tricarboxylic acid (TCA) cycle. Pyruvate is converted to lactate. Only 2 mol of ATP are formed from anaerobic catabolism of 1 mol of glucose. (Adapted from Giuliani, E. R., et al.: *Cardiology: Fundamentals and Practice*, 2nd ed. By permission of the Mayo Foundation, Rochester, MN.)

Figure 19.2 • Regulation of smooth muscle contraction. Contraction is triggered by an influx of Ca^{2+} . The increase of free Ca^{2+} causes binding to calmodulin (CM). The Ca^{2+} —CM complex binds to myosin light-chain kinase (MLCK) and causes its activation (MLCK*). MLCK* phosphorylates myosin, which combines with actin to produce contraction of smooth muscle. Myosin is dephosphorylated in the presence of myosin phosphatase to cause muscle relaxation. The β -agonists activate adenylate cyclase (AC) to raise levels of cAMP, which in turn activates kinases that phosphorylate MLCK, inactivating it to prevent muscle contraction.

vascular smooth muscle cells to form nitric oxide (NO). NO mediates smooth muscle relaxation by activating guanylate cyclase to increase intracellular concentrations of cGMP. cGMP activates protein kinases that can regulate free Ca^{2+} levels in the muscle cell and cause relaxation of smooth muscle by phosphorylating MLCK.

A short-lived free radical gas, NO is widely distributed in the body and plays an important role by its effect through cGMP on the smooth muscle vasculature. It is synthesized in the vascular endothelial cell from the semiessential amino acid L-arginine by NO synthase. After production in the cell, it diffuses to the smooth muscle cell, where it activates the enzyme guanylate cyclase, which leads to an increase in cGMP and then muscle relaxation (Fig. 19.3). Endothelium-derived relaxing factor (EDRF), released from the endothelial cell to mediate its smooth muscle-relaxing properties through cGMP, is identical with NO.

Inhibitors of phosphodiesterases of cAMP and cGMP also cause smooth muscle relaxation. These inhibitors increase cellular levels of cAMP and cGMP by preventing their hydrolysis to AMP and GMP, respectively. Drugs such as papaverine (see Chapter 17), theophylline (see chapter on

Diuretics), and sildenafil (this chapter), which relax smooth muscle, do so in part by inhibiting phosphodiesterases.

METABOLISM OF NITROVASODILATORS

After oral administration, organic nitrates are metabolized rapidly by the liver, kidney, lungs, intestinal mucosa, and vascular tissue. Buccal absorption reduces the immediate hepatic destruction of the organic nitrates because only 15% of the cardiac output is delivered to the liver; this allows a transient but effective circulating level of the intact organic nitrate before it is inactivated.⁵

Organic nitrates, nitrites, nitroso compounds, and a variety of other nitrogen-containing substances, such as sodium nitroprusside, for the most part cause their pharmacological effects by generating or releasing NO in situ. In some ways, these drugs are viewed as “replacement agents” for the endogenous NO generated by the NO synthase pathway from arginine. The mechanisms by which vasodilatory drugs release NO have become better understood recently. Table 19.1 shows the oxidation state of various nitrosyl compounds that are common in nitrovasodilatory drugs. A common feature of these drugs is that they release nitrogen in the form of NO and contain nitrogen in an oxidation state higher than +3 (as would occur in ammonia, amines, amides, and most biological nitrogen compounds). The nitrogen in NO has an oxidation state of +2. Compounds such as nitroprusside, nitrosoamines, and nitrothiols with oxidation states of +3 release NO nonenzymatically. Although their spontaneous liberation of NO is by an unknown mechanism, it involves only a one-electron reduction, which may occur on exposure of these chemicals to various reducing agents in the tissue of vascular smooth muscle membranes. Organic nitrites such as amyl nitrite react with available thiol groups to form unstable S-nitrosothiols, which rapidly decompose to NO by homolytic cleavage of their S—N bond. In mammalian smooth muscle, this will occur almost exclusively with glutathione as the most abundant thiol compound.⁶

The pharmacodynamic action of nitroglycerin is preceded by metabolic changes that follow various paths. Biotransformation of nitroglycerin to the dinitrates and the

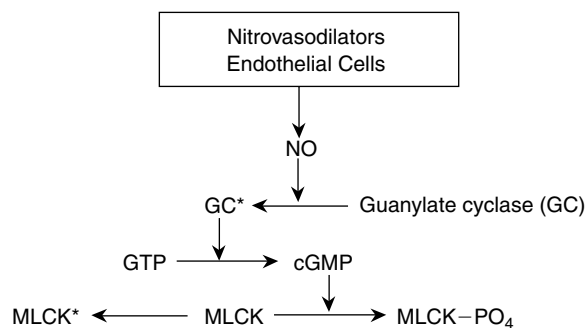

Figure 19.3 • Mechanism of nitrovasodilators. Nitric oxide (NO) formed in smooth muscle from nitrovasodilators or from endothelial cells (EDRF) activates guanylate cyclase (GC*). GC* activates cGMP-dependent protein kinases that phosphorylate myosin light-chain kinase (MLCK), causing its inactivation and subsequent muscle relaxation (see also Fig. 19.2).

TABLE 19.1 Nitrosyl Vasodilatory Substances and Their Oxidation State

Nitrosyl Compound	Structure	Nitrogen Oxidation State
Nitric oxide	N=O	+2
Nitrite	—ONO	+3
Nitrate	—ONO ₂	+5

increase of intracellular cGMP precede vascular relaxation. Sulfhydryl-containing compounds, such as cysteine, react chemically with organic nitrates to form inorganic nitrite ions. The release of NO from an organic nitrate, such as nitroglycerin, appears to occur in a stepwise fashion involving nonenzymatic and enzymatic steps. Because nitroglycerin requires a three-electron reduction to release NO, thiols may be involved in the process. Nitroglycerin may decompose nonenzymatically by interaction with various thiols, such as cysteine or *N*-acetylcysteine, which may be present in tissue, to form a nitrosothiol intermediate before undergoing enzymatic transformation to release NO. Nitroglycerin also readily releases NO by acting on an enzyme system attached to the cellular surface membrane of smooth muscle. The process may include glutathione-*S*-transferases, which convert nitroglycerin to a vasoinactive nitrite, which then may release NO nonenzymatically.⁷

ESTERS OF NITROUS AND NITRIC ACIDS

Inorganic acids, like organic acids, will form esters with an alcohol. Pharmaceutically, the important ones are sulfate, nitrite, and nitrate. Sulfuric acid forms organic sulfates, of which methyl sulfate and ethyl sulfate are examples.

Nitrous acid (HNO₂) esters may be formed readily from an alcohol and HNO₂. The usual procedure is to mix sodium nitrite, sulfuric acid, and the alcohol. Organic nitrites are generally very volatile liquids that are only slightly soluble in water but soluble in alcohol. Preparations containing water are very unstable because of hydrolysis.

The organic nitrates and nitrites and the inorganic nitrites have their primary utility in the prophylaxis and treatment of

angina pectoris. They have a more limited application in treating asthma, gastrointestinal spasm, and certain cases of migraine headache. Their application may be regarded as causal therapy, because they act by substituting an endogenous factor, the production or release of NO, which may be impaired under pathophysiological circumstances associated with dysfunction of the endothelial tissue. Nitroglycerin (glyceryl trinitrate) was one of the first members of this group to be introduced in medicine and remains an important member of the group. Varying the chemical structure of the organic nitrates yields differences in speed of onset, duration of action, and potency (Table 19.2). Although the number of nitrate ester groups may vary from two to six or more, depending on the compound, there is no direct relationship between the number of nitrate groups and the level of activity.

It appears that the higher the oil/water partition coefficient of the drug, the greater the potency. The orientation of the groups within the molecule also may affect potency. Lipophilicity of the nitrogen oxide-containing compound produces a much longer response of vasodilatory action. The highly lipophilic ester nitroglycerin permeates the cell membrane, allowing continual formation of NO within the cell. The same effect appears to occur for sodium nitroprusside, nitroso compounds, and other organic nitrate and nitrite esters.⁴

ANTIANGINAL ACTION OF NITROVASODILATORS

The action of short-acting sublingual nitrates in the relief of angina pectoris is complex. Although the sublingual nitrates relax vascular smooth muscle and dilate the coronary arteries of normal humans, there is little improvement of coronary blood flow when these chemicals are administered to individuals with coronary artery disease. Nitroglycerin is an effective antianginal agent because it causes redistribution of coronary blood flow to the ischemic regions of the heart and reduces myocardial oxygen demand. This latter effect is produced by a reduction of venous tone resulting from the nitrate vasodilating effect and a pooling of blood in the peripheral veins, which results in a reduction in ventricular volume, stroke volume, and cardiac output. It also causes reduction of peripheral resistance during myocardial contractions. The combined vasodilatory effects cause a decrease in cardiac work and reduce oxygen demand.

PRODUCTS

Amyl Nitrite, United States Pharmacopeia (USP). Amyl nitrite, isopentyl nitrite [(CH₃)₂CHCH₂CH₂ONO], is a mixture of isomeric amyl nitrites but is principally isoamyl nitrite. It may be prepared from amyl alcohol and HNO₂ by several procedures. Usually, amyl nitrite is dispensed in

TABLE 19.2 Relationship between Speed and Duration of Action of Sodium Nitrite and Certain Inorganic Esters

Compound	Action Begins (minutes)	Maximum Effect (minutes)	Duration of Action (minutes)
Amyl nitrite	0.25	0.5	1
Nitroglycerin	2	8	30
Isosorbide dinitrate	3	15	60
Sodium nitrite	10	25	60
Erythryl tetranitrate	15	32	180
Pentaerythritol tetranitrate	20	70	330

ampul form and used by inhalation or orally in alcohol solution. Currently, it is recommended for treating cyanide poisoning; although not the best antidote, it does not require intravenous injections.

Amyl nitrite is a yellowish liquid with an ethereal odor and a pungent taste. It is volatile and inflammable at room temperature. Amyl nitrite vapor forms an explosive mixture in air or oxygen. Inhalation of the vapor may involve definite explosion hazards if a source of ignition is present, as both room and body temperatures are within the flammability range of amyl nitrite mixtures with either air or oxygen. It is nearly insoluble in water but is miscible with organic solvents. The nitrite also will decompose in valeric acid and nitric acid.

Nitroglycerin. Glyceryl trinitrate is the trinitrate ester of glycerol and is listed as available in tablet form in the *USP*. It is prepared by carefully adding glycerin to a mixture of nitric and fuming sulfuric acids. This reaction is exothermic, and the reaction mixture must be cooled to between 10°C and 20°C.

The ester is a colorless oil, with a sweet, burning taste. It is only slightly soluble in water, but it is soluble in organic solvents.

	Deponit
	Transderm-Nitro

Nitroglycerin is used extensively as an explosive in dynamite. A solution of the ester, if spilled or allowed to evaporate, will leave a residue of nitroglycerin. To prevent an explosion of the residue, the ester must be decomposed by adding alkali. Even so, the material dispensed is so dilute that the risk of explosions does not exist. It has a strong vasodilating action and, because it is absorbed through the skin, is prone to cause headaches among workers associated with its manufacture. This transdermal penetration is why nitroglycerin is useful in a patch formulation. In medicine, it has the action typical of nitrites, but its action develops more slowly and is of longer duration. Of all the known coronary vasodilatory drugs, nitroglycerin is the only one capable of stimulating the production of coronary collateral circulation and the only one able to prevent experimental myocardial infarction by coronary occlusion.

Previously, the nitrates were thought to be hydrolyzed and reduced in the body to nitrites, which then lowered the blood pressure. This is not true, however. The mechanism of vasodilation of nitroglycerin through its formation of NO is described previously.

Nitroglycerin tablet instability was reported in molded sublingual tablets.⁸ The tablets, although uniform when

manufactured, lost potency both because of volatilization of nitroglycerin into the surrounding materials in the container and intertablet migration of the active ingredient. Nitroglycerin may be stabilized in molded tablets by incorporating a “fixing” agent such as polyethylene glycol 400 or polyethylene glycol 4000.⁹ In addition to sublingual tablets, the drug has been formulated into an equally effective lingual aerosol for patients who have problems with dissolution of sublingual preparations because of dry mucous membranes. Transdermal nitroglycerin preparations appear to be less effective than other long-acting nitrates, as absorption from the skin is variable.

Diluted Erythryl Tetranitrate, USP. Erythritol tetranitrate, 1,2,3,4-butanetetrol, tetranitrate (*R**, *S**)-(Cardilate), is the tetranitrate ester of erythritol and nitric acid. It is prepared in a manner analogous to that used for nitroglycerin. The result is a solid, crystalline material. This ester is also very explosive and is diluted with lactose or other suitable inert diluents to permit safe handling; it is slightly soluble in water and soluble in organic solvents.

Erythryl Tetranitrate
(Cardilate)

Erythryl tetranitrate requires slightly more time than nitroglycerin to produce its effect, which is of longer duration. It is useful when mild, gradual, and prolonged vascular dilation is warranted. The drug is used in the treatment of, and as prophylaxis against, attacks of angina pectoris and to reduce blood pressure in arterial hypertension.

Erythryl tetranitrate produces a reduction of cardiac preload as a result of pooling blood on the venous side of the circulatory system by its vasodilating action. This action results in a reduction of blood pressure on the arterial side during stressful situations and is an important factor in preventing the precipitation of anginal attacks.

Diluted Pentaerythritol Tetranitrate, USP. Pentaerythritol tetranitrate, 2,2-bis (hydroxymethyl)-1,3-propanediol tetranitrate (Peritrate, Pentritol), is a white, crystalline material with a melting point of 140°C. It is insoluble in water, slightly soluble in alcohol, and readily soluble in acetone. The drug is a nitric acid ester of the tetrahydric alcohol pentaerythritol and is a powerful explosive. Accordingly, it is diluted with lactose, mannitol, or other suitable inert diluents to permit safe handling.

Pentaerythritol Tetranitrate
(Peritrate)
(Pentritol)

It relaxes smooth muscle of smaller vessels in the coronary vascular tree. Pentaerythritol tetranitrate is used prophylactically to reduce the severity and frequency of anginal attacks and is usually administered in sustained-release preparations to increase its duration of action.

Diluted Isosorbide Dinitrate, USP. Isosorbide dinitrate, 1,4:3,6-dianhydro-D-glucitol dinitrate (Isordil, Sorbitrate), occurs as a white, crystalline powder. Its water solubility is about 1 mg/mL.

Isosorbide Dinitrate
(Isordil)

Isosorbide Mononitrate
(ISMO Imdur)

This molecule is lacking one of the nitro substitutions

Isosorbide dinitrate, as a sublingual or chewable tablet, is effective in the treatment or prophylaxis of acute anginal attacks. When it is given sublingually, the effect begins in about 2 minutes, with a shorter duration of action than when it is given orally. Oral tablets are not effective in acute anginal episodes; the onset of action ranges from 15 to 30 minutes. The major route of metabolism involves denitration to isosorbide 5-mononitrate. This metabolite has a much longer half-life than the parent isosorbide dinitrate. As such, this particular metabolite is marketed in a tablet form that has excellent bioavailability with much less first-pass metabolism than isosorbide dinitrate. Isosorbide is marketed as a combination therapy with hydralazine under the tradename BiDil specifically for African Americans with CHF.

Calcium Antagonists

EXCITATION-CONTRACTION COUPLING MUSCLE

Stimulation of the cardiac cell initiates the process of excitation, which has been related to ion fluxes through the cell membrane. Depolarization of the tissue in the atria of the heart is mediated by two inwardly directed ionic currents. When the cardiac cell potential reaches its threshold, ion channels in the membrane are opened, and Na^+ enters the cell through ion channels. These channels give rise to the fast sodium current that is responsible for the rapidly rising phase, phase 0, of the ventricular action potential (Fig. 19.4). The second current is caused by the slow activation of an L-type Ca^{2+} ion channel that allows the movement of Ca^{2+} into the cell. This "slow channel" contributes to the maintenance of the plateau phase (phase 2) of the cardiac action potential. We now understand that the Ca^{2+} that enters with the action potential initiates a second and larger release of Ca^{2+} from the sarcoplasmic reticulum in the cell. This secondary release of Ca^{2+} is sufficient to initiate the contractile process of cardiac muscle.

Figure 19.4 • Diagrammatic representation of the membrane action potential, as recorded from a Purkinje fiber, and an electrogram recorded from an isolated ventricular fiber. The membrane resting potential is 90 mV relative to the exterior of the fiber. At the point of depolarization, there is a rapid change (phase 0) to a more positive value. Phases 0 to 4 indicate the phases of depolarization and repolarization. Note that phases 0 and 3 of the membrane action potential correspond in time to the inscription of the QRS and T waves, respectively, of the local electrogram.

Contraction of cardiac and other muscle occurs from a reaction between actin and myosin. In contrast to smooth vascular muscle, the contractile process in cardiac muscle involves a complex of proteins (troponins I, C, and T and tropomyosin) attached to myosin, which modulates the interaction between actin and myosin. Free Ca^{2+} ions bind to troponin C, uncovering binding sites on the actin molecule and allowing interaction with myosin, causing contraction of the muscle. The schematic diagram in Figure 19.5 shows the sequence of events.¹⁰ Contraction of vascular smooth muscle, like that of cardiac muscle, is regulated by the concentration of cytoplasmic Ca^{2+} ions. The mechanism by which the contraction is effected, however, includes a calcium- and calmodulin-dependent kinase as opposed to a Ca^{2+} -sensitive troponin-tropomyosin complex (Fig. 19.2). The activating effect depends on a different type of reaction. The elevated free cytosolic Ca^{2+} in vascular smooth muscle cells binds to a high-affinity binding protein, calmodulin.

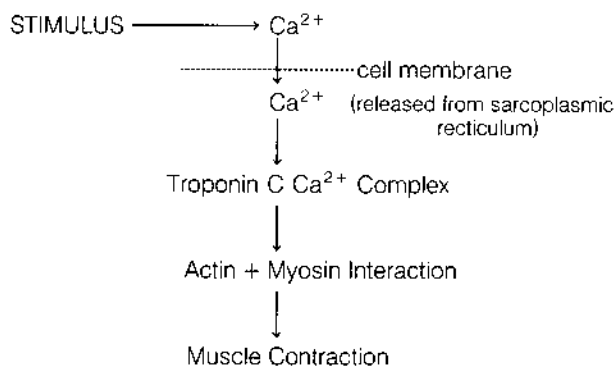

Figure 19.5 • Sequence of events showing excitation-contraction coupling in cardiac muscle.

ION CHANNELS AND CALCIUM

Calcium ions play an important role in the regulation of many cellular processes, such as synaptic transmission and muscle contraction. The role of calcium in these cellular functions is as a second messenger, for example, regulating enzymes and ion channels. The entry of extracellular Ca^{2+} in the cytosol of myocardial cells and the release of Ca^{2+} from intracellular storage sites is important for initiating contractions of the myocardium. Normally, the concentration of Ca^{2+} in the extracellular fluid is in the millimolar range, whereas the intracellular concentration of free Ca^{2+} is less than 10^{-7} M, even though the total cellular concentration may be 10^{-3} M or higher. Most of the Ca^{2+} is stored within intracellular organelles or tightly bound to intracellular proteins. The free Ca^{2+} needed to satisfy the requirements of a contraction resulting from a stimulus may result from activation of calcium channels on the cell membrane and/or the release of calcium from bound internal stores. Each of these methods of increasing free cytosolic Ca^{2+} involves channels that are selective for the calcium ion. Calcium channel blockers reduce or prevent the increase of free cytosolic calcium ions by interfering with the transport of calcium ions through these pores.

Calcium is one of the most common elements on earth. Most calcium involved in biological systems occurs as hydroxyapatite, a static, stabilizing structure like that found in bone. The remaining calcium is ionic (Ca^{2+}). Ionic calcium functions as a biochemical regulator, more often within the cell. The importance of calcium ions to physiological functions was realized first by Ringer, who observed in 1883 the role of Ca^{2+} in cardiac contractility.

The ionic composition of the cytosol in excitable cells, including cardiac and smooth muscle cells, is controlled to a large extent by the plasma membrane, which prevents the free movement of ions across this barrier. Present in the membranes are ion-carrying channels that open in response to either a change in membrane potential or binding of a ligand. Calcium-sensitive channels include (a) Na^+ to Ca^{2+} exchanger, which transports three Na^+ ions in return for one Ca^{2+} ; (b) a voltage-dependent Ca^{2+} channel, which provides the route for entry of Ca^{2+} for excitation and contraction in cardiac and smooth muscle cells and is the focus of the channel-blocking agents used in medicine; and (c) receptor-operated Ca^{2+} channels mediated by ligand binding to membrane receptors such as in the action of epinephrine on the α -adrenergic receptor. The membrane of the sarcolemma within the cell also has ion-conducting channels that facilitate movement of Ca^{2+} ions from storage loci in the sarcoplasmic reticulum.

Four types of calcium channels, differing in location and function, have been identified: (a) L type, located in skeletal, cardiac, and smooth muscles, causing contraction of muscle cells; (b) T type, found in pacemaker cells, causing Ca^{2+} entry, inactivated at more negative potentials and more rapidly than the L type; (c) N type, found in neurons and acting in transmitter release; and (d) P type, located in Purkinje cells but whose function is unknown at this time.

Calcium antagonists act only on the L-type channel to produce their pharmacological effects. The L channels are so called because once the membrane has been depolarized, their action is long lasting. Once the membrane has been depolarized, L channels must be phosphorylated to open.

Figure 19.6 • Schematic representation of an L-type Ca^{2+} channel.

Although there are similarities between L-type calcium channels that exist in cardiac and smooth muscle, there are distinct differences between the two. Cardiac L channels are activated through β -adrenergic stimulation via a cAMP-dependent phosphorylation process,¹¹ whereas L channels in smooth muscle may be regulated by the inositol phosphate system linked to G-protein-coupled, receptor-linked phospholipase C activation.¹²

CALCIUM CHANNEL BLOCKERS

The L-type calcium channel, acted on by calcium channel blockers, consists of five different subunits, designated α_1 , α_2 , β , γ , and δ . The α_1 subunit provides the central pore of the channel (Fig. 19.6). Calcium channel blockers can be divided conveniently into the three different chemical classes of the prototype drugs that have been used: phenylalkylamines (verapamil), 1,4-dihydropyridines (nifedipine), and benzothiazepines (diltiazem). These prototype compounds sometimes are termed the “first generation” of calcium channel blockers because two of the groups of drug classes have been expanded by the introduction of a “second generation” of more potent analogs (Table 19.3).

The specific Ca^{2+} channel antagonists verapamil, nifedipine, and diltiazem interact at specific sites on the calcium channel protein. These blockers do not occlude the channel physically but bind to sites in the channel, because they can promote both channel activation and antagonism. Affinity for binding sites on the channel varies, depending on the status of the channel. The channel can exist in either an open (O), resting (R), or inactivated (I) state, and the equilibrium between them is determined by stimulus frequency and membrane potential (Fig. 19.7). Verapamil

TABLE 19.3 First- and Second-Generation Calcium Channel Blockers

Chemical Classification	First Generation	Second Generation
Phenylalkylamines	Verapamil	Anipamil Bepridil
1,4-Dihydropyridine	Nifedipine	Amlodipine Felodipine Isradipine Nicardipine Nimodipine
Benzothiazepine	Diltiazem	—

Figure 19.7 • Schematic representation of an ion channel existing in an equilibrium of resting (*R*), open (*O*), and inactivated (*I*) states.

and diltiazem do not bind to a channel in the resting state, only after the channel has been opened. They are ionized, water-soluble Ca^{2+} -entry blockers that reach their binding sites by the hydrophilic pathway when the channel is open. Verapamil and diltiazem are use dependent (i.e., their Ca^{2+} -blocking activity is a function of the frequency of contractions). An increase in contraction frequency causes a reduction, rather than an augmentation, of contractions. Nifedipine is a neutral molecule at physiological pH and can cause interference with the Ca^{2+} in the open or closed state. In the closed state, nifedipine can traverse the phospholipid bilayer to reach its binding site because of its lipid solubility.

CARDIOVASCULAR EFFECTS OF CALCIUM ION CHANNEL BLOCKERS

All Ca^{2+} antagonists yet developed are vasodilators. Vasodilation is a result of the uncoupling of the contractile mechanism of vascular smooth muscle, which requires Ca^{2+} . Coronary artery muscle tone is reduced in healthy humans but is particularly pronounced in a condition of coronary spasm. Peripheral arteriole resistance is reduced more than venous beds. The vasodilatory effect of these drugs is the basis for their use in the control of angina and hypertension.¹³

Although verapamil, nifedipine, and diltiazem can cause vasodilation, they are not equally effective at blocking the Ca^{2+} channels found in various tissues. The phenylalkylamine verapamil and the benzothiazepine diltiazem have both cardiac and vascular actions. These drugs have antiarrhythmic, antianginal, and antihypertensive activity. They depress the cardiac neural network, and so slow sinus node automaticity, prolong atrioventricular (AV) nodal conductance, and depress myocardial contractility, as well as reduce peripheral vascular resistance to prevent a coronary vascular spasm. Nifedipine and other 1,4-dihydropyridines are more effective at causing vasodilation than affecting pacemaker and tension responses in the heart. This is especially important because selectivity occurs as a consequence of disease states. Hypertensive smooth muscle is more sensitive to Ca^{2+} channel blockers than is normotensive tissue.¹⁴ This makes verapamil and diltiazem more useful in ischemic conditions, because they have a more profound effect on cardiac muscle calcium channels.¹⁵

The inhibition of Ca^{2+} influx into cardiac tissue by Ca^{2+} antagonists is also the basis for the use of these drugs as antiarrhythmic agents. The Ca^{2+} channel blockers dampen Ca^{2+} -dependent automaticity in the regular pacemaker cells in the sinoatrial (SA) node and depress the

origination of ectopic foci. Calcium antagonists can block reentry pathways in myocardial tissue, an integral component of arrhythmias. Numerous side effects in the heart, such as bradycardia, decreased cardiac contractility, and reduced AV conductance, are traced to Ca^{2+} channel-blocking activity.

PRODUCTS

Verapamil. Verapamil, 5-[(3,4-dimethoxyphenethyl) methylamino]-2-(3,4-dimethoxyphenyl)-2-isopropylvaleronitrile (Calan, Isoptin), was introduced in 1962 as a coronary vasodilator and is the prototype of the Ca^{2+} antagonists used in cardiovascular diseases. It is used in the treatment of angina pectoris, arrhythmias from ischemic myocardial syndromes, and supraventricular arrhythmias.

Verapamil's major effect is on the slow Ca^{2+} channel. The result is a slowing of AV conduction and the sinus rate. This inhibition of the action potential inhibits one limb of the reentry circuit believed to underlie most paroxysmal supraventricular tachycardias that use the AV node as a reentry point. It is categorized as a class IV antiarrhythmic drug (see "Classes of Antiarrhythmic Drugs" later in this chapter). Hemodynamically, verapamil causes a change in the preload, afterload, contractility, heart rate, and coronary blood flow. The drug reduces systemic vascular resistance and mean blood pressure, with minor effects on cardiac output.

Verapamil is a synthetic compound possessing slight structural similarity to papaverine. It can be separated into its optically active isomers, of which the levorotatory enantiomer is the most potent. It is absorbed rapidly after oral administration. The drug is metabolized quickly and, as a result, has low bioavailability. The liver is the main site of first-pass metabolism, forming several products. The preferential metabolic step involves *N*-dealkylation, followed by *O*-demethylation, and subsequent conjugation of the product before elimination. The metabolites have no significant biological activity. Verapamil has an elimination half-life of approximately 5 hours.

The route traveled by a Ca^{2+} channel blocker, such as verapamil, to its receptor site parallels that observed with many local anesthetic-like antiarrhythmic agents. It is believed that verapamil, like most of the Ca^{2+} channel blockers, crosses the cell membrane in an uncharged form to gain access to its site of action on the intracellular side of the membrane. Data show a greater affinity of verapamil and other Ca^{2+} channel blockers to the inactivated state of the channel.¹⁶

Diltiazem Hydrochloride. Diltiazem hydrochloride, (+)-*cis*-3-(acetoxy)-5-[2(dimethylamino)ethyl]-2,3-dihydro-2-(4-methoxyphenyl)1,5-benzothiazepin-4(5*H*)one hydrochloride (Cardizem), was developed and introduced in Japan as a cardiovascular agent to treat angina pectoris. It was observed to dilate peripheral arteries and arterioles. The drug increases myocardial oxygen supply by relieving coronary artery spasm and reduces myocardial oxygen demand by decreasing heart rate and reducing overload. Diltiazem hydrochloride is used in patients with variant angina. The drug has electrophysiological properties similar to those of verapamil and is used in clinically similar treatment conditions as an antiarrhythmic agent, but it is less potent.

The drug is absorbed rapidly and almost completely from the digestive tract. It reaches peak plasma levels within 1 hour after administration in gelatin capsules. Oral formulations on the market are sustained-release preparations providing peak plasma levels 3 to 4 hours after administration.

Diltiazem hydrochloride is metabolized extensively after oral dosing, by first-pass metabolism. As a result, the bioavailability is about 40% of the administered dose. The drug undergoes several biotransformations, including deacetylation, oxidative *O*- and *N*-demethylations, and conjugation of the phenolic metabolites. Of the various metabolites (Fig. 19.8), only the primary metabolite, deacetyldiltiazem, is pharmacologically active. Deacetyldiltiazem has about 40% to 50% of the potency of the parent compound.

Nifedipine. Nifedipine, 1,4-dihydro-2,6-dimethyl-4-(2-nitrophenyl)-3,5-pyridinedicarboxylate dimethyl ester

(Adalat, Procardia), is a dihydropyridine derivative that bears no structural resemblance to the other calcium antagonists. It is not a nitrate, but its nitro group is essential for its antianginal effect.¹⁷ As a class, the dihydropyridines possess a central pyridine ring that is partially saturated. To this, positions 2 and 6 are substituted with an alkyl group that may play a role in the agent's duration of action. In addition, positions 3 and 5 are carboxylic groups that must be protected with an ester functional group. Depending on the type of ester used at these sites, the agent can be distributed to various parts of the body. Finally, position 4 requires an aromatic substitution possessing an electron-withdrawing group (i.e., Cl or NO₂) in the *ortho* and/or *meta* position.

The prototype of this class, nifedipine, has potent peripheral vasodilatory properties. It inhibits the voltage-dependent calcium channel in the vascular smooth muscle but has little or no direct depressant effect on the SA or AV nodes, even though it inhibits calcium current in normal and isolated cardiac tissues. Nifedipine is more effective in patients whose anginal episodes are caused by coronary vasospasm and is used in the treatment of vasospastic angina as well as classic angina pectoris. Because of its strong vasodilatory properties, it is used in selected patients to treat hypertension.

Nifedipine is absorbed efficiently on oral or buccal administration. A substantial amount (90%) is protein bound. Systemic availability of an oral dose of the drug may be approximately 65%. Two inactive metabolites are the major products of nifedipine metabolism and are found in equilibrium with each other (Fig. 19.9). Only a trace of unchanged nifedipine is found in the urine.¹⁸

Figure 19.8 • Biotransformations of diltiazem.

Figure 19.9 • Nifedipine metabolism.

Amlodipine. Amlodipine, 2-[(2-aminoethoxy)methyl]4-(2-chlorophenyl)-1,4-dihydro-6-methyl-3,5-pyridinedicarboxylic acid 3-ethyl 5-methyl ester (Norvasc), is a second-generation 1,4-dihydropyridine derivative of the prototypical molecule nifedipine. Like most of the second-generation dihydropyridine derivatives, it has greater selectivity for the vascular smooth muscle than myocardial tissue, a longer half-life (34 hours), and less negative inotropy than the prototypical nifedipine. Amlodipine is used in the treatment of chronic stable angina and in the management of mild-to-moderate essential hypertension. It is marketed as the benzene sulfonic acid salt (besylate). Amlodipine was approved in September 2007 as a combination product with olmesartan (Azor), an angiotensin II receptor antagonist (Chapter 18), for the treatment of hypertension. Amlodipine is also marketed as a combination therapy with atorvastatin under the tradename Norvasc for the management of high cholesterol and high blood pressure.

Amlodipine
(Norvasc)

Felodipine. Felodipine, 4-(2,3-dichlorophenyl)-1,4-dihydro-2,6-dimethyl-3,5-pyridinedicarboxylic acid ethyl methyl ester (Plendil), is a second-generation dihydropyridine channel blocker of the nifedipine type. It is more selective for vascular smooth muscle than for myocardial tissue and serves as an effective vasodilator. The drug is used in the treatment of angina and mild-to-moderate essential hypertension. Felodipine, like most of the dihydropyridines, exhibits a high degree of protein binding and has a half-life ranging from 10 to 18 hours.

Felodipine
(Plendil)

Isradipine. Isradipine, 4-(4-benzofuranazyl)-1,4-dihydro-2,6-dimethyl-3,5-pyridinedicarboxylic acid methyl 1-methylethyl ester (DynaCirc), is another second-generation dihydropyridine-type channel blocker. This drug, like the other second-generation analogs, is more selective for vascular smooth muscle than for myocardial tissue. It is effective in the treatment of stable angina, reducing the frequency of anginal attacks and the need to use nitroglycerin.

Isradipine
(DynaCirc)

Nicardipine Hydrochloride. Nicardipine hydrochloride, 1,4-dihydro-2,6-dimethyl-4-(3-nitrophenyl)-3,5-pyridinedicarboxylic acid methyl 2-[methyl(phenylmethyl)amino]ethyl ester hydrochloride (Cardene), is a more potent vasodilator of the systemic, coronary, cerebral, and renal vasculature and has been used in the treatment of mild, moderate, and severe hypertension. The drug is also used in the management of stable angina.

Nicardipine
(Cardene)

Nimodipine. Nimodipine, 1,4-dihydro-2,6-dimethyl-4-(3-nitrophenyl)-3,5-pyridinedicarboxylic acid 2-methoxyethyl 1-methylethyl ester (Nimotop), is another dihydropyridine calcium channel blocker but differs in that it dilates the cerebral blood vessels more effectively than do the other dihydropyridine derivatives. This drug is indicated for treatment of subarachnoid hemorrhage-associated neurological deficits.

Nisoldipine. In vitro studies show that the effects of nisoldipine, 1,4-dihydro-2,6-dimethyl-4-(2-nitrophenyl)-3,5-pyridinecarboxylic acid methyl 2-methylpropyl ester (Sular), on contractile processes are selective, with greater potency on vascular smooth muscle than on cardiac muscle.

Nisoldipine is highly metabolized, with five major metabolites identified. As with most of the dihydropyridines, the cytochrome P450 (CYP) 3A4 isozyme is mainly responsible for the metabolism of nisoldipine. The major biotransformation pathway appears to involve the hydroxylation of the isobutyl ester side chain. This particular metabolite has approximately 10% of the activity of the parent compound.

Nitrendipine. Nitrendipine, 1,4-dihydro-2,6-dimethyl-4-(3-nitrophenyl)-3,5-pyridinecarboxylic acid methyl ethyl ester (Baypress), is a second-generation dihydropyridine channel blocker of the nifedipine type. It is more selective for vascular smooth muscle than for myocardial tissue and serves as an effective vasodilator. The drug is used in the treatment of mild-to-moderate essential hypertension.

Bepridil Hydrochloride. Bepridil hydrochloride, β -[(2-methylpropoxy)methyl]-*N*-phenyl-*N*-(phenylmethyl)-1-pyrrolidineethylamine hydrochloride (Vasacor), is a second-

generation alkylamine-type channel blocker, structurally unrelated to the dihydropyridines. Its actions are less specific than those of the three prototypical channel blockers, verapamil, diltiazem, and nifedipine. In addition to being a Ca^{2+} channel blocker, it inhibits sodium flow into the heart tissue and lengthens cardiac repolarization, causing bradycardia. Caution should be used if it is given to a patient with hypokalemia. Bepridil hydrochloride is used for stable angina. The drug has a half-life of 33 hours and is highly bound to protein (99%).

Sodium Channel Blocker

Ranolazine. Ranolazine, *N*-(2,6-dimethylphenyl)-2-[4-[2-hydroxy-3-(2-methoxyphenoxy)propyl]piperazin-1-yl]acetamide (Ranexa), is an antianginal medication that was approved by the Food and Drug Administration (FDA) in January 2006 for the treatment of chronic angina. Ranolazine is believed to elicit its effects by altering the transcellular late sodium current. This, in turn, alters the sodium-dependent calcium channels during myocardial ischemia. Thus, ranolazine indirectly prevents the calcium overload that is associated with cardiac ischemia. Ranolazine is metabolized by the cytochrome CYP3A enzymes in the liver.¹⁹

Antithrombotic Agents

Platelet activation and platelet aggregation play an important role in the pathogenesis of thromboses. These, in turn, play an important role in unstable angina, myocardial infarction, stroke, and peripheral vascular thromboses. Because many cardiovascular diseases are associated with platelet activation, many agents possessing antiplatelet or antithrombotic effects have been investigated. This has revolutionized cardiovascular medicine, in which vascular stenting or angioplasty can be used without compromising normal hemostasis or wound healing. Although most of these agents act by different mechanisms, many of the newer agents are being developed to antagonize the GPIIb/IIIa receptors of platelets.

Aspirin. Aspirin, acetylsalicylic acid, has an inhibitory effect on platelet aggregation not only because of its ability to inhibit cyclooxygenase (COX) but also because of its

ability to acetylate the enzyme. Aspirin irreversibly inhibits COX (prostaglandin H synthase), which is the enzyme involved in converting arachidonate to prostaglandin G₂ and ultimately thromboxane 2, an inducer of platelet aggregation. Aspirin's mechanism of action includes not only the inhibition in the biosynthesis of thromboxane 2, but also its ability to acetylate the serine residue (529) in the polypeptide chain of platelet prostaglandin H synthetase-1. This explains why other nonsteroidal anti-inflammatory agents that are capable of inhibiting the COX enzyme do not act as antithrombotics—they are not capable of acetylating this enzyme. Because platelets cannot synthesize new enzymes, aspirin's ability to acetylate COX lasts for the life of the platelet (7–10 days) and is, thus, irreversible.

Aspirin

Dipyridamole. Dipyridamole, 2,2',2'',2'''-[(4,8-dipiperidinylpyrimido[5,4-*d*]pyrimidine-2,6-diyl)dinitrilo]-tetrakisethanol (Persantine), may be used for coronary and myocardial insufficiency. Its biggest use today, however, is as an antithrombotic in patients with prosthetic heart valves. It is a bitter, yellow, crystalline powder, soluble in dilute acids, methanol, or chloroform. A formulation containing dipyridamole and aspirin (Aggrenox) is currently being marketed as an antithrombotic.

Dipyridamole is a long-acting vasodilator. Its vasodilating action is selective for the coronary system; it is indicated for long-term therapy of chronic angina pectoris. The drug also inhibits adenosine deaminase in erythrocytes and interferes with the uptake of the vasodilator adenosine by erythrocytes. These actions potentiate the effect of prostacyclin (PGI₂), which acts as an inhibitor to platelet aggregation.

Clopidogrel. Clopidogrel, methyl (+)-(*S*)- α -(2-chlorophenyl)-6,7-dihydrothieno[3,2-*c*]pyridine-5(4*H*)-acetate sulfate (Plavix), is useful for the preventative

management of secondary ischemic events, including myocardial infarction, stroke, and vascular deaths. It may be classified as a thienopyridine because of its heterocyclic system. Several agents possessing this system have been evaluated as potential antithrombotic agents. These agents have a unique mechanism, in that they inhibit the purinergic receptor located on platelets. Normally, nucleotides act as agonists on these receptors, which include the P2Y type. Two P2Y receptor subtypes (P2Y1 and P2Y2) found on platelets, when stimulated by adenosine diphosphate (ADP), cause platelet aggregation. Clopidogrel acts as an antagonist to the P2Y2 receptor. It is probably a prodrug that requires metabolic activation, because *in vitro* studies do not interfere with platelet aggregation. Although platelet aggregation is not normally seen in the first 8 to 11 days after administration to a patient, the effect lasts for several days after the drug therapy is discontinued. Unlike other thienopyridines currently used, clopidogrel does not seriously reduce the number of white cells in the blood, and therefore, routine monitoring of the white blood cell count is not necessary during treatment.

Clopidogrel
(Plavix)

Ticlopidine. Ticlopidine, 5-[(2-chlorophenyl)methyl]-4,5,6,7-tetrahydrothieno [3,2-*c*]pyridine hydrochloride (Ticlid), is useful in reducing cardiac events in patients with unstable angina and cerebrovascular events in secondary prevention of stroke. It belongs to the thienopyridine class and facilitated the development of clopidogrel. One of the drawbacks to this agent is its side effect profile, which includes neutropenia, and patients receiving this antithrombotic should have their blood levels monitored. Its mechanism of action is similar to that of clopidogrel, in that it inhibits the purinergic receptors on platelets.

Ticlopidine
(Ticlid)

GPIIb/IIIa RECEPTORS

Located on platelets is a site that serves to recognize and bind fibrinogen. This site is a dimeric glycoprotein that allows fibrinogen to bind, leading to the final step of platelet aggregation. The receptor must be activated before it will associate with fibrinogen, and this may be accomplished by thrombin, collagen, or thromboxane A₂ (TXA₂). Once the receptor is activated, fibrinogen most likely binds to the

platelet through the arginine-glycine-aspartic acid (RGD) sequences at residues 95-96-97 and 572-573-574 of the α -chain of fibrinogen. This particular feature has been used in the design of nonpeptide antagonists that mimic the RGD system in which a distance of 15 to 17 Å (16–18 atoms) separates the amine group of arginine and the carbonyl oxygen of aspartic acid.

Eptifibatide. Eptifibatide (Integrilin) is a synthetic cyclic heptapeptide that acts as a GPIIb/IIIa receptor antagonist, thus causing inhibition of platelet aggregation. Its structure is based on the natural product barbourin, a peptide isolated from the venom of a pygmy rattlesnake (*Sistrurus milarud barbouri*). As part of the structure, there is a sequence RGD that can bind to the RGD receptor found on platelets and block its ability to bind with fibrinogen. This agent is used in the treatment of unstable angina and for angioplastic coronary interventions.

Tirofiban. Tirofiban is a nonpeptide that appears unrelated chemically to eptifibatide, but actually has many similarities. The chemical architecture incorporates a system that is mimicking the RGD moiety that is present in eptifibatide. This can be seen in the distance between the nitrogen of the piperidine ring, which mimics the basic nitrogen of arginine in the RGD sequence, and the carboxylic acid, which mimics the acid of aspartate in the RGD sequence. The basic nitrogen and the carboxylic acid of tirofiban are separated by approximately 15 to 17 Å (16–18 atoms). This is the optimum distance seen in the RGD sequence of the platelet receptor. Tirofiban is useful in treating non-Q wave myocardial infarction and unstable angina.

Abciximab. Abciximab (ReoPro) is a chimeric Fab fragment monoclonal antibody that can bind to the GPIIa/IIIb receptor of platelets and block the ability of fibrinogen to associate with the platelet. This results in less platelet aggregation. Abciximab is useful in treating unstable angina and as an adjunct to percutaneous coronary intervention (PCI). The half-life of abciximab is about 30 minutes, whereas its effects when bound to the GPIIa/IIIb may last up to 24 hours. A significant drawback to using abciximab lies in its cost, which is approximately \$1,500 for a single dose.

ANTIARRHYTHMIC DRUGS

Cardiac arrhythmias are caused by a disturbance in the conduction of the impulse through the myocardial tissue, by disorders of impulse formation, or by a combination of these factors. The antiarrhythmic agents used most commonly affect impulse conduction by altering conduction velocity and the duration of the refractory period of heart muscle tissue. They also depress spontaneous diastolic depolarization, causing a reduction of automaticity by ectopic foci.

Many pharmacological agents are available for the treatment of cardiac arrhythmias. Agents such as oxygen, potassium, and sodium bicarbonate relieve the underlying cause of some arrhythmias. Other agents, such as digitalis, propranolol, phenylephrine, edrophonium, and neostigmine, act on the cardiovascular system by affecting heart muscle or on the autonomic nerves to the heart. Finally, there are drugs that alter the electrophysiological mechanisms causing arrhythmias. The latter group of drugs is discussed in this chapter.

Within the past 5 decades, research on normal cardiac tissues and, in the clinical setting, on patients with disturbances of rhythm and conduction has brought to light information on the genesis of cardiac arrhythmias and the mode of action of antiarrhythmic agents. In addition, laboratory tests have been developed to measure blood levels of antiarrhythmic drugs such as phenytoin, disopyramide, lidocaine, procainamide, and quinidine, to help evaluate the pharmacokinetics of these agents. As a result, it is possible to maintain steady-state plasma levels of these drugs, which allows the clinician to use these and other agents more effectively and with greater safety. No other clinical intervention has been more effective at reducing mortality and morbidity in coronary care units.

Cardiac Electrophysiology

The heart depends on the synchronous integration of electrical impulse transmission and myocardial tissue response to carry out its function as a pump. When the impulse is released from the SA node, excitation of the heart tissue takes

place in an orderly manner by a spread of the impulse throughout the specialized automatic fibers in the atria, the AV node, and the Purkinje fiber network in the ventricles. This spreading of impulses produces a characteristic electrocardiographic pattern that can be equated to predictable myocardial cell membrane potentials and Na^+ and K^+ fluxes in and out of the cell.

A single fiber in the ventricle of an intact heart, during the diastolic phase (see phase 4, Fig. 19.4), has a membrane potential (resting potential) of 90 mV. This potential is created by differential concentrations of K^+ and Na^+ in the intracellular and extracellular fluid. An active transport system (pump) on the membrane is responsible for concentrating the K^+ inside the cell and maintaining higher concentrations of Na^+ in the extracellular fluid. Diastolic depolarization is caused by a decreased K^+ ionic current into the extracellular tissue and a slow inward leakage of Na^+ until the threshold potential (60–55 mV) is reached. At this time, the inward sodium current suddenly increases, and a self-propagated wave occurs to complete the membrane depolarization process. Pacemaker cells possess this property, which is termed *automaticity*. This maximal rate of depolarization (MRD) is represented by phase 0 or the spike action potential (Fig. 19.4).

The form, duration, resting potential level, and amplitude of the action potential are characteristic for different types of myocardial cells. The rate of rise of the response (phase 0) is related to the level of the membrane potential at the time of stimulation and has been termed *membrane responsiveness*. Less negative potentials produce smaller slopes of phase 0 and are characterized by slower conduction times. The phase 0 spike of the SA node corresponds to the inscription of the P wave on the electrocardiogram (Fig. 19.10). Repolarization is divided into three phases. The greatest amount of repolarization is represented by phase 3, in which there is a passive flux of K^+ ions out of the cell. Phase 1 repolarization is caused by an influx of Cl^- ions. During phase 2, a small inward movement of Ca^{2+} ions occurs through a slow channel mechanism that is believed to be important in the process of coupling excitation with contraction. The process of repolarization determines the duration

Figure 19.10 • Normal electrocardiogram. (From Ganong, W. F.: Review of Medical Physiology, 9th ed. San Francisco, Lange Medical Publications, 1985.)

of the action potential and is represented by the QT interval. The action potential duration is directly related to the refractory period of cardiac muscle.

Mechanisms of Arrhythmias

The current understanding of the electrophysiological mechanisms responsible for the origin and perpetuation of cardiac arrhythmias is caused by altered impulse formation (i.e., change in automaticity), altered conduction, or both, acting simultaneously from different locations of the heart. The generation of cardiac impulses in the normal heart is usually confined to specialized tissues that spontaneously depolarize and initiate the action potential. These cells are located in the right atrium and are referred to as the *SA node* or the *pacemaker cells*. Although the spontaneous electrical depolarization of the SA pacemaker cells is independent of the nervous system, these cells are innervated by both sympathetic and parasympathetic fibers, which may cause an increase or decrease of the heart rate, respectively. Other special cells in the normal heart that possess the property of automaticity may influence cardiac rhythm when the normal pacemaker is suppressed or when pathological changes occur in the myocardium to make these cells the dominant source of cardiac rhythm (i.e., ectopic pacemakers). Automaticity of subsidiary pacemakers may develop when myocardial cell damage occurs because of infarction or from digitalis toxicity, excessive vagal tone, excessive catecholamine release from sympathomimetic nerve fibers to the heart, or even high catecholamine levels in plasma. The development of automaticity in specialized cells, such as that found in special atrial cells, certain AV node cells, bundle of His, and Purkinje fibers, may lead to cardiac arrhythmias. Because production of ectopic impulses is often caused by a defect in the spontaneous phase 4 diastolic depolarization ("T wave"), drugs that can suppress this portion of the cardiac stimulation cycle are effective agents for these types of arrhythmia.

Arrhythmias are also caused by disorders in the conduction of impulses and changes in the refractory period of the myocardial tissue. Pharmacological intervention is based on these two properties. The Purkinje fibers branch into a network of interlacing fibers, particularly at their most distant positions. This creates several pathways in which a unidirectional block in a localized area may establish circular (circus) microcellular or macrocellular impulse movements that reenter the myocardial fibers and create an arrhythmia (Fig. 19.11). Unidirectional block results from localized

Figure 19.11 • Reentry mechanism of Purkinje fibers. **A.** Normal conduction of impulses through triangular arrangement of cardiac fibers. **B.** Unidirectional block on left arm of triangular section allows impulse to reenter the regional conducting system and recycle.

TABLE 19.4 Classes of Antiarrhythmic Drugs

Class	Drugs	Mechanism of Action
IA	Quinidine, procainamide, disopyramide	Lengthens refractory period
IB	Lidocaine, phenytoin, tocainide, mexiletine	Shortens duration of action potential
IC	Encainide, flecainide, lorcaïnide, moricizine, propafenone	Slows conduction
II	β -Adrenergic blockers (e.g., propranolol)	Slows AV conduction time, suppresses automaticity
III	Amiodarone, bretylium, sotalol	Prolongs refractoriness
IV	Calcium channel blockers (e.g., verapamil, diltiazem)	Blocks slow inward Ca^{2+} channel

myocardial disease (*infarcts*) or from a change in dependence of the tissue to Na^+ fluxes that causes a longer conduction time and allows the tissue to repolarize to propagate the retrograde impulse.

Classes of Antiarrhythmic Drugs

Antiarrhythmic drugs can be placed into four separate classes, based on their mechanism of action or pattern of electrophysiological effects produced on heart tissue. Table 19.4 summarizes the four-part classification of antiarrhythmic drugs as first proposed by Vaughan Williams²⁰ in 1970 and expanded in 1984.²¹ Note that drugs within the same category are placed there because they demonstrate similar clinical actions. That patients do not respond to a drug in this class, however, should not rule out use of other drugs in the same class.²² Despite the well-intentioned use of these agents, most antiarrhythmic drugs have the potential to aggravate the arrhythmia they treat (*proarrhythmia*). Proarrhythmia develops from an increase in the density of single ectopic beats and is more likely to occur in patients who have a dysfunction in the left ventricle or sustained ventricular tachycardia. Class I antiarrhythmic agents (discussed under “Class I. Membrane-Depressant Drugs”) are especially proarrhythmic in myocardial infarction patients.

CLASS I. MEMBRANE-DEPRESSANT DRUGS

Class I antiarrhythmic agents are drugs that have membrane-stabilizing properties (i.e., they shift membranes to more negative potentials). Drugs in this class act on the fast Na^+ channels and interfere with the process by which the depolarizing charge is transferred across the membrane. It is assumed that these drugs bind to the Na^+ channel and block its function, preventing Na^+ conductance as long as the drug is bound. The prototypical drugs in this class are quinidine and procainamide. During the 1970s, several drugs were studied for their antiarrhythmic effects. Most of them were local anesthetics that affected Na^+ membrane channels, and they were grouped in a single class (class I). Studies on the antiarrhythmic properties of these chemicals have shown that there are sufficient differences to place them into separate subgroups.²²

Class I antiarrhythmic drugs can be subdivided based on the relative ease with which they dissociate from the Na^+ ion channel. Drugs in class IC, such as encainide,

lorcaïnide, and moricizine, are the most potent sodium channel-blocking agents of the class I antiarrhythmic drugs. They slowly dissociate from the Na^+ channel, causing a slowing of the conduction time of the impulse through the heart. Class IB drugs, which include lidocaine, tocainide, and mexiletine, dissociate rapidly from the Na^+ channels and thus have the lowest potency as sodium channel blockers. They produce little, if any, change in action potential duration. Quinidine, procainamide, and disopyramide are drugs that have an intermediate rate of dissociation from Na^+ channels. These are categorized as class IA antiarrhythmic agents, and they lengthen the refractory period of cardiac tissue to cause cessation of arrhythmias.²³

Studies have shown that Na^+ channels on the membranes of Purkinje fiber cells normally exist in at least three states: *R*, rested, closed near the resting potential but able to be opened by stimulation and depolarization; *A*, activated, allowing Na^+ ions to pass selectively through the membrane; and *I*, inactivated and unable to be opened (i.e., inactive).²⁴ The affinity of the antiarrhythmic drug for the receptor on the ion channel varies with the state of the channel or with the membrane potential. Because of this, *R*, *A*, and *I* ion channels can have different kinetics of interaction with antiarrhythmic drugs. A review of the recent literature shows that the antiarrhythmic drugs have low affinity for *R* channels but relatively high affinity for the *A* or *I* channels or both. Regardless of which channel state is blocked by class I antiarrhythmic drugs, the unblocking rate directly determines the amount of depression present at normal heart rates.

CLASS II. β -ADRENERGIC BLOCKING AGENTS

β -Adrenergic blocking drugs cause membrane-stabilizing or depressant effects on myocardial tissue. Their antiarrhythmic properties, however, are considered to be principally the result of inhibition of adrenergic stimulation to the heart. The principal electrophysiological property of these β -blocking agents is reduction of the phase 4 slope of potential sinus or ectopic pacemaker cells, such that the heart rate decreases and ectopic tachycardias are either slowed or converted to sinus rhythm.

CLASS III. REPOLARIZATION PROLONGATORS

Drugs in this class (e.g., amiodarone, bretylium, sotalol, ibutilide, dofetilide) cause several different electrophysiological changes on myocardial tissue but share one common effect, prolonging the action potential, which increases the effective refractory period of the membrane action potential without altering the phase of depolarization or the resting membrane potential. Drugs in this class produce their effects by more than one mechanism. Sotalol is a K^+ channel blocker and has some β -adrenergic blocking properties.² Amiodarone and bretylium, drugs that also prolong the action potential by means that are unclear, also have Na^+ channel-blocking properties.

CLASS IV. CALCIUM CHANNEL BLOCKERS

Although not all Ca^{2+} channel blockers possess antiarrhythmic activity, some members of this class of antiarrhythmic drugs (verapamil, diltiazem) block the slow inward current of Ca^{2+} ions during phase 2 of the membrane action

potential in cardiac cells. For example, the prototypical drug in this group, verapamil, selectively blocks entry of Ca^{2+} into the myocardial cell. It acts on the slow-response fibers found in the sinus node and the AV node, slowing conduction velocity and increasing refractoriness in the AV node.

pH and Activity

The action of class I local anesthetic-type antiarrhythmic drugs is pH dependent and may vary with each drug.²⁵ Antiarrhythmic drugs are weak bases, with most having pK_a values ranging from 7.5 to 9.5. At physiological pH of 7.40, these bases exist in an equilibrium mixture consisting of both the free base and the cationic form. Ionizable drugs, such as lidocaine (pK_a 7.86), have stronger electrophysiological effects in ischemic rather than normal myocardial cells. This potentiation has been attributed in part to the increase in H^+ concentration within the ischemic areas of the heart. Acidosis increases the proportion of Na^+ ion channels occupied by the protonated form of the antiarrhythmic agent. Nevertheless, the effect of pH on the antiarrhythmic activity of drugs can be complex, as both the free base and cationic species have been proposed as the active form of some drugs. The uncharged form of the Na^+ channel blocker can penetrate directly from the lipid phase of the surrounding cell membrane to block the channel.

Small changes in pH can alter these drugs' effectiveness by changing the charged-to-uncharged molecular ratio in the myocardial cells. Acidosis external to the myocardial cell promotes the cationic form. Because this species does not partition in the membrane as readily, onset of these drugs' action would be delayed. Furthermore, concentration of these drugs in the membrane would be reduced. Therefore, drugs that act on the channel only in the inactivated (closed) state would have a reduced effect in acidotic conditions. Acidosis may also prolong the effect of these drugs. External acidosis facilitates protonation of receptor-bound drugs. Because only neutral drugs can dissociate from closed channels, recovery is prolonged by acidosis.

Alkalosis tends to hyperpolarize the cell membrane and, thereby, reduces the effect of antiarrhythmic drugs. Because of this, alkalosis promotes the formation of more of the free-base antiarrhythmic agent, increasing the rate of recovery from the block. Alkalosis-inducing salts such as sodium lactate have been used to counteract toxicity caused by the antiarrhythmic quinidine.

CLASS I ANTIARRHYTHMICS

Quinidine Sulfate, USP. Quinidine sulfate is the sulfate of an alkaloid obtained from various species of *Cinchona* and their hybrids. It is a dextrorotatory diastereoisomer of quinine. The salt crystallizes from water as the dihydrate, in the form of fine, needlelike, white crystals. Quinidine sulfate contains a hydroxymethyl group that serves as a link between a quinoline ring and a quinuclidine moiety. The structure contains two basic nitrogens, of which the quinuclidine nitrogen is the stronger base (pK_a 10). Quinidine sulfate is bitter and light sensitive. Aqueous solutions are nearly neutral or slightly alkaline. It is soluble to the extent of 1% in water and more highly soluble in alcohol or chloroform.

Quinidine
(Cardioquin)
(Quinora)
(Auinidex)

Quinidine sulfate is the prototype of antiarrhythmic drugs and a class IA antiarrhythmic agent according to the Vaughan Williams classification. It reduces Na^+ current by binding the open ion channels (i.e., state A). The decreased Na^+ entry into the myocardial cell depresses phase 4 diastolic depolarization and shifts the intracellular threshold potential toward zero. These combined actions diminish the spontaneous frequency of pacemaker tissues, depress the automaticity of ectopic foci, and, to a lesser extent, reduce impulse formation in the SA node. This last action results in bradycardia. During the spike action potential, quinidine sulfate decreases transmembrane permeability to passive influx of Na^+ , thus slowing the process of phase 0 depolarization, which decreases conduction velocity. This is shown as a prolongation of the QRS complex of electrocardiograms. Quinidine sulfate also prolongs action potential duration, which results in a proportionate increase in the QT interval. It is used to treat supraventricular and ventricular ectopic arrhythmias, such as atrial and ventricular premature beats, atrial and ventricular tachycardia, atrial flutter, and atrial fibrillation.

Quinidine sulfate is used most frequently as an oral preparation and is occasionally given intramuscularly. Quinidine sulfate that has been absorbed from the gastrointestinal tract or from the site of intramuscular injection is bound 80% to serum albumin.¹⁸ The drug is taken up quickly from the bloodstream by body tissues; consequently, a substantial concentration gradient is established within a few minutes. Onset of action begins within 30 minutes, with the peak effect attained in 1 to 3 hours. Quinidine is metabolized primarily in the liver by hydroxylation, and a small amount is excreted by the liver.²⁶ Because of serious side effects and the advent of more effective oral antiarrhythmic agents, quinidine is now used less, except in selected patients for long-term oral antiarrhythmic therapy.

Quinidine Gluconate, USP. Quinidinium gluconate (Duraquin, Quinaglute) occurs as an odorless, very bitter, white powder. In contrast with the sulfate salt, it is freely soluble in water. This is important because there are emergencies when the condition of the patient and the need for a rapid response make the oral route of administration inappropriate. The high water solubility of the gluconate salt along with a low irritant potential makes it valuable when an injectable form is needed in these emergencies. Quinidine gluconate forms a stable aqueous solution. When used for

injection, it usually contains 80 mg/mL, equivalent to 50 mg of quinidine or 60 mg of quinidine sulfate.

Quinidine Polygalacturonate. Quinidine polygalacturonate (Cardioquin) is formed by reacting quinidine and polygalacturonic acid in a hydroalcoholic medium. It contains the equivalent of approximately 60% quinidine. This salt is only slightly ionized and slightly soluble in water, but studies have shown that although equivalent doses of quinidine sulfate give higher peak blood levels earlier, a more uniform and sustained blood level is achieved with the polygalacturonate salt.

In many patients, the local irritant action of quinidine sulfate in the gastrointestinal tract causes pain, nausea, vomiting, and especially diarrhea, often precluding oral use in adequate doses. Studies with the polygalacturonate salt yielded no evidence of gastrointestinal distress. It is available as 275-mg tablets. Each tablet is the equivalent of 200 mg of quinidine sulfate or 166 mg of free alkaloid.

Procainamide Hydrochloride, USP. Procainamide hydrochloride, *p*-amino-*N*-[2-(diethylamino)ethyl]benzamide monohydrochloride, procainamidium chloride (Pronestyl, Procan SR), has emerged as a major antiarrhythmic drug. It was developed in the course of research for compounds structurally similar to procaine, which had limited effect as an antiarrhythmic agent because of its central nervous system (CNS) side effects and short-lived action caused by rapid hydrolysis of its ester linkage by plasma esterases. Because of its amide structure, procainamide hydrochloride is also more stable in water than is procaine. Aqueous solutions of procainamide hydrochloride have a pH of about 5.5. A kinetic study of the acid-catalyzed hydrolysis of procainamide hydrochloride showed it to be unusually stable to hydrolysis in the pH range 2 to 7, even at elevated temperatures.²⁷

Procainamide
(Pronestyl)
(Procan SR)

Procainamide hydrochloride is metabolized through the action of *N*-acetyltransferase. The product of enzymatic metabolism of procainamide hydrochloride is *N*-acetylprocainamide (NAPA), which possesses only 25% of the activity of the parent compound.²⁶ A study of the disposition of procainamide hydrochloride showed that 50% of the drug was excreted unchanged in the urine, with 7% to 24% recovered as NAPA.^{28,29} Unlike quinidine, procainamide hydrochloride is bound only minimally to plasma proteins. Between 75% and 95% of the drug is absorbed from the gastrointestinal tract. Plasma levels appear 20 to 30 minutes after administration and peak in about 1 hour.³⁰

Procainamide hydrochloride appears to have all of the electrophysiological effects of quinidine. It diminishes automaticity, decreases conduction velocity, and increases action potential duration and, thereby, the refractory period of myocardial tissue. Clinicians have favored the use of procainamide hydrochloride for ventricular tachycardias and

quinidine for atrial arrhythmias, even though the two drugs are effective in either type of disorder.

Disopyramide Phosphate, USP. Disopyramide phosphate, α -[2(diisopropylamino)ethyl]- α -phenyl-2-pyridine-acetamide phosphate (Norpace), is an oral and intravenous class IA antiarrhythmic agent. It is quite similar to quinidine and procainamide in its electrophysiological properties, in that it decreases phase 4 diastolic depolarization, decreases conduction velocity, and has vagolytic properties.³¹ It is used clinically in the treatment of refractory, life-threatening ventricular tachyarrhythmias. Oral administration of the drug produces peak plasma levels within 2 hours. The drug is bound approximately 50% to plasma protein and has a half-life of 6.7 hours in humans. More than 50% is excreted unchanged in the urine. Therefore, patients with renal insufficiency should be monitored carefully for evidence of overdose. Disopyramide phosphate commonly exhibits side effects of dry mouth, constipation, urinary retention, and other cholinergic blocking actions because of its structural similarity to anticholinergic drugs.

Disopyramide
(Norpace)

Lidocaine Hydrochloride, USP. Lidocaine hydrochloride, 2-(diethylamino)-2',6'-acetoxy lidide monohydrochloride (Xylocaine), was conceived as a derivative of gramine (3-dimethylaminomethylindole) and introduced as a local anesthetic. It is now being used intravenously as a standard parenteral agent for suppression of arrhythmias associated with acute myocardial infarction and cardiac surgery. It is the drug of choice for the parenteral treatment of premature ventricular contractions.

Lidocaine
(Xylocaine)

Lidocaine hydrochloride is a class IB antiarrhythmic agent with a different effect on the electrophysiological properties of myocardial cells from that of procainamide and quinidine. It binds with equal affinity to the active (A) and inactive (I) Na^+ ion channels. It depresses diastolic depolarization and automaticity in the Purkinje fiber network and increases the functional refractory period relative to action potential duration, as do procainamide and quinidine. It differs from the latter two drugs, however, in that it does not decrease, and may even enhance, conduction velocity

Figure 19.12 • Metabolism of lidocaine.

and increase membrane responsiveness to stimulation. There are fewer data available on the subcellular mechanisms responsible for the antiarrhythmic actions of lidocaine than on the more established drug quinidine. It has been proposed that lidocaine has little effect on membrane cation exchange of the atria. Sodium ion entrance into ventricular cells during excitation is not influenced by lidocaine because it does not alter conduction velocity in this area. Lidocaine hydrochloride does depress Na^+ influx during diastole, as do all other antiarrhythmic drugs, to diminish automaticity in myocardial tissue. It also alters membrane responsiveness in Purkinje fibers, allowing increased conduction velocity and ample membrane potential at the time of excitation.³²

Lidocaine hydrochloride administration is limited to the parenteral route and is usually given intravenously, although adequate plasma levels are achieved after intramuscular injections. Lidocaine hydrochloride is not bound to any extent to plasma proteins and is concentrated in the tissues. It is metabolized rapidly by the liver (Fig. 19.12). The first step is deethylation with the formation of monoethylglycinexylidide, followed by hydrolysis of the amide.³³ Metabolism is rapid, the half-life of a single injection ranging from 15 to 30 minutes. Lidocaine hydrochloride is a popular drug because of its rapid action and its relative freedom from toxic effects on the heart, especially in the absence of hepatic disease. Monoethylglycinexylidide, the initial metabolite of lidocaine, is an effective antiarrhythmic agent; its rapid hydrolysis by microsomal amidases, however, prevents its use in humans.

Precautions must be taken so that lidocaine hydrochloride solutions containing epinephrine salts are not used as cardiac depressants. Such solutions are intended only for local anesthesia and are not used intravenously. The aqueous solutions without epinephrine may be autoclaved several times, if necessary.

Phenytoin Sodium, USP. Phenytoin sodium, 5,5-diphenyl-2,4-imidazolidinedione, 5,5-diphenylhydantoin, diphenyl-hydantoin sodium (Dilantin), has been used for decades in the control of grand mal types of epileptic seizure. It is structurally analogous to the barbiturates but does not possess their extensive sedative properties. The compound is available as the sodium salt. Solutions for parenteral administration contain 40% propylene glycol and 10% alcohol to dissolve the sodium salt.

Phenytoin sodium's cardiovascular effects were uncovered during observation of toxic manifestations of the drug in patients being treated for seizure disorders. Phenytoin sodium was found to cause bradycardia, prolong the PR interval, and produce T-wave abnormalities on electrocardiograms. It is a class IB antiarrhythmic agent. Today, phenytoin sodium's greatest clinical use as an antiarrhythmic drug is in the treatment of digitalis-induced arrhythmias.³⁴ Its action is similar to that of lidocaine. It depresses ventricular automaticity produced by digitalis, without adverse intraventricular conduction. Because it also reverses the prolongation of AV conduction by digitalis, phenytoin sodium is useful in supraventricular tachycardias caused by digitalis intoxication.

Phenytoin sodium is located in high amounts in the body tissues, especially fat and liver, leading to large gradients between the drug in tissues and the plasma concentrations. It is metabolized in the liver.

Mexiletine Hydrochloride. Mexiletine hydrochloride, 1-methyl-2-(2,6-xylyloxy)ethylamine hydrochloride (Mexitil) (pK_a 8.4), is a class IB antiarrhythmic agent that is effective when given either intravenously or orally. It resembles lidocaine in possessing a xylyl moiety but otherwise is different chemically. Mexiletine hydrochloride is an ether and is not subject to the hydrolysis common to the amides lidocaine and tocainide. Its mean half-life on oral administration is approximately 10 hours.

Although not subject to hydrolysis, mexiletine hydrochloride is metabolized by oxidative and reductive processes in the liver. Its metabolites, *p*-hydroxymexiletine and hydroxymethylmexiletine, are not pharmacologically active as antiarrhythmic agents.³⁵

Mexiletine hydrochloride, like class I antiarrhythmic agents, blocks the fast Na^+ channel in cardiac cells. It is especially effective on the Purkinje fibers in the heart. The drug increases the threshold of excitability of myocardial cells by reducing the rate of rise and amplitude of the action potential and decreases automaticity.

Mexiletine hydrochloride is used for long-term oral prophylaxis of ventricular tachycardia. The drug is given in 200- to 400-mg doses every 8 hours.

Tocainide Hydrochloride. Tocainide hydrochloride, 2-amino-2',6'-propionoxyxylylidide hydrochloride (Tonocard) (pK_a 7.7), is an analog of lidocaine. It is orally active and has electrophysiological properties like those of lidocaine.³⁶ Total body clearance of tocainide hydrochloride is only 166 mL/min, suggesting that hepatic clearance is not large. Because of low hepatic clearance, the hepatic extraction ratio must be small; therefore, tocainide hydrochloride is unlikely to be subject to a substantial first-pass effect. The drug differs from lidocaine, in that it lacks two ethyl groups, which provides tocainide hydrochloride some protection from first-pass hepatic elimination after oral ingestion. Tocainide hydrochloride is hydrolyzed in a manner similar to that of lidocaine. None of its metabolites is active.

Tocainide
(Tonocard)

Tocainide hydrochloride is classed as a IB antiarrhythmic agent and used orally to prevent or treat ventricular ectopy and tachycardia. The drug is given in 400- to 600-mg doses every 8 hours.

Flecainide Acetate. Flecainide acetate, *N*-(2-piperidinylmethyl)-2,5-bis(2,2,2-trifluoroethoxy)benzamide monoacetate (Tambocor), is a class IC antiarrhythmic drug with local anesthetic activity; it is a chemical derivative of benzamide. The drug undergoes biotransformation, forming a meta-O-dealkylated compound, whose antiarrhythmic properties are half as potent as those of the parent drug, and a meta-O-dealkylated lactam of flecainide with little pharmacological activity.³⁷ Flecainide acetate is given orally to suppress chronic ventricular ectopy and ventricular tachycardia. It has some limitations because of CNS side effects.

Flecainide
(Tambocor)

Moricizine. Moricizine, ethyl 10-(3-morpholino-propionyl)phenothiazine-2-carbamate (Ethmozine), is a

phenothiazine derivative used for the treatment of malignant ventricular arrhythmias. It is categorized as a class IC antiarrhythmic agent, blocking the Na^+ channel with 1:1 stoichiometry. The drug has higher affinity for the inactivated state than the activated or resting states. It appears to bind to a site on the external side of the Na^+ channel membrane.³⁸ It has been used to suppress life-threatening ventricular arrhythmias.

Moricizine
(Ethmozine)

Propafenone. Propafenone, 2-[2'-hydroxy-3-(propylamino)propoxy]-3-phenylpropiophenone (Rythmol), a class IC antiarrhythmic drug, contains a chiral center and is marketed as the racemic mixture. Therapy with the racemic mixture of propafenone produces effects that can be attributed to both (S) and (R) enantiomers. Although (R) and (S) enantiomers exert similar Na^+ channel-blocking effects, the (S) enantiomer also produces a β -adrenergic blockade. As a result, the (S) enantiomer is reported to be 40-fold more potent than the (R) enantiomer as an antiarrhythmic agent.³⁹ The enantiomers also display stereoselective disposition characteristics. The (R) enantiomer is cleared more quickly. Hepatic metabolism is polymorphic and determined genetically. Ten percent of Caucasians have a reduced capacity to hydroxylate the drug to form 5-hydroxypropafenone. This polymorphic metabolism accounts for the interindividual variability in the relationships between dose and concentration and, thus, variability in the pharmacodynamic effects of the drug. The 5-hydroxy metabolites of both enantiomers are as potent as the parent compound in blocking Na^+ channels. Propafenone also depresses the slow inward current of Ca^{2+} ions. This drug has been used for acute termination or long-term suppression of ventricular arrhythmias. It is bound in excess of 95% to α_1 -acid glycoprotein in the plasma. It is absorbed effectively, but bioavailability is estimated to be less than 20% because of first-pass metabolism. Less than 1% is eliminated as unchanged drug. Therapy with propafenone may produce effects that can be attributed to both (S) and (R) enantiomers. Thus, the effects may be modulated because of an enantiomer-enantiomer interaction when patients are treated with the racemate.⁴⁰

Propafenone
(Rythmol)

CLASS II ANTIARRHYTHMICS

Class II antiarrhythmics are discussed under the heading, "Adrenergic System Inhibitors."

CLASS III ANTIARRHYTHMICS

Amiodarone. Amiodarone, 2-butyl-3-benzofuranyl-4-[2-(diethylamino)ethoxy]-3,5-diiodophenyl ketone (Cordarone), was introduced as an antianginal agent. It has very pronounced class III action and is especially effective in maintaining sinus rhythm in patients who have been treated by direct current shock for atrial fibrillation.⁴¹ Like class III antiarrhythmic drugs, amiodarone lengthens the effective refractory period by prolonging the action potential duration in all myocardial tissues. Amiodarone is eliminated very slowly from the body, with a half-life of about 25 to 30 days after oral doses.⁴² Although the drug has a broad spectrum of antiarrhythmic activity, its main limitation is a slow onset of action. Drug action may not be initiated for several days, and the peak effect may not be obtained for several weeks.

Amiodarone has adverse effects involving many different organ systems. It also inhibits metabolism of drugs cleared by oxidative microsomal enzymes. It contains iodine in its molecular structure and, as a result, has an effect on thyroid hormones. Hypothyroidism occurs in up to 11% of patients receiving amiodarone.⁴³ The principal effect is the inhibition of peripheral conversion of T_4 to T_3 . Serum reverse T_3 (rT_3) is increased as a function of the dose as well as the length of amiodarone therapy. As a result, rT_3 levels have been used as a guide for judging adequacy of amiodarone therapy and predicting toxicity.⁴⁴

Bretylum Tosylate. Bretylum tosylate, (*o*-bromobenzyl)ethyl dimethylammonium *p*-toluenesulfonate (Bretylol), is an extremely bitter, white, crystalline powder. The chemical is freely soluble in water and alcohol. Bretylum tosylate is an adrenergic neuronal-blocking agent that accumulates selectively in the neurons and displaces norepinephrine. Because of this property, bretylum was used initially, under the trade name of Darenthin, as an antihypertensive agent. It caused postural

decrease in arterial pressure.⁴⁴ This use was discontinued because of the rapid development of tolerance, erratic oral absorption of the quaternary ammonium compound, and persistent pain in the parotid gland on prolonged therapy. Currently, bretylum is reserved for use in ventricular arrhythmias that are resistant to other therapy. Bretylum does not suppress phase 4 depolarization, a common action of other antiarrhythmic agents. It prolongs the effective refractory period relative to the action potential duration but does not affect conduction time and is categorized as a class III antiarrhythmic agent. Because bretylum does not have properties similar to those of the other antiarrhythmic agents, it has been suggested that its action is a result of its adrenergic neuronal-blocking properties; the antiarrhythmic properties of the drug, however, are not affected by administration of reserpine. Bretylum is also a local anesthetic, but it has not been possible to demonstrate such an effect on atria of experimental animals, except at very high concentrations.⁴⁵ Therefore, the precise mechanism of the antiarrhythmic action of bretylum remains to be resolved.

Bretylum
(Bretylol)

Dofetilide. Dofetilide, *N*-[4-(3-{[2-(4-methanesulfonylamino)phenyl]ethyl}methylamino)propoxy)phenyl]methane-sulfonamide (Tikosyn), acts by blocking the cardiac ion channel carrying the rapid component of the delayed rectifier potassium currents (I_{kr}) and is used to terminate supraventricular arrhythmias, prevent the recurrence of atrial fibrillation, and treat life-threatening ventricular arrhythmias. Unlike sotalol and ibutilide, which are also methanesulfonamides, it has no effect on adrenergic receptors or sodium channels, respectively. Dofetilide has high specificity for the delayed rectifier potassium currents.⁴⁶

Ibutilide. Ibutilide, *N*-{4-[4-(ethylheptylamino)-1-hydroxybutyl]phenyl}methanesulfonamide (Corvert), a class III antiarrhythmic belonging to the methanesulfonamide class of agents, is indicated for rapid conversion of atrial fibrillation or atrial flutter to normal sinus rhythm.

Dofetilide
(Tikosyn)

Unlike dofetilide, it is not highly specific for the delayed rectifier potassium currents (I_{kr}) and does have some affinity for sodium channels.

Sotalol. Sotalol, 4' [1-hydroxy-2-(isopropylamino)ethyl]methylsulfonamide (Betapace), is a relatively new antiarrhythmic drug, characterized most often as a class III agent, and although it has effects that are related to the class II agents, it is not therapeutically considered a class II antiarrhythmic. It contains a chiral center and is marketed as the racemic mixture. Because of its enantiomers, its mechanism of action spans two of the antiarrhythmic drug classes. The $l(-)$ enantiomer has both β -blocking (class II) and potassium channel-blocking (class III) activities. The $d(+)$ enantiomer has class III properties similar to those of the $(-)$ isomer, but its affinity for the β -adrenergic receptor is 30 to 60 times lower. The sotalol enantiomers produce different effects on the heart. Class III action of d -sotalol in the sinus node is associated with slowing of sinus heart rate, whereas β -adrenergic blockade contributes to the decrease in heart rate observed with l - or d,l -sotalol. Sotalol is not metabolized, nor is it bound significantly to proteins. Elimination occurs by renal excretion, with more than 80% of the drug eliminated unchanged. Sotalol is characteristic of class III antiarrhythmic drugs, in that it prolongs the duration of the action potential and, thus, increases the effective refractory period of myocardial tissue. It is distinguished from the other class III drugs (amiodarone and bretylium) because of its β -adrenergic receptor-blocking action.

Azimilide. Azimilide, E -1-[[[5-(4-chlorophenyl)-2-furanyl]methylene]amino]-3-[4-(4-methyl-1-piperazinyl)butyl]-2,4-imidazolidinedione, is a class III agent that sig-

nificantly blocks the delayed rectifier potassium current, I_{ks} , including the I_{kr} component. Its ability to block multi-channels may be caused by a lack of the methane sulfonamide group that is common to other class III agents, which selectively block the I_{kr} potassium current. It is believed that blocking both I_{kr} and I_{ks} potassium currents yields consistent class III antiarrhythmic effects at any heart rate.⁴⁷

CLASS IV ANTIARRHYTHMICS

Verapamil and Diltiazem. Both verapamil and diltiazem block the slow inward Ca^{2+} currents (voltage-sensitive channel) in cardiac fibers. This slows down AV conduction and the sinus rate. These drugs are used in controlling atrial and paroxysmal tachycardias and are categorized as class IV antiarrhythmic agents according to the Vaughan Williams classification.²¹ (A more detailed description of calcium channel blockers is given previously.)

ANTIHYPERTENSIVE AGENTS

Hypertension is a consequence of many diseases. Hemodynamically, blood pressure is a function of the amount of blood pumped by the heart and the ease with which the blood flows through the peripheral vasculature (i.e., resistance to blood flow by peripheral blood vessels). Diseases of components of the central and peripheral nervous systems, which regulate blood pressure and abnormalities of the hormonal system, and diseases of the kidney and peripheral vascular network, which affect blood volume, can create a hypertensive state in humans. Hypertension is generally defined as mild when the diastolic pressure is between 90 and 104 mm Hg, moderate when it is 105 to 114 mm Hg, and severe when it is above 115 mm Hg. It is estimated that about 15% of the adult population in the United States (about 40 million) are hypertensive.

Primary (essential) hypertension is the most common form of hypertension. Although advances have been made in the identification and control of primary hypertension, the etiology of this form of hypertension has not yet been resolved. *Renal hypertension* can be created by experimentally causing renal artery stenosis in animals. Renal artery stenosis also may occur in pathological conditions of the kidney, such as nephritis, renal artery thrombosis, renal artery infarctions, or other conditions that restrict blood flow through the renal artery. Hypertension also may originate from pathological states in the CNS, such as malignancies. Tumors in the adrenal medulla that cause release of large amounts of catecholamines create a hypertensive condition known as *pheochromocytoma*. Excessive secretion of aldosterone by the adrenal cortex, often because of adenomas, also produces hypertensive disorders.

Arterial blood pressure is regulated by several physiological factors, such as heart rate, stroke volume, peripheral vascular network resistance, blood vessel elasticity, blood volume, and viscosity of blood. Endogenous chemicals also play an important part in the regulation of arterial blood pressure. The peripheral vascular system is influenced greatly by the sympathetic–parasympathetic balance of the autonomic nervous system, the control of which originates in the CNS. Enhanced adrenergic activity is a principal contributor to primary (essential) hypertension.

Therapy using antihypertensive agents evolved rapidly between 1950 and 1960. During that time, several drugs for the treatment and control of hypertensive disease were discovered. Despite the many years of experience, treatment remains empiric because the etiology of the principal form of hypertension, primary hypertension, is unknown. The first drugs used to produce symptomatic relief of hypertension were α -adrenergic blocking agents. These drugs had limitations because their duration of action was far too short and side effects precluded long-term therapy. Contemporary therapy of primary hypertension uses one of several drug classes as the first course. These drugs may be diuretics to reduce blood volume, inhibitors of the renin–angiotensin system (ACE inhibitors, Chapter 18), and agents that reduce peripheral vascular resistance (e.g., calcium channel blockers, vasodilators, and sympathetic nervous system depressants). The antihypertensive drug classes discussed in this section include endothelin receptor antagonists, sympathetic nervous system depressants, and vasodilators acting on smooth muscle. Calcium channel blockers and other vasodilators are included in previous discussions in this chapter. Diuretics and renin angiotensin system are discussed in Chapter 18.

ENDOTHELIN RECEPTOR ANTAGONISTS

Endothelin-1 is a 21-amino acid peptide that is produced in the vascular endothelium, which plays a role in the regulation of smooth muscle contraction. Two types of endothelin receptors, ET_A and ET_B , have been identified on smooth muscle. The physiological role these play varies depending on the location of the receptor. Overall, the receptors are linked to a Gq-protein and when activated, results in the formation of IP_3 . This, in turn, results in the release of calcium by the sarcoplasmic reticulum that results in increased smooth muscle contraction and vasoconstriction. It is of interest to note that ET_B receptors located on the endothelium have a slightly different role than those found on the vascular smooth muscle. When the endothelium ET_B receptors are stimulated, NO is formed from L-arginine. The NO that is released produces vasodilation in much the same fashion as nitroglycerin. This effect is generally transient, whereas the overall effects of stimulation of the vascular endothelin receptors is prolong. Agents that antagonize these receptors (endothelin receptor antagonists [ETRA]) have usefulness in treating hypertension, heart failure, and coronary vasospasm. Currently, the approved agents are only indicated for pulmonary hypertension.⁴⁸

PRODUCTS

Ambrisentan. Ambrisentan, (+)-(2S)-2-[(4,6-dimethylpyrimidin-2-yl)oxy]-3-methoxy-3,3-diphenylpropanoic acid (Letaris), is a potent ET_A selective endothelin antagonist that, is indicated, in the treatment of pulmonary arterial hyperten-

sion (PAH). PAH is a rare disease that if left untreated has a high mortality rate. In June of 2007, the FDA granted approval of ambrisentan for once-daily treatment of PAH. Studies have shown that it improves a 6-minute walk by about 30 to 60 m for patients receiving placebo.⁴⁹

Ambrisentan

Bosentan. Bosentan, N-[6-(2-hydroxyethoxy)-5-(2-methoxyphenoxy)-2-pyrimidin-2-yl-pyrimidin-4-yl]-4-tert-butyl-benzenesulfonamide (Tracleer, Bozentan), was the first endothelin receptor antagonist marketed in the United States. Bosentan works by competitively blocking the endothelin receptor subtypes ET_A and ET_B . In binding to the receptors, it blocks the effects of endothelin, which include constriction of the vascular smooth muscle, which leads to narrowing of the blood vessels and hypertension. Although it is not selective for the ET_A receptors, it does have a higher affinity for that subtype over ET_B . However, the clinical significance of selectivity over preferential receptor binding has not been demonstrated. Bosentan is an inducer of CYP2C9 and CYP3A4, and patients using bosentan must be monitored for liver toxicity.⁵⁰

Bosentan

Sitaxsentan Sodium. Sitaxsentan, N-(4-chloro-3-methyl-oxazol-5-yl)-2-[2-(6-methylbenzo[1,3]dioxol-5-yl)acetyl]thiophene-3-sulfonamide (Thelin), belongs to the sulfonamide class of endothelin receptor antagonists.

Although it has 6,000-fold selectivity for the ET_A receptor, clinical trials have not demonstrated a greater efficacy over bosentan. However, it has much lower liver toxicity than bosentan. The manufacturer is attempting to meet efficacy outcomes set by the FDA, which must be met before approval of sitaxsentan as a therapeutic agent will be granted.

Sitaxsentan

ADRENERGIC SYSTEM INHIBITORS

Drugs that reduce blood pressure by depressing the activity of the sympathetic nervous system have been used as effective agents in the treatment of hypertension. This can be accomplished in several ways: (a) depleting the stores of neurotransmitter, (b) reducing the number of impulses traveling in sympathetic nerves, (c) antagonizing the actions of the neurotransmitter on the effector cells, and (d) inhibiting neurotransmitter release.

AGENTS DEPLETING NEUROTRANSMITTER STORES

Folk remedies prepared from species of *Rauwolfia*, a plant genus belonging to the Apocynaceae family, were reported as early as 1563. The root of the species *Rauwolfia serpentina* has been used for centuries as an antidote to stings and bites of insects, to reduce fever, as a stimulant to uterine contractions, for insomnia, and particularly for the treatment of insanity. Its use in hypertension was recorded in the Indian literature in 1918, but not until 1949 did hypotensive properties of *Rauwolfia* spp. appear in the Western literature.⁵¹ *Rauwolfia* preparations were introduced in psychiatry for the treatment of schizophrenia in the early 1950s, following confirmation of the folk remedy reports on their use in mentally deranged patients. By the end of the 1960s, however, the drug had been replaced by more efficacious neurotropic agents. Reserpine and its preparations remain useful in the control of mild essential hypertension.

The effects of reserpine do not correlate well with tissue levels of the drug. The pharmacological effects of reserpine were still present in animals when it could no longer be detected in the brain.⁵² Reserpine depletes catecholamines and serotonin from central and peripheral neurons by interfering with the uptake of these amines from the cytosol into the vesicles and granules.^{53,54} As a consequence, norepinephrine cannot be stored intraneuronally in adrenergic neurons, and much of the norepinephrine in the cytosol is metabolized by monoamine oxidase (MAO) (Fig. 19.13). The binding of reserpine to the storage vesicle membrane is

Figure 19.13 • Action of reserpine at adrenergic nerve ending.

firm, and as a result, the storage granule is destroyed, reducing the ability of the nerve to concentrate and store norepinephrine. Because reserpine acts on both central and peripheral adrenergic neurons, its antihypertensive effects may result from neurotransmitter depletion from both of these sites.

Chemical investigations of the active components of *R. serpentina* roots have yielded several alkaloids (e.g., ajmaline, ajmalicine, ajmalinine, serpentine, and serpentinine). Reserpine, which is the major active constituent of *Rauwolfia*,⁵⁵ was isolated in 1952 and is a much weaker base than the alkaloids just mentioned. Reserpinoid alkaloids are yohimbine-like bases that have an additional functional group on C-18. Only three naturally occurring alkaloids possess reserpine-like activity strong enough for use in treating hypertension: reserpine, deserpidine, and rescinnamine.

Reserpine is absorbed rapidly after oral administration. Fat tissue accumulates reserpine slowly, with a maximal level reached between 4 and 6 hours. After 24 hours, small amounts of reserpine are found in the liver and fat, but none is found in the brain or other tissues. Reserpine is metabolized by the liver and intestine to methyl reserpate and 3,4,5-trimethoxybenzoic acid.

Powdered *Rauwolfia Serpentina*, USP. *Rauwolfia* (Raudixin, Rauserpal, Rauval) is the powdered whole root of *R. serpentina* (Benth). It is a light tan to light brown powder, sparingly soluble in alcohol and only slightly soluble in water. It contains the total alkaloids, of which reserpine accounts for about 50% of the total activity. Orally, a dosage of 200 to 300 mg is roughly equivalent to 500 μ g of reserpine. It is used in the treatment of mild or moderate hypertension or in combination with other hypotensive agents in severe hypertension.

Reserpine, USP. Reserpine (Serpasil, Reserpid, Raused, Sandril) is a white to light yellow, crystalline alkaloid, practically insoluble in water, obtained from various species of *Rauwolfia*. In common with other compounds with an indole nucleus, it is susceptible to decomposition by light and oxidation, especially when in solution. In the dry state, discoloration occurs rapidly when reserpine is exposed to light, but the loss in potency is usually small. In solution,

reserpine may break down with no appreciable color change when exposed to light, especially in clear glass containers; thus, color change cannot be used as an index of the amount of decomposition.

Reserpine is effective orally and parenterally for the treatment of hypertension. After a single intravenous dose, the onset of antihypertensive action usually begins in about 1 hour. After intramuscular injection, the maximum effect occurs within approximately 4 hours and lasts about 10 hours. When it is given orally, the maximum effect occurs within about 2 weeks and may persist up to 4 weeks after the final dose. When used in conjunction with other hypotensive drugs in the treatment of severe hypertension, the daily dose varies from 100 to 250 μg .

Guanethidine and Related Compounds. Guanethidine has been classified traditionally as an adrenergic blocking agent because it can prevent the release of norepinephrine from postganglionic neurons in response to adrenergic stimulation. Guanethidine and other compounds discussed in this section have other actions on catecholamine metabolism and can cause significant depletion of these amines in adrenergic neurons. They do not interfere with release of epinephrine from the adrenal medulla.

Guanethidine
(Ismelin)

Guanethidine Monosulfate, USP. Guanethidine monosulfate, [2-(hexahydro-1 (2*H*)-azocinyl)ethyl]guanidine sulfate (Ismelin sulfate), is a white, crystalline material that is very soluble in water. It was one of a series of guanidine compounds prepared in the search for potent antitrypanosomal agents. There is an absence of CNS effects, such as depression, because the drug is highly polar and does not easily cross the blood-brain barrier. Guanethidine monosulfate produces a gradual, prolonged fall in blood pressure. Usually, 2 to 7 days of therapy are required before the peak effect is reached, and usually, this peak effect is maintained for 3 or 4 days. Then, if the drug is discontinued, the blood pressure returns to pretreatment levels over a period of 1 to 3 weeks. Because of this slow onset and prolonged duration of action, only a single daily dose is needed.

Guanethidine monosulfate is metabolized by microsomal enzymes to 2-(6-carboxyhexylamino)ethylguanidine and guanethidine *N*-oxide (Fig. 19.14). Both metabolites have very weak antihypertensive properties. Guanethidine monosulfate is taken up by the amine pump located on the neuronal membrane and retained in the nerve, displacing norepinephrine from its storage sites in the neuronal granules. The displaced norepinephrine is metabolized to homovanillic acid by mitochondrial MAO, depleting the nerve ending of the neurotransmitter. The usefulness of guanethidine monosulfate also resides in the fact that once it is taken up by the nerve, it produces a sympathetic blockade by inhibiting release of norepinephrine that would occur on neuronal membrane response to stimulation²⁹ by the nerve action potential. Guanethidine monosulfate stored in the granules is released by the nerve action potential but has very low intrinsic activity for the adrenergic receptors on the postjunctional membrane. Moderate doses for a prolonged period or large doses may produce undesirable side effects by causing neuromuscular blockade and adrenergic nerve conduction blockade.

Guanadrel Sulfate. Guanadrel sulfate, (1,4-dioxaspiro[4.5]dec-2-ylmethyl)guanidine sulfate (Hylorel), is similar to guanethidine monosulfate in the manner in which it reduces elevated blood pressure. It acts as a postganglionic adrenergic blocking agent by displacing norepinephrine in adrenergic neuron storage granules, thereby preventing release of the endogenous neurotransmitter on nerve stimulation. Guanadrel sulfate has a much shorter half-life (10 hours) than guanethidine monosulfate, whose

Figure 19.14 • Metabolism of guanethidine monosulfate.

half-life is measured in days. In the stepped-care approach to hypertension, guanadrel sulfate is usually a step 2 agent.

Guanadrel
(Hylorel)

SELECTIVE α -ADRENERGIC ANTAGONISTS

The principal clinical use of α -adrenergic antagonists is in the treatment of catecholamine-dependent hypertension. Classic drugs such as phentolamine and phenoxybenzamine are non-specific-blocking agents of both α_1 - and α_2 -receptors on the presynaptic membrane of the adrenergic neuron. Specific antagonists of α_1 -receptors are effective antihypertensive agents by blocking the vasoconstricting effect on smooth muscle and not interfering with the activation of α_2 -receptors on the adrenergic neuron, which when activated inhibit further release of norepinephrine.

Prazosin Hydrochloride. The antihypertensive effects of prazosin hydrochloride, 1-(4-amino-6,7-dimethoxy-2-quinazolinyl)-4-(2-furoyl)piperazine monohydrochloride (Minipress), are caused by peripheral vasodilation as a result of its blockade of α_1 -adrenergic receptors. In ligand-binding studies, prazosin hydrochloride has 5,000-fold greater affinity for α_1 -receptors than for some α_2 -adrenergic receptors.⁵⁶

Prazosin
(Minipress)

Prazosin hydrochloride is readily absorbed, and plasma concentrations reach a peak about 3 hours after administration. Plasma half-life is between 2 and 3 hours. Prazosin hydrochloride is highly bound to plasma protein; it does not cause adverse reactions, however, with drugs that might be displaced from their protein-binding sites (e.g., cardiac glycosides). It may cause severe orthostatic hypertension because of its α -adrenergic blocking action, which prevents the reflex venous constriction that is activated when an individual sits up from a prone position.

Terazosin Hydrochloride. Terazosin hydrochloride, 1-(4-amino-6,7-dimethoxy-2-quinazolinyl)-4-(tetrahydro-2-furoyl)piperazine monohydrochloride (Hytrin), is a structural congener of prazosin hydrochloride. It possesses similar selective properties of specifically inhibiting α_1 -adrenergic receptors. The drug is slightly less potent than prazosin hydrochloride. Terazosin hydrochloride has a half-life of approximately 12 hours, which is much longer than that of prazosin. This lends itself to a once-daily dose to control hypertension in many patients.

Terazosin
(Hytrin)

Doxazosin. Doxazosin, 1-(4-amino-6,7-dimethoxy-2-quinazolinyl)-4-(1,4-benzodioxan-2-ylcarbonyl)piperazine (Cardura), is a quinazolinone compound that selectively inhibits the α_1 -subtype of α -adrenergic receptors. This agent is very useful in the management of hypertension associated with pheochromocytoma.

Doxazosin
(Cardura)

CENTRALLY ACTING ADRENERGIC DRUGS

The use of agents that directly affect the peripheral component of the sympathetic nervous system represents an important approach to the treatment of hypertension. A second approach to modifying sympathetic influence on the cardiovascular system is through inhibition or reduction of CNS control of blood pressure. Several widely used medications act by stimulating α_2 -receptors, which in the CNS reduces sympathetic outflow to the cardiovascular system and produces a hypotensive effect.

Methyldopate Hydrochloride, USP. Methyldopate hydrochloride, L-3-(3,4-dihydroxyphenyl)-2-methylalanine ethyl ester hydrochloride (Aldomet ester hydrochloride), α -methyldopa, lowers blood pressure by inhibiting the outflow of sympathetic vasoconstrictor impulses from the brain. Early studies had suggested that the hypotensive action of α -methyldopa was a result of the peripheral properties of the drug as a decarboxylase inhibitor or a false transmitter.

Methyldopa
(Aldomet)

The current hypothesis concerning the hypotensive activity of methyldopa involves the CNS as the site of action.⁵⁷ Methyldopa, on conversion to α -methylnorepineph-

rine, acts on α_2 -adrenergic receptors to inhibit the release of norepinephrine, resulting in decreased sympathetic outflow from the CNS and activation of parasympathetic outflow.

Methyldopa is used as a step 2 agent and is recommended for patients with high blood pressure who are not responsive to diuretic therapy alone. Methyldopa, suitable for oral use, is a zwitterion and is not soluble enough for parenteral use. The problem was solved by making the ester, leaving the amine free to form the water-soluble hydrochloride salt. It is supplied as a stable, buffered solution, protected with antioxidants and chelating agents.

Clonidine Hydrochloride. Clonidine hydrochloride, 2-[(2,6-dichlorophenyl)imino]imidazolidine monohydrochloride (Catapres), was the first antihypertensive known to act on the CNS. It was synthesized in 1962 as a derivative of the known α -sympathomimetic drugs naphazoline and tolazoline, potential nasal vasoconstrictors, but instead it proved to be effective in the treatment of mild-to-severe hypertension.

Clonidine hydrochloride acts by both peripheral and central mechanisms in the body to affect blood pressure. It stimulates the peripheral α -adrenergic receptors to produce vasoconstriction, resulting in a brief period of hypertension. Clonidine hydrochloride acts centrally to inhibit the sympathetic tone and cause hypotension that is of much longer duration than the initial hypertensive effect. Administration of clonidine hydrochloride thus produces a biphasic change in blood pressure, beginning with a brief hypertensive effect and followed by a hypotensive effect that persists for about 4 hours. This biphasic response is altered by dose only. Larger doses produce a greater hypertensive effect and delay the onset of the hypotensive properties of the drug. Clonidine hydrochloride acts on α_2 -adrenoreceptors located in the hindbrain to produce its hypotensive action. Clonidine hydrochloride also acts centrally to cause bradycardia and to reduce plasma levels of renin. Sensitization of baroreceptor pathways in the CNS appears to be responsible for the bradycardia transmitted by way of the vagus nerve. The central mechanism that results in decreased plasma renin is not known, however. The hypotensive properties of clonidine in animals can be blocked by applying α -adrenergic blocking agents directly to the brain.⁵⁸

Clonidine hydrochloride has advantages over antihypertensive drugs such as guanethidine monosulfate and prazosin hydrochloride, in that it seldom produces orthostatic hypotensive side effects. It does, however, have some sedative properties that are undesirable; it also may cause constipation and dryness of the mouth.

Clonidine hydrochloride is distributed throughout the body, with the highest concentrations found in the organs of elimination: kidney, gut, and liver. Brain concentrations are low but higher than plasma concentrations. The high concentration in the gut is caused by an enterohepatic cycle in which clonidine hydrochloride is secreted into the bile in rather high concentrations. The half-life in humans is about 20 hours. Clonidine hydrochloride is metabolized by the body to form two major metabolites, *p*-hydroxyclo-nidine and its glucuronide. *p*-Hydroxyclo-nidine does not cross the blood-brain barrier and has no hypotensive effect in humans.

Guanabenz Acetate. Guanabenz acetate, [(2,6-dichlorobenzylidene)amino]guanidine monoacetate (Wytensin), is a central α_2 -adrenergic agonist that reduces the release of norepinephrine from the neuron when stimulated. The effect of the drug results in decreased sympathetic tone in the heart, kidneys, and peripheral blood vessels. The drug does not produce orthostatic hypotension.

Guanfacine Hydrochloride. Guanfacine hydrochloride, *N*-(aminoiminomethyl)-2,6-dichlorobenzeneacetamide (Tenex), is structurally related to clonidine hydrochloride and guanabenz acetate and shares many of their pharmacological properties. The drug has a longer duration of action than either clonidine hydrochloride or guanabenz acetate. It lasts up to 24 hours. It also requires much longer (8–12 hours) for a peak effect to occur after the drug is administered.

VASODILATORY DRUGS ACTING ON SMOOTH MUSCLE

Reduction of arterial smooth muscle tone may occur by many mechanisms, such as reduction in sympathetic tone, stimulation of β -adrenergic receptors, or even direct action on the vasculature without interference from the autonomic innervation. Drugs acting on the arteriolar smooth muscle also increase sympathetic reflex activity, causing an increase in heart rate and cardiac output and stimulating renin release, which increases sodium retention and plasma volume. As a result, it is common to coadminister saluretics and β -adrenergic blocking drugs with these agents.

Antihypertensive agents that produce vasodilation of smooth muscle can be divided into two categories: direct-acting and indirect-acting vasodilators. Indirect-acting vasodilators may be distinguished from direct-acting vasodilators, in that they produce their effect by interfering with the

vasoconstrictor stimuli, and their primary site of action is not necessarily the vascular smooth muscle itself. Indirect-acting vasodilators include sympatholytic drugs, such as reserpine; α -adrenergic antagonists, such as prazosin hydrochloride; ACE inhibitors; and angiotensin II receptor antagonists, such as saralysin. Direct-acting vasodilators include hydralazine hydrochloride, sodium nitroprusside, potassium channel openers, and calcium channel-blocking agents.⁵⁸

Hydralazine Hydrochloride, USP. Hydralazine hydrochloride, 1-hydrazinophthalazine monohydrochloride (Apresoline hydrochloride), originated from the work of a chemist⁵⁹ attempting to produce some unusual chemical compounds and from the observation⁶⁰ that this compound had antihypertensive properties. It occurs as yellow crystals and is soluble in water to the extent of about 3%. A 2% aqueous solution has a pH of 3.5 to 4.5.

Hydralazine hydrochloride is useful in the treatment of moderate-to-severe hypertension. It is often used in conjunction with less potent antihypertensive agents, because side effects occur frequently when it is used alone in adequate doses. In combinations, it can be used in lower and safer doses. Its action appears to be centered on the smooth muscle of the vascular walls, with a decrease in peripheral resistance to blood flow. This results in increased blood flow through the peripheral blood vessels. It also has the unique property of increasing renal blood flow, an important consideration in patients with renal insufficiency.

Hydralazine hydrochloride acts on vascular smooth muscle to cause relaxation. Its mechanism of action is unclear. It interferes with Ca^{2+} entry and Ca^{2+} release from intracellular stores and reportedly causes activation of guanylate cyclase, resulting in increased levels of cGMP. All of these biochemical events can cause vasodilation.

Absorption of hydralazine hydrochloride taken orally is rapid and nearly complete. The maximal hypotensive effect is demonstrable within 1 hour. The drug is excreted rapidly by the kidneys, and within 24 hours, 75% of the total amount administered appears in the urine as metabolites or unchanged drug. Hydralazine hydrochloride undergoes benzylic oxidation, glucuronide formation, and *N*-acetylation by the microsomal enzymes in the tissues (Fig. 19.15). Acetylation appears to be a major determinant of the rate of hepatic removal of the drug from the blood and, therefore, of systemic availability.⁶¹ Rapid acetylation results in a highly hepatic extraction ratio from blood and greater first-pass elimination.

Figure 19.15 • Metabolism of hydralazine hydrochloride.

Hydralazine hydrochloride is more effective clinically when coadministered with drugs that antagonize adrenergic transmission (e.g., β -adrenergic antagonists, reserpine, guanethidine monosulfate, methyldopa, and clonidine hydrochloride). When given with diuretics, it is useful in the treatment of CHF.

Hydralazine hydrochloride is marketed as a combination therapy with isosorbide under the trade name BiDil specifically for African Americans with CHF.

Hydralazine
(Apresoline)

Sodium Nitroprusside, USP. Sodium nitroprusside, sodium nitroferrocyanide, disodium pentacyanonitrosylferate(2) $\text{Na}_2[\text{Fe}(\text{CN})_5\text{NO}]$ (Nipride, Nitropress), is one of the most potent blood pressure-lowering drugs. Its use is limited to hypertensive emergencies because of its short duration of action. The effectiveness of sodium nitroprusside as an antihypertensive has been known since 1928, but not until 1955 was its efficacy as a drug established.⁶² The drug differs from other vasodilators, in that vasodilation occurs in both venous and arterial vascular beds. Sodium nitroprusside is a reddish brown water-soluble powder that is decomposed by light when in solution. The hypotensive effect of the chemical is a result of the formation of NO in situ (discussed under the heading, “Nitrovasodilators”), elevating cellular levels of cGMP. Sodium nitroprusside is metabolized by the liver, yielding thiocyanate. Because thiocyanate is excreted by the kidneys, patients with impaired renal function may suffer thiocyanate toxicity.

PHOSPHODIESTERASE TYPE 5 INHIBITORS

As discussed throughout this chapter, the cyclic nucleotide phosphodiesterases constitute a group of enzymes that catalyze the hydrolysis of various cyclic nucleotides including cAMP and cGMP. The contractility of all muscle types is regulated primarily by reversible phosphorylation of the protein myosin. The phosphorylation of myosin allows it to interact with actin, which results in muscle contraction. Through different mechanisms, cAMP and cGMP interfere with the ability of myosin to be phosphorylated and/or interact with actin. This, in turn, results in muscle relaxation. Agents that interfere with the degradation of the cyclic nucleotide have usefulness in treating hypertension, erectile dysfunction, etc. Phosphodiesterase type 5 (PDE5) is responsible for the catalytic hydrolysis of cGMP in the smooth muscle of the arteries in the penis and lungs. Inhibitors of this particular phosphodiesterase have been shown to relax arteries in the penis, thus allowing the corpus cavernosum to fill with blood and aiding in an erection.⁶³

PRODUCTS

Sildenafil Citrate. Sildenafil, 1-[4-ethoxy-3-(6,7-dihydro-1-methyl-7-oxo-3-propyl-1H-pyrazolo[4,3-d]pyrimidin-5-yl)-phenylsulfonyl]-4-methylpiperazine citrate (Viagra), is a potent inhibitor of PDE5. It was initially studied for use in hypertension and angina pectoris because of its ability to increase intracellular levels of cyclic nucleotides. However, during phase I clinical trials, it was noted that the drug had little effect on angina and was unpredictable in managing hypertension. However, patients noted that there were improved effects in their sexual dysfunction. Therefore, the manufacturer decided to develop the investigational compound for treating erectile dysfunction, rather than for angina or hypertension. In March 1998, the FDA approved the drug for use in erectile dysfunction, becoming the first oral agent approved to treat erectile dysfunction in the United States. Within a year, it soon had annual sales exceeding \$1 billion per year. The chemical structure of sildenafil is similar to that of cGMP and acts as a competitive binding agent of PDE5.

Sildenafil is also effective in the rare disease, PAH (presented earlier in this chapter under "Endothelin Receptor Antagonist"). By increasing cyclic nucleotide levels, it relaxes the arterial wall, leading to decreased pulmonary arterial resistance and pressure. As a result of the selective distribution of PDE-5 within the arterial smooth muscle of the lungs and penis, sildenafil acts selectively in these areas. In June 2005, the FDA approved sildenafil (Revatio) for the management of PAH. To avoid confusion with its use in either PAH or erectile dysfunction, the product used for erectile dysfunction is a blue oval tablet, whereas the product used for management of PAH is a round white tablet.⁶³

Vardenafil Hydrochloride. Vardenafil, 4-[2-ethoxy-5-(4-ethylpiperazin-1-yl)sulfonyl-phenyl]-9-methyl-7-propyl-3,5,6,8-tetraza-bicyclo[4.3.0]nona-3,7,9-trien-2-one (Levitra), was the second PDE5 introduced in the U.S. market. The metabolism of vardenafil is primarily by CYP3A4. As such, concomitant use of CYP3A4 inhibitors such as ritonavir, indinavir, ketoconazole, as well as moderate CYP3A inhibitors such as erythromycin typically results in significant increases of plasma levels of vardenafil.

Vardenafil

Tadalafil. Tadalafil, (6*R*-trans)-6-(1,3-benzodioxol-5-yl)-2,3,6,7,12,12a-hexahydro-2-methyl-pyrazino[1', 2':1,6]pyrido[3,4-*b*]indole-1,4-dione (Cialis), is a potent PDE5 inhibitor. It received FDA approval for the treatment of erectile dysfunction in December 2003. Because of its half-life of 17.5 hours, it is marketed as a 36-hour treatment. Tadalafil is predominantly metabolized by hepatic enzymes, including CYP3A4. The concomitant use of CYP3A4 inhibitors such as ritonavir, indinavir, ketoconazole, as well as moderate CYP3A inhibitors such as erythromycin have been shown to result in significant increases in tadalafil plasma levels. Much like sildenafil, tadalafil is under clinical investigation for managing PAH.⁶⁴

Tadalafil

POTASSIUM CHANNEL AGONISTS

The two agents that can be classified in this category are diazoxide and minoxidil. These drugs are also called *potassium channel openers*. These agents activate ATP-sensitive potassium channels, which leads to a decrease of intracellular Ca²⁺ and reduces the excitability of smooth muscle. The primary action of these drugs is to open potassium channels in

the plasma membrane of vascular smooth muscle. An efflux of potassium from the cell follows, resulting in hyperpolarization of the membrane, which produces an inhibitory influence on membrane excitation and subsequent vasodilation.

Diazoxide, USP. Diazoxide is used as the sodium salt of 7-chloro-3-methyl-2*H*-1,2,4-benzothiadiazine 1,1-dioxide (Hyperstat IV). Diazoxide lowers peripheral vascular resistance, increases cardiac output, and does not compromise renal blood flow.

This is a des-sulfamoyl analog of the benzothiazine diuretics and has a close structural similarity to chlorothiazide. It was developed intentionally to increase the antihypertensive action of the thiazides and to minimize the diuretic effect.

It is used by intravenous injection as a rapidly acting antihypertensive agent for emergency reduction of blood pressure in hospitalized patients with accelerated or malignant hypertension. More than 90% is bound to serum protein, and caution is needed when it is used in conjunction with other protein-bound drugs that may be displaced by diazoxide. The injection is given rapidly by the intravenous route to ensure maximal effect. The initial dose is usually 1 mg/kg of body weight, with a second dose given if the first injection does not lower blood pressure satisfactorily within 30 minutes. Further doses may be given at 4- to 24-hour intervals if needed. Oral antihypertensive therapy is begun as soon as possible.

The injection has a pH of about 11.5, which is necessary to convert the drug to its soluble sodium salt. There is no significant chemical decomposition after storage at room temperature for 2 years. When the solution is exposed to light, it darkens.

Diazoxide
(Hyperstat)

Minoxidil, USP. Minoxidil, 2,4-diamino-6-piperidinopyrimidine-3-oxide (Loniten), was developed as a result of isosteric replacement of a triaminotriazine moiety by triaminopyrimidine. The triaminotriazines were initially observed to be potent vasodilators in cats and dogs, following their formation of *N*-oxides in these animals. The triazines were inactive in humans because of their inability to form *N*-oxide metabolites; this led to the discovery of minoxidil. Minoxidil is the only direct-acting vasodilator that requires metabolic activation to produce its antihypertensive effect (Fig. 19.16). It is converted to minoxidil sulfate in the liver by a sulfotransferase enzyme.⁶⁵

The antihypertensive properties of minoxidil are similar to those of hydralazine hydrochloride, in that minoxidil can decrease arteriolar vascular resistance. Minoxidil exerts its vasodilatory action by a direct effect on arteriolar smooth muscle and appears to have no effect on the CNS or on the adrenergic nervous system in animals.⁶⁶ The serum half-life is 4.5 hours, and the antihypertensive effect may last up to 24 hours.

Minoxidil is used for severe hypertension that is difficult to control with other antihypertensive agents. The drug has

Figure 19.16 • Activation of minoxidil.

some of the characteristic side effects of direct vasodilatory drugs. It causes sodium and water retention and may require coadministration of a diuretic. Minoxidil also causes reflex tachycardia, which can be controlled by use of a β -adrenergic blocking agent.

Minoxidil topical solution is used to treat alopecia androgenetica (male-pattern baldness). Although the mechanism is not clearly understood, topical minoxidil is believed to increase cutaneous blood flow, which may stimulate hair growth. The stimulation of hair growth is attributed to vasodilation in the vicinity of application of the drug, resulting in better nourishment of the local hair follicles.

Minoxidil
(Loniten)

POSITIVE INOTROPIC AGENTS

Agents that successfully increase the force of contraction of the heart may be particularly useful in the treatment of CHF. In CHF, the heart cannot maintain sufficient blood flow to various organs to provide oxygen-rich blood. Agents that increase the force of contraction allow greater amounts of blood to be distributed throughout the body and, in turn, reduce the symptoms associated with CHF. Most of the positive inotropic agents exhibit their effects on the force of contraction by modifying the coupling mechanism involved in the myocardial contractile process.

Digitalis glycosides, a mixture of products isolated from foxglove, *Digitalis* spp., were first used as a heart medication as early as 1500 BC when in the *Ebers Papyrus*, the ancient Egyptians reported their success in using these products. Throughout history, these plant extracts have also been used as arrow poisons, emetics, and diuretics. The dichotomy of the poisonous effects and the beneficial heart properties is still evident today. Cardiac glycosides are still used today in the treatment of CHF and atrial fibrillation, with careful attention paid in monitoring the toxicity that these agents possess.

The cardiac glycosides include two distinct classes of compounds—the cardenolides and the bufadienolides. These differ in the substitutions at the C-17 position, where the cardenolides possess an unsaturated butyrolactone ring, whereas

the bufadienolides have an α -pyrone ring. Pharmacologically, both have similar properties and are found in many of the same natural sources, including plant and toad species. By far, the most important sources include *Digitalis purpurea* and *Digitalis lanata*. In 1785, William Withering published *An Account of the Foxglove and Its Medical Uses: With Practical Remarks on Dropsy and Other Diseases*, in which he describes the beneficial use of foxglove in dropsy (edema), which often exists in CHF.

Even with recent advances in synthetic organic chemistry coupled with the use of combinatorial chemistry, no new therapeutics have displaced the cardiac glycosides. Furthermore, the perennial use of these agents over many centuries is even more remarkable when one considers the useful life of a "blockbuster" drug in today's marketplace. This remarkable fact is based, quite simply, on the unique ability of nature to produce extraordinarily bioactive substances, which characteristically possess both a lipophilic portion in the steroidal ring and a hydrophilic moiety in the glycosidic rings. The therapeutic use of these agents depends largely on a balance between the different solubility characteristics of the steroid structure, and the type and number of sugar units attached to it. Although the fundamental pharmacological properties reside with the steroidal nucleus, the sugars play a critical role in the biological effects elicited, because they increase the water solubility of the lipid system, making them more available for translocation in an aqueous environment and, at the same time, allowing transportation across fatty sites. These properties uniquely balance each other and allow successful translocation to the receptive sites in the body. Ultimately, the lipophilic steroid also plays a specific role in the agent's onset and duration of action. As the steroidal rings are modified with polar groups (e.g., hydroxyls), the onset increases, and the duration of action decreases. The sugar residues are substituted on C-3 of the steroid and generally are digitoxose, glucose, rhamnose, or cymarose.

The cardiac glycosides elicit their effects through inhibition of the Na^+/K^+ -ATPase pump. Inhibition of this pump increases the intracellular Na^+ concentration, which affects $\text{Na}^+/\text{Ca}^{2+}$ exchange. This increases intracellular concentrations of Ca^{2+} , which is available to activate the contractile proteins actin and myosin, thereby enhancing the force of contraction. Also, it is suggested that these agents have other compensatory mechanisms including baroreceptor sensitivity, which result in improved conditions for patients suffering from CHF.

Digoxin. Digoxin (Lanoxin) is a purified digitalis preparation from *D. lanata* and represents the most widely used digitalis glycoside. This wide use is primarily a result of its fast onset and short half-life. Position 3 of the steroid is substituted with three digitoxose residues that, when removed, provide a genin or aglycone steroid that is still capable of receptor binding but with altered pharmacokinetics.

Digitalis. Digitalis (Crystodigin) is isolated from *D. lanata* and *D. purpurea* among other *Digitalis* spp., and is the chief active glycoside in digitalis leaf, with 1 mg digitoxin equal to 1 g of digitalis leaf therapy. In patients who miss doses, digitalis is very useful for maintenance therapy because of the longer half-life it provides. The longer duration and increased half-life are a result of the lack of the C-12 hydroxy that is present in digoxin. In digoxin, this hydroxy plays two roles: (a) it serves as a site for metabolism, which

reduces the compound's half-life; and (b) it gives more hydrophilic character, which results in greater water solubility and ease in renal elimination.

Amrinone. During normal heart function, cAMP performs important roles in regulating intracellular calcium levels. That is, certain calcium channels and storage sites for calcium must be activated by cAMP-dependant protein kinases. Because cAMP plays an indirect role in the contractility process, agents that inhibit its degradation will provide more calcium for cardiac contraction. One phosphodiesterase enzyme that is involved in the hydrolysis of myocardium cAMP is F-III. Amrinone, 5-amino (3,4'-dipyridin)-6

(*H*)-one (Inocor), possesses positive isotropic effects as a result of its ability to inhibit this phosphodiesterase. In 1999, the *USP* Nomenclature Committee and the United States Adopted Names (USAN) Council approved changing the nonproprietary name and the current official monograph title of amrinone to inamrinone. This change in nomenclature was a result of amrinone being confused with amiodarone because of the similarity of the names. This was reported to cause confusion between the products that led to medication errors, some of which resulted in serious injury or death.

Amrinone
(Inocor)

Milrinone. Milrinone, 1,6-dihydro-2-methyl-6-oxo-3,4'-bipyridine-5-carbonitrile (Primacor), is another dipyridine phosphodiesterase F-III inhibitor that possesses pharmacological properties similar to those of amrinone. The inhibition of the degradation of cAMP results in an increase in the cardiac muscle's force of contraction.

Milrinone
(Primacor)

Dopamine. Dopamine (Intropin) acts primarily on α_1 - and β_1 -adrenergic receptors, increasing systemic vascular resistance and exerting a positive inotropic effect on the heart. It must be administered by an intravenous route, because oral administration results in rapid metabolism by MAO and/or catechol-*O*-methyltransferase (COMT).

Dobutamine. Dobutamine (Dobutex) is a sympathomimetic drug that is a β_1 -adrenergic agonist with α_1 -activity. It is primarily used in cases of cardiogenic shock, which result from its β_1 -inotropic effects, which increase heart contractility and cardiac output. The drug is dispensed and administered as a racemic mixture consisting of both (+) and (-) isomers. The (+) isomer is a potent β_1 -agonist, whereas the (-) isomer is an α_1 -agonist.

ANTHYPERLIPIDEMIC AGENTS

The major cause of death in the Western world today is vascular disease, of which the most prevalent form is atherosclerotic heart disease. Although many causative factors of this disease are recognized (e.g., smoking, stress, diet),

atherosclerotic disease can be treated through medication or surgery.

Hyperlipidemia is the most prevalent indicator for susceptibility to atherosclerotic heart disease; it is a term used to describe elevated plasma levels of lipids that are usually in the form of lipoproteins. Hyperlipidemia may be caused by an underlying disease involving the liver, kidney, pancreas, or thyroid, or it may not be attributed to any recognizable disease. In recent years, lipids have been implicated in the development of atherosclerosis in humans. *Atherosclerosis* may be defined as degenerative changes in the intima of medium and large arteries. This degeneration includes the accumulation of lipids, complex carbohydrates, blood, and blood products and is accompanied by the formation of fibrous tissue and calcium deposition on the intima of the blood vessels. These deposits or *plaques* decrease the lumen of the artery, reduce its elasticity, and may create foci for thrombi and subsequent occlusion of the blood vessel.

Lipoprotein Classes

Lipoproteins are macromolecules consisting of lipid substances (cholesterol, triglycerides) noncovalently bound with protein and carbohydrate. These combinations solubilize the lipids and prevent them from forming insoluble aggregates in the plasma. They have a spherical shape and consist of a nonpolar core surrounded by a monolayer of phospholipids whose polar groups are oriented toward the lipid phase of the plasma. Included in the phospholipid monolayer are a small number of cholesterol molecules and proteins termed *apolipoproteins*. The apolipoproteins appear to be able to solubilize lipids for transport in an aqueous surrounding such as plasma (Fig. 19.17).

The various lipoproteins found in plasma can be separated by ultracentrifugal techniques into chylomicrons, very-low-density lipoprotein (VLDL), intermediate-density lipoprotein (IDL), low-density lipoprotein (LDL), and high-density lipoprotein (HDL). These correlate with the electrophoretic separations of the lipoproteins as follows: chylomicrons, pre- β -lipoprotein (VLDL), broad

Figure 19.17 • Hypothetical model of lipoprotein particle.

β -lipoprotein (IDL), β -lipoprotein (LDL), and α -lipoprotein (HDL).

Chylomicrons contain 90% triglycerides by weight and originate from exogenous fat from the diet. They are the least dense of the lipoproteins and migrate the least under the influence of an electric current. Chylomicrons are normally absent in plasma after 12 to 24 hours of fasting. The VLDL is composed of about 60% triglycerides, 12% cholesterol, and 18% phospholipids. It originates in the liver from FFAs. Although VLDL can be isolated from plasma, it is catabolized rapidly into IDL, which is degraded further into LDL. Normally, IDL also is catabolized rapidly to LDL, but it is usually not isolated from plasma. The LDL consists of 50% cholesterol and 10% triglycerides. This is the major cholesterol-carrying protein. In normal persons, this lipoprotein accounts for about 65% of the plasma cholesterol and is of major concern in hyperlipidemic disease states. The LDL is formed from the intravascular catabolism of VLDL. The HDL is composed of 25% cholesterol and 50% protein and accounts for about 17% of the total cholesterol in plasma.

Lipoprotein Metabolism

The rate at which cholesterol and triglycerides enter the circulation from the liver and small intestine depends on the supply of the lipid and proteins necessary to form the lipoprotein complexes. Although the protein component must be synthesized, the lipids can be obtained either from de novo biosynthesis in the tissues or from the diet. Reduction of plasma lipids by diet can delay the development of atherosclerosis. Furthermore, the use of drugs that decrease assimilation of lipids into the body plus diet decreases mortality from cardiovascular disease.⁶⁷

The lipid transport mechanisms that exist shuttle cholesterol and triglycerides among the liver, intestine, and other tissues. Normally, plasma lipids, including lipoprotein cholesterol, are cycled in and out of plasma and do not cause extensive accumulation of deposits in the walls of arteries. Genetic factors and changes in hormone levels affect lipid transport by altering enzyme concentrations and apoprotein content, as well as the number and activity of lipoprotein receptors. This complex relationship makes the treatment of all hyperlipoproteinemias by a singular approach difficult, if not impractical.

Lipids are transported by both *exogenous* and *endogenous* pathways. In the exogenous pathway, dietary fat (triglycerides and cholesterol) is incorporated into large lipoprotein particles (chylomicrons), which enter the lymphatic system and are then passed into the plasma. The chylomicrons are acted on by lipoprotein lipase in the adipose tissue capillaries, forming triglycerides and monoglycerides. The FFAs cross the endothelial membrane of the capillary and are incorporated into triglycerides in the tissue for storage as fat or are used for energy by oxidative metabolism. The chylomicron remnant in the capillary reaches the liver and is cleared from the circulation by binding to a receptor that recognizes the apoprotein E and B-48 protein components of the chylomicron remnant.

In the endogenous pathway of lipid transport, lipids are secreted from the liver. These are triglycerides and cholesterol combined with apoprotein B-100 and apoprotein E to form VLDL. The VLDL is acted on by lipoprotein lipase in the capillaries of adipose tissue to generate FFAs and an IDL.

Figure 19.18 • Exogenous and endogenous pathways of lipoprotein metabolism.

Some IDL binds to LDL receptors in the liver and is cleared from plasma by endocytosis. Approximately half of the circulating IDL is converted to LDL in the plasma by additional loss of triglycerides. This LDL has a half-life in plasma of about 1.5 days and represents 60% to 70% of the cholesterol in plasma. These LDL particles bind to LDL receptors in extrahepatic tissues and are removed from the plasma. Levels of LDL receptors vary depending on the need of extrahepatic tissues to bind LDL to use cholesterol. The extrahepatic tissue subsequently releases HDL. Free plasma cholesterol can be adsorbed onto HDL and the cholesterol esters formed by the enzyme lecithin-cholesterol acyltransferase (LCAT). These esters are transferred from HDL to VLDL or LDL in plasma to complete the cycle. The pathways for plasma lipoprotein metabolism by the exogenous and endogenous routes are shown in Figure 19.18.

Hyperlipoproteinemias

Lipid disorders are related to problems of lipoprotein metabolism⁶⁸ that create conditions of hyperlipoproteinemia. The hyperlipoproteinemias have been classified into six types, each of which is treated differently (Table 19.5).

The abnormal lipoprotein pattern characteristic of type I is caused by a decrease in the activity of lipoprotein lipase, an enzyme that normally hydrolyzes the triglycerides present in chylomicrons and clears the plasma of this lipoprotein fraction. Because the triglycerides found in chylomicrons come primarily from exogenous sources, this type of hyperlipoproteinemia may be treated by decreasing the intake of dietary fat. There are no drugs at present that can be used to counteract type I hyperlipidemia effectively.

Type II hyperlipoproteinemia has been divided into types IIa and IIb. Type IIa is characterized by elevated levels of LDL (β -lipoproteins) and normal levels of triglycerides. This subtype disorder is very common and may be caused by disturbed catabolism of LDL. Type IIb differs from type IIa, in that this hyperlipidemia has elevated VLDL levels in addition to LDL levels. Type II hyperlipoproteinemia is often clearly familial and frequently inherited as an autosomal dominant abnormality with complete penetrance and expression in infancy. Patients have been treated by use of dietary restrictions on cholesterol and saturated fats. This

TABLE 19.5 Characterization of Hyperlipoproteinemia Types

Hyperlipoproteinemia	Abnormality		Appearance of Plasma ^a	Total Triglycerides	Cholesterol
	Electrophoresis	Ultracentrifuge			
I	Massive chylomicronemia	Clear; creamy layer of chylomicronemia on top	Massively elevated	Slightly to moderately elevated	
IIa	β -Lipoproteins elevated	LDL increased	Clear	Normal	Heavily elevated
IIb	Pre- β -lipoproteins elevated	LDL + VLDL increased	Slightly turbid	Slightly elevated	Heavily elevated
III	Broad β -lipoprotein band	VLDL/LDL of abnormal composition	Slightly turbid to turbid	Elevated	Elevated
IV	Pre- β -lipoproteins elevated	VLDL increased	Turbid	Moderately to heavily elevated	Normal to elevated
V	Pre- β -lipoproteins elevated; chylomicronemia	VLDL increased; chylomicronemia	Turbid; on top, chylomicronemia	Massively elevated	Slightly elevated

Adapted from Witte, E. C.: Prog. Med. Chem. 11:199, 1975.

^aAfter having been kept standing at 4°C for 25 hours.

type of hyperlipoproteinemia responds to some form of chemotherapy. The combined therapy may bring LDL levels back to normal.

Type III is a rare disorder characterized by a broad band of β -lipoprotein. Like type II, it is also familial. Patients respond favorably to diet and drug therapy.

In type IV hyperlipoproteinemia, levels of VLDL are elevated. Because this type of lipoprotein is rich in triglycerides, plasma triglyceride levels are elevated. The metabolic defect that causes type IV is still unknown; this form of hyperlipidemia, however, responds to diet and drug therapy.

Type V hyperlipoproteinemia has high levels of chylomicrons and VLDL, resulting in high levels of plasma triglycerides. The biochemical defect of type V hyperlipoproteinemia is not understood. Clearance of dietary fat is impaired, and reduction of dietary fat is indicated along with drug therapy.

Clofibrate, USP. Clofibrate, ethyl 2-(*p*-chlorophenoxy)-2-methylpropionate (Atromid-S), is a stable, colorless to pale yellow liquid with a faint odor and a characteristic taste. It is soluble in organic solvents but insoluble in water.

Clofibrate is prepared by a Williamson synthesis, condensing *p*-chlorophenol with ethyl α -bromoisobutyrate, or by the interaction of a mixture of acetone, *p*-chlorophenol, and chloroform in the presence of excess potassium hydroxide. The acid obtained by either of these methods is esterified to give clofibrate. Both acid and ester are active; the latter, however, is preferred for medicinal use. Clofibrate is hydrolyzed rapidly to 2-*p*-chlorophenoxy-2-methylpropionic acid by esterases in vivo and, bound to serum albumin, circulates in blood. The acid has been investigated as a hypolipidemic agent. It is absorbed more slowly and to a smaller extent than is the ester. The aluminum salt of the acid gives even lower blood levels than *p*-chlorophenoxy-2-methylpropionic acid.⁶⁹

Clofibrate is the drug of choice in the treatment of type III hyperlipoproteinemias and may also be useful, to a lesser extent, in types IIb and IV hyperlipoproteinemias. The drug is not effective in types I and IIa.

Clofibrate can lower plasma concentrations of both triglycerides and cholesterol, but it has a more consistent clinical effect on triglycerides. It also affects lipoprotein plasma levels by enhancing removal of triglycerides from the circulation and causes reduction of VLDL by stimulating

lipoprotein lipase to increase the catabolism of this lipoprotein to LDL.⁷⁰ Clofibrate lowers triglyceride levels in the serum much more than cholesterol levels and decreases levels of FFAs and phospholipids. The lowering of cholesterol levels may result from more than one mechanism. Clofibrate inhibits the incorporation of acetate into the synthesis of cholesterol, between the acetate and mevalonate step, by inhibiting *sn*-glyceryl-3-phosphate acyltransferase. Clofibrate also regulates cholesterol synthesis in the liver by inhibiting microsomal reduction of 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA), catalyzed by HMG-CoA reductase. Clofibrate may lower plasma lipids by means other than impairment of cholesterol biosynthesis, such as increasing excretion through the biliary tract.

Clofibrate is tolerated well by most patients; the most common side effects are nausea and, to a smaller extent, other gastrointestinal distress. The dosage of anticoagulants, if used in conjunction with this drug, should be reduced by one third to one half, depending on the individual response, so that the prothrombin time may be kept within the desired limits.

Clofibrate
(Atromid)

Gemfibrozil. Gemfibrozil, 5-(2,5-dimethylphenoxy)-2,2-dimethylpentanoic acid (Lopid), is a congener of clofibrate that was used first in the treatment of hyperlipoproteinemia in the mid-1970s. Its mechanism of action and use are similar to those of clofibrate. Gemfibrozil reduces plasma levels of VLDL triglycerides and stimulates clearance of VLDL from plasma. The drug has little effect on cholesterol plasma levels but does cause an increase of HDL.

Gemfibrozil is absorbed quickly from the gut and excreted unchanged in the urine. The drug has a plasma half-life of 1.5 hours, but reduction of plasma VLDL concentration takes between 2 and 5 days to become evident. The peak effect of

its hypolipidemic action may take up to 4 weeks to become manifest.

Fenofibrate. Fenofibrate, 2-[4-(4-chlorobenzoyl)phenoxy]-2-methylpropanoic acid 1-methylethyl ester (Tricor), has structural features represented in clofibrate. The primary difference involves the second aromatic ring. This imparts a greater lipophilic character than exists in clofibrate, resulting in a much more potent hypocholesterolemic and triglyceride-lowering agent. Also, this structural modification results in a lower dose requirement than with clofibrate or gemfibrozil.

Dextrothyroxine Sodium, USP. Dextrothyroxine sodium, *O*-(4-hydroxy-3,5-diiodophenyl)-3,5-diiodo-D-tyrosine monosodium salt hydrate, sodium D-3,3',5,5'-tetraiodothyronine (Choloxin), occurs as a light yellow to buff powder. It is stable in dry air but discolors on exposure to light; hence, it should be stored in light-resistant containers. It is very slightly soluble in water, slightly soluble in alcohol, and insoluble in acetone, chloroform, and ether.

The hormones secreted by the thyroid gland have marked hypocholesterolemic activity along with their other well-known actions. The finding that not all active thyroid principles possessed the same degree of physiological actions led to a search for congeners that would cause a decrease in serum cholesterol levels without other effects such as angina pectoris, palpitation, and congestive failure. D-Thyroxine resulted from this search. At the dosage required, however, L-thyroxine contamination must be minimal; otherwise, it will exert its characteristic actions. One route to optically pure (at least 99% pure) D-thyroxine is the use of an L-amino acid oxidase from snake venom, which acts only on the L-isomer and makes separation possible.

The mechanism of action of D-thyroxine appears to be stimulation of oxidative catabolism of cholesterol in the liver through stimulation of 7- α -cholesterol hydroxylase, the rate-limiting enzyme in the conversion of cholesterol to bile acids. The bile acids are conjugated with glycine or taurine and excreted by the biliary route into the feces. Although thyroxine does not inhibit cholesterol biosynthesis, it increases the number of LDL receptors, enhancing removal of LDL from plasma.

Use of thyroxine in the treatment of hyperlipidemias is not without adverse effects. The drug increases the frequency and severity of anginal attacks and may cause cardiac arrhythmias.

D-Thyroxine potentiates the action of anticoagulants such as warfarin or dicumarol; thus, the dosage of the anticoagulants used concurrently should be reduced by one third and then, if necessary, further modified to maintain the prothrombin time within the desired limits. Also, it may increase the dosage requirements for insulin or oral hypoglycemic agents if used concurrently with them.

Cholestyramine Resin, USP. Cholestyramine (Cuemid, Questran) is the chloride form of a strongly basic anion-exchange resin. It is a styrene copolymer with divinylbenzene with quaternary ammonium functional groups. After oral ingestion, cholestyramine resin remains in the gastrointestinal tract, where it readily exchanges chloride ions for bile acids in the small intestine, to be excreted as bile salts in the feces. Cholestyramine resin is also useful in lowering plasma lipids. The reduction in the amounts of reabsorbed bile acids results in increased catabolism of cholesterol in bile acids in the liver. The decreased concentration of bile acids returning to the liver lowers the feedback inhibition by bile acids of 7- α -hydroxylase, the rate-limiting enzyme in the conversion of cholesterol to bile acids, increasing the breakdown of hepatic cholesterol. Although biosynthesis of cholesterol is increased, it appears that the rate of catabolism is greater, resulting in a net decrease in plasma cholesterol levels by affecting LDL clearance. The increase of LDL receptors in the liver that occurs when its content of cholesterol is lowered augments this biochemical event.

Cholestyramine resin does not bind with drugs that are neutral or with amine salts; acidic drugs (in the anion form) could be bound, however. For example, in animal tests, absorption of aspirin given concurrently with the resin was depressed only moderately during the first 30 minutes.

Cholestyramine resin is the drug of choice for type IIa hyperlipoproteinemia. When used in conjunction with a controlled diet, it reduces β -lipoproteins. The drug is an insoluble polymer and, thus, probably one of the safest because it is not absorbed from the gastrointestinal tract to cause systemic toxic effects.

Colestipol Hydrochloride. Colestipol (Colestid) is a high-molecular-weight, insoluble, granular copolymer of tetraethylenepentamine and epichlorohydrin. It functions as an anion-exchange, resin-sequestering agent in a manner similar to that of cholestyramine resin. Colestipol hydrochloride reduces cholesterol levels without affecting triglycerides and seems to be especially effective in the treatment of type II hyperlipoproteinemias.

Colestipol
(Colestid)

Colesevelam. Colesevelam (Welchol) is one of the more recent additions to the class of bile acid-sequestering agents. Its structure is rather novel, and at first glance, it appears to look like the previous examples of cholestyramine and colestipol. It does not possess the chloride ions, however, and, strictly speaking, is not an anion-exchange resin. This compound has good selectivity for both the trihydroxy and dihydroxy bile acids. The selectivity for these hydroxylated derivatives lends some insight into the reduced side effects colesevelam possesses, compared with cholestyramine and colestipol. Unlike the older agents, colesevelam does not have a high incidence of causing constipation. This results from the compound's ability to "pick up" water as a result of its affinity for hydroxyl system (i.e., hydrogen bonding with either the bile acid or water). In turn, this yields softer, gel-like materials that are easier to excrete.

Colesevelam
(Welchol)

Nicotinic Acid. Nicotinic acid, 3-pyridinecarboxylic acid (Niacin), is effective in the treatment of all types of hyperlipoproteinemia except type I, at doses above those given as a vitamin supplement. The drug reduces VLDL synthesis and, subsequently, its plasma products, IDL and LDL. Plasma triglyceride levels are reduced because of the decreased VLDL production. Cholesterol levels are lowered, in turn, because of the decreased rate of LDL formation from VLDL. Although niacin is the drug of choice for type II hyperlipoproteinemias, its use is limited because of the vasodilating side effects. Flushing occurs in practically all patients but generally subsides when the drug is discontinued.

The hypolipidemic effects of niacin may be caused by its ability to inhibit lipolysis (i.e., prevent the release of FFAs and glycerol from fatty tissues). Therefore, there is a reduced reserve of FFA in the liver and diminution of lipoprotein biosynthesis, which reduces the production of VLDL. The decreased formation of lipoproteins leads to a pool of unused cholesterol normally incorporated in VLDL. This excess cholesterol is then excreted through the biliary tract.

Niacin (nicotinic acid) may be administered as aluminum nicotinate (Nicalax). This is a complex of aluminum hydroxy nicotinate and niacin. The aluminum salt is hydrolyzed to aluminum hydroxide and niacin in the stomach. The aluminum salt seems to have no advantage over the free acid. Hepatic reaction appears more prevalent than with niacin.

Nicotinic acid has been esterified to prolong its hypolipidemic effect. Pentaerythritol tetranicotinate has been more effective experimentally than niacin in reducing cholesterol levels in rabbits. Sorbitol and *myo*-inositol hexanicotinate polyesters have been used in the treatment of patients with atherosclerosis obliterans.

The usual maintenance dose of niacin is 3 to 6 g/day given in three divided doses. The drug is usually given at mealtimes to reduce the gastric irritation that often accompanies large doses.

Nicotinic Acid
(Niacin)

β -Sitosterol. Sitosterol is a plant sterol, whose structure is identical with that of cholesterol, except for the substituted ethyl group on C-24 of its side chain. Although the mechanism of its hypolipidemic effect is not clearly understood, it is suspected that the drug inhibits the absorption of dietary cholesterol from the gastrointestinal tract. Sitosterols are absorbed poorly from the mucosal lining and appear to compete with cholesterol for absorption sites in the intestine.

Probucol, USP. Probucol, 4,4'-[(1-methylethylidene)bis(thio)]bis[2,6-bis(1,1-dimethylethyl)phenol], DH-581 (Lorelco), is a chemical agent that was developed for the plastics and rubber industry in the 1960s. The probucol molecule has two tertiary butylphenol groups linked by a dithiopropylidene bridge, giving it a high lipophilic character with strong antioxidant properties. In humans, it causes reduction of both liver and serum cholesterol levels, but it does not alter plasma triglycerides. It reduces LDL and (to a lesser extent) HDL levels by a unique mechanism that is still not clearly delineated. The reduction of HDL may be caused by the ability of probucol to inhibit the synthesis of apoprotein A-1, a major protein component of HDL.⁷¹ It is effective at reducing levels of LDL and is used in hyperlipoproteinemias characterized by elevated LDL levels.

Ezetimibe. Ezetimibe, (3*R*,4*S*)-1-(4-fluorophenyl)-3-((3*S*)-3-(4-fluorophenyl)-3-hydroxypropyl)-4-(4-hydroxyphenyl)-2-azetidinone (Zetia), is an antihyperlipidemic agent that has usefulness in lowering cholesterol levels. It acts by decreasing cholesterol absorption in the intestine by blocking the absorption of the sterol at the Brush boarder. Specifically, the β -lactam binds to the Niemann-Pick C1-Like 1 (NPC1L1) protein on the gastrointestinal tract that is

responsible for cholesterol absorption. Although it may be used alone, it is marketed as a combination product with simvastatin under the trade name Vytorin.⁷²

HMG-CoA Reductase Inhibitors

Drugs in this class of hypolipidemic agents inhibit the enzyme HMG-CoA reductase, responsible for the conversion of HMG-CoA to mevalonate in the synthetic pathway for the synthesis of cholesterol (Fig. 19.19). HMG-CoA reductase is the rate-limiting catalyst for the irreversible conversion of HMG-CoA to mevalonic acid in the synthesis of cholesterol. The activity of HMG-CoA reductase is also under feedback regulation. When cholesterol is available in sufficient amounts for body needs, the enzyme activity of HMG-CoA reductase is suppressed.

Elevated plasma cholesterol levels have been correlated with an increase in cardiovascular disease. Of the plasma lipoproteins, the LDL fraction contains the most cholesterol. The source of cholesterol in humans is either the diet or the de novo synthesis with the reduction of HMG-CoA by HMG-CoA reductase as the rate-limiting step. Ingested cholesterol as the free alcohol or ester is taken up after intestinal absorption and transported to the liver and other body organs through the exogenous pathway (Fig. 19.19). The LDL delivers cholesterol to peripheral cells. This process occurs after binding of LDL to specific LDL receptors located on the surface of cell membranes. After binding and endocytosis of the receptor and LDL, lysosomal degradation of this complex in the cell makes cholesterol available for use in cellular membrane synthesis. It is generally accepted that total plasma cholesterol is lowered most effectively by reducing LDL levels. Therefore, the population of LDL receptors is an important component of clearing the plasma of cholesterol. HMG-CoA reductase inhibitors contribute to this by directly blocking the active site of the enzyme. This action has a twofold effect on cholesterol plasma levels; it causes a decrease in de novo cholesterol synthesis and an increase in hepatic LDL receptors. These HMG-CoA reduc-

Figure 19.19 • HMG-CoA reductase reaction.

tase inhibitors are effective hypocholesteremic agents in patients with familial hypercholesteremia.

Three drugs, lovastatin, simvastatin, and pravastatin, compose the list of approved HMG-CoA reductase inhibitors for the treatment of hyperlipidemia in patients. The three drugs have structures similar to the substrate, HMG-CoA, of the enzyme HMG-CoA reductase. Lovastatin and simvastatin are lactones and prodrugs, activated by hydrolysis in the liver to their respective β -hydroxy acids. Pravastatin, in contrast, is administered as the sodium salt of the β -hydroxy acid.

Lovastatin. Lovastatin, 2-methylbutanoic acid 1,2,3,7,8,8a-hexahydro-3,7-dimethyl-8-[2-(tetrahydro-4-hydroxy-6-oxo-2H-pyran-2-yl)ethyl]-1-naphthalenyl ester, mevinolin, MK-803 (Mevacor) (formerly called mevinolin), is a potent inhibitor of HMG-CoA. The drug was obtained originally from the fermentation products of the fungi *Aspergillus terreus* and *Monascus ruber*. Lovastatin was one of two original HMG-CoA reductase inhibitors. The other drug, mevastatin (formerly called compactin), was isolated from cultures of *Penicillium cillium citrum*. Mevastatin was withdrawn from clinical trials because it altered intestinal morphology in dogs. This effect was not observed with lovastatin. For inhibitory effects on HMG-CoA reductase, the lactone ring must be hydrolyzed to the open-ring heptanoic acid.

Simvastatin. Simvastatin, 2,2-dimethyl butanoic acid, 1,2,3,7,8,8a-hexahydro-3,7-dimethyl-8-[2-(tetrahydro-4-hydroxy-6-oxo-2-pyran-2-yl)ethyl]-1-naphthalenyl ester (Zocor), is an analog of lovastatin. These two drugs have many similar properties. Both drugs, in the prodrug form, reach the liver unchanged after oral administration, where they undergo extensive metabolism to several open-ring hydroxy acids, including the active β -hydroxy acids. They are also highly bound to plasma proteins. These actions make the bioavailability of simvastatin rather poor but better than that of lovastatin, which has been estimated to be 5%.

Pravastatin. Pravastatin, sodium 1,2,6,7,8,8a-hexahydro- β , δ ,6-trihydroxy-2-methyl-8-(2-methyl-1-oxobutoxy)-1-naphthaleneheptanoate (Pravachol), is the most rapid acting of the three HMG-CoA reductase inhibitor drugs, reaching a peak concentration in about 1 hour. The sodium salt of the β -hydroxy acid is more hydrophilic than the lactone forms of the other two agents, which may explain this property. In addition, the open form of the lactone ring contributes to a more hydrophilic agent, which, in turn, results in less CNS penetration. This explains, in part, why pravastatin has fewer CNS side effects than the more lipophilic lactone ester of this class of agents. Absorption of pravastatin following oral administration can be inhibited by resins such as cholestyramine because of the presence of the carboxylic acid function on the drug. The lactone forms of lovastatin and simvastatin are less affected by cholestyramine.

Fluvastatin. Fluvastatin, [R^* , S^* -(E)]-(\pm)-7-[3-(4-fluorophenyl)-1-(1-methylethyl)-1H-indol-2-yl]-3,5-dihydroxy-6-heptenoic acid monosodium salt (Lescol), is very similar to pravastatin. It possesses a heptanoic acid side chain that is superimposable over the lactone ring found in lovastatin and simvastatin. This side chain is recognized by HMG-CoA reductase. Also, much like pravastatin, the CNS side effects of this lipid-lowering agent are much lower than those of the agents that possess a lactone ring as part of their architectural design.

Atorvastatin. Atorvastatin, [R -(R^* , R^*)]-2-(4-fluorophenyl)-b,d-dihydroxy-5-(1-methylethyl)-3-phenyl-4-[(phenylamino)carbonyl]-1H-pyrrole-1-heptanoic acid (Lipitor), also possesses the heptanoic acid side chain, which is critical for inhibition of HMG-CoA reductase. Although the side chain is less lipophilic than the lactone form, the high amount of lipophilic substitution causes this

agent to have a slightly higher level of CNS penetration than pravastatin, resulting in a slight increase in CNS side effects. Even so, its CNS profile is much lower than that of lovastatin. Atorvastatin is marketed as a combination therapy with amlodipine under the trade name Norvasc for management of high cholesterol and high blood pressure.

Rosuvastatin. Rosuvastatin, 7-[4-(4-fluorophenyl)-6-(1-methylethyl)-2-(methyl-methylsulfonyl-amino)-pyrimidin-5-yl]-3,5-dihydroxy-hept-6-enoic acid (Crestor), is one of the more recently introduced statins in the United States. As with all statins, there is a concern of rhabdomyolysis and as such, the FDA has mandated that a warning about this side effect, as well as a kidney toxicity warning, be added to the product label (http://www.fda.gov/CDER/Drug/advisory/crestor_3_2005.htm). This should not come as a surprise because of the relationship in the chemical architecture to cerivastatin, which was withdrawn from the market as a result of its adverse side effects.

Cerivastatin. Cerivastatin (Baycol) is one of the newer agents in this class of cholesterol-lowering agents. However, it carries a higher incidence of rhabdomyolysis and, as a result, was voluntarily withdrawn from the market by its manufacturer in 2001.

ANTICOAGULANTS

A theory of blood clotting introduced in 1905 was based on the existence of four factors: thromboplastin (thrombokinase), prothrombin, fibrinogen, and ionized calcium. The clotting sequence proposed was that when tissue damage occurred, thromboplastin entered the blood from the platelets and reacted with prothrombin in the presence of calcium to form thrombin. Thrombin then reacted with fibrinogen to form insoluble fibrin, which enmeshed red blood cells (RBCs) to create a clot. The concept remained unchallenged for almost 50 years, but it has now been modified to accommodate the discovery of numerous additional factors that enter into the clotting mechanism (Table 19.6).

Mechanism of Blood Coagulation

The fluid nature of blood can be attributed to the flat cells (endothelial) that maintain a nonthrombogenic environment in the blood vessels. This is a result of at least four phenomena: (a) the maintenance of a transmural negative electric charge that prevents adhesion between platelets; (b) the release of a plasminogen activator, which activates the fibrinolytic pathway; (c) the release of thrombomodulin, a cofactor that activates protein C, a coagulation factor inhibitor; and (d) the release of PGI₂, a potent inhibitor of platelet aggregation.

The process of blood coagulation (Fig. 19.20) involves a series of steps that occur in a cascade and terminate in the formation of a fibrin clot. Blood coagulation occurs by activation of either an intrinsic pathway, a relatively slow process of clot formation, or an extrinsic pathway, which has a much faster rate of fibrin formation. Both pathways merge into a common pathway for the conversion of prothrombin to thrombin and subsequent transformation of fibrinogen to the insoluble strands of fibrin. Lysis of intravascular clots occurs through a plasminogen-plasmin system, which consists of plasminogen, plasmin, urokinase, kallikrein, plasminogen activators, and some undefined inhibitors.

The *intrinsic* pathway refers to the system for coagulation that occurs from the interaction of factors circulating in the

TABLE 19.6 Roman Numerical Nomenclature of Blood-Clotting Factors and Some Common Synonyms

Factor	Synonyms
I	Fibrinogen
II	Prothrombin
III	Thromboplastin, tissue factor
IV	Calcium
V	Proaccelerin, accelerator globulin, labile factor
VI	(This number is not used now)
VII	Proconvertin, stable factor, autoprothrombin I, SPCA
VIII	Antihemophilic factor, antihemophilic globulin, platelet cofactor I, antihemophilic factor A
IX	Plasma thromboplastin component (PTC), Christmas factor, platelet cofactor II, autoprothrombin II, antihemophilic factor B
X	Stuart-Power factor, Stuart factor, autoprothrombin III
XI	Plasma thromboplastin antecedent (PTA), antihemophilic factor C
XII	Hageman factor
XIII	Fibrin-stabilizing factor, fibrinase, Laki-Lorand factor

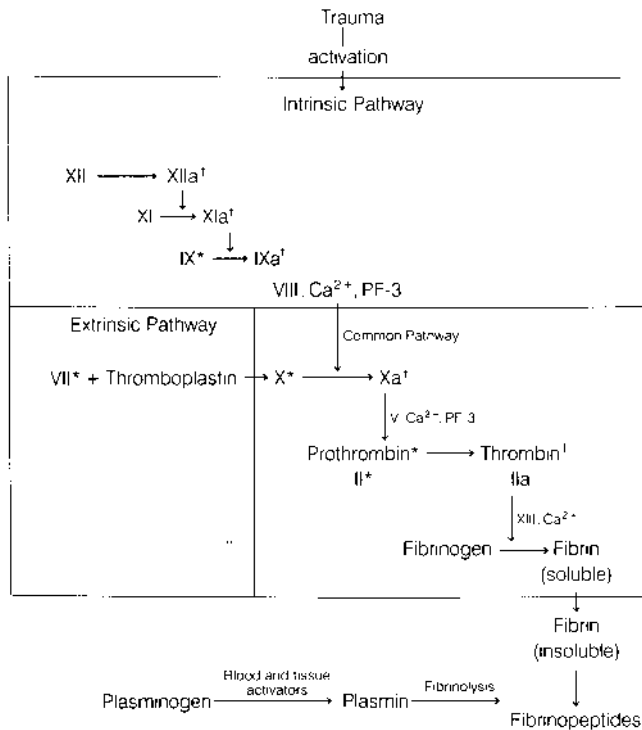

Figure 19.20 • Scheme of blood coagulation and fibrinolysis. (*, a vitamin K–dependent factor; †, inhibition by heparin and antithrombin III.)

blood. It is activated when blood comes into contact with a damaged vessel wall or a foreign substance. Each of the plasma coagulation factors (Table 19.6), with the exception of factor III (tissue thromboplastin), circulates as an inactive proenzyme. Except for fibrinogen, which precipitates as fibrin, these factors are usually activated by enzymatic removal of a small peptide in the cascade of reactions that make up the clotting sequence (Fig. 19.20). The *extrinsic* clotting system refers to the mechanism by which thrombin is generated in plasma after the addition of tissue extracts. When various tissues, such as brain or lung (containing thromboplastin), are added to blood, a complex between thromboplastin and factor VII in the presence of calcium ions activates factor X, bypassing the time-consuming steps of the intrinsic pathway that form factor X.

The intrinsic and extrinsic pathways interact *in vivo*. Small amounts of thrombin formed early after stimulation of the extrinsic pathway accelerate clotting by the intrinsic pathway by activating factor VIII. Thrombin also speeds up the clotting rate by activating factor V, located in the common pathway. Thrombin then converts the soluble protein fibrinogen into a soluble fibrin gel by acting on Gly–Arg bonds to remove small fibrinopeptides from the N-terminus, enabling the remaining fibrinogen molecule to polymerize. It also activates factor XIII, which stabilizes the fibrin gel in the presence of calcium by cross-linking between the chains of the fibrin monomer through intermolecular γ -glutamyl–lysine bridges to form an insoluble mass.

Anticoagulant Mechanisms

In the milieu of biochemicals being formed to facilitate the clotting of blood, the coagulation cascade *in vivo* is controlled by a balance of inhibitors in the plasma to prevent all of the

blood in the body from solidifying. Thrombin plays a pivotal role in blood coagulation. It cleaves fibrinogen, a reaction that initiates formation of the fibrin gel, which constitutes the framework of the blood clot. As mentioned previously, it activates the cofactors factor V and factor VIII to accelerate the coagulation process. Intact endothelial cells express a receptor, thrombomodulin, for thrombin. When thrombin is bound to thrombomodulin, it does not have coagulant activity, which thus prevents clot formation beyond damaged areas and onto intact endothelium. In this bound state, however, thrombin does activate protein C, which then inactivates two cofactors and impedes blood clotting. Thrombin also activates factor XIII, leading to cross-linking of the fibrin gel. The activity of thrombin is regulated by its inactivation by plasma protein inhibitors: α_1 -proteinase inhibitor, α_2 -macroglobulin, antithrombin (antithrombin III), and heparin cofactor II. These belong to a family of proteins called *serpins*, an acronym for *serine protease inhibitors*.

Antithrombin III, an α_2 -globin, neutralizes thrombin and the serine proteases in the coagulation cascade—Xa, IXa, XIa, and XIIa. Although antithrombin III is a slow-acting inhibitor, it becomes a rapid-acting inhibitor of thrombin in the presence of heparin. Heparin is a naturally occurring anticoagulant that requires antithrombin III (discussed previously) for its biological property of preventing blood clot formation. It binds at the lysine site of the antithrombin III molecule, causing a change in the conformation of antithrombin III and increasing its anticoagulant properties. Heparin can then dissociate from antithrombin III to bind to another antithrombin III molecule. An additional system, which controls unwanted coagulation, involves protein C, a vitamin K–dependent zymogen in the plasma. Protein C is converted to a serine protease when thrombin and factor Xa, formed in the blood in the coagulation cascade, interact with thrombomodulin. The now-activated protein C inhibits factors V and VIII and, in so doing, blocks further production of thrombin. Protein C also enhances fibrinolysis by causing release of the tissue plasminogen activator.

The biosynthesis of prothrombin (factor II) depends on an adequate supply of vitamin K. A deficiency of vitamin K results in the formation of a defective prothrombin molecule. The defective prothrombin is antigenically similar to normal prothrombin but has reduced calcium-binding ability and no biological activity. In the presence of calcium ions, normal prothrombin adheres to the surface of phospholipid vesicles and greatly increases the activity of the clotting mechanism. The defect in the abnormal prothrombin is in the NH₂-terminal portion, in which the second carboxyl residue has not been added to the γ -carbon atom of some glutamic acid residues on the prothrombin molecule to form γ -carboxyglutamic acid.⁷³ Administration of vitamin K antagonists decreases synthesis of a biologically active prothrombin molecule and increases the clotting time of blood in humans.⁷⁴

Vitamin K is critical to the formation of clotting factors VII, IX, and X. These factors are glycoproteins that have γ -carboxyglutamic acid residues at the N-terminal end of the peptide chain. The enzyme involved in forming an active prothrombin is a vitamin K–dependent carboxylase located in the microsomal fraction of liver cells. It has been suggested that vitamin K drives the carboxylase reaction by abstracting a proton from the relatively unreactive methylene carbon of the glutamyl residue, forming a 2,3-epoxide. Oral

Figure 19.21 • Mechanism of action of vitamin K and sites of action of warfarin.

anticoagulants interfere with the γ -carboxylation of glutamic acid residues by preventing the reduction of vitamin K to its hydroquinone form (Fig. 19.21).

Hemophilia A, a blood disease characterized by a deficiency of coagulation factor VIII, is the most common inherited blood coagulation disorder. Treatment of this disease over the past 25 years has depended on the concentration of the antihemophilic factor (factor VIII) by cryoprecipitation and immunoaffinity chromatography separation technology. The impact of this therapy has been diminished by the presence of viruses that cause the acquired immunodeficiency syndrome (AIDS) and other less tragic viral diseases in humans. Recombinant antihemophilic factor preparations have been produced since 1989 with use of mammalian cells genetically altered to secrete human factor VIII. Kogenate and Helixate are recombinant preparations, obtained from genetically altering baby hamster kidney cells that contain high concentrations of factor VIII. Recombinant factor VIIa, an active factor in the extrinsic pathway, now in phase III clinical trials (Novo Seven), has been used to treat patients with hemophilia A factor VII deficiency. Hemophilia B, another genetic blood disorder, which constitutes about 20% of hemophilia cases, is caused by a deficiency of factor IX and has been treated from cryoprecipitated fractions obtained from plasma. Monoclonal antibody technology has produced an essentially pure, carrier-free preparation of native factor IX (Mononine). Recombinant technology has solved the problem of limited supply and viral contamination of these critical blood factors.

Blood Degredation

Some patients suffer from a rare, potentially life-threatening disease of the blood characterized by hemolytic anemia and

thrombosis, which is known as paroxysmal nocturnal hemoglobinuria (PNH). One symptom of the disease includes red urine, which results from the breakdown of RBC products (hemoglobin and hemosiderin) in the urine. An inconsistent, but potentially life-threatening, complication of PNH is the development of venous thrombosis.

Platelet Aggregation and Inhibitors

Blood platelets play a pivotal role in hemostasis and thrombus formation. Actually, they have two roles in the cessation of bleeding: a hemostatic function, in which platelets, through their mass, cause physical occlusion of openings in blood vessels, and a thromboplastic function, in which the chemical constituents of the platelets take part in the blood coagulation mechanism. The circulatory system is self-sealing because of the clotting properties of blood. The pathological formation of clots within the circulatory system, however, creates a potentially serious clinical situation that must be dealt with through the use of anticoagulants.

Platelets do not adhere to intact endothelial cells. They do become affixed to subendothelial tissues, which have been exposed by injury, to cause hemostasis. Platelets bind to collagen in the vessel wall and trigger other platelets to adhere to them. This adhesiveness is accompanied by a change in shape of the platelets and may be caused by mobilization of calcium bound to the platelet membrane. The growth of the platelet mass depends on the ADP released by the first few adhering cells and enhances the aggregation process. A secondary phase (phase II) immediately follows, with additional platelet aggregation. In this secondary phase, the platelets undergo a secretory process during which enzymes such as cathepsin and acid hydrolases, along with fibrinogen, are

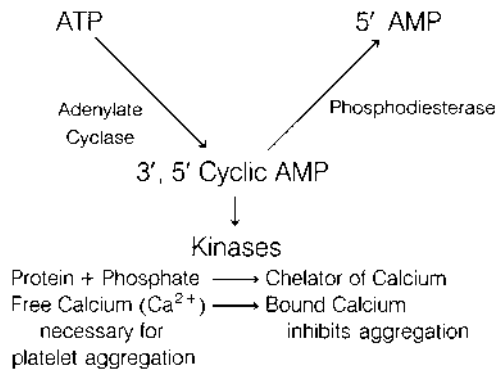

Figure 19.22 • Role of adenosine 3',5'-cyclic monophosphate (cAMP) in inhibition of platelet aggregation.

released from α -granules in the platelets and ADP, ATP, serotonin, and calcium are released from dense bodies in the platelets. The dense bodies are likened to the storage granules associated with adrenergic neurons. Increased levels of cAMP inhibit platelet aggregation. cAMP activates specific dependent kinases, which form protein–phosphate complexes that chelate calcium ions. The reduced levels of calcium inhibit aggregation (Fig. 19.22). Inhibitors of platelet aggregation can increase cAMP levels by either stimulating adenylate cyclase or inhibiting phosphodiesterase.⁷⁴ Substances such as glucagon, adenosine, and isoproterenol increase cAMP levels and inhibit platelet aggregation. Drugs such as theophylline, aminophylline, dipyridamole, papaverine, and adenosine inhibit phosphodiesterase and aggregation of platelets. Epinephrine, collagen, and serotonin inhibit adenylate cyclase and stimulate platelet aggregation.⁷⁵ The role of platelets in arterial thrombosis is similar to that in hemostasis. The factors contributing to venous thrombosis are circulatory stasis, excessive generation of thrombin formation of fibrin, and, to a lesser extent than in the artery, platelet aggregation.

Aspirin, sulfinpyrazone, and indomethacin have an inhibitory effect on platelet aggregation. They inhibit COX, the enzyme that controls the formation of prostaglandin endoperoxides and increases the tendency for platelets to aggregate.⁷⁶ Aspirin also inhibits the platelet-release reaction. Dipyridamole inhibits adenosine deaminase and adenosine uptake by platelets. As a result, the increased plasma concentrations of adenosine inhibit ADP-induced aggregation of platelets.

Among the many pharmacological actions of prostaglandins is the ability of some to stimulate or inhibit the aggregation of platelets and alter the clotting time of blood. Prostaglandins are synthesized from 20-carbon polyunsaturated fatty acids containing from three to five double bonds. These fatty acids are present in the phospholipids of cell membranes of all mammalian tissues. The main precursor of prostaglandins is arachidonic acid. Arachidonic acid is released from membrane phospholipids by the enzyme phospholipase A₂. Once released, arachidonic acid is metabolized by COX synthetase to form unstable cyclic endoperoxides, PGG₂ and PGH₂, which subsequently are transformed into PGI₂ and TXA₂. The conversion to TXA₂ is aided by the enzyme thromboxane synthetase. The formation of PGI₂ can occur nonenzymatically. Blood platelets convert arachidonic acid to TXA₂, whereas PGI₂ is formed mainly by the vascular endothelium. Both PGI₂ and TXA₂

are unstable at physiological pH and temperatures. Their half-lives are 2 to 3 minutes.

PGI₂ inhibits platelet aggregation by stimulating adenylate cyclase to increase cAMP levels in the platelets. PGI₂ is also a vasodilator and, as a result, has potent hypotensive properties when given intravenously or by intra-arterial administration. TXA₂ induces platelet aggregation. Together with PGI₂, TXA₂ plays a role in the maintenance of vascular homeostasis. In addition to being a platelet aggregator, TXA₂ is a potent vasoconstrictor.

Retardation of clotting is important in blood transfusions, to avoid thrombosis after surgery or from other causes, to prevent recurrent thrombosis in phlebitis and pulmonary embolism, and to lessen the propagation of clots in the coronary arteries. This retardation may be accomplished by agents that inactivate thrombin (heparin) or substances that prevent the formation of prothrombin in the liver (the coumarin derivatives and the phenylindanedione derivatives).

Although heparin is a useful anticoagulant, it has limited applications. Many of the anticoagulants in use today were developed following the discovery of dicumarol, an anticoagulant present in spoiled sweet clover. These compounds are orally effective, but there is a lag period of 18 to 36 hours before they increase the clotting time significantly. Heparin, in contrast, produces an immediate anticoagulant effect after intravenous injection. A major disadvantage of heparin is that the only effective therapeutic route is parenteral.

Dicumarol and related compounds are not vitamin K antagonists in the classic sense. They appear to act by interfering with the function of vitamin K in the liver cells, which are the sites of synthesis of the clotting factors, including prothrombin. This lengthens the clotting time by decreasing the amount of biologically active prothrombin in the blood.

The discovery that dicumarol and related compounds were potent reversible competitors of vitamin K coagulant-promoting properties (although at high levels, dicumarol is not reversed by vitamin K) led to the development of antivitamin K compounds such as phenindione, which was designed in part according to metabolite–antimetabolite concepts. The active compounds of the phenylindanedione series are characterized by a phenyl, a substituted phenyl, or a diphenylacetyl group in the 2-position. Another requirement for activity is a keto group in the 1- and 3-position, one of which may form the enol tautomer. A second substituent, other than hydrogen, at the 2-position prevents this keto–enol tautomerism, and the resulting compounds are ineffective as anticoagulants.

PRODUCTS

Protamine Sulfate, USP. Protamine sulfate has an anticoagulant effect, but if used in the proper amount, it counteracts the action of heparin and is used as an antidote for the latter in cases of overdose. It is administered intravenously in a dose that depends on the circumstances.

Dicumarol, USP. Dicumarol, 3,3'-methylenebis[4-hydroxycoumarin], is a white or creamy white crystalline powder with a faint, pleasant odor and a slightly bitter taste. It is practically insoluble in water or alcohol, slightly soluble in chloroform, and dissolved readily by solutions of fixed alkalis. The effects after administration require 12 to 72 hours to develop and persist for 24 to 96 hours after discontinuance.

Dicumarol

Dicumarol is used alone or as an adjunct to heparin in the prophylaxis and treatment of intravascular clotting. It is used in postoperative thrombophlebitis, pulmonary embolus, acute embolic and thrombotic occlusion of peripheral arteries, and recurrent idiopathic thrombophlebitis. It has no effect on an already-formed embolus but may prevent further intravascular clotting. Because the outcome of acute coronary thrombosis depends largely on extension of the clot and formation of mural thrombi in the heart chambers, with subsequent embolization, dicumarol has been used in this condition. It has also been administered to arrest impending gangrene after frostbite. The dose, after determination of the prothrombin clotting time, is 25 to 200 mg, depending on the size and the condition of the patient. The drug is given orally in the form of capsules or tablets. On the second day and thereafter, it may be given in amounts sufficient to maintain the prothrombin clotting time at about 30 seconds. If hemorrhages should occur, a dosage of 50 to 100 mg of menadione sodium bisulfite is injected, supplemented by a blood transfusion.

Warfarin Sodium, USP. Warfarin sodium, 3-(α -acetylbenzyl)-4-hydroxycoumarin sodium salt (Coumadin, Panwarfin), is a white, odorless, crystalline powder, with a slightly bitter taste; it is slightly soluble in chloroform and soluble in alcohol or water. A 1% solution has a pH of 7.2 to 8.5.

By virtue of its great potency, warfarin sodium at first was considered unsafe for use in humans and was used very effectively as a rodenticide, especially against rats. At the proper dosage level, however, it can be used in humans, especially through the intravenous route.

Warfarin Sodium
(Coumadin)

Warfarin Potassium, USP. Warfarin potassium, 3-(α -acetylbenzyl)-4-hydroxycoumarin potassium salt (Athrombin-K), is readily absorbed after oral administration, and a therapeutic hypoprothrombinemia is produced within 12 to 24 hours after administration of 40 to 60 mg. This salt is therapeutically interchangeable with warfarin sodium.

Pentamidine

Anisindione, USP. Anisindione, 2-(*p*-methoxyphenyl)-1,3-indandione, 2-(*p*-anisyl)-1,3-indandione (Miradon), is a *p*-methoxy congener of phenindione. It is a white, crystalline powder, slightly soluble in water, tasteless, and absorbed well after oral administration.

In instances when the urine may be alkaline, an orange color may be detected. This is caused by metabolic products of anisindione and is not hematuria.

Anisindione
(Miradon)

Eculizumab. Eculizumab (Soliris) is a monoclonal antibody that binds to the terminal complement protein C5 in RBCs. This blocks the cleavage of C5 and halts the process of complement-mediated cell destruction of the RBCs. Eculizumab has been shown to be effective in treating PNH and in March 2007 was approved by the FDA for treating PNH.⁷⁷

SYNTHETIC HYPOGLYCEMIC AGENTS

The discovery that certain organic compounds will lower the blood sugar level is not recent. In 1918, guanidine was shown to lower the blood sugar level. The discovery that certain trypanosomes need much glucose and will die in its absence was followed by the discovery that galegine lowered the blood sugar level and was weakly trypanocidal. This led to the development of several very active trypanocidal agents, such as the bisamidines, diisothioureas, bisguanidines, and others. Synthalin (trypanocidal at 1:250 million) and pentamidine are outstanding examples of very active trypanocidal agents. Synthalin lowers the blood sugar level in normal, depancreatized, and completely alloxanized animals. This may be caused by reduced oxidative activity of mitochondria, resulting from inhibition of the mechanisms that simultaneously promote phosphorylation of ADP and stimulate oxidation by nicotinamide adenine dinucleotide (NAD) in the citric acid cycle. Hydroxystilbamidine isethionate, *USP*, is used as an antiprotozoan agent.

Galegine

Synthalin

In 1942, *p*-aminobenzenesulfonamidoisopropylthiadiazole (an antibacterial sulfonamide) was found to produce hypoglycemia. This result stimulated research for the development of synthetic hypoglycemic agents, several of which are in use today.

Sulfonylureas became widely available in 1955 for the treatment of non-ketosis-prone mild diabetes and are still the drugs of choice. A second class of compounds, the biguanides, in the form of a single drug, phenformin, has been used since 1957. Phenformin was withdrawn from the U.S. market, however, because it causes lactic acidosis, from which fatalities have been reported.

Phenformin

Sulfonylureas

The sulfonylureas may be represented by the following general structure:

These are urea derivatives with an arylsulfonyl group in the 1-position and an aliphatic group at the 3-position. The aliphatic group, R', confers lipophilic properties to the molecule. Maximal activity results when R' consists of three to six carbon atoms, as in chlorpropamide, tolbutamide, and acetohexamide. Aryl groups at R' generally give toxic compounds. The R group on the aromatic ring primarily influences the duration of action of the compound. Tolbutamide disappears quite rapidly from the bloodstream by being metabolized to the inactive carboxy compound, which is excreted rapidly. Chlorpropamide, however, is metabolized more slowly and persists in the blood much longer.

The mechanism of action of the sulfonylureas is to stimulate the release of insulin from the functioning β -cells of the intact pancreas. In the absence of the pancreas, they have no significant effect on blood glucose. The sulfonylureas may have other actions, such as inhibition of secretion of glucagon and action at postreceptor intracellular sites to increase insulin activity.

For a time, tolbutamide, chlorpropamide, and acetohexamide were the only oral hypoglycemic agents. Subsequently, a second generation of these drugs became available. Although they did not present a new method of lowering blood glucose levels, they were more potent than the existing drugs. Glipizide and glyburide are the second-generation oral hypoglycemic agents.

Whether they are first- or second-generation oral hypoglycemic drugs, this group of agents remains a valuable ad-

junct to therapy in adult-onset diabetes patients. Accordingly, the sulfonylureas are not indicated in juvenile-onset diabetes.

Tolbutamide, USP. Tolbutamide, 1-butyl-3-(*p*-tolylsulfonyl)urea (Orinase), occurs as a white, crystalline powder that is insoluble in water and soluble in alcohol or aqueous alkali. It is stable in air.

Tolbutamide
(Orinase)

Tolbutamide is absorbed rapidly in responsive diabetic patients. The blood sugar level reaches a minimum after 5 to 8 hours. It is oxidized rapidly *in vivo* to 1-butyl-3-(*p*-carboxyphenyl)sulfonylurea, which is inactive. The metabolite is freely soluble at urinary pH; if the urine is strongly acidified, however, as in the use of sulfosalicylic acid as a protein precipitant, a white precipitate of the free acid may be formed.

Tolbutamide should be used only when the diabetic patient is an adult or shows adult-onset diabetes, and the patient should adhere to dietary restrictions.

Tolbutamide Sodium, USP. Tolbutamide sodium, 1-butyl-3-(*p*-tolylsulfonyl)urea monosodium salt (Orinase Diagnostic), is a white, crystalline powder, freely soluble in water, soluble in alcohol and chloroform, and very slightly soluble in ether.

This water-soluble salt of tolbutamide is used intravenously for the diagnosis of mild diabetes mellitus and of functioning pancreatic islet cell adenomas. The sterile dry powder is dissolved in sterile water for injection to make a clear solution, which then should be administered within 1 hour. The main route of breakdown is to butylamine and sodium *p*-toluene sulfonamide.

Tolbutamide Sodium

Chlorpropamide, USP. Chlorpropamide, 1-[(*p*-chlorophenyl)-sulfonyl]-3-propylurea (Diabinese), is a white, crys-

talline powder, practically insoluble in water, soluble in alcohol, and sparingly soluble in chloroform. It will form water-soluble salts in basic solutions. This drug is more resistant to conversion to inactive metabolites than is tolbutamide and, as a result, has a much longer duration of action. One study showed that about half of the drug is excreted as metabolites, with the principal one being hydroxylated in the 2-position of the propyl side chain.⁷⁸ After control of the blood sugar level, the maintenance dose is usually on a once-a-day schedule.

Chlorpropamide
(Diabinese)

Tolazamide, USP. Tolazamide, 1-(hexahydro-1*H*-azepin-1-yl)-3-(*p*-tolylsulfonyl)urea (Tolinase), is an analog of tolbutamide and is reported to be effective, in general, under the same circumstances in which tolbutamide is useful. Tolazamide, however, appears to be more potent than tolbutamide and is nearly equal in potency to chlorpropamide. In studies with radioactive tolazamide, investigators found that 85% of an oral dose appeared in the urine as metabolites that were more soluble than tolazamide itself.

Tolazamide
(Tolinase)

Acetohexamide, USP. Acetohexamide, 1-[(*p*-acetylphenyl)sulfonyl]-3-cyclohexylurea (Dymelor), is related chemically and pharmacologically to tolbutamide and chlorpropamide. Like the other sulfonylureas, acetohexamide lowers the blood sugar level, primarily by stimulating the release of endogenous insulin.

Acetohexamide
(Dymelor)

Acetohexamide is metabolized in the liver to a reduced form, the α -hydroxyethyl derivative. This metabolite, the main one in humans, possesses hypoglycemic activity. Acetohexamide is intermediate between tolbutamide and chlorpropamide in potency and duration of effect on blood sugar levels.

Glipizide. Structurally, glipizide, 1-cyclohexyl-3-[[*p*-[2(methylpyrazinecarboxamido)ethyl]phenyl]sulfonyl]urea (Glucotrol), is a cyclohexylsulfonylurea analog similar to acetohexamide and glyburide. The drug is absorbed rapidly on oral administration. Its serum half-life is 2 to 4 hours, and it has a hypoglycemic effect that ranges from 12 to 24 hours.

Glyburide. Similar to glipizide, glyburide, 1-[[*p*-[2-(5-chloro-*o*-anisamido)ethyl]-phenyl]sulfonyl]-3-cyclohexylurea (DiaBeta, Micronase, Glynase), is a second-generation oral hypoglycemic agent. The drug has a half-life elimination of 10 hours, but its hypoglycemic effect remains for up to 24 hours.

Glipizide
(Glucotrol)

Glyburide
(DiaBeta, Micronase, Glynase)

Glipizide
(Glucotrol)

Glipizide. Glipizide, 1-cyclohexyl-3-[[*p*-(2-(5-methylpyrazinecarboxamido)ethyl)phenyl]sulfonyl]urea (Glucotrol), is an off-white, odorless powder with a pK_a of 5.9. It is insoluble in water and alcohols, but soluble in 0.1 N NaOH. Even though on a weight basis, it is approximately 100 times more potent than tolbutamide, the maximal hypoglycemic effects of these two agents are similar. It is rapidly absorbed on oral administration, with a serum half-life of 2 to 4 hours, whereas the hypoglycemic effects range from 12 to 24 hours. Metabolism of glipizide is generally through oxidation of the cyclohexane ring to the *p*-hydroxy and *m*-hydroxy metabolites. A minor metabolite that occurs involves the *N*-acetyl derivative, which results from the acetylation of the primary amine following hydrolysis of the amide system by amidase enzymes.

Glimpiride. Glimpiride, 1-[[*p*-[2-(3-ethyl-4-methyl-2-oxo-3-pyrroline-1-carboxamido)ethyl]phenyl]sulfonyl]-3-(*trans*-4-methylcyclohexyl)urea (Amaryl), is very similar to glipizide with the exception of their heterocyclic rings. Instead of the pyrazine ring found in glipizide, glimepiride contains a pyrrolidine system. It is metabolized primarily through oxidation of the alkyl side chain of the pyrrolidine, with a minor metabolic route involving acetylation of the amine.

Gliclazide. Chemically, gliclazide, 1-(3-azabicyclo[3.3.0]oct-3-yl)-3-*p*-tolylsulphonylurea (Diamicon), is very similar to tolbutamide, with the exception of the bicyclic heterocyclic ring found in gliclazide. The pyrrolidine increases its lipophilicity over that of tolbutamide, which increases its half-life. Even so, the *p*-methyl is susceptible to the same oxidative metabolic fate as observed for tolbutamide, namely, it will be metabolized to a carboxylic acid.

Nonsulfonylureas—Metaglinides

The metaglinides are nonsulfonylurea oral hypoglycemic agents used in the management of type 2 diabetes (non-insulin-dependent diabetes mellitus, NIDDM). These agents tend to have a rapid onset and a short duration of action. Much like the sulfonylureas, these induce insulin release from functioning pancreatic β cells. The mechanism of action for the metaglinides, however, differs from that of the sulfonylureas. The mechanism of action is through binding to specific receptors in the β -cell membrane, leading to the closure of ATP-dependent K^+ channels. The K^+ channel blockade depolarizes the β -cell membrane, which in turn

leads to Ca^{2+} influx, increased intracellular Ca^{2+} , and stimulation of insulin secretion. Because of this different mechanism of action from the sulfonylureas, there are two major differences between these seemingly similar classes of agents. The first is that the metaglinides cause much faster insulin production than the sulfonylureas. As a result, the metaglinides should be taken during meals, as the pancreas will produce insulin in a much shorter period. The second difference is that the effects of the metaglinides do not last as long as the effects of the sulfonylureas. The effects of this class appear to last less than 1 hour, whereas sulfonylureas continue to stimulate insulin production for several hours. One advantage of a short duration of action is that there is less risk of hypoglycemia.

Repaglinide. Repaglinide, (+)-2-ethoxy-4-[*N*-[3-methyl-1(*S*)-[2-(1-piperidinyl)phenyl]butyl]carbamoyl-methyl]benzoic acid (Prandin), represents a new class of nonsulfonylurea oral hypoglycemic agents. With a fast onset and a short duration of action, the medication should be taken with meals. It is oxidized by CYP 3A4, and the carboxylic acid may be conjugated to inactive compounds. Less than 0.2% is excreted unchanged by the kidney, which may be an advantage for elderly patients who are renally impaired. The most common side effect involves hypoglycemia, resulting in shakiness, headache, cold sweats, anxiety, and changes in mental state.

Nateglinide. Although nateglinide, *N*-(4-isopropylcyclohexanecarbonyl)-D-phenylalanine (Starlix), belongs to the metaglinides, it is a phenylalanine derivative and represents a novel drug in the management of type 2 diabetes.

Thiazolidiones

The thiazolidiones represent a novel nonsulfonylurea class of hypoglycemic agents for the treatment of NIDDM. Much like the sulfonylureas, the use of these agents requires a functioning pancreas that can successfully secrete insulin from β cells. Although insulin may be released in normal levels from the cells, peripheral sensitivity to this hormone may be reduced or lacking. The thiazolidinediones are highly selective agonists for the peroxisome proliferator-activated receptor- γ (PPAR γ), which is responsible for improving glycemic control, primarily through the improvement of insulin sensitivity in muscles and adipose tissue. In addition, they inhibit hepatic gluconeogenesis. These agents normalize glucose metabolism and reduce the amount of insulin needed to achieve glycemic control. They are only effective in the presence of insulin.

Rosiglitazone. Rosiglitazone, (\pm)-5-[[4-[2-(methyl-2-pyridinylamino)ethoxy]phenyl]methyl]-2,4-thiazolidinedione (Avandia), is a white to off-white solid with pK_a values of 6.8 and 6.1. Rosiglitazone is readily soluble in ethanol and a buffered aqueous solution with pH of 2.3; solubility decreases with increasing pH in the physiological range. The molecule has a single chiral center and is present as a racemate. Even so, the enantiomers are functionally indistinguishable because of rapid interconversion.

Rosiglitazone
(Avandia)

Pioglitazone. Pioglitazone, (\pm)-5-[[4-[2-(5-ethyl-2-pyridinyl)ethoxy]phenyl]methyl]-2,4-thiazolidinedione (Actos), is an odorless, white, crystalline powder that must be converted to a salt such as its hydrochloride before it will have any water solubility. Although the molecule contains one chiral center, the compound is used as the racemic mixture. This is primarily a result of the *in vivo* interconversion of the two enantiomers. Thus, there are no differences in the pharmacological activity of the two enantiomers.

Bisguanidines

Metformin. Metformin, *N,N*-dimethylimidodicarbonyl diamide hydrochloride (Glucophage), is a bisguanidine. This class of agents is capable of reducing sugar absorption

Pioglitazone
(Actos)

from the gastrointestinal tract. Also, they can decrease gluconeogenesis while increasing glucose uptake by muscles and fat cells. These effects, in turn, lead to lower blood glucose levels. Unlike the sulfonylureas, these are not hypoglycemic agents but rather can act as antihyperglycemics. This difference in nomenclature is caused by the inability of these agents to stimulate the release of insulin from the pancreas. Often, metformin is coadministered with the nonsulfonylureas to improve the efficacy of those agents.

Metformin
(Glucophage)

α -Glucosidase Inhibitors

The enzyme α -glucosidase is present in the brush border of the small intestine and is responsible for cleaving dietary carbohydrates and facilitating their absorption into the body. Inhibition of this enzyme allows less dietary carbohydrate to be available for absorption and, in turn, less available in the blood following a meal. The inhibitory properties of these agents are greatest for glycoamylase, followed by sucrose, maltase, and dextranase, respectively. Because these do not enhance insulin secretion when used as monotherapy, hypoglycemia is generally not a concern when using these agents.

Acarbose. Acarbose, *O*-4,6-dideoxy-4-[[[(1*S*,4*R*,5*S*,6*S*) 4,5,6-trihydroxy-3-(hydroxymethyl)-2-cyclohexen-1-yl]amino] α -D-glucopyranosyl-(1,4)-*O*- α -D-glucopyranosyl-(1,4)-D-glucose (Precose), is a naturally occurring oligosaccharide, which is obtained from the microorganism *Actinoplanes utahensis*. It is a white to off-white powder

Acarbose
(Precose)

that is soluble in water and has a pK_a of 5.1. As one might expect, its affinity for α -glucosidase is based on it being a polysaccharide that the enzyme attempts to hydrolyze. This allows acarbose to act as a competitive inhibitor, which in turn reduces the intestinal absorption of starch, dextrin, and disaccharides.

Miglitol. Miglitol, 1-(2-hydroxyethyl)-2-(hydroxymethyl)-[2*R*-(2 α ,3 β ,4 α ,5 β)]-piperidine (Glyset), a desoxyojirimycin derivative, is chemically known as 3,4,5-piperidinetriol. It is a white to pale yellow powder that is soluble in water, with a pK_a of 5.9. In chemical structure, this agent is very similar to a sugar, with the heterocyclic nitrogen serving as an isosteric replacement of the sugar oxygen. This feature allows recognition by the α -glucosidase as a substrate. This results in competitive inhibition of the enzyme and delays complex carbohydrate absorption from the gastrointestinal tract.

THYROID HORMONES

Desiccated, defatted thyroid substance has been used for many years as replacement therapy in thyroid gland deficiencies. The efficacy of the whole gland is now known to depend on its thyroglobulin content. This is an iodine-containing globulin. Thyroxine was obtained as a crystalline derivative by Kendall⁷⁹ of the Mayo Clinic in 1915. It showed much the same action as the whole thyroid substance. Later, thyroxine was synthesized by Harington and Barger⁸⁰ in England. Later studies showed that an even more potent iodine-containing hormone existed, which is now known as triiodothyronine. Evidence now indicates that thyroxine may be the storage form of the hormone, whereas triiodothyronine is the circulating form. Another point of view is that in the blood, thyroxine is bound more firmly to the globulin fraction than is triiodothyronine, which can then enter the tissue cells.

Levothyroxine Sodium, USP. Levothyroxine sodium, *O*-(4-hydroxy-3,5-diiodophenyl)-3,5-diiodo-2-tyrosine monosodium salt, hydrate (Synthroid, Letter, Levoxine, Levoid), is the sodium salt of the *levo* isomer of thyroxine, which is an active physiological principle obtained from the thyroid gland of domesticated animals used for food by humans. It is also prepared synthetically. The salt is a light yellow, tasteless, odorless powder. It is hygroscopic but stable in dry air at room temperature. It is soluble in alkali hydroxides, 1:275 in alcohol, and 1:500 in water, to give a pH of about 8.9.

Levothyroxine Sodium
(Synthroid, Letter, Levoxine, Levoid)

Levothyroxine sodium is used in replacement therapy of decreased thyroid function (hypothyroidism). In general, a dosage of 100 μ g of levothyroxine sodium is clinically equivalent to 30 to 60 mg of thyroid *USP*.

Liothyronine Sodium, USP. Liothyronine sodium, *O*-(4-hydroxy-3-iodophenyl)-3,5-diiodo-*L*-thyroxine monosodium salt (Cytomel), is the sodium salt of *L*-3,3',5-triiodothyronine. It occurs as a light tan, odorless, crystalline powder, which is slightly soluble in water or alcohol and has a specific rotation of +18 to 22 degrees in a mixture of diluted HCl and alcohol.

Liothyronine Sodium
(Cytomel)

Liothyronine sodium occurs *in vivo* together with levothyroxine sodium; it has the same qualitative activities as thyroxine but is more active. It is absorbed readily from the gastrointestinal tract, is cleared rapidly from the bloodstream, and is bound more loosely to plasma proteins than is thyroxine, probably because of the less acidic phenolic hydroxyl group.

Its uses are the same as those of levothyroxine sodium, including treatment of metabolic insufficiency, male infertility, and certain gynecological disorders.

ANTITHYROID DRUGS

Hyperthyroidism (excessive production of thyroid hormones) usually requires surgery, but before surgery the patient must be prepared by preliminary abolition of the hyperthyroidism through the use of antithyroid drugs. Thiourea and related compounds show an antithyroid activity, but they are too

toxic for clinical use. The more useful drugs are 2-thiouracil derivatives and a closely related 2-thioimidazole derivative. All of these appear to have a similar mechanism of action (i.e., prevention of the iodination of the precursors of thyroxine and triiodothyronine). The main difference in the compounds lies in their relative toxicities.

These compounds are absorbed well after oral administration and excreted in the urine.

The 2-thiouracils, 4-keto-2-thiopyrimidines, are undoubtedly tautomeric compounds and can be represented as follows:

Some 300 related structures have been evaluated for antithyroid activity, but of these, only the 6-alkyl-2-thiouracils and closely related structures possess useful clinical activity. The most serious adverse effect of thiouracil therapy is agranulocytosis.

Propylthiouracil, USP. Propylthiouracil, 6-propyl-2-thiouracil (Propacil), is a stable, white, crystalline powder with a bitter taste. It is slightly soluble in water but readily soluble in alkaline solutions (salt formation).

Propylthiouracil
(Propacil)

This drug is useful in the treatment of hyperthyroidism. There is a delay in appearance of its effects because propylthiouracil does not interfere with the activity of thyroid hormones already formed and stored in the thyroid gland. This lag period may vary from several days to weeks, depending on the condition of the patient. The need for three equally spaced doses during a 24-hour period is often stressed, but evidence now indicates that a single daily dose is as effective as multiple daily doses in the treatment of most hyperthyroid patients.⁸¹

Methimazole, USP. Methimazole, 1-methylimidazole-2-thiol (Tapazole), occurs as a white to off-white, crystalline powder with a characteristic odor and is freely soluble in water. A 2% aqueous solution has a pH of 6.7 to 6.9. It should be packaged in well-closed, light-resistant containers.

Methimazole
(Tapazole)

Methimazole is indicated in the treatment of hyperthyroidism. It is more potent than propylthiouracil. The side effects are similar to those of propylthiouracil. As with other antithyroid drugs, patients using this drug should be under medical supervision. Also, like the other antithyroid drugs, methimazole is most effective if the total daily dose is subdivided and given at 8-hour intervals.

REVIEW QUESTIONS

- Nitroglycerin can be used as an antianginal agent because of its vasodilator effects. Also, nitroglycerin is a liquid used in dynamite; why does not Mrs. Smith blow up when using this drug as a vasodilator?
 - It is not really the same nitroglycerin as the one used to make dynamite.
 - Nitroglycerin must be used while it is fresh so it will not detonate.
 - There are stabilizers added to nitroglycerin that prevent its detonation.
 - Nitroglycerin is very dilute when used as an antianginal agent so it will not detonate.
- Although the agent shown here (Losartan [Cozaar]) has some pharmacological effects, one of its metabolites is reported to be more potent. Identify this metabolite.
 - N*-dealkylation that releases the imidazole ring (*N*-deimidazole metabolite)
 - oxidation of the 5-methanol to a carboxylic acid
 - oxidation of the aromatic (benzene) ring to a phenol
 - oxidation of the omega-1 carbon on the 2-position alkyl side chain
 - None of the above is true because only the parent compound is active.

3. After a patient is administered an organic nitrate, these are then metabolized to nitric oxide (NO) by first reacting with _____ to form _____.

 - a. sulfhydryls; *S*-nitrosothiols
 - b. amidase; carboxylic acids and amines
 - c. esterases; carboxylic acids and alcohols
 - d. hydroxyl residues; *O*-nitrosoalcohols

Hormone-Related Disorders: Nonsteroidal Therapies

RONALD A. HILL

CHAPTER OVERVIEW

A large and growing number of medicinal substances act on endocrine systems. Many are steroid analogs (i.e., ligands for estrogen, progesterin, and androgen receptors), and, as suggested by the title of this chapter, will not be considered herein, but instead in Chapter 25. Neither will all nonsteroidal endocrine modulators be considered in the present chapter, however. Medicinals acting to modulate calcium deposition and resorption, particularly within bone, are discussed in Chapter 21 (including ligands for vitamin D receptors, parathyroid hormone receptors, and calcitonin receptors). Coverage of thyroid hormones, and of agents for treating hyperthyroid states, has been retained in Chapter 19 for this edition of the text. Numerous other endocrine system interventions are, at present, solely accomplished by administering a naturally occurring human protein produced by artificial means. For now, agents of this nature receive primary consideration within a chapter dedicated to “biologics” (Chapter 27); examples include human growth hormone, somatostatin, and the follitropins.

For more than 6 decades, a collection of disorders of primary metabolism, chiefly type 1 and type 2 diabetes, have, for obvious reasons, received great attention from the drug discovery community. These efforts have intensified over the past several decades, evolving to include a significant fraction of the biotechnology enterprise. Insulin remains central to the treatment of type 1 diabetes, and various details of insulin chemistry, biochemistry, and pharmacology are provided in Chapter 27. Within the past decade or so, however, various modified insulins have reached the market, and the molecular bases of their diverse characteristics are considered in the present chapter, along with a brief introduction to insulin itself. Two general classes of drugs that act primarily—but not necessarily exclusively—as insulin secretagogues for treating type 2 diabetes, namely the sulfonylureas and the glinides, are then considered in detail. It has long been realized that defective responsiveness to insulin plays a major role in the etiology and progression of type 2 diabetes. On this basis, biguanides that act, at least in part, as “insulin sensitizers” have been in clinical use for many years, and more recently the thiazolidinediones appeared on the market.

Hormones other than insulin and glucagon also play important roles in regulating the body’s glucose handling and associated aspects of food consumption and primary metabolism. The identification of two of these, and subsequent

characterization of their physiological actions and biochemistry, led to the creation of amylin and glucagon-like peptide type 1 (GLP-1) receptor agonists, which to date are represented in the market by analogs of the endogenous proteins. Enzymes catalyzing the degradation of these hormones were also identified as potential molecular targets for therapeutic intervention; thus, the first inhibitor of dipeptidyl peptidase type 4 (DPP-4 or DPP-IV), sitagliptin, recently reached the U.S. market, with others expected in the near future.

Given the fact that endocrine signals of a suitable nature are requisite to the survival and proliferation of many cancerous cells, various therapeutics used in oncology (Chapter 10) fall within the potential scope of this chapter. Among these, the gonadotropin-releasing hormone receptor (GnRH-R) agonists and antagonists receive consideration herein. These drugs represent treatment options for various gonadal hormone-dependent cancers, but also see such clinical uses as fertility modulation, mitigation of various uterine disorders, and in treating precocious puberty. The GnRH-R agonists and antagonists currently on the market are modified peptides, and examining how the molecular features of each of these drugs endow them with their particular pharmacological and biopharmaceutical properties offers the medicinal chemistry student some excellent lessons within a realm that is often lightly emphasized. Entry points to the literature in this area have been selected and provided to facilitate further explorations by students who may be motivated to expand the breadth and depth of these lessons.

DISORDERS OF GLUCOSE METABOLISM: DIABETES AND THE METABOLIC SYNDROME

Various forms of diabetes afflict a large and increasing proportion of the population of much of the developed world, and (somewhat surprisingly) rapidly increasing numbers of individuals in the developing world. Diabetes causes impairments, and eventually often kills, in large measure, because of the secondary effects of excessively elevated circulating and tissue glucose levels. Perhaps more insidiously, tolerance to hypoglycemic excursions as a result of progressively impaired counterregulatory responses to the administration of insulin and drugs that elicit insulin release can cause individuals to suffer severe hypoglycemic episodes, involving shock and, in more extreme cases, coma or death.

Diabetes can be broadly classified as “type 1” or “type 2.” Type 1 diabetes is also often referred to as insulin-dependent diabetes mellitus (IDDM), or sometimes as juvenile-onset diabetes mellitus, although onset can in fact occur in adults. The hallmark of type 1 diabetes is absent or insufficient insulin secretion by the insulin-secreting cells of the pancreas, namely the beta cells (β cells) of the islets of Langerhans. In some individuals, this arises because of a genetic defect, whereas in other individuals, the disease is “idiopathic” (i.e., the cause is indeterminate), but in most cases, the β -islet cells are partially or completely destroyed as a result of an erroneous autoimmune response. Regardless of cause, type 1 diabetes must, at present, be treated with one or more types of insulin. Type 2 diabetes is often referred to as non-insulin-dependent diabetes mellitus (NIDDM). In type 2 diabetes, the insulin secretory response is impaired—increasingly so as the disease progresses with time, but in most cases, a comorbid defect is the failure of many cells of the body to properly respond to circulating insulin, particularly certain cells in the liver and skeletal muscles having a primary glucose storage role, and certain cells in adipose tissue. Another way of stating this is that the “insulin sensitivity” of these cells becomes impaired. This impairment often occurs secondary to obesity, although this contributor is apparently not obligatory, and the “obesity” may be so mild as to hardly be recognizable as such. In recent years, states of health have been characterized that, without intervention, often lead to type 2 diabetes. Such prediabetic states are now often broadly referred to as “the metabolic syndrome,”^{1,2} and various medical organizations are establishing criteria and treatment guidelines intended to avert further development into full-blown type 2 diabetes—that is, preventive medicine tactics. Although historically type 2 diabetes has most often been treated with insulin secretagogues (such as one of the sulfonylurea drugs, *vide infra*) or, in some cases, insulin, the recognition that this disorder—which is really an array of related disorders—is most often one of defective cellular insulin responsiveness has, in recent years, guided basic and drug discovery research onto paths culminating with the testing and marketing of therapeutic agents, having completely new mechanisms of action. Clinical results in some cases provide the hope not only that the damaging out-of-safe-range excursions of blood and tissue glucose levels might be prevented, but also that individuals with type 2 diabetes might be cured, and individuals with prediabetic syndromes be saved from developing the full-blown disease. For type 1 diabetics or those type 2 patients requiring insulin supplementation, devices allowing for continuous monitoring of blood glucose and microprocessor-controlled on-demand insulin delivery seem likely to soon revolutionize treatment. Until very recently, though, alternatives to lifelong insulin therapy for such patients seemed no

more than hopeful dreams. Yet, scientific advances now suggest that, before many more years pass, it should be possible to implant alternative glucose-responsive, insulin-secreting cells in the pancreas or liver. Even more excitingly, it appears that it will be possible to stimulate regeneration of β -cell populations within the pancreatic islets while simultaneously arresting the autoimmune attack that would otherwise destroy them; therefore, type 1 diabetes could, for all practical purposes, be cured.

Insulins and Modified Insulins

Type 1 diabetes must, for now, be treated with insulin replacement therapy. After the demonstration c. 1900 that this disorder, which was invariably fatal within a short time, was one of pancreatic β -cell failure, more than 20 years passed before insulin was isolated and purified from fetal calf pancreases, and its clinical relevance demonstrated. Commercially viable production was achieved by Eli Lilly and Co., with initial marketing in 1923 (Iletin). The primary structure of human insulin was not reported until 1958 (Nobel Prize in Chemistry to Frederick Sanger, 1964), and the tertiary structure was not available until reported by Dorothy Crowfoot Hodgkin in 1969, a triumph of x-ray crystallography. Prior to the 1980s, treatment of type 1 diabetes was achieved via injections of porcine or bovine insulin, or combinations thereof. Although preparations containing porcine or bovine insulin may remain in use around the globe, the availability of human insulin produced artificially via methods of “biotechnology” has widely supplanted insulin from animal sources, and, undoubtedly, will soon completely replace them as cost barriers are conquered. No animal-sourced preparations are now available in the United States. Moreover, several modified insulin preparations have come on the market in recent years, and the development of technology for alternative routes of administration besides injection is also rapidly changing the therapeutic landscape.

Human insulin is a heterodimer (Fig. 20.1), consisting of two different peptide subunits linked covalently by two disulfide bridges. This heterodimer is produced from a single, continuous, and substantially larger (110-amino-acid) protein, namely preproinsulin. Among other reasons, production in this manner ensures proper three-dimensional (3D) folding and cross-linking of insulin. Preproinsulin is converted to proinsulin (86-amino-acid residues), from which insulin is produced by removal of a 35-amino-acid segment joining the two subunits. Chapter 27 includes a more detailed treatment of the biosynthesis and structural attributes of human insulin, as well as further information regarding its storage within, and release from, pancreatic β cells.

Figure 20.1 • The primary structure of human insulin.

TABLE 20.1 Modified Insulins^a

	Trade Name	Structural Differences vs. Human Insulin	Characteristics Achieved
Bovine insulin		Thr ^{A8} →Ala, Ile ^{A10} →Val Thr ^{B30} →Ala	
Porcine insulin		A chain same as hIns Thr ^{B30} →Ala	
Insulin aspart	NovoLog	A chain same as hIns Pro ^{B28} →Asp	Rapidity of onset increased, duration substantially decreased vs. regular human insulin ^b
Insulin lispro	Humalog	A chain same as hIns Pro ^{B28} →Lys, Lys ^{B29} →Pro	Rapidity of onset increased, duration substantially decreased vs. regular human insulin ^b
Insulin glulisine	Apidra	A chain same as hIns Asn ^{B3} →Lys, Lys ^{B29} →Glu	Rapidity of onset increased, duration substantially decreased vs. regular human insulin ^b
Insulin glargine	Lantus	Asn ^{A21} →Gly Arg ^{B31} and Arg ^{B32} added to B chain C terminus	Extended action
Insulin detemir	Levemir	A chain same as hIns Lys ^{B29} derivatized: N ^ε -CO(CH ₂) ₁₂ CH ₃ Thr ^{B30} removed	Soluble and long-acting

^aSee also Table 20.2 for other details and information pertaining to modified insulins.

^bSolution dimerization is reduced or abolished, the onset rate is thus substantially increased because the monomer remains in solution; completion of release into the systemic circulation occurs substantially sooner because the molecules mostly stay in solution at the injection site.

Porcine insulin differs from human insulin by only a single amino acid: The carboxyl terminus residue of the B chain in human insulin is threonine, whereas in porcine insulin, it is alanine (Fig. 20.1 and Table 20.1). Bovine insulin differs in this same manner, but also at two additional positions in the A chain (Thr^{A8}Ala and Ile^{A10}Val; again see Table 20.1). Even though these differences are quite modest, and allow either bovine or porcine insulin to bind to and activate human insulin receptors comparably to human insulin, immunogenicity to the animal insulins can and does occur. (Although it is now realized that, historically, more incidences of immune intolerance were likely traceable to minor impurities in the insulin preparations than to the animal insulin itself.) Human recombinant insulin is produced commercially in *Escherichia coli* or yeast. Because proper folding of the final product must be achieved, and purification is nontrivial, the production processes for human recombinant insulin are highly complex and demanding (see Chapter 27, and references therein, for further details). Human insulin had also been produced commercially by conversion of porcine insulin, which requires only the B³⁰ Ala→Thr replacement, and can be done in such a way as to preserve 3D structure.

Insulin is monomeric in solution only at very low concentrations, less than about 0.1 μm. In many pharmaceutical preparations, it is dimeric; that is, it exists in a form in which one molecule of A-B covalently linked heterodimer associates noncovalently with another A-B heterodimer. In solutions of pH near neutral, the addition of suitable amounts of Zn²⁺ to such dimeric preparations results in the formation of hexamers (i.e., 6 × A-B heterodimer). Hexamer formation also occurs without Zn²⁺ in solutions having of concentrations higher than ~0.2 μm. Pharmaceutical advantage has been taken of the formation of such noncovalent multimers, because solubilities of the various insulin species differ and, thus, release rates from the injection site can be considerably altered, and reliably so. Consequently, products such as protamine zinc insulin suspension, semilente insulin, and ultralente insulin were created (see Chapter 27). The B21→B30 sequence was found to play a crucial role in this

noncovalent insulin dimerization, and a more detailed understanding of this fact has allowed, yet additional pharmaceutical manipulations, resulting in such products as neutral protein Hagedorn (NPH) insulin, also known as isophane insulin. Amino acid substitutions in the B21→B30 region, in some cases in conjunction with a further single amino acid substitution elsewhere in the A-B heterodimer, have, over the past decade, provided several therapeutically valuable “modified insulins,” including lispro insulin, insulin aspart, insulin glargine, insulin glulisine, and insulin detemir (see Table 20.2). In these products, enhanced solution stabilities, modified solubilities, increased rapidity of onset, and varied (shortened or extended) durations of action are achieved.

Sulfonylureas and Glinides

Sulfonylureas act at the molecular level primarily as “insulin secretagogues,” that is, these compounds elicit insulin secretion from pancreatic β-islet cells. Glinides (also known as meglitinides) exert their action mainly by this means as well. A sufficient complement of functioning β cells must, therefore, be present in a patient in order for any one of these compounds to exert at least this component of its intended action, thus only patients with type 2 (not type 1) diabetes are candidates for pharmacotherapy with such compounds. In recent years, it has become apparent that for insulin secretagogues, homeostatic (biochemical) adjustments cause a progressive loss of at least some effectiveness over the course of several months after initiation of therapy.³ The entirety of the consequent implications in clinical practice has not yet been established.

The insulin-secreting response that a sulfonylurea or glinide elicits from β cells is brought about at the macromolecular target level by interaction of these drug molecules with adenosine triphosphate (ATP)-sensitive K⁺ channels. (Secondary pharmacological targets leading to significant differences between and among sulfonylureas and glinides will be briefly discussed later in the chapter.) More specifically, a sulfonylurea or glinide molecule binds to an sulfonylurea receptor (SUR) subunit

TABLE 20.2 Marketed Insulin Products^a

	Trade Name	Formulation and Administration	Onset Characteristics	Peak (hr)	Duration	Other Information
Regular human insulin, recombinant ^b	Humulin R Humulin R Pen Novolin R	100 U/mL (OTC)	Rapid 0.5–1 hr	Varies by formulation	8–12 hr	
Regular human insulin, recombinant	Exubera (Pfizer)	Powder, 1 mg or 3 mg per inhalation	10–20 min	2 hr	~6 hr	Restricted availability
Regular human insulin, recombinant, concentrated	Humulin R (Lilly)	500 U/mL (R _x)	Rapid	Extended	up to 24 hr	Zinc-insulin preparation; clear solution but precipitates upon injection
Recombinant human insulin isophane suspension	Humulin N Novolin N	100 U/mL (OTC)	1–1.5 hr	4–12 hr	24 hr	NPH (neutral protein Hagedorn): a crystalline protamine zinc insulin suspension
Insulin suspension isophane human recombinant; insulin human recombinant	Humulin 70/30, Humulin 70/30 Pen (Lilly)	70 U/mL	Rapid	Mixed	24 hr	
Insulin glulisine recombinant	Novolin 70/30 (Novo Nordisk)	30 U/mL sc				
Insulin as part recombinant	Apidra, Apidra Solostar (Sanofi-Aventis)	100 U/mL sc 15 min before meal, or infusion sc or iv	Rapid	0.5–1.5 hr	1–2.5 hr	Produced in a nonpathogenic laboratory strain of <i>E. coli</i> (K12)
Insulin as part recombinant	NovoLog (Novo Nordisk)	100 U/mL sc	Rapid 0.25 hr	1–3 hr	3–5 hr	Produced in <i>Saccharomyces cerevisiae</i> (baker's yeast)
Insulin lispro recombinant	Humalog, Humalog Pen, Humalog Kwikpen (Lilly)	100 U/mL sc	Rapid 0.25 hr	0.5–1.5 hr	2–5 hr	Consists of zinc-insulin lispro crystals dissolved in clear aqueous fluid
Insulin glargine recombinant	Lantus (Sanofi-Aventis)	100 U/mL sc	1.1 hr	Extended release—no distinct peak	24+ hr	Formulated upon as a solution at pH 4; injection, hexameric insulin microcrystals precipitate, from which insulin in biologically active form is slowly released
Insulin detemir recombinant	Levemir (Novo Nordisk)	100 U/mL sc or iv infusion	0.8–2 hr	Extended release—no distinct peak	24 hr	
Insulin lispro protamine recombinant; insulin lispro recombinant	Humalog Mix, Humalog Mix Kwikpen (Lilly)	50 U/mL/50 U/mL or 75 U/mL/75 U/mL sc	Rapid	Mixed	up to 24 hr	
Insulin as part protamine recombinant; insulin aspart recombinant	NovoLog Mix 70/30 (Novo Nordisk)	70 U/mL 30 U/mL sc	Rapid	Mixed	12–16 hr	

^aSee Table 20.1 for structural details of modified insulins.

^bUltralente (U) and Lente (L) insulins have been discontinued in the United States, supplanted by newer modified insulins and insulin mixtures.

iv, intravenous; OTC, over-the-counter; rDNA, recombinant DNA; sc, subcutaneous; U, international activity units.

of an octameric protein complex (Fig. 20.2), which includes four channel-forming K_v6 protein subunits, and four SUR1 protein subunits. SUR proteins are so named for their ability to bind various sulfonylureas with high affinity. Sulfonylurea (or glinide) binding favors channel closure, intracellular K⁺ concentrations ([K⁺]_{in}) consequently increase, which in turn increases the propensity of β cells to depolarize (Fig. 20.3). Sufficient β-cell depolarizations bring about insulin release from membrane-associated vesicular stores, which, under normal conditions, are continuously replenished from intracellular insulin storage vesicles. Normally functioning β-islet cells

similarly release insulin in response to sufficiently elevated blood glucose concentrations: glucose catabolism (glycolysis) within the cells increases the intracellular ATP:adenosine diphosphate (ADP) concentration ratio (i.e., [ATP]/[ADP] increases), thereby increasing the chances that ATP rather than ADP will be bound to specific adenosine nucleotide-binding sites on the SUR subunits of ATP-sensitive K⁺ channels, which in turn favors channel closure. Thus, sufficient tissue-level concentrations of sulfonylureas or glinides in effect mimic the high (ATP)/(ADP) situation that would normally result from elevated blood glucose concentrations, and can,

Figure 20.2 • Structure of SUR1/K_{ir}6.2 assemblies as pertains to sulfonylurea and glinide binding. **A.** Schematic of the 17-transmembrane SUR subunits,⁴ indicating the two nucleotide binding folds NBF1 and NBF2; the two-transmembrane Kir6.X subunits; and the general locations of the "A" ligand-binding domains and the "B" ligand-binding domains (Fig. 20.7); **B.** Schematic of the octameric (4+4) channel assemblies illustrating the central pore created by four Kir_{ir}6.2 subunits, and the four surrounding SUR1 subunits.^{5,6} A sulfonylurea or glinide ligand simultaneously engages the portions of the SUR1 and Kir_{ir}6.2 subunits comprising the "B" ligand-binding domain.

in this way, compensate for a loss of proper intracellular responsiveness to food-associated hyperglycemic excursions.

Insulin secretagogue sulfonylureas are more specifically referred to as *N*-(phenylsulfonyl)-*N'*-alkylureas. Sulfonylureas commonly referred to as "first-generation" (Fig. 20.4) and "second-generation" (Fig. 20.5) molecules differ mainly with respect to elaboration on the benzene ring at the *para* position of the phenylsulfonyl moiety. Glimepiride is sometimes classified as a third-generation molecule, but structurally, there is no real basis for this distinction.

Figure 20.3 • Simplified diagram of sulfonylurea action on pancreatic β cells leading to insulin release (adapted from Bounds et al.,⁷ with permission). Glucose entering the cell via a membrane transporter (1) results in ATP synthesis (2), and sufficiently elevated ATP/ADP ratios favor ATP binding (3) over ADP binding at the nucleotide binding sites on the channel assemblage, in turn favoring K⁺ channel closure. Sulfonylureas or glinides also bind to the channel assemblage (4), also favoring channel closure. Increased K⁺ channel closure traps a greater portion of K⁺ ions within the cell, rendering the intracellular milieu less negative versus extracellular fluids (i.e., depolarization [5]). Sufficient depolarization favors calcium channel opening (6), allowing Ca²⁺ to flow into the cell. Sufficient increases in cytoplasmic [Ca²⁺] cause insulin exocytosis (7), and also increase trafficking of insulin granules to the cell membrane.

Sulfonylureas were fortuitously discovered because of the hypoglycemic side effects of various sulfonamide antibiotics ("sulfa drugs"), including the isopropylthiadiazole derivative of sulfanilamide and, during its clinical testing, carbutamide (see Fig. 20.6). In the subsequent process of creating such first-generation insulin secretagogues as tolbutamide and chlorpropamide, and thereafter second-generation compounds such as glyburide and glimepiride, many thousands of analogs were synthesized and evaluated pharmacologically. The structure–activity results are somewhat self-evident from the information in Table 20.3, to the extent that molecular-level potency (insulin-releasing action) correlates with dose. In fact, upon accounting for the consequences of relatively modest oral bioavailability and pharmacokinetic differences, observed hypoglycemic potencies correlate very well with molecular-level affinities of the SUR1 binding of these compounds, and with functional potencies obtained from *in vitro* physiological assays. Invariably, optimized alkyl, cycloalkyl, or cycloazalkyl *N*3 (*N'*) substituents provide the highest affinities and potencies. Substitution of *N*1 with a benzenesulfonyl moiety (or a comparable arylsulfonyl moiety) is necessary, with *para* substituents generally increasing the potency. Further elaboration at the *para* position with a β -(acylamino)ethyl moiety (as in, for example, the structure of glyburide) was found to greatly enhance the activities among compounds of this general structural class, based on which finding all of the marketed second-generation hypoglycemic sulfonylureas were created.

Figure 20.4 • First-generation sulfonylurea structures.

Figure 20.5 • Second-generation sulfonylurea structures.

sulfanilamide

was used to treat typhoid fever (1940s);
(high incidence of hypoglycemia
side effect, sometimes fatal)

sulfisoxazole
(a "sulfa drug" antibiotic;
hypoglycemia side effect rare)

carbutamide
(early hypoglycemic agent,
marketed 1956 (Ger.),
demarketed by 1960
due to toxicities, especially
to bone marrow)

tolbutamide
(first-generation hypoglycemic agent,
marketed 1956 (Ger.), 1961 (USA),
still on market)

Figure 20.6 • Structural genesis of hypoglycemic sulfonylureas.

The sulfonylureas behave as weak acids within the physiological pH range, with pK_a values typically 5 to 6 (Table 20.3); thus, at the pH of blood, the negatively charged conjugate base predominates to the extent of >95%. In addition to the presence of the anionic moiety, portions of these ionized molecules are also relatively lipophilic; such structural combinations often lend themselves to extensive binding to serum and tissue proteins, and this is found to be the case with all of these drugs. In their free acid states, all of the marketed sulfonylureas are quite lipophilic (see log P values, Table 20.3). This characteristic facilitates absorption from the gut lumen, especially in initial portions of the small intestine where the pH remains below or near the pK_a of the drug. Despite the lipophilicity of these molecules in their free-acid form, diffusion through the blood-brain barrier (BBB) is reported to be minimal for drugs of this class, presumably attributable to the combination of high serum protein binding and low percentage of free acid species in blood. Efflux transporters are known to be involved in some cases.⁸ For some of these drugs, however, the high potency coupled with

the presence of ATP-sensitive K^+ channels within the brain might possibly account for certain undesirable side effects (notably, weight gain).

Glinides (Figs. 20.7 and 20.8) contain a carboxylic acid moiety that, in its carboxylate form, interacts with the same anion recognition site on ATP-sensitive K^+ channels as does the ionized (conjugate base) form of the sulfonylurea moiety.¹⁰ The pK_a 's for the carboxylic acid moieties of repaglinide and nateglinide fall within the expected range. Repaglinide includes a tertiary amine moiety, incorporated within a piperidine ring. The effective pK_a of this structural moiety (6.0–6.2),¹² which gives account of two dissociation microconstants (see Fig. 20.9), is well above the pK_a of aniline (4.6), owing to the sterically demanded twist of the piperidine nitrogen's lone-pair out of optimal conjugation with the benzene ring. Because of the presence of two ionizable moieties, at no solution pH does an uncharged form predominate. Even so, the carboxylate anion (with the piperidine moiety as uncharged free base), which is the predominant molecular species at plasma pH, is relatively

α-GP, alpha 1 acid glycoprotein; ER, extended release; hsa, human serum albumin; NA, not available.

Figure 20.7 • Relationship of first- and second-generation sulfonylurea structures to those of repaglinide and nateglinide, and structural segments engaging the “A” and “B” binding regions at one of the four binding sites (at each SUR1:K_i6.2 interface) of the channel assemblage. Ability to appropriately engage the “A” site confers SUR1 selectivity; after Winkler et al.,⁴ Vila-Carriles et al.,⁹ Grell et al.,¹⁰ and Slevi.¹¹

lipophilic ($\log P \sim 1.8$). Moreover, $\log D$ peaks near 4.0 between pH 5 and pH 6, even though the amphoteric (doubly charged) form predominates 76:1 over the uncharged species at the pH of $\log D$ maximum. Thus, absorption from the gut occurs readily, although there is significant loss caused by first-pass biotransformation (CYP3A4 and CYP2C8; see Table 20.4).

The “structural heritage” of repaglinide is made more obvious by comparison of the structure of meglitinide, a long-known molecule that has not been commercially marketed

as a hypoglycemic agent, to that of glyburide (Fig. 20.10). Moreover, structure–activity relationships reported by Grell et al.¹⁰ in conjunction with the molecular biology studies of the receptor by several groups^{4,9,13} clarify the interactions of these molecules at the interface of the SUR1 protein subunit and the K_i6.2 protein subunits, and provide a basis for selectivity of hypoglycemic sulfonylureas and glinides for SUR₁ over the SUR_{2A}-containing channels found in heart and skeletal muscle or the SUR_{2B}-containing channels found in smooth muscle (Figs. 20.2 and 20.7).

Figure 20.8 • Glinide structures, including the prototypical compound meglitinide (see Fig. 20.10).

Figure 20.9 • Repaglinide solution ionization. The proton dissociation microconstants combine to account for the observed macro pK_a values, as well as the lipid/aqueous phase partitioning characteristics.¹²

Recently, evidence indicates that ATP-sensitive K⁺ channels involved in mediating insulin secretion are found not only on the cell surface, but also at insulin-storage granules,¹⁴ and various drugs may differ at least with respect to access to these two sites of action. Also, additional pharmacological targets probably have considerable clinical relevance. For example, gliquidone, glipizide, and nateglinide exhibit peroxisome proliferator-activated receptor- γ (PPAR γ) activity at concentrations reached in tissues under standard pharmacotherapy regimens of these drugs.¹⁵ The noteworthiness of this finding will be more apparent to the reader upon completing the section on thiazolidinediones further on in this chapter. Nateglinide and mitglinide, but not sulfonylureas, evidently elicit insulin se-

cretion in part via a ryanodine-receptor-mediated pathway.¹⁶ Still, other molecular targets have been identified for various of these drugs, and these may partly account for the significant pharmacodynamic variations among the sulfonylureas and glinides that have yet to be fully explained. Active metabolites (see succeeding discussion), tissue and serum protein binding, and transporters also undoubtedly play important roles in these variations, some of which are already characterized, and in each such case, the possibility of pharmacogenomic variations among individuals accordingly arises. As an example, repaglinide and nateglinide are substrates of the *SLCO1B1*-encoded hepatic anion uptake transporter (i.e., OATP1B1), and at least one single-nucleotide polymorphism significantly alters repaglinide pharmacokinetics (PK)¹⁷ and nateglinide PK.¹⁸

Regarding biotransformation ("drug metabolism") of the various hypoglycemic sulfonylureas in clinical use, although each drug exhibits a unique fate, common themes are, as is to be expected, associated with structural commonalities among the molecules (Fig. 20.11). Those that include a cyclohexyl ring are hydroxylated on that ring. Just within the past decade, it became clear that for glyburide, not only does hydroxylation occur in humans at each of the possible positions (2, 3, and 4), but with each of the possible stereochemical orientations (*cis* and *trans* in relative disposition to the attached urea nitrogen); see Figure 20.12.¹⁹ Moreover, an ethylene-bridge-hydroxylated metabolite of glyburide (Fig. 20.13), presumably the benzylic hydroxylation product, was identified only within the past decade, and is now known to be a major metabolite in humans.²⁰ Some of these metabolites are known to confer a significant portion of the hypoglycemic effects of this drug, and may account for certain significant pharmacodynamic characteristics of this drug as well as for side effects, especially hypoglycemic episodes. Pharmacologically active metabolites are also known to be important for other sulfonylureas. Notably, the ketone moiety of the *p*-acetyl substituent on the phenyl ring of acetohexamide is reduced to the corresponding benzylic alcohol (Fig. 20.11), which exhibits a longer pharmacokinetic half-life than the parent drug, and is approximately

Figure 20.10 • Comparison of the structure of the prototypical glinide, meglitinide, with that of its "ancestor," glyburide. Comparison to Figure 20.7 will reveal that meglitinide lacks the SUR1 selectivity-bestowing pendant lipophilic group that engages the "A" binding site of the receptor (see Fig. 20.2).

Figure 20.11 • Biotransformations of first-generation sulfonylureas (see also Fig. 20.12).

equiactive with respect to hypoglycemic effect. ω -Hydroxylated or $(\omega-1)$ -hydroxylated metabolites of alkyl chain-containing sulfonylureas are formed and are either known or suspected to contribute to hypoglycemic activity. Those molecules having a *p*-methylphenyl moiety undergo benzylic hydroxylation. Because this transformation is

effected, at least in part, by CYP2C9, pharmacogenomic variations in PK are to be expected.²¹ For gliclazide, CYP2C19 genetic polymorphism rather than CYP2C9 genetic polymorphism accounts for pharmacogenomic variations in PK.^{22,23} In each case, though the resulting hydroxymethyl metabolite, which is either known to be able to

Figure 20.12 • P450-catalyzed cyclohexane ring hydroxylations of glyburide. Evidence suggests that the 2-*cis*-hydroxy metabolite (not shown) is also formed, but definitive proof has not been obtained. Also note that some of these metabolites can exist as a pair of enantiomers, concerning which nothing is known.

Figure 20.13 • Major biotransformations of second-generation sulfonylureas.

exert significant target-level hypoglycemic activity (e.g., tolbutamide) or undoubtedly can, probably plays a relatively insignificant role with respect to *in vivo* pharmacological activity: because of relatively rapid oxidation to aldehyde and thence to inactive carboxylic acid, as well as conjugation to inactive β -D-glucuronide, blood and tissue concentrations do not build to sufficient levels. Similarly, because of rapid conversion to glucuronide or sulfate conjugates, which are eliminated mainly in bile, the *O*-demethylated metabolite of gliquidone (Fig. 20.13) does not contribute substantively to the hypoglycemic activity of this drug.

Repaglinide undergoes extensive biotransformation in humans,²⁴ and this fact primarily accounts for the modest 56% average oral bioavailability of this drug.²⁵ Oxidative biotransformation catalyzed predominantly by CYP3A4 and CYP2C8^{26,27} produces a dicarboxylic acid (M2, see Fig. 20.14) as the major metabolite, reported to account for >65% of an administered dose of [¹⁴C]-repaglinide, and to have no hypoglycemic effect.^{24,28} Subsequent *N*-dealkylation to the aniline M1 also occurs, and M1 was found at a slightly higher concentration than M2 in urine,²⁴ but most (~90%) of an administered dose is excreted in feces, of which some 72% is M2. On the other hand, the major circulating fraction of an administered dose is repaglinide,

which is rapidly cleared from plasma. Direct phase II conjugation to the acyl glucuronide has been reported.

Biotransformation plays the predominant role in the clearance of nateglinide, with isopropyl side chain-centered phase I biotransformation and direct phase II conjugation as key components (Fig. 20.15). Although the *p*-hydroxyphenyl metabolite has been identified, with respect to phase I biotransformations, only products resulting from the actions of P450s on the isopropyl moiety are reported to be formed in significant quantities in humans. Monohydroxylation of the terminal isopropyl methyls produces two diastereomeric primary alcohols (M2 and M3), both of which are reportedly about a third as pharmacologically active as nateglinide.²⁹ Urinary excretion accounts for about 85% of the elimination of an administered dose, about half of which is M1 and unchanged nateglinide (2:1).³⁰ Following nateglinide administration, M1 is prominent in plasma but reportedly exerts about fivefold or sixfold less potent hypoglycemic activity (intravenous [iv]) than nateglinide. M7 is either formed via direct dehydrogenation of repaglinide, or by elimination of water from M1, M2, or M3. M7 is also interesting because it exhibits hypoglycemic activity of comparable potency and nature to nateglinide's, although circulating concentrations are almost 10-fold lower than that of nateglinide. Two

Figure 20.14 • Important biotransformations of repaglinide. (UDP, uridine-3',5'-diphosphate; UDPGA, 3'-phosphouridine-5'-phospho- β -D-glucuronic acid.)

Figure 20.15 • Important biotransformations of nateglinide. The abbreviations UDPGA and UDP are defined in the caption to Figure 20.14.

diastereomeric dihydroxylated metabolites (M11, M12, not pictured), together representing ~8% of administered dose, may be formed from M7 via epoxidation and spontaneous or epoxide hydrolase-mediated hydrolysis, but detection of the epoxide has yet to be reported, so direct ω -1 hydroxylation of M2 and M3, cannot be ruled out as pathways to M11 and M12. Although, apparently, no glucuronides of any of the isopropyl-hydroxylated species have been detected in humans, an acyl β -D-glucuronopyranoside is produced from the carboxylic acid moiety. Two apparent rearrangement products have also been characterized, in which the acyl group is shifted to the 2'-hydroxyl or 3'-hydroxyl of the sugar (Fig. 20.15), and the three glucuronides in aggregate appear in urine and account for 5% (oral) or 8% (iv) of an administered dose. Because CYP2C9 plays a major role in nateglinide biotransformation, pharmacogenomic variations in PK have been characterized.^{21,31}

PRODUCTS (SEE ALSO TABLES 20.3 AND 20.4)

Tolbutamide is *N*-[(butylamino)carbonyl]-4-methylbenzenesulfonamide; or 1-butyl-3-(*p*-tolylsulfonyl)urea (Orinase, generic). Orinase Diagnostic was the sodium salt, which is freely soluble in water for injection, but this product was discontinued c. 2000.

Acetohexamide is 4-acetyl-*N*-[(cyclohexylamino)carbonyl]benzenesulfonamide; or 1-[(*p*-acetylphenyl)sulfonyl]-3-cyclohexylurea; or 1-(*p*-acetylbenzenesulfonyl)-3-cyclohexylurea (generic). Acetohexamide incorporates the nearly op-

timal (for potency) cyclohexyl moiety in the "right-hand" side of its molecular structure, but a *p*-acetyl substituent on the "left-side" benzene ring that decreases lipophilicity and is rapidly biotransformed by reduction to an active metabolite that is cleared relatively rapidly (see preceding discussion) independently of any P450s.

Tolazamide is *N*-[[hexahydro-1*H*-azepin-1-yl)amino]carbonyl]-4-methylbenzenesulfonamide; or 1-(hexahydro-1*H*-azepin-1-yl)-3-(*p*-tolylsulfonyl)urea; or 1-(4-methylphenylsulfonyl)-3-(hexahydro-1*H*-azepin-1-yl)urea (generic). Tolazamide incorporates a fully saturated azepine moiety that is but weakly basic, with a pK_a of ~3.³² The pK_a of the sulfonylurea group lies within the typical range; thus, in areas of the duodenum wherein the pH falls within the range of 4 to 5, the uncharged form of the drug is the predominant species, and its lipophilicity lends to rapid absorption by passive diffusion.

Chlorpropamide is 4-chloro-*N*-[(propylamino)carbonyl]benzenesulfonamide; or 1-[(*p*-chlorophenyl)sulfonyl]-3-propylurea; or 1-(*p*-chlorobenzenesulfonyl)-3-propylurea (Diabinese, generic). The *p*-chlorophenyl moiety is quite resistant to P450-mediated hydroxylations; hence, blood levels of the drug are sustained for a markedly long length of time, as aliphatic hydroxylation constitutes most of the clearance, and this happens relatively slowly. Although the ω -hydroxyl and (ω -1)-hydroxyl metabolites (the latter formed in much greater portion) exert hypoglycemic potencies not much less than does the parent drug, elimination of these by conversion

to the corresponding glucuronides occurs more rapidly than hydroxylation of chlorpropamide,³³ so blood levels of these metabolites remain low, and thus they probably do not make an appreciable contribution to the hypoglycemic action of this drug in clinical application. Removal of the entire propyl side chain (oxidative *N*-dealkylation) also occurs to a significant extent (up to 20% of an orally administered dose), creating the inactive metabolite *p*-chlorobenzenesulfonylurea, about 10% of which degrades to the corresponding benzene-sulfonamide.³⁴

Glipizide is *N*-[2-[4-[[[(cyclohexylamino)carbonyl]amino]sulfonyl]phenyl]ethyl]-5-methyl-2-pyrazinecarboxamide; this compound can also be named as the urea—see preceding discussion (Glucotrol, generic). In the United States, combinations are available with metformin (Metaglip, generic; tablets, mg glipizide/mg metformin as hydrochloride: 2.5/250, 2.5/500, 5/500). Extended-release tablets are available (Glucotrol XL, generic). The pyrazine moiety within this structure renders the molecule significantly more hydrophilic than the similar molecule glyburide, albeit also moderately less potent on a dosage as well as target-level basis.

Glyburide (glibenclamide) is 5-chloro-*N*-[2-[4-[[[(cyclohexylamino)carbonyl]amino]sulfonyl]phenyl]ethyl]-2-methoxybenzamide; this compound can also be named as the urea—see preceding discussion (Diabeta, Glynase, generic). Some tablet formulations contain micronized drug (formerly Micronase, now only generic). Combinations are available with metformin in the United States (Glucovance, generic; tablets, mg glipizide/mg metformin as hydrochloride: 1.25/250, 2.5/500, 5/500).

Glimepiride is 3-ethyl-2,5-dihydro-4-methyl-*N*-[2-[4-[[[(*trans*-4-methylcyclohexyl)amino]-carbonyl]amino]sulfonyl]phenyl]ethyl]-2-oxo-1*H*-pyrrole-1-carboxamide; this compound can also be named as the urea—see preceding discussion (Amaryl, generic). Combinations are available with rosiglitazone in the United States (Avandaryl tablets; mg glimepiride/mg rosiglitazone as maleate salt: 1/4, 2/4, 4/4, 2/8, 4/8); and with pioglitazone (Duetact tablets; mg glimepiride/ mg pioglitazone as hydrochloride salt: 2/30, 4/30).

Repaglinide is 2-ethoxy-4-[2-[[1*S*]-3-methyl-1-[2-(1-piperidinyl)phenyl]butyl]amino]-2-oxoethyl]benzoic acid (Prandin); approvals for generics are pending. Combinations are available with metformin in the United States (Prandimet), and the drug may also be coprescribed with one of the thiazolidinediones (typically pioglitazone or rosiglitazone; see previous discussion). To establish the most clinically valuable dose, the patient is titrated while monitoring blood glucose levels and hemoglobin glycosylation (HbA_{1c}) as an index of longer-term overall control.

Nateglinide (Starlix) is *D*-Phenylalanine, *N*-[[*trans*-4-(1-methylethyl)cyclohexyl]carbonyl]-; or (-)-*N*-[[*trans*-4-isopropylcyclohexyl]carbonyl]-*D*-phenylalanine. In addition to the information given previously and in Table 20.4, it is noteworthy that, although nateglinide is much less potent on a dosage basis than is repaglinide and most of the sulfonylureas, this drug seems to exhibit unique molecular pharmacodynamics. Nateglinide closes ATP-sensitive K⁺ channels some threefold more rapidly than repaglinide, and exhibits an off-rate twice as fast as that of glyburide or glimepiride and five times faster than repaglinide.³⁵ These

characteristics are reflected by the systemic pharmacodynamics of this drug, translating clinically to improved safety, among other apparent benefits.

Thiazolidinediones (Glitazones)

The thiazolidinedione class of hypoglycemic agents, which are also commonly called glitazones, are represented on the U.S. market by rosiglitazone and pioglitazone (Fig. 20.16). The 2,4-thiazolidinedione (or thiazolidine-2,4-dione) moiety is acidic (Fig. 20.17), with the glitazones exhibiting p*K*_a values near 6.5 to 6.8, and this characteristic is crucial to the target-level pharmacological activity: the negatively charged conjugate base mimics the carboxylate anion of the natural fatty acid ligands (Fig. 20.18).

On the molecular level, the glitazones are thought to mainly exert their hypoglycemic action via binding to the PPAR γ . The endogenous ligands for PPARs are free fatty acids and eicosanoids (prostaglandins and leukotrienes). The PPARs are nuclear, wherein the glitazone-PPAR γ complex binds with a retinoid X receptor (RXR). This interaction in turn causes release of corepressor protein by the RXR:HRE complex (HRE, hormone response elements), and upon recruitment of coactivator protein, interaction of the resulting multiprotein complex with DNA promotes transcription. Several biological effects result from the activation of PPAR γ , but the action of main interest here is sensitization to insulin within key tissues, including the liver, skeletal muscle, and adipose tissue.^{36,37} Induction of adiponectin synthesis may be a crucial component of this beneficial effect.^{38,39} Expression levels of PPAR γ (both subtypes—PPAR γ 1 and PPAR γ 2) are particularly high in adipose tissue, where thiazolidinediones can upregulate adipose triglyceride lipase,⁴⁰ and exert effects on the expression of several genes suggestive of significant adipose tissue remodeling.³⁷ Allowing for tissue access differences, the potency of the beneficial effects of these compounds on carbohydrate metabolism for type 2 diabetics parallels potency of agonist effect on PPAR γ . A relatively recent body of evidence indicates that pancreatic β -cell function is improved as a result of chronic treatment with PPAR γ agonists.⁴¹

Ciglitazone (see Fig. 20.16), a Takeda compound, was the first molecule of this series brought to clinical testing, from which it was withdrawn because of an elevated incidence of cataracts among patients enrolled in longer-term chronic studies. Takeda replaced ciglitazone with pioglitazone, which received Food and Drug Administration (FDA) approval (Actos) in 1999. During the same period, troglitazone was developed by Dai-ichi Sankyo and received FDA approval in January 1997. The trimethylchromanol moiety in troglitazone is the same as in the α -tocopherol form of vitamin E, and troglitazone thereby exhibits significant antioxidant activity. Unfortunately, incidence of hepatotoxicity was substantially higher for troglitazone than either rosiglitazone or pioglitazone, both of which came on the U.S. market in the summer of 1999. By this time, demarketing of troglitazone worldwide was already occurring, and the FDA issued a formal recall in the following year. A probable basis for troglitazone's hepatotoxicity, involving one or more reactive metabolites, has recently been elucidated (see succeeding discussion).

Selectivity for PPAR γ over PPAR α or PPAR δ constitutes a necessary characteristic of molecules intended to therapeutically exploit this mechanism of obtaining insulin-sensitization (although there is rationale for PPAR α activity,

Figure 20.16 • Structures of thiazolidinediones used currently or historically, or in late-stage development for treating type 2 diabetes.

and aleglitazar—see structure Fig. 20.18—is a dual PPAR γ /PPAR α agonist currently in clinical trials). Extensive x-ray crystallographic, nuclear magnetic resonance (NMR), and computational chemistry studies provided an understanding that the thiazolidinedione ring not only constitutes a carboxylate anion isostere in receptor binding, but also that a network of hydrogen bonds to complementary side chain moieties of Ser-289, His-323, Tyr-473, and His-449 accounts for the PPAR γ selectivity. Moreover, NMR studies suggest that agonist binding selects among a set of interchanging ligand-binding domain (LBD) conformations (i.e., the LBD region is mobile in the aporeceptor), bestowing a conformation that enables the coactivator recruitment necessary for promoting transcription, over conformations that are not enabling.^{42–44} In PPAR α , the residue corresponding to His-323 is instead a prohibitively positioned tyrosine, and in PPAR δ the binding pocket is too narrow to accommodate the thiazolidinedione ring or substituents α to the acidic moiety, such as occurs in aleglitazar (structure Fig. 20.18). Structure–activity relationships for PPAR γ ligands have been extensively investigated,¹¹ and many originally empirical observations can now be readily explained based on the knowledge of the binding-pocket structure as discussed previously.

Rosiglitazone and pioglitazone are formulated as their salts (maleate and hydrochloride, respectively). The salts are much more water soluble than the parent acids, conferring rapid dissolution of the drug upon disintegration of a tablet in

the stomach. Although the monosubstitution at C5 of the thiazolidinedione ring allows for stereoisomers, interconversion is rapid under physiological conditions, caused by the acidity of the hydrogen at this position, and drugs of this class are therefore sold as racemates. Besides the two products in the list that follows, agents of the thiazolidine class in later stages of clinical development include netoglitazone (RWJ 241947, also known as isaglitazone, MCC 555) and rivoglitazone.⁴⁵

PRODUCTS (SEE ALSO TABLE 20.5)

Rosiglitazone is 5-[4-[2-(*N*-methyl-*N*-(2-pyridyl)amino)ethoxy]benzyl]thiazolidine-2,4-dione, and is available as the maleate salt in tablets containing the drug alone (Avandia) or in combination products with metformin (Avandamet) or with glimepiride (Avandaryl). The 2-aminopyridine moiety allows for salt formation; the marketed formulations contain the 1:1 salt with maleic acid, in which the pyridine nitrogen accepts a proton, forming the 2-aminopyridinium species.

Although rosiglitazone is extensively biotransformed—essentially no unchanged drug appears in urine or feces—in humans, only ~35% of the administered radioactivity was recovered within 48 hours, and more than a week was required to reach 90% recovery.⁴⁶ The major routes of biotransformation (Fig. 20.19) are *N*-demethylation and hydroxylation of the pyridine ring *para* to the amino nitrogen, with CYP2C8

hsa, human serum albumin.

playing the major role in both transformations, and some involvement of CYP2C9.^{21,47} The sulfate conjugate M10 is the predominant circulating metabolite by 4-hour postdose. The extraordinarily high plasma protein binding of this metabolite (and the *N*-demethylated sulfate conjugate M4) in humans accounts for the lengthy residence time of the radioactivity in the

body, despite the relatively short pharmacokinetic half-life (4–4.5 hours) of rosiglitazone itself.

Pioglitazone is 5-(4-[2-(5-ethylpyridin-2-yl)ethoxy]benzyl)thiazolidine-2,4-dione, and is available in tablets containing the hydrochloride salt alone (Actos in the United

States, Glustin in Europe and Zactos in Mexico), or in combination with glimepiride (Duetact, see “Glimepiride” previously in this chapter) or metformin (Actoplus Met; see under “Metformin” later in this chapter).

Pioglitazone is extensively biotransformed,^{48–50} and at least three metabolites are known to be pharmacologically active, although only two of these (M-IV and M-III, see Fig. 20.20) are thought to significantly contribute to the therapeutic effects.⁵¹ CYP2C8 and CYP3A4 predominantly account for the observed biotransformations, with the former playing a greater role. Ring-opened metabolites (M-X, M-A) have also been identified in human liver mi-

crocytes,⁴⁸ but although the pathway leading to these may play a role in the hepatotoxicity of troglitazone, pioglitazone seems not to have the same liability to any significant extent, most likely because the pioglitazone doses are sufficiently lower (by about 10-fold) than those that had been needed with troglitazone.

Biguanides

The biguanide class of insulin-sensitizing agents includes only one marketed medicinal in the United States, namely metformin (Fig. 20.21), but this drug is a first-line drug in the

Figure 20.21 • Structures of biguanide hypoglycemic agents.

treatment of type 2 diabetes, for which it is prescribed heavily, alone and in combinations. Having been brought to market in France in 1979 (though not until 1995 in the United States), metformin has a long history of use, despite which fact the mechanisms underlying its effects remain uncertain.^{52–56} Activation by metformin of adenosine monophosphate-activated protein kinase (AMPK) has commonly been stated as the molecular mechanism in recent years; however, the as-yet-to-be-identified primary target(s) must either be upstream of AMPK, or trigger downstream mechanisms that deliver stimulatory feedback upstream of AMPK, or cause changes in crosstalk mechanisms (such as those involving insulin receptor substrate 1) to indirectly enhance AMPK action, or some combination thereof. A month of chronic metformin therapy increases basal levels of protein kinase C type zeta (PKC ζ) in the muscle tissue of type 2 diabetics, in turn restoring glucose handling to a more normal state,^{57,58} and PKC ζ acts through serine-threonine kinase 11 (STK11/LKB1) to modulate AMPK activity;⁵⁵ however, PKC ζ is clearly not the direct macromolecular target of metformin, either. Some evidence suggests that subtle

metformin-caused changes in mitochondrial membrane potential may circuitously bring about the beneficial collateral changes in other pathways, including the aforementioned PKC ζ →STK11→AMPK signaling chain; metformin inhibits complex I (NADH:ubiquinone dehydrogenase) of the electron transport chain.^{59,60} In any case, over a period of weeks, metformin enhances the sensitivity of various cells of the body to insulin. Recently, much activity has centered on fully characterizing the roles of the organic cation transporter 1 (OCT1), the functioning of which is clearly essential to metformin's action.⁶¹ Presumably, this transporter allows the drug to reach its intracellular target(s), and pharmacogenomic variations with respect to the OCT1 complex that decrease or abolish the effectiveness of metformin have been identified.^{61,62} OCT1 is richly expressed in those hepatocytes participating most directly in the regulation of glucose levels.

The bioavailability of metformin at normal clinical doses ranges from 40% to 60%, which is quite high for such an extensively ionized and hydrophilic drug (calculated log D ~ -6 at pH 7)⁶³; the biguanide moiety is extremely basic (Fig. 20.22), thus, metformin exists almost

Figure 20.22 • Biguanides: basis of the “biguanide” designation, tautomeric forms of the protonated species, and canonical (resonance) structures representing delocalization of the positive charge in the conjugate acid.

exclusively as protonated, positively charged molecular species throughout the entire physiological pH range. Absorption from the gut was recently shown to occur by a paracellular route, which, surprisingly, was found to be saturable;⁶⁴ the exact molecular basis for this observation, if yet known, has not been reported. Renal elimination is also transporter mediated (active tubular secretion). Elimination of absorbed metformin is essentially 100% by the kidneys, at a rate about 3.5-fold creatinine clearance, thus renal insufficiency precludes metformin pharmacotherapy because of the resultant risk of lactic acidosis that otherwise essentially never occurs with this drug. Other drugs of this class (phenformin, buformin, structures Fig. 20.21) were abandoned because of lactic acidosis-linked fatalities, even though the incidence with phenformin was actually quite rare. Little metformin binding to plasma proteins occurs, but partitioning into erythrocytes is considerable, significantly impacting the PK of this drug.

Metformin is *N,N*-dimethylimidodicarbonimidic diamide, but can accurately and much more simply be named as 1,1-dimethylbiguanide. Metformin is available, as its hydrochloride salt, in tablets ranging in strengths from 500-mg to 1-g (Glucophage, numerous generics), extended-release tablets (Fortamet, Glumetza), and an oral solution (Riomet); and in combinations with rosiglitazone (Avandamet), pioglitazone (Actoplus Met), glipizide (Metaglip, generics), glyburide (Glucovance), repaglinide (Prandimet), and most recently, sitagliptin (Janumet).

α -Glucosidase Inhibitors

Medicinals acting as α -glucosidase inhibitors slow the breakdown of disaccharides (notably sucrose) and starch-

derived polysaccharides into monosaccharides in the gastrointestinal (GI) tract, delaying production and thereby absorption of glucose following consumption of meals. This approach to reducing peak postprandial serum glucose levels is highly effective, with the caveat that these drugs cause very uncomfortable GI side effects in a high percentage of patients; fortunately, artful inception of therapy, with monitoring, can greatly reduce the impact of this liability. The α -glucosidase inhibitors marketed in the United States include acarbose and miglitol; an additional α -glucosidase inhibitor, voglibose, is marketed in Japan and several other countries including Brazil (structures Fig. 20.23).

Digestion of amylose and amylopectin forms of starch begins with reactions catalyzed by a pair of related α -amylases, which are endoglucosidase enzymes contained in pancreatic secretions. Complete digestion also requires debranching for amylopectin, and further cleavage of various disaccharides and small oligosaccharides. These reactions are catalyzed by α -glucosidases, which are a highly similar set of enzymes that cleave the glycoside linkage between particular sugar moieties; more specifically, hydrolysis occurs at the acetal oxygen bridging the C1 of a glucose residue and either C4 or C6 of another glucose in α -(1 \rightarrow 4) or α -(1 \rightarrow 6) linkage (maltose or isomaltose, respectively; see Fig. 20.24), but not β -(1 \rightarrow 4) glucose–glucose linkages (as in cellobiose) or the β -(1 \rightarrow 4) galactose–glucose linkage in lactose. α -Glucosidases are exoglycosidases, cleaving terminal glucose residues from the nonreducing end of an oligosaccharide. Four separate maltase enzymes found in the luminal membrane of enterocytes (more specifically, the brush-border epithelial cells) actually constitute these activities: two associated with “sucrase-isomaltase” (SI)

Figure 20.23 • Structures of antihyperglycemic α -glucosidase inhibitors on the market worldwide.

Figure 20.24 • Polysaccharide linkages of relevance to the actions of α -glucosidase inhibitors, and the relationship of inhibitor structures to postulated high-energy intermediates in the hydrolysis of the disaccharide bonds.

activity and two with “maltase–glucoamylase” (MGAM) activity.^{65,66} The sucrase activity represents catalytic hydrolysis of the $\alpha(1\rightarrow2)$ linkage between glucose C1 and fructose C2 in sucrose.

Acarbose potently and competitively inhibits the MGAM activity,⁶⁶ and more specifically, the glucoamylase—but not the maltase—activity.⁶⁷ The former activity was recently shown to reside within the C-terminal subunit of the enzyme, which extends into the intestinal lumen, and to which acarbose binds with considerably higher affinity than it does to the N-terminal subunit.⁶⁸ The latter subunit is mostly membrane-imbedded, although both subunits are catalytically active and are closely related members of the glycosyl hydrolase family 31. Miglitol potently inhibits glucoamylase and sucrase activities, but not isomaltase activity.⁶⁹ Voglibose inhibits sucrase and maltase activities⁷⁰ with such potency that clinically effective doses of voglibose are more than 100-fold lesser than the doses required for acarbose or miglitol.

Structure–activity relationships for molecules inhibiting α -glucosidases were extensively reviewed in 1996 by Junge et al.⁷¹; however, interpretations are complicated by substrate-dependent inhibitor binding and inhibition kinetics for these enzymes. These complexities are now understood to arise, in part, as manifestations of allosteric crosstalk between binding sites in these multisubunit enzymes.^{68,72}

PRODUCTS

Acarbose is *O*-4,6-dideoxy-4-[[*(1S,4R,5S,6S)*-4,5,6-trihydroxy-3-(hydroxymethyl)-2-cyclohexen-1-yl]amino]- α -D-glucopyranosyl-(1 \rightarrow 4)-*O*- α -D-glucopyranosyl-(1 \rightarrow 4)-D-glucose. It is sold as 25-, 50-, and 100-mg tablets (Precose, generics) dosed with the first bite of each meal, up to t.i.d. Acarbose potently inhibits the glucoamylase activity of MGAM α -glucosidases and the sucrase activity of SI α -glucosidases, whereas isomaltase activity is at most moderately inhibited at concentrations in the range of those in the intestinal lumen upon oral dosing, and trehalase and lactase are not significantly inhibited.⁷³ Some inhibition of pancreatic α -amylases may also contribute to the clinical effects.

Based on the structure of acarbose, it should come as no surprise that little intact acarbose reaches the systemic circulation; instead, acarbose is extensively biotransformed by the action of microbes and digestive enzymes in the gut. Only about 35% of the radioactivity in a dose of ¹⁴C-labeled acarbose administered orally to men was excreted in the urine, appearing as several metabolites, some of which are phase II conversion products of 4-methylpyrogallol (*O*-methyl, *O*-sulfate, or *O*-glucuronide conjugates)⁷⁴; the methylpyrogallol fragment arises from the terminal valienamine pseudosugar. That these biotransformation products are mostly formed in the gut is shown by the fact that nearly 90% of an intravenously administered dose of acarbose is excreted intact in urine.

the periphery, if any, remain poorly characterized.⁸¹ Unsurprisingly, though, the appetite-suppressing actions, and benefits of pramlintide and amylin agonists in general, are receiving significant clinical and scientific attention.

Pramlintide has a relatively short pharmacokinetic half-life of about 50 minutes. One conversion product, *des*-Lys¹-pramlintide, retains full agonist activity and exhibits an elimination time-course similar to that of pramlintide itself. Amylin is degraded by IDE at three sites (as indicated in Fig. 20.25); in vivo administration of IDE inhibitors increases toxicities of the same nature as those associated with excessive endogenous or exogenously administered amylin.⁸² Pramlintide possesses amino acid residue pairs identical with those of amylin at each of the IDE cleavage sites, thus this enzyme probably governs the elimination rates of pramlintide and *des*-Lys¹-pramlintide.

Despite the fact that pramlintide is a relatively large and clearly nonnative polypeptide, systemic immunosensitivity has not proven to be an issue of clinical concern, even upon long-term pramlintide pharmacotherapy.

Incretin System Modulating Agents: Incretin Mimetics and Dipeptidyl Peptidase Type 4 Inhibitors

Several polypeptide hormones have been identified that are synthesized in the cells of the upper intestines and act to

modulate carbohydrate metabolism. Among these are the *incretins*, a term first coined by La Barre in 1932.⁸³ The “incretin effect” refers to insulin secretion stimulated by orally administered glucose independent of any increase in blood glucose. Eventually, two incretins were identified, in 1971 and 1985, respectively: glucose-dependent insulinotropic peptide (GIP) and GLP-1.⁸⁴ GIP was originally named gastric inhibitory peptide by its discoverers,⁸⁵ but it was later renamed in such a way as to retain the acronym while better reflecting its physiological roles.

The gene encoding proglucagon (PG), besides being expressed in pancreatic islet α cells (and in some neurons in the hypothalamus and brainstem, and certain taste cells of the tongue), is also expressed in endocrine cells of the lower intestinal mucosa. From PG, gut L cells produce the peptides glicentin, oxyntomodulin, intervening peptide-2, and GLP-1. PG(72–108) is equivalent to GLP-1(1–37), and is derived from PG via the action of the convertase PC1/3. GLP-1(1–37) is further shortened, apparently also by PC1/3, to GLP-1(7–37) or GLP-1(7–36)amide (Fig. 20.26); at least 80% of “GLP-1” released into the bloodstream is the latter. Secretion occurs upon ingestion of lipid- or carbohydrate-containing foodstuffs.^{86–88} Following their release, both bioactive forms of GLP-1 are very short-lived (plasma $t_{1/2}$ ~1–2 min): DPP-4 or DPP-IV rapidly cleaves two residues from the amino terminus, generating GLP-1(9–37) and GLP-1(9–36)amide, respectively.⁸⁸ Release of

Figure 20.26 • Primary sequences of endogenous human incretins and incretin mimetic pharmacotherapeutic agents. Arrows indicate a peptide bond cleaved by DPP-4 catalysis, carets (^) indicate sites of cleavage by neutral endopeptidase 24.11 (neprilysin) catalysis (double-caret-marked bonds are likely more prominently cleaved). Underscored residues in the structure of exenatide indicate nonconservative substitutions versus GLP-1 or GIP. The numbering for GLP-1 is “slipped” by six residues; the corresponding numberings are given below the GIP structure for reference. (HSA, human serum albumin.)

the bioactive forms of GLP occurs within minutes of food intake, even though L cells are found predominantly in the ileum and caecum, and considerable evidence indicates that some combination of neural or endocrine signaling mediates this response. GLP-1 acts via specific GPCRs in the portal vein to trigger vagal afferents that, mediated by neuronal pathways within the brain, generate efferent signals stimulating pancreatic insulin release and inhibiting glucagon release.⁸⁹ GPCRs for GLP-1 (GLP-1Rs) are also expressed in pancreatic islet β cells, as well as in the GI tract, kidney, vagus nerve, and neurons in areas of the brain, including the hypothalamus and hindbrain; in β -islet cells, agonist binding to GLP-1Rs increases the biosynthesis of insulin, as well as of glucokinase and the GLUT2 glucose transporter.⁹⁰

Structure–activity studies indicate that the C-terminal portions of the GLP-1 peptides provide an important component of receptor binding, whereas the N-terminal segment is necessary for receptor activation.⁹¹ Accordingly, once DPP-4 removes the N-terminal dipeptide from either GLP-1(7–37) or GLP-1(7–36)NH₂, agonist activity is lost. GLP-1(9–36)NH₂ finds some use as a pharmacological tool for its antagonist activity at GLP-1Rs.

GIP is synthesized via the action of a prohormone convertase on a 153-amino-acid proprotein coded by a specific gene in gut K cells, which are found mainly in the mucosa of the duodenum and jejunum.⁸⁴ In contrast to the mostly indirect stimulation of GLP-1 release, GIP secretion is mainly triggered directly by the enteral presence of glucose and lipids, providing what amounts to an early warning system for the pancreas. The bioactive GIP(1–42) is rapidly converted (plasma $t_{1/2}$ ~5–7 min) to inactive GIP(3–42). Like the two GLP-1 hormones, this inactivation is also effected via DPP-4 catalyzed cleavage of a dipeptide from the amino terminus.⁹² GIP activates insulin secretion via binding to seven-transmembrane-segment GPCRs on islet β cells, distinct receptors from those activated by GLP-1(7–37) and GLP-1(7–36)NH₂.⁸⁸ GIP-stimulated insulin secretion only occurs when blood glucose is substantively elevated, and receptor knockout studies in mice indicate that GIP receptors (GIPRs, which are also present in brain, pituitary, adipocytes, upper GI tract, adrenal cortex, and bone) are required for a proper gluconormative response to hyperglycemia. Notably, in type 2 diabetics, exogenously administered (iv) GIP cannot facilitate glucose-stimulated insulin secretion as it does in healthy patients.

Relatively recently, compelling direct evidence from rodent and in vitro experimentation and some indirect but inconclusive evidence from human clinical studies of incretin mimetics (see discussion that follows) and DPP-4 inhibitors suggests that incretins may exert preservative, proliferative, and even neogenerative effects on β -cell mass and β -cell populations, thereby arresting—and potentially even reversing—the progressive declines that have, heretofore, been inevitable in type 2 diabetes.^{90,93} If so, a truly new age in the treatment of this common and insidious disorder has begun, particularly when technology allows reliable detection of prediabetic states amenable to prophylactic treatment.

Exenatide, at the time of this writing, is currently the only incretin mimetic approved (2005) for the U.S. market (Byetta, Amylin Pharmaceuticals). Exenatide must be

administered parenterally (subcutaneous [sc]); injection is typically made in the abdomen about an hour before the first and last meals of the day. Exenatide is synthetically produced exendin-4, a 39-residue hormone (see Fig. 20.26) present in the venom of the Gila monster. Exenatide's actions mimic those of GLP-1; exenatide differs from GLP-1 in 14 of its first 30 amino acids (the length of GLP-1(7–36)NH₂), although at least four of these substitutions may be regarded as conservative. Exenatide is not, however, a DPP-4 substrate, by virtue of the presence of a glycine rather than an alanine in the second position, and partly for this reason has a greatly increased serum half-life of 2 to 3 hours⁹⁴; some of the other amino acid changes almost certainly also render exenatide less susceptible to neutral endopeptidase 24.11 (NEP-24.11),⁹⁵ which is a membrane-bound zinc metallopeptidase also known as neprilysin, and which may account for as much as half of the elimination of GLP-1(7–37) and GLP-1(7–36)NH₂. Although approved as adjunctive therapy (with metformin, or with a sulfonylurea, or with metformin + a sulfonylurea, or with metformin + a thiazolidinedione), in fact none of these other medicinals are necessary for exenatide to produce its clinically beneficial effects. Exenatide administration alone in pharmacological doses restores the early stage insulin release, loss of which is a hallmark of type 2 diabetes, and increases the robustness of the second-stage insulin release. Pre-meal exenatide injections (5 or 10 μ g) also suppress glucagon release following a meal (but do not affect normal hypoglycemia-stimulated glucagon release), slow gastric emptying, induce satiety, and promote normalcy of postprandial glucose uptake while suppressing hepatic glucose release. Moreover, the glucose dependency of exenatide-stimulated insulin secretion means that this drug cannot cause abnormal hypoglycemic episodes, although this can, of course, happen when the drug is adjunctive to a sulfonylurea. Although there are GLP-1 receptors expressed in hindbrain and hypothalamus that are probably involved in mediating exenatide-induced satiety effects, evidence suggests that direct agonist action on these receptors by circulating exenatide is likely not involved.⁹⁶

Liraglutide is GLP-1(1–37) modified at Lys²⁶: the ϵ -amino group is acylated with an (*N*-hexadecanoyl)glutam- γ -yl moiety (Fig. 20.26) that noncovalently but avidly binds to human serum albumin. (Also, Lys³⁴ is conservatively replaced with Arg.) These changes provide for a greatly extended serum $t_{1/2}$ of ~10 to 15 hours after sc administration (0.6–1.8 mg), allowing for once-daily dosing.^{97–99} Liraglutide (Victoza, Novo Nordisk) is awaiting approval by the FDA, EMEA, and the Kōrō-shō (Japan).

Albiglutide (also known as naliglutide, GSK 716155) is a sequential dimer of GLP-1(7–36)(Ala⁸→Gly) covalently linked to modified human serum albumin (i.e., it is a “fusion protein” with modified HSA). This molecule is currently well into phase III clinical trials. Although albiglutide, if marketed (Syncria, GlaxoSmithKline), will—like exenatide—be administered by injection, the half-life and duration of 6 to 7 days¹⁰⁰ would allow for weekly administration.

Taspoglutide (R1583, Roche) is GLP-1 modified at residues 8 and 35 (see Fig. 20.26) with α -methylalanine in

place of the Ala and Gly, respectively. These modifications greatly retard degradation by DPP-IV and neutral endopeptidase 24.11, respectively (see preceding discussion for exenatide). The phase III trials, which commenced in 2008, are being conducted with a zinc-based preparation, prolonging the duration in a manner similar to zinc-containing insulin preparations, so that once-weekly injections of 20 to 30 mg will be possible.

Besides the aforementioned list of products, a number of other incretin mimetics are being created and developed. A long-acting version of exenatide ("exenatide LAR") consisting of microspheres of a poly(lactide-coglycolide) polymeric matrix has been devised, from which exenatide is slowly released from the injection site through diffusion and erosion.¹⁰¹ An adenoviral vector has also been created for exenatide "gene therapy," and was reported to successfully generate exenatide and modulate glucose control and other GLP-1-mediated responses in mice for at least 15 weeks following treatment¹⁰²; other gene therapy approaches for delivering GLP-1 itself are also being explored. Boc5,¹⁰³ a cyclobutanedicarboxylic acid (CAS Reg. No. 917569-14-3, structure still undisclosed), is reported to be a nonpeptide GLP-1 agonist exerting incretin effects in C57BL/6J and *db/db* mice. The variety of the developments described above provide some sense of the current level of interest in incretin mimetics among researchers and clinicians, interest undoubtedly based on perceived strength of promise. The relative merits of incretin receptor agonists as compared to the indirect incretin-enhancing approach achieved with inhibitors of DPP-IV (discussed next) or neutral endopeptidase 24.11 largely remain to be discerned, which will likely happen during the coming decade or so.

DPP-4 or DPP-IV is a serine protease that selectively binds and hydrolyzes substrates that incorporate alanine (as in GLP(7–36)NH₂, see earlier discussion and Fig. 20.26) or proline (as in neuropeptide Y and peptide YY) at the second position. Because there are many serine proteases, excellent selectivity is an essential design feature requisite to bestowing pharmacotherapeutic usefulness.¹⁰⁴ In particular, minimizing inhibition of the closely related enzymes DPP-2, fibroblast activation protein (FAP), DPP-7 (also known as quiescent cell proline peptidase, QPP), DPP-8, and DPP-9 has proved to be crucial.^{105,106} These serine proteases are among a relatively few peptidases that can cleave at proline, and they do so on the carboxyl side. Human DPP-4 is a 766-amino-acid transmembrane glycoprotein and a member of peptidase clan SC, and more specifically a member of family S9, subfamily S9B. Clan SC serine proteases include a catalytic triad in the specific order Ser, Asp, His—different from the classical serine proteases such as trypsin (class SA: His, Asp, Ser) or subtilisin (class SB: Asp, His, Ser).

DPP-4 was first identified in 1967, and early inhibitors were created by relatively simple modifications of proline-based structures. After the later realization that this enzyme might likely be an important pharmacotherapeutic target, compound library screening provided inhibitors with a variety of new base structures, including the lead compound from which sitagliptin was created (Fig. 20.27). In due course, a significant number of x-ray crystal structures were generated, for complexes in which the catalytic pocket is occupied with various inhibitors, the first two reports occurring in

2003.^{107,108} This body of structural information very quickly grew to be sufficient to enable true de novo structure-based drug design; an excellent overview is provided by Kuhn et al.¹⁰⁹ The catalytic site of DPP-4 is extracellular, and includes an α/β -hydrolase fold containing the Ser⁶³⁰-Asp⁷⁰⁸-His⁷⁴⁰ catalytic triad, and an eight-bladed β -propeller domain¹⁰⁸ that participates in the binding of various known inhibitors, including sitagliptin.¹⁰⁹ The S1 pocket within the protein, which accommodates proline (or, less favorably, alanine, as is found in the GLP-1 peptides and in GIP), is enclosed by the largely hydrophobic residues Tyr⁶³¹, Val⁶⁵⁶, Trp⁶⁶², Tyr⁶⁶⁶, and Val⁷¹¹, and among the reported x-ray structures of enzyme:inhibitor complexes the shape of this pocket changes very little, even for structurally very disparate inhibitors.

The discovery of sitagliptin at Merck preceded the availability of x-ray structures, and was accomplished by more classical (albeit highly refined) screening and lead-optimization approaches. Thornberry and Weber¹⁰⁶ provide an informative account of this process. Although initially commencing with preclinical development of in-licensed compounds, extensive screening of a very large compound collection was also conducted c. 2001, from which effort these authors report that relatively few hits—and only three suitable leads—were gleaned. Sitagliptin was ultimately created (Fig. 20.27) from one of these leads, which was a β -amino acid derivative and thus unlike the α -amino-acid-based compounds divulged prior to this discovery. The in-licensed compounds were abandoned at about the same time because of toxicities that were found to be traceable to DPP-8 or DPP-9 inhibition; the existence of these enzymes, as well as of QPP (see previous discussion), were first reported circa this same time frame. Some characteristics of a few of the "way-station" compounds created during the lead optimization process that led to sitagliptin provide a sense of the process, particularly the large changes in target-level activity, biopharmaceutics characteristics, and deleterious effects profile, which can result from seemingly very subtle changes to the molecular structure. The necessity to monitor and optimize multiple characteristics simultaneously (such as target affinity and oral bioavailability) during the process of creating a marketable drug should also be readily apparent from this outline. Sufficient preclinical studies were completed for sitagliptin by January 2002 that it was moved to first priority for development. (Marketing approval was obtained from the FDA in late 2006, representing an impressively and exceptionally compressed timeline from screening hit identification to marketing.)

An x-ray structure of DPP-4 with bound sitagliptin later provided an understanding of the structure–affinity observations.¹¹⁰ The trifluorophenyl moiety occupies the S1 pocket. The triazolopyrazine-ring-attached trifluoromethyl substituent—where a buildup of electron density occurs—situates near the positively charged side chain of Arg³⁵⁸; the protonated (cationic) form of the primary amino group forms a hydrogen bond with Tyr⁶⁶², and salt bridges to the γ -carboxylates of Glu²⁰⁵ and Glu²⁰⁶; the triazolopiperazine group engages the phenyl group of residue Phe³⁵⁷.

Other DPP-4 inhibitors are either on the market elsewhere (vildagliptin in the EU, Novartis [Galvus]), or are under regulatory review (alogliptin, Takeda; saxagliptin,

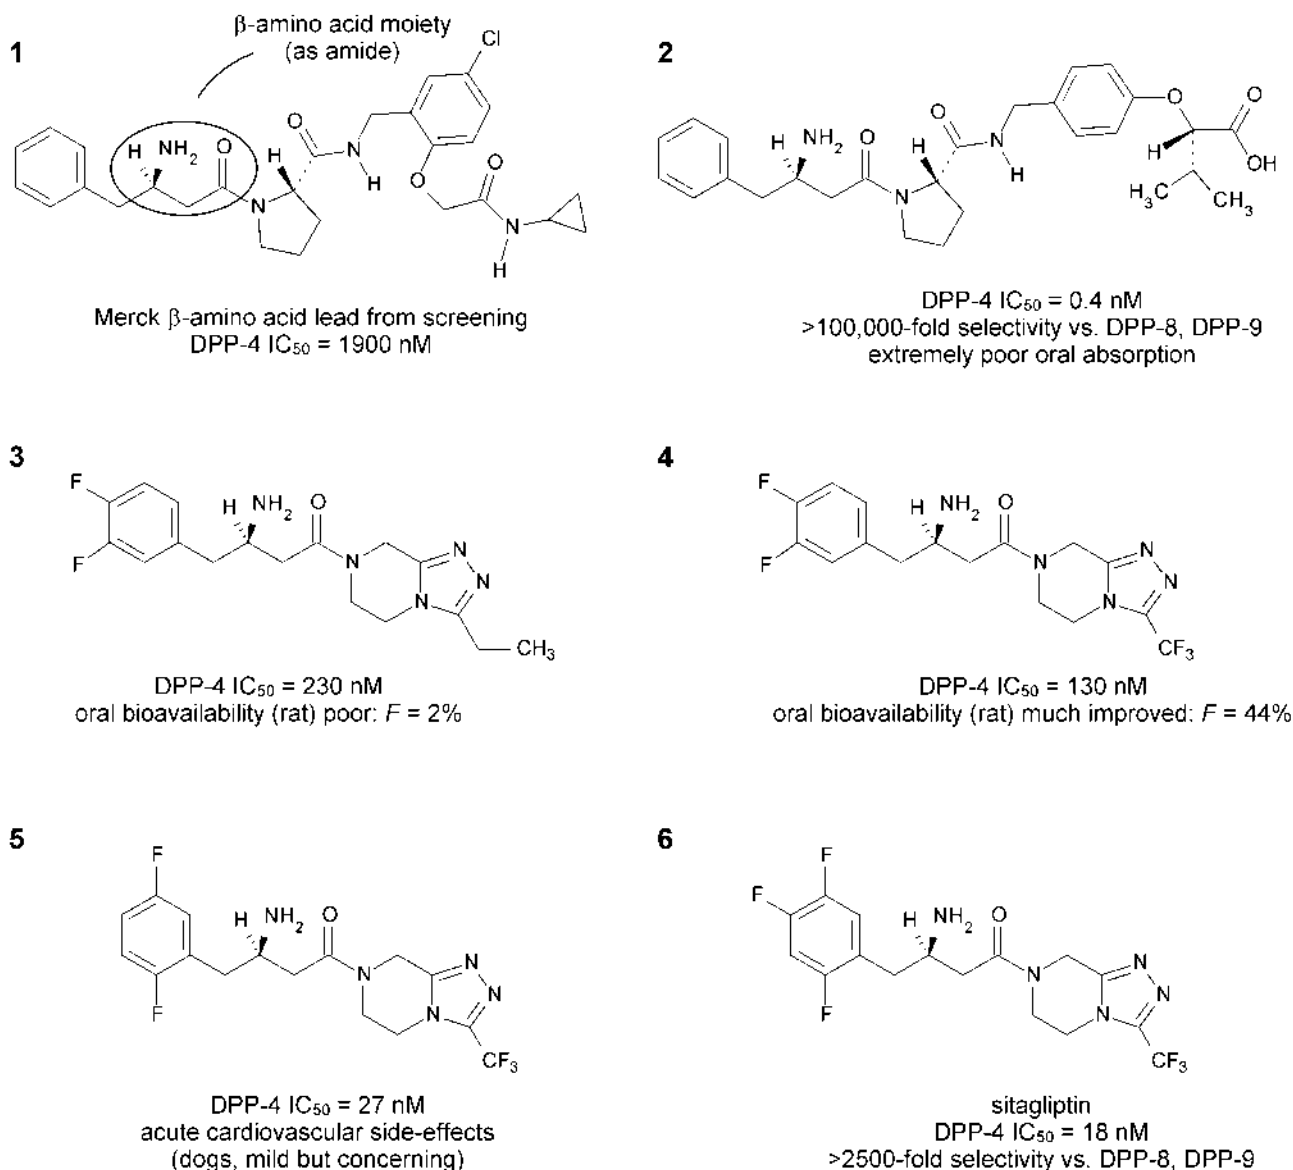

Figure 20.27 • Sitagliptin creation outline. The β -amino acid–lead compound (1) was discovered by screening of a large library of compounds. Compound 2 bound with very high affinity to the enzyme but was not endowed with useful oral bioavailability. Changing the metabolically labile ethyl substituent in compound 3 to trifluoromethyl gave a compound (4) with acceptable bioavailability, albeit binding with considerably lower affinity than molecule 2. Relocating the fluorines on the phenyl ring improved the binding affinity but a cardiovascular side effect appeared in preclinical studies of 5 in dogs. Adding one additional fluorine increased the affinity and eliminated the worrisome preclinical side effect; molecule 6 was ultimately marketed as sitagliptin phosphate.

Bristol Myers Squibb [Onglyza]),¹¹¹ or are well along in phase III studies (linagliptin, Boehringer Ingelheim). Three of these (Fig. 20.28) incorporate a nitrile (cyano) moiety: vildagliptin and saxagliptin a 2-cyanopyrrolidine, alogliptin a 2-cyanophenyl. In each case, the nitrile engages the enzyme at the same position as does the scissile bond in peptide substrates such as GLP-1 or GIP. The nitrile group is attacked by the hydroxyl of the catalytic serine (Ser⁶³⁰), forming a covalent imidate species (Fig. 20.29). Hydrolysis of this imidate occurs slowly; thus, these inhibitors may be described as slowly reversible or pseudoirreversible.

Sitagliptin phosphate is the 1:1 phosphoric acid salt of sitagliptin free base (i.e., (2*R*)-4-oxo-4-[3-(trifluoromethyl)-5,6-dihydro[1,2,4]triazolo[4,3-*a*]pyrazin-7(8*H*)-yl]-1-(2,4,5-trifluorophenyl)-2-butanamine), see Figure 20.30, and is marketed (Januvia, 2006) in 25-, 50-, and 100-mg tablets. A combination product with metformin (Janumet, 2007) in two strengths (50 mg/500 mg and 50 mg/1,000 mg sitagliptin/metformin) is also available, and sitagliptin may also be prescribed with a thiazolidinedione, or possibly a sulfonylurea. The phosphate salt provides very high water solubility.¹¹² The bioavailability of orally administered sitagliptin is ~87%.¹¹³ The drug exhibits relatively low plasma protein

Figure 20.28 • Structures of DPP-4 inhibitors on the global market or in advanced stages of clinical development.

binding (~38%), a relatively large volume of distribution (198 L), and a terminal elimination half-life of ~12 hours. About 79% of a 100-mg oral dose is excreted unchanged in urine, the balance as trace-level metabolites (CYP3A4, lesser contribution by CYP2C8) in urine or feces: 87% of administered radioactivity is excreted in urine, and 13% in feces. Active tubular excretion is reported to play a key role in renal clearance of unchanged drug, and may be mediated at least in part via the organic anion transporter hOAT-3.

Glucose Elevating Agents

Apart from administration of glucose, either glucagon (rDNA origin) or diazoxide represent therapeutic options for

pharmacotherapy of hypoglycemia. Applications are limited and specialized, as will be discussed here.

Glucagon produced by recombinant DNA technology is marketed by Novo Nordisk (glucagon [recombinant] hydrochloride, GlucaGen HypoKit, GlucaGen Diagnostic Kit) and by Eli Lilly (glucagon [recombinant] Emergency Kit). Details regarding the structure and chemistry of this 29-amino-acid peptide are available in Chapter 27. As discussed earlier in this chapter, endogenous glucagon is produced from the gene-derived protein PG in the α cells of the islets of Langerhans in the pancreas. The core function of this hormone is to renormalize blood glucose levels when they fall too low, by stimulating production from glycogen

stores in liver and muscle, and stimulating hepatic gluconeogenesis. Glucagon also elicits biochemical processes (such as fatty acid oxidation) that supply the needed precursors for gluconeogenesis. Glucagon supplied exogenously (i.e., injected) in response to emergency hypoglycemia acts rapidly to elicit these same responses. Clinically, glucagon also provides an alternative to cholinergic antagonists for reducing GI motility and secretory activity during radiologic imaging procedures.

Diazoxide is 7-chloro-3-methyl-4*H*-benzo[*e*][1,2,4]thiadiazine-1,1-dioxide (structure Fig. 20.31), and is currently available in the United States only as a 50-mg/mL oral suspension (Proglycem); discontinued formulations included capsules for oral administration, and injectable forms that typically found use for indications other than hypoglycemic conditions. Diazoxide is a cyclic benzenesulfonamide, although the free acid in solution can exist in three tautomeric forms, and the 4*H* tautomer most likely predominates to a very high proportion.¹¹⁴ Partly because of the additional nitrogen in the quinazoline ring structure, the molecule is somewhat more acidic ($pK_a \sim 8.4$,¹¹⁵ 8.6¹¹⁶) than benzenesulfonamide ($pK_a \sim 10$).

Diazoxide acts as an ATP-sensitive potassium channel opener, thus inhibiting basal insulin secretion. This action may be viewed as the reverse of the insulin secretagogue actions of the sulfonyleureas discussed earlier in this chapter; however, diazoxide is much less selective for SUR_1 over SUR_{2A} , SUR_{2B} , or SUR_{2C} receptor types,¹¹⁷ acts on mitochondrial ATP-sensitive potassium channels,¹¹⁸ and exerts various extrapancreatic effects that will not be discussed here.¹¹⁹ The action of diazoxide on β -islet cells may trigger glucagon release from α -islet cells via paracrine pathways.¹²⁰

Structurally, diazoxide closely resembles (Fig. 20.31) hydrochlorothiazide, a diuretic that inhibits the sodium chloride symporter in the distal convoluted tubule. Diazoxide does not act as a diuretic, however, instead exerting an antidiuretic effect. The discovery/creation/development of pancreas-selective ATP-sensitive potassium channel openers continues to be an area of ongoing investigation.^{121–123}

Diazoxide binds extensively (>90%) to serum proteins, which greatly retards its renal excretion, by which route this drug is almost exclusively eliminated, with a terminal elimination half-life about 28 ± 8 hours. Lacking this serum binding (or active tubular reuptake), the hydrophilicity of this molecule would otherwise confer a much more rapid rate of renal excretion.

In contrast to the acute clinical uses of glucagon, diazoxide finds use in chronic hypoglycemic conditions: inoperable islet cell adenoma or carcinomas, extrapancreatic malignancies of insulin-secreting cells, or islet cell hyperplasias. In children, additional indications include congenital hyperinsulinemia¹²⁴ and leucine sensitivity. Experimentally, diazoxide is among an array of ATP-sensitive potassium channel openers being studied for intermittently bringing about β -cell rest (see discussion of β -cell “fatigue” earlier in this chapter).¹²⁵

• GONADOTROPINS, GONADOTROPIN-RELEASING HORMONE, AND GNRH RECEPTOR AGONISTS AND ANTAGONISTS

As discussed elsewhere in this book (Chapters 25 and 27), the term *gonadotropin* encompasses three large-peptide

Figure 20.31 • Diazoxide structure. The 4H structure shown predominates in dimethylsulfoxide and is thought to predominate in aqueous solutions (although the solubility of the free acid is very low). Canonical (resonance) structures represent delocalization of the negative charge in the anionic conjugate base. Structures of the conjugate base of the sulfonyleurea tolbutamide, and of the diuretic hydrochlorothiazide, are provided for comparison.

hormones: luteinizing hormone (LH), follicle-stimulating hormone (FSH), and chorionic gonadotropin (CG). LH and FSH are produced by the anterior pituitary, CG by the placenta during pregnancy; human CG is more commonly denoted as hCG. In broad brushstrokes sufficient for the needs of the information that follows, the major actions of LH and FSH in women are encapsulated by Figure 25.9 (Chapter 25). Release of LH and FSH by the pituitary is stimulated by gonadotropin-releasing hormone (GnRH, also known as luteinizing hormone-releasing hormone (LHRH), or simply—but less commonly—gonadoliberin). GnRH is produced in the arcuate nucleus and preoptic areas of the hypothalamus, and upon its release, is carried to the pituitary via the portal circulation. Although LH and FSH are named for their actions on the ovaries during the estrus cycle of women (see Chapter 25, Fig. 25.11), these hormones similarly regulate spermatogenesis in the testes of men (see Fig. 25.10). GnRH acts in the pituitary on cells known as gonadotropes, binding to seven-transmembrane-segment GPCRs (GnRH-Rs)¹²⁶ and activating them, thereby triggering signaling pathways involving phospholipase C, ultimately bringing about an increase in cytoplasmic calcium concentrations, which in turn prompts LH or FSH release.¹²⁷ The control of pituitary release of either LH or FSH or both, in disparate amounts and timings (as

depicted in Fig. 25.11) with only one hypothalamic releasing hormone, is made possible via variations in magnitude and frequency of the pulsatile release of GnRH, in conjunction with feedback regulation by circulating estrogens, progestins, and androgens. (For further details, the reader is referred to other information sources, as the focus herein is intended to be the medicinal chemistry rather than the intricacies of physiology; see, e.g., Knobil,¹²⁸ and references given in Chapter 25.) A relatively thorough understanding of these pathways and systems, gained over nearly a century at least, now allows for their therapeutic exploitation despite their complexities, although new findings regularly alter clinical practice as well as drug discovery directions.

Inadequate production by the pituitary of gonadotropins causes hypogonadism, the consequences of which include infertility. Exogenously administered gonadotropins thus provide one means of fertility enhancement (see Chapter 27). Functional deficits in the gonads diminish production of estrogen, progestin, and testosterone (depending on gender and cycle stage), which otherwise inhibit release of LH or FSH from the pituitary, and also of GnRH from the hypothalamus (negative feedback loops). Gonadotropin (LH, FSH) levels rise, so that in the hypothalamus, the net impacts on GnRH release are relatively complex.

Gonadotropin-Releasing Hormone Agonists

Upon acute administration, GnRH agonists produce an initial stimulation of either LH release (called the “flare” response) or FSH release (in this case to stimulate ovulation), but upon chronic administration, the effect is to downregulate pituitary release of gonadotropins. In turn, during the initial flare response there is an increase in gonadal steroidogenesis (testosterone and dihydrotestosterone in men, estrone and estradiol in premenopausal women). Following the flare response, steroidogenesis decreases over the next

2 to 4 weeks. Examples of therapeutic applications (see Table 20.6) include controlling timing of estrus cycle events in women and—in veterinary medicine—female animals to allow for artificial insemination or in vitro fertilization; suppression of precocious puberty; inducing ovarian suppression and a hypoestrogenic state in women when beneficial (e.g., menorrhagia, endometriosis, adenomyosis, or uterine fibroids); induction of hypogonadal states in oncology (notably, prostate cancer); and fertility suppression in male dogs. For chronic administration, long-lasting depot injections enable monthly or quarterly administration, and implantable devices allow release for as long as a year.

TABLE 20.6 GnRH Agonists

Drug	Indications	Dosing	Volume of Distribution	Serum Protein Binding	Serum Time-course	Elimination
Leuprolide acetate (Lupron, Eligard, Lupron Depot, Viadur, generic)	A, B, C, D off-label: E, F, G	Injection, implant, or depot; amount varies from 1–45 mg for adult indications, depending on indication and type of administration (i.e., immediate-release vs. depot).	27 L ^a	43%–49% ^b	(Bolus dose) terminal $t_{1/2} \approx 3$ hr (two-compartment model) ^a $Cl_{ss} = 140$ mL/min ^a	Not fully characterized

Figure 20.32 • Primary sequences and selected substructures for endogenous human GnRH, and marketed GnRH agonists.

Nafarelin acetate is formulated for intranasal administration, the only nonparenteral formulation among the currently available GnRH agonists. Deslorelin acetate currently finds use only in veterinary medicine, such as for stimulating ovulation in mares (acute administration → flare effect) or helping to stabilize and maintain high-risk pregnancies in livestock, although clinical trials in humans for certain breast cancers, precocious puberty, and congenital adrenal hyperplasia are in progress or completed.

The marketed GnRH agonists are all close structural analogs of GnRH itself (Fig. 20.32). They are often called “superagonists” because they have increased potency and increased duration of action versus the endogenous agonist (GnRH), which is rapidly cleaved in the pituitary by endopeptidases (24.11 and 24.15)¹²⁹ and has a very short half-life (2–4 minutes) in the systemic circulation. The reported agonist potencies relative to GnRH for some of these molecules are leuprolide (15-fold), buserelin (20-fold), deslorelin (144-fold), and histrelin (210-fold).¹³⁰ All of the marketed synthetic agonists incorporate, like GnRH, *pyro*-glutamic acid at the amino terminus, in which the N-terminal α-amino group has undergone cyclocondensation with the γ-carboxyl moiety of the same glutamate residue, forming a five-membered amide-containing ring—that is, a lactam moiety (more specifically, this constitutes a 5-oxopyrrolidine-2-carboxylic acid residue). The

following four amino acids (positions 2–5) are also the same in all. Position 6 is the main point of structural variation among these GnRH-analog agonists; substitution is consistently with a D amino acid to confer peptidase resistance (see discussion that follows). Leuprolide (leuprorelin), buserelin, histrelin, and deslorelin are nonapeptides rather than decapeptides: They lack the amidated C-terminal glycine, instead terminating at Pro⁹, which is amidated with ethylamine, thus forming an *N*-ethylprolinamide terminus. This terminal *N*-ethyl moiety can be viewed as an abbreviated stand-in for the terminal glycynamide moiety of GnRH. Goserelin terminates in an unusual (among medicinal substances) aminocarbonylhydrazide moiety, whereas nafarelin and triptorelin maintain the same structure at the C-terminus as GnRH. The goserelin N-terminus can be seen as a bioisosteric substitution: It is identical to that of the natural hormone except that an –NH– is substituted for the methylene (–CH₂–) of the terminal glycine. All of the marketed agonists include the strongly basic Arg⁸ residue, so that, with no appreciably acidic groups elsewhere within the structure to provide an internal counterion, a salt form is obligatory; acetate is the counterion for most. Triptorelin is marketed in the United States as its pamoate salt (see Fig. 20.32), which provides for long duration of action by virtue of depot creation upon intramuscular injection.

The elimination processes and fates of these peptides are not fully characterized. For leuprolide, available information suggests that elimination is mostly via peptidase-catalyzed cleavage, and subsequent urinary excretion of peptide fragments.¹³¹ In healthy men, a pentapeptide is the prominent metabolite, and formation is relatively rapid, with levels of this metabolite peaking between 2- and 6-hour postdose. Following administration of the 3.75-mg depot suspension formulation, less than 5% of an administered dose was recovered as leuprolide and the pentapeptide metabolite. Such extensive fragmentation does not occur with all of these analogous compounds; however, more than 40% of an iv bolus dose of triptorelin, for example, is recovered intact in urine.¹³² Although the overall elimination of histrelin has reportedly not been studied following insertion of 50-mg implants, biotransformation in human hepatic microsomes showed the presence of a single prominent metabolite resulting from *N*-deethylation of the C-terminal amide moiety.¹³³ Peptidase-generated histrelin fragments are also likely, but the molecule is designed to be resistant to hydrolysis by endopeptidases 24.11 and 24.15. Nafarelin is extensively biotransformed. Following administration of (¹⁴C)nafarelin subcutaneously to men, at least six metabolites appeared in urine, collectively accounting for about half of the dose, with ~3% of the dose appearing in urine as unchanged nafarelin.

Hexapeptide Tyr⁵-Gly¹⁰(NH₂) was the most prominent metabolite.¹³⁴ The metabolites collectively persist in serum for much longer than the parent drug.

Gonadotropin-Releasing Hormone Antagonists

To some extent, the clinical uses of GnRH antagonists (Table 20.7) parallel those of the agonists discussed previously; however, antagonists do not, of course, generate the flare response.¹³⁵ Instead, GnRH receptors in the gonadotrope cells of the pituitary are blocked, so that pituitary output of FSH and LH is reduced or abolished. This response occurs rapidly, unlike the desensitization that develops over several weeks when GnRH agonists are used for gonadotropin suppression. Return to a pretreatment state also occurs relatively quickly, within 2 days after stopping lower doses of GnRH antagonists (except, of course, with depot injections).

The marketed GnRH antagonists (Fig. 20.33) were designed based on the GnRH structure,¹³⁶ but contain many more alterations as compared with agonists, including more D amino acids, and numerous unnatural or derivatized side chains (the full structure of ganirelix, Fig. 20.34, provides an exemplary illustration). His² was identified early on as important to receptor activation,¹³⁷ and this residue is re-

Figure 20.33 • Primary sequences and selected substructures for marketed GnRH antagonists.

placed in the antagonists with structural moieties that engage the receptor but do not allow receptor activation. Additional structure–activity information came from studies of cyclic peptides,^{138,139} which, together with information from protein structure modeling (see discussion that follows), indicated a relatively large binding pocket formed within the bundle of the transmembrane helices I to VII of the GnRH-R. (Although there are genes corresponding to GnRH-R₁ and GnRH-R₂ subtypes, the latter is apparently

not expressed in humans.) Abarelix incorporates backbone *N*-methylation at Tyr⁵. All are decapeptides like GnRH itself, but unlike GnRH, incorporate alaninamide rather than glycylamide at the *C*-terminus. Rather than having a *pyro*-Glu at the *N*-terminus as in the native hormone, all are instead *N*-acetylated. Each has at least one strongly basic amino acid in its sequence, at residue 8, thus these peptides are formulated as salts. The counterion is acetate in all cases. Ganirelix is a diacetate, having an additional basic

Figure 20.34 • Full structure of ganirelix.

residue—a derivatized lysine—at position 6; the diacetate salt endows the drug with excellent water solubility for preparation of an aqueous solution (0.5 mg/mL, pH 5.0) for parenteral administration (sc injection); the solution stability at pH 5.0 is such that ganirelix can be marketed as a sterile solution rather than a powder requiring reconstitution.

An overview of key structure–activity aspects for peptidic GnRH antagonists was provided within a pair of papers by Rivier et al.^{140,141} Although structural determinants of GnRH-R affinity and efficacy are now rather well understood, structural bases for alterations in duration of action remain much less so. Changes in peptide structure alter solubility characteristics, resistance to degrading enzymes, and plasma and tissue protein binding, all of which affect duration, and none of which can readily and reliably be predicted at present. The need for parenteral administration, especially for chronic applications, represents a liability among all of the marketed GnRH antagonists. Also, there is a modest but significant incidence of severe generalized hypersensitivity reactions; this problem with the Plenaxis product of abarelix acetate undoubtedly played a part in the decision by Pracis Pharmaceuticals to voluntarily discontinue sales in 2005, although components of the formulation other than the drug may have accounted for many of these reactions. (Defined structure–activity relationships for stimulation of histamine release from mast cells by peptides of this class have been reported, however—notably for variation at position 8.¹⁴²) In any case, nonpeptide, orally bioavailable GnRH antagonists have been sought, and several compounds have advanced through phase II trials. Developments in this area were reviewed in detail by Betz et al. in mid-2008¹⁴³; the interested reader is particularly encouraged to study this review, as the authors provide a highly instructive exposition of the structural determinants for agonist and antagonist actions at GnRH-Rs, and for receptor selectivity among GPCR ligands in general, based on the picture that emerged from a large collection of elegant reports. This review also offers up important lessons with regard to molecular pharmacodynamics—notably, the significances of ligand-binding kinetics with regard to efficacy and affinity variations, and to the origins of insurmountable versus surmountable antagonism. As yet, no crystal structures have become available for either unliganded or ligand-bound GnRH-R, but the aggregate work in this area makes abundantly clear the power of advanced protein modeling in conjunction with analysis of the effects of site-directed mutagenesis on the binding and action of ligands from various

structural classes. Readily apparent also is the great worth of time- and resource-demanding efforts to discover/create such a variety of ligands, and conduct artfully designed and executed biological experiments with them.

The biological fates of the peptidic GnRH antagonists are partly characterized. Cetrorelix elimination occurs by renal and biliary routes.^{144–146} Following a 10-mg sc dose given to men and women, only unchanged cetrorelix was detected in urine, whereas chain-shortened fragments produced by the actions of peptidases were found in bile, with fragment (1–4) predominating and fragments (1–9), (1–7), and (1–6) present in significant quantities. Dose dependencies of elimination clearly show that these elimination pathways are saturable, and other than peptide hydrolysis, no other phase I biotransformations, nor any phase II transformations, occur significantly for cetrorelix. For ganirelix, cumulative elimination over 288 hours for a single 1-mg dose (iv) resulted in recovery of 75% of the dose in feces and 22% in urine.^{147,148} Any excretion in urine was reported to be complete within the first 24 hours, whereas fecal elimination did not approach completion until nearly 200-hour postdose. Elimination was found to be dose-proportional within the range of 0.125 to 0.5 mg. Fragment peptides (1–4 and 1–6) were the major components of fecal radioactivity, whereas no unchanged drug was detected in feces. Following depot injection, degarelix undergoes peptide hydrolysis primarily in the hepatobiliary system, whereupon the majority of the cleavage products are excreted in bile.¹⁴⁹

◆ CONCLUDING REMARKS

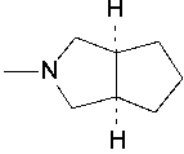

Rapid advances in endocrinology on many scientific fronts (and similarly, with respect to autocrine, paracrine, and juxtacrine systems) have brought about the identification of numerous new potential molecular targets for therapeutic intervention in a wide range of maladies. Among the new medicinals that have been created as a result, enzyme inhibitors or ligands for GPCRs are prominently represented, and will undoubtedly continue to be; however, as intimated in a few instances in this chapter, we should anticipate that an ever-increasing fraction of emerging therapeutic agents will be of a less-traditional nature. Accordingly, gaining a solid understanding of the molecular-level attributes underlying the actions and limitations of medicinals will be of ever-greater importance to clinicians who seek the best choices for their patients.

◆ R E V I E W Q U E S T I O N S ◆

1. Drugs of the hypoglycemic sulfonylurea class have the general molecular structure shown at right. The potencies of these molecules as oral hypoglycemic agents parallel to a very great extent the affinity with which they bind to ATP-sensitive potassium channels, as discussed in an early section of this chapter. Using the information from Table 20.3, and the structures shown in Figures 20.4 and 20.5, fill in the following table, listing the drugs from top to bottom according to daily dose

range, with the least potent at the top. As an example, a row has been completed for gliclazide, which is not included in Table 20.3.

Drug	Daily Dose Range	R ₁	R ₂
glipizide	80–240 mg	H ₃ C—	

2. The sulfonylureas are weak acids, and all drugs of this class are poorly water soluble, though some more so than others. One possible strategy for increasing the dissolution rate for a sulfonylurea to be formulated in an oral solid dosage form would be to make a salt, which would be expected to have a considerably greater water solubility (although none of the marketed sulfonylureas are currently formulated as their salts). Draw, explicitly, the structure of the potassium salt of glipizide.

3. (a) Draw the structure of *N*1-(*trans*-4-hydroxycyclohexyl)-*N*3-[*p*-(1-hydroxyethyl)phenyl-sulfonyl]urea.
 (b) Your structure, if correctly drawn, represents that of a metabolite of which hypoglycemic drug discussed in this chapter?
 (c) How many biotransformative steps are required to produce this metabolite from the parent drug you (hopefully) named in part b?
 (d) What enzymes are required to catalyze the biotransformations that can produce this metabolite from its parent drug?
 (e) Would you expect this metabolite to be a prominent one, or a minor one for this drug, and why?

4. Glipizide undergoes a pair of biotransformations that were not discussed in this chapter (a less-prominent route of biotransformation than those that were mentioned). A

glipizide molecule is acted on by a liver amidase, and one of the two products thereby produced is then *N*-acetylated, a reaction catalyzed by an *N*-acetyltransferase.

- (a) Draw the structure of the product of these two steps of biotransformation, and also the structure of the other product (a carboxylic acid) produced in the first step.
 (b) Would you expect the *N*-acetylated metabolite to (1) have significant pharmacological activity at the molecular level of the same nature as that of the glipizide, or (2) to exert hypoglycemic activity of clinical importance following oral administration? In each case, provide a justification for your answer.
5. In each of the following blanks, list a drug discussed in this chapter that acts at the molecular level in a way meeting the given description.
- _____ an enzyme inhibitor
- _____ a ligand for a protein complex that activates gene transcription
- _____ an inhibitor of ion channel opening
- _____ an agonist for a G-protein-coupled receptor

6. Diazoxide increases the propensity of ATP-sensitive potassium channels in β -islet cells of the pancreas to open, whereas glyburide exerts essentially the opposite effect. Yet, diazoxide is being studied clinically as a prospective aid in the treatment of type 2 diabetes, and significant drug discovery activity currently focuses on finding molecules that exert the same action as diazoxide, but with greater target selectivity, for the same therapeutic purpose. What is the basis for these efforts?
7. Why, based on its molecular nature and physicochemical properties, must exenatide be administered only via a parenteral route?
8. Within the structure of ganirelix (Fig. 20.34), how many amino acid residues come from the set of 20 amino acids abundant in proteins (including stereochemistry)? List them.

Agents Treating Bone Disorders

JOHN H. BLOCK

CHAPTER OVERVIEW

Bone is a dynamic tissue. Ninety-nine percent of the body's calcium is found in bone as a complex mixed salt called *hydroxyapatite* $[(Ca_5(PO_4)_3(OH))]$. Because the crystal unit cell has two molecules of hydroxyapatite, it is also written as $Ca_{10}(PO_4)_6(OH)_2$. Bone is the body's calcium reservoir with calcium constantly being removed by osteoclast cells (bone resorption) and laid down by osteoblast cells (calcium deposition). The former are derived from monocyte–macrophage cell lines. Together, bone resorption and calcium deposition are known as *bone remodeling*. The large bones such as the femur and hip harbor the body's marrow containing stem cells that produce a wide variety of cells including erythrocytes, platelets, B cells, T cells, neutrophils, basophils, eosinophils, monocytes, and mast cells.

It should not be surprising that bone, being a dynamic tissue, is subject to several diseases, and there are pharmacological treatments for these diseases. These diseases range from deterioration of bone structure, defects in bone remodeling, and malignancies. Some of these pathological conditions have a genetic basis, others can be ascribed to lifestyle, and some attributed to an aging population. This chapter will be restricted to those bone diseases for which there are approved drug treatments. Antineoplastic agents used to treat malignancies of the bone are discussed in Chapter 10.

DISEASES OF BONE TISSUE UTILIZING APPROVED DRUG THERAPIES

Paget Disease of Bone (Osteo Deformans)

Paget disease can be thought of as improper resorption of bone. Essentially, bones grow larger leading to deformation of the affected bones and become weaker than normal with increasing risk of fracture. It can occur on several bones or be isolated to one bone. It most likely occurs in the pelvis, skull, spine, or leg bones. The bones may become misshapen and break more easily. There may or may not be pain. Manifestations of Paget disease tend to appear in the patient's late 40s. Although there is some evidence of hereditary factors, slow viruses also have been considered a cause. Diagnosis begins with a determination of the patient's alkaline phosphatase levels followed by bone scans and x-rays. Drug therapy includes bisphosphonates and calcitonin.¹

Heterotopic Ossification

This diagnosis consists of various diseases resulting in abnormal formation of true bone within extraskelatal soft tissues. The latter include fascia, tendons, and other mesenchymal soft tissues. Many times the cause is related to traumatic injury. Treatment includes surgery, radiation, nonsteroidal anti-inflammatory drugs (NSAIDs, Chapter 24) and bisphosphonates.

Hypercalcemia of Malignancy

A malignancy is the most common cause of hypercalcemia and can be an indication of a malignancy, the most common being multiple myeloma, breast, or lung cancer. It is caused by increased osteoclastic activity within the bone. Primary hyperparathyroidism is the second most common cause of hypercalcemia. In addition to treating the cause, approved drug treatments for hypercalcemia of malignancy include bisphosphonates, calcitonin, gallium nitrate, and cinacalcet.

Osteoporosis

Osteoporosis is the most common of the bone diseases. It is a pathological condition characterized by decreased bone mass and structural deterioration of bone tissue.² The result is bone fragility leading to increased risk of fractures of the hip, spine, and wrist. Many times the broken hip is considered the result of the patient falling when, in actuality, the broken hip was the initial event causing the fall. The economic impact of this disease is tremendous. Osteoporosis is responsible for more than 1.5 million fractures annually distributed among 300,000 hips, 700,000 vertebrae, 250,000 wrists, and 300,000 other sites. It is more common in women than men because women, on average, have a smaller bone mass than men. Diagnosis, prior to an actual fracture, is done by bone density measurements.

Osteoporosis has been considered a disease of aging, but inflammation may be an important variable. Calcium flux favors bone mineralization through adolescence. Bone resorption and deposition are in balance in adults and become negative beginning in the late 50s. Loss of calcium from bone increases relative to calcium deposition onto bone increases with menopause. The importance of estrogen is shown by it acting directly on osteoblasts and possibly inhibiting osteoclasts. The loss of estrogen production results in a significant alteration of the osteoblast–osteoclast ratio because of increased osteoclastogenesis and decreased osteoclast apoptosis. The role of estrogen on osteoblast function has led to the development of selective estrogen receptor modifiers (SERM)

for the prevention and treatment of osteoporosis. These are discussed in more detail in Chapter 25.

Associated with menopause and the loss of estrogen is an increase in the production of proinflammatory cytokines including interleukin-1 (IL-1), tumor necrosis factor- α (TNF- α), and interleukin-6 (IL-6). Paralleling this increased production of proinflammatory cytokines is increased osteoclastic bone resorption. Of particular importance for osteoclast differentiation and activation and, therefore, progression of osteoporosis, is the receptor activator of nuclear factor- κ B (RANK), a membrane-bound receptor on osteoblast precursor cells and the receptor's functional ligand, RANK ligand (RANKL), also a cytokine. When RANKL binds to RANK, there is increased osteoclastic activity and increased osteoclast numbers because of decreased osteoclast apoptosis. Opposing RANKL is osteoprotegerin, an endogenous inhibitor of RANKL, specifically binding it and blocking its interaction with RANK. Osteoprotegerin, by inhibiting RANKL, normalizes the osteoblast-osteoclast ratio decreasing bone resorption and loss of calcium from bone.³

There are medical conditions that can increase the risk of osteoporosis (secondary osteoporosis) or exacerbate an existing osteoporotic condition. Chronic use of glucocorticoids can accelerate calcium loss. In addition, some anticonvulsants (i.e., phenobarbital and phenytoin) can negatively affect calcium flux involving bone. Medical conditions that immobilize individuals for extensive time periods can also lead to calcium loss.

There are controllable risk factors that reduce the risk and severity of the disease. These include anorexia in the age span when humans are accumulating dietary calcium, a diet low in calcium and vitamin D (cholecalciferol), inactive lifestyle, cigarette smoking, and excessive use of alcohol. Staying as physically active as possible throughout one's life span is important, particularly focusing on activities that include working against gravity (walking, hiking, jogging, stair climbing, and dancing). It is important for all age groups to consume calcium, but because calcium deposition onto bone is at its greatest through adolescence, it is important to consume quantities of calcium equal to the daily adequate intake (AI) of, depending on age, 500 to 1,300 mg/day. Younger people can obtain their calcium from diet, primarily dairy. Older individuals may need to take calcium supplements. Paralleling adequate calcium intake is vitamin D consumption. The current adult AI is 5 to 10 μ g (200–400 IU). This has been considered too conservative with recommendations that it be increased to 20 to 25 μ g (800–1,000 IU). A person's vitamin D status can be checked by measuring 25-hydroxycholecalciferol blood levels.

Osteoporosis is a greater problem in women mainly because women live longer and have less bone mass than men. Nevertheless, osteoporosis is a disease of older men. A 60-year-old white man has a 25% lifetime risk for an osteoporotic fracture, with consequences more severe than in women.⁴ The 1-year mortality rate in men after hip fracture is twice that in women.⁵ The factors that increase the risk of osteoporotic fracture in men are the same as those found in women.⁶

Osteomalacia

Osteomalacia is caused by a vitamin deficiency and can be thought of as the adult version of rickets. Whereas osteo-

porosis is caused by loss of both calcium and cartilage from bone, the cartilage matrix of bone remains with osteomalacia. Because of the vitamin D deficiency, dietary calcium is not transported across the intestinal mucosa to be deposited onto adult bone. The latter process is referred to as mineralization of the bone. The result is "soft" bone that becomes misshapen, because the bones cannot support the body. Inward curvature of the vertebral column and collapsed pelvis are two common results from osteomalacia. Treatment is increased vitamin D intake, but it may not be possible to correct the misshapen bone.

DRUGS USED TO TREAT DISEASES OF THE BONE

Bisphosphonates

The general bisphosphonate structure is illustrated in Figure 21.1. Bisphosphonates should not be confused with bisphosphates. Bisphosphonates have covalent carbon-phosphorous bonds, and bisphosphates carbon-oxygen-phosphorous bonds. In other words, the latter are phosphate esters very similar in chemistry to biochemical phosphate esters. Most in vivo bisphosphates are substrates for phosphatase enzymes, whereas bisphosphonates are stable in the presence of hydrolytic phosphatases. The phosphonate groups are required both for binding to bone hydroxyapatite and cell-mediated antiresorptive activity.

Bisphosphonates were first reported in 1897. The discovery for treating and preventing osteoporosis began in the early 1960s with Procter & Gamble's detergent division searching for better additives for use in hard water areas. Bisphosphonates have excellent affinity for Ca^{2+} and Mg^{2+} . The research moved to the company's dental division where it was discovered that bisphosphonates prevent tartar buildup by forming a thin film on the surface of teeth because it is strongly chemisorbed onto hydroxyapatite.⁷

Bisphosphonates approved for treating bone diseases can be divided into two groups: non-*N*-containing and *N*-containing (Table 21.1). The rank order of bisphosphonates binding to hydroxyapatite, from weaker to stronger binding is clodronate (lowest) < etidronate < risedronate < ibandronate

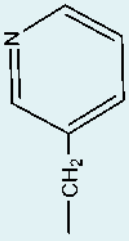

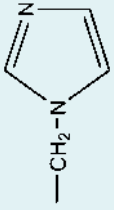

Figure 21.1 • Bisphosphonate and bisphosphate chemistry. Bisphosphonates have carbon-phosphorous bonds, whereas bisphosphates are phosphate esters with carbon-oxygen-phosphorous bonds. The therapeutic bisphosphonates (Table 21.1) differ by the substituents at positions R_1 and R_2 .

TABLE 21.1 Bisphosphonates

Generic Name	Brand Name	R ₁	R ₂	Approved Indications	Nonapproved Indications	Contraindications	Dosing
Non-<i>N</i>-containing Bisphosphonates							
Etidronate disodium	Didronel	—OH	—CH ₃	Heterotopic ossification; Hypercalcemia of malignancy; Paget disease		Clinically overt osteomalacia	Daily
Tiludronate disodium	Skelid	—OH		Postmenopausal osteoporosis; Paget disease			Daily
<i>N</i>-Containing Bisphosphonates							
Alendronate sodium	Fosamax	—OH	—(CH ₂) ₃ NH ₂	Male osteoporosis; Corticosteroid-induced osteoporosis; postmenopausal osteoporosis; prophylaxis of postmenopausal osteoporosis	Osteoporosis from Crohn disease; hypercalcemia of pregnancy	Esophageal abnormalities that delay esophageal emptying; Inability to stand or sit upright for 30 minutes; patients at increased risk of aspiration should not receive oral solution	Weekly or daily
Pamidronate disodium	Aredia	—OH	—(CH ₂) ₂ NH ₂	Osteolytic bone metastasis; hypercalcemia of pregnancy; Paget disease			Daily to monthly, depending on the condition
Risedronate sodium	Actonel	—OH		Corticosteroid-induced osteoporosis; prophylaxis of corticosteroids induced osteoporosis; postmenopausal osteoporosis; prophylaxis of postmenopausal osteoporosis; Paget disease		Hypocalcemia; inability to sit or stand upright for at least 30 minutes	Daily to monthly
Zoledronic acid	Zometa	—OH		Bone metastasis; Hypercalcemia of malignancy; multiple myeloma; Paget disease; postmenopausal osteoporosis		Hypocalcemia	IV; spacing depends on the indication

< alendronate < pamidronate < zoledronate (highest). As noted in later discussion, this order does not completely parallel antiresorptive potency. A key difference between the non-*N*-containing and *N*-containing bisphosphonates is the ability of the latter to form positive charges on their nitrogens at physiological pH. In general, the more positively charged bisphosphonates (zoledronate, ibandronate, and alendronate) produce a positive surface on the bone, attracting additional bisphosphonates to bone.

The non-*N*-containing and *N*-containing bisphosphonates differ in their mechanism of action. The former's (etidronate, tiludronate) site of action is the osteoclast's aminoacyl-transverse ribonucleic acid (tRNA) synthetase reversing the reactions normally involved in activating amino acids during protein synthesis. These two bisphosphonates replace the terminal pyrophosphate moiety of adenosine triphosphate (ATP). This initiates apoptosis in the osteoclast leading to a decrease in bone resorption. There is some evidence that the bisphosphonate-modified ATP may affect mitochondrial function that also would lead to apoptosis. The two non-*N*-containing bisphosphonates are indicated for Paget disease and, in the case of etidronate disodium, also heterotopic ossification and hypercalcemia of malignancy.

The *N*-containing bisphosphonates have a different site of action. They interfere with the mevalonate pathway required for biosynthesis of cholesterol and subsequent sterols. The specific sites appear to be that portion of the pathway utilizing isoprenoid diphosphates as substrates for farnesyl diphosphate synthase (FPPS) as the primary target. The bisphosphonates may be false substrates for the isoprenoid diphosphates. The impact of FPPS inhibition may be more than inhibiting sterol synthesis. FPPS is required for the synthesis of farnesyl pyrophosphate, which is the precursor for geranylgeranyl diphosphate. Both farnesyl pyrophosphate and geranylgeranyl pyrophosphate are required for lipid modification (prenylation) of subcellular membranes where signaling proteins are located. This causes loss of osteoclast function and may be more important than apoptosis of the cells necessary for bone resorption to occur.

X-ray crystallography indicates the bisphosphonate nitrogen binds to the FPPS threonine (T201) or the backbone carbonyl of lysine (K200). The optimal distance between the drug's nitrogen and the amino acid oxygen is approximately 3 Å. From lowest to highest, binding to FPPS is pamidronate < alendronate < ibandronate < risedronate < zoledronate, which closely matches antiresorptive potency. The latter two with their heterocyclic nitrogens are significantly better inhibitors of FPPS than the other three.⁸

No drug is without adverse reactions, and this is true of bisphosphonates. They can be very irritating to the gastrointestinal mucous linings. The recommended procedure for oral administration directs the patient to sit upright, consume a full glass of water with the tablet, and remain in the upright position for at least 30 minutes. Oral bisphosphonates should be taken an hour before food. They are poorly absorbed.

A rare but serious adverse reaction is osteonecrosis of jaws. A suggested mechanism is oversuppression of bone turnover.⁹ In the majority of reported cases, there had been a previous dental surgical procedure. In this model, bisphosphonates, by disrupting the osteoblast-osteoclast balance, impair proper healing of the jaw following

surgery. Unfortunately, there are no definitive guidelines that help the clinician decide if the patient has medical condition that increase his or her risk of osteonecrosis when using bisphosphonates.¹⁰

The bisphosphonates also may cause severe and sometimes incapacitating pain in bone, joint, and/or muscle (musculoskeletal). This adverse reaction is difficult to define because it can appear within days, months, or years after starting treatment. Some patients report that the pain disappears after discontinuing the bisphosphonate, whereas others have reported slow or incomplete resolution after stopping the drug.¹¹

It is difficult to describe any type of rank ordering of efficacy for bisphosphonates. There have been no head-to-head comparisons of several of the drugs in a single trial using the same diagnostic criteria. Measurements of efficacy include incidence of vertebral fracture, nonvertebral fracture, and bone mineral density. Comparisons are more likely focusing on convenience of dosing. Because bisphosphonates adhere strongly to the bone surface, dosing has moved from daily to weekly or monthly for oral administration. Depot injections permit annual administration.

HORMONE THERAPY

It is important to keep in mind that calcium's biochemical functions include much more than being the main mineral component of bones and teeth. All cells have calcium channels that strictly control calcium flux into and out of cells. Therefore, it is important that blood calcium levels be tightly regulated. This is done with three hormones: parathyroid, calcitonin, and 1,25-dihydroxycholecalciferol (1,25-diOH-D₃). Parathyroid hormone (PTH) is produced by the parathyroid gland located behind the thyroid gland. The parathyroid gland has calcium receptors that sense blood calcium levels. If there is hypocalcemia, PTH is released increasing osteoclastic activity on bone, resulting in increased bone resorption.¹² PTH also acts on the kidney, maximizing tubular reabsorption of calcium and activating the cytochrome P450 mixed function oxidase hydroxylation of 25-hydroxycholecalciferol to 1,25-diOH-D₃. The latter travels to the intestinal mucosa where it is a ligand for the vitamin D receptor (VDR). The result is active transport of dietary calcium into systemic circulation. 1,25-diOH-D₃ can be thought of as a kidney hormone. A patient with kidney failure is prescribed 1,25-diOH-D₃ because of the inability to carry out the final hydroxylation. In addition to regulating the uptake of dietary calcium from the intestinal tract, 1,25-diOH-D₃, along with PTH, enhances calcium flux from bone.

Calcitonin is produced in the thyroid gland and sometimes is called thyrocalcitonin. It is released when there is hypercalcemia. This hormone reduces blood calcium levels by suppressing tubular reabsorption of calcium, thereby enhancing calcium urinary excretion and inhibiting bone resorption minimizing calcium flux from bone.

Calcitonin-Salmon (sCT; Miacalcin, Calcimar)

Human and salmon calcitonins differ from each other by 16 of the total 32 amino acids. Although each calcitonin has a

Figure 21.2 • Drugs based on the ergocalciferol indicated for hyperparathyroidism.

cys-S-S-cys disulfide bridge between cysteines 1 and 7 at the amino terminal end, and each ends at the carboxyl end with a prolinamide, the differences in the other amino acids between the two differ in their tertiary structures. These differences cause calcitonin-salmon to be one order of magnitude greater than human calcitonin in reducing calcium concentration in the blood stream of mammals.^{13,14} Nevertheless, these significant differences in amino acid sequence increase the risk of adverse reactions caused by the patient's immune system.

There are two dosage forms: intramuscular and nasal. Because of the adverse effects, there can be inflammation at the injection site plus flushing, nausea, and vomiting following an injection. Use of the nasal dosage form can cause backache and rhinitis. The approved indications for calcitonin-salmon are hypercalcemia, Paget disease, and postmenopausal osteoporosis.

Teriparatide Injection [hPTH(1-34); Forteo]

Teriparatide contains the first 34 amino acids of the 84 amino acid human parathyroid hormone and is produced by recombinant DNA technology. The N-terminal region of endogenous PTH contains most of the biological activity. Timing the administration of PTH determines the response. Teriparatide is administered once daily because once-daily administration stimulates new bone formation by stimulation of osteoblastic activity over osteoclastic activity. In contrast, continuous infusion leads to greater bone resorption than formation.

Teriparatide is indicated for primary postmenopausal osteoporosis in women who are at high risk of fracture and for increasing bone mass in men with primary or hypogonadal osteoporosis who are at high risk for fracture. It is not indicated for pseudohypoparathyroidism or secondary hypoparathyroidism. "True" hypoparathyroidism is caused by a PTH deficiency, and teriparatide acts as a PTH replacement. Pseudohypoparathyroidism usually is caused by a PTH receptor defect. Treatment for the latter includes calcium supplements and vitamin D with the goal to maintain blood calcium levels.

There is a boxed warning regarding a potential risk of developing osteosarcoma. It is based on studies in male and

female rats. The effect was observed at systemic exposures to teriparatide ranging from 3 to 60 times the exposure in humans given a 20- μ g dose. The boxed warning also warns against administering teriparatide to patients with Paget disease because of the active osteoblastic activity associated with this disease.

Hyperparathyroidism

The focus on this chapter has been on diseases that interfere with bone remodeling. A key gland is the parathyroid, particularly when there is hypoparathyroidism. The opposite can occur with an overactive gland or hyperparathyroidism. There are two vitamin D analogs that are indicated for renal failure when patients are on dialysis. These patients cannot carry out the final cytochrome P450-catalyzed hydroxylation of 25-hydroxycholecalciferol (25-OH-D₃) to 1,25-diOH-D₃ (calcitriol). It is common to prescribe calcitriol to prevent vitamin D-resistant rickets or osteomalacia. Because of the defective kidney, or lack of kidney, there is inactive feedback to the parathyroid, and the patient's parathyroid can over secrete parathyroid hormone to maintain blood calcium levels. There are two drugs (Fig. 21.2) based on the ergocalciferol structure that better regulate the parathyroid gland with less transport of dietary calcium and phosphorus. These are paricalcitol (19-nor-1,3,25-trihydroxyergocalciferol) and doxercalciferol (25-norhydroxy-1,3-dihydroxyergocalciferol). A third drug, cinacalcet (Fig. 21.3), either mimics calcium because it is a ligand for the calcium-sensing receptor on the parathyroid

Figure 21.3 • Cinacalcet (Sensipar).

gland or sensitize the receptor's sensitivity to extracellular calcium. The end result is that the parathyroid gland secretes less hormone. Cinacalcet is indicated for secondary hyperparathyroidism in patients undergoing renal dialysis and hypercalcemia caused by parathyroid carcinoma.

FUTURE DIRECTIONS

Serotonin Regulation of Bone Formation

The low-density lipoprotein (LDL)-receptor-related protein 5 (Lrp5) is a regulator of bone remodeling (balanced osteoblast and osteoclast activity). Among its functions is limiting biosynthesis of serotonin in the gut. Using knock-out mice models that are deficient in Lrp5, increased serotonin levels results in decreased bone formation. The site of approximately 95% of the body's serotonin production is the gut, and this serotonin cannot cross the blood-brain barrier. Most of the gut-produced serotonin is taken up by platelets with much of the remainder possibly affecting bone formation by controlling osteoblast proliferation.¹⁵ Consistent with this model is the observation that patients

taking selective serotonin reuptake inhibitors (SSRIs), where there is increased peripheral serotonin, can have reduced bone mass.¹⁶

Monoclonal Antibodies

A monoclonal antibody target for the treatment of osteoporosis is the RANKL, which is the essential mediator of osteoclasts. As pointed out in the osteoporosis discussion, the loss of calcium by increased osteoclastic activity and decreased osteoclast apoptosis is opposed by a RANKL inhibitor, osteoprotegerin a 401-amino acid glycoprotein, and a member of the TNF superfamily. Rather than develop a pharmaceutically acceptable osteoprotegerin, a fully human monoclonal antibody, denosumab, that binds to the RANKL preventing its binding to RANK is being evaluated for the treatment of osteoporosis. The reported result is inhibition of all stages of osteoclast activity.¹⁷ It is important to keep a perspective when administering drugs that interfere with the immune system over long periods of time. RANKL is part of the normal bone remodeling process as well as with pathological bone loss. The key is balance, and this will require long-term studies in patients with postmenopausal osteoporosis.

REVIEW QUESTIONS

- Name the two cell lines responsible for bone remodeling and function of each.
- What is found in the large bones and what is its function?
- How does osteoporosis differ from osteomalacia?
- How does the site of action of the non-*N*-bisphosphonates differ from the *N*-containing bisphosphonates?
- What is the basis for the adverse reactions seen with administration of calcitonin-salmon?
- What is teriparatide?

CHAPTER 22

Anesthetics

CAROLYN J. FRIEL

CHAPTER OVERVIEW

This chapter focuses on the general and local anesthetic drugs used to block the transmission of pain. The general anesthetic section covers both the inhaled and the intravenous drugs. The local anesthetic section includes the topical and parenteral drugs. This chapter includes the mechanism of action, structure–activity relationships (SAR), and individual drug monographs for the general and the local anesthetic agents.

THE INHALED GENERAL ANESTHETICS

In 1846, a Boston dentist, William Morton, demonstrated the use of ether as a general anesthetic in a public demonstration. The publication of the successful operation led to the use of general anesthetics by surgeons and ushered in the “age of anesthesia.” The first paper that described the use of the general anesthetic ended with the warning that “Its action is not yet thoroughly understood, and its use should be restricted to responsible persons.”¹ Although it has been 160 years since that statement was written, the sentiment remains today.

The pharmacological mechanism of action of the anesthetic drugs is not clear. The idea that we can understand the mechanism of action for a general anesthetic supposes that we understand what the term anesthesia means. A clinical definition of general anesthesia is a state where no movement occurs in response to what should be painful. Although this gives us a working definition of the drug’s action, it does not explain the physiology behind the action. Much research remains to be done on the physiological mechanism of action of the drugs discussed in this chapter. The general anesthetic section will begin by reviewing the stages of general anesthesia, followed by a summary of the SAR of the inhaled anesthetics and their proposed mechanism of action and will conclude with individual drug monographs.

Stages of General Anesthesia²

Analgesia (Stage I): The stage of analgesia lasts from onset of drowsiness to loss of eyelash reflex (blinking when the eyelash is stroked). Variable levels of amnesia and analgesia are seen in this stage. The patient is considered unconscious at the end of stage I.

Excitement (Stage II): The stage of excitement is characterized by agitation and delirium. During this stage, salivation may be copious. Heart rate and respiration

may be irregular. Induction agents are designed to move the patient through this undesirable stage quickly.

Surgical Anesthesia (Stage III): This stage is divided into four planes but for the purpose of this chapter, it is sufficient to understand that this stage of anesthesia is the target depth for the procedure. During this stage, a painful stimuli will not elicit a somatic reflex or deleterious autonomic response.

Impending Death (Stage IV): This stage lasts from onset of apnea to failure of circulation and respiration and ends in death.

The ideal anesthetic combination will allow the patient to proceed quickly from stage I to stage III and avoid stage IV. Inhaled anesthetics are used in combination with other drugs to induce anesthesia. The drug combinations used to achieve this are complex and will not be addressed here; the reader is referred to a general anesthesia textbook for a more detailed description.

The Ideal Inhaled Anesthetic

The ideal inhaled anesthetic will be inexpensive, potent, pleasant to inhale, minimally soluble in the blood and tissues, stable on the shelf and during administration, and lack undesirable side effects such as cardiotoxicity, hepatotoxicity, renal toxicity, and neurotoxicity. The ideal inhaled anesthetic has not been developed yet and all of these factors must be kept in mind when choosing an anesthetic for a particular patient.

POTENCY

The most common way to measure inhaled anesthetic potency is by recording the minimum alveolar concentration (MAC) needed to prevent movement to a painful stimulus. The MAC concentrations are recorded at 1 atmosphere and reported as the mean concentration needed to abolish movement in 50% of subjects. The MACs for the inhaled anesthetics are listed in Table 22.1. Potency of the inhaled anesthetics is extremely important as the anesthetic gas is displacing oxygen in the inspired gas. Inhaled agents with low potencies (high MACs) such as nitrous oxide require administration at increased pressure or are used only in combination with more potent inhaled agents.

SOLUBILITY

The ideal general anesthetic will have low solubility in blood conveyed by the blood:gas partition coefficient listed

TABLE 22.1 Properties of the Inhaled Anesthetics

Anesthetic	MAC (%)	Blood:Gas	Oil:Gas
Nitrous oxide	104	0.46	1.1
Halothane	0.75	2.4	137
Enflurane	1.68	1.8	98
Methoxyflurane	0.16	16.0	970
Isoflurane	1.15	1.43	90.8
Sevoflurane	2.10	0.65	50
Desflurane	7.3	0.42	18.7
Xenon	71	0.12	1.9

in Table 22.1. The blood:gas partition coefficient is defined as the ratio of the concentration of the drug in the blood to the concentration of the drug in the gas phase (in the lung), at equilibrium. The volatile anesthetic is inhaled into the lungs, diffuses into the blood, and when equilibrium is reached, it diffuses into tissues. For the drug to have a quick onset, the solubility in the blood should be low, thus saturation will occur quickly, and the drug can then move into the tissue compartment. Recovery is also expected to be faster for those drugs with a low blood:gas partition coefficient as the drug will be eliminated quicker if it has a low solubility in the blood and quickly passes into the lungs for exhalation.

When a patient is exposed to the volatile gas for prolonged procedures, greater than 5 hours, the solubility of the drug in the tissues will also effect the recovery period. In these cases, it is necessary to consider the solubility of the drug in fat and lean organs as well as the body mass of the individual patient to determine how recovery could be affected by drug solubility. Most inhaled anesthetics have similar solubilities in lean organs, but their solubilities in fat vary as predicted by their oil:gas partition coefficients listed in Table 22.1.³ Obese patients may have increased recovery times if an inhaled anesthetics with high-fat solubility is used for a prolonged period.

STABILITY

The early inhaled anesthetics suffered from stability problems, leading to explosions and operating room fires. By halogenating the ether and hydrocarbon anesthetics, the explosiveness and flammability of the drugs were diminished, and the number of operating room fires decreased. Halogenation clearly stabilizes the inhaled agent and all inhaled anesthetics used today contain halogens.

Sporadic reports of fires involving sevoflurane can be found in the literature.⁴⁻⁶ The operating room fires involving sevoflurane all involved the recapture process and recirculating equipment. In an attempt to decrease operating room personnel exposure to the volatile anesthetics being exhaled by the patient, as well as to reduce the acquisition costs of the drug, recirculating breathing apparatus were developed. These breathing apparatus are designed to capture the expired gas, remove the carbon dioxide, and then allow the patient to inhale the anesthetic gas again. Different carbon dioxide absorbents are used such as calcium hydroxide, barium hydroxide, and sodium hydroxide. When the absorbent inadvertently dries out, as a result of the continuous flow of fresh gas, sevoflurane can break down and produce hydrogen in an exothermic reaction. The generation of hydrogen and heat may have been

responsible for the reported fires that began in the anesthetic equipment.⁶ Other anesthetics have not had this same problem but all are monitored for their degradation products when exposed to carbon dioxide absorbents. Toxic metabolites of the inhaled anesthetics, such as the fluoride anion, are also a concern and discussed in the individual drug monographs.

Structure-Activity Relationships of the Volatile General Anesthetics

The inhalation anesthetics in use today are nitrous oxide, halothane, isoflurane, desflurane, and sevoflurane. The chemical structures for these compounds and some of historical interest can be seen in Figure 22.1. While it is true that there is no single pharmacophore for the inhaled anesthetics, the chemical structure is related to the activity of the drug molecule.

ALKANE/CYCLOALKANE

The first SAR studies conducted independently by Meyer and Overton in the 1880s showed a distinct positive correlation between anesthetic potency and solubility in olive oil. Many series of compounds confirm this simple relationship but exceptions to the model exist. The potency of alkanes, cycloalkanes, and aromatic hydrocarbons increases in direct proportion to the number of carbon atoms in the structure up to a cutoff point.⁷ Within the n-alkane series, the cutoff number is 10, with n-decane showing minimal anesthetic potency. In the cycloalkane series, the cutoff number in most studies is eight with cyclooctane showing no anesthetic activity in the rat. The reduced activity of the compounds beyond their cutoff number could be a result of problems getting to the site of action (reduced vapor pressure or high blood solubility) or inability to bind to the site of action and induce the conformational change required for anesthetic action.⁸

Figure 22.1 • The chemical structures of the inhaled anesthetic agents.

The cycloalkanes are more potent anesthetics than the straight chain analog with the same number of carbons. For example, the MAC of cyclopropane in rats is about one fifth of the MAC of n-propane.⁸

ALKANOL SERIES

A similar increase in potency with increase in carbon length was seen in the n-alkanol series. In addition, the n-alkanol with a given number of carbons is more potent than the n-alkane with the same chain length.⁹

EFFECT OF HALOGENATION/ETHER HALOGENATION

The first inhaled anesthetics used in the late 1800s, diethyl ether and cyclopropane caused laryngospasms. These compounds were also explosive and flammable requiring careful handling. Early studies found that halogenating the ethers decreased the flammability of the compounds, enhanced their stability and increased their potency. Higher atomic mass halogens increased potency compared to lower atomic mass halogens. For example, replacing the fluorine in desflurane ($\text{CF}_2\text{HOC}\underline{\text{F}}\text{HCF}_3$) with a chlorine to form isoflurane ($\text{CF}_2\text{HOC}\underline{\text{C}}\text{HCF}_3$) increased potency more than fourfold.¹⁰ Replacing the chlorine with bromine in the investigational agent I-537 ($\text{CF}_2\text{HOC}\underline{\text{B}}\text{rHCF}_3$) increased potency threefold further. In general, halogenated ether compounds also caused less laryngospasms than unhalogenated compounds. Unfortunately, halogenation also increased the propensity of the drugs to cause cardiac arrhythmias and/or convulsions.¹¹ Halogenated methyl ethyl ethers were found to be more stable and potent than halogenated diethyl ethers. The commonly used inhaled anesthetics are ethers or aliphatic hydrocarbons with 2 to 5 carbon atoms.

The effect of halogenating the alkane, cycloalkane, and alkanol compounds has been extensively studied in animal models. For the n-alkane series, fully saturating the alkane with fluorine abolished activity except when n equaled one.⁷ When n was 2 to 4 carbons the highest potency was seen when the terminal carbon contained one hydrogen ($\text{CHF}_2(\text{CF}_2)_n\text{CHF}_2$). When n was greater than 5 carbons the potency decreased in this series. The potency of the dihydrogen compounds ($\text{CH}_2\text{F}(\text{CF})_n\text{CH}_2\text{F}$) ($n = 2-4$) was greater than the equivalent nonfluorinated alkane compound. Similar findings for the n-alkanol series were found. The most potent fluorinated n-alkanols were the $\text{CHF}_2(\text{CF}_2)_n\text{CH}_2\text{OH}$ series, when n was between 2 and 5.⁷ The decrease in activity for the completely fluorinated compounds would not be predicted by the Meyer-Overton hypothesis. Another interesting phenomenon that does not follow the Meyer-Overton hypothesis can be found using the structural isomers isoflurane and enflurane. (Fig. 22.1) The compounds have similar solubility in oil, yet the MAC for enflurane is greater than the MAC for isoflurane (Table 22.1). The stereoisomers of isoflurane (+) and (−) have also been isolated and tested for anesthetic potency in rats. The (+) isomer was found to be 53% more potent than the (−) isomer. This observation would not be predicted based on the Meyer-Overton hypothesis.

EFFECT OF SATURATION

Molecular flexibility of the inhaled anesthetics is not required. The addition of double and/or triple bonds to small anesthetic molecules having 6 carbon atoms or less increases potency.¹²

Mechanism of Action of the Inhaled Anesthetics

The mechanism of action of the inhaled anesthetics is not known. Most theories of the inhaled anesthetics leave room for the possibility of multiple mechanisms, receptors, and regions of the nervous system (spinal cord and brain) to explain their action. It seems likely that the individual anesthetic molecules act with different potencies on multiple receptors that lead to similar clinical states of anesthesia. Some of theories of anesthetic action are briefly covered below.

MEYER-OVERTON THEORY

As discussed, work of Meyer and Overton in the 1880s showed that there was strong correlation between the potency of the anesthetic and its solubility in olive oil. This correlation holds true for a surprising number of inhaled anesthetics but it does not explain the drugs mechanism of action. When biological membranes were found to be composed mainly of lipids, the work of Meyer and Overton was extended to offer a proposed mechanism of action of the inhaled anesthetics. Namely, that the lipid-soluble drug somehow disrupted the biological membrane and produced anesthesia. This “unitary hypothesis” has led to research focused on the effect of the anesthetics on the lipid membrane. The inhaled anesthetics do disrupt the lipid bilayer but it is unclear if they make enough changes to effect cell signaling.¹³ If lipid solubility were the only factor for anesthetic potency, then chiral enantiomers would have the same potencies as their log P’s are identical. This is not the case. The stereoisomers of isoflurane do not have the same in vivo potency (~20%) despite having the same effect on the lipid membrane.¹³ It is also clear that all lipophilic chemicals are not anesthetics and thus the unitary theory of anesthesia cannot adequately explain the mechanism of action of the inhaled anesthetic drugs.

INTERACTION WITH ION CHANNELS¹⁴

Inhaled anesthetics interact with various ion channels to influence the electrical activity of cells and their physiological response. The most studied receptor that inhaled anesthetics act on is the GABA_A receptor. Inhaled anesthetics enhance chloride ion conductance into the cell and thus hyperpolarize the cell membrane and prevent impulse transmission. They act at the GABA_A receptor in a manner similar to the benzodiazepines but not identical. Molecular modeling studies based on mutagenesis data and structurally homologous proteins predict the existence of an inhaled anesthetic binding site on the GABA_A receptor. The binding site is postulated to be between the second and third transmembrane segments of the GABA_A α₁-receptor subunits.¹⁵ Chloride channel blockers and benzodiazepine antagonists show only a small effect on the potency of the anesthetics, thus GABA_A potentiation cannot universally explain their mechanism of action.¹³ Inhaled anesthetics are also known

to enhance the major inhibitory receptors in the spinal cord, the glycine receptors.

Inhaled anesthetics are also proposed to inhibit the excitatory synaptic channel activity of neuronal nicotinic acetylcholine receptors, glutamate receptors (*N*-methyl-D-aspartate [NMDA] and α -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid [AMPA]), sodium channels, potassium channels, calcium channels (voltage-gated cardiac and neuronal), and ryanodine receptors. The multitude of receptor channels that are affected to various degrees by specific inhaled anesthetics leads to the current theory that multiple receptors are targets of the volatile anesthetics and no single receptor–drug interaction can fully explain their mechanism of action.

General Anesthetic Monographs, Individual Products Including Adverse Reactions

The chemical structures of the inhaled anesthetic agents are shown in Figure 22.1.

NITROUS OXIDE

Nitrous oxide is a gas at room temperature and is supplied as a liquid under pressure in metal cylinders. Nitrous oxide is a “dissociative anesthetic” and causes slight euphoria and hallucinations. The low potency of nitrous oxide (MAC = 104%) precludes it from being used alone for surgical anesthesia. To use it as the sole anesthetic agent the patient would have to breathe in pure N₂O to the exclusion of oxygen. This situation would obviously cause hypoxia and potentially lead to death. Nitrous oxide can inactivate methionine synthase, a B₁₂-dependent enzyme necessary for the synthesis of DNA and therefore should be used with caution in pregnant and B₁₂-deficient patients. Nitrous oxide is also soluble in closed gas containing body spaces and can cause these spaces to enlarge when administered possibly leading to adverse occurrences (occluded middle ear, bowel distension, pneumothorax). Nitrous oxide is a popular anesthetic in dentistry where it is commonly referred to as “laughing gas.” It is used in combination with more potent anesthetics for surgical anesthesia and remains a drug of recreational abuse.¹⁶ Nitrous oxide undergoes little or no metabolism.³

HALOTHANE

Halothane is a nonflammable, nonpungent, volatile, liquid, halogenated (F, Cl, and Br) ethane (bp = 50°C), introduced in 1956. Halothane may increase heart rate, cause cardiac arrhythmias, increase cerebral blood flow, and increase intracranial pressure.¹⁷ It can undergo spontaneous oxidation when exposed to ultraviolet light to yield HCl, HBr, Cl⁻, Br⁻, and phosgene (COCl₂). To prevent oxidation it is packaged in amber bottles with a low concentration of thymol (0.01%) as a stabilizer. The drug has a high potency (MAC = 0.75%), a blood:gas partition coefficient of 2.4, and high adipose solubility. Halothane undergoes both reductive and oxidative processes with up to 20% of the dose undergoing metabolism (Fig. 22.2).¹⁸ The trifluoroacetyl chloride metabolite is electrophilic and can form covalent bonds with proteins leading to immune responses and halothane hepatitis upon subsequent halothane exposure. Halothane hepatitis is rare with 1 case reported for every 6,000 to 35,000 patients exposed.^{17,18}

The use of inhaled anesthetics and halothane in particular can produce malignant hyperthermia (MH) in genetically susceptible individuals. This results in an increase in body temperature, tachycardia, tachypnea, acidosis, and rhabdomyolysis. MH is a result of the excessive release of calcium from the sarcoplasmic reticulum (SR). Patients with an inherited mutation in the ryanodine receptor (RYR1), which is located in the SR, are at an increased risk of developing MH when exposed to an inhaled anesthetic triggering agent. Treatment entails discontinuing the anesthetic agent, rapid cooling, intravenous dantrolene sodium, and supportive measures. MH has been reported to occur with all anesthetics agents and with succinylcholine, a depolarizing neuromuscular blocker. The combination of halothane and succinylcholine appears to trigger a great extent of the MH episodes. Patients with a family history of MH can be genetically screened for MH susceptibility via the caffeine–halothane contracture test. This test is invasive requiring a piece of skeletal muscle to conduct and it is expensive costing approximately \$5,000 (cost in 2008). Noninvasive molecular genetic screening is currently being developed.¹⁹

Figure 22.2 • Halothane metabolism.

METHOXYFLURANE

Methoxyflurane is a volatile liquid (bp = 105°C) with a high blood:gas partition coefficient and thus a slow induction and prolonged recovery.²⁰ Approximately 75% of the drug undergoes metabolism yielding dichloroacetate, difluoromethoxyacetate, oxalate, and fluoride ions. The intrarenal inorganic fluoride concentration, as a result of renal defluorination, may be responsible for the nephrotoxicity seen with methoxyflurane. Both the concentration of F⁻ generated and the duration for which it remained elevated were factors in the development of methoxyflurane nephrotoxicity.²¹ Methoxyflurane was removed from the U.S. market in 2000 because of safer alternatives. Both isoflurane and enflurane produce less fluoride ion upon metabolism than methoxyflurane.

ENFLURANE

Enflurane is a volatile liquid (bp = 56.5°C) with a blood:gas partition coefficient of 1.8 and an MAC of 1.68%. Approximately 2% to 8% of the drug is metabolized primarily at the chlorofluoromethyl carbon. Little chlorofluoroacetic acid is produced suggesting minor metabolism at the difluoromethyl carbon. Difluoromethoxydifluoroacetate and fluoride ion have been reported as metabolites. Enflurane may increase heart rate, cause cardiac arrhythmias, increase cerebral blood flow, and increase intracranial pressure but all to a smaller degree than halothane.¹⁷ Enflurane also causes electroencephalographic (EEG) patterns consistent with electrical seizure activity. It has caused tonic-clonic convulsive activity in patients when used at high concentrations or during profound hypocarbic periods. Enflurane is therefore not recommended in patients with seizure disorders.²²

ISOFLURANE

Isoflurane is a volatile liquid (bp = 48.5°C) with an MAC of 1.15, a blood:gas partition coefficient of 1.43 and high solubility in fat. Isoflurane is a structural isomer of enflurane. It is a known respiratory irritant, but less so than desflurane. Approximately 0.2% of the administered drug undergoes metabolism, the rest is exhaled unchanged. The metabolism of isoflurane yields low levels of the nephrotoxic fluoride ion as well as a potentially hepatotoxic trifluoroacetylating compound (Fig. 22.3).²³ The relatively low concentrations of these compounds have resulted in very low risks of hepatotoxicity and nephrotoxicity. There have been no reports of

seizures caused by isoflurane and only transient increases in heart rate have been reported.

DESFLURANE

Desflurane is a nonflammable, colorless, very volatile liquid packaged in amber-colored vials. The boiling point is 22.8°C, and it requires a vaporizer specifically designed for desflurane. The manufacturer states that the vials can be stored at room temperature. Desflurane has a blood:gas partition coefficient of 0.42, an MAC of 7.3% and an oil:gas partition coefficient of 18.7. The low blood:gas partition coefficient leads to fast induction times and short recovery times. Desflurane is not recommended for induction anesthesia in children because of the high incidence of laryngospasms (50%), coughing (72%), breath holding (68%), and increase in secretions (21%).²⁴ Desflurane can produce a dose-dependent decrease in blood pressure and concentrations exceeding 1 MAC may cause transient increases in heart rate. Desflurane can react with desiccated carbon dioxide adsorbents to produce carbon monoxide that may result in elevated levels of carboxyhemoglobin.²⁴

Desflurane is metabolized minimally with less than 0.02% of the administered dose recovered as urinary metabolites. Desflurane produces minimal free fluoride ion and very little trifluoroacetic acid and has not been reported to cause either kidney or liver damage.

SEVOFLURANE

Sevoflurane is a volatile, nonpungent, nonflammable, and nonexplosive liquid with a boiling point of 58.6°C. The blood:gas partition coefficient is 0.65, the oil:gas partition coefficient is 50, and the MAC is 2.1%. Sevoflurane reacts with desiccated carbon dioxide adsorbents, to produce compounds (A and B) with known toxicity (Fig. 22.4). The type of CO₂ adsorbent used, the temperature of the adsorbent, and the duration of exposure can influence the degree to which sevoflurane breaks down.²⁵ The major breakdown product, compound A, pentafluoroisopropenyl fluoromethyl ether, (PIFE, C₄H₂F₆O) has been studied extensively.²⁵ Compound A is nephrotoxic in rats and nonhuman primates and remains a theoretical risk to humans.²⁶⁻²⁸ As discussed previously under the stability of inhaled anesthetics, sevoflurane breakdown by CO₂ adsorbents generates heat and has resulted in sporadic operating room fires.^{5,29}

Figure 22.3 • Isoflurane metabolism.

Figure 22.4 • Sevoflurane metabolism and chemical instability.

Approximately 5% to 8% of the administered dose of sevoflurane is metabolized in man by CYP2E1 to hexafluoroisopropanol, CO_2 and the potentially nephrotoxic fluoride ion. (Fig. 22.4).^{27,30,31} Patients should be monitored for increases in blood urea nitrogen (BUN) and creatine levels as high fluoride ion levels, and concerns about Compound A exposure, may induce renal toxicity. Sevoflurane has been studied in a small number of patients with preexisting renal insufficiency (creatinine >1.5 mg/dL). Creatinine levels increased in 7% of renally impaired patients and the manufacturer recommends that it be used with caution in this patient population.³² To reduce the potential toxicity in humans the use of sevoflurane should be limited to less than 2 MAC hours.¹⁷

Sevoflurane has been shown to cause epileptic changes on EEGs and case reports of seizures during surgery, especially in children, have been reported.³³

XENON

Xenon is an inert gas that is nonflammable and nonexplosive. The outer shell of xenon is complete thus it is not a highly reactive compound neither seeking, nor donating electrons to biological molecules. Despite its "inert" status, xenon has been shown to interact with biological molecules by forming an induced dipole in the presence of a cationic site.³⁴ An induced dipole could also result from an interaction with another fleeting dipole formed at the proposed binding site to form an induced dipole-induced dipole or London dispersion force.³⁵ The mechanism of xenon anesthesia and the site of action are still unknown.

The low blood:gas partition coefficient (0.12) leads to quick onset and recovery, but the potency is low with an MAC of 71%. Xenon gas is produced in low quantities and presently is expensive to obtain. The low incidence of reported side effects, lack of environmental concerns (it will not contribute to the destruction of the ozone layer), and absence of metabolites makes xenon an interesting anesthetic for development.^{36,37} Xenon is being tested in Japan and Europe presently and if a closed system anesthetic circulator is developed that can recapture the exhaled xenon the fiscal concerns may lessen. Patents have been awarded in the United States for xenon anesthetic equipment.

THE INJECTABLE GENERAL ANESTHETICS

General anesthesia includes the use of the inhalation anesthetics covered previously in this chapter and many intravenous drugs used during surgical procedures. The reader is referred to other chapters in this textbook for information on the benzodiazepines (Chapter 12), the barbiturates (Chapter 12), and the neuromuscular blockers (Chapter 17). Three additional drugs will be covered here that are solely used for their anesthetic effects: propofol, etomidate, and ketamine.

Propofol

Propofol

Propofol is an injectable sedative-hypnotic used for the induction and maintenance of anesthesia or sedation. Propofol is only slightly soluble in water with an octanol/water partition coefficient of 6,761:1; thus, it is formulated as an oil-in-water emulsion. The fat component of the emulsion consists of soybean oil, glycerol, and egg lecithin. The pK_a of the propanol hydroxyl is 11 and the injectable emulsion has a pH of 7 to 8.5. Formulations contain either disodium ethylenediaminetetraacetic acid (EDTA) (0.005%) or sodium metabisulfite to retard the growth of microorganisms. EDTA is a metal chelator and patients on propofol containing EDTA for extended periods of time excrete more zinc and iron in their urine.³⁸ The clinical consequence of this is not known but the manufacturer recommends that a drug holiday or zinc supplementation be considered after 5 days of therapy.³⁹ Generic formulations of propofol may contain sodium metabisulfite as the antimicrobial agent, and patients allergic to sulfites, especially asthmatic patients, should avoid this formulation.⁴⁰ Aseptic technique must be followed and unused portions of the drug must be discarded according to the

Figure 22.5 • Metabolism of propofol.

manufacturer's instructions to prevent microbial contamination and possible sepsis.

Although unrelated chemically to the inhaled anesthetics, propofol has been shown to be a positive modulator of the GABA_A receptor. The binding site on GABA_A is distinct from the benzodiazepine binding site, and propofol binding is not inhibited by the benzodiazepine antagonist flumazenil.⁴¹ The propofol binding site is believed to be on the β subunit. Propofol also directly activates Cl currents at glycine receptors, the predominant spinal inhibitory receptor. Unlike many volatile general anesthetics, propofol does not enhance the function of serotonin 5-HT₃ receptors and this may explain its low incidence of postoperative nausea and vomiting.⁴² Propofol shows no analgesic properties, but it does not increase sensitivity to pain like some barbiturates.⁴³ Propofol causes a dose-dependent decrease in blood pressure and heart rate and a threefold to fourfold increase in serum triglyceride concentrations after 7 days of administration.⁴⁰

Propofol is quickly and extensively metabolized with 88% of a ¹⁴C-labelled intravenous administered dose appearing in the urine as conjugates. Less than 2% of the dose is found unchanged in the feces and less than 0.3% found unchanged in the urine (Fig 22.5). Thirty minutes after the ¹⁴C-labelled dose was administered, 81% of the radioactivity was in the form of metabolites.⁴³ Propofol has a quick onset of action (arm-to-brain circulation time) and a quick recovery time.

Etomidate

Etomidate

Etomidate is a carboxylated imidazole intended for the induction of general anesthesia. It is marketed as the more potent *R* (+) isomer. It is believed to exert its anesthetic effect via positive modulation of the GABA_A receptor.⁴⁴ It is not water soluble and is available in the United States as a 2-mg/mL solution containing 35% v/v propylene glycol and in Europe as a soybean oil and medium-chain triglycerides formulation.^{45,46} The propylene glycol has been associated with moderate-to-severe pain on injection and irritation of the vascular tissue.⁴⁶ A high incidence of skeletal muscle movements were noted in about 32% of patients following etomidate injection. Case reports of seizures are also found in the literature.⁴⁷ Administration of etomidate has little effect on cardiac output, peripheral, or pulmonary circulation. Studies have found that etomidate, even after a single dose, reduces plasma cortisol and aldosterone levels. Etomidate should not be used in patients with severe sepsis as the adrenal insufficiency has been shown to increase the risk of death in these patients.⁴⁸ This is probably a result of the inhibition of the 11 β -hydroxylase enzyme. Etomidate should only be used for induction of anesthesia when the cardiac benefits outweigh the risks associated with adrenal insufficiency.

Etomidate is quickly distributed throughout most organs in the body after intravenous administration and the tissue concentrations equal and sometimes exceed the plasma concentrations. The lipid solubility of the drug allows it to rapidly penetrate into the brain with peak concentrations occurring within 1 minute of administration. Etomidate is rapidly metabolized in the plasma and liver via esterases. About 75% of the drug is eliminated in the urine as the inactive ester hydrolyzed carboxylic acid.⁴⁹

Ketamine

Ketamine

Ketamine is formulated as an acidic solution, pH 3.5 to 5.5, available with or without 0.1 mg/mL benzethonium chloride preservative. Ketamine is marketed as the racemic mixture and some properties of the individual isomers have been elucidated.⁵⁰ Ketamine is a rapid-acting agent that can be used for induction, used as the sole agent for general anesthesia or combined with other agents. Unlike the proposed mechanism of action for most anesthetics, ketamine does not act at the GABA_A receptor. Ketamine acts as a noncompetitive antagonist at the glutamate, NMDA receptor, a nonspecific ion channel receptor. The NMDA receptor is located throughout the brain and contains four well-studied binding sites. The primary binding site binds L-glutamate, NMDA, and aspartate. The allosteric site binds glycine, which facilitates primary ligand binding. There is also a magnesium binding site that blocks ion flow through the channel and a phencyclidine (PCP) binding site that blocks the ion channel when occupied. Ketamine is believed to bind to the PCP site in a stereoselective manner and block the ion flow in the channel.⁵¹ By blocking the flow of calcium ions into the cell, ketamine prevents the calcium

Figure 22.6 • Metabolism of ketamine.

concentration from building and triggering excitatory synaptic transmissions in the brain and spinal cord.

Ketamine causes a transient increase in blood pressure after administration and is contraindicated in patients whom a significant elevation of blood pressure would constitute a serious hazard. Ketamine has also been found to bind to mu, delta, and kappa opioid receptors as well as the sigma receptors. The S(+)-ketamine is two to three times more potent than the R(-)-ketamine as an analgesic.⁵¹ Ketamine has different effects at different doses on the opioid receptors and the use of ketamine as a postoperative analgesic or for chronic pain requires more study.^{52,53}

Ketamine is classified as a “dissociative anesthetic,” and psychological manifestations during emergence of anesthesia occur in 12% of patients. These vary from pleasant dreamlike states to vivid hallucinations and delirium. The duration is usually for only a few hours but patients have reported recurrences taking place up to 24 hours postoperatively. The incidence of this appears to be less in children younger than 16 years of age and in patients older than 65 years of age. Like other dissociative anesthetics, ketamine is abused for its hallucinatory effects. Most of the illegally used ketamine comes from stolen legitimate sources, particularly from veterinary clinics or smuggled in from Mexico.⁵⁴

Ketamine is metabolized via *N*-demethylation to form the main metabolite norketamine. Norketamine has about one third the potency of the parent compound. Minor meta-

bolic pathways include hydroxylation of the cyclohexanone ring; hydroxylation followed by glucuronide conjugation, and hydroxylation followed by dehydration to the cyclohexenone derivative (Fig. 22.6).^{55,56}

THE LOCAL ANESTHETICS

Drugs classified as local anesthetics inhibit the conduction of action potentials in all afferent and efferent nerve fibers. Thus, pain and other sensations are not transmitted effectively to the brain, and motor impulses are not transmitted effectively to muscles. Local anesthetics have various clinical uses to treat acute or chronic pain or to prevent the sensation of pain during procedures. To understand the mechanism of action of the local anesthetics, an introduction to the physiology of nerve fibers and the transmission of pain sensation is briefly discussed below.

Physiology of Nerve Fibers and Neurotransmission

The nervous system functions to receive stimulation and transmit stimulus via the nerve cells or neurons. A neuron is a single cell typically composed of a cell body connected via an axon to the axon terminal (Fig. 22.7). The axon terminal is the presynaptic component of the nerve synapse and may contain neurotransmitters ready to be released upon receiving an action potential “message”. The axon

Figure 22.7 • Schematic diagram of a neuron. Representation of the various branching found in dendrites.

Figure 22.8 • Representations of myelinated (A) and unmyelinated (B) axons.

varies in length from a few millimeters to a meter or longer. Most axons are too long to transmit the signal to the terminal ending by simple chemical diffusion. Thus, the message received by the neuron cell body is transmitted as an electrical impulse to the axon terminal. The electrical impulse is most often generated at the axon hillock, the region of the cell body where the axon emerges. The electrical impulse is conducted by changes in the electrical potential across the neural membrane. The rate at which the message is transmitted down the axon depends on the thickness of the axon and the presence or absence of myelin. The axon may be bare or it may be surrounded by the membrane of a glial cell that forms a myelin sheath (Fig. 22.8). Between the myelin sheaths are areas of the axonal membrane that are unmyelinated, these bare areas are called the nodes of Ranvier. The nodes of Ranvier allow the nerve impulse to skip from node to node down the length of the axon to increase the speed of the action potential conduction (Fig. 22.9). In unmyelinated neurons, the change in the electrical potential of one part of the membrane causes a change in electrical potential of the adjacent membrane, thus the impulse moves along the axon slower. Nerve impulses travel at speeds of up to 120 m/s in myelinated axons and 10 m/s in unmyelinated axons.

The electrical potential difference between the inner and outer surfaces of the cell membrane is a result of the movement of ions across the membrane. At rest, most neurons have a resting potential of about -70 mV. This means that the inside of the neuron contains more anionic charges than the external side. The ions that move across the nerve membrane and contribute to most of the electrochemical potential are Ca^{2+} , Na^+ , K^+ , and Cl^- . For a nerve cell to transmit an impulse, the internal charge must increase about 20 mV to -50 mV, the firing threshold for a nerve cell. If this initial depolarization reaches the firing threshold, an action potential will be generated. During an action potential the internal charge will quickly increase to about $+35$ mV and the membrane is now *depolarized*. This spike is quickly followed by the *hyperpolarization* of the membrane, to

Figure 22.9 • Representation of the transmission of a nerve impulse along a neuron fiber by saltatory conduction.

below -70 mV, followed by the return of the membrane to the resting potential (Fig. 22.10). The generation of the action potential from the axon hillock to the terminal end of the nerve may result in the release of neurotransmitters that cross the synaptic cleft to deliver the “message” to the adjacent neuron or target organ.

Neuronal Membrane Ion Permeability During an Action Potential

By definition, the membrane potential is the difference in the polarity of the inside of the cell compared to the outside of the cell, with the outside of the cell conventionally set at 0 mV. During an action potential, the membrane potential changes from a -70 to a $+35$ mV. Exactly how does a membrane change its electrical potential? It changes its potential by the movement of ions. For an ion to move from one side of the lipophilic membrane to the other, it must go through a channel. There are many specialized protein channels that can change their three-dimensional configuration to allow ions to flow through. If the ion is moving with its concentration gradient, it can simply diffuse through an open channel, no energy would be required. For an ion to move against the electrical gradient, energy is required and the channels are therefore coupled to ATP pumps.

The axolemma is more permeable to K^+ ions than to Na^+ ions. These ions diffuse out of the neuron through the so-called *potassium leak channels*, whose opening does not appear to require a specific membrane change. The movement of K^+ ions is concentration driven; K^+ ions move from inside the neuron, where the concentration is high, to the extracellular fluid, where the concentration is lower. This tendency of K^+ ions to leak out of the neuron (*driven by the concentration gradient*) is balanced to some extent by a limited movement of K^+ ions back into the neuron, both by diffusion through K^+ channels and by active transport mechanisms such as the sodium/potassium ATPase pump. These movements of K^+ result in a potential difference across the membrane, which is a major contributor to the *equilibrium potential* that exists between the opposite faces

Figure 22.10 • Changes in electrical potential observed during a nerve impulse.

of a biological membrane in a normal cell at rest with a switched-on sodium pump.

The initial depolarization of the neuron (Fig. 22.10) was shown by Hodgkin and Huxley in 1953 to be a result of increased movement of Na^+ into the neuron, which is followed almost immediately by increased movement of K^+ ions out of the neuron. It is thought that the action potential is triggered by a stimulation that causes a momentary shift of the membrane potential of a small section of the membrane to a less negative value (*depolarization of the membrane*). This causes the gated Na^+ channels in this section of the membrane to open, which allows Na^+ to enter the cell. This process depolarizes the membrane still further, until the action potential reaches a critical value (the *firing threshold*), when it triggers the opening of large numbers of adjacent Na^+ channels so that Na^+ ions flood into the axon. This process continues until the membrane potential of this section of membrane reaches the equilibrium potential for Na^+ ions when the cell is at rest. At this point, all the Na^+ channels of the membrane should be permanently open. This situation is not reached, however, because each channel has an automatic closing mechanism that operates even though the cell membrane is still depolarized. Once closed, the ion channel cannot open again until the membrane potential in its vicinity returns to its original negative value, which is brought about by the leakage of K^+ ions out of the neuron through K^+ channels. Hodgkin and Huxley showed that a membrane becomes more permeable to K^+ ions, a fraction of a millisecond after the Na^+ channels have started to open. As a result, K^+ ions flow out of the neuron, which reduces the electrical potential of the membrane, and so at the peak of the action potential, the membrane potential has a value of about +40 mV. The movement of the K^+ ions out of the axon, coupled with the automatic closing of the sodium channel gates and the slower action of the sodium/potassium ATPase pump that transports 3 Na^+ ions out of the neuron for every 2 K^+ ions into the neuron, results in a net flow of positive ions out of the neuron. This briefly *hyperpolarizes* the membrane and causes the membrane potential to drop below its resting potential. As the sodium channels close and K^+ ions flow back into the axon, the membrane potential returns to its resting value. The entire process of depolarization and repolarization is normally accomplished within 1 millisecond.

Ligand-Gated Sodium Channel Structure and Function

Based on mutation studies and electrophysiology studies, a three-dimensional picture relating the structure of the sodium channel to its function is emerging. The sodium channel is a complicated protein with multiple polypeptide sections that are responsible for specific functions of the channel. The channel must (a) be selective for sodium ions, (b) be able to detect and then open when the membrane is slightly depolarized, (c) be able to detect and then close when the membrane becomes hyperpolarized, and (d) convert to a resting state ready to depolarize again. There is much work currently being conducted on all of these functions of the sodium channel.

The mammalian brain sodium channel is comprised of an α subunit and one or more auxiliary β subunits (Figs.

22.11–22.12). The α subunit is composed of four domains (DI–DIV) that fold to make the pore that the sodium ions pass through. Each of the four domains is composed of six transmembrane α -helical segments (S1–S6). The β subunits are involved in the kinetics and voltage dependence of sodium channel opening and closing. The β subunits have large extracellular domains with many sites of glycosylation and only one transmembrane segment.⁵⁷

The sodium channel contains specific amino acids that act as a *selectivity filter*, only allowing sodium ions to pass through the channel. The amino acids that make up the selectivity filter of an ion channel are referred to as the P region. Sodium channels have a P region that gives specificity to sodium ions, whereas potassium and calcium channels have their own P regions that confer selectivity for their respective ions. The selectivity filter of the sodium channel is composed of two rings made up of amino acids from the four homologous domains (DI–DIV). The first ring is composed entirely of negatively charged amino acids. Approximately two to three amino acids deeper into the pore, the second ring is found. The second ring of the P region of the sodium channel is composed of the amino acid sequence DEKA (Asp Glu Lys Ala), whereas the P region of a calcium channel is EEEE (Glu Glu Glu Glu).⁵⁸ By selectively mutating the four amino acids from DEKA to EEEE, selectivity for calcium could be conferred to the sodium channels.⁵⁹ Other studies also showed that when external solutions were made highly acidic the negative charges of the selectivity filter amino acids could be neutralized ($\text{COO}^- \rightarrow \text{COOH}$) and ion conductivity decreased.⁵⁸

The sodium channel must also be able to change conformations in response to small changes in the membrane potential. How do sodium channels detect voltage changes and then change shape in response to them? The voltage sensing units of the sodium channels are the S4 segments of the α subunit. These segments contain positively charged amino acids at every third residue. It is postulated that the S4 segments move in response to the change in the local membrane potential and cause a further conformational change that opens the gate of the sodium channel, thus allowing sodium to flow in.⁶⁰ The S4 voltage sensors are also responsible for causing conformational changes in the receptor that close the channel to sodium conductance. Exactly how the conformational changes occur is being studied (Fig. 22.12).

Further down the pore of the sodium channel, beyond the selectivity filter lays the putative *local anesthetic binding site* (Fig. 22.13). Site directed mutagenesis studies and molecular modeling studies suggest that local anesthetic binding involves multiple interactions. The positively charged nitrogen of the local anesthetic molecule may form a cation – π electron interaction with a phenylalanine residue from the DIVS6 domain.^{61,62} The aromatic ring of the anesthetic may also interact with a tyrosine amino acid in the DIVS6 domain. The putative local anesthetic binding site is believed to involve the S6 subunits of the α DI, DIII, and DIV domains. The exact amino acids involved depend on the source and the state of the sodium channel being studied. These studies also suggest that the positively charged nitrogen of the local anesthetic may lie in the center of the pore to create an electrostatic repulsive force that, in addition to the steric block, would prevent sodium ion passage through the pore (Fig. 22.13).⁵⁷

Figure 22.11 • Structure of voltage-gated sodium channels. Schematic representation of the sodium-channel subunits. The α subunit of the $\text{Na}_v1.2$ channel is illustrated together with the $\beta 1$ and $\beta 2$ subunits; the extracellular domains of the β subunits are shown as immunoglobulin-like folds, which interact with the loops in the α subunits as shown. Roman numerals indicate the domains of the α subunit; segments 5 and 6 (dark gray) are the pore-lining segments and the S4 helices (light gray) make up the voltage sensors. Light gray circles in the intracellular loops of domains III and IV indicate the inactivation gate IFM motif and its receptor (h, inactivation gate); P, phosphorylation sites, in dark gray circles, sites for protein kinase A; in dark gray diamonds, sites for protein kinase C; ψ , probable N-linked glycosylation site. The circles in the re-entrant loops in each domain represent the amino acids that form the ion selectivity filter (the outer rings have the sequence EEDD and inner rings DEKA). Mechanism of Action of Local Anesthetics

The mechanism of action of the local anesthetics is believed to be via their sodium channel blocking effects. The local anesthetic drug binds to the channel in an area just beyond the selectivity filter or P region (Fig. 22.13). When the local anesthetic binds, it blocks sodium ion passage into the cell and thus blocks the formation and propagation of the action potential. This blocks the transmittance of the message of “pain” or even “touch” from getting to the brain. The ability of a local anesthetic to block action potentials depends on the ability of the drug to penetrate the tissue surrounding the targeted nerve as well as the ability of the drug to access the binding site on the sodium channel.

Local anesthetics do not access the binding site by entering into the sodium channel from the exterior of the neuron. The molecules are too big to pass by the selectivity filter. When local anesthetics are synthesized with a permanent charge, such as compound QX-314 below, they are unable to access the binding site unless they are applied directly to the interior of the neuron.⁶³ (For more information on QX-314 see “Future Directions,” at the end of this chapter.)

QX-314

If local anesthetics do not access the binding site via the external side, how do they get to their site of action? There is much experimental evidence to show that local anesthetics must access the binding site via a hydrophobic or via a hydrophilic pathway (Fig. 22.13).^{64,65} The anesthetics pass through the membrane in their uncharged form (Fig. 22.13 hydrophobic pathway A). In the axoplasm, they reequilibrate with their cationic species. It is postulated that the anesthetic molecule may access the binding site via a hydrophilic pathway by entering into the sodium channel from the interior of the pore, when the channel is open (Fig. 22.13 hydrophilic pathway C). The local anesthetic molecule is believed to bind to the binding site in its ionized form. Another possibility is that before passing all the way through the lipid membrane, the anesthetic may be able to directly access the local anesthetic binding site (Fig. 22.13 hydrophobic pathway B).

Studies using local anesthetics containing a tertiary nitrogen also confirm that the local anesthetic is accessing the binding site from either the hydrophobic or hydrophilic pathways described previously. When this type of anesthetic is applied externally, and the pH of the external media is increased, and thus the local anesthetic is predominantly in the unionized form, the onset of block is more rapid. The neutral form of the drug molecule penetrates the membrane and then accesses the binding site through pathway B or C described in Figure 22.13. The pH of the solution had no effect on sodium conduction block when the local anesthetic used was the neutral molecule benzocaine, suggesting that the change in pH affects the drug charge and not the receptor.^{63,66}

The sodium channel has been shown to have a great deal of flexibility and can change shape when the electrical environment around the channel changes. There are at least three conformations that the sodium channel can form. (a) An open state, such as that depicted in Figure 22.12 (drawing on the left) where the sodium ion has a clear pathway from the external side of the membrane to the internal side of the membrane. (b) A “closed/inactive” state shown in Figure 22.12 (drawing on the right), where the sodium channel undergoes a conformational change to prevent sodium ion passage into the cell. The sodium channel undergoes this conformational change in response to the huge influx of sodium causing depolarization of the cell membrane. The sodium channel is now closed and inactive, it cannot open again until the membrane has reached its resting potential. (c) The third conformation of the sodium channel is formed when the membrane potential returns to the resting potential. The sodium channel is now closed but able to open when a stimulus reaches the threshold potential. At this point, the sodium channel is in a “closed/resting” state that is different from the “closed/inactive” state.

The affinity of the local anesthetics for the binding site has complex voltage and frequency dependant relationships. Affinity depends on what state the sodium channel is in as well as the specific drug being tested. In general, at resting states, when the membrane is hyperpolarized, the local anesthetics bind with low affinity. When the membrane has been depolarized and the channel is open, local anesthetics bind with high affinity. Local anesthetics also bind with high affinities when the sodium channel is in the “closed/inactive” conformation, perhaps stabilizing the inactive form of the receptor.

The ability of the local anesthetic to block conduction also depends on the targeted neuron. In general, autonomic fibers, small unmyelinated C fibers (mediating pain sensations), and small myelinated A γ fibers (mediating pain and temperature sensations) are blocked before the larger myelinated A γ , A β , and A α fibers (mediating postural, touch, pressure, and motor information).⁶⁷

SARs of Local Anesthetics

The structure of most local anesthetic agents consists of three parts as shown above. They contain (a) a lipophilic ring that may be substituted, (b) a linker of various lengths that usually contains either an ester or an amide, and (c) an amine group that is usually a tertiary amine with a pK_a between 7.5 and 9.0.

1. The Aromatic Ring

The aromatic ring adds lipophilicity to the anesthetic and helps the molecule penetrate through biological membranes. It is also thought to have direct contact with the local anesthetic binding site on the sodium channel. The exact amino acids involved in binding depend on the sodium channel being studied as well as the state (open, closed/inactive, closed/active) of the sodium channel. The aromatic ring is believed to interact with the local anesthetic binding site in a π - π interaction or a π -cation interaction with the S6 domain of the α component of the sodium channel. Substituents on the aromatic ring may increase the lipophilic nature of the aromatic ring. An SAR study of para substituted ester type local anesthetics showed that lipophilic substituents and electron-donating substituents in the para position increased anesthetic activity.⁶⁸ The lipophilic substituents are thought to both increase the ability of the molecule to penetrate the nerve membrane and increase their affinity at the receptor site. Buchi and Perlia suggested that the electron-donating groups on the aromatic ring created a resonance effect between the carbonyl group and the ring, resulting in the shift of electrons from the ring to the carbonyl oxygen. As the electronic cloud around the oxygen increased, so did the affinity of the molecule with the receptor (Fig. 22.14).⁶⁹ When the aromatic ring was substituted with an electron-withdrawing group, the electron cloud around the carbonyl oxygen decreased and the anesthetic activity decreased as well.

2. The Linker

The linker is usually an ester or an amide group along with a hydrophobic chain of various lengths. In general, when the number of carbon atoms in the linker is increased, the lipid solubility, protein binding, duration of action, and toxicity increases.⁷⁰ Esters and amides are bioisosteres having similar sizes, shapes, and electronic structures. The similarity in their structures means that esters and amides have similar binding properties and usually differ only in their stability in vivo and in vitro. For molecules that only differ at the linker functional groups, amides are more stable than esters and thus have longer half-lives than esters. Plasma protein binding may

Figure 22.14 • Schematic representation of the binding of an ester-type local anesthetic agent to a receptor site. (Reprinted with permission from Buchi, J., Perlia, X.: Design of local anesthetics. In Ariens, E. J. [ed.] Drug Design. New York, Academic Press, 1972, Vol. 3, p. 243.)

be more prevalent for the amide anesthetics as well, contributing to the increased half-life.⁷¹ Individual drugs are discussed in the drug monograph section.

As described previously, the nature of the substituents on the aromatic ring can affect the electronic nature of the linker and can contribute to the drug's potency and stability. Substituents on the aromatic ring may also confer a steric block to protect the linker from metabolism. Thus, the binding affinity and stability of the anesthetic molecule is affected by the linker as well as the functional groups on the aromatic ring. In general, ester groups are more susceptible to hydrolysis than amide functional groups because of the prevalence of esterases in the blood and the liver. The first ester type local anesthetic synthesized was procaine (Novocain) in 1905. Procaine metabolism can be seen in Figure 22.15. The para-aminobenzoic acid (PABA) metabolite, common to the ester class of drugs, is believed to be responsible for the allergic reactions some patients have experienced with local anesthetics.⁷²

3. The Nitrogen

Most local anesthetics contain a tertiary nitrogen with a pK_a between 7.5 and 9.5. Therefore, at physiological pH, both the cationic and neutral form of the molecule exists. At physiological pH, the ionized to unionized form of the anesthetic can be calculated using the Henderson-Hasselbalch equation:

$$pH = pK_a + \log \left(\frac{[B]}{[BH^+]} \right)$$

Extensive work using both internally and externally applied compounds, changing the pH of the solution, and using permanently charged anesthetic analogs has led to the present theory of anesthetic SARs. Namely, that the anesthetic compounds bind to the anesthetic receptor site on the sodium channel in the ionized form. From Figure 22.13, it can be seen that the molecule can penetrate the nerve membrane in its neutral form and then reequilibrate with its cationic form on the internal side of the membrane. Permanently charged, quaternary anesthetics applied to the

external side of the nerve membrane do not penetrate and cannot access the local anesthetic binding site.

To keep the anesthetic soluble in commercial solutions, most preparations are acidified. In an attempt to decrease pain on injection and to increase the onset of action, some practitioners advocate adding sodium bicarbonate to the commercial preparation. By adding sodium bicarbonate, the solution will become less acidic and more of the drug will be found in the neutral form. The neutral form will thus cross the nerve membrane quicker and have a quicker onset of action. Although this theoretically makes sense, many studies have found no difference in the onset of action between alkalized and nonadjusted anesthetics. Manufacturers formulate solutions at a pH that gives them adequate shelf life. When the pH is increased, the stability of the preparation decreases and outright precipitation can occur if too much of the water-soluble cationic form is converted to the anesthetic base. If this practice is followed, very careful titration of the added base is required. The solution should be observed for precipitation and the solution must be used immediately.

Vasoconstrictors Used in Combination with Local Anesthetics

Many anesthetic preparations are commercially available combined with the vasoconstrictor epinephrine. Some anesthetics are also combined with other agents such as norepinephrine, phenylephrine, oxymetolazone, or clonidine to achieve a desired formulation. The epinephrine in the anesthetic solution has multiple purposes. As a vasoconstrictor, the injected epinephrine will constrict capillaries at the injection site and thus limit blood flow to the area. The local anesthetic will thus stay in the immediate area of injection longer and not be carried away to the general circulation. This will help keep the drug where it is needed and allow minimal drug to be absorbed systemically. Thus, anesthetics with epinephrine used for infiltration anesthesia consistently result in lower plasma levels of the anesthetic. This will reduce the systemic toxicity from the anesthetic and increase

Figure 22.15 • Metabolism of procaine.

the duration of anesthetic activity at the site of injection. The lack of blood flow in the immediate area will also decrease the presence of metabolizing enzymes and this also increase the duration of action of the anesthetic locally. The characteristic blanching that follows epinephrine infiltration anesthesia also makes suturing or manipulating the area easier because of the lack of blood flow in the area. It is not recommended that anesthetics with a vasoconstrictor be used in tissue served by end-arterial blood supply (fingers, toes, earlobes, etc.). This is to prevent ischemic injury or necrosis of the tissue. Epinephrine has also been shown to counteract the myocardial depressant effects of bupivacaine when added to a bupivacaine epidural solution.⁷³

Allergic Reactions to Local Anesthetics

True allergic reactions to local anesthetics are very rare. Patients may be allergic to the anesthetic, a metabolite of the anesthetic or a preservative in the anesthetic. Allergies to the ester anesthetics are more common than allergies to the amide anesthetics. As discussed, the ester anesthetics may be metabolized to PABA, which is believed to be responsible for the allergic reactions (Fig. 22.15).

Although the amide type local anesthetics are not metabolized to PABA they may contain a paraben preservative that can be metabolized to PABA like compounds. Parabens are methyl, ethyl, propyl, and butyl aliphatic esters of PABA. In addition to parabens, anesthetics may be preserved with metabisulfites that are also known to cause allergic reactions in sensitive patients, especially patients with asthma.⁷⁴ Thus, patients that are allergic to ester type local anesthetics should receive a preservative free amide type anesthetic.

PABA also blocks the mechanism of action of the sulfonamide antibiotics. Sulfonamide antibiotics bind to and inhibit the action of the dihydropteroate synthetase enzyme, the enzyme bacteria used to convert PABA to folate. The inhibition of this enzyme is competitive, therefore if enough PABA is present it will compete with the antibiotic for the binding site on the enzyme and bacterial folate would be synthesized. Thus, there is at least a theoretical reason not to use a PABA forming anesthetic in a patient being treated with a sulfonamide antibiotic.

Methemoglobinemia

Cyanosis as a result of the formation of methemoglobinemia may occur after the administration of the local anesthetics lidocaine,⁷⁵ prilocaine,^{76,77} and benzocaine.⁷⁸ When normal hemoglobin is oxidized by a drug or drug metabolite, it forms methemoglobin. Methemoglobin contains the oxidized form of iron, ferric iron (Fe^{3+}) rather than the reduced ferrous iron (Fe^{2+}) that hemoglobin contains. The oxidized iron cannot bind to oxygen, and methemoglobinemia results when the methemoglobin concentration in the blood reaches 10 to 20 g/L (6%–12% of the normal hemoglobin concentration). Cyanosis results and does not respond to treatment with 100% oxygen. Patients with increased risk factors for developing drug-induced methemoglobinemia include children younger than 2 years, anemic patients, those with a genetic deficiency of glucose-6-phosphate dehydrogenase or nicotinamide adenine dinucleotide methemoglobin reductase or those exposed to excessive doses of the causative local anesthetic. If clinical

symptoms of methemoglobinemia occur, treatment is an intravenous infusion of a 1% methylene blue solution, 1 mg/kg body weight, over 5 minutes.

LOCAL ANESTHETIC MONOGRAPHS, INDIVIDUAL PRODUCTS INCLUDING ADVERSE REACTIONS

The Ester Local Anesthetics

COCAINE

Cocaine

Cocaine was the first agent used for topical anesthesia. It was isolated from the coca leaves that native peoples of the Andes Mountains chew for multiple effects including local anesthesia and stimulant properties to ward off fatigue. Chemists working with the coca alkaloids noticed that the crystals could numb their tongues. In 1884, a German surgeon demonstrated the successful use of cocaine to anesthetize the cornea during eye surgery. One of the most prominent surgeons at Johns Hopkins University, Dr. William Halsted, read about this account and began investigations with cocaine for general surgery. They successfully used cocaine during surgery, but unfortunately Dr. Halsted and several colleagues became addicted.⁷⁹ Today, cocaine is used for topical anesthesia of mucous membranes using a 4% to 10% solution. If the solution remains on the membrane for 5 minutes, anesthesia and vasoconstriction of the area will occur. Cocaine has inherent vasoconstrictor properties thus requires no additional epinephrine. The toxicity of cocaine is a result of its vasoconstrictor properties and ability to inhibit catecholamine, including norepinephrine reuptake. Toxic manifestations include excitation, dysphoria, tremor, seizure activity, hypertension, tachycardia, myocardial ischemia, and infarction. Cocaine is used primarily for nasal surgeries, although its abuse potential has resulted in a decrease in use and a search for alternate anesthetics. When cocaine was compared with lidocaine/phenylephrine for nasal intubations, the results were the same with less toxicity in the lidocaine/phenylephrine group.⁸⁰

PROCAINE

Procaine

Procaine was synthesized in 1904 to address the chemical instability of cocaine and the local irritation it produced. The

pK_a of procaine is 8.9; it has low lipid solubility and the ester group is unstable in basic solutions. Procaine is available in concentrations ranging from 0.25% to 10% with pHs adjusted to 5.5 to 6.0 for chemical stability. Procaine is also included in some formulations of penicillin G to decrease the pain of intramuscular injection. Procaine is very quickly metabolized in the plasma by cholinesterases and in the liver via ester hydrolysis by a pseudocholinesterase (Fig. 22.15). The in vitro elimination half-life is approximately 60 seconds. Any condition that decreases the cholinesterase concentration may increase exposure to procaine and potential toxicity. Decreased enzyme activity can be found with genetic deficiency, liver disease, malignancy, malnutrition, renal failure, burns, third trimester of pregnancy, and following cardiopulmonary bypass surgery. Ester hydrolysis produces PABA, the compound responsible for the allergic reactions common to the ester anesthetics. Procaine is not used topically because of its inability to pass through lipid membranes and finds use as an infiltration agent for cutaneous or mucous membranes, for short procedures. Procaine is also used for peripheral nerve block and as an epidural agent to diagnose pain syndromes.⁷³

CHLOROPROCAINE

2-Chloroprocaine

The 2-chloride substitution on the aromatic ring of chloroprocaine is an electron-withdrawing functional group. Thus, it pulls the electron density from the carbonyl carbon into the ring. The carbonyl carbon is now a stronger electrophile and more susceptible to ester hydrolysis. Therefore, chloroprocaine has a more rapid metabolism than procaine. The in vitro plasma half-life is approximately 25 seconds. The 2-chloro-4-aminobenzoic acid metabolite precludes this from being used in patients allergic to PABA. The very short duration of action means that this drug can be used in large doses for conduction block (with rapid onset and short duration of action.) As with procaine, a decrease in the plasma cholinesterase activity will prolong the half-life. The pK_a of the chloroprocaine alkyl amine is 9.0 and thus chloroprocaine is almost exclusively ionized at physiological pH. Chloroprocaine is formulated with a pH between 2.5 and 4.0 using hydrochloric acid. The acidic pH of the formulation is responsible for considerable irritation and pain on injection.

Chloroprocaine is used for cutaneous or mucous membrane infiltration for surgical procedures, epidural anesthesia (without preservatives) and for peripheral conduction block.

TETRACAINE

Tetracaine

Tetracaine was developed to address the low potency and short duration of action of procaine and chloroprocaine. The

addition of the butyl side chain on the para nitrogen increases the lipid solubility of the drug and enhances the topical potency of tetracaine. The plasma half-life is 120 to 150 seconds. Topically applied tetracaine to unbroken skin requires 30 to 45 minutes to confer topical anesthesia. Tetracaine 4% gel is superior than eutectic mixture with lidocaine (EMLA) (an emulsion of lidocaine and prilocaine) in preventing pain associated with needle procedures in children.⁸¹ Tetracaine metabolism is similar to procaine ester metabolism yielding parabuty-laminobenzoic acid and dimethylaminoethanol and conjugates excreted in the urine. The pK_a of the dimethylated nitrogen is 8.4 and tetracaine is formulated as a hydrochloride salt with a pH of 3.5 to 6.0. The increased absorption from topical sites has resulted in reported toxicity. Overdoses of tetracaine may produce central nervous system (CNS) toxicity and seizure activity with fatalities from circulatory depression reported.⁸² No selective cardiac toxicity is seen with tetracaine although hypotension has been reported. Tetracaine is employed for infiltration anesthesia, spinal anesthesia, or topical use.

BENZOCAINE

Benzocaine

Benzocaine is a unique local anesthetic because it does not contain a tertiary amine. The pK_a of the aromatic amine is 3.5 ensuring that benzocaine is uncharged at physiological pH. Because it is uncharged, it is not water soluble but is ideal for topical applications. The onset of action is within 30 seconds and the duration of drug action is 10 to 15 minutes. Benzocaine is used for endoscopy, bronchoscopy, and topical anesthesia. Benzocaine is available as a 20% solution topical spray, in a 1% gel for mucous membrane application, and a 14% glycerin suspension for topical use in the outer ear.

Toxicity to benzocaine can occur when the topical dose exceeds 200 to 300 mg resulting in methemoglobinemia. Infants and children are more susceptible to this and methemoglobinemia has been reported after benzocaine lubrication of endotracheal tubes and after topical administration to treat a painful diaper rash.^{83,84}

The Amino Amide Local Anesthetics

LIDOCAINE

Lidocaine

Lidocaine was the first amino amide synthesized in 1948 and has become the most widely used local anesthetic. The tertiary amine has a pK_a of 7.8 and it is formulated as the hydrochloride salt with a pH between 5.0 and 5.5. When lidocaine is formulated premixed with epinephrine the pH of the solution is adjusted to between 2.0 and 2.5 to prevent

Figure 22.16 • Metabolism of lidocaine.

the hydrolysis of the epinephrine. Lidocaine is also available with or without preservatives. Some formulations of lidocaine contain a methylparaben preservative that may cause allergic reactions in PABA-sensitive individuals. The low pK_a and medium water solubility provide intermediate duration of topical anesthesia of mucous membranes. Lidocaine can also be used for infiltration, peripheral nerve and plexus blockade, and epidural anesthesia.

The metabolism of lidocaine is typical of the amino amide anesthetics and is shown in Figure 22.16. The liver is responsible for most of the metabolism of lidocaine and any decrease in liver function will decrease metabolism. Lidocaine is primarily metabolized by de-ethylation of the tertiary nitrogen to form monoethylglycinexylidide (MEGX). At low lidocaine concentrations, CYP1A2 is the enzyme responsible for most MEGX formation. At high lidocaine concentrations, both CYP1A2 and CYP3A4 are responsible for the formation of MEGX. The amide functional group is fairly stable because of the steric block provided by the ortho methyl groups although amide hydrolysis products are reported.⁸⁵⁻⁸⁷

The toxicity associated with lidocaine local anesthesia is low when used at appropriate doses. Absorption of lidocaine will be decreased with the addition of epinephrine to the local anesthetic. Toxicity increases in patients with liver disease and those with acidosis, which decreases plasma protein binding of lidocaine. CNS toxicity is low with seizure activity reported with high doses. The cardiac toxicity of lidocaine is manifested by bradycardia, hypotension, and cardiovascular collapse, which may lead to cardiac arrest and death.

MEPIVACAINE

Mepivacaine

Mepivacaine hydrochloride is available in 1% to 3% solutions and is indicated for infiltration anesthesia, dental procedures, peripheral nerve block, or epidural block. The onset of anesthesia is rapid, ranging from about 3 to 20 minutes for sensory block. Mepivacaine is rapidly metabolized in the liver with 50% of the administered dose excreted into the bile as metabolites. The metabolites are reabsorbed in the intestine and excreted in the kidney with only a small percentage found in the feces. Less than 5% to 10% of the administered dose is found unchanged in the urine. The primary metabolic products are the *N*-demethylated metabolite and the 3 and 4 phenolic metabolites excreted as their glucuronide conjugates.

PRILOCAINE

Prilocaine

Prilocaine hydrochloride is a water-soluble salt available as a solution for nerve block or infiltration in dental procedures. Prilocaine is used for intravenous regional anesthesia as the risk of CNS toxicity is low because of the quick metabolism. Prilocaine prepared in the crystal form is used in EMLA for topical administration to decrease painful needle sticks in children. Prilocaine 4% solution should be protected from light and the manufacturer recommends discarding if the solution turns pinkish or slightly darker than light yellow. Solutions are available in various concentrations up to 4%, with or without epinephrine and with or without preservatives.

The pK_a of the secondary amine is 7.9 and commercial preparations have a pH of 5.0 to 5.6. Prilocaine has only one ortho substitution on the aromatic ring, making it more susceptible to amide hydrolysis and giving it a shorter duration

Figure 22.17 • Metabolism of prilocaine.

of action than lidocaine. Prilocaine metabolism has been studied extensively in animal models, less is known about the human metabolites or the human CYP enzymes involved in their formation (Fig. 22.17).^{88,89} The metabolism of prilocaine in the liver yields *o*-toluidine, which is a possible carcinogen. Many aromatic amines, including *o*-toluidine have been shown to be mutagenic, and metabolites of *o*-toluidine have been shown to form DNA adducts. Metabolites of *o*-toluidine are also believed to be responsible for the methemoglobinemia observed with prilocaine use. To decrease the potential for methemoglobinemia, strict adherence to the maximum recommended dose should be followed. Metabolism of prilocaine is extensive with less than 5% of a dose excreted unchanged in the urine.

ETIDOCAINE

Etidocaine differs from lidocaine by the addition of an alkyl chain and the extension of one ethyl group on the tertiary amine to a butyl group. The additional lipophilicity gives etidocaine a quicker onset, longer half-life, and an increased potency compared with lidocaine. This may make etidocaine desirable for use when A and C nerve fibers are being anesthetized for long surgical procedures (>2 hours).⁹⁰ The tertiary nitrogen pK_a is 7.74, which is similar to lidocaine's pK_a (7.8).

Etidocaine is the most potent amino amide local anesthetic and is used for epidural anesthesia, topical anesthesia, and for peripheral nerve or plexus block. Etidocaine blocks large fast-conducting neurons quicker than the sensory neurons and may leave epidural patients unable to move yet sensitive to painful procedures.⁷³ Etidocaine has the same potential for cardiac toxicity as bupivacaine and the decreased reports probably are results of the decreased use of etidocaine.

BUPIVACAINE AND LEVOBUVACAINE

Bupivacaine

Levobupivacaine S (-)

Bupivacaine was synthesized simultaneously with mepivacaine in 1957 but was at first overlooked because of the increased toxicity compared with mepivacaine. When the methyl on the cyclic amine of mepivacaine is exchanged for a butyl group the lipophilicity, potency and the duration of action all increase. Literature reports of cardiovascular toxicity, including severe hypotension and bradycardia, are abundant in the literature.⁹¹ Bupivacaine is highly bound to plasma proteins (95%), and thus the free concentration may remain low until all of the protein binding sites are occupied. After that point, the plasma levels of bupivacaine rise rapidly and patients may progress to overt cardiac toxicity without ever showing signs of CNS toxicity.⁹² The cardiotoxicity of bupivacaine is a result of its affinity to cardiac tissues and its ability to depress electrical conduction and predispose the heart to reentry types of arrhythmias. The cardiotoxicity of bupivacaine was found to be significantly more prominent with the "R" isomer, or the racemic mixture, thus the "S" stereoisomer is now on the market as levobupivacaine.⁹³

Levobupivacaine is the pure "S" enantiomer of bupivacaine and in vivo and in vitro studies confirm that it does not undergo metabolic inversion to R(+) bupivacaine. The pK_a of the tertiary nitrogen is 8.09, the same as bupivacaine's

pK_a . Levobupivacaine is available in solution for epidural administration, peripheral nerve block administration, and infiltration anesthesia. Clinical trials have shown that levobupivacaine and bupivacaine have similar anesthetic effects.⁹⁴ Levobupivacaine has lower CNS and cardiotoxicity than bupivacaine although unintended intravenous injection when performing nerve blocks may result in toxicity. Racemic bupivacaine is metabolized extensively with no unchanged drug found in the urine or feces. Liver enzymes including the CYP3A4 and CYP1A2 isoforms are responsible for *N*-dealkylation and 3-hydroxylation of levobupivacaine followed by glucuronidation or sulfation.⁹⁵

ROPIVACAINE

Ropivacaine

The recognized increase in cardiotoxicity of one bupivacaine isomer led to the stereospecific production of ropivacaine as the single “S” (–) enantiomer. Ropivacaine is the propyl analog of mepivacaine (methyl) and bupivacaine (butyl). The pK_a of the tertiary nitrogen is 8.1, and it displays the same degree of protein binding as bupivacaine (~94%). Although ropivacaine has similar properties as bupivacaine, it displays less cardiotoxicity. The shortened alkyl chain gives it approximately one third of the lipid solubility of bupivacaine. Animal studies have shown that ropivacaine dissociates from cardiac sodium channels more rapidly than bupivacaine. This decreases the sodium channel block in the heart and may be responsible for the reduced cardiotoxicity of ropivacaine.⁹²

Ropivacaine undergoes extensive metabolism in humans with only 1% of a dose excreted unchanged in the urine.⁹⁶ Four metabolites of ropivacaine have been identified from human liver microsome incubations and in vivo studies. The CYP1A2 isoform was found to be responsible for the formation of 3-OH ropivacaine, the primary ropivacaine metabolite. The CYP3A4 isoform was responsible for the formation of 4-OH ropivacaine, 2-OH methyl-ropivacaine, and the *N*-dealkylated metabolite (S)-2',6'-pipecoloxylidide.⁹⁷ Coadministered inhibitors of CYP1A2 may be of clinical importance, CYP3A4 inhibitors seem to be of less clinical relevance.⁹⁸

Ropivacaine is a long-acting amide-type local anesthetic with inherent vasoconstrictor activities, so it does not require the use of additional vasoconstrictors. It is approved for epidural, nerve block, infiltration, and intrathecal anesthesia.

DIBUCAINE

Dibucaine

Dibucaine is a topical amide anesthetic available in over-the-counter creams and ointments used to treat minor conditions such as sunburns and hemorrhoids. Dibucaine has been found to be highly toxic when taken orally, inducing seizures, coma, and death in several children who accidentally ingested it.⁹⁹ Metabolites of dibucaine identified in the urine of rats, rabbits, and humans included hydroxylated metabolites of the quinoline ring, monohydroxylated and dihydroxylated metabolites of the *O*-alkyl side chain (2'- and 3'-position), and the *N*-de-ethylated dibucaine metabolite.¹⁰⁰

ARTICAINE

Articaine

Articaine has a secondary nitrogen with a pK_a of 7.8. It contains an aromatic thiophene ring bioisostere of the phenyl ring found in most other amide anesthetics. The log *P* of a benzene ring is 2.13 and the thiophene ring log *P* is 1.81, thus the thiophene ring is more hydrophilic than a phenyl ring. Although the thiophene ring has less lipid solubility than a phenyl ring, articaine is a lipid-soluble compound due to the propylamine, the branched methyl and the substitutions on the thiophene ring. The onset of action of articaine is similar to lidocaine's onset of action. Articaine is available in a 4% solution with epinephrine for use in infiltration and nerve block anesthesia.

Articaine is metabolized rapidly via plasma and tissue carboxylesterase to its primary metabolite, the inactive, water-soluble carboxylic acid. Approximately 40% to 70% of articaine administered epidurally is metabolized to the carboxylic acid, articainic acid. Approximately 4% to 15% of the articainic acid undergoes glucuronide conjugation and only 3% of the dose is recovered unchanged in the urine. The rapid plasma metabolism and reported inactivity of the carboxylic acid metabolite make articaine a potentially safer anesthetic agent when multiple or large doses are necessary.^{101,102}

Future Directions of Local Anesthetic Research

One of the issues of local anesthetic use is that they are not specific to sensory nociceptors, the “pain neurons.” Local anesthetics also block pressure, touch, and motor axons leading to numbness and loss of muscle control. Recent studies in rats have shown that administering the quaternary lidocaine molecule, QX-314, along with capsaicin allows the permanently charged anesthetic access to pain-sensing neurons only. The quaternary charge on QX-314 prevents it from entering all neurons via simple diffusion through the lipophilic membrane. Capsaicin was found to bind to a protein only found on pain-sensing neurons, TRPV1 channels. When capsaicin binds to TRPV1, the channel opens to allow QX-314 to enter the axoplasm and then access the local

anesthetic binding site in the sodium channel from the hydrophilic pathway (Fig. 22.13 hydrophilic pathway C). By specifically blocking the sodium channels of only pain neurons, other nerve function is preserved. This type of pain management would make it possible to have a dental procedure with no pain, yet not leave the entire face numb, or have an epidural during labor and still be able to walk. This is an exciting new opportunity in pain management that is undergoing research presently.¹⁰³

Another area of research is the formulation of local anesthetic liposomes and microspheres. The principle behind this

research is that the local anesthetic molecules are amphiphatic, with both a hydrophilic and hydrophobic component. The anesthetic molecule can be suspended inside carrier substances made of egg phospholipids and cholesterol liposomes or biodegradable polymers of lactic acid or glycolic acid. The carrier molecule will allow a controlled delivery of the local anesthetic and provide a long duration of action, potentially with less systemic toxicity.^{91,104} Carrier molecules are also being designed that combine a local anesthetic with an opioid analgesic that may offer alternative analgesic delivery methods.¹⁰⁵

● R E V I E W Q U E S T I O N S ●

- A nurse anesthetist calls the OR pharmacy to discuss a patient history and get your input on choosing a general anesthetic for an upcoming operation.
ML is a 32-year-old, 5'4", 460-pound woman who is scheduled for an elective gastropasty (stomach stapling). She has a history of hypertension (150/98 mm Hg), hyperlipidemia (LDL-cholesterol = 140mg/dL), and a large stage III pressure ulcer on her lower back. The last time that the patient underwent surgery, she could not be roused from the sedation and spent 24 hours in the postanesthetic care unit (PACU). Her prior surgery required 3 hours of general anesthesia maintained with isoflurane. The nurse anesthetist would like to know if one of the other formulary agents offers a shorter recovery time. General anesthetics on the formulary include nitrous oxide, desflurane, sevoflurane, isoflurane, enflurane, and halothane.
- A medical student was assigned the task of debriding ML's decubitus ulcer and calls the pharmacy to obtain procaine to inject locally before beginning the painful procedure. You review the patient's chart for allergies (no known drug allergies [NKDA]) and notice that the patient is also receiving 1% silver sulfadiazine cream to prevent bacterial colonization of the ulcer. You recommend against using the procaine and suggest a 1% lidocaine with epinephrine instead. Why?
- An anesthesiologist from the obstetric unit calls to request stat delivery of 20% intralipid to treat an inadvertent intravascular injection of bupivacaine. The patient is in cardiac arrest. Why is the anesthesiologist requesting intralipid?
- TG, a 45-year-old male woodworker, presents to the ER with an injured index finger. While cleaning a circular saw blade, he accidentally severed the tip (fleshy part, no bone) of his finger. The ER resident calls to request lidocaine 2% with epinephrine 1:200,000 to decrease the pain associated with suturing. You suggest an alternate. Why did you NOT fill the original requested anesthetic?
- JF, a patient with a severe allergic reaction to 2-chloroprocaine, is having plastic surgery to remove three moles from her face. The physician calls to request your input in choosing a local anesthetic. The plastic surgeon has the five drugs shown at the bottom of this page available in his clinic. Which drug would you recommend that he use?
- While working as a pharmacy intern at a retail pharmacy, a woman carrying an infant asks you to ring up three tubes of Maximum Strength Vagisil Creme. In conversation with her, you find out that she has been treating her 2-month-old daughter's painful, excoriated diaper rash with the cream for the last week. She claims to have received the advice on a mothers' chat room on the Internet. You observe that her 2-month-old daughter has bluish lips and very pale translucent skin that also has a bluish tint. You immediately advise her to take her daughter to the emergency room. Why?

Histamine and Antihistaminic Agents

JACK DERUITER

CHAPTER OVERVIEW

Histamine or β -imidazolylethylamine is synthesized from L-histidine by histidine decarboxylase, an enzyme that is expressed in many mammalian tissues including gastric-mucosa parietal cells, mast cells, and basophils and the central nervous system (CNS).¹ As a result, histamine plays an important role in human physiology including regulation of the cardiovascular system, smooth muscle, exocrine glands, the immune system, and central nerve function. It is also involved in embryonic development, the proliferation and differentiation of cells, hematopoiesis, inflammation, and wound healing. Histamine exerts its diverse biologic effects through four types of receptors. The involvement of histamine in the mediation of immune and hypersensitivity reactions and the regulation of gastric acid secretion has led to the development of important drug classes useful in the treatment of symptoms associated with allergic and gastric hypersecretory disorders.

HISTAMINE CHEMISTRY

Nomenclature

Histamine, known trivially as 4(5)-(2-aminoethyl)imidazole, structurally is composed of an imidazole heterocycle and ethylamine side chain. The methylene groups of the aminoethyl side chain are designated α and β . The side chain is attached, via the β -CH₂ group, to the 4-position of an imidazole ring. The imidazole N at position 3 is designated the *pros* (π) N, whereas the N at position 1 is termed the *tele* (τ) N. The side chain N is distinguished as N $^{\alpha}$ (Fig. 23.1).

Ionization and Tautomerization

Histamine is a basic organic compound (N $^{\pi}$, pK_{a1} = 5.80; N pK_{a2} = 9.40; N $^{\alpha}$, pK_{a3} = 14.0) capable of existing as a mixture of different ionic and uncharged tautomeric species (Fig. 23.2).^{2,3} Histamine exists almost exclusively (96.6%) as the monocationic conjugate species (α NH₃⁺) at physiological pH (7.4). At lower pHs, a higher percentage of the dicationic species exists. In water, the ratio of the concentrations of the tautomers N $^{\tau}$ -H/N $^{\pi}$ -H has been calculated to be 4.2, indicating that 80% of the histamine monocation exists as N $^{\tau}$ -H and 20% exists as N $^{\pi}$ -H in aqueous solution.^{2,3} However, crystalline forms of histamine salts appear to exist primarily as N $^{\pi}$ -H tautomer to facilitate crystal packing. Also, for derivatives of histamine, the ratio of

tautomers is dependent on the presence of imidazole ring substituents as discussed later in this chapter.⁴

Structure-activity relationship studies suggest that the α NH₃⁺ monocation is important for agonist activity at histamine receptors and that transient existence of the more lipophilic uncharged histamine species may contribute to diffusion across cell membranes. Other studies support proposal that the N $^{\tau}$ -H tautomer of the histamine monocation is the pharmacophoric species at the H₁-receptor, while a 1,3-tautomeric system is important for selective H₂-agonism.

Stereochemistry

While histamine is an achiral molecule, histamine receptors exert high stereoselectivity toward chiral ligands.⁵ Molecular modeling and steric-activity relationship studies of the influence of conformational isomerism suggest the importance of *trans-gauche* rotameric structures in the receptor binding of histamine (Fig. 23.3). Although both conformers exist in solution, studies with conformationally restricted histamine analogs suggest that the *trans*-rotamer of histamine possesses affinity for both H₁- and H₂-receptors, and the *gauche* conformer is preferred for H₃-receptors, but not H₁- or H₂-receptors.⁴

HISTAMINE AS A CHEMICAL MESSENGER

Knowledge of the biodisposition of histamine is important in understanding the involvement of this substance in various pathophysiologies as well as the actions of various ligands that either enhance or block its actions. Each of the steps in the “life cycle” of histamine represents a potential point for pharmacological intervention.

Biosynthesis and Distribution

Histamine is synthesized in Golgi apparatus of its principal storage cells, mast cells, and basophils.⁶ Histamine is formed from the naturally occurring amino acid L-histidine (*S*-histidine) via the catalysis of either the pyridoxal phosphate dependent enzyme histidine decarboxylase (HDC, EC 4.1.1.22) or L-aromatic amino acid decarboxylase (L-AAAD) (Fig. 23.4). Substrate specificity is higher for HDC versus L-AAAD. HDC inhibitors (HDCIs) include α -fluoromethylhistidine (FMH), a mechanism-based inhibitor, and certain flavonoids.⁷ Although useful as pharmacologic probes, HDCIs have not proved to be useful clinically.

Figure 23.1 • Histamine.

Histamine is found in almost all mammalian tissues in concentrations ranging from 1 to more than $100 \mu\text{g/g}$. Mast cells and histamine are in particularly high concentration in skin and the mucosal cells of the bronchi, intestine, urinary tract, and tissues adjacent to the circulation. It is found in higher concentrations in mammalian cerebrospinal fluid than in plasma and other body fluids.

Storage and Release

Most histamine is biosynthesized and stored as protein complexes in mast cells (complexed with heparin) and basophilic granulocytes (complexed with chondroitin).^{8,9} Protein-complexed histamine is stored in secretory granules and released by exocytosis in response to a wide variety of immune (antigen and antibody) and nonimmune (bacterial products, xenobiotics, physical effects, and cholinergic effects) stimuli. The release of histamine as one of the mediators of

Figure 23.2 • Histamine tautomers and cations.

Figure 23.3 • Histamine rotamers.

hypersensitivity reactions is initiated by the interaction of an antigen-IgE complex with the membrane of a histamine storage cell. This interaction triggers activation of intracellular phosphokinase C (PKC), leading to accumulation of inositol phosphates, diacylglycerol, and calcium. Exocytotic release of histamine follows the degranulation of histamine storage cells.¹⁰ Degranulation also results in the release of other mediators of inflammation including prostaglandins, leukotrienes, platelet-activating factor, kinins, etc.¹⁰ The release of mast cell mediators can be inhibited by several agents as described in the sections that follow. Histamine is released from mast cells in the gastric mucosa by gastrin and acetylcholine. Neurochemical studies also suggest that histamine is stored in and released from selected neuronal tracts in the CNS.

Histamine Receptors and Histamine-Mediated Physiologic Functions

Once released, the physiological effects of histamine are mediated by specific cell-surface receptors. Extensive pharmacological and molecular biology studies have revealed the presence of at least four different histamine receptor subtypes in mammalian systems designated as H₁, H₂, H₃, and H₄ (Table 23.1).¹⁰ All histamine receptor subtypes are heptahelical transmembrane molecules (TM1-TM7) that transduce extracellular signals via G-proteins to intracellular second-messenger systems. These receptors have constitu-

tive receptor G-protein–signaling activity that is independent of histamine agonist binding.^{10,11} Thus, they exist in two conformations that are in equilibrium—an active (constitutive) and inactive state. The four histamine receptor subtypes differ in their expression, location, primary structure, precise signal transduction processes, and physiologic functions as indicated in Table 23.1 and detailed here. In general, H₁- and H₂-receptors appear to be more widely expressed than H₃- and H₄-receptors.¹⁰

Histamine H₁-receptor expression is widespread including CNS neurons, the smooth muscle of respiratory, gastrointestinal (GI), uterine tissues, epithelial and endothelial cells, neutrophils, eosinophils, monocytes, dendritic cells, T cells, B cells, hepatocytes, and chondrocytes.¹⁰ This receptor is composed of 487 amino acids and has a molecular mass of 56 kd. Its seven transmembrane domains consist of a short intracellular C-terminal tail (17 amino acids), N-terminal glycosylation sites, phosphorylation sites for protein kinases A and C, and a large intracellular loop (212 amino acids, TM3).^{12,13} Based on data from site-directed mutagenesis studies, the third (TM3) and fifth (TM5) transmembrane domains are responsible for binding of H₁-receptor ligands. An acidic aspartate residue in TM3 (position 107) appears to be responsible for binding of the protonated amino group of the ethylamine side chain of histamine via ionic interactions. An asparagine (position 207) of the TM5 domain appears to interact with the N⁷-nitrogen atom of the imidazole ring of histamine and lysine (200) interacts with the nucleophilic N⁷-nitrogen of the natural ligand.^{12,13}

Signal transduction at the H₁-receptor involves the activation of G_{αq11} that stimulates intracellular phospholipase C (PLC) to hydrolyze phosphatidylinositide to inositol-1,4,5-triphosphate (IP₃) and 1,2-diacylglycerol (DAG). IP₃ promotes intracellular calcium release, whereas DAG may stimulate various biochemical pathways including phospholipase A₂ and D, NFκB-mediated gene transcription, as well as cyclic adenosine monophosphate (cAMP) and nitric oxide synthase (NOS) production.^{10–13} Human H₁-receptors have approximately 45% homology with muscarinic M₁- and M₂-receptors, perhaps accounting for some of the overlap in ligands bound by each receptor subtype. H₁-receptor polymorphisms have been described, although it is not yet clear how they influence the histamine binding or clinical response to H₁-antihistamine drugs.¹⁴

As a result of widespread tissue localization and the varied functions of these tissues, H₁-receptors mediate a host of physiologic processes including pruritus, pain, vasodilation, vascular permeability, hypotension, flushing, headache, tachycardia, bronchoconstriction, stimulation of airway vagal

Figure 23.4 • Histamine biosynthesis.

TABLE 23.1 Histamine Receptor Subtypes

Characteristic	H ₁ -Receptor	H ₂ -Receptor	H ₃ -Receptor	H ₄ -Receptor
Receptor proteins in humans	487 amino acids, 56 kd	359 amino acids, 40 kd	445 amino acids, 70 kd; splice variants	390 amino acids

afferent nerves and cough receptors, and decreased atrioventricular-node conduction time. With respect to the cells involved in the immune response, released histamine acting at H₁-receptors causes increased cellular adhesion–molecule expression and chemotaxis of eosinophils and neutrophils, increased antigen-presenting–cell capacity, costimulatory activity on B cells, blocking of humoral immunity and IgE production, induction of cellular immunity (Th1), and increased interferon-gamma (IFN-γ) autoimmunity.^{9,10,15,16} These processes contribute to the allergic inflammation associated with histamine release and are the basis for antihistamine drug therapy for the treatment of allergy. It should be noted, however, that other mediators released with histamine also contribute to these immunologic and allergenic actions.^{15,16} In the CNS H₁-receptor activation influences cycles of sleeping and waking, food intake, thermal regulation, emotions and aggressive behavior, locomotion, memory, and learning.¹⁰

H₂-receptors are expressed in various tissues where they mediate gastric acid secretion, vascular permeability, hypotension, flushing, headache, tachycardia, chronotropic and inotropic activity, bronchodilatation and respiratory mucus production. This receptor is composed of 359 amino acids and has a molecular mass of 40 kd. Like the H₁-receptor, this receptor has N-terminal glycosylation sites and phosphorylation sites in the C-terminus.^{10,12,13} It also has an aspartate residue in TM3 and threonine/aspartate and tyrosine/aspartate residues in TM5, which bind agonists. The most notable difference between structures of cloned H₁- and H₂-receptors is the much shorter third intracellular loop and longer C-terminal loop of the H₂-receptor protein.

In most tissues, signal transduction of the H₂-receptor involves the activation of G_{αs}, which stimulates adenylate cyclase promoting the synthesis of cAMP. In some tissues, H₂-receptors may be linked to G_q proteins that stimulate PLC to form IP₃ and DAG, which regulate intracellular calcium levels and other processes including protein kinases.^{10,12,13} A more detailed discussion of the role of H₂-receptors in gastric acid secretion is included under “Histamine H₂-Antagonist” later in this chapter.

In addition to regulation of gastric acid secretion and cardiovascular functions listed previously, H₂-receptors modulate immune function by decreasing eosinophil and neutrophil chemotaxis, inducing interleukin-10, suppressing interleukin-12 by dendritic cells, developing Th2 or tolerance-inducing dendritic cells, inducing humoral immunity, suppressing cellular immunity, and suppressing Th2 cells and cytokines.¹⁰ Thus, this receptor also plays an

indirect role in allergy, autoimmunity, malignant disease, and graft rejection. It may also have a neuroendocrine role in the CNS.

The highest density of H₃-receptors occurs in the CNS, mainly in the striatum, substantia nigra, and the cortex.^{10,17} In the CNS, this receptor subtype may be a presynaptic heteroreceptor and regulate histamine, dopamine, serotonin, noradrenaline, and acetylcholine release. H₃-receptors also play a lesser role in peripheral nerve and tissues where they appear to prevent excessive bronchoconstriction; mediate pruritus (no mast-cell involvement) and may be involved in the control of neurogenic inflammation through local neuron–mast cell feedback loops. The H₃-receptor consists of 445 amino acids and has a mass of 70 kd. It is coupled to a G_{i/o} protein, which inhibits the action of adenylate cyclase and regulates MAP kinase and intracellular calcium levels. There is little sequence homology between H₃- and H₁- and H₂-receptors (only 20% per receptor subtype).¹⁷

H₄-receptors appear to be involved in the differentiation of hematopoietic cells (myeloblasts and promyelocytes) and to modulate immune function by increasing cytosolic calcium in eosinophils, increasing eosinophil chemotaxis and increasing interleukin-16 production.¹⁰ Thus, these receptor subtypes may also be involved in the allergic inflammatory response. A role for this receptor subtype in the CNS remains to be defined. The H₄-receptor is composed of 390 amino acids and is coupled to a G_{i/o} protein, which transmits intracellular signals similar to H₃-receptors.^{10,18}

The role of histamine in the inflammation of allergy merits additional discussion, because so many histamine-based therapeutic products target this process. Inflammation results from a complex set of cellular events that involve redundant mediators and signals. Histamine is released from the granules of mast cells and basophils (also known as FcεRI+ cells) along with tryptase and other preformed mediators, as well as leukotrienes, prostaglandins, and other newly generated mediators. This release in response to cross-linking of surface IgE by allergen or through mechanisms that are independent of IgE. While most of the effects of histamine in allergic disease are mediated via H₁-receptors, hypotension, tachycardia, flushing, and headache occur as a result of histamine action at both the H₁- and H₂-receptors in the vasculature. Also, cutaneous itch and nasal congestion may occur through both the H₁- and H₃-receptors. In addition to its role in the early allergic response to antigen, histamine acts as a stimulatory signal for the production of cytokines and the expression of cell-adhesion molecules and class II antigens, thereby contributing to the late allergic response.^{9–11}

In addition to those actions, histamine exerts other important and variable immunomodulatory effects through its receptor subtypes.^{10,19} First, the expression of the receptors changes according to the stage of cell differentiation and local tissue influences. Second, depending on the predominance of the type of receptor, histamine may have proinflammatory or anti-inflammatory effects. Through the H₁-receptor, histamine has proinflammatory activity and is involved in the development of several aspects of antigen-specific immune response, including the maturation of dendritic cells and the modulation of the balance of type 1 helper (Th1) T cells and type 2 helper (Th2) T cells. Histamine may induce an increase in the proliferation of Th1 cells and in the production of interferon and may block humoral immune responses by means of this mechanism. It also induces the release of proinflammatory cytokines and lysosomal enzymes from human macrophages and has the capacity to influence the activity of basophils, eosinophils, and fibroblasts. Finally, histamine may play a role in autoimmunity and malignant disease through the H₁-receptor.

Termination of Histamine Action

Three principal ways exist to terminate the physiological effects of histamine^{3,20,21}:

- Cellular uptake: Animal studies have documented the uptake of histamine by many cells. In particular, uptake is a temperature- and partially Na⁺-dependent process in rabbit gastric glands and the histamine is metabolized once in the cell.
- Desensitization of cells: Some H₁-receptor-containing tissues exhibit a homogeneous loss of sensitivity to the actions of histamine, perhaps as a result of receptor modification.
- Metabolism: The most common pathway for terminating histamine action involves enzymatic inactivation, as discussed in more detail here.

Released histamine is rapidly inactivated by metabolism via two pathways as shown in Figure 23.5. One pathway involves N⁷-methylation via the enzyme histamine N-methyltransferase (HMT; EC 2.1.1.8). This enzyme is widely distributed in mammalian tissues and catalyzes the transfer of a methyl group from S-adenosyl-L-methionine (SAM) to the ring *tele*-nitrogen of histamine, producing N⁷-methylhistamine and S-adenosyl-L-homocysteine (Fig. 23.5). The other pathway of catabolism involves oxidative deamination by diamine oxidase (DAO; EC 1.4.3.6), yielding imidazole acetaldehyde, which is further oxidized to imidazole acetic acid by aldehyde dehydrogenases (ALD-DH). Similarly, N⁷-methylhistamine is converted by both DAO and monoamine oxidase (MAO), followed by ALD-DH to N-methyl imidazole acetic acid (Fig. 23.5). All of these metabolites are devoid of histamine receptor agonist activity.

Functions of Histamine as Related to Pharmacological Intervention

Histamine exhibits a wide variety of both physiological and pathological functions in different tissues and cells. The actions of histamine that are of interest from both a pharmacological and therapeutic point of view include (a) its important, but limited, role as a chemical mediator of hypersensitivity and allergic inflammatory reactions, (b) a major role in the regulation of gastric acid secretion, and (c) an emerging role as a neurotransmitter in the CNS.

ANTIHISTAMINES

The term *antihistamine* historically has referred to drugs that block the actions of histamine at H₁-receptors rather than other histamine receptor subtypes. The development of antihistamine drugs began decades ago with the discovery by Fourneau and Bovet²² that piperoxan could protect animals from the bronchial spasm induced by histamine. This finding was followed by the synthesis of several N-phenylethylenediamines with antihistaminic activities superior to those of piperoxan.²³ Further traditional structure–activity studies in this series, based largely on the principles of isosterism and functional group modification, led to the introduction in the 1940s to 1970s of various H₁-antihistamine containing the diarylalkylamine framework.^{23,24} These antihistamines, referred to now as the first-generation or classical antihistamines, are related structurally and include several aminoalkyl ethers, ethylenediamines, piperazines, propylamines, phenothiazines, and dibenzocycloheptenes. In addition to H₁-antihistaminic action, these compounds display an array of other pharmacological activities that contribute either toward additional therapeutic applications, or limit use as adverse reactions. More recently, several second-generation or “nonsedating” antihistamines have been developed and introduced.^{10,23} The second-generation agents are derivatives of several first-generation agents, but have been modified to be more specific in pharmacologic action and limited in their tissue distribution or accumulation profiles.

Mechanism of Action

It is now known that H₁-antihistamines act as inverse agonists that combine with and stabilize the inactive form of the H₁-receptor, shifting the equilibrium toward the inactive state.¹⁰ Thus, they effectively antagonize the actions of histamine at H₁-receptors. Historically, H₁-antihistamines have been evaluated *in vitro* in terms of their ability to inhibit histamine-induced spasms in an isolated strip of guinea pig ileum. Antihistamines may be evaluated *in vivo* in terms of their ability to protect animals against the lethal effects of histamine administered intravenously or by aerosol.

To distinguish antagonism of histamine from other modes of action, the index pA is applied in *in vitro* assays. The index pA₂ is defined as the inverse of the logarithm of the molar concentration of the antagonist that reduces the response of a double dose of the agonist to that of a single one. The more potent H₁-antihistamines exhibit a pA₂ value significantly higher than 6. Although there are many pitfalls to be avoided in the interpretation of structure–activity relationship (SAR) studies using pA₂ values, the following example illustrates distinguishing competitive antagonism. pA₂ values for pyrilamine (mepyramine) antagonism range from 9.1 to 9.4 with human bronchi and guinea pig ileum.^{24,25} By contrast, the pA₂ value in guinea pig (H₂-receptor) is 5.3. Thus, one may conclude that pyrilamine is a weak, noncompetitive inhibitor of histamine at the H₂-receptors and a competitive inhibitor at H₁-receptors. The structural features required for effective interaction of these receptors are discussed next. Some H₁-antihistamines can also block histamine release. The concentrations, however, are considerably higher than those required to produce significant histamine receptor blockade. The H₁-antihistamines do not, however, block antibody production or antigen–antibody interactions.^{10,26}

Figure 23.5 • Metabolism of histamine. (ALD-DH, aldehyde dehydrogenase; PRT, phosphoribosyltransferase.)

Structure–Activity Relationships at H₁-Receptors

The H₁-antihistamines are now commonly subdivided into two broad groups—the first-generation or classical antihistamines and the second-generation or “nonsedating” antihistamines—based primarily on their general pharmacological profiles.^{10,23,27} The differences between these two series are discussed in more detail in the sections that follow. The most detailed published SAR analyses for antihistamines, however, focus on the structural requirements for the first-generation agents.^{22–24} From these studies, the structural requirements for H₁-antihistaminic action were identified as shown in Figure 23.6. In this structure, Ar is aryl (including phenyl, substituted phenyl, and heteroaryl groups such as 2-pyridyl); Ar' is a second aryl or arylmethyl group; X is a connecting atom of O, C, or N; (CH₂)_n represents a carbon chain, usually ethyl; and NRR' represents a basic, terminal amine function. The nature of the connecting atom as well as the diaryl substitution pattern and amine moiety has been used to subclassify the first-generation antihistamines as indicated in the succeeding sections.

This diaryl substitution pattern is present in both the first- and second-generation antihistamines and is essentially a significant H₁-receptor affinity.^{22–24} Furthermore, several SAR studies suggest that the two aryl moieties must be able to adopt a noncoplanar conformation relative to each other for optimal interaction with the H₁-receptor.²⁸ The two aromatic systems may be linked, as in the tricyclic antihistamines (phenothiazines, dihenzocycloheptanes, and heptenes), but again they must be noncoplanar for effective receptor interaction. Most H₁-antihistamines contain substituents in one of the aryl rings (usually benzene), and these influence histamine potency as well as biodisposition, as discussed for the individual classes of compounds in the succeeding sections.

In many of the first-generation, or classical, antihistamines, the terminal nitrogen atom is a simple dimethyl moiety. The amine may also be part of a heterocyclic structure, however, as illustrated by the piperazines, some propylamines (pyrrolidines and piperidines), some phenthiazines, the dibenzocycloheptenes, and the second-generation antihistamines. In all cases, the amino moiety is basic, with pK_as ranging from 8.5 to 10, and thus is presumed to be protonated when bound on the receptor. The amine moiety is also important in the development of stable, solid dosage forms through salt formation.

The carbon chain of typical H₁-antihistamines consists of two or three atoms.^{22–24} As a result, the distance between the central point of the diaryl ring system and the terminal nitrogen atom in the extended conformation of these compounds ranges from 5 to 6 angstroms (Å). A similar distance between these key moieties is observed for those antihistamines with less conformational freedom. In some structural series, branching of the carbon chain results in reduced

Figure 23.6 • General antihistamine structure.

antihistaminic activity. There are exceptions, however, as evidenced by promethazine, which has greater activity than its nonbranched counterpart. When the carbon adjacent to the terminal nitrogen atom is branched, the possibility of asymmetry exists. Stereoselective H₁-receptor binding is typically not observed, however, when chirality exists at this site.²⁹ Also, in compounds with an asymmetrically substituted unsaturated carbon chain (pyrrobutamine and triprolidine), one geometric isomer typically displays higher receptor affinity than the other.

The X connecting moiety of typical H₁-antihistamines may be a saturated carbon–oxygen moiety or simply a carbon atom. This group, along with the carbon chain, appears to serve primarily as a spacer group for the key pharmacophoric moieties. Many antihistamines containing a carbon atom in the connecting moiety are chiral and exhibit stereoselective receptor binding. For example, in the pheniramine series and carbinoxamine, this atom is chiral, and *in vitro* analyses indicate that enantiomers with the S configuration have higher H₁-receptor affinity.³⁰

Generally, the first- and second-generation antihistamines are substantially more lipophilic than the endogenous agonist, histamine (or the H₂-antagonists).³¹ This lipophilicity difference results primarily from the presence of the two aryl rings and the substituted amino moieties and thus may simply reflect the different structural requirements for antagonist versus agonist action at H₁-receptors.

The nature of the connecting moiety and the structural nature of the aryl moieties have been used to classify the antihistamines as indicated in the sections that follow. Furthermore, variations in the diaryl groups, X-connecting moieties, and the nature of substitution in the alkyl side chain or terminal nitrogen among the various drugs account for differences observed in antihistaminic potency as well as pharmacological, biodisposition, and adverse reaction profiles. The ability of these drugs to display an array of pharmacological activities is largely because they can interact with H₁-receptors throughout the body, and that they contain the basic pharmacophore required for binding to muscarinic as well as adrenergic and serotonergic receptors (Table 23.2). The relationships of antihistamine structure to these overlapping actions (H₁-antihistaminic, anticholinergic, and local anesthetic) have been analyzed.

General Pharmacological and Therapeutic Considerations

The classical antihistamines have been used extensively for the symptomatic treatment (sneezing, rhinorrhea, and itching of eyes, nose, and throat) of allergic rhinitis (hay fever, pollinosis), chronic idiopathic urticaria, and several other histamine-related diseases.¹⁰ These uses are clearly attributed to their ability to counter the action of histamine at peripheral H₁-receptors, which mediate the immune and inflammatory processes characteristic of these pathologies. These drugs best relieve the symptoms of allergic diseases at the beginning of the season when pollen counts are low. The antihistamines also reduce the number, size, and duration of wheals and itching in chronic urticaria when used promptly. Most clinical evidence suggests that there is no significant difference in therapeutic efficacy for first- and second-generation agents in the treatment of these conditions. The antihistamines have been widely used to relieve the symptoms of

asthma and upper respiratory infections including the common cold, otitis media, and sinusitis. Most clinical evidence¹⁰ does not support such use unless asthma or infection is accompanied by allergic inflammation. Also, the antihistamines should not be used alone in anaphylaxis, but may be used with epinephrine to relieve any H₁-receptor-mediated symptoms.¹⁰

As the aforementioned general pharmacological profiles suggests, many antihistamines can interact with various neurotransmitter receptors and other biomacromolecular targets.¹⁰ This is most evident among the first-generation agents, many of which function as antagonists at muscarinic receptors and, to a lesser extent, adrenergic, serotonergic, and dopamine receptors. The first-generation agents also tend to achieve and maintain higher levels in the brain than the second-generation agents, resulting in CNS-based pharmacologic actions.¹⁰ Although some of these non-target-receptor interactions may have therapeutic value (as discussed next), more frequently they are manifested as adverse reactions that limit drug use. This is particularly true of the peripheral anticholinergic effects produced by these drugs and of interactions with several neurotransmitter systems in the CNS that result in sedation, fatigue, and dizziness (see Table 23.2).

Several first-generation antihistamines, particularly the phenothiazines and aminoalkyl ethers, have antiemetic actions

and thus may be useful in the treatment of nausea and vomiting and for vertigo and motion sickness.^{10,26,27} Several of the phenothiazines have limited use in parkinsonism as a result of their ability to block central muscarinic receptors.^{10,26,27} Antihistamines, including promethazine, pyrilamine, tripelennamine, and diphenhydramine, also display local anesthetic activity that may be therapeutically useful.³²

Many of the first-generation antihistamines readily penetrate the blood-brain barrier (BBB) because of their lipophilicity, and maintain significant CNS concentrations because they are not substrates for P-glycoprotein efflux pump that are expressed on endothelial cells of the CNS vasculature. The lack of affinity by P-glycoprotein efflux pumps appears to be directly related to the relatively low molecular weight and small size of the first-generation antihistamines.^{10,33} Blockade of central H₁-receptors results in sedation, an effect that has contributed to the historical use of antihistamines as nonprescription sleep aids, as well as drugs for perioperative sedation.¹⁰ However, the sedative actions of antihistamines are undesired effects in the treatment of allergy-based diseases. Furthermore, the blockade of central H₁-receptors also results in decreased cognitive and psychomotor performance, as well as increased appetite and weight gain, all considered to be therapy-limiting adverse effects.^{10,33}

TABLE 23.3 Antihistamine Pharmacokinetic Properties

H ₁ -Antihistamine (Metabolite)	T _{max} after a Single Dose (hrs)	Terminal Elim. Half-life (hrs)	% Elim. Unchanged in Urine/Feces	Clinically Relevant DIs?	Onset, Dur. of Action (hrs)	Usual Adult Dose	Dose Adjustment Required for Impairment?

Source: Simons, F. E. R.: Advances in H₁-antihistamines. N. Engl. J. Med. 351:2203–2217, 2004.

Cardiac toxic effects induced by H₁-antihistamines occur rarely and are independent of H₁-receptor occupation.^{10,33,34} As mentioned previously, first-generation H₁-antihistamines have antimuscarinic and α -adrenergic blockade activity and thus may cause dose-related prolongation of the QT interval. The first two second-generation H₁-antihistamines, astemizole and terfenadine, were found to be even more cardiotoxic than the first-generation agents, especially when used in combination with other drugs. This led to their withdrawal from the market. The cardiac effects of the second-generation antihistamines are discussed in more detail in the next section of this chapter.

The primary objective of antihistamine drug development over the past several decades has centered on developing new drugs with higher selectivity for H₁-receptors and lacking undesirable CNS and cardiovascular actions.^{10,33,34} These efforts led to the introduction of the second-generation antihistamines, which are classified as “nonsedating” and have little antagonist activity at other neurotransmitter receptors, including muscarinic receptors, and cardiac ion channels at therapeutic concentrations. The pharmacological properties of these agents will be discussed in more detail.

There are relatively few published studies concerning the pharmacokinetic and biodisposition profiles of the first-generation antihistamines.^{10,31} Generally, the compounds are orally active and well absorbed, but oral bioavailability may be limited by first-pass metabolism. The metabolites formed depend on drug structure to a large extent but commonly involve the tertiary amino moiety. This functionality may be subject to successive oxidative *N*-dealkylation, deamination, and amino acid conjugation of the resultant acid. The amine group may also undergo *N*-oxidation (which may be reversible) or direct glucuronide conjugation. First-generation agents with unsubstituted and activated aromatic rings (phenothiazines) may undergo aromatic hydroxylation to yield

phenols, which may be eliminated as conjugates. More detailed pharmacokinetic data are available for the second-generation agents and are included in the monographs that follow and Table 23.3.

The H₁-antihistamines display various significant drug interactions when coadministered with other therapeutic agents. For example, MAO inhibitors prolong and intensify the anticholinergic actions of the antihistamines. Also, the sedative effects of these agents may potentiate the depressant activity of barbiturates, alcohol, narcotic analgesics, and other depressants.^{10,23,31}

First-Generation Antihistamine Classes

AMINOALKYL ETHERS (ETHANOLAMINES)

The aminoalkyl ether antihistamines are characterized by the presence of a CHO connecting moiety (X) and a two- or three-carbon atom chain as the linking moiety between the key diaryl and tertiary amino groups (Fig. 23.7). Most compounds in this series are simple *N,N*-dimethylethanolamine derivatives and are so classified in several texts. Clemastine and diphenylpyraline differ from this basic structural pattern, in that the basic nitrogen moiety and at least part of the carbon chain are part of a heterocyclic ring system and

Figure 23.7 • General structure of the aminoalkyl ethers.

there are three carbon atoms between the oxygen and nitrogen atoms. The basic nitrogen in all of these compounds is not only essential for binding affinity, but also serves as a moiety for the formation of stable, solid salts.

The simple diphenyl derivative diphenhydramine was the first clinically useful member of the ethanolamine series and serves as the prototype. Other therapeutically useful derivatives of diphenhydramine have been obtained by para substitution of methyl (methyldiphenhydramine), methoxy (medrylamine), chloro (chlorodiphenhydramine), or bromo (bromodiphenhydramine) on one of the phenyl rings. These derivatives reportedly have better therapeutic profiles than diphenhydramine because of reduced adverse effects.^{10,31} Replacement of one of the phenyl rings of the diphenhydramine with a 2-pyridyl group, as in doxylamine and carbinoxamine, enhances antihistaminic activity as demonstrated by pA_2 values in vitro and therapeutic dosing data (Table 23.2). These compounds display oral antihistaminic activities 40 and 2 greater, respectively, than diphenhydramine in animal test models.³¹

As a result of an asymmetrically substituted benzylic carbon, most of the aminoalkyl ethers are optically active. Most studies indicate that the individual enantiomers differ significantly in antihistaminic activity, with activity residing predominantly in the S-enantiomers.^{30,35}

The diaryl tertiary aminoalkyl ether structure that characterizes these compounds also serves as a pharmacophore for muscarinic receptors (Table 23.2). As a result, the drugs in this group possess significant anticholinergic activity, which contributes not only to their therapeutic use as antiemetic, motion sickness, and anti-Parkinson drugs but also to their adverse effect profile (dry mouth, blurred vision, urinary retention, constipation, tachycardia). Drowsiness, as well as other CNS effects, is a common side effect to the tertiary aminoalkyl ethers, presumably as a result of the ability of these compounds to penetrate the BBB and occupy central H_1 -receptors. Although this central action is exploited in over-the-counter (OTC) sleeping aids, it may interfere with the performance of tasks requiring mental alertness.^{10,26,27} The frequency of GI side effects in this series of antihistamines is relatively low, compared with the ethylenediamine antihistamines.^{10,26,27}

In spite of their long and extensive use, pharmacokinetic data on this series of compounds are relatively limited. Most members of this series appear to be extensively metabolized by pathways including *N*-oxidation and successive oxidative *N*-dealkylation followed by aldehyde oxidation and amino acid conjugation.³¹ The known kinetic properties of representative members of this class of antihistamines are summarized in Table 23.3.¹⁰

The structures of the aminoalkyl ether derivatives with physicochemical properties, basic therapeutic activity data, and dosage form information are provided in the monographs that follow.

Diphenhydramine Hydrochloride, Tannate, and Citrate. Diphenhydramine hydrochloride, 2-(diphenylmethoxy)-*N,N*-dimethylethanamine hydrochloride (Benadryl), is an oily, lipid-soluble free base available as the bitter-tasting hydrochloride salt, which is a stable, white crystalline powder soluble in water (1:1), alcohol (1:2) and chloroform (1:2). The salt has a pK_a value of 9, and a 1% aqueous solution has a pH of about 5. The other salts display comparable properties.

Diphenhydramine Hydrochloride

In addition to antihistaminic action, diphenhydramine exhibits antidyskinetic, antiemetic, antitussive and antimuscarinic, and sedative properties. In the usual dose range of 25 to 400 mg, diphenhydramine is not a highly active H_1 -antihistamine. Conversion to a quaternary ammonium salt does not alter the antihistaminic action greatly but does increase the anticholinergic action.

As an antihistaminic agent, diphenhydramine is recommended in various allergic conditions and, to a lesser extent, as an antitussive and Parkinsonism drug. It is also used in OTC sleep-aid products. It is administered either orally or parenterally in the treatment of urticaria, seasonal rhinitis (hay fever), and some dermatoses. The most common side effect is drowsiness, and the concurrent use of alcohol and other CNS depressants should be avoided.

Dosage forms: Tablets (12.5, 25, and 50 mg); capsules (25 and 50 mg); oral disintegrating strips (12.5 and 25 mg); solutions, elixirs, and syrups (12.5 mg/5 mL); suspension (25 mg/5 mL); and injection (50 mg/mL).

Usual adult doses:

- Antihistamine: 25 to 50 mg every 4 to 6 hours (maximum of 300 mg/day)
- Antitussive liquid: 25 to 50 mg every 4 hours (liquid) or 25 mg every 4 hours (syrup); do not exceed 300 mg/day
- Motion sickness: 25 to 50 mg every 4 to 6 hours (maximum of 300 mg/day)

Dimenhydrinate. The 8-chlorotheophyllinate (theoclate) salt of diphenhydramine, 8-chlorotheophylline 2-(diphenylmethoxy)-*N,N*-dimethylethylamine (Dramamine), is a white crystalline, odorless powder that is highly soluble in water and freely soluble in alcohol and chloroform.

Dimenhydrinate is recommended for nausea of motion sickness and for hyperemesis gravidarum (nausea of pregnancy). For the prevention of motion sickness, the dose should be taken at least 0.5 hour before beginning a trip. The cautions listed for diphenhydramine should be observed.

Dosage forms: Tablets (50 mg), liquid (12.5 mg/5 mL, 15.62 mg/5 mL), injection (50 mg/mL)

Usual dosage (motion sickness):

- Adult/children >12 years of age: 1 to 2 chewable tablets or tablets (50–100 mg) every 4 to 6 hours, not to exceed 8 chewable tablets or tablets (400 mg) in 24 hours

Dimenhydrinate

- Children 6 to younger than 12 years of age: ½ to 1 chewable tablet or tablet (25–50 mg) every 6 to 8 hours, not to exceed 3 tablets in 24 hours
- Children 2 to younger than 6 years of age: ¼ to ½ chewable tablet or tablet (12.5–25 mg) every 6 to 8 hours, not to exceed 1 ½ tablets in 24 hours

Bromodiphenhydramine Hydrochloride. Bromodiphenhydramine hydrochloride, 2-[(4-bromophenyl)phenylmethoxy]-*N,N*-dimethylethanamine hydrochloride (Ambodryl Hydrochloride), is a white to pale buff crystalline powder that is freely soluble in water and in alcohol. Relative to diphenhydramine, bromodiphenhydramine is more lipid soluble and was twice as effective in protecting against the lethal effects of histamine aerosols.

Bromodiphenhydramine Hydrochloride

Dosage forms: Capsules and elixir
Usual adult dose: Oral, 25 mg/4 to 6 hours

Doxylamine Succinate. The acid succinate salt (bisuccinate) of doxylamine, 2-[α -[2-(dimethylamino)ethoxy]- α -methylbenzyl]pyridine bisuccinate (Decapryn Succinate), is a white to creamy-white powder with a characteristic odor. It is soluble in water (1:1), alcohol (1:2), and chloroform (1:2). A 1% solution has a pH of about 5.

Doxylamine succinate is comparable in potency to diphenhydramine. It is indicated for the relief of seasonal

Doxylamine Succinate

rhinitis symptoms, but is also used as a nighttime sedative. Concurrent use of alcohol and other CNS depressants should be avoided.

Dosage forms: Tablets (5 mg), oral suspension (1 mg/mL), and oral liquid (2.5 mg/2.5 mL)

Usual adult dose: Oral, 12.5 to 25 mg/4 to 6 hours

Carbinoxamine Maleate. Carbinoxamine is available as a bitter bimaleate salt, (d, l)-2-[*p*-chloro- α -[2-(dimethylamino)ethoxy]benzyl]pyridine bimaleate (Clistin), which is a white crystalline powder that is very soluble in water and freely soluble in alcohol and in chloroform. The pH of a 1% solution is between 4.6 and 5.1.

Carbinoxamine Maleate

Carbinoxamine is a potent antihistaminic and is available as the racemic mixture. It differs structurally from chlorpheniramine only in having an oxygen atom separate the asymmetric carbon atom from the aminoethyl side chain. The more active *levo* isomer of carbinoxamine has the (*S*) absolute configuration³⁰ and can be superimposed on the more active *dextro* isomer (*S* configuration) of chlorpheniramine.

Dosage forms: Tablets (4 and 8 mg), capsules (10 mg), liquid (1.67 mg/5 mL), solution (4 mg/5 mL), and suspension (3.2 mg/5 mL)

Usual dose (tablets):

- Adults and children 12 years of age and older: 1 tablet (8 mg) twice daily
- Children 6 to 12 years of age: ½ tablet twice daily (every 12 hours). The tablets are not recommended for children younger than 6 years of age.

Clemastine Fumarate. Dextrorotatory clemastine, R,R-2[2[1-(4-chlorophenyl)-1-phenylethoxy]ethyl]-1-methylpyrrolidine hydrogen fumarate (1:1) (Tavist), has two chiral centers, each of which has the (*R*) absolute configuration. A comparison of the activities of the enantiomers indicates that the asymmetric center close to the terminal side chain nitrogen is of lesser importance to antihistaminic activity.³⁶

This member of the ethanolamine series is characterized by a long duration of action, with an activity that reaches a maximum in 5 to 7 hours and persists for 10 to 12 hours. It is well absorbed when administered orally, and it is excreted primarily in the urine. The side effects are those usually encountered with this series of antihistamines. Clemastine is closely related to chlorphenoxamine, which is used for its central cholinergic-blocking activity. Therefore, it is not surprising that clemastine has significant antimuscarinic activity.

Dosage forms: Tablets (1.34 and 2.68 mg) and syrup (0.67 mg/5 mL)

Usual adult dose:

- Allergic rhinitis: 1.34 mg every 12 hours or twice daily (maximum 8.04 mg/day for the syrup or 2.68 mg in 24 hours for the tablets) for adults; 0.67 mg twice daily (maximum 4.02 mg) for children 6 to 12 years of age (syrup only)
- Urticaria/angioedema: 2.68 mg twice daily, not to exceed 8.04 mg/day for adults; 1.34 mg twice daily, not to

exceed 4.02 mg/day for children 6 to 12 years of age (syrup only)

Diphenylpyraline Hydrochloride. Diphenylpyraline hydrochloride, 4-(diphenylmethoxy)-1-methylpiperidine hydrochloride (Hispril, Diafen) is a white or slightly off-white crystalline powder that is soluble in water or alcohol. Diphenylpyraline is structurally related to diphenhydramine with the aminoalkyl side chain incorporated in a piperidine ring. It is a potent antihistaminic, and the usual dose is 2 mg 3 or 4 times daily.

Diphenylpyraline Hydrochloride

Dosage forms: Extended-release capsules (5 mg)
Usual adult dose: Oral, 5 mg/12 hours

ETHYLENEDIAMINES

The ethylenediamine antihistamines are characterized by the presence of a nitrogen-connecting atom (X) and a two-carbon atom chain as the linking moiety between the key diaryl and tertiary amino moieties (Fig. 23.8). All compounds in this series are simple diarylethylenediamines except antazoline, in which the terminal amine and a portion of the carbon chain are included as part of an imidazoline ring system. Because it differs significantly in its pharmacological profile, antazoline is not always classified as an ethylenediamine derivative.

Phenbenzamine was the first clinically useful member of this class and served as the prototype for the development of more effective derivatives. Replacement of the phenyl moiety of phenbenzamine with a 2-pyridyl system yielded

Clemastine Fumarate

Figure 23.8 • General structure of the ethylenediamines.

tripelennamine, a significantly more effective histamine receptor blocker as was also observed in the aminoalkyl ether series described previously.³¹ Substitution of a *para* methoxy (pyrilamine or mepyramine), chloro (chloropyramine), or bromo (bromtripelennamine) further enhances activity, as observed earlier. Replacement of the benzyl group of tripelennamine with a 2-thienylmethyl group provided methapyrilene, and replacement of tripelennamine's 2-pyridyl group with a pyrimidinyl moiety (along with *p*-methoxy substitution) yielded thonzylamine, both of which function as potent H₁-receptor antagonists.³¹

In all of these compounds, the aliphatic or terminal amino group is required for H₁-blocking activity and is significantly more basic than the nitrogen atom bonded to the diaryl moiety; the nonbonded electrons on the diaryl nitrogen are delocalized by the aromatic ring, and the resultant reduction in electron density on nitrogen decreases basicity. Thus, the aliphatic amino group in the ethylenediamines is sufficiently basic for the formation of pharmaceutically useful salts.

Historically, the ethylenediamines were among the first useful antihistamines. They are moderately effective H₁-antihistamines based on pA₂ values and doses, but they also display a relatively high frequency of CNS depressant and GI side effects.^{27,31} The anticholinergic and antiemetic actions of these compounds are relatively low compared with those of most other classical, first-generation antihistamines (Table 23.2). The piperazine- and phenothiazine-type antihistamines also contain the ethylenediamine moiety, but these agents are discussed separately because they exhibit significantly different pharmacological properties.

Relatively little information is available concerning the pharmacokinetics of this series of compounds. Tripelennamine is metabolized in humans by *N*-glucuronidation, *N*-oxidation, and pyridyl oxidation followed by phenol glucuronidation. It is anticipated that other members of this series are similarly metabolized.³¹ The known pharmacokinetic properties of representative members of this class of antihistamines are summarized in Table 23.3.

The structures of the salt forms of the marketed ethylenediamine antihistamines, along with physicochemical properties, therapeutic activity profiles, and dosage form information, are provided in the monographs that follow.

Pyrilamine Maleate

Tripelennamine Citrate. Tripelennamine citrate, 2-[benzyl[2-dimethylamino)-ethyl]amino]pyridine citrate (1:1), PBZ (Pyribenzamine Citrate), is available as a monocitrate salt, which is a white crystalline powder freely soluble in water and in alcohol. A 1% solution has a pH of 4.25. For oral administration in liquid dose forms, the citrate salt is less bitter and thus more palatable than the hydrochloride. Because of the difference in molecular weights, the doses of the two salts must be equated—30 mg of the citrate salt is equivalent to 20 mg of the hydrochloride salt.

Tripelennamine HCl or Citrate

Dosage forms: Elixir

Usual adult dose: Oral, 25 to 50 mg/4 to 6 hours

Tripelennamine Hydrochloride. Tripelennamine hydrochloride is a white crystalline powder that darkens slowly on exposure to light. The salt is soluble in water (1:0.77) and in alcohol (1:6). It has a pK_a of about 9, and a 0.1% solution has a pH of about 5.5.

Tripelennamine, the first ethylenediamine developed in the United States and is well absorbed when given orally. It appears to be as effective as diphenhydramine and may have the advantage of fewer and less severe side reactions. Drowsiness may occur, however, and may impair the ability to perform tasks requiring alertness. The concurrent use of alcoholic beverages should be avoided.

Dosage forms: Tablets, extended-release tablets

Usual adult dose: Oral tablets, 25 to 50 mg/4 to 6 hours;
extended-release tablets, 100 mg/8 to 12 hours

Pyrilamine Maleate. Pyrilamine, 2-[4-methoxybenzyl[2-dimethylamino)ethyl]-amino]pyridine, is available as the acid maleate salt (1:1), which is a white crystalline powder with a faint odor and a bitter, saline taste. The salt is soluble in water (1:0.4) and freely soluble in alcohol. A 10% solution has a pH of approximately 5. At a pH of 7.5 or above, the free base begins to precipitate.

Pyrilamine differs structurally from tripeleminamine by having a methoxy group in the *para* position of the benzyl radical. It differs from its more toxic and less potent precursor phenbenzamine (Antergan) by having a 2-pyridyl group on the nitrogen atom in place of a phenyl group.

Clinically, pyrilamine and tripeleminamine are considered among the less potent antihistaminics. They are highly potent, however, in antagonizing histamine-induced contractions of guinea pig ileum.²² Because of the pronounced local anesthetic action, the drug should not be chewed, but taken with food.

Dosage forms: Tablets

Usual adult dose: Oral, 25 to 50 mg/6 to 8 hours

Methapyrilene Hydrochloride. Methapyrilene hydrochloride, 2-[[2-(dimethylamino)-ethyl]-2-thienylarnino]pyridine monohydrochloride (Histadyl) is available as the bitter-tasting, white crystalline powder that is soluble in water (1:0.5), in alcohol (1:5), and in chloroform (1:3). Its solutions have a pH of about 5.5. It differs structurally from tripeleminamine in having a 2-thiophene—methylene group in place of the benzyl group. The thiophene ring is considered isosteric with the benzene ring, and the isosteres exhibit similar activity. A study of the solid-state conformation of methapyrilene hydrochloride showed that the *trans*-conformation is preferred for the two ethylenediamine nitrogen atoms. The Food and Drug Administration declared methapyrilene a potential carcinogen in 1979, and all products containing it have been recalled.

Methapyrilene Hydrochloride

Thonzylamine Hydrochloride. Thonzylamine hydrochloride, 2-[[2-(dimethylamino)-ethyl](*p*-methoxybenzyl)amino]pyrimidine hydrochloride, is a white crystalline powder soluble in water (1:1), in alcohol (1:6), and in chloroform (1:4). A 2% aqueous solution has a pH of 5.5. It is

Thonzylamine Hydrochloride

similar in activity to tripeleminamine but is claimed to be less toxic. The usual dose is 50 mg taken up to 4 times daily. It is available in certain combination products.

Antazoline Phosphate. Antazoline phosphate, 2-[(*N*-benzylanilino)methyl]-2-imidazoline dihydrogen phosphate, is a bitter, white to off-white crystalline powder that is soluble in water. It has a pK_a of 10.0, and a 2% solution has a pH of about 4.5. Antazoline, like the ethylenediamines, contains an *N*-benzylanilino group linked to a basic nitrogen through a two-carbon chain.

Antazoline Phosphate

Antazoline is less active than most of the other antihistaminic drugs, but it is characterized by the lack of local irritation. The more soluble phosphate salt is applied topically to the eye in a 0.5% solution. The less soluble hydrochloride is given orally. In addition to its use as an antihistamine, antazoline has more than twice the local anesthetic potency of procaine and also exhibits anticholinergic actions.

PIPERAZINES (CYCLIZINES)

The piperazines or cyclizines can also be considered ethylenediamine derivatives or cyclic ethylenediamines (cyclizines); in this series, however, the connecting moiety (*X*) is a CHN group, and the carbon chain, terminal amine functionality, and the nitrogen atom of the connecting group are all part of a piperazine moiety (Fig. 23.9). Both nitrogen atoms in these compounds are aliphatic and thus display comparable basicities. The primary structural differences within this series involve the nature of the *para* aromatic ring substituent (H or Cl) and, more importantly, the nature of the terminal piperazine nitrogen substituent.

The piperazines are moderately potent antihistaminics with a relatively high potential to cause drowsiness and psychomotor and cognitive dysfunction (Table 23.2).^{26,27,31} The activity of the piperazine-type antihistaminics is characterized by a slow onset, but a long duration of action. These

Figure 23.9 • General structure of the piperazines.

agents exhibit peripheral and central antimuscarinic activity, and thereby diminish vestibular stimulation and act on the medullary chemoreceptor trigger zone.^{10,26,27} Thus, as a group, these agents have found significant use as antiemetics and antivertigo agents and in the treatment of motion sickness (Table 23.2).

Some members of this series have exhibited a strong teratogenic potential, inducing several malformations in animal models. The *N*-dealkylated metabolites, the norchlorcyclizines, have been proposed as responsible for the teratogenic effects of the parent drugs.³⁷ Although teratogenicity has not been observed in humans, its use during pregnancy is discouraged. Metabolic studies in this series of compounds have focused primarily on cyclizine and chlorcyclizine, and these compounds undergo similar biotransformation. The primary pathways involve *N*-oxidation and *N*-demethylation, and both of these metabolites are devoid of antihistaminic activity.

The structures of the marketed salt forms of the piperazine antihistamines, along with physicochemical properties, basic therapeutic activity profiles, and dosage form information, are provided in the monographs that follow. The known kinetic properties of representative members of this class of antihistamines are summarized in Table 23.3.

Cyclizine Hydrochloride. Cyclizine hydrochloride, 1-(diphenylmethyl)-4-methylpiperazine monohydrochloride

(Marezine), occurs as a light-sensitive, white crystalline powder with a bitter taste. It is slightly soluble in water (1:115), in alcohol (1:115), and in chloroform (1:75). It is used primarily in the prophylaxis and treatment of motion sickness. The lactate salt (Cyclizine Lactate Injection, *United States Pharmacopoeia [USP]*) is used for intramuscular (IM) injection because of the limited water solubility of the hydrochloride. The injection should be stored in a cold place, because if it is stored at room temperature for several months, a slight yellow tint may develop. This does not indicate a loss in biologic potency.

Cyclizine Hydrochloride or Lactate

Dosage forms: Tablets HCl (25 and 50 mgHCl) and injection (lactate)

Usual adult dose: 1 tablet every 4 to 6 hours for adults and children 12 years of age and older; ½ tablet every 6 to 8 hours, not to exceed 1½ tablets in 24 hours for children from 6 to 12 years of age

Chlorcyclizine Hydrochloride. Chlorcyclizine hydrochloride, 1-(*p*-chloro- α -phenylbenzyl)-4-methylpiperazine monohydrochloride, is a light-sensitive, white crystalline powder that is soluble in water (1:2), in alcohol (1:11), and in chloroform (1:4). A 1% solution has a pH between 4.8 and 5.5. Disubstitution or substitution of halogen in the 2- or 3-position of the benzhydryl rings results in a much less potent compound. Chlorcyclizine is indicated for the symptomatic relief of urticaria, hay fever, and certain other conditions.

Meclizine Hydrochloride. Meclizine hydrochloride, 1-(*p*-chloro- α -phenylbenzyl)-4-(*m*-methylbenzyl)piperazine dihydrochloride monohydrate (Bonine, Antivert), is a tasteless, white or slightly yellowish crystalline powder that

Chlorcyclizine Hydrochloride

Meclizine Hydrochloride

is practically insoluble in water (1:1,000). It differs from chlorcyclizine in having an *N-m*-methylbenzyl group in place of the *N*-methyl group. Although it is a moderately potent antihistaminic, meclizine is used primarily as an anti-nauseant in the prevention and treatment of motion sickness and in the treatment of nausea and vomiting associated with vertigo.

Dosage forms: Tablets (12, 5, 25, 50 mg) and capsules (25 mg)

Usual adult dose:

- Motion sickness: 25- to 50-mg meclizine HCl should be taken 1 hour prior
- Vertigo: 25 to 100 mg daily in divided doses

Bucizine Hydrochloride. Bucizine hydrochloride, 1-(*p*-tertbutylbenzyl)-4-(*p*-chloro- α -phenylbenzyl)piperazine dihydrochloride (Bucladin-S), is a white to slightly yellow crystalline powder that is insoluble in water. The highly lipid-soluble bucizine has CNS depressant, antiemetic, and antihistaminic properties. This drug has been discontinued in the United States.

PROPYLAMINES (MONOAMINOPROPYL OR ALKYLAMINE DERIVATIVES)

The propylamine antihistamines are characterized structurally by an sp^3 or sp^2 carbon-connecting atom with a carbon chain of two additional carbons linking the key tertiary amino and diaryl pharmacophore moieties (Fig. 23.10). Those propylamines with a saturated carbon-connecting moiety are commonly referred to as the pheniramines. All of

the pheniramines consist of a phenyl and a 2-pyridyl aryl group and a terminal dimethylamino moiety. These compounds differ only in the phenyl substituent at the *para* position: H (pheniramine), Cl (chlorpheniramine), and Br (brompheniramine). The halogenated pheniramines are significantly more potent (20–50 times) and have a longer duration of action than pheniramine.³¹

All pheniramines are chiral molecules, and the halogen-substituted derivatives have been resolved by crystallization of salts formed with d-tartaric acid. Antihistaminic activity resides almost exclusively in the *S*-stereoisomers (200–1,000 times higher H_1 -receptor binding affinities).^{30,38} The pheniramines are widely used in OTC products for seasonal allergies.

The propylamines with an unsaturated connecting moiety include the simple open-chain alkene derivatives pyrbutamine and triprolidine and the cyclic alkene analogs dimethindene and phenindamine. In the open-chain propylamines, a coplanar aromatic double-bond system appears to be an important factor for antihistaminic activity. Also, these compounds are asymmetric and the *E*-isomers are significantly more potent than the *Z*-isomers.^{4,39} The pyrrolidino group of these compounds is the side chain tertiary amine that imparts greatest antihistaminic activity. The conformational rigidity of the cyclic alkene propylamines has provided a useful model to determine distances between the key diaryl and tertiary pharmacophoric moieties in H_1 -antagonists, a distance of 5 to 6 Å.³⁹

The antihistamines in this group are among the most active H_1 -antagonists in terms of pA_2 values and doses (Table 23.2 and 23.3). They also have greater receptor selectivity and

Bucizine Hydrochloride

Figure 23.10 • General structure of the propylamines.

fewer anticholinergic and CNS side effects than other first-generation antihistamines. The propylamines have relatively long half-lives and are in many OTC preparations for once-a-day treatment of mild allergy symptoms. Although they produce less sedation, a significant proportion of patients do experience this effect.

In the propylamine series, the pharmacokinetics of chlorpheniramine have been studied most extensively in humans.^{10,31} Oral bioavailability is relatively low (30%–50%) and may be limited by first-pass metabolism. The primary metabolites for this compound and other members of this series are the mono- and di-*N*-dealkylation products. Complete oxidation of the terminal amino moiety followed by glycine conjugation has also been reported for brompheniramine. In general, the members of this group have long half-lives, allowing for once-daily dosing. Chlorpheniramine's plasma half-life ranges from about 12 to 28 hours, depending on the route of administration (Table 23.3). The known kinetic properties of representative members of this class of antihistamines are summarized in Table 23.3.

The structures of the marketed salt forms of the propylamine antihistamines, along with physicochemical properties, basic therapeutic activity profiles, and dosage form information, are provided in the monographs that follow.

Pheniramine Maleate. Pheniramine maleate, 2-[α -[2-dimethylaminoethyl]benzyl]-pyridine bimalate (Trimeton, Inhiston), is a white crystalline powder, with a faint amine-like odor, which is soluble in water (1:5) and very soluble in alcohol. This drug is the least potent member of the series and is marketed as the racemate. The usual adult dose is 20 to 40 mg 3 times daily. It is available in certain combination products.

Pheniramine Maleate

Chlorpheniramine Maleate. Chlorpheniramine maleate, (\pm)-2-[*p*-chloro- α -[2-dimethylaminoethyl]benzyl]pyridine bimalate (Chlor-Trimeton), is a white crystalline powder that is soluble in water (1:3.4), in alcohol (1:10), and in chloroform (1:10). It has a pK_a of 9.2, and an aqueous solution has a pH between 4 and 5. Chlorination of pheniramine in the *para* position of the phenyl ring increases potency 10-fold with no appreciable change in toxicity. Most of the antihistaminic activity resides with the dextro isomer (see under "Dexchlorpheniramine Maleate"). The usual dose is 2 to 4 mg 3 or 4 times a day. It has a half-life of 12 to 15 hours.

Chlorpheniramine Maleate
Dexchlorpheniramine Maleate

Dosage forms: Tablets (2, 4, 8, and 12 mg), extended-release capsules (8 and 12 mg), syrup (2 mg/5 mL), and oral suspension (4 and 8 mg/5 mL)

Usual adult dose: Oral, 4 mg/4 to 6 hours; extended release, 8 to 12 mg/8 to 12 hours; IM, intravenous (IV), or subcutaneous, 5 to 40 mg

Dexchlorpheniramine Maleate. Dexchlorpheniramine (Polaramine) is the dextrorotatory enantiomer of chlorpheniramine. In vitro and in vivo studies of the enantiomers of chlorpheniramine showed that the antihistaminic activity exists predominantly in the dextro isomer. As mentioned previously, the dextro isomer has the (*S*) configuration, which is superimposable on the (*S*) configuration of the more active levorotatory enantiomer of carbinoxamine.³⁰

Dosage forms: Extended-release tablets (4 and 6 mg), syrup (2 mg/5mL)

Usual adult dose: 4 or 6 mg at bedtime or every 8 to 10 hours

Brompheniramine Maleate and Tannate. Brompheniramine maleate, (+)-2-[*p*-bromo- α -[2-(dimethylamino)ethyl]benzyl]pyridine bimalate (Dimetane), differs from chlorpheniramine by the substitution of a bromine atom for the chlorine atom. Its actions and uses are like those of chlorpheniramine. It has a half-life of 25 hours, which is almost twice that of chlorpheniramine.

Brompheniramine Maleate

Dosage forms: Tablets (6 and 12 mg), oral drops (1 mg), capsules (12 mg), liquid (2 mg/5mL), oral suspension (4, 8, 10, and 12 mg/5 mL)

Usual adult dose: 1 or 2 tablets (6–12 mg) every 12 hours, or 5 to 10 mL of solution or suspension

Dexbrompheniramine Maleate. Like the chlorine derivative, the antihistaminic activity of brompheniramine exists predominantly in the dextro isomer, dexbrompheniramine maleate (D-isomer), and is of comparable potency.

Pyrrbutamine Phosphate. Pyrrbutamine phosphate, (E)-1-[4-(4-chlorophenyl)-3-phenyl-2-butenyl]pyrrolidine diphosphate (Pyronil), is a white crystalline powder that is soluble to the extent of 10% in warm water. Pyrrbutamine was investigated originally as the hydrochloride salt, but the diphosphate was absorbed more readily and completely. Clinical studies indicate that it is long acting, with a comparatively slow onset of action. The weak antihistaminic properties of several analogs point to the importance of having a planar $\text{ArC}=\text{CH}-\text{CH}_2\text{N}$ unit and a pyrrolidino group as the side chain tertiary amine.³⁹

Pyrrbutamine Phosphate

Tripolidine Hydrochloride. Tripolidine hydrochloride, (E)-2-[3-(1-pyrrolidinyl)-1-*p*-tolylpropenyl]pyridine monohydrochloride monohydrate (Actidil), is a white crystalline

powder with a slight, but unpleasant, odor. It is soluble in water and in alcohol, and its solutions are alkaline to litmus.

Tripolidine Hydrochloride

The antihistaminic activity is confined mainly to the geometric isomer in which the pyrrolidinomethyl group is *trans* to the 2-pyridyl group. Pharmacological studies confirm the high activity of tripolidine and the superiority of (*E*) over corresponding (*Z*) isomers as H_1 -antihistamines.³⁹ At guinea pig ileum sites, the affinity of tripolidine for H-receptors was more than 1,000 times the affinity of its (*Z*) diastereomer.

The relative potency of tripolidine is of the same order as that of dexchlorpheniramine. The peak effect occurs about 3.5 hours after oral administration, and the duration of effect is about 12 hours.

Dosage forms: Oral liquid (1.25 mg/5 mL) and oral suspension (2.5 mg/5 mL)

Usual adult dose: 10 mL every 4 to 6 hours; do not exceed 40 mL in 24 hours

Phenindamine Tartrate. Phenindamine tartrate, 2,3,4,9-tetrahydro-2-methyl-9-phenyl-1H-indeno[2,1-c]pyridine bitartrate, occurs as a creamy-white powder, usually with a faint odor and sparingly soluble in water (1:40). A 2% aqueous solution has a pH of about 3.5. It is most stable in the pH range of 3.5 to 5.0 and is unstable in solutions of pH 7 or higher. Oxidizing substances or heat may cause isomerization to an inactive form.

Phenindamine Tartrate

Structurally, phenindamine can be regarded as an unsaturated propylamine derivative, in that the rigid ring system contains a distorted, *trans*-alkene. Like the other commonly used antihistamines, it may produce drowsiness and sleepiness; it may also cause a mildly stimulating action in some patients and insomnia when taken just before bedtime.

Dosage forms: Tablets (25 mg)

Usual adult dose: 1 tablet every 4 to 6 hours, not to exceed 6 tablets in 24 hours

Dimethindene Maleate. Dimethindene maleate, (\pm)-2-[1-[2-[2-dimethylamino)ethyl]-inden-3-yl]ethyl]pyridine bimalate (1:1) (Forhista Maleate), is a white to off-white crystalline powder that has a characteristic odor and is sparingly soluble in water. This potent antihistaminic agent may be considered a derivative of the unsaturated propylamines. The principal side effect is some sedation or drowsiness. The antihistaminic activity resides mainly in the levorotatory isomer.

PHENOTHIAZINES

Beginning in the mid-1940s, several antihistaminic drugs were being discovered as a result of bridging the aryl units of agents related to the ethylenediamines. The search for effective antimalarials led to the investigation of phenothiazine derivatives in which the bridging entity is sulfur. Subsequent testing found that the phenothiazine class of drugs had not only antihistaminic activity but also a pharmacological profile of its own, considerably different from that of the ethylenediamines (Fig. 23.11). Thus began the era of development of useful psychotherapeutic agents, the phenothiazine antipsychotics.

The phenothiazine derivatives that display therapeutically useful antihistaminic actions contain a two- or three-carbon, branched alkyl chain between the ring system and terminal nitrogen atom. This differs significantly from the phenothiazine antipsychotic series in which an unbranched propyl chain is required. The branched alkyl chain contains a chiral carbon, giving rise to optical isomerism. The enantiomers of the pro-

Figure 23.11 • General structure of the phenothiazines.

totype of this class, promethazine, have been resolved and found to possess similar antihistaminic and other pharmacological properties as described later.^{40,41} This is in contrast with results of studies of the pheniramines and carbinoxamine compounds in which the chiral center is closer to the aromatic moieties of the molecule. Thus, asymmetry appears to have less influence on antihistaminic activity when the chiral center lies near the positively charged side-chain nitrogen. In general, the combination of lengthening of the side chain and substitution of lipophilic groups in the 2-position of the aromatic ring results in compounds with decreased antihistaminic activity and increased psychotherapeutic properties. Also, unlike the phenothiazine antipsychotics, the heterocyclic ring of the antihistamines is unsubstituted.

Promethazine, the parent member of this series, is a moderately potent antihistamine based on pA_2 values and doses with pronounced sedative effects (Table 23.2). It is a relatively long-acting antihistamine as a result of slow metabolic inactivation, perhaps because of sterically hindered cytochrome *N*-dealkylation. In addition to its antihistaminic and sedating action, it is a potent antiemetic, anticholinergic, and significantly potentiates the action of analgesic and other sedative drugs.³⁰ The other members of this series display a similar pharmacological profile and thus may cause drowsiness and impair the ability to perform tasks requiring alertness. Also, concurrent administration of alcoholic beverages and other CNS depressants with the phenothiazines should be avoided.¹⁰

Although few pharmacokinetic data are available for the phenothiazine antihistamines, the metabolism of a close structural analog promethazine has been studied in detail.³¹ This compound undergoes mono- and di-*N*-dealkylation, sulfur oxidation, aromatic oxidation at the 3-position to yield the phenol, and *N*-oxidation. Several of these metabolites, particularly the phenol, may yield glucuronide conjugates. It is expected that the phenothiazine antihistamines would display similar metabolic profiles.

Promethazine Hydrochloride. Promethazine hydrochloride, (\pm)-10-[2-(dimethylamino)-propyl]phenothiazine monohydrochloride (Phenergan), occurs as a white to faint yellow crystalline powder that is very soluble in water, in hot absolute alcohol, and in chloroform. Its aqueous solutions are slightly acid to litmus.

Dosage forms: Tablets (12.5, 25, and 50 mg), oral syrup (6.25 mg/5 mL), rectal suppositories (12.5, 25, and 50 mg), injection (25 and 50 mg/mL)

Usual adult dose:

- Allergy: 25 mg taken before retiring; however, 12.5 mg may be taken before meals or on retiring, if necessary

- Transfusion reactions: 25-mg doses to control minor transfusion reactions
- Motion sickness: 25 mg taken 30 to 60 minutes before travel and repeated 8 to 12 hours later, if necessary
- Nausea and vomiting: 12.5 to 25 mg every 4 to 6 hours as necessary
- Prophylactic dosage: 25 mg every 4 to 6 hours as necessary for prophylactic dosing (given during surgery and the postoperative period) and 25 to 50 mg with analgesics postoperatively or preoperatively
- Sedation: 25 to 50 mg for nighttime, presurgical, or obstetrical sedation

Trimeprazine Tartrate. Trimeprazine tartrate, (\pm)-10-[3-(dimethylamino)-2-methylpropyl] phenothiazine tartrate (Temaryl), occurs as a white to off-white crystalline powder that is freely soluble in water and soluble in alcohol. Its antihistaminic action is reported to be from 1.5 to 5 times that of promethazine. Clinical studies have shown it has a pronounced antipruritic action that may be unrelated to its histamine-antagonizing properties.

Trimeprazine Tartrate

Dosage forms: Syrup and tablets
Usual adult dose: Oral, 2.5 mg 4 times a day

Methdilazine. Methdilazine, 10-[(1-methyl-3-pyrrolidinyl)methyl]phenothiazine (Tacaryl), is a light-tan crystalline powder that has a characteristic odor and is practically insoluble in water. Methdilazine, as the free base, is used in chewable tablets because its low solubility in water contributes to its tastelessness. Some local anesthesia of the buccal mucosa may be experienced if the tablet is chewed and not swallowed promptly.

Methdilazine Hydrochloride

Methdilazine Hydrochloride. Methdilazine hydrochloride (Tacaryl Hydrochloride), also occurs as a light-tan crystalline powder with a slight characteristic odor. The salt is freely soluble in water and in alcohol, however. The activity is like that of methdilazine, and it is administered orally for its antipruritic effect.

DIBENZOCYCLOHEPTENES AND DIBENZOCYCLOHEPTANES

The dibenzocycloheptene and dibenzocycloheptane antihistamines may be regarded as phenothiazine analogs in which the sulfur atom has been replaced by an isosteric vinyl group (cyproheptadine) or a saturated ethyl bridge (azatadine), and the ring nitrogen has been replaced by an sp^2 carbon atom (Fig. 23.12). The two members of this series are closely related in structure; azatadine is an aza (pyridyl) isostere of cyproheptadine in which the 10,11-double bond is reduced. These agents are potent antihistamines with moderate sedation and anticholinergic potential, and little antiemetic activity (Table 23.2).

Cyproheptadine Hydrochloride. Cyproheptadine hydrochloride, 4-(5H-dibenzo-[a,d]-cyclohepten-5-ylidene)-1-methylpiperidine hydrochloride sesquihydrate (Periactin), is slightly soluble in water and sparingly soluble in alcohol.

Cyproheptadine Hydrochloride

Cyproheptadine possesses both antihistamine and anti-serotonin activity and is used as an antipruritic agent. It is indicated for the treatment of hypersensitivity reactions, perennial, and seasonal allergic rhinitis; vasomotor rhinitis; allergic conjunctivitis, uncomplicated allergic skin manifestations of urticaria and angioedema; amelioration of allergic reactions to blood or plasma; and cold urticaria. It is also used off-label for nightmares associated with posttraumatic stress disorder (PTSD), prevention of migraine, suppression of vascular headaches, and appetite stimulation. Sedation is the most prominent side effect, and this is usually brief, disappearing after 3 or 4 days of treatment.

Dosage forms: Tablets (4 mg) and syrup (2 mg/5 mL)
Usual adult dose: Oral, 4 mg 3 or 4 times a day

Azatadine Maleate. Azatadine maleate, 6,11-dihydro-11-(1-methyl-4-piperidylidene)-5H-benzo-[5,6]cyclo-

Figure 23.12 • General structure of the dibenzocycloheptenes and dibenzocycloheptanes.

hepta(1,2-b)pyridine maleate (1:2) (Optimine), is a potent, long-acting antihistaminic with antiserotonin activity. In early testing, azatadine exhibited more than three times the potency of chlorpheniramine in the isolated guinea pig ileum screen and more than seven times the oral potency of chlorpheniramine in protection of guinea pigs against a double lethal dose of intravenously administered histamine.⁴¹

Dosage forms: Tablets (1 mg)
Usual dosage: 1 to 2 mg twice daily

Second-Generation Antihistamines

Initial design efforts toward new or second-generation antihistamines focused on developing agents with a lower sedation potential and reduced binding affinities for nontarget proteins including muscarinic, adrenergic, and serotonergic receptors. These efforts led to the introduction of astemizole and terfenadine, derivatives of the first-generation agents with substantially larger *N*-tertiary amine substituents (Fig. 23.13). Astemizole and terfenadine proved to be “nonsedating” and target-receptor selective, but extensive clinical use uncovered serious cardiovascular toxicities (QT prolongation and

arrhythmias).^{10,33,34} These cardiac actions appear to result from the blockade of the rapid component of delayed rectifier potassium current (IKr) by astemizole and terfenadine, even at therapeutic concentrations. Blocking the rectifier current causes prolongation of the monophasic cardiac action potential and QT interval, as well as induction of early afterdepolarizations and dispersion (slowing) of repolarization, resulting in torsades de pointes.¹⁰ Furthermore, such cardiac effects were observed more commonly when astemizole and terfenadine were administered with other drugs that inhibit their cytochrome metabolism, such as the imidazole antifungals (ketoconazole, itraconazole) and the macrolides (erythromycin, clarithromycin). Through this drug interaction, astemizole and terfenadine levels would rise and the incidence of untoward cardiac events increases. As a result of these concerns, both astemizole and terfenadine have been withdrawn from the U.S. market. The newer second-generation H₁-antihistamines described later have significantly reduced IKr current-blocking capacity, and have demonstrated significantly lower cardiotoxicity in clinical use.

Further drug design efforts resulted in the discovery of new second-generation agents, which retained the nonsedating and receptor-selectivity properties, but lacked the cardiotoxicity of astemizole and terfenadine. These newer agents are structurally diverse, but are derivatives of first-generation drugs, containing larger, polar functionality connected either to the terminal tertiary amine, or as a substituent of one of the aromatic rings. The new second-generation drugs currently on the market include acrivastine, an alkene-acid derivative of triprolidine; cetirizine and levocetirizine, oxidation metabolites of hydroxyzine; desloratadine, an oxidation-hydrolysis metabolite of loratadine; and fexofenadine, an oxidative metabolite of terfenadine.¹⁰ In addition to their H₁-receptor selectivity, these second-generation agents do not accumulate in the CNS because their hydrophilicity (in some cases) and high affinity for P-glycoprotein efflux pumps of cells associated with the BBB.^{10,42,43} The propensity of these drugs to occupy CNS H₁-receptors varies from 0% for fexofenadine to 30% for cetirizine. The properties of these drugs are described in more detail in the monographs that follow.⁴⁴

Fexofenadine Hydrochloride. Fexofenadine hydrochloride, (±)-4-[1-hydroxy-4-[4-(hydroxy)diphenylmethyl]-1-piperinyl]butyl- α,α -dimethylbenzeneacetic acid (Allegra), occurs as a white to off-white crystalline powder that is freely soluble in methanol and ethanol, slightly soluble in chloroform and water, and insoluble in hexane. This compound is marketed as a racemate and exists as a zwitterion in aqueous media at physiological pH.

Fexofenadine is a primary oxidative metabolite of terfenadine.⁴⁵ Terfenadine was developed during a search for new butyrophenone antipsychotic drugs as evidenced by the presence of the *N*-phenylbutanol substituent. It also contains a diphenylmethyl-piperidine moiety analogous to that found in the piperazine antihistamines. Terfenadine is a selective, long-acting (>12 hours) H₁-antihistamine with little affinity for muscarinic, serotonergic, or adrenergic receptors. The histamine receptor affinity of this compound is believed to be related primarily to the presence of the diphenylmethylpiperidine moiety. The prolonged action results from very slow dissociation from these receptors. The lack of anticholinergic, adrenergic, or serotonergic actions appears to be linked to the presence of the *N*-phenylbutanol substituent (Table 23.2). This substituent contributes to P-glycoprotein efflux pump affinity,

Figure 23.13 • Structures of terfenadine and astemizole.

which serves to limit accumulation of terfenadine in the CNS. Terfenadine undergoes significant first-pass cytochrome P450 (CYP)-based metabolism, with the predominant metabolite being fexofenadine, an active metabolite resulting from methyl group oxidation. When drugs that inhibit this transformation, such as the imidazole antifungals and macrolides, are used concurrently, terfenadine levels may rise to toxic levels, resulting in potentially fatal heart rhythm problems that were described. The observation that fexofenadine displays antihistaminic activity comparable with that of terfenadine but is less cardiotoxic led to its development as an alternative to terfenadine for the relief of the symptoms of seasonal allergies.

Fexofenadine, like terfenadine, is a selective peripheral H_1 -receptor ligand that produces no clinically significant anticholinergic effects or α_1 -adrenergic receptor blockade at

therapeutic doses (Table 23.2). No sedative or other CNS effects have been reported for this drug, and animal studies indicate that fexofenadine does not cross the BBB. In vitro studies also suggest that unlike terfenadine, fexofenadine does not block potassium channels in cardiocytes. Furthermore, in drug interaction studies, no prolongation of the QTc interval or related heart rhythm abnormalities were detected when fexofenadine was administered concurrently with erythromycin or ketoconazole.^{10,46}

Fexofenadine is indicated for the treatment of seasonal allergic rhinitis and chronic idiopathic urticaria. It is rapidly absorbed after oral administration, producing peak serum concentrations in about 2.5 hours. Fexofenadine is 60% to 70% plasma protein bound. Unlike its parent drug, only 5% of the total dose of fexofenadine is metabolized. The re-

mainder is excreted primarily in the urine; the mean elimination half-life is about 14 hours (Table 23.3).¹⁰

Dosage form: Tablets (30, 60, and 180 mg), oral disintegrating tablets (30 mg), and an oral suspension (6 mg/mL)

Usual doses:

- Chronic idiopathic urticaria: 60 mg twice daily or 180 mg once daily in adults and children >12; lower doses are recommended in children
- Seasonal allergic rhinitis: 60 mg twice daily or 180 mg once daily in adults and children >12; lower doses are recommended in children

Loratadine. Loratadine, 4-(8-chloro-5, 6-dihydro- 11H-benzo[5,6]-cyclohepta[1,2-b]pyridin-1-ylidene-1-carboxylic acid ethyl ester, is a white to off-white powder insoluble in water but very soluble in acetone, alcohols, and chloroform. Loratadine is structurally related to the antihistamines azatadine and cyproheptadine, and to some tricyclic antidepressants. It differs from azatadine, in that a neutral carbamate group has replaced the basic tertiary amino moiety, and a phenyl ring has been substituted with a chlorine atom.

Loratadine is a selective peripheral H₁-antihistamine with a receptor-binding profile like that of the other members of this series, except that it has more antiserotonergic activity (Table 23.2). Thus, it produces no substantial CNS or autonomic side effects or cardiac toxicity. Loratadine displays potency comparable with that of astemizole and greater than that of terfenadine.

Loratadine is indicated for the relief of nasal and non-nasal symptoms of seasonal allergic rhinitis. It is rapidly absorbed after oral administration, producing peak plasma levels in about 1.5 hours. This drug is extensively metabolized by oxidation of the carbamate methylene group, a reaction catalyzed by CYP3A4 and, to a lesser extent, CYP2D6 (Table 23.3). This oxidation metabolite readily undergoes O-demethylation and decarboxylation to form the descarboethoxy metabolite (desloratadine), which appears to be responsible for antihistaminic activity.⁴⁷⁻⁴⁹ In the presence of a CYP3A4 inhibitor ketoconazole, loratadine is metabolized to descarboethoxyloratadine predominantly by CYP2D6. Concurrent administration of loratadine with either ketoconazole, erythromycin (both CYP3A4 inhibitors),

or cimetidine (CYP2D6 and CYP3A4 inhibitor) is associated with substantially increased plasma concentrations of loratadine.^{10,48} Both parent drug and active metabolite have elimination half-lives ranging from 8 to 15 hours. The metabolite is excreted renally as a conjugate (Table 23.3).¹⁰

Dosage forms: Tablets (5 and 10 mg), oral disintegrating tablets (5 and 10 mg), syrup (5 mg/5 mL)

Usual adult dose (allergic rhinitis): 10 mg once daily (adults and children 6 years of age and older), 5 mg (chewable tablets, syrup) once daily for children 2 to 5 years of age

Desloratadine. Desloratadine, 8-chloro-6,11-dihydro-11-(4-piperidinylidene)-5H-benzo[5,6]cyclohepta[1,2-b]pyridine (Clarinet) is a white to off-white powder that is slightly soluble in water, but very soluble in ethanol and propylene glycol. It is the proposed active metabolite loratadine and has a very similar receptor binding and safety profile (Table 23.2). It is indicated for the symptomatic relief of pruritus and reduction in the number and size of hives in chronic idiopathic urticaria patients 6 months of age and older and for the relief of the nasal and nonnasal symptoms of perennial allergic rhinitis (in patients 6 months of age and older) and seasonal allergic rhinitis (in patients 2 years of age and older).

Desloratadine is extensively metabolized to 3-hydroxydesloratadine, also an active metabolite, which is subsequently glucuronidated (Table 23.3). The cytochrome enzymes responsible for the formation of 3-hydroxydesloratadine have not been reported. Coadministration of desloratadine with CYP3A4 inhibitors results in marginal increases in plasma concentrations of desloratadine and 3-hydroxydesloratadine, but no significant changes in safety or efficacy.⁴⁸ The mean elimination half-life of desloratadine is about 6 hours, and the drug and its metabolites are eliminated in the urine and feces (Table 23.3).

Dosage forms: Tablets (5 mg), rapidly disintegrating tablets (2.5 and 5.0 mg), syrup (2.5 mg/5 mL)

Usual doses:

Adults and children 12 years of age and older: 5 mg once daily
Children 6 to 11 years of age: 2.5 mg once daily

Cetirizine. Cetirizine, (±)-[2-[4-[(4-chlorophenyl)phenylmethyl]-1-piperazinyl]ethoxy]acetic acid (Zyrtec), is a racemic compound available as a white crystalline powder that

Cetirizine

is water soluble. Cetirizine is the primary acid metabolite of hydroxyzine, resulting from complete oxidation of the primary alcohol moiety. This compound is zwitterionic and relatively polar and thus does not penetrate or accumulate in the CNS.^{10,50,51} Before its introduction in the United States, cetirizine was one of the most widely prescribed H₁-antihistamines in Europe. It is highly selective in its interaction with various neuronal binding sites and highly potent (>> terfenadine) as well (Table 23.2). The advantages of this compound appear to be its long action (once-daily dosing), rapid onset of activity, minimal CNS effects and a lack of clinically significant effects on cardiac rhythm.^{10,50}

Cetirizine produces qualitatively different effects on psychomotor and psychophysical functions from the first-generation antihistamines.^{10,50} The drug has been associated with dose-related somnolence, however, so patients should be advised that cetirizine may interfere with the performance of certain jobs or activities. Other effects of this drug include fatigue, dry mouth, pharyngitis, and dizziness. Because the drug is extensively eliminated by a renal route, its adverse reactions may be more pronounced in individuals suffering from renal insufficiency. No cardiotoxic effects, such as QT prolongation, are observed with the new drug when used at its recommended or higher doses or when coadministered with imidazole antifungals and macrolide antibiotics.¹⁰ Other typical drug interactions of H₁-antihistamines, however, apply to cetirizine and concurrent use of this drug with alcohol and other CNS depressants should be avoided.

Cetirizine is indicated for the temporary relief of runny nose, sneezing, itching of the nose or throat, and/or itchy, watery eyes caused by hay fever or other upper respiratory allergies. It also relieves itching caused by hives (urticaria), but it will not prevent hives or an allergic skin reaction from occurring.

Dose-proportional C_{max} values are achieved within 1 hour of oral administration of cetirizine. Food slows the rate of cetirizine absorption but does not affect the overall extent. Consistent with the polar nature of this carboxylic acid drug, less than 10% of peak plasma levels have been measured in the brain. Cetirizine is not extensively metabolized, and more than 60% of a 10-mg oral dose is excreted in the urine (>60% as unchanged drug) and 10% is recovered in the feces (Table 23.3). The drug is highly protein bound (93%) and has a terminal half-life of 8.3 hours. The clearance of cetirizine is reduced in elderly subjects and in renally and hepatically impaired patients.

Dosage forms: Tablets (5 and 10 mg) and oral syrup (1 mg/mL)

Usual adult dose (allergies/hay fever and urticaria): 5 to 10 mg once daily depending on the severity of symptoms, up to maximum of 10 mg/day in adults and chil-

dren 6 or older; 2.5 mg once daily of the oral solution for children younger than the age of 6

Levocetirizine Dihydrochloride. Levocetirizine dihydrochloride, (R)-[2-[4-[(4-chlorophenyl) phenylmethyl]-1-piperazinyl] ethoxy] acetic acid dihydrochloride, (Xyzal) is a white, crystalline powder and is water soluble. This R-enantiomer has a 30-fold higher affinity than the S-enantiomer, and dissociates more slowly from H₁-receptors.⁵¹ Pharmacologically, it displays the same receptor and CNS selectivity profile as the racemate, cetirizine (Table 23.2), and thus the same therapeutic advantages. Levocetirizine is indicated for the relief of symptoms associated with allergic rhinitis (seasonal and perennial) in adults and children 6 years of age and older and for the treatment of the uncomplicated skin manifestations of chronic idiopathic urticaria in adults and children 6 years of age and older. Its pharmacokinetics and clearance profile are essentially the same as the racemate, cetirizine (Table 23.3).

Dosage forms: Tablets (5 mg) and solution (2.5 mg/5 mL)
Usual dose: 5 mg (one tablet or 10-mL oral solution) once daily in the evening for adults and children 12 years of age and older; 2.5 mg (half of a tablet or 5-mL oral solution) once daily in the evening for children 6 to 11 years old

Acrivastine. Acrivastine, (*E, E*)-3-[6-[1-(4-methylphenyl)-3-(1-pyrrolidinyl)-1-propenyl]-2-pyridinyl]-2-propenoic acid (Semprex), is a fixed-combination product of the antihistamine acrivastine (8 mg) with the decongestant pseudoephedrine (60 mg). Acrivastine is an odorless, white to pale cream crystalline powder that is soluble in chloroform and alcohol and slightly soluble in water.

Acrivastine Hydrochloride

Acrivastine is an analog of triprolidine containing a carboxyethenyl moiety at the 6-position of the pyridyl ring. Acrivastine shows antihistaminic potency and duration of action comparable to those of triprolidine (Table 23.2). Unlike triprolidine, acrivastine does not display significant anticholinergic activity at therapeutic concentrations. Also, the enhanced polarity of this compound resulting from carboxyethenyl substitution limits BBB accumulation, and thus, this compound produces less sedation than triprolidine.

Limited pharmacokinetic data are available for this compound. Orally administered drug has a half-life of about 1.7 hours and a total body clearance of 4.4 mL/min per kilogram. The mean peak plasma concentrations are reported to vary widely, and the drug appears to penetrate the CNS poorly. The metabolic fate of acrivastine has not been reported.

Dosage forms: Tablets: various combination products
Usual adult dose: Oral, 8 or 60 mg 3 to 4 times a day

INHIBITION OF HISTAMINE RELEASE: MAST CELL STABILIZERS

The discovery of the bronchodilating activity of the natural product khellin, obtained from the plant *Ammi visnaga*, led to the development of the bis(chromones) as compounds that stabilize mast cells and inhibit the release of histamine and other mediators of inflammation.⁵² The first therapeutically significant member of this class was cromolyn sodium. Further research targeting more effective agents resulted in the introduction of nedocromil, followed more recently by pemirolast and lodoxantide. Generally, the mast cell stabilizers inhibit activation of, and mediator release from, various inflammatory cell types associated with allergy and asthma, including eosinophils, neutrophils, macrophages; mast cells, monocytes, and platelets. In addition to histamine, these drugs inhibit the release of leukotrienes (C4, D4, E4) and prostaglandins.^{53,54} In vitro studies suggest that these drugs stimulate the protein kinase C-mediated phosphorylation of moesin. This phosphorylated protein then binds with key proteins on the secretory granule (such as actin) and stabilizes them to prevent exocytosis. Other studies suggest that the bischromones indirectly inhibit calcium ion entry into the mast cell and that this action prevents mediator release.

In addition to their inhibition of mediator release, some of these drugs also inhibit the chemotaxis of eosinophils at the site of application (i.e., ocular tissue).⁵⁴ In lung tissue, pretreatment with the mast cell stabilizers cromolyn and nedocromil blocks the immediate and delayed bronchoconstrictive reactions induced by the inhalation of antigens. These drugs also attenuate the bronchospasm associated with exercise, cold air, environmental pollutants, and certain drugs (aspirin). However, the mast cell stabilizers do not have intrinsic bronchodilator, antihistamine, anticholinergic, vasoconstrictor, or glucocorticoid activity, and, when delivered by inhalation at the recommended dose, have no known therapeutic systemic activity. The structures, chemical properties, pharmacological profiles, and dosage data for these agents are provided in the monographs that follow.

Cromolyn Sodium. Cromolyn sodium, disodium 1,3-bis(2-carboxychromon-5-yloxy)-2-hydroxypropane (Intal), is a hygroscopic, white, hydrated crystalline powder that is soluble in water (1:10). It is tasteless at first but leaves a very slightly bitter aftertaste. The pK of cromolyn is 2. It is available as a solution for a nebulizer, an aerosol spray, a nasal solution, an ophthalmic solution, and an oral concentrate.

Nebulized and aerosol cromolyn has been used for prophylactic management of bronchial asthma and prevention of exercise-induced bronchospasm.⁵² Cromolyn nasal solution is used for the prevention and treatment of allergic rhinitis, and oral concentrate is used to treat the histaminic symptoms of mastocytosis (diarrhea, flushing, headaches, vomiting, urticaria, abdominal pain, nausea, and itching). Topical cromolyn (eye drops) is used to treat allergic conjunctivitis and keratitis. In the treatment of asthma, cromolyn efficacy is manifested by decreased severity of clinical symptoms, or need for

concomitant therapy, or both. Long-term use is justified if the drug significantly reduces the severity of asthma symptoms; permits a significant reduction in, or elimination of, steroid dosage; or improves management of those who have intolerable side effects to sympathomimetic agents or methylxanthines. For cromolyn to be effective, it must be administered at least 30 minutes prior to antigen challenge and administered at regular intervals (see dosing information that follows). When inhaled, the powder does produce irritation in some patients. Also, overuse of cromolyn can result in tolerance.

Dosage forms: Oral concentrate (100 mg/5 mL), nasal solution (40 mg/mL), solution for inhalation (20 mg/2 mL), aerosol (800 mg), ophthalmic solution (4%)

Usual adult dose:

- Inhalation solution (adults and children at least 2 years of age): 20 mg (one ampule per vial) by nebulization 4 times/day at regular intervals
- Aerosol (asthma in adults and children at least 5 years of age): 2 metered sprays inhaled 4 times per day at regular intervals
- Nasal solution (adults and children): one spray in each nostril 3 to 6 times daily at regular intervals every 4 to 6 hours
- Oral: two ampules 4 times per day 30 minutes before meals and at bedtime
- Ophthalmic: 1 drop of a 2% to 4% solution 4 to 6 times daily; Oral: two ampules 4 times a day 30 minutes before meals and at bedtime

Nedocromil Sodium. Nedocromil sodium, disodium 9-ethyl-6, 9-dihydro-4,6-dioxo-10-propyl-4H-pyrano[3, 2-g]quinoline-2,8-dicarboxylate (Tilade), is structurally re-

lated to cromolyn and displays similar, but broader, pharmacological actions.⁵² It was available as an aerosol in a metered-dose inhaler for asthma treatment, and currently remains available as ophthalmic solution for the treatment of itching associated with allergic conjunctivitis. The inhalation formulation was marketed for maintenance therapy in the management of patients with mild-to-moderate bronchial asthma, but since has been withdrawn.

Dosage forms: Ophthalmic solution (2% or 20 mg/mL)

Usual adult dose: 1 or 2 drops in each eye twice a day at regular intervals

Lodoxamide Tromethamine. Lodoxamide tromethamine, *N, N'*-(2-chloro-5-cyano-*m*-phenylene)dioamic acid (Alomide), is a white crystalline, water-soluble powder. The only significant structural similarity between lodoxamide and cromolyn and nedocromil is the presence of two acidic groups. Lodoxamide is indicated in the treatment of the ocular disorders including vernal keratoconjunctivitis, vernal conjunctivitis, and vernal keratitis.⁵⁵ Lodoxamide is available as a 0.1% solution, with each milliliter containing 1.78 mg of lodoxamide tromethamine equivalent to 1 mg of lodoxamide. The solution contains the preservative benzalkonium chloride (0.007%) as well as mannitol, hydroxypropyl methylcellulose, sodium citrate, citric acid, edetate disodium, tyloxapol, hydrochloric acid and/or sodium hydroxide (to adjust pH), and purified water.

The dose for adults and children older than 2 years of age is 1 to 2 drops in each affected eye 4 times daily for up to 3 months. The most frequently reported ocular adverse experiences were transient burning, stinging, or discomfort on instillation.

Pemirolast Potassium Ophthalmic Solution.

Pemirolast potassium, 9-methyl-3-(1H-tetrazol-5-yl)-4H-pyrido[1, 2- α]pyrimidin-4-one potassium (Alamast), is a yellow, water-soluble powder. It can be considered an analog of one portion of the cromolyn structure in which the carboxyl group has been replaced with an isosteric tetrazole moiety. Pemirolast is indicated for the prevention of itching of the eye caused by allergic conjunctivitis. The commercial preparation is available as a 0.1% sterile ophthalmic solution for topical administration to the eyes. Each milliliter of this solution contains 1 mg of pemirolast potassium, as well as the preservative lauralkonium chloride (0.005%), and glycerin, phosphate buffers, and sodium hydroxide to maintain a solution pH of 8.0. The solution has an osmolality of 240 mOsm/L. The recommended dose is 1 to 2 drops instilled into each affected eye 4 times a day. This drug product is for ocular administration only and not for injection or oral use and should be used with caution during pregnancy or while nursing.⁵⁶

Pemirolast Potassium

RECENT ANTIHISTAMINE DEVELOPMENTS: THE "DUAL-ACTING" ANTIHISTAMINES

Over the several past decades, there has been considerable interest in the development of novel antihistaminic compounds with dual mechanisms of action including H_1 -receptor antihistaminic action and mast cell stabilization. Currently available drugs that exhibit such dual antihistaminic actions include azelastine and ketotifen. These compounds contain the basic pharmacophore to produce relatively selective antihistaminic action (diarylalkylamines) as well as inhibition of the release of histamine and other mediators (e.g., leukotrienes and PAP) from mast cells involved in the allergic response. In vitro studies suggest that these compounds also decrease chemotaxis and activation of eosinophils. Azelastine and ketotifen currently are indicated for the treatment of itching of the eye associated with allergic conjunctivitis. Their antiallergy actions occur within minutes after administration and may persist for up to 8 hours. The structures, chemical properties, pharmacological profiles, and dosage data for these agents are provided in the monographs that follow.

Azelastine Hydrochloride Ophthalmic Solution.

Azelastine hydrochloride, (\pm) -4-[(4-chlorophenyl)methyl]-2-(hexahydro-1-methyl-1H-azepin-4-yl)-1-(2H)-phthalazinone monohydrochloride (Optivar), is a white crystalline powder that is sparingly soluble in water, methanol, and propylene glycol and slightly soluble in ethanol, octanol, and glycerine. The commercial preparation is available as a 0.05% sterile ophthalmic solution for topical administration to the eyes. Each milliliter of azelastine solution contains 0.5-mg azelastine hydrochloride equivalent to 0.457 mg of azelastine base, the preservative benzalkonium chloride (0.125 mg), and inactive ingredients including disodium edetate dihydrate, hydroxypropylmethylcellulose, sorbitol solution, sodium hydroxide, and water for injection. The solution has a pH of approximately 5.0 to 6.5 and an osmolality of approximately 271 to 312 mOsm/L.

Azelastine

The recommended dose of azelastine solution is 1 drop instilled into each affected eye twice a day. This drug product is for ocular administration only and not for injection or oral use. Absorption of azelastine following ocular administration is relatively low (less than 1 ng/rnL). Absorbed drug undergoes extensive oxidative *N*-demethylation by CYP, and the parent drug and metabolite are eliminated primarily in the feces. The most frequently reported adverse reactions are transient eye burning or stinging, headaches, and bitter taste. Azelastine solution should be used with caution during pregnancy or while nursing, because its safety has not been studied under these circumstances.⁵⁷

Ketotifen Fumarate Ophthalmic Solution.

Ketotifen fumarate, 4-(1-methyl-4-piperidylidene)-4H-benzo[4,5]cyclohepta[1,2-b]thiophen-10(9H)-one hydrogen fumarate (Zaditor), is a fine crystalline powder. Ketotifen is a ketothiophene isostere analog of the dibenzocycloheptane antihistamines. The solution contains 0.345 mg of ketotifen fumarate, which is equivalent to 0.25 mg of ketotifen. The solution also contains the preservative benzalkonium chloride (0.01%) as well as glycerol, sodium hydroxide and/or hydrochloric acid (to adjust pH), and purified water. It has a pH of 4.4 to 5.8 and an osmolality of 210 to 300 mOsm/kg.

Ketotifen Fumarate

The recommended dose of ketotifen solution is 1 drop instilled into each affected eye every 8 to 12 hours. The most frequently reported adverse reactions are conjunctival infection, headaches, and rhinitis. This drug product is for ocular administration only and not for injection or oral use. Ketotifen solution should be used with caution during pregnancy or while nursing, because its safety has not been studied under these circumstances.⁵⁸

HISTAMINE H₂-ANTAGONISTS

Drugs whose pharmacological action primarily involves antagonism of the action of histamine at its H₂-receptors find therapeutic application in the treatment of acid-peptic disorders including heartburn, gastroesophageal reflux disease (GERD), erosive esophagitis, gastric and duodenal ulcers, and gastric acid pathologic hypersecretory diseases such as Zollinger-Ellison syndrome. They are also useful in combination with H₁-antihistamines for the treatment of chronic urticaria and for the itching of anaphylaxis and pruritis.^{59–62}

Gastric Acid Secretion

A characteristic feature of the mammalian stomach is its ability to secrete acid as part of its processes to digest food for absorption later in the intestine. The presence of acid and proteolytic pepsin enzymes, whose formation is facilitated by the low gastric pH, is generally assumed to be required for the hydrolysis of proteins and other food constituents. The acid secretory unit of the gastric mucosa is the parietal (oxyntic) cell. Parietal cells contain an H⁺, K⁺-ATPase or hydrogen ion pump that secretes proton (H⁺) in exchange for the uptake of K⁺ ion (Fig. 23.14).^{61,62} Secretion of acid by gastric parietal cells is stimulated by various mediators at receptors located on the basolateral membrane, including histamine agonism of H₂-receptors (cellular), gastrin activity at G receptors (blood), and acetylcholine (ACh) at M₂ muscarinic receptors (neuronal). Gastric and muscarinic receptors modulate acid secretion through calcium-dependent processes, while the H₂-receptor is coupled to adenylate cy-

clase (Fig. 23.14). The adenylate cyclase pathway, and therefore acid secretion, is inhibited by intracellular prostaglandins of the E series. These prostaglandins also stimulate other GI epithelial cells to secrete mucous and bicarbonate, and enhance blood flow through gastric tissues. All of these prostaglandin-mediated actions have acid-neutralizing and gastric tissue protective properties referred to generally as "cytoprotection." When there is hypersecretion of gastric acid or breakdown of mucosal cell defenses, including bacterial infection, gastric tissues and contiguous structures (esophagus, intestines) may become compromised and ulcerated.^{61,62}

Peptic Ulcer Disease

Peptide ulcer disease (PUD) is a group of upper GI tract disorders characterized by mucosal erosions equal to or greater than 0.5 cm that result from the erosive action of acid and pepsin.⁶³ Duodenal ulcer and gastric ulcer are the most common forms, although PUD may occur in the esophagus or small intestine. Factors involved in the pathogenesis and recurrence of PUD include hypersecretion of acid and pepsin and GI infection by *Helicobacter pylori*, a Gram-negative spiral bacterium. *H. pylori* have been found in virtually all patients with duodenal ulcers and approximately 75% of patients with gastric ulcers. Some risk factors associated with recurrence of PUD include cigarette smoking, chronic use of ulcerogenic drugs (e.g., nonsteroidal anti-inflammatory drugs [NSAIDs]), male gender, age, alcohol consumption, emotional stress, and family history. About 4% of gastric ulcers are caused by a malignancy, whereas duodenal ulcers are generally benign.

The goals of PUD therapy are to promote healing, relieve pain, and prevent ulcer complications and recurrences. Medications used to heal or reduce ulcer recurrence include antacids, histamine H₂-antagonists, protective mucosal barriers, proton pump inhibitors (PPIs), prostaglandins, and bismuth salt and combinations of these drugs with antibiotics to eradicate *H. pylori* infection.

Structural Derivation of the "H₂-Antagonists"

The H₂-antagonists are used to treat acid indigestion (an OTC application), GERD, peptic ulcers, and pathologic hypersecretory disorders, as well as some of the symptoms of urticaria and anaphylaxis. Cimetidine, the original member of this drug class, was developed by a classical structure-activity study beginning with the endogenous agonist, histamine as shown in Table 23.4.⁶⁴ Methylation of the 5-position of the imidazole heterocycle of histamine produced a selective agonist at atrial histamine receptors (H₂). The guanidino analog of histamine was then found to possess weak antagonist activity to the acid-secretory actions of histamine. Increasing the length of the side chain from two to four carbons, coupled with replacement of the strongly basic guanidino group by a neutral methyl thiourea function, led to development of burimamide, the first full H₂-receptor antagonist, albeit one of low potency. The low potency of burimamide was postulated to be related to its nonbasic, electron-releasing side chain, which favors the nonpharmacophoric N⁷-H imidazole tautomer over the basic, electron-withdrawing side chain in histamine, which predominantly presents the higher-affinity N⁷-H imidazole tautomer to the

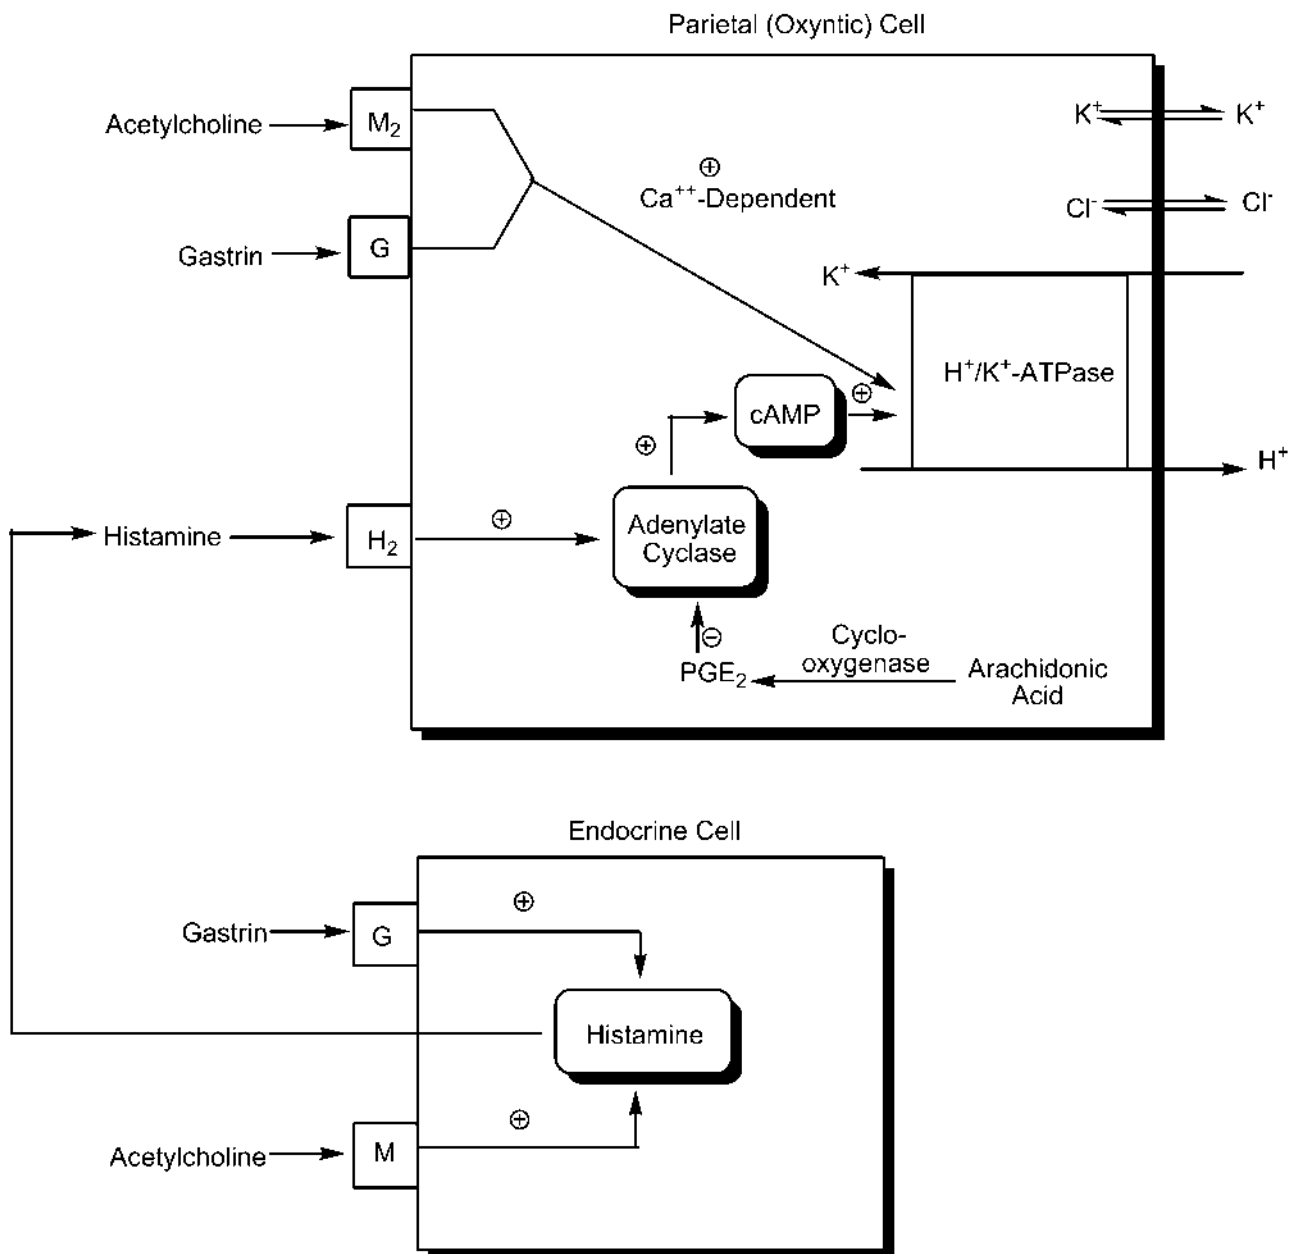

Figure 23.14 • Hormonal regulation of acid secretion by parietal cells.

receptor. Insertion of an electronegative thioether function in the side chain in place of a methylene group favors the N^7-H tautomer, and introduction of the 5-methyl group favors H_2 selectivity and led to metiamide, an H_2 -blocker of higher potency and oral bioavailability than burimamide. Unfortunately, drug-related toxicities including agranulocytosis prevented further development of this compound. However, replacement of the thiourea moiety of metiamide with a cyano-imino function produced cimetidine, the first clinically effective and relatively safe member of this therapeutic class (Table 23.4).⁶⁴

Introduction of cimetidine into medicine revealed an effective gastric antisecretory agent that promotes the healing of duodenal ulcers. Cimetidine is not without several limitations, however. Because it is short acting, it requires a frequent-dosing schedule. Also, cimetidine was found to possess antiandrogenic activity, which can lead to gynecomastia, and to

cause confusional states in some elderly patients and decreased renal function. Also, cimetidine inhibits CYP isozymes and renal tubular secretion, resulting in clinically significant drug interactions.⁶⁵ The drug interaction potential and several adverse effects (gynecomastia) of cimetidine appear to be directly related to the presence of the imidazole group. These limitations prompted additional drug design and development efforts, which revealed that the imidazole ring was not required for H_2 -antagonist activity (discussed next). In fact, replacement of the imidazole ring with a furan (ranitidine) or a thiazole (famotidine, nizatidine) heterocycle with a basic ring substituent (guanidine or dimethylaminomethyl) not only enhances both potency and selectivity of H_2 -antagonism, but also reduces cytochrome and renal secretory drug interactions.⁶⁴

The pharmacokinetic properties of the H_2 -antagonists are summarized in Table 23.5.⁶⁶ Cimetidine, ranitidine, and

TABLE 23.4 Development of H₂-Antagonists

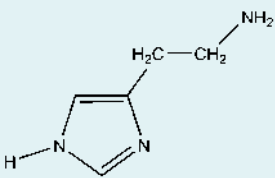

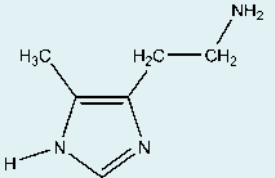

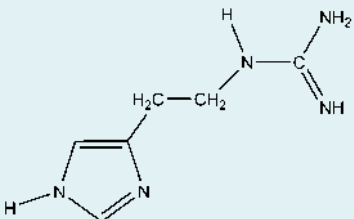

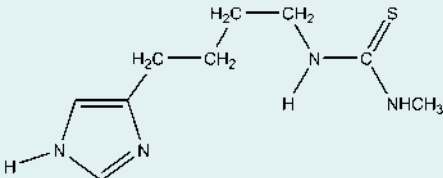

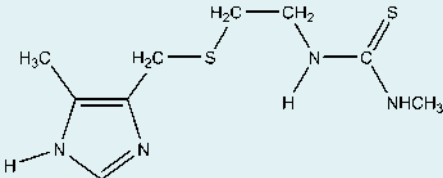

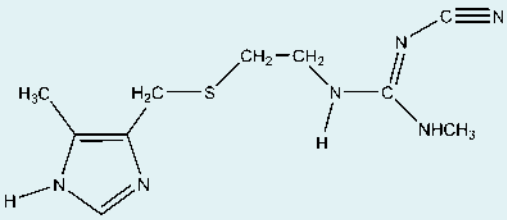

Structure–Activity Relationship	Structure
Histamine: Nonselective histamine receptor agonist (H ₁ = H ₂)	
5-Methylhistamine: Selective H ₂ -agonist (H ₂ > H ₁)	
N ^ε -Guanylhistamine: Partial H ₂ -receptor agonist (weak antagonist)	
Burimamide: Full H ₂ -receptor antagonist; but low potency and poor oral bioavailability	
Metiamide: Full H ₂ -receptor antagonist with higher potency and improved oral bioavailability; but toxicity resulting from the thiourea	
Cimetidine: Full H ₂ -receptor antagonist with higher potency and improved oral bioavailability and low systemic toxicity	

TABLE 23.5 Potency and Pharmacokinetics of the H₂-Antagonists

H ₂ -Blocker	Relative Potency	Oral Bioaval	Metabolites	% Dose Metab	Elimination
Cimetidine	1	63–78	S-oxide, Hydroxy-methyl	25	Renal
Famotidine	40	37–45	S-oxide	30	Renal
Nizatidine	10	98	N2-desmethyl, N-oxide	37	Renal
Ranitidine	6	52	N-desmethyl, N-oxide, S-oxide	30	Renal, biliary

Source: Facts and Comparisons 4.0, Wolters Kluwer Health, Amsterdam, Netherlands, 2009.

famotidine have lower oral bioavailabilities than nizatidine as a result of greater first-pass metabolism. Based on their common structural features, most of these agents are metabolized by *S*- and *N*-oxidation. The imidazole ring of cimetidine serves as an addition site for oxidative metabolism, as do the *N,N*-dimethyl functionalities of nizatidine and ranitidine. All of these metabolites are presumed to be inactive, or at least less active than the parent drugs. Also, a significant proportion of the dose of each of the H₂-antagonists is excreted renally in unmetabolized form. The half-lives of these agents range from 1 to 4 hours, with nizatidine having the shortest half-life.⁶⁶ The properties of the individual H₂-antagonists that are in clinical use in the United States are described and compared in the monographs that follow.

Cimetidine, USP. Cimetidine, *N*⁷-cyano-*N*-methyl-*N'*-[2-[[5-methylimidazol-4-yl)methyl]thio]ethyl]guanidine (Tagamet), is a colorless crystalline solid that is slightly soluble in water (1.14% at 37°C). The solubility is greatly increased by the addition of dilute acid to protonate the imidazole ring (apparent pK_a of 6.8). At pH 7, aqueous solutions are stable for at least 7 days. Cimetidine is a relatively hydrophilic molecule with an octanol/water partition coefficient of 2.5.

Cimetidine inhibits the hepatic metabolism of drugs biotransformed by various CYP isozymes, delaying elimination and increasing serum levels of these drugs. Thus, concomitant therapy with cimetidine and drugs metabolized by hepatic cytochrome isozymes or in patients with renal or hepatic impairment may require dosage adjustment. This is particularly true for drugs with relatively low therapeutic indices including warfarin-type anticoagulants, phenytoin, propranolol, nifedipine, benzodiazepines, certain tricyclic antidepressants, lidocaine, theophylline, and metronidazole.⁶⁶ Additionally, cimetidine administration may increase gastric pH and decrease the absorption of drugs such as the azole antifungals (e.g., ketoconazole), which require an acidic environment for dissolution.⁶⁶ If concurrent azole therapy is required, it is best to administer it at least 2 hours before cimetidine administration. Cimetidine has a weak antiandrogenic effect, and it may cause gynecomastia in patients treated for 1 month or more.

Cimetidine exhibits relatively good bioavailability (60%–70%) and a plasma half-life of about 2 hours, which is increased in renal and hepatic impairment and in the elderly. Approximately 30% to 40% of a cimetidine dose is metabolized (*S*-oxidation, 5-CH₃ hydroxylation), and the parent drug and metabolites are eliminated primarily by renal excretion.⁶⁶ Antacids interfere with cimetidine absorption and should be administered at least 1 hour before or after a cimetidine dose.

Dosage forms: Tablet (200, 300, 400, 800 mg), liquid (300 mg/5 mL), injection (150/mL and 6 mg/mL)

Usual adult oral dose:

- Benign gastric ulcer: 800 or 300 mg 4 times a day
- Duodenal ulcer: 800 or 300 mg 4 times a day (with meals and at bedtime); maintenance dose, 400 mg 4 times a day
- Gastroesophageal reflux disease, erosive: 1,600 mg daily in divided doses (800 mg twice daily or 400 mg 4 times per day) for 12 weeks
- Heartburn relief or prevention (OTC): 200 mg with water as symptoms occur or right before or any time up to 30 minutes before eating food or drinking; maximum dosage, 400 mg/day
- Pathological hypersecretory conditions: 300 mg 4 times per day with meals and at bedtime; maximum dosage, 2,400 mg/day
- Usual pediatric dose: Oral, 20 to 40 mg (base) per kilogram of body weight 4 times a day with meals and at bedtime

Famotidine, USP. Famotidine, *N'*-(aminosulfonyl)-3-[[[2[(diaminomethylene)amino]-4-thiazolyl]methyl]thio]propanimidamide (Pepcid), is a white to pale-yellow crystalline compound that is very slightly soluble in water and practically insoluble in ethanol. It is a thiazole bioisotere of cimetidine that contains a guanidine substituent that may mimic the imidazole of cimetidine.

Famotidine is a competitive inhibitor of histamine H₂-receptors with a potency significantly greater than cimetidine. It inhibits basal and nocturnal gastric secretion as well as secretion stimulated by food and pentagastrin. Its current labeling indications are for the short-term treatment of duodenal and benign gastric ulcers, GERD, pathological hypersecretory conditions (e.g., Zollinger-Ellison syndrome), and heartburn (OTC only).⁶⁶

No cases of gynecomastia, increased prolactin levels, or impotence have been reported, even at the higher dosage levels used in patients with pathological hypersecretory conditions. Studies with famotidine in humans, in animal models, and in vitro have shown no significant interference with the disposition of compounds metabolized by cytochrome isozymes. No significant interactions have been detected with warfarin, theophylline, phenytoin, diazepam, aminopyrine, and antipyrine.

Famotidine is incompletely absorbed (37%–45% bioavailability).⁶⁶ The drug is eliminated by renal (65%–70%) and metabolic (30%–35%) routes. Famotidine sulfoxide is the only metabolite identified in humans. The effects of food or antacid on the bioavailability of famotidine are not clinically significant.

Famotidine

Dosage forms: Tablets (20 and 40 mg), oral disintegrating tablets (20 and 40 mg), gelcaps (10 mg), oral suspension (40 mg/5 mL), injection (10 mg/mL and 20 mg/50 mL)

Usual adult oral dose:

- Benign gastric ulcer: 40 mg once daily (bedtime)
- Duodenal ulcer: Treatment dose, 40 mg once to twice a day at bedtime; maintenance dose, 20 mg once daily at bedtime
- Gastroesophageal reflux disease: 20 mg twice a day
- Heartburn: 10 to 20 mg for relief or 1 hour before a meal for prevention
- Esophagitis, including erosions and ulcerations: 20 or 40 mg twice a day
- Pathological hypersecretory conditions: individualize dosage; typically 20 mg every 6 hours
- Severe Zollinger-Ellison syndrome: up to 160 mg every 6 hours

Ranitidine, USP. Ranitidine, *N*-[2-[[[5-(dimethylamino)methyl]-2-furanyl]methyl]thio]ethyl]-*N'*-methyl-2-nitro-1,1-ethenediamine (Zantac), is a white solid, which in its hydrochloride salt form is highly soluble in water. It is an aminoalkyl furan derivative with pK_a values of 2.7 (side chain) and 8.2 (dimethylamino). Ranitidine is more potent than cimetidine, but less potent than famotidine. Like other H_2 -antagonists, it does not appear to bind to other receptors.⁶⁶

Bioavailability of an oral dose of ranitidine is about 50% and is not significantly affected by the presence of food.⁶⁶ Some antacids may reduce ranitidine absorption and should not be taken within 1 hour of administration of this drug. The plasma half-life of the drug is 2 to 3 hours, and it is excreted along with its metabolites in the urine. Three metabolites, ranitidine *N*-oxide, ranitidine *S*-oxide, and desmethyl ranitidine,

have been identified. Ranitidine is only a weak inhibitor of the hepatic cytochrome isozymes, and recommended doses of the drug do not appear to inhibit the metabolism of other drugs. However, there have been isolated reports of drug interactions (warfarin, triazolam) that suggest that ranitidine may affect the bioavailability of certain drugs by some unidentified mechanism, perhaps by pH-dependent effect on absorption or a change in volume of distribution.⁶⁶

In addition to being available in various dosage forms as the hydrochloride salt, ranitidine is also available as a bis-muth citrate salt for use with the macrolide antibiotic clarithromycin in treating patients with an active duodenal ulcer associated with *H. pylori* infection. Eradication of *H. pylori* reduces the risk of duodenal ulcer recurrence.

Dosage forms: Tablets (75, 150, and 300 mg of HCl salt); effervescent tablets (25 and 150 mg); capsules (150 and 300 mg); syrup (15 mg/mL as HCl salt); injection (1 and 25 mg/mL as HCl salt)

Usual adult oral dose:

- Erosive esophagitis: 150 mg 4 times daily initially and then 150 mg twice daily for maintenance
- Benign gastric ulcer: 150 mg twice a day
- Duodenal ulcer: 150 mg twice a day or 300 mg daily initially and then 150 mg once daily for maintenance
- Heartburn (OTC only): Initial dosage for relief 1 tablet, can be used up to twice daily for maintenance
- Gastroesophageal reflux disease: 150 mg twice a day
- Pathological hypersecretory conditions: 150 mg twice a day

Nizatidine. Nizatidine, *N*-[2-[[[2-(dimethylamino)methyl]-4-thiazolyl]methyl]thio]ethyl]-*N'*-methyl-2-nitro-1,1-ethenediamine (Axid), is an off-white to buff crystalline solid that is soluble in water, alcohol, and chloroform. It is a thiazole derivative of ranitidine and has pK_a s of 2.1 (side

Ranitidine

chain) and 6.8 (dimethylamino). Nizatidine's mechanism of action is similar to other H_2 -antagonists, as is its receptor selectivity. It is more potent than cimetidine.

Nizatidine has excellent oral bioavailability (>90%). The effects of antacids or food on its bioavailability are not clinically significant.⁶⁶ The elimination half-life is 1 to 2 hours. It is excreted primarily in the urine (90%) and mostly as unchanged drug (60%). Metabolites include nizatidine sulfoxide (6%), *N*-desmethylnizatidine (7%), and nizatidine *N*-oxide (dimethylaminomethyl function).⁶⁶ Nizatidine has no demonstrable antiandrogenic action, effects on other hormones, or inhibitory effects on cytochrome isozymes involved in the metabolism of other drugs.

Dosage forms: Tablets (75 mg), capsules (150 and 300 mg), oral solution (15 mg/mL)

Usual adult oral dose:

- Benign gastric ulcer: 150 mg twice a day or 300 mg once daily at bedtime.
- Duodenal ulcer: Treatment, 300 mg once to twice a day; maintenance, 150 mg once daily
- GERD: 150 mg twice a day
- Heartburn (OTC products only): 1 tablet with a full glass of water, up to 2 tablets in 24 hours.
- Hypersecretory condition: 150 mg twice a day

Other Antiulcer and Gastric Acid Hypersecretory Disease Therapies: Proton Pump Inhibitors

The final step in acid secretion in the parietal cell is the extrusion or “pumping” of protons into the lumen of stomach by the membrane H^+ , K^+ -ATPase pump as described previously (Fig. 23.14). Thus, inhibition of this proton pump acts beyond the site of action of second messengers (e.g., calcium and cAMP) and is independent of the action of secretagogues histamine, gastrin, and acetylcholine. Thus, acid pump inhibitors block both basal and stimulated acid secretion.

In 1972, a group of Swedish medicinal chemists discovered that certain pyridylmethyl benzimidazole sulfides were capable of functioning as H^+ , K^+ -ATPase or PPIs.^{67,68} These compounds were subsequently converted to sulfoxide

derivatives, which exhibited highly potent, irreversible inhibition of the proton pump. The benzimidazole PPIs are prodrugs that are rapidly converted to a sulfenamide intermediate in the highly acidic environment of gastric parietal cells. The weakly basic benzimidazole PPIs accumulate in these acidic compartments on the luminal side of the tubulovesicular and canalicular structures of the parietal cells. The benzimidazole PPIs are then chemically converted by acid to a sulfenamide intermediate that inhibits the proton pump via covalent interaction with sulfhydryl groups with cysteine residues of the H^+ , K^+ -ATPase pump (Fig. 23.15).^{67,68} All of the PPIs have been shown to react with cysteine 813 of pump, but some bind to additional pump sulfhydryl residues as well.⁶⁹ For example, omeprazole and esomeprazole also react with cysteine 892, and pantoprazole with cysteine 822 and lansoprazole to cysteine 321.^{69,70} Cysteines 321, 813, and 822 are all in the proton-transport domain of the H^+ , K^+ -ATPase system, whereas cysteine 892 is on the external luminal surface and does not affect pump transport ability.^{69,70} The bioaccumulation and activation of the PPIs within the acidic environment of the parietal cell also ensures specificity of pharmacologic action. The acid lability of the benzimidazole PPIs dictates that these drugs must be formulated as delayed-release, enteric-coated granular dosage forms.

To date, five structurally related benzimidazole sulfoxide PPIs have been approved for use in the United States to treat various gastric acid hypersecretory disorders. These include omeprazole, esomeprazole (the active enantiomers of omeprazole), lansoprazole, patoprazole, and rabeprazole. The PPIs differ only in the nature and degree of pyridine and imidazole ring substituents, which has an impact on pK_a values and pharmacokinetic properties. The extent of initial PPI protonation and, thereby, parietal cell accumulation is governed by the pK_a of the pyridine ring nitrogen that ranges from 3.8 for lansoprazole and pantoprazole to 4.5 for rabeprazole (Table 23.6).⁷¹ Thus, all drugs are believed to be concentrated at their physiologic site of action to a similar extent. The rate of conversion of PPIs to their active sulfenamides, however, is determined largely by the pK_a of the benzimidazole group (pK_a2). Omeprazole, lansoprazole, and rabeprazole with higher pK_a2 s (0.62–0.79) undergo

Figure 23.15 • Mechanism of action of PPIs.

TABLE 23.6 pK_as of the Proton Pump Inhibitors

PPI	X	Y	X	R	pK _a 1	pK _a 2
Omeprazole	CH ₃	CH ₃ O	CH ₃	CH ₃ O	4.06	0.79
Lansoprazole	CH ₃	CF ₃ CH ₂ O	H	H	3.83	0.62
Pantoprazole	CH ₃ O	CH ₃ O	H	CHF ₂ O	3.83	0.11
Rabeprazole	CH ₃	CH ₃ OCH ₂ CH ₂ CH ₂ O	H	H	4.53	0.62

*Including Zollinger-Ellison syndrome.

benzimidazole protonation and sulfenamide formation faster than pantoprazole with a pK_{a2} of 0.11.⁷¹

The duration of PPI antisecretory action is determined by several factors including the extent and nature of cysteine residues inactivated, pump protein turnover, activation of inactive pumps, and reactivation of inhibited pumps by endogenous reducing agents capable of breaking the PPI-pump disulfide bonds.^{72–74} PPIs that inactivate cysteine 822 (pantoprazole) tend to have the longest duration of effect, because this cysteine residue is on the pump transport domain, is resistant to reductive reactivation, and therefore, requires replacement by new pump protein. Thus, pantoprazole has an effective half-life of 46 hours, whereas omeprazole is 28 hours, and lansoprazole is less than 15 hours.^{72–75} The significance of the differences in rates of PPI activation or duration of action does not appear to have overwhelming clinical significance.

Most clinical data suggests that these PPIs are more effective in the short term than the H_2 -blockers in healing duodenal ulcers and erosive esophagitis and can even heal esophagitis resistant to treatment with the H_2 -antagonists.^{73,74} In addition, the benzimidazole PPIs are reported to have antimicrobial activity against *H. pylori*, and thus, possess efficacy in treating gastric ulcers or with one or more antimicrobials, in eradicating infection by this organ-

ism. A host of clinical trials have been performed in an attempt to compare the relative clinical efficacies of the PPIs in various hypersecretory disease states (see Table 23.7 for indications). Often the results of these studies have been difficult to interpret because of many variables in PPI formulation, dosage strength, pharmacokinetic properties, diagnostic criteria, etc. Most studies have concluded, however, that comparable dosage strengths and formulations of all of these agents are therapeutically interchangeable in terms of clinical efficacy.^{73,74} The PPIs also share a very similar adverse reaction profile, with the most common adverse effects involving abdominal pain, diarrhea, and headache. Several other, more severe, adverse reactions (serious allergy, blood dyscrasias) have been reported rarely with PPI use, but have not been linked causally with the drugs.^{73,74}

The PPIs vary in their oral bioavailability from 30% (omeprazole) to 80% (lansoprazole), and bioavailability generally increases upon repeated dosing. All, except rabeprazole, achieve peak plasma levels by about 2 hours (Table 23.8).⁶⁶ All of PPIs are eliminated almost entirely as cytochrome-based metabolites and, with the exception of lansoprazole, predominantly by the renal route. Virtually no unchanged drug is excreted in the urine and feces. The cytochrome isozymes primarily involved in PPI metabolism in-

TABLE 23.8 Pharmacokinetic Properties of the Proton Pump Inhibitors

PPI	Oral Bioavail*	T_{max}	PPB	Plasma $t_{1/2}$		Linear Kinetics?
Omeprazole	30%–40%	0.5–3.5 hr	95%	0.7 hr	Hydroxy acid sulfide and sulfone	77% urine as metabolites
Esomeprazole	64%	1.6 hr	97%	0.9 hr	Hydroxy, desmethyl, sulfone	80% urine as metabolites
Lansoprazole	80%	1.7 hr	97%	1.2 hr	Hydroxylated sulfinyl and sulfone	33% urine as metabolites 66% feces as metabolites
Pantoprazole	77%	2.5 hr	98%	1.2 hr	Demethylation, with subsequent sulfation	71% urine as metabolites 18% feces as metabolites
Rabeprazole	52%	2–5 hr	96%	1.0 hr	Thioether carboxylic acid, its glucuronide, sulfone, mercapturic acid	90% urine as metabolites

*Increases with repeated once-daily dosing.

clude CYP2C19 and CYP3A4, and these catalyze pyridine ring methyl oxidation (CYP2C19: omeprazole, esomeprazole), benzimidazole ring *O*-demethylation (CYP2C19: omeprazole and esomeprazole) and sulfoxide oxidation (all PPIs as illustrated in Fig. 23.16) for omeprazole.^{75,76} The primary metabolite of omeprazole, a racemate, is 5-hydroxymethylomeprazole, whereas the main metabolite formed from esomeprazole (the *S*-isomer) is the sulfone.^{75,76} Lansoprazole, pantoprazole, and rabeprazole lack the pyridyl 5-methyl group and benzimidazole 5-methoxy group, so they do not undergo these oxidative processes (see structures that follow).^{75,76}

As a result of their metabolic clearance profiles, the PPIs, and especially omeprazole, can interact with other drugs that are also processed by CYP2C19 and CYP3A4 isozymes (Table 23.9). Inhibition of oxidative metabolism by omeprazole (but not esomeprazole) is responsible for prolonging the clearance of benzodiazepines, phenytoin, and warfarin.⁶⁶ Lansoprazole decreases theophylline concentration slightly and may decrease the efficacy of oral contraceptives. Pantoprazole and rabeprazole appear to be free of these interactions. Further, the profound and long-lasting inhibition of gastric acid secretion by the PPIs may interfere with the bioavailability of drugs when gastric pH is an important determinant, such as the azole antifungals (e.g.,

ketoconazole), ampicillin, iron salts, digoxin, and cyanocobalamin (Table 23.9).⁶⁶

Omeprazole. Omeprazole, 5-methoxy-2-(((4-methoxy-3, 5-dimethyl-2-pyridinyl)methyl) sulfinyl)-1H-benzimidazole (Losec), is a white to off-white crystalline powder with very slight solubility in water. Omeprazole is an amphoteric compound (pyridine N, pK_a 4.06; benzimidazole N-H, pK_a 0.79), and consistent with the proposed mechanism of action of the substituted benzimidazoles, is acid labile. Hence, the omeprazole product is formulated as delayed-release capsules containing enteric-coated granules.

The absolute bioavailability of orally administered omeprazole is 30% to 40% related to substantial first-pass biotransformation (Table 23.8).⁶⁶ The drug has a plasma half-life of about 1 hour. Most (77%) of an oral dose of omeprazole is excreted in the urine as metabolites with insignificant antisecretory activity. The primary metabolites of omeprazole are 5-hydroxymethylomeprazole (CYP2C19) and omeprazole sulfone (CYP3A4). The antisecretory actions of omeprazole persist for 24 to 72 hours, long after the drug has disappeared from plasma, which is consistent with its suggested mechanism of action involving irreversible inhibition of the proton pump.

Figure 23.16 • Metabolic transformations of benzimidazole PPIs.

TABLE 23.9 PPI Drug Interactions

PPI Drug Interaction	Mechanism of Drug Interaction
Azole antifungals	Inhibition of PPI (especially omeprazole, esomeprazole) metabolism, resulting in significantly higher drug levels. PPIs may reduce the GI absorption of azoles by elevating gastric pH and reducing azole solubility in the GI tract
Macrolide antibiotics	Inhibition of PPI (especially omeprazole, esomeprazole) metabolism, resulting in significantly higher drug levels.
Herbals (e.g., ginkgo biloba, St. John's wort)	Certain herbals may induce the metabolism of PPIs, especially omeprazole, reducing their plasma concentrations and efficacy.
Hydantoins (e.g., phenytoin)	PPIs, especially omeprazole, may increase serum hydantoin levels. Dose adjustment may be required.
Benzodiazepines (e.g., diazepam, triazolam)	PPIs, especially omeprazole and esomeprazole, may decrease the oxidative metabolism of certain benzodiazepines, thereby reducing their clearance, increasing their half-life and serum levels, and increasing the risk of benzodiazepine-associated adverse effects. Benzodiazepine dosage should be decreased (or dosing interval increased).
Cilostazol, digoxin	PPIs, especially omeprazole, may increase the plasma concentrations of these drugs, thereby increasing their therapeutic effect and adverse effect potential. Consider dosage adjustment of cilostazol.
Protease inhibitors (e.g., atazanavir, indinavir)	PPIs may reduce the absorption and plasma levels certain protease inhibitors. Concurrent use of atazanavir and omeprazole is not recommended.
Warfarin	PPIs may increase the hypoprothrombinemic effects of warfarin. The anticoagulant efficacy of warfarin should be monitored when starting or stopping omeprazole.

Source: Facts and Comparisons 4.0, Wolters Kluwer Health, Amsterdam, Netherlands, 2009.

Omeprazole is approved for the treatment of heartburn, GERD, duodenal ulcer, erosive esophagitis, gastric ulcer, and pathological hypersecretory conditions.

Dosage form: Delayed-release tablets (20 mg) and capsules (20 and 40 mg)

Usual adult doses:

- Heartburn (OTC): 20 mg daily for 14 days
- GERD without esophageal lesions: 20 mg/daily for up to 4 weeks
- GERD with erosive esophagitis: 20 mg/daily for 4 to 8 weeks; an additional 4 weeks of treatment may be beneficial
- Duodenal ulcer: 20 mg/day for 4 or more weeks
- Duodenal ulcer associated with *H. pylori*: Triple therapy with omeprazole 20 mg plus clarithromycin 500 mg plus amoxicillin 1,000 mg, each twice daily for 10 days. If an ulcer is present at the initiation of therapy, continue omeprazole 20 mg for an additional 14 days.
- Erosive esophagitis: 20 mg daily for 4 to 8 weeks; not beyond 12 months

- Gastric ulcer: 40 mg once a day for 4 to 8 weeks
- Pathological hypersecretory conditions: 60 mg daily for as long as indicated; dosages up to 120 mg 3 times per day have been administered.

Esomeprazole Magnesium. Esomeprazole magnesium, *S*-bis(5-methoxy-2-[(*S*)-[(4-methoxy-3,5-dimethyl-2-pyridinyl)methyl]sulfinyl]-1*H*-benzimidazole-1-yl) magnesium trihydrate (Nexium), is the *S*-enantiomer of omeprazole. The benzimidazole PPIs contain a chiral sulfur atom that form an enantiomeric pair that is stable and insoluble under standard conditions. The *S*-isomer of omeprazole has slightly greater PPI activity, and its intrinsic clearance is approximately three times lower than that of *R*-omeprazole (15 vs. 43 $\mu\text{L}/\text{min}$). The lower clearance of *S*-omeprazole is related to slower metabolic clearance by the CYP2C19 isozyme.^{66,76} Although *R*-omeprazole is primarily transformed to the 5-hydroxy metabolite, the *S*-isomer is metabolized by *O*-demethylation and sulfoxidation, which contribute little to intrinsic clearance (Table 23.7).

Dosage forms: Delayed-release capsules (20 or 40 mg), powder for suspension (10, 20, and 40 mg), and powder for injection (20 and 40 mg)

Usual adult doses:

- Symptomatic gastroesophageal reflux disease: 20 mg daily usually for 4 weeks
- Erosive esophagitis: 20 or 40 mg daily usually for 4 to 8 weeks
- Duodenal ulcer associated *H. pylori* eradication: Triple therapy with esomeprazole (40 mg once daily), amoxicillin (1,000 mg twice daily), and clarithromycin (500 mg twice daily), each for 10 days
- Risk reduction of NSAIDs-associated gastric ulcer: 20 or 40 mg daily for up to 6 months
- Pathological hypersecretory conditions, including Zollinger-Ellison syndrome: 40 mg twice daily but doses of up to 240 mg daily have been used

Lansoprazole. Lansoprazole, 2-[[[3-methyl-4-(2,2,2-trifluoroethoxy)-2-pyridyl]methyl]sulfinyl]-1H-benzimidazole (Prevacid), is a white to brownish white, odorless crystalline powder that is practically insoluble in water. Lansoprazole is a weak base (pyridine N, pK_a 3.83.) and a weak acid (benzimidazole N-H, pK 0.62). Like other PPIs, lansoprazole is essentially a prodrug that, in the acidic biophase of the parietal cell, forms an active metabolite that irreversibly interacts with the target ATPase of the pump. Lansoprazole must be formulated as encapsulated enteric-coated granules for oral administration to protect the drug from the acidic environment of the stomach.

In the fasting state, about 80% of a dose of lansoprazole (vs. 50% of omeprazole) reaches the systemic circulation, where it is 97% bound to plasma proteins (Table 23.8).⁶⁶ The drug is metabolized in the liver (sulfone and hydroxy metabolites) and excreted in bile and urine, with a plasma half-life of about 1.5 hours.

Dosage form: Delayed-release and orally disintegrating tablets (15 and 30 mg), delayed-release capsules (5 and 30 mg), delayed-release granules for oral suspension (15 and 30 mg), and a powder for injection (30 mg/vial)

Usual adult dose:

- GERD: 15 mg once daily for up to 8 weeks
- Erosive esophagitis: Initially 30 mg once daily for up to 8 weeks. For adults who do not heal within 8 weeks (5%–10%), an additional 8 weeks of treatment may be given. Then, 15 mg once daily to maintain healing of erosive esophagitis.

- Gastric ulcer: 30 mg once daily for up to 8 weeks
- Gastric associated with NSAIDs: 30 mg once daily for up to 8 weeks to promote healing 15 mg once daily for up to 12 weeks to reduce the risk of NSAID-induced ulcer. Controlled studies did not extend beyond indicated duration.
- Duodenal ulcer: Short-term treatment: 15 mg once daily for 4 weeks for short-term treatment and 15 mg once daily to maintain healing of duodenal ulcers
- Duodenal ulcer associated with *H. pylori*: Dual therapy with lansoprazole (30 mg) and amoxicillin (1 g) both taken 3 times/day (every 8 hours) for 14 days for patients intolerant or resistant to clarithromycin
- Duodenal ulcer associated with *H. pylori*: Triple therapy with lansoprazole (30 mg) plus clarithromycin (500 mg) and amoxicillin (1 g), all taken twice daily (every 12 hours) for 10 or 14 days
- Hypersecretory conditions, including Zollinger-Ellison syndrome: Usually an initial dose of 60 mg once daily; dosages up to 90 mg twice daily have been administered

Pantoprazole Sodium. Pantoprazole sodium, racemic-sodium 5-(difluoromethoxy)-2-[[[3,4-dimethoxy-2-pyridinyl]methyl]sulfinyl]-1H-benzimidazole sesquihydrate is a white to off-white crystalline powder that is freely soluble in water, very slightly soluble in phosphate buffer at pH 7.4, and practically insoluble in n-hexane. The benzimidazole of this drug has a weakly basic nitrogen (pyridine N, pK_a 3.83) and a benzimidazole proton (pK_a 0.11), facilitating formulation as a sodium salt. The stability of the compound in aqueous solution is pH dependent; the rate of degradation increases with decreasing pH. At ambient temperature, the degradation half-life is approximately 2.8 hours at pH 5.0 and approximately 220 hours at pH 7.8.

The absorption of pantoprazole is rapid (C_{max} of 2.5 $\mu\text{g/mL}$, T_{max} 2.5 hours) after single or multiple oral 40-mg doses. Pantoprazole is well absorbed (77% bioavailability). Administration with food may delay its absorption but does not alter pantoprazole bioavailability. Pantoprazole is distributed mainly in extracellular fluid. The serum protein binding of pantoprazole is about 98%, primarily to albumin. Pantoprazole is extensively metabolized in the liver through the CYP system, including *O*-demethylation (CYP2C19), with subsequent sulfation. Other metabolic pathways include sulfur oxidation by CYP3A4 (Table 23.8).⁶⁶ There is no evidence that any of the pantoprazole metabolites have significant pharmacological activity. Approximately 71% of a dose

Pantoprazole Sodium

of pantoprazole is excreted in the urine, with 18% excreted in the feces through biliary excretion.

Dosage forms: Delayed-release tablets (20 and 40 mg), delayed-release oral suspension (40 mg), and a powder for injection (40 mg)

Usual adult dose:

- Erosive esophagitis (maintenance): Usually 40 mg once daily for up to 8 weeks. For those patients who have not healed after 8 weeks of treatment, an additional 8-week course of pantoprazole may be considered. The maintenance dose is 40 mg daily.
- Pathological hypersecretory conditions, including Zollinger-Ellison syndrome: The usual starting dosage is 40 mg twice daily. Adjust dosage regimens to individual patient needs and continue for as long as clinically indicated. Doses of up to 240 mg daily have been administered.

Rabeprazole Sodium. Rabeprazole sodium, 2[[[4-(3-methoxypropoxy)-3-methyl-2-pyridinyl]methyl]sulfinyl]-1H-benzimidazole sodium salt (Aciphex), is a white to slightly yellowish white solid. It is very soluble in water and methanol, freely soluble in ethanol, chloroform, and ethyl acetate, and insoluble in ether and hexane. Rabeprazole is a weak base (pyridine N, pK_a 4.53) and a weak acid (benzimidazole N-H, pK_a 0.62), facilitating sodium salt formation.

Rabeprazole Sodium

Rabeprazole sodium is formulated as enteric-coated, delayed-release tablets to allow the drug to pass through the stomach relatively intact. After oral administration of 20-mg peak plasma concentrations (C_{max}) occur over a range of 2 to 5 hours (T_{max}). Absolute bioavailability for a 20-mg oral tablet of rabeprazole (vs. IV administration) is approximately 52% (Table 23.8).⁶⁶ The plasma half-life of rabeprazole ranges from 1 to 2 hours. The effects of food on the absorption of rabeprazole have not been evaluated. Rabeprazole is 96% bound to human plasma proteins. Rabeprazole is extensively metabolized in the liver. The thioether and sulfone are the primary metabolites measured in human plasma resulting from CYP3A oxidation. Additionally, desmethyl rabeprazole is formed via the action of CYP2C19. Approximately 90% of the drug is eliminated in the urine, primarily as thioether carboxylic acid and its glucuronide and mercapturic acid metabolites. The remainder of the dose is recovered in the feces. No unchanged rabeprazole is excreted in the urine or feces (Table 23.8).⁶⁶

Dosage form: Delayed-release tablets (20 mg)

Usual adult dose:

- Duodenal ulcers (healing): Usually 20 mg once daily after the morning meal for a period of up to 4 weeks
- Erosive or ulcerative GERD: 20 mg once daily for 4 weeks. If symptoms do not resolve completely after 4 weeks, an additional course of treatment may be considered.
- *H. pylori* eradication: Triple therapy with rabeprazole (20 mg), amoxicillin (1 g), and clarithromycin (500 mg)
- Treatment of pathological hypersecretory conditions: Usually 60 mg once daily, but doses should be adjusted to individual patient needs and should continue for as long as clinically indicated. Some patients may require divided doses. Dosages of up to 100 mg daily and 60 mg twice daily have been administered.

CHEMICAL COMPLEXATION

The sulfate esters and sulfonate derivatives of polysaccharides and lignin form chemical complexes with the enzyme pepsin. These complexes have no proteolytic activity. Because polysulfates and polysulfonates are poorly absorbed from the GI tract, specific chemical complexation appears

to be a desirable mechanism of pepsin inhibition.⁷⁷ Unfortunately, these polymers are also potent anticoagulants.

The properties of chemical complexation and anticoagulant action are separable by structural variation. In a comparison of selected sulfated saccharides of increasing number of monosaccharide units, from disaccharides through starch-derived polysaccharides of differing molecular size, three conclusions are supported by the data: (a) the anticoagulant activity of sulfated saccharide is positively related to molecular size; (b) anticoagulant activity is absent in the disaccharides; and (c) the inhibition of pepsin activity and the protection against experimentally induced ulceration depend on the degree of sulfation and not on molecular size.⁷⁷ The readily available disaccharide sucrose has been used to develop a useful antiulcer agent, sucralfate.

Sucralfate. Sucralfate, 3,4,5,6-tetra-(polyhydroxyaluminum)- α -D-glucopyranosyl sulfate-2,3,4,5-tetra-(polyhydroxyaluminum)- β -D-fructofuranoside sulfate (Carafate), is the aluminum hydroxide complex of the octasulfate ester of sucrose. It is practically insoluble in water and soluble in strong acids and bases. It has a pK_a value between 0.43 and 1.19.

Sucralfate is minimally absorbed from the GI tract by design, and thus exerts its antiulcer effect through local rather than systemic action. It has negligible acid-neutralizing or buffering capacity in therapeutic doses. Although its mechanism of action has not been established, studies suggest that sucralfate binds preferentially to the ulcer site to form a protective barrier that prevents exposure of the lesion to acid and pepsin. In addition, it adsorbs pepsin and bile salts. Either would be very desirable modes of action.

The simultaneous administration of sucralfate may reduce the bioavailability of certain agents (e.g., tetracycline, phenytoin, digoxin, or cimetidine).⁷⁸ It further recommends restoration of bioavailability by separating administration of these agents from that of sucralfate by 2 hours. Presumably, sucralfate binds these agents in the GI tract.⁷⁸ The most frequently reported adverse reaction to sucralfate is constipation (2.2%). Antacids may be prescribed as needed but should not be taken within 0.5 hour before or after sucralfate.

Dosage forms: Tablets (1 g) and suspension (1 g/10 mL)
Usual adult dose: 1 g (10 mL or 2 teaspoons of the oral suspension) 4 times a day on an empty stomach. Oral, 1 g 4 times a day on an empty stomach. Treatment should be continued for 4 to 8 weeks.

PROSTAGLANDINS

The prostaglandins are endogenous 20-carbon unsaturated fatty acids biosynthetically derived from arachidonic acid. These bioactive substances and their synthetic derivatives have been of considerable research and development interest as potential therapeutic agents because of their widespread physiological and pharmacological actions on the cardiovascular system, GI smooth muscle, the reproductive system, the nervous system, platelets, kidney, the eye, etc. Prostaglandins of the E, F, and I series are found in significant concentrations throughout the GI tract. The GI actions of the prostaglandins include inhibition of basal and stimulated gastric acid and pepsin secretion in addition to prevention of ulcerogen or irritant-induced gross mucosal lesions of the stomach and intestine (termed cytoprotection). The prostaglandins can both stimulate (PGFs) and inhibit (PGEs and PGIs) intestinal smooth muscle contractility and accumulation of fluid and electrolytes in the gut lumen (PGEs). Therapeutic application of the natural prostaglandins in the treatment of GI disorders is hindered by their lack of pharmacological selectivity coupled with a less-than-optimal biodisposition profile.

Misoprostol. Misoprostol, (\pm)-methyl 11 α , 16-dihydroxy-16-methyl-9-oxoprost-13 E -en-1-oate, is a semisynthetic derivative of PGE₁ that derives some pharmacological selectivity as well as enhanced biostability from its 16-methyl, 16-hydroxy substitutions. A mixture of misoprostol diastereomers are present in the commercial product, but most of the activity is associated with the 11 r , 16 S -isomer.⁷⁹ Misoprostol exhibits both antisecretory and cytoprotectant effects characteristic of the natural prostaglandins and has a therapeutically acceptable biodis-

Misoprostol

position profile. Although the antisecretory effects of misoprostol are thought to be related to its agonistic actions at parietal cell prostaglandin receptors, its cytoprotective actions are proposed to be related to increases in GI mucus and bicarbonate secretion, increases in mucosal blood flow, and/or prevention of back diffusion of acid into the gastric mucosa.⁸⁰

Misoprostol is rapidly absorbed following oral administration and undergoes rapid deesterification to the pharmacologically active free acid with a terminal half-life of 20 to 40 minutes. Misoprostol is commonly used to prevent NSAID-induced gastric ulcers in patients at high risk of complications from a gastric ulcer, such as elderly patients and patients with a history of ulcer. Misoprostol has also been used in treating duodenal ulcers unresponsive to histamine H₂-antagonists; the drug does not prevent duodenal ulcers, however, in patients taking NSAIDs. Misoprostol can cause miscarriage, often associated with potentially dangerous bleeding.

Dosage form: 100- and 200- μ g tablets

Usual adult dose: Oral, 200 mg 4 times a day with food

HISTAMINE H₃- AND H₄-RECEPTOR LIGANDS

As discussed earlier, H₃-receptors are presynaptic receptors that regulate the release of histamine (autoreceptors) and other neurotransmitters (heteroreceptor).^{10,17} The H₃-heteroreceptors have been identified in CNS, stomach, lung and cardiac tissues where they appear to regulate neurotransmitter release from histaminergic, noradrenergic, dopaminergic, cholinergic, serotonergic, and peptidergic neurons. Histaminergic nerves are located in the hippocampus and project into many brain regions where they regulate sleep, alertness, feeding behavior, and memory. Thus, H₃-receptor antagonists have a potential therapeutic role in learning and memory impairment, attention-deficit hyperactivity disorder, obesity, and even epilepsy. Furthermore, studies of the regulation of inflammatory processes, gastroprotection, and cardiovascular function suggest several therapeutic possibilities for peripherally acting histamine H₃-agonists.¹⁰ To date, no histamine H₃-receptor ligands have been approved for marketing in the United States.

Potent H₃-agonists (Fig. 23.17) are obtained by simple modifications of the histamine molecule.^{81,82} The imidazole

ring is a common structural feature in almost all H₃-agonists. Methylation of the aminoethyl side chain of histamine favors H₃ activity. Introduction of one or two methyl groups to give α -methylhistamine and α,α -dimethylhistamine yields potent H₃-agonists that show little selectivity among the histamine receptors. The increased potency of α -methylhistamine is ascribed almost completely to its R-enantiomer (H₃/H₁ ratio = 17). The clinical use of R- α -methylhistamine is compromised by rapid catabolism by histamine-N-methyltransferase. Azomethine derivatives of R- α -methylhistamine have been developed and shown to possess anti-inflammatory and antinociceptive properties. Other H₃-agonists include the isothioureia derivative, imetit, a highly selective, full agonist that is more potent than R- α -methylhistamine. A third type of H₃-agonist is imnepip, which may be considered as a histamine analog with an elongated and cyclized side chain. Imnepip is both a highly selective and potent H₃-agonist.^{81,82}

A large number of H₃-antagonists have been described.⁸³ In general, antagonist structures conform to the general representation shown in Figure 23.18. The heterocycle component of this general structure is most commonly a 4-monosubstituted imidazole or bioisosteric equivalent. Chains A and B can be of various structures and lengths, and there is also wide latitude in the structural requirements for the polar group. Halogenated phenyl, cycloalkyl, and heteroaryl structures are usually found for the lipophilic moiety.

Thioperamide (Fig. 23.18) was the first potent H₃-antagonist to be described. This agent enhances arousal and/or vigilant patterns in a dose-dependent fashion in animals, suggesting possible use of CNS-acting H₃-antagonists in treating sleep disorders characterized by excessive daytime sleep, such as narcolepsy.⁸³ Other H₃ structures are shown in Figure 23.18, including the natural product verongamine, isolated from a sea sponge.

As discussed earlier, the H₄-receptor appears to be involved in the differentiation of hematopoietic cells (myeloblasts and promyelocytes) and to modulate immune function by modulating eosinophil calcium levels and chemotaxis. Several H₃-agonists (R- α -methylhistamine, imetit) and antagonists (thioperamide) are also ligands for H₄-receptors.⁸⁴ Based on its physiological role in immune and inflammatory processes, H₄-antagonists may have utility in various autoimmune (rheumatoid arthritis, asthma) and allergic disorders (allergic rhinitis, etc.).¹⁰ To date, no histamine H₄-receptor ligands have been approved for marketing in the United States.

Figure 23.18 • Histamine H₃-receptor antagonists.

REVIEW QUESTIONS

- Briefly describe how the various histamine receptor subtypes are structurally and functionally similar. In what ways are the histamine receptor subtypes different?
- What are the primary metabolic pathways of histamine inactivation?
- Rank (from highest to lowest) diphenhydramine, chlorpheniramine, and cetirizine with respect to their relative sedation potential and antimuscarinic activity.
- Show the mechanism whereby omeprazole is converted to its pharmacologically active form in the presence of acid.
- What are the primary enzymes involved in the metabolism of most PPIs and what reactions do they catalyze? What is the therapeutic significance of PPI metabolism?

Analgesics

CAROLYN J. FRIEL AND MATTHIAS C. LU

CHAPTER OVERVIEW

The terms *analgesics* and *analgetic drugs* are often used interchangeably to describe a diverse group of pain medications such as opioids, nonsteroidal anti-inflammatory drugs (NSAIDs), and triptans, each with very different mechanisms of action for relieving pains of a wide array of causes.

Analgesics can be broadly categorized, according to their therapeutic use, into several drug classes: (a) the opioids (or narcotic analgesics), which play a major role in the relief of acute pain and in the management of moderate to severe chronic pain; (b) the NSAIDs and acetaminophen, which are the most widely used analgesic drugs for relieving mild to moderate pain and reducing fever; (c) the triptans (the antimigraine medications), which are specifically designed and targeted for acute and abortive treatment of migraine and cluster headaches; and (d) a new emerging class of analgesics known as analgesic adjuvants that include tricyclic antidepressants such as amitriptyline, anti-convulsants such as gabapentin and pregabalin, and topical analgesics such as lidocaine patches that can be used to treat neuropathic pains.

In this chapter, only the first three classes of pain medications are covered. The main objectives of this chapter will be focusing on their mechanism of action, structure–activity relationships (SARs), pharmacokinetic properties, and their clinical applications for pain management. Readers should consult other chapters under anticonvulsants, antidepressants, and local anesthetics for a detailed discussion of drugs used for treating neuropathic and other incidental pains associated with minor cuts, burns, and insect bites.

PAIN AND PAIN MANAGEMENT

Pain, one of the most common complaints for which patients seek medical attention, is also the hardest to manage despite the availability of many analgesic medications as well as other nonpharmacologic treatment options. Pain management, especially the use of opioids in patients with chronic pains, is one of the most troublesome public health issues for patients, doctors, and other healthcare providers.^{1,2} As early as the 1970s, the National Institutes of Health formed a committee, at the request of the president, to investigate therapies for rare diseases, but the initial focus was on pain management. The committee found that the problem associated with the use of the opioid analgesics was a lack of training of physicians in pain management and misinformation among

healthcare providers because of fear of psychological dependence (commonly referred to as addiction), disciplinary action, or adverse effects such as tolerance and physical dependence of the pain medications.^{2,3} As a result, many patients with moderate to severe pain are often undertreated or untreated.^{3–5} Another possible reason for treatment failure is the fact that pain perception may also vary among individuals especially across racial and ethnic origins.⁶

Origin of Pain

Pain differs in its underlying causes, symptoms, and neurobiological mechanisms and has been classified into three major types: physiological (nociceptive), inflammatory, and neuropathic.^{7,8} Physiological pain is the most common and is often caused by an injury to body organs or tissues. It is further categorized, according to the source of the pain, into cutaneous pains (skin and surface tissues), somatic pains (ligaments, tendons, bones, blood vessels), and visceral pains (body organs and internal cavities). Inflammatory pain originates from an infection or inflammation as a result of the initial tissue or organ damage. Neuropathic pain is a very complex, chronic pain, resulting from injury of the nervous systems.⁹ Neuropathic pain may originate from limb amputation, spinal surgery, viral infections such as shingles, or worsening of disease states associated with diabetes, acquired immunodeficiency syndrome (AIDS), or multiple sclerosis. The pharmacological interventions are very complex and often require the use of other analgesic adjuvants not covered in this chapter. Readers should consult a recent review for a practical guide to the current clinical management of neuropathic pain.¹⁰

Acute and Chronic Pain

Pain may be acute or chronic.¹¹ Acute pain is often severe but usually lasts only until the removal of the source that triggered the pain. Acute pain includes nociceptive, somatic, or visceral pain, postoperative and posttraumatic pain, burn pain, acute pain during childbirth, acute headache, etc. Acute and postoperative pains are most often treated with the opioid analgesics.

Chronic pain, on the other hand, is defined as a pain lasting longer than 6 months that persists even when the initial cause has been resolved through appropriate medical intervention. Chronic pain can be further divided into chronic malignant pain (e.g., cancer, human immunodeficiency virus [HIV]/AIDS, amyotrophic lateral sclerosis, multiple sclerosis, end-stage organ failure) and chronic non-malignant pain (e.g., lower-back pain, chronic degenerative

arthritis, osteoarthritis (OA), rheumatoid arthritis (RA), migraine and chronic headache, and bond pain). Pain therapy in patients with chronic pain only provides transient pain relief but does not resolve the underlying pathological process.⁷ Chronic pain is also often associated with behavior and psychological components that make effective pain management quite subjective and difficult to resolve.^{10,12,13} Chronic pain is also the leading cause of disability among the elderly; the prevalence of pain may be as high as 80%.³

Significant advances in understanding the pathophysiology and neurobiology of pain have occurred in the past 10 years.^{5,13–17} However, a full discussion of complex pain-signaling mechanisms and the etiology of pain is beyond the scope of this chapter.

Approaches to Pain Management

The World Health Organization (WHO), through its *Access to Controlled Medications Programme*, has brought together an international, multidisciplinary group of experts to discuss and formulate a series of WHO guidelines, including the “three-step analgesic ladder” on pain management.^{11,18} The use of the WHO three-step analgesic ladder has allowed physicians to select the most appropriate drug treatment regimen and has resulted in adequate analgesia for their patients, according to a 10-year prospective study published in 1995.¹⁸ This guideline has now been adapted for treating other noncancer pains.¹⁹ According to this analgesic ladder model (see Fig. 24.1), the choice of analgesic therapy is based on assessment of pain intensity. Thus, nonopioid analgesics such as acetaminophen and NSAIDs are the drugs of choice for mild pain. The patients should continue on this regimen for as long as they are receiving adequate pain control, although an analgesic adjuvant may

be added to help relieve the side effects associated with pain medications. For moderate pain, a combination of an NSAID (or acetaminophen) and a weak opioid such as codeine should be used. Morphine, fentanyl, and other potent opioids are reserved only for severe pain, especially in patients who are terminally ill, to control pain and to improve their quality of life.¹¹

OPIOIDS

Opioid Receptor Discovery and Endogenous Ligands

There was no direct evidence for the existence of specific opioid receptors until the 1970s when Goldstein et al.²⁰ found that radiolabeled levorphanol bound stereospecifically to certain mouse brain fractions. They hypothesized that this compound bound to an “opiate receptor.” This prediction gained credence in 1973 when additional studies showed that opioid agonists and opioid antagonists compete for the same binding site. Building on these studies, Pert²¹ was able to show that the pharmacologic potencies of the opioid drugs were proportional to their ability to compete with the antagonist for opioid receptor binding.

As it seemed unlikely that these receptors evolved in response to a plant alkaloid, the search for endogenous ligands was intense. The discovery and identification of endogenous substrates for the opioid receptor by Hughes^{22,23} in 1975 further confirmed the existence of an opioid receptor and intensified the SAR studies of the analgesic opioids. The endogenous peptide ligands for the opioid receptors were originally isolated from pig brains but have been found in every mammal studied. The first

WHO 3-Step Analgesic Ladder - Is the pain...

Figure 24.1 • Algorithm for pain management based on the WHO three-Step Analgesic Ladder. (Source: <http://www.who.int/cancer/palliative/painladder/en/>.)

endogenous peptide was termed *enkephalin*, which was found to be a mixture of the two pentapeptides that only differ in their terminal amino acid.

Both methionine-enkephalin (Met-enkephalin) and leucine-enkephalin (Leu-enkephalin) were shown to inhibit the contraction of electrically stimulated guinea pig ileum (GPI) and mouse vas deferens (MVD). These two tests are still used as screening methods for opioid activity. Naloxone completely reversed the inhibitory effects of enkephalin, which led Hughes to infer that the peptides were acting on an opioid receptor.²² The central administration of enkephalins in rats produced short analgesic activity. The transient nature of the enkephalins' actions correlated with the rapid degradation of the enkephalin Tyr-Gly bond by aminopeptidases. Much synthetic work has been done in an attempt to increase the duration of action of the opioid peptides and maintain their analgesic effect.

SARs of Enkephalins

TYR¹

The first amino acid of the pentapeptide shows a distinct preference for tyrosine. Most changes to this amino acid, either by substituting with other amino acids or masking the phenolic hydroxyl (OH) or amino function, produce an inactive or weakly active peptide.

GLY²

Replacing the naturally occurring L-Gly with various D-amino acids produces a peptide that is resistant to peptide cleavage by aminopeptidases. Replacement with D-Ser is the most effective replacement, and all L-amino acid analogs had low activities. Substituting D-amino acids for L-amino acids produces stable peptides, and the stereochemical change may give the peptide access to additional binding sites on the receptors; both of these actions may explain their increased potencies. Replacing the Gly² with D-Ala² while simultaneously replacing the L-Leu⁵ with D-Leu⁵ produces the peptide known as D-Ala², D-Leu⁵ enkephalin (DADLE), which is commonly used as a selective δ -agonist.

GLY³

Almost all changes to this amino acid result in a drop in potency, unless they are also accompanied by another change such as replacing the Gly² with D-Ala² as described above.

PHE⁴

The aromatic nature of the fourth residue is required for high activity. When combined with the D-Ala² replacement, the addition of an electron withdrawing, lipophilic substituent (e.g.,

NO₂, Cl, and Br) in the para position of Phe⁴ greatly increases activity. Para substitutions with electron donating, hydrophilic functional groups (e.g., NH₂ and OH) abolish activity.

MET⁵/LEU⁵

Position 5 appears to tolerate more residue changes than the other positions. Many amino acid substitutions at this position maintain activity (e.g., Ala, Gly, Phe, Pro). Even the loss of the fifth residue to yield the tetrapeptide Tyr¹-Gly²-Gly³-Phe⁴ maintains weak activity in both the GPI and MVD assays. The protected peptide, Tyr¹-D-Ala²-Gly³-MePhe⁴-Gly-ol⁵, known as DAMGO is highly selective for the μ -receptor.

The pituitary gland, hypothalamus, and the adrenal medulla all produce various opioid peptides. Many of these materials were found to be fragments of β -lipotropin (β -LPT) a 91 amino acid peptide. β -LPT has no opioid activity itself. The fraction containing amino acids 61–91 is designated β -endorphin (a word derived from combining *endogenous* and *morphine*). It is much more potent than the enkephalins in both in vivo and in vitro tests. The search for opioid peptides continued, and additional precursor proteins were discovered. Many additional precursor proteins synthesized in the pituitary, adrenal glands, and brain nerve terminals were found to contain sequences of amino acids that were enkephalins or other active opioid peptides. It appears that naturally occurring peptides may serve roles as both short-acting analgesics and long-term neuronal or endocrine modulators. Acupuncture, running, or other physical activity may induce the release of neuropeptides although studies exist that both confirm and refute these claims.^{24,25} A complete discussion on the neuropeptides is beyond the scope of this chapter. Some examples of opioid peptides are given in Figure 24.2.^{26–29}

Opioid Receptors

The discovery of the endogenous opioid peptides paralleled the development of radiolabeling techniques. During the 1970s, researchers were able to label opioid receptors with reversible radioactive ligands that allowed pharmacological actions of specific receptors and their locations to be identified. These techniques allowed for the identification of opioid receptor locations in the brain. Additional pharmacological advances in gene expression studies led to the identification of peripheral opioid receptor locations.³⁰ Opioid receptors are distributed throughout the brain, spinal cord, and peripheral tissues. The distribution of specific opioid receptor subtypes (μ , δ , and κ) usually overlaps. In rats, high concentrations of all three genes for the μ -, δ -, and κ -receptors were found in the hypothalamus and cerebral

cortex. Intermediate concentrations were found in the small intestine, adrenal gland, testes, ovary, and uterus. Low concentrations of all the three gene transcripts were found in the lung and kidney. The gene for the μ -opioid receptor was not found in the stomach, heart, endothelium, or synovium of the rat.³⁰ Opioid receptors are also found on the peripheral terminals of sensory neurons in inflamed rat paws.³¹ Thus, the central and peripheral distribution of opioid receptors is complex. This complicates the interpretation of pharmacological data of individual drugs that may have overlapping binding at multiple opioid receptor subtypes. In addition, opioid receptors form homodimers and heterodimers with opioid receptors and nonopioid receptors such as the α_{2a} -adrenergic receptors resulting in different pharmacologic actions and altered coupling to second messengers.³²

Genes for the four major opioid receptor subtypes have been cloned; the MOP = μ -receptor (mu for morphine), the KOP = κ -receptor (kappa for ketocyclazocine), the DOP = δ -receptor (delta for deferens because it was originally discovered in the MVD), and the NOP = nociception/orphanin FQ receptor (named as an orphan receptor because the endogenous/exogenous ligand was unknown at its time of discovery).³³ The opioid receptor subtypes share extensive residue homology in their transmembrane (TM) domains with most of the variation found in the extracellular loops (Fig. 24.3).³³ All of the opioid receptors belong to the G-protein-coupled receptor class and as such, they are composed of seven TM domains. When the receptor is activated, a portion of the G protein diffuses within the membrane and causes an inhibition of adenylate cyclase activity. The decreased enzyme activity results in a decrease in cyclic adenosine monophosphate (cAMP) formation, which regulates numerous cellular processes. One process that is inhibited is the opening of voltage-gated calcium influx channels on nociceptive C-fibers. This results in the hyperpolarization of the nerve cell and decreased firing and release of pain neurotransmitters such as glutamate and substance P.³⁴

OPIOID LIGAND BINDING SITE

There are no x-ray crystal structures reported for any opioid receptor, and most modeling work has been based on the crystal structure of rhodopsin. Many groups have attempted to find the specific binding site through homology modeling, molecular dynamics, site-directed mutagenesis, chimeric receptors, truncated receptors, and SAR studies. As of yet, no definitive model of the ligand-binding site is available. The opioid-binding site for all four opioid receptors is believed to be an inner cavity formed by conserved residues on TM helices TM3, TM4, TM5, TM6, and TM7.^{33,35} Not all groups agree that the binding pocket is formed via TM domains; some evidence suggest that the amino terminus is an important determinant of ligand binding affinity as well.³⁶ The ligand specificity that each receptor shows may be a result of differences in the extracellular loops that form lids on the binding cavities or differences in amino acids within the binding cavity. Within the cavity, agonists are thought to bind toward the bottom of the cavity via interactions with a conserved Asp from TM3 and a His from TM6. Molecular modeling calculations show that the phenolic OH of the Tyr¹ opioid peptide, or the ring A OH of nonpeptide opioids, forms a hydrogen bond with the conserved His on TM6. The Tyr¹-charged nitrogen, or the N⁺ of the nonpeptide agonist, forms an ionic bond with the conserved Asp of TM3. Antagonist ligands are thought to bind deeper in the binding pocket but retain the ionic bond with the Asp of TM3. The bulky substituent on the charged nitrogen of antagonists is believed to insert itself between TM3 and TM6, preventing the shifts required for activation. Thus, antagonists prevent the necessary movement of TM3 and TM6 resulting in functional antagonism.^{33,35}

THE μ -RECEPTOR

Mu receptors are found primarily in the brainstem and medial thalamus.³⁴ Endogenous peptides for the μ -receptor include endomorphin-1, endomorphin-2, and β -endorphin

Figure 24.3 • Structure of opioid receptors. (Left) Serpentine model of the opioid receptor. Each transmembrane helix is labeled with a roman number. The white empty circles represent nonconserved amino acids among the MOP, DOP, KOP, and NOP receptors. White circles with a letter represent identical amino acids among all four opioid receptors. Violet circles represent further identity between the MOP-R, DOP-R, and KOP-R. Green circles highlight the highly conserved fingerprint residues of family A receptors, Asn I:18 in TM1, AspII:10 in TM2, CysIII:01 in TM3, TrpIV:10 in TM4, ProV:16 in TM5, ProVI:15 in TM6, and ProVII:17 TM7. Yellow circles depict the two conserved cystines in EL loops 1 and 2, likely forming a disulfide bridge. (IL, intracellular loop, and EL, extracellular loop.) (Right) Proposed arrangement of the seven transmembrane helices of opioid receptors as viewed from the top (extracellular side). The seven transmembrane helices are arranged sequentially in a counterclockwise manner. Each transmembrane helix is labeled with a roman number. (Fig. 24.2). Exogenous agonists for the μ -receptor include drugs from the five structural classes discussed later in this chapter (4,5-epoxymorphinan, morphinan, benzomorphan, 4-phenyl/4-anilido piperidines, and the diphenylheptanes) and exogenous peptides such as dermorphin isolated from the skin of South American frogs. Recently, human neuroblastoma cells have been shown to be capable of synthesizing morphine via biosynthesis from radiolabeled tyramine. The synthetic route involves at least 19 steps and is similar, but not exact, to the synthetic route used by the poppy plant.³⁷ The exact role of endogenous morphine is unknown at this time. In general, agonists at the μ -receptor produce analgesia, respiratory depression, decreased gastrointestinal (GI) motility, euphoria, feeding, and the release of hormones. Agonists are also responsible for the addictive effects of the opioid analgesics. Most clinically used opioid drugs bind to the μ -opioid receptor.

THE δ -RECEPTOR

Opioid peptides for the δ -receptor include the endogenous peptides described previously, Met and Leu enkephalin, as well as some synthetic peptides such as DADLE, DSLET, and DPDPE (see Fig. 24.2 for amino acid sequences). These peptides have high affinity for the receptor but low bioavailability and thus limited clinical usefulness. They are used in animal in vitro studies as probes for δ -receptor location and function.

In an attempt to distinguish the amino acids responsible for δ -receptor ligand specificity, point mutations of the δ -receptor, and μ/δ -receptor chimeras were constructed.³⁸ The altered receptors had a decreased ability to bind to δ -receptor selective peptide and nonpeptide ligands, when amino acids in the extracellular top of TM6 and TM7 and the extracellular loop (EC loop 3) that connected them were mutated.

Specifically, amino acids Try²⁸⁴, Val²⁹⁶, and Val²⁹⁷ were crucial to selective δ -ligand binding. These amino acids may provide recognition sites on the receptor that the ligand would have to pass through to reach the putative binding site deeper in the TM cavity. Befort et al.³⁹ also used site-directed point mutant receptors along with molecular modeling to identify Tyr¹²⁹ in TM3 as the most crucial amino acid for ligand binding. In addition, they found a role for amino acid Tyr³⁰⁸ (TM7) in ligand binding.

Nonpeptide agonists and antagonists have been designed to further study the function of the δ -receptor. The first nonpeptide lead compound selective for the δ -receptor came from screening. Modifications to the lead compound led to the identification of SNC-80 as a potent agonist specific for the δ -receptor (Fig. 24.4). This compound has weak antinociceptive effects in monkeys, an effect that can be reversed with the δ -antagonist naltrindole (NTI) (Fig. 24.4).⁴⁰ A series of SNC-80 analog, prepared by multiple groups, found that the amide nitrogen appears to be the most sensitive to modifications and may play an important role in δ -receptor selectivity.⁴¹ Portoghesi designed 7-spiroindanyloxymorphone (SIOM) (Fig. 24.4) based on the idea that the indole of NTI is acting as an “address” mimic of the Phe⁴ phenyl group of enkephalin. The “address–message” concept proposes that one part of the molecule may act as an “address,” essentially directing the chemical to the correct receptor by binding specifically to that receptor, and another part of the molecule acts as the “message,” which gives the compound the biological action. The indole of NTI was replaced with a spiroindane functional group equivalent address in SIOM. The *N*-methyl group of SIOM confers an agonist message as opposed to the antagonist message of the NTI cyclopropyl methyl.⁴² Additional agonists for the δ -receptor have been

Figure 24.4 • Selective δ-receptor ligands.

developed based on the octahydroisoquinoline structure with five-membered ring spacers being δ-receptor antagonists and six-membered ring spacers, agonists. TAN-67 is the most extensively studied in this class (Fig. 24.4).⁴¹ The δ-receptor tolerates multiple chemical structures, and no pharmacophore has been identified that can accommodate all of the diverse structures.^{38,43}

Transgenic mice lacking the δ-receptor have been generated and found to display increased levels of anxiety. In addition, δ-receptor agonist show antidepressant activity in rat models.^{32,44} These results suggest that ligands targeting this receptor may represent new leads for the treatment of schizophrenia, bipolar disorders, and depression. There are few clinical reports of selective δ-receptor agonist use in humans, although they are reported to have proconvulsive activity that may limit their use.⁴⁴

THE κ-RECEPTOR

Kappa receptors are primarily found in the limbic, brain stem, and spinal cord.³⁴ The κ-receptor shows less structural homology to the μ-receptor than the δ-receptor does. (Fig. 24.3) Unlike the μ- and δ-receptors that bind the (enkephalin) peptide sequence Tyr-Gly-Gly-Phe-(Leu/Met), the κ-receptor does not. The κ-receptor shows a clear preference for binding peptides with an arginine in position 6 as seen in the dynorphin peptides (Fig. 24.2).⁴⁵

The structure of some κ-agonists and an antagonist can be seen in Figure 24.5.^{46,47} TRK-820 is a κ-agonist displaying approximately 15 times selectivity toward κ-receptors versus μ-receptors.⁴⁶ The 4,5-epoxymorphinan structure of TRK-820 is proposed to mimic the tyrosine-glycine moiety of endogenous opioid peptides, in effect the agonist message. The additional 6β-substituent constitutes the address directing the compound to the κ-receptor. Spiradoline was one of the earliest compounds to show improved κ-receptor selectivity (125 times over μ-receptors). SARs on this class of compounds revealed that methyl-substituted nitrogen amides, a methylene spacer between the amide and

the aromatic ring and the (–) isomer were all required for κ-activity. The dichlorophenyl ring could be replaced with a 4-benzothiophene or a 4-benzofuran for increased potency and κ-receptor selectivity.⁴¹ Salvinorin A (Fig. 24.5) a nonnitrogen-containing natural compound found in the herb sage is a potent agonist at the κ-receptor.⁴⁸ The hallucinogenic properties of *salvia divinorum* (sage) have been known for hundreds of years but recently, these properties have been exploited by online groups attempting to sell legal hallucinogenic compounds. The κ-antagonist nor-binaltorphimine (nor-BNI) was made by incorporating a rigid pyrrole spacer linking two κ-pharmacophores. Nor-BNI is used in the laboratory to determine if κ-receptors are involved in an observed activity.⁴¹ The second pharmacophore of nor-BNI is not required for κ-antagonism, and compounds that are missing the second aromatic ring have been found to be even more selective and potent antagonists at the κ-receptor.

In clinical trials, most κ-agonists produce dysphoria and thus may be less psychologically addicting but also less acceptable to patients. Some compounds with κ-agonist activity (e.g., pentazocine, nalbuphine) are available, but the clinical development of pure κ-agonists has been limited by the centrally mediated side effects. Spiradoline was developed under the premise that a selective κ-agonist would be an analgesic without the μ-opioid-mediated problems associated with addiction and respiratory depression. Clinical trials in humans found that spiradoline did not produce analgesic effects within a dose range that did not also cause dysphoria, diuresis, and sedation.⁴⁷ The selective κ-agonist TRK-820 shows some promise for the treatment of uremic pruritus, the itch associated with dialysis.⁴⁹

THE ORPHANIN RECEPTOR/FQ/NOP₁

The traditional opioid peptides do not elicit any biological effect at the orphanin receptor. An endogenous peptide for the orphanin receptor has been found and termed orphanin FQ or *nociceptin* (Fig. 24.2). This 17 amino acid peptide can reverse the analgesic effects of morphine thus is antiopioid

Figure 24.5 • Selective κ -receptor ligands.

in some situations.⁵⁰ The carboxy-terminal half of the receptor may serve as the portion that excludes binding to the μ -, δ -, and κ -opioid ligands. The functional role of the receptor is still being investigated, but selective agonists have been shown to delay gastric emptying and decrease gastric secretory functions in rats.⁵¹ In addition, this receptor is found on airway nerves, and agonists decrease bronchospasms in guinea pigs and cats. This receptor is a target for the design of novel peripherally acting antitussive agents, although no compounds are on the market at present.

STRUCTURE-ACTIVITY RELATIONSHIPS

Relating the structure of the chemical ligand to the physiologic activity it induces can only be accomplished by looking at each receptor type individually. The chemically diverse nature of agonists and antagonists found for the μ -, δ -, and κ -receptors is testimony to the adaptability of the

receptors to multiple chemical backbones and tolerance for divergent functional groups. The reader is referred to reviews of the κ - and δ -receptor for detailed SARs for ligands at those receptors.⁴¹ A summary review of the SARs of the μ -receptor compounds is included in the drug monograph section below. For the purpose of this chapter, the drug classes covered will be 4,5-epoxymorphinans, morphinans, benzomorphanes, 4-phenylpiperidines/4-anilidopiperidines, diphenylheptanes, and the miscellaneous category.

DRUG MONOGRAPHS

4,5-Epoxymorphinans

A summary of the SARs of the 4,5-epoxymorphinan structure can be seen in Figure 24.6, and these are discussed in the succeeding individual drug monographs.

Changes on Morphine that increase analgesic activity

- C6 - OH to OAc
- C3 and C6 - OH to OAc
- C6 - OH to O-Sulfate or O-glucuronic acid
- C6 - OH to =O and C7-C8 single bond
- C6 - OH to H and C7-C8 single bond
- C14 - H to β OH
- N - CH₃ to CH₂CH₂Ph
- N - CH₃ to CH₂CH₂furan
- N - CH₃ to CH₂C=OPh
- Removal of C4-C5 ether link

Changes on Morphine that produce antagonists

- N - CH₃ to CH₂CH=CH₂
- N - CH₃ to CH₂-

Figure 24.6 • Summary of functional group changes on morphine structure.

MORPHINE

The prototype ligand for the μ -receptor is morphine. The numbering and ring lettering (A, B, C, . . .) can be seen in Figure 24.6. Morphine contains 5 chiral centers and has 16 optical isomers (not 32 because of the restriction of C-9 to C-13 ethanamine bridge). The naturally occurring, active form of morphine is the levorotatory enantiomorph with the stereochemistry 5(R), 6(S), 9(R), 13(S), and 14(R). The x-ray determined conformation of morphine is a “T” shape with the A, B, and E rings forming the vertical portion, and the C and D ring forming the top (Fig. 24.6).⁴¹

Morphine was isolated from opium in 1806 by a German pharmacist, Seturner. He named the compound “morphine” after the Greek god of dreams “Morpheus.” The first mention of the opium poppy was found in Iraq on clay tablets inscribed in cuneiform script in about 3000 BC.⁵² Opium has been used throughout history and is found in ancient Egyptian, Greek, Roman, Arabic, Indian, and Chinese writing. Opium is isolated from the opium poppy, *Papaver somniferum*, by lancing the unripe pod and collecting and drying the latex that seeps from the incision. Opium contains over 40 different alkaloids with most alkaloids represented in the following five structures: morphine (8%–17%), codeine (0.7%–5%), thebaine (0.1%–2.5%), pappaverine (0.5%–1.5%), and noscapine (1%–10%).⁵²

Although the total synthesis of morphine has been accomplished by various chemical processes, it is still produced from the poppy latex.⁵³ Thus far, no synthetic pathway is efficient enough to make it competitive with the preparation of morphine from either isolation or semisyn-

thesis from a precursor compound from the poppy plant. The endogenous synthesis of morphine in human neuroblastoma cells has been elegantly described.³⁷ The function of endogenous morphine is unknown at this time, but the genes and enzymes involved in morphine biosynthesis may become targets for novel drugs used to treat pain.

Morphine is the prototype μ -receptor agonist; it is the drug to which all other μ -agonists are compared. The pharmacological properties of morphine are well documented and include analgesia, its primary use. For equivalent analgesic effect, the oral dose must be 3 times the intravenous (IV) dose to account for the morphine lost to first-pass hepatic metabolism. The equianalgesic dose of morphine congeners can be seen in Figure 24.7.

Morphine is extensively metabolized via phase II conjugation to morphine-3-glucuronide (~60%), morphine-6-glucuronide (~9%), and, to a lesser extent, the *N*-demethylated metabolite (~3%)⁵⁴ (Fig. 24.8). Much controversy exists on the contribution of the metabolites of both codeine-6-glucuronide and morphine-6-glucuronide to their analgesic effect. In some studies, the 6-glucuronide metabolite of both drugs contributes significantly to their potency.^{55–57} In other studies, the 6-glucuronide metabolites of morphine and codeine produces very little analgesic effect.^{58,59}

Morphine, or another potent opioid drug, is introduced in the WHO stepladder when pain is severe and no relief is obtained from NSAIDs or a combination of NSAIDs and a less potent opioid. Morphine is a monoacidic base and readily forms water-soluble salts with most acids. Because morphine itself is poorly soluble in water (1 g/5,000 mL at 25°C), the

Figure 24.7 • 4,5-Epoxymorphinans and morphinans.

Figure 24.8 • Metabolism of morphine and codeine.

sulfate salt is formed for both oral, IV, and suppository use. The usual starting parenteral dose of morphine in adults is 2.5 to 5 mg q 4 hours. Morphine is available for oral use both as an immediate release and sustained release formulation. The immediate release preparations are dosed q 4 hours, and the sustained release formulations are dosed q 12 to q 24 hours depending on the formulation.

CODEINE

Codeine is an alkaloid that occurs naturally in opium, but the amount present is usually too small to be of commercial importance. Consequently, most commercial codeine is prepared from morphine by methylating the phenolic OH group. It occurs as levorotatory, colorless, efflorescent crystals, or as a white crystalline powder. It is light sensitive. Codeine is a monoacidic base and readily forms salts with acids, with the most important being the sulfate and the phosphate. The acetate and methylbromide derivatives have been used to a limited extent in cough preparations.

The general pharmacological action of codeine is similar to that of morphine, but it does not possess the same analgesic potency. The equianalgesic dose of parenteral morphine 3 to 5 mg q 4 hours is codeine 30 to 65 mg q 4 hours. The equianalgesic dose of oral morphine 10 mg q 4 hours is codeine 60 mg q 4 hours. The decreased potency also leads to a lower addiction potential compared with morphine. Side effects include respiratory depression, miosis, constipation, nausea, itching, dry mouth, and drowsiness. Approximately 5% of codeine is metabolized to morphine via *O*-demethylation. (Fig. 24.8) The enzyme responsible for the *O*-demethylation of codeine is cytochrome P450 (CYP) 2D6. This enzyme exhibits genetic polymorphism with an estimated 7% to 10% of Caucasians designated as poor metabolizers, and thus only able to form traces of morphine after codeine is administered.⁶⁰ The analgesic component of codeine has long been assumed to

be the *O*-demethylated metabolite, morphine. If codeine has no analgesic potency itself, then patients who lack this enzyme should have no analgesic effect to administered codeine. This has been shown not to be the case, so codeine itself may possess analgesic activity, or codeine-6-glucuronide may be the active analgesic.^{56,57}

Codeine's role as an effective antitussive agent has been questioned. A Cochrane evidence-based review of the literature shows that codeine is no more effective than placebo for acute cough in children or adults.⁶¹ Codeine is available in several combination products with either aspirin, ibuprofen, or acetaminophen for the treatment of moderate pain.

HEROIN

Heroin, was first commercially synthesized in 1898 by Bayer company in Germany as an alternate analgesic to morphine. Heroin is the 3,6 diacetylated form of morphine (Fig. 24.7). The laboratory researchers, which also used the acetylation process to convert salicylic acid into acetyl salicylic acid (aspirin), believed that heroin would be an effective analgesic with no addictive properties. This was unfortunately not the case. They named the product "heroin" because it made the test subjects, including some of the chemists, feel "heroic." With both OH groups protected as an ester, heroin can pass through the blood-brain barrier quicker than morphine and lead to the euphoric "rush" that becomes so addictive to addicts, especially after IV injection. Once heroin is in the brain, it is quickly metabolized to 3-acetylmorphine, which has low to zero activity at the μ -receptor and 6-acetylmorphine, which is 2 to 3 times more potent at the μ -receptor than morphine.⁶²

Heroin is not available as a prescription product in the United States, although it is available in some countries to treat pain associated with cancer and myocardial infarctions. It remains one of the most widely used narcotics for illicit purposes and places major economic burdens on society.

HYDROMORPHONE

Hydromorphone, (Dilaudid) is a synthetic derivative of morphine prepared by the catalytic hydrogenation and dehydrogenation of morphine under acidic conditions, using a large excess of platinum or palladium.⁶³ Oxidation of the 6-OH of morphine resulted in a compound with decreased potency. Reducing the 7,8 double bond of morphine increased the flexibility of the molecule and resulted in a compound with slightly enhanced binding. Making both of these structural changes to morphine-produced hydromorphone, a compound approximately 5 times as potent as morphine. Hydromorphone was introduced in 1926 and is available as an immediate release tablet, a liquid, and a suppository. A sustained release form is available in some countries but not in the United States. The sustained release form was removed from the U.S. market in 2005 when studies showed that drinking 8 oz of alcohol (40%) could cause the drug to be released from the capsule immediately and lead to concentrations that were 5.5 times higher than in patients that did not drink alcohol. This potentially lethal combination prompted the Food and Drug Administration (FDA) to remove it from the market.

HYDROCODONE

Hydrocodone is the 3-methoxy version of hydromorphone. The loss of the 3-OH group yields a compound that is approximately 4 to 5 times less potent than hydromorphone, thus about equal to morphine. Unlike codeine, the agonist activity of hydrocodone does not require 3-*O*-demethylation, although it does occur via CYP2D6 representing 4.6% of total clearance.⁶⁴ The protected 3-position has better brain penetration, and the 7,8-dihydro-6-keto C ring contributes to the increased binding of the compound to the μ -receptor.

There are no pure hydrocodone products available on the U.S. market. All FDA-approved products containing hydrocodone are combination products. Like codeine, hydrocodone is marketed as an antitussive agent. It is available combined with the anticholinergic agent homatropine as a syrup and a tablet. The addition of the anticholinergic agent is to discourage abuse. It is also available in a delayed release suspension form (Tussionex). This formulation uses a sulfonated styrene divinylbenzene copolymer complexed with hydromorphone and chlorpheniramine that acts as a cation-exchange resin slowly releasing the drugs over a 12-hour period. Hydrocodone is also marketed in combination with acetaminophen (Vicodin, Lortab) or aspirin (Lortab ASA) for the treatment of pain. The dose of acetaminophen consumed by the patient must be closely monitored, and prescriptions that allow for greater than 4 grams of acetaminophen per 24-hour period should not be dispensed.

OXYCODONE

Oxycodone is synthesized from the natural opium alkaloid thebaine. Oxycodone is the 14 beta-hydroxyl version of hydrocodone. This additional functional group gives oxycodone greater potency (1.5 times orally) than hydrocodone presumably by increasing receptor affinity. The oral bioavailability of oxycodone is 65% to 87%.⁶⁵ The metabolism of oxycodone follows the similar pattern of opioid metabolism with *N*-demethylation, *O*-demethylation, and their glucuronides all identified. Per the manufacturer, the analgesic effect of oxycodone correlates well with oxycodone plasma concentrations, not the minimal amount of oxymorphone formed, thus

oxycodone is not assumed to be a prodrug. There are no large-scale studies of oxycodone used for analgesia in CYP2D6 poor metabolizers that can confirm this.

Oxycodone is marketed in combination with acetaminophen (Percocet), aspirin (Percodan), and ibuprofen (Combunox). It has been available for over 50 years as an immediate-release tablet, and in 1995 an extended-release tablet was approved by the FDA (OxyContin). OxyContin is manufactured in eight strengths from 10 to 160 mg, and the high-dose preparations quickly became attractive to drug abusers. The extended-release tablets are crushed and then injected or snorted to give an immediate high. The Drug Abuse Warning Network (DAWN) is a public health surveillance system that monitors drug-related emergency room visits and drug-related deaths. In 1995, they estimated that 598,542 emergency room visits involved the nonmedical use of a pharmaceutical (e.g., antidepressant, anxiolytic, stimulant). Of these ER visits, 160,363 visits were attributed to opiates with an estimated 42,810 involving oxycodone or an oxycodone combination. Methadone and hydrocodone/combinations were estimated to be similar to oxycodone.⁶⁶

OXYMORPHONE

Oxymorphone is the 14 beta-hydroxyl version of hydromorphone, analogous to the hydrocodone, oxycodone pair discussed above. Although the addition of the 14 beta-hydroxyl group to hydrocodone (30 mg) yielded oxycodone (20 mg), a more potent drug, the opposite is true for the conversion of hydromorphone (7.5 mg) to oxymorphone (10 mg). The reason for this is that the oral bioavailability of oxymorphone (10%) is lower than that of hydromorphone (35%) because of decreased absorption and increased first-pass metabolism. Presumably, the addition of the OH group does increase its binding affinity at the receptor as the injectable form of oxymorphone (1 mg) is more potent than injectable hydromorphone (1.5 mg).

Oxymorphone is available as a suppository (5 mg), an injection (1 mg/mL), an immediate-release tablet (5 mg, 10 mg), and in 2003 the FDA approved a sustained release formulation (Opana ER 5 mg, 10 mg, 20 mg, and 40 mg). The 12-hour coverage of the extended release tablet provides another option for those patients suffering from chronic pain. The side effect profile of the extended release formulations of morphine, oxycodone, and oxymorphone are similar, and there appears to be no clear advantage of one over the other.

Morphinans

The morphinans were made by removing the E ring of morphine, the 4,5-ether bridge, in an attempt to simplify the structure (Fig. 24.7).

LEVORPHANOL

Levorphanol tartrate is the levorotatory form of methorphan and is approximately 7.5 times more potent than morphine orally. The loss of the 4,5-epoxide and the 7,8-double bond allows levorphanol greater flexibility and presumably leads to the increased binding affinity at all opioid receptor subtypes compared with morphine. The plasma half-life of levorphanol is about 6 to 8 hours but displays great interperson variability and may increase upon repeated dosing. The excretion of levorphanol is dependent on the kidneys, so caution must be used in renally compromised patients.⁶⁷

The analgesic effect of levorphanol may not match the long plasma half-life, and patients must be closely monitored for drug accumulation and respiratory depression. Levorphanol has strong agonist activity at the μ -, κ -, and δ -opioid receptors and has also been shown to be a noncompetitive *N*-methyl-D-aspartate (NMDA)-receptor antagonist.⁶⁸ The pharmacodynamic properties of levorphanol are sufficiently different to make it an attractive alternate for patients that receive inadequate pain relief from morphine. Levorphanol is available as a 2-mg oral tablet (Levo-Dromoran), and a 2-mg/mL solution for injection.

DEXTROMETHORPHAN

Dextromethorphan is the dextrorotatory form of levorphanol with a methoxy group on the 3-position (Fig. 24.7). It is available in more than 140 over-the-counter (OTC) cough and cold formulations.⁶⁹ Evidence-based reviews have been unable to conclude that it is more effective than placebo in reducing cough.^{61,70} Like (+) and (–) levorphanol, (+) dextromethorphan is a potent NMDA antagonist and, in higher than recommended doses, has the potential for causing dissociative anesthetic effects similar to ketamine or phencyclidine (PCP). The OTC status and availability of pure dextromethorphan powder online has contributed greatly to its abuse in recent years. DAWN reports that in 2004, there were approximately 12,500 emergency room visits involving dextromethorphan with 44% of those involving abuse of the drug.⁷¹ The 2006 *National Survey on Drug Abuse* report shows that nearly 1 million persons aged 12 to 25 years (1.7%) misused OTC cough and cold medications in the past year.⁶⁹

Dextromethorphan's ability to antagonize the NMDA receptor has led to its use to treat phantom pain, diabetic neuropathy, and postoperative acute pain.^{72,73}

Benzomorphans

Structural simplification of the morphine ring system further, by removing the C ring of the morphinan structure, yields the benzomorphans also referred to as the *benzazocines*.

Pentazocine

PENTAZOCINE

The benzomorphans are prepared synthetically and thus result in several stereoisomers. The active benzomorphans are those that have the equivalent bridgehead carbons in the same absolute configuration of morphine (carbons 9, 13, and 14 of morphine). The only benzomorphan in clinical use is pentazocine, which is prepared as the 2(R), 6(R), 11(R) enantiomer (*Chemical Abstracts* numbering).⁷⁴ Pentazocine is a mixed agonist/antagonist displaying differing intrinsic activity at the opioid receptor subtypes. At the μ -receptor, pentazocine is a partial agonist and a weak antagonist.

According to the manufacturer, a 50-mg dose of pentazocine has about the same analgesic potency as 60 mg of codeine and about 1/50th the antagonistic activity of nalorphine.⁷⁴ Pentazocine is also an agonist at the κ -receptor, and this may be responsible for the higher percentage of patients that experience dysphoria with pentazocine versus morphine.⁷⁵ Some evidence also exists that women respond better to κ -agonists than men.^{76,77} Pentazocine is available in a 50-mg tablet along with a low dose of the antagonist naloxone 0.5 mg (Talwin NX). Naloxone 0.5 mg orally is expected to have no pharmacological effect but is included to dissuade IV drug abusers from dissolving and injecting Talwin NX.

4-Phenylpiperidines and 4-Anilidopiperidines

Further structural simplification of the benzomorphan ring system, via removal of the B ring of the benzomorphans yields the 4-substituted piperidines. The resultant structures are flexible and, without the B ring locking the A ring in an axial position relative to the piperidine (D) ring, the A ring can exist in either an axial or an equatorial position. Much SAR work has been conducted on these compounds, and the reader is referred to Casey's book for a detailed review.⁶²

MEPERIDINE

Meperidine (Demerol) (Fig. 24.9) was discovered in 1939 during a serendipitous screening of compounds being studied for antispasmodic activity. Mice given meperidine were noted to carry their tails in an erect position (the Straub tail reaction), which was indicative of narcotic analgesia. This led to the study of meperidine and derivatives as analgesic agents. Meperidine was found to have low potency at the receptor compared with morphine (0.2%) but much higher penetration into the brain resulting in a compound with about 10% of the potency of morphine.⁴¹ Meperidine is an agonist at the μ -receptor and a 300-mg oral or 75-mg IV dose is reported to be equianalgesic with morphine 30-mg oral or 10-mg IV dose.

The 4-ethyl ester was found to be the optimal length for analgesic potency. Increasing or decreasing the chain length decreased activity.⁴¹ Structural changes that increase the potency of meperidine include the introduction of an *m*-hydroxyl on the phenyl ring, substituting the methyl on the N for a phenylethyl or a *p*-aminophenylethyl.⁴¹ Replacing the *N*-methyl with an *N*-allyl or *N*-cyclopropylmethyl group does not generate an antagonist, unlike the similar substitution of the morphine congeners. Meperidine quickly penetrates the blood-brain barrier and thus has a quick onset of activity and a high abuse potential. Meperidine is metabolized to normeperidine (Fig. 24.10) by the liver enzymes CYP3A4 and CYP2C18 and in the brain by CYP2B6. Meperidine and normeperidine are also metabolized by liver carboxylesterases.^{78,79} The metabolism to normeperidine has clinical consequences. The duration of analgesia of meperidine may be shorter than the 3- to 4-hour half-life of the drug. This may necessitate frequent dosing to relieve pain, and thus the excessive formation of normeperidine. Normeperidine has been shown to cause central nervous system (CNS) excitation that presents clinically as tremors, twitches, "shaky feelings," and multifocal myoclonus potentially followed by grand mal seizures.⁸⁰ Patients at the greatest risk of developing normeperidine toxicity are those that are on high doses, long durations (greater than 3 days), have

Figure 24.9 • 4-Phenylpiperidines and 4-anilidopiperidines.

renal dysfunction, thus cannot eliminate the normeperidine, and those on CYP inducers.⁸¹

In addition to the CNS toxicity of normeperidine, meperidine has also been found to be a weak serotonin reuptake inhibitor and has been involved in serotonin toxicity reactions when used with monoamine oxidase inhibitors or serotonin reuptake inhibitors.⁸² Meperidine is available in tablet, liquid, and injectable forms. The use of meperidine should be limited to those patients that have true allergies to the morphine-type opioids, and patients should be monitored for toxicity.

DIPHENOXYLATE

Diphenoxylate (Fig. 24.9) is a weak opioid agonist and is available combined with atropine (Lomotil) for use as an antidiarrheal agent. At low doses, the opioid effect is minimal,

and the atropine is added to dissuade abuse. One study found both codeine and loperamide to be superior to diphenoxylate for treating chronic diarrhea.⁸³ The manufacturer has strict dosing guidelines for pediatric use because opioid intoxication and deaths from diphenoxylate have been reported.⁸⁴

LOPERAMIDE

Loperamide (Imodium) is a 4-phenylpiperidine with a methadone-like structure attached to the piperidine nitrogen (Fig. 24.9). It acts as an antidiarrheal by directly binding to the opiate receptors in the gut wall. Loperamide inhibits acetylcholine and prostaglandin release, decreasing peristalsis and fluid secretion thus increasing the GI transit time and reducing the volume of fecal matter.^{85,86} Loperamide is

Figure 24.10 • Metabolism of meperidine.

sufficiently lipophilic to cross the blood-brain barrier, yet it displays no CNS-opioid effects. The reason for this is that it is actively pumped out of the brain via the P-glycoprotein pump (MDR1).⁸⁷ Knockout mice with the P-glycoprotein pump genetically removed were given radiolabeled loperamide and sacrificed 4 hours later. The [³H]loperamide concentrations were measured and compared with wild-type mice. A 13.5-fold increase in loperamide concentration was found in the brain of the knockouts. In addition, the mice lacking the P-glycoprotein pump displayed pronounced signs of central opiate agonism.⁸⁷ Loperamide is available as 2-mg capsules for treatment of acute and chronic diarrhea. Recommended dosage is 4 mg initially, with 2 mg after each loose stool for a maximum of 16 mg/d.

FENTANYL

When the 4-phenyl substituent of meperidine was replaced with a 4-aniline with a nitrogen connection, the potency increased. This led to the development of the 4-anilidopiperidine series of compounds seen in Figure 24.9. Fentanyl (Sublimaze) was the first compound marketed and was found to be almost 500 times more potent than meperidine. The high lipophilicity of fentanyl gave it a quick onset, and the quick metabolism led to a short duration of action. The combination of potency, quick onset, and quick recovery led to the use of fentanyl as an adjunct anesthetic. In addition to the injectable formulation, fentanyl is available in a unique transdermal system (Duragesic). This formulation is beneficial to many chronic pain sufferers unable to take oral medication. The transdermal system releases fentanyl from the drug reservoir patch into the skin, forming a depot layer. The fentanyl is then absorbed into the systemic circulation. Patches are replaced every 72 hours, and serum concentrations of fentanyl can be maintained relatively constant. A transmucosal lollipop form (Actiq) for breakthrough pain only in opioid tolerant cancer patients is also available.

The SAR studies of the 4-phenylpiperidine analgesics found that the propionamide is the optimal chain length. Adding polar groups to the 4-piperidine carbon (CH₂OCH₃ in sufentanil and alfentanil, COOCH₃ in remifentanil) increases potency. The piperidine nitrogen of fentanyl contains a phenethyl substituent that appears to be the correct chain length for optimal potency. Molecular docking studies speculate that the phenethyl group of fentanyl binds to a crevice between TM2 and TM3 of the μ -opioid receptor. This model also aligns the cationic nitrogen of fentanyl with the conserved Asp but leaves the aromatic pocket of the ring unoccupied.⁸⁸ Substituting the *N*-phenethyl group with bioisosteres led to the development of fentanyl congeners alfentanil, sufentanil, and remifentanil.

ALFENTANIL

The addition of a methoxy methyl on the 4-piperidine and the substitution of the phenethyl ring for an ethyl-substituted tetrazole-one yielded a compound with about one fourth to one third the potency of fentanyl (Fig. 24.9). Although less potent, it has a quicker onset of action, a shorter duration of action, and thus a better, safety profile for use as an anesthetic adjunct. The piperidine amine has a pK_a of 6.5 compared with fentanyl's pK_a of 8.4. This results in a higher proportion of unionized drug for alfentanil leading to quicker penetration through the blood-brain barrier and thus onset of action.⁴¹ Alfentanil (Alfenta) is available as an IV injection for use as an analgesic adjunct for induction of general anesthesia and to maintain analgesia during general surgical procedures.

SUFENTANIL

Sufentanil (Sufenta) contains the same 4-methoxy methyl substituent as alfentanil along with an isosteric replacement of the phenyl of the phenethyl group with a thiophene ring (Fig. 24.9). The resulting compound is about 7 times more potent than fentanyl with an immediate onset of action and a similar recovery time compared with fentanyl. Sufentanil is only available in an injectable formulation and is also used as an anesthetic adjunct.

REMIFENTANIL

Remifentanil (Ultiva) was designed as a "soft drug." Soft drugs are designed to undergo metabolism quickly and thus have ultrashort durations of action. In place of the ethyl aromatic ring seen on the other piperidine opioids, remifentanil has an ester group (Fig. 24.9). This ester group is metabolized by esterases in the blood and tissue to a weakly active metabolite (1:300–1:1,000 the potency of remifentanil).⁸⁹ The *n*-octanol/water partition coefficient of remifentanil is 17.9. The pK_a of remifentanil is 7.07, thus it is predominately unionized at physiological pH. Both of these properties account for its rapid distribution across the blood-brain barrier (<1 minute). The ester hydrolysis leads to a quick recovery (5–10 minutes) independent of duration of drug administration, renal, or liver function. The favorable pharmacodynamics of remifentanil have led to its use for induction and maintenance of surgical anesthesia.

Diphenylheptanes

METHADONE

Methadone (Dolophine) (Fig. 24.11) is a synthetic opioid approved for analgesic therapy and for the maintenance and treatment of opioid addiction. Methadone is marketed as the

Figure 24.11 • Diphenylheptanes.

Figure 24.12 • Metabolism of methadone.

racemate, although the opioid activity resides in the R-enantiomer (7–50 times more potent than the S-enantiomer). Methadone may only be dispensed for the treatment of opioid addiction by a program certified by the Federal Substance Abuse and Mental Health Services Administration. Methadone is a μ -receptor agonist with complex and highly variable pharmacokinetic parameters. Bioavailability following oral administration ranges from 36% to 100%. Steady-state volume of distribution ranges between 1.0 to 8.0 L/kg. Methadone is highly bound to plasma α_1 -acid glycoprotein (85%–90%), and $t_{1/2}$ elimination ranged between 8 and 59 hours. The wide range in parameters leads to difficulty when trying to switch from one opioid to methadone for either treatment of pain or substance abuse. Methadone doses and administration schedules need to be individualized and closely monitored. The metabolism and elimination of methadone also lead to much interpatient variability and can be effected by genetic CYP levels, drug–drug interactions, and the pH of the urine (Fig. 24.12).⁹⁰ The major metabolic pathway of methadone metabolism is via N-demethylation to an unstable product that spontaneously cyclizes to form the inactive 2-ethylidene-1,5-dimethyl-3,3-diphenylpyrrolidine (EDDP). Initial reports concluded that CYP3A4 was the major isoform responsible for this pathway, but more recent reports indicate that CYP2B6 is primarily responsible for the N-demethylation.^{91–95}

Adverse effects of methadone include all of the standard opioid effects including constricted pupils, respiratory depression, physical dependence, extreme somnolence, coma, cardiac arrest, and death. In addition, QT interval prolongation and torsades de pointes have been reported. The QT interval prolongation reported for methadone was also observed in another diphenylheptane, levomethadyl, or levo- α -acetyl-methadol (LAAM) (Orlaam) that was also used to treat opioid addiction. The severe cardiac-related adverse events resulted in the removal of LAAM from the U.S. market in 2003.

PROPOXYPHENE

Most of the structural changes to the methadone skeleton resulted in compounds with decreased opioid potencies, thus most of these compounds, with the exception of LAAM were not developed. Propoxyphene is a derivative of methadone marketed in 1957 as the enantiomerically pure (2S, 3R)-

4-(Dimethylamino)-3-methyl-1,2,-diphenyl-2-butanol propionate (ester). It is only about 1/10th as potent as morphine as an analgesic yet retains all the same opioid adverse effects. One propoxyphene 65-mg capsule has the same analgesic effect of 650 mg of aspirin or 1,000 mg of acetaminophen, thus overdoses of propoxyphene can occur if patients do not follow the prescribed dose. Between 1981 and 1999, 2,110 accidental deaths were reported because of propoxyphene. Propoxyphene and all propoxyphene combination products are listed using the Beers criteria as medications to avoid in patients older than 65 years of age.⁹⁶ The metabolism of propoxyphene also contributes to the potential dangers of the drug. Propoxyphene is metabolized via N-demethylation to form norpropoxyphene. Norpropoxyphene has been shown to build up in cardiac tissues and result in naloxone-insensitive cardiotoxicity.⁹⁷ The weak analgesic action and potential risk to the patient have some health practitioners advocating to remove all drugs containing propoxyphene from the market.⁹⁸ The hydrochloride salt is marketed as Darvon, the napsylate salt as Darvon-N, both salts are also available combined with acetaminophen (Darvocet, Darvocet-N) and a propoxyphene, aspirin, caffeine product is also available.

Miscellaneous

TRAMADOL

Tramadol (Ultram) is an analgesic agent with multiple mechanisms of action. It is a weak μ -agonist with approximately 30% of the analgesic effect antagonized by the opioid antagonist naloxone. Used at recommended doses, it has minimal effects on respiratory rate, heart rate, blood pressure, or GI transit times. Structurally, tramadol resembles codeine with

the B, D, and E ring removed. The manufacturer states that patients allergic to codeine should not receive tramadol, because they may be at increased risk for anaphylactic reactions.⁹⁹ Tramadol is synthesized and marketed as the racemic mixture of two (the [2S, 3S] [-] and the [2R, 3R] [+]) of the four possible enantiomers.¹⁰⁰ The (+) enantiomer is about 30 times more potent than the (-) enantiomer; however, racemic tramadol shows improved tolerability.^{101,102} Neurotransmitter reuptake inhibition is also responsible for some of the analgesic activity with the (-) enantiomer primarily responsible for norepinephrine reuptake and the (+) enantiomer responsible for inhibiting serotonin reuptake.^{101,103} Like codeine, tramadol is *O*-demethylated via CYP2D6 to a more potent opioid agonist having 200-fold higher affinity for the opioid receptor than the parent compound. Tramadol was initially marketed as nonaddictive, and a 3-year follow up study showed that the abuse potential is very low, but not zero. Most abusers of tramadol have abused opioid drugs in the past.¹⁰⁴ Both enantiomers of tramadol and the major *O*-demethylated metabolite are proconvulsive, and tramadol should not be used in patients with a low-seizure threshold including patients with epilepsy.¹⁰¹

Mixed Agonist/Antagonist

NALBUPHINE

Nalbuphine (Nubain) is structurally a member of the phenanthrene class of compounds and resembles oxycodone with a cyclobutyl methyl group on the nitrogen, equivalent to naloxone's substitution. It was introduced in 1979 as an agonist/antagonist with the hope of becoming an effective pain reliever with little abuse potential. Although the abuse potential of nalbuphine is low, it is not zero, and increasing reports of diversion and abuse can be found in the literature and the Internet.¹⁰⁵ At low parenteral doses (<0.5 mg), it has an analgesic potency approximately two thirds that of morphine, and it has a similar degree of respiratory depression. However, escalating doses above 30 mg does not produce further respiratory depression.¹⁰⁶ The oral bioavailability of nalbuphine is only 12%, and the drug is only marketed as an injectable.¹⁰⁷ Patents have been filed for an oral extended-release formulation, and it is presently in phase II testing.¹⁰⁸ The pharmacologic profile of nalbuphine in animal studies includes agonist activity at the κ -receptor and antagonist activity at the μ -receptor.¹⁰⁹ Clinical studies have shown that nalbuphine, and κ -agonists in general, may have better analgesic activity in female patients compared with male patients.⁷⁷ Used as the sole opioid agent, nalbuphine has been used successfully to treat the pain of labor, cesarean section, dental extraction, hip replacement, and hysterectomy surgery.¹¹⁰ Nalbuphine also may have a role in

treating opioid-induced pruritus, because it can reverse the pruritus without reversing the analgesic effect when used in low doses. Nalbuphine is marketed as an injectable (10 and 20 mg/mL). The usual dose is 10 mg administered subcutaneously, intramuscularly, or intravenously at 3- to 6-hour intervals, with a maximal daily dose of 160 mg.

BUTORPHANOL

Structurally, butorphanol is a morphinan and shares the same cyclobutyl methyl group on the nitrogen as nalbuphine. Like nalbuphine, butorphanol is an agonist at the κ -receptor but at the μ -receptor butorphanol is both a partial agonist and an antagonist.¹¹¹ The affinity for opioid receptors *in vitro* is 1:4:25 for the μ -, δ -, and κ -receptors respectively.¹¹¹ The high affinity for the κ -receptors is proposed to give butorphanol its analgesic properties and is also responsible for the CNS adverse effects such as hallucinations, psychosis, and paranoid reactions. Butorphanol binds with μ -receptors as a partial agonist, and administration to humans maintained on high-potency μ -agonists such as morphine may precipitate withdrawal. Butorphanol was found to produce convulsions in morphine-deprived, morphine-dependent monkeys.¹¹²

The parenteral injection is used for moderate to severe pain associated with orthopedic procedures, obstetric surgery, and burns. The recommended dose is 1 mg IV or 2 mg intramuscular (IM) every 3 to 4 hours as needed. Early studies proposed a "ceiling effect" for butorphanol's antinociception and respiratory depressant effect. More recently, the WHO Expert Committee on Drug Dependence performed a critical review of butorphanol and found no ceiling effect to the respiratory depressant effect of parenteral butorphanol in monkeys and humans.¹¹² The nasal preparation (Stadol NS) is an effective analgesic for the relief of moderate to severe pain such as migraine attacks, dental, or other surgical pain where an opioid is appropriate. The nasal spray is administered 1 mg (1 spray in one nostril) with an additional spray 60 to 90 minutes later if adequate pain relief is not achieved. Respiratory depression is not an issue with normal doses of the nasal preparation, but CNS side effects are the same as parenteral butorphanol. Increased reports of abuse and addiction of the nasal spray led the FDA to change the product to a Schedule IV drug in 1997.

BUPRENORPHINE

Buprenorphine is a semisynthetic, highly lipophilic opiate derived from thebaine. Pharmacologically, it is classified as a mixed μ -agonist/antagonist (a partial agonist) and a weak κ -antagonist. It has a high affinity for the μ -receptors (1,000 times greater than morphine) and a slow dissociation rate leading to its long duration of action (6–8 hours).¹¹³ At recommended doses, it acts as an agonist at the μ -receptor with approximately 0.3 mg IV equianalgesic to 10 mg of IV morphine. One study in humans found that buprenorphine displays a ceiling effect to the respiratory depression, but not the analgesic effect over a dose range of 0.05 to 0.6 mg.¹¹⁴ In practice, this makes buprenorphine a safer opiate (when used alone) than pure μ -agonists. Relatively few deaths from buprenorphine overdose (when used alone) have been reported.¹¹³ The tight binding of the drug to the receptor also has led to mixed reports on the effectiveness of using naloxone to reverse the respiratory depression. In animal studies, normal doses of the pure antagonist naloxone were unable to remove buprenorphine from the receptor site and precipitate withdrawal. In a human study designed to precipitate withdrawal from buprenorphine, a naloxone dose (mean = 35 mg) 100 times the dose usually needed to precipitate withdrawal in methadone-dependent subjects was used. For comparison, approximately 0.3 mg, 4 mg, 4 mg, and 10 mg of naloxone would be required to precipitate withdrawal from heroin, butorphanol, nalbuphine, or pentazocine respectively.¹¹⁵

The unique pharmacologic and pharmacokinetic profile of buprenorphine made it a drug of interest for the treatment of opioid dependence. The first study of buprenorphine for this purpose was published in 1978 and confirmed that buprenorphine was an acceptable alternative to methadone for addicts and that it blocked the effects of large single doses of morphine for at least 24 hours.¹¹⁶ Early clinical studies showed that the oral bioavailability of buprenorphine was low because of intestinal and liver metabolism. Therefore, a sublingual (SL) formulation (Subutex) was developed that would bypass this metabolism. The SL tablet has a bioavailability of 55% but varies widely among individuals.¹¹⁶ SL buprenorphine is also available combined with naloxone (Suboxone) in sufficient quantity (25% of the buprenorphine dose) to discourage crushing and injecting the SL tablet. SL naloxone is 0% to 10% bioavailable, and it does not change the absorption or action of the SL buprenorphine. Abrupt withdrawal of chronically administered buprenorphine produces mild to moderate opioid withdrawal symptoms peaking between 3 and 5 days following the last buprenorphine dose. These symptoms require no therapeutic intervention. Suboxone and Subutex are the first medications approved for office-based treatment of opioid dependence under the Drug Addiction Treatment Act of 2000. U.S. pharmacists may only dispense these medications when prescribed by physicians that meet special train-

ing criteria and are registered with the Center for Substance Abuse Treatment, a component of the Substance Abuse and Mental Health Services Administration. A transdermal buprenorphine patch is available outside the United States for use in chronic pain.¹¹⁷ This product is currently undergoing phase III clinical trials in the United States.

Buprenorphine is oxidatively metabolized by *N*-dealkylation by hepatic CYP3A4 and to a lesser extent CYP2C8 to the active metabolite norbuprenorphine. Both the parent and major metabolite undergo glucuronidation at the phenolic-3 position. Minor metabolites include hydroxylation of the aromatic ring of buprenorphine and norbuprenorphine at an unspecified site.¹¹⁸

Opioid Antagonists

NALTREXONE

Naltrexone (Fig. 24.13) is a pure opioid antagonist at all opioid receptor subtypes with the highest affinity for the μ -receptor. Naltrexone is orally bioavailable and blocks the effects of opiate agonists for approximately 24 hours after a single dose of 50 mg. It produces no opioid agonist effects and is devoid of any intrinsic actions other than opioid receptor blockade. Theoretically, it should work well to treat opioid dependence but in clinical practice, patients have shown poor compliance and high relapse rates. Naltrexone has also been studied to treat alcohol dependence with mixed results. To address the compliance issues and effectively remove the “choice” of taking the antagonist, naltrexone was developed into an extended-release injectable microsphere formulation for IM injection once a month (Vivitrol). This formulation provides steady-state plasma concentrations of naltrexone threefold to fourfold higher than the 50-mg oral dose 4 times a day.¹¹⁹ Currently, Vivitrol is only indicated for the treatment of alcohol dependence. A Cochrane review found insufficient evidence from randomized controlled trials to evaluate its effectiveness for treating opioid dependence.¹²⁰ Currently, phase II and phase III clinical trials of an implantable pellet form of naltrexone are being conducted for treating opioid dependence.

The CYP450 system is not involved in naltrexone metabolism. Naltrexone is reduced to the active antagonist 6- β -naltrexol by dihydrodiol dehydrogenase, a cytosolic enzyme. Naltrexone has a black box warning, because it has the potential to cause hepatocellular injury when given in excessive doses.¹¹⁹

NALOXONE

Naloxone (Narcan) (Fig. 24.13) is a pure antagonist at all opioid receptor subtypes. Structurally, it resembles oxycodone except that the methyl group on the nitrogen is replaced by an allyl group. This minor structural change

Figure 24.13 • Opioid antagonists.

retains high binding affinity to the receptor, but no intrinsic activity. It is used to reverse the respiratory depressant effects of opioid overdoses.

Naloxone is administered intravenously with an onset of action within 2 minutes. Because it is competing with the opioid for the receptor sites, the dose and frequency of administration will depend on the amount and type of narcotic being antagonized. Overdoses of long-acting opioids (methadone) may require multiple IV doses of naloxone or continuous infusions. Neonates born to opioid-exposed mothers may be given IV naloxone at birth to reverse the effects of opiates.

Very few metabolism studies on naloxone have been conducted, although the major metabolite found in the urine is naloxone-3-glucuronide.^{121,122}

NALMEFENE

Nalmefene (Revex) is a pure opioid antagonist that is the 6-methylene analog of naltrexone. It is available as a solution for IV, IM, or subcutaneous (SC) administration to reverse the effects of opioids after general anesthesia and in the treatment of overdose. It is longer acting than naloxone but otherwise has a similar pharmacodynamic and metabolic (3-glucuronidation) profile. Nalmefene has higher oral bioavailability (approximately 40%)¹²³ than naloxone or naltrexone and is currently being investigated as an oral treatment for pathological gambling¹²⁴ and alcohol abuse.¹²⁵

METHYLNALTREXONE

Methylnaltrexone (Relistor) is the methylated, quaternary form of naltrexone (Fig. 24.13). The permanently charged nitrogen prevents the drug from crossing the blood-brain barrier. Thus, it only acts as an antagonist at peripheral opioid receptors. Relistor was approved in April 2008 to treat opioid-induced constipation in patients receiving palliative care. It is administered as a SC injection once every other day.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

NSAIDs including aspirin and acetaminophen, two of the oldest pain medications, are among the most widely prescribed drugs worldwide for the treatment of rheumatic arthritis and other degenerative inflammatory joint diseases.^{126,127} Although NSAIDs are very effective in relieving mild to moderate pains and inflammation, their use is also often associated with many undesirable side effects, including GI irritation and bleeding, platelet dysfunction, kidney damage, and bronchospasm.¹²⁶⁻¹²⁹

With the exception of acetaminophen (Tylenol) and the newer "coxibs" drugs, the conventional NSAIDs (also commonly referred to as the *aspirin-like drugs*), share very similar therapeutic and side effect profiles. The conventional NSAIDs exert their therapeutic action by inhibiting two isoforms of cyclooxygenase (COX-1, the constitutive isozyme and COX-2, the inducible isozyme), which is the rate-limiting enzyme responsible for the biosynthesis of the proinflammatory prostaglandins (PGs) such as the PGD₂, PGE₂,

PGF_{2 α} , and PGI₂ and thereby modulating pain transmission, attenuating inflammation, and reducing fever.^{127,128} They also produce their undesirable side effects such as GI bleeding, ulcerations, or renal impairments by blocking the same cyclooxygenases responsible for synthesizing PGs that modulate platelet activity (TXA₂ and PGI₂), gastric acid secretion and cytoprotection (PGE₂ and PGI₂), and renal blood flow (PGE₂).¹²⁸⁻¹³²

In early 1990, Vane et al.^{133,134} hypothesized that the undesirable side effects of the conventional NSAIDs are a result of inhibition of the COX-1 isozyme, whereas the therapeutic effects are related mainly to their inhibitory action on the inducible COX-2 isozyme. This hypothesis has stimulated extensive drug development and hasty market introductions of many selective COX-2 inhibitors, or coxibs drugs.^{130,135} However, all of the marketed coxibs drugs except celecoxib (Celebrex), the first FDA-approved COX-2 drug in 1998, have been withdrawn from the market because of the potential risk of a cardiovascular event, including heart attack or stroke, especially in cardiac patients.¹³⁶ Recent clinical trials have placed all NSAIDs under surveillance for their potential cardiovascular risk, thus the indiscriminate use of any NSAIDs including naproxen in cardiac patients should be avoided.¹³⁵⁻¹³⁷

Mechanism of Action and NSAID-Induced Side Effects

For aspirin and many of the conventional NSAIDs, despite their worldwide use as pain medications for over a century, their mechanism of action was not completely known until 1971 when Vane first identified the cyclooxygenases as their molecular targets.¹²⁸ Cyclooxygenase (also known as prostaglandin endoperoxide synthase or PGH synthase) is the rate-limiting enzyme responsible for the biosynthesis of PGs.

PGs are short-lived, lipidlike molecules that play a vital role in modulating many important physiological and pathophysiological functions including pain, inflammation, gastric acid secretion, wound healing, and renal function. They are biosynthesized via a tissue-specific cyclooxygenase pathway (COX-1 or COX-2) either on an as-needed basis (mostly via the COX-1 isozyme) or via the induced and overexpressed COX-2 isozyme because of an injury, inflammation, or infection.^{126,129} Some of the salient features of the cyclooxygenase pathway involved in the biosynthesis of these PGs from arachidonic acid (AA) (5,8,11,14-eicosatetraenoic acid), a polyunsaturated fatty acid released from membrane phospholipids by the action of phospholipase A₂, are depicted in Figure 24.14.

As stated earlier, all classes of NSAIDs strongly inhibit prostaglandin synthesis in various tissues, especially at the site of the tissue damage or inflammation. This inhibition occurs at the stage of oxidative cyclization of AA, catalyzed by the rate-limiting enzyme, cyclooxygenase (or PGH synthase), to the hydroperoxy-endoperoxide (prostaglandin G₂, PGG₂) and its subsequent reduction to key intermediate, prostaglandin H₂ (PGH₂) needed for all prostaglandin biosynthesis.¹³⁸

Blockade of PGH₂ production, thus prevents its further conversion, by tissue-specific terminal prostaglandin synthases or isomerases, into different biologically active PGs

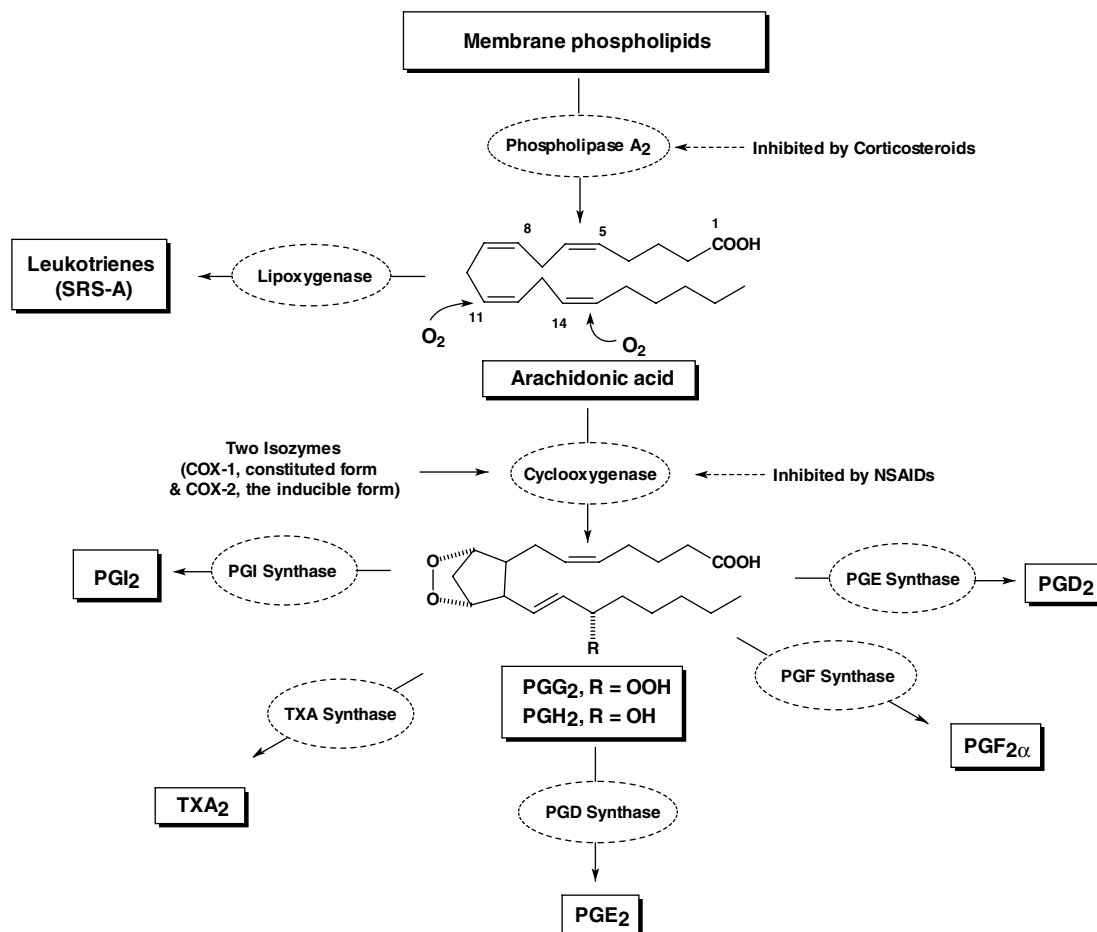

Figure 24.14 • Conversion of arachidonic acid to prostaglandins.

including PGE_2 , PGD_2 , $\text{PGF}_{2\alpha}$, PGI_2 (prostacyclin), and thromboxane A_2 (TXA_2) (Fig. 24.14).^{138,139}

Among the PGs synthesized by the action of either COX-1 or COX-2 isozymes, PGI_2 and PGE_2 made at the site of injury (via COX-2 isozyme in the inflammatory cells such as monocytes and macrophages) and also in the brain, are known to play a dominant role in mediating inflammation and inducing hyperalgesia.¹³² However, their synthesis in the GI tract (via COX-1 isozyme) and in the renal tubules (via COX-1 and COX-2 isozymes), is essential to provide cytoprotective action for restoring the integrity of the stomach lining and maintaining renal functions in an otherwise compromised kidney as a result of constant insult.^{132,138} Thus, inhibition of PGE_2 synthesis by the conventional NSAIDs in the parietal cells removes its ability to modulate histamine-mediated release of gastric acid from the parietal cells, whereas blockade of PGI_2 and PGE_2 synthesis in the epithelial cells in the stomach linings also prevents their action on the biosynthesis and release of bicarbonate and mucous gel desperately needed to repair damage resulting from erosion caused by gastric acid and other aggressive factors.^{127,129,132} Thus, it should not be surprising to note that NSAID-induced gastric ulcers can only be prevented clinically with coadministration of misoprostol, a stable PGE_2 analog, but not with either the histamine H_2 -antagonists, sucralfate, or any proton pump inhibitors such as omeprazole.¹²⁷ Furthermore, maintenance of kidney function,

especially in patients with congestive heart failure, liver cirrhosis, or renal insufficiency, is reliant on the action of PGI_2 and PGE_2 to restore normal renal blood flow. Thus, NSAID use (both COX-1 and COX-2 inhibitors) will increase the risk of renal ischemia and therefore is contraindicated in these patients.¹²⁹

The readers should consult Chapter 26 of this text on “Prostaglandins, Leukotrienes, and Other Eicosanoids” for a detailed discussion of PGs, their physiological and pathophysiological functions, and their corresponding PG receptors.

Structure-Activity Relationships of NSAIDs

It is well established that the therapeutic potency of the conventional NSAIDs are highly correlated with their ability to induce upper GI toxicity.¹²⁷ But, are all NSAIDs other than coxibs really equally effective in the treatment of pain and inflammation? Some insight might be found by exploring how these chemically diverse classes of drugs bind to their molecular targets (i.e., their selectivity for COX-2 relative to COX-1).¹⁴⁰ Thus, the benefit/risk profile of individual NSAIDs, as reflected by their COX selectivity, may be more clinically relevant for predicting the risk of GI complications. Table 24.1 summarizes a few representative drugs from different NSAID classes with their recommended daily

TABLE 24.1 Comparison of Relative Risk of NSAID-Induced Gastrointestinal Complication

Drug	Trade Name	Dosing Range (Total Daily Dose)	Relative Risk for GI complication	COX-2/COX-1 Selectivity Ratio
Not on NSAIDs or Aspirin			1.0	—
Celecoxib	Celebrex	100–200 mg BID ^a (200–400 mg)	—	0.7
Meloxicam	Mobic	7.5–15 mg daily	—	0.37

dosages and their relative risks of bleeding peptic ulcer complications.^{130,141,142}

ENZYMATIC STRUCTURE OF CYCLOOXYGENASES

Cyclooxygenases (COX-1 and COX-2) are heme-containing, membrane-bound proteins that share a high degree of sequence identity and also have very similar active site topography.^{138,143–145} Note that the homologous residues of the COX-2 isozyme are numbered in parallel with the similar amino acid residues found at the active site of COX-1 isozyme for easier comparison of their structural differences in the following discussion (i.e., the actual Arg-106 of human COX-2 [hCOX-2] is numbered as Arg-120).¹⁴³ The actual hCOX-2 assignments for these residues are provided in parentheses.

Thus, despite their similarity, the active site for hCOX-2 is approximately 20% larger than the COX-1 binding site because of the replacement of Ile-523 in COX-1 with a smaller Val-523 in hCOX-2 (Val-509).^{138,144,145} There are a total of 24 amino acid residues lining the largely hydrophobic AA binding site with only one difference between the isozymes (i.e., Ile-523 in COX-1 and Val-509 in hCOX-2). The hCOX-2 isozyme has an additional hydrophilic side pocket accessible for drug binding, extended from the main binding pocket.¹⁴³ The size and nature of this hydrophilic side pocket for binding in hCOX-2 is a result of further substitutions Ile-434 and His-513 in COX-1 with a smaller Val-434 (Val 420 in hCOX-2) and a more basic Arg-513 (Arg-499 in hCOX-2).¹⁴⁶ Thus, it is not surprising that this basic amino acid residue in hCOX-2 (Arg-499) may provide an additional binding interaction for selective COX-2 inhibitors such as celecoxib.¹⁴⁴ Although there is only a very limited amount of published data showing how the substrate, AA, binds to cyclooxygenases, the relative positioning of the double bonds in AA at the active site, proposed by Gund and Shen based on the conformational analysis of indomethacin and other conventional NSAIDs, is still currently valid.¹⁴⁷

Interestingly, Arg-120 (Arg-104 in hCOX-2) is the only positively charged amino acid residue in the COX active site, on one end of the active site as depicted by Luong^{144,148} and is responsible for binding, via an ionic interaction, with the carboxylate anion of the substrate

(AA) or the conventional NSAIDs. The amino acid residue Tyr-385 (Tyr-371 in hCOX-2) is located on the opposite end of the COX active site and is believed to serve as the catalytic residue for activating molecular oxygen and its initial addition to the Δ^{11} -double bond of the substrate to form PGG₂.^{143–148} Furthermore, the presence of an amino acid residue, Ser-530 (Ser-516 in hCOX-2) is believed to be involved only in the irreversible inactivation by aspirin and NSAID action but not contributing to any substrate binding.¹⁴³

BINDING OF NSAID TO CYCLOOXYGENASE

Most NSAIDs possess a free carboxylic acid (COOH) for an ionic interaction with the positively charged arginine residue at the active site of the cyclooxygenases (i.e., Arg-120 in COX-1 or Arg-106 in COX-2 isozymes). This acidic moiety is further linked to an aromatic (or heteroaromatic) ring for binding to either the Δ^5 -double-bond or Δ^8 -double-bond binding regions, and an additional center of lipophilicity in the form of an alkyl chain (e.g., ibuprofen) or an additional aromatic ring (e.g., indomethacin) for binding to the Δ^{11} -double-bond binding region.

A hypothetical binding model for indomethacin and related analogs to the COX-1 isozyme is shown in Figure 24.15-A, based on the crystallographic and SAR data found in the literature.^{146,149} The suggested orientation and placement of the *N-p*-chlorobenzoyl group to the Δ^{11} -double-bond binding region and the indole ring to the Δ^5 - and Δ^8 -double-bond binding regions is made from assuming that a preferred, lower-energy conformation of indomethacin is essential for its binding to COX isozymes¹⁴⁷, and the fact that this orientation also allows correct positioning of the amide carbonyl oxygen for possible binding interactions to Ser-530 and the 5-methoxy group to Ser-355 at the active site of the enzymes.¹⁴⁶

Additional support for this model can be obtained from the observation that the (*Z*)-isomer of sulindac, an indene isosteric analog of indomethacin, is much more potent than the corresponding (*E*)-isomer and the fact that replacement of the 5-methoxy group with a fluorine atom on the indole ring further enhances its analgesic action.^{145,149} Furthermore, because there is limited space available for

binding around either Leu-384 or Ile-523 (i.e., both around the Δ^{11} -double-bond binding region), it is not surprising to see a facile conversion of the indomethacin from a nonselective COX inhibitor into a potent and highly selective COX-2 inhibitor with just a simple substitution of the *p*-chlorine with a larger bromine atom or by addition of two chlorine atoms to the *o,o'* positions of the *N-p*-chlorobenzoyl group reported by Kalgutkar et al.¹⁵⁰ This observation can explain why a lower risk for GI complications was reported with sulindac than indomethacin, because it requires metabolic activation, via reduction of its bulky sulfoxide moiety into a much smaller methyl sulfide for binding into the Leu-384 pocket. The fact that kidneys possess a high level of the flavin-containing monooxygenases for deactivating the active metabolite of sulindac back into its inactive sulfoxide or sulfone, further provided evidence for this binding model.^{149,151}

With this binding model, it is also possible to see why the relative therapeutic potency of the conventional NSAIDs and their ability to induce GI complication is in the order: indomethacin > ketoprofen ~ diclofenac > naproxen > ibuprofen. Ibuprofen is the least potent because it can only bind to the Δ^2 -double-bond region with additional weak van der Waals interactions to the Δ^{11} -double-bond region. Naproxen is slightly more active than ibuprofen, because its naphthalene ring, isosteric to the indole ring, can interact with both the Δ^5 - and Δ^8 -double-bond regions. Ketoprofen and diclofenac are slightly less potent than indomethacin because of the absence of an additional ring for binding to either the Δ^5 - or the Δ^8 -double-bond regions.

BINDING OF CELECOXIB TO COX-2 ISOZYME

The hypothetical binding model for binding of celecoxib, the only selective “coxibs” type COX-2 inhibitor shown on Figure 24.15B, is purely speculative, based only on the crystallographic binding data reported for SC-558 (the *p*-bromophenyl analog of celecoxib) with the murine COX-2 isozyme.¹⁴⁶ However, the celecoxib selectivity toward the COX-2 isozyme is most likely a result of the extension of the sulfonamide moiety into the extra hydrophilic-binding pocket, surrounded by His-90 (His-76 in hCOX-2) and Arg-513 (Arg-499 in hCOX-2). The opening of this additional pocket for binding is the result of the replacement of Ile-523

in the COX-1 with a smaller valine residue (Val 509 in hCOX-2). It should be pointed out that a similar hydrophilic pocket does exist in the COX-1 isozyme, but it is inaccessible because of the bulkier Ile-523 residue that guards the entrance to this side pocket of the COX-1 isozyme (see Fig. 24.15-A).

The COX-2/COX-1 selectivity ratios, estimated by different research groups, can be quite different (e.g., the reported selectivity ratio for celecoxib ranges anywhere from 0.003–0.7; for piroxicam, the range is 3.3–600). Thus, the selectivity ratios included in Table 24.1, obtained from one such study, is only valid for comparing their differences among these NSAIDs. Furthermore, recent reviews comparing the SAR among different structural classes of COX-2 inhibitors have indicated that there is little or no common pharmacophore required for their COX-2 selectivity, but minor changes within the structure type, in terms of molecular shape, lipophilicity, electronic density, flexibility, polarity, and hydrogen-bonding properties, can all have drastic effects in its COX selectivity.^{152,153}

PIROXICAM AND MELOXICAM: THE DIFFERENCE IN THEIR COX SELECTIVITY

Piroxicam and meloxicam have nearly identical structural features but also have at least a ninefold difference in selectivity for meloxicam to COX-2 isozyme and an even larger difference in their relative risks for GI complications (i.e., piroxicam has the highest risk among NSAIDs, whereas meloxicam has very little or no such side effects) (Table 24.1). A closer comparison of their structure (Fig. 24.16), however, reveals no apparent reason for these differences, either in size, lipophilicity, or electronic properties, between the 2-pyridyl group (in piroxicam) and the 5-methyl-2-thiazoyl group (meloxicam) that may alter their ability to bind COX isozymes. It is unlikely that these drastic differences in their COX selectivity, especially the drug-induced GI toxicity, could be due solely to the binding of the parent molecules with such minor changes in their structures. Thus, could the observed differences, especially the differences in drug-induced GI side effects, be attributed to the involvement of an active metabolite of piroxicam and/or meloxicam?

The metabolism of piroxicam to its major active metabolite, 5'-hydroxypiroxicam and meloxicam to its

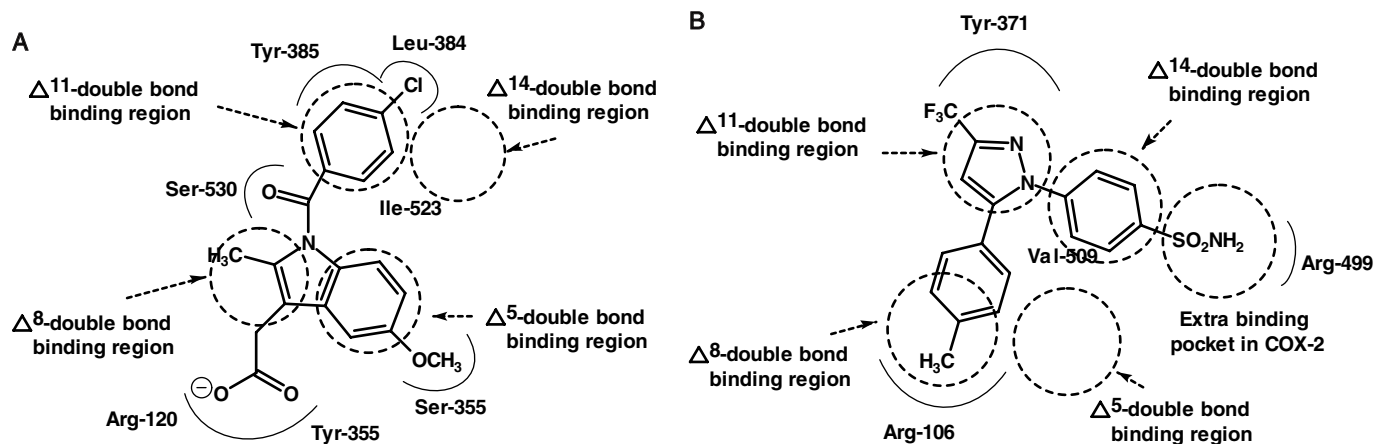

Figure 24.15 • Hypothetical binding models of indomethacin to COX-1 and Celecoxib to COX-2. **A.** Binding of the conventional NSAID, indomethacin, to the active site of COX-1; **B.** Binding of celecoxib, a selective COX-2 inhibitor to the active site of COX-2 with crystallographic maps suggested by Luong et al. (Flexibility of the NSAID binding site in the structure of human cyclooxygenase-2. *Nat. Struct. Biol.* 1996;3:927–933)

Figure 24.16 • Metabolism of piroxicam and meloxicam.

5'-hydroxy-methylmeloxicam and 5'-carboxymeloxicam metabolites are shown in Figure 24.16.^{154–156} Thus, with the proposed binding interaction of indomethacin described earlier (Fig. 24.15), it is reasonable to assume that the pyridyl group of the piroxicam or the 5'-hydroxypyridyl group of its active metabolite will be directed to bind to the Δ^{11} -double-bond binding region (especially the active metabolite caused by an additional H-bonding to the Tyr-385 residue), in a similar manner as the *N-p*-chlorobenzoyl group of the indomethacin. This would also allow the OH group of the acidic enol carboxamide moiety of the piroxicam or its active metabolite to position itself for binding to the Ser-530 residue of the COX-1 isozyme. However, a similar binding interaction of the active metabolites of meloxicam, especially the 5'-carboxy metabolite, to the active site of the COX-1 isozyme may not be possible, because it will reorient itself for a stronger ionic interaction with the Arg-120 of the COX-1 isozyme. Thus, they can fit only into the active site of the COX-2 isozyme because the binding of an acidic moiety to Arg-106 in the active site of the COX-2 isozyme is believed to play a lesser role in the inhibitory action of the COX-2 selective inhibitors like celecoxib¹⁵² (i.e., the most acidic moiety, sulfonamide is extended into the side pocket instead of binding to Arg-106).

ASPIRIN AND ITS COX-1 SELECTIVITY

Aspirin covalently modifies COX-1 and hCOX-2 isozymes by acetylating the OH group of Ser-530 in COX-1 and Ser-516 in hCOX-2 isozymes. This is made possible by an ionic attraction between the carboxylate anion of aspirin and the arginine cation of Arg-120 in COX-1 (or Arg-106 in hCOX-2), thereby positioning the acetyl group of aspirin for acetylating the COX isozymes. Even though both COX isozymes are irreversibly acetylated by aspirin, acetylation of Ser-530 totally blocks the accessibility of substrate AA from entering into the active site, whereas an acetylated hCOX-2 is still able to form a significant amount of PGG₂.¹⁴³ Thus, aspirin, among all conventional NSAIDs,

exhibits the highest selectivity toward the COX-1 isozyme, especially the COX-1 isozyme present in the platelets.

Aspirin and Salicylic Acid Derivatives

Aspirin and the salicylates were among the first group of NSAIDs introduced into medicine for their use as analgesics to relieve pain and as antipyretics to reduce fever.¹⁵⁷ As early as 1763, the Reverend Edward Stone of Chipping Norton in Oxfordshire, England reported the use of dried willow bark to parishioners suffering from rheumatic fever.^{129,158} The active ingredient of willow bark was isolated by Leroux, in 1827 and named salicin, which is a salicylic acid containing glycoside. After these discoveries, Cahours (1844) obtained salicylic acid from oil of wintergreen (methyl salicylate), and Kolbe and Lautermann (1860) prepared it synthetically from phenol. Sodium salicylate was introduced in 1875 by Buss, followed by the introduction of phenyl salicylate by Nencki in 1886. Aspirin, or acetylsalicylic acid, was first prepared in 1853 by Gerhardt but remained obscure until Felix Hoffmann from Bayer discovered its pharmacological activities in 1899. It was tested and introduced into medicine by Dreser (1899), who named it *aspirin* by taking the *a* from acetyl and *spirin*, an old name for salicylic or spiric acid, derived from its natural source of spirea plants.

Most of the salicylic acid drugs (commonly referred to as the salicylates) are either marketed as salts of salicylic acid (sodium, magnesium, bismuth, choline, or triethanolamine) or as ester or amide derivatives (aspirin, salsalate, salicylamide). (Fig. 24.17) Children, between the ages of 3 and 12, who are recovering from flu or chicken pox, should not be taking aspirin or any salicylates because of the perceived risks of a rare disease known as Reye syndrome.¹⁵⁹

MECHANISM OF ACTION OF SALICYLATES

Salicylates, in general, exert their antipyretic action in febrile patients by increasing heat elimination of the body via the mobilization of water and consequent dilution of

Figure 24.17 • Salicylates and their metabolism.

the blood. This brings about perspiration, causing cutaneous dilatation. This does not occur with normal temperatures. The antipyretic and analgesic actions are believed to work by inhibiting cyclooxygenase and reducing the levels of PGE₂, a proximal mediator of the febrile response, in the hypothalamic area of the brain that regulates body temperature.¹⁵⁷

It is well established that a low daily dose of aspirin (75–100 mg or one tablet of baby aspirin) is sufficient to completely block platelet TXA₂ production and its ability to induce platelet aggregation after only 1 week of dosing, thereby preventing the risk of a cardiovascular event, including myocardial infarction and ischemic stroke.^{160,161} This antiplatelet action of aspirin is because COX-2 is not expressed in platelets; therefore, aspirin can selectively and irreversibly inhibit platelet TXA₂ production for 8 to 10 days (i.e., until new platelets are formed) at such a low dose (i.e., via the irreversible acetylation of Ser-530 of the COX-1 isozymes discussed earlier). However, the analgesic, antipyretic, and anti-inflammatory action of aspirin is more complex and may involve other mechanisms of action than simply based on its ability to irreversibly inhibit the COX isozymes.^{157,162,163} Furthermore, it is worth noting that up to 50% of the oral analgesic dose of aspirin is rapidly deacetylated before it reaches general circulation, and its major active metabolite, salicylic acid, is found to have comparable *in vivo* antipyretic and anti-inflammatory properties to aspirin but is a very weak inhibitor of cyclooxygenases (i.e., *in vitro* binding studies).¹⁶⁴ Several possible mechanisms of action have recently been suggested for aspirin and especially the salicylates including blocking the induction of the COX-2 isozyme at the genetic levels,¹⁶⁵ turning off the

nuclear factor- κ B-mediated polymorphonuclear leukocyte apoptosis signaling^{166,167} or blocking the activation of the mitogen-activated kinase, Erk signaling associated with inflammatory responses.¹⁶⁸

PHARMACOKINETICS OF SALICYLATES

The salicylates, being acidic in nature, are readily absorbed from the stomach and the small intestine. However, their absorption depends strongly on the pH of the environment, thus coadministration of an antacid or other buffering agents should be avoided because it greatly hinders their absorption and reduces their bioavailability and onset of action. They are also highly bound to plasma proteins, a major source of potential drug interactions with other medications.

Salicylic acid undergoes extensive phase-II metabolism (see Fig. 24.17) and is excreted via the kidneys as the water-soluble glycine conjugate, salicyluric acid, the major metabolite (>75%) or as the corresponding acyl glucuronides (i.e., the ester type, via the COOH) or *O*-glucuronides (i.e., the ether type, via the phenolic OH) (~15%). Alkalinization of the urine increases the rate of excretion of the free salicylates.

Aspirin

Aspirin, acetylsalicylic acid (Aspro, Empirin), was introduced into medicine by Dreser in 1899.

Aspirin occurs as white crystals or as a white crystalline powder and must be kept under dry conditions. It is not advisable to keep aspirin products in the kitchen or bathroom cabinets, because aspirin is slowly decomposed into acetic and salicylic acids in the presence of heat and moisture. Several proprietaries (e.g., Bufferin) use compounds such as

sodium bicarbonate, aluminum glycinate, sodium citrate, aluminum hydroxide, or magnesium trisilicate to counteract aspirin's acidic property. One of the better antacids is dihydroxyaluminum aminoacetate. Aspirin is unusually effective when prescribed with calcium glutamate. The more stable, nonirritant calcium acetylsalicylate is formed, and the glutamate portion (glutamic acid) maintains a pH of 3.5 to 5. Practically all salts of aspirin, except those of aluminum and calcium, are unstable for pharmaceutical use. These salts appear to have fewer undesirable side effects and induce analgesia faster than aspirin. A timed release preparation of aspirin is available. It does not appear to offer any advantages over aspirin, except for bedtime dosage.

Aspirin is used as an analgesic for minor aches and pains and as an antipyretic to reduce fever. Although higher doses of aspirin can also be used to treat inflammation, its use is often associated with many unwanted side effects including ulcers, stomach bleeding, and tinnitus. A low dosage form of aspirin, 81 mg, equivalent to the dose recommended for infants (the "baby aspirin"), is recommended as a daily dose for individuals who are at even a low cardiovascular risk. Several large studies have found that this low dose of aspirin reduces the number of heart attacks and thrombotic strokes.^{160,161} Other salicylates and NSAIDs have not shown similar effects. In fact, a recent report indicated using ibuprofen can interfere with aspirin's cardiovascular benefits, and they should not be taken within 12 hours of each other.¹⁶⁹

Aspirin and other potent NSAIDs (except salicylates) are also known to precipitate asthma attacks and other hypersensitivity reactions in up to 10% of the patients who have any type of respiratory problems.¹⁷⁰ This hypersensitivity reaction is believed to occur as a result of shifting the substrate, AA from the inhibited cyclooxygenase pathway to the lipoxygenase pathway (see Fig. 24.14), therefore resulting in overproduction of anaphylactic leukotrienes because of the blockade of the cyclooxygenase pathway by aspirin and other potent NSAIDs.¹⁷¹

Salsalate

Salsalate, salicylsalicylic acid (Amigesic, Disalcid, Salflex), is the ester formed between two salicylic acid molecules. It is rapidly hydrolyzed to salicylic acid following its absorption. It reportedly causes less gastric irritation than aspirin, because it is relatively insoluble in the stomach and is not absorbed until it reaches the small intestine.

Diflunisal

Diflunisal (Dolobid), is a longer acting and more potent drug than aspirin because of its hydrophobic, 2,4-difluorophenyl group attached to the 5-position of the salicylic acid. In a large-scale comparative study with aspirin, it was also better tolerated with less GI complications than aspirin.¹⁷² It is marketed in tablet form for treating mild to moderate post-operative pain as well as RA and OA.

Diflunisal is highly protein bound. Its metabolism is subject to a dose-dependent, saturable, and capacity-limited glucuronide formation.¹⁷³ This unusual pharmacokinetic profile is a result of an enterohepatic circulation and the re-absorption of 65% of the drug and its glucuronides, followed by cleavage of its unstable, acyl glucuronide back to the active drug. Thus, diflunisal usage in patients with renal impairment should be closely monitored.

Sodium Salicylate

Sodium salicylate may be prepared by the reaction, in aqueous solution, by adding equal molar ratio of salicylic acid and sodium bicarbonate; evaporating to dryness yields the white salt. In solution, particularly in the presence of sodium bicarbonate, the salt will darken on standing. This is the salt of choice for salicylate medication and usually is administered with sodium bicarbonate to lessen gastric distress, or it is administered in enteric coated tablets. However, the use of sodium bicarbonate is ill advised, because it decreases the plasma levels of salicylate and increases the excretion of free salicylate in the urine.

Sodium salicylate, even though not as potent as aspirin for pain relief, also has less GI irritation and is useful for patients who are hypersensitive to aspirin.

OTHER SALTS OF SALICYLIC ACID

Sodium thiosalicylate (Rexolate) is the sulfur or thio analog of sodium salicylate. It is more soluble and better absorbed, thus allowing lower dosages. It is recommended for gout, rheumatic fever, and muscular pains, but it is available only for injection.

Magnesium salicylate (Mobidin, Magan) is a sodium-free salicylate preparation for use when sodium intake is restricted. It is claimed to produce less GI irritation.

Choline salicylate (Arthropan) is extremely soluble in water and is available as a flavored liquid. It is claimed to be absorbed more rapidly than aspirin, giving faster peak blood levels. It is used when salicylates are indicated. It is also available in combination with magnesium salicylate (Trilisate, Tricosal, Trisalcid, CMT) for the relief of minor to moderate pains and fever associated with arthritis, bursitis, tendinitis, menstrual cramps, and others.

Salicylamide

Salicylamide, *o*-hydroxybenzamide, is a derivative of salicylic acid that is fairly stable to heat, light, and moisture. It reportedly exerts a moderately quicker and deeper analgesic effect than aspirin because of quicker CNS penetration. Its metabolism differs from aspirin, because it is not metabolized to salicylic acid but rather excreted exclusively as the ether glucuronide or sulfate.¹⁷⁴ Thus, as a result of lack of contribution from salicylic acid, it has a lower analgesic and antipyretic efficacy than that of aspirin. However, it can be used in place of salicylates for patients with a demonstrated sensitivity to salicylates. It is also excreted much more rapidly than other salicylates, which accounts for its lower toxicity. It is available in several nonprescription products, in combination with acetaminophen and phenyltoloxamine (e.g., Rid-A Pain compound, Cetazone T, Dolorex, Ed-Flex, Lobac) or with aspirin, acetaminophen, and caffeine (e.g., Saleto, BC Powder).

The Conventional Nonselective Cyclooxygenase Inhibitors

With the removal of rofecoxib (Vioxx) from the market and the concern of cardiovascular risk associated with celecoxib (Celebrex), the conventional NSAIDs, being more potent than aspirin and related salicylates, once again become the drug of choice for the treatment of RA and other inflammatory diseases.¹³⁰ The conventional NSAIDs vary considerably in terms of their selective inhibitory action for COX-2 relative to COX-1 isozymes and also their relative

drug-induced toxicities discussed earlier in this text. Although several drugs in this class are available OTC, they are no safer than prescription medications with regard to their drug-induced GI liability.¹²⁷ The conventional NSAIDs, as a group, are highly protein bound and exhibit both pharmacokinetic as well as pharmacodynamic interactions with many drugs, especially anticoagulants, diuretics, lithium, and other arthritis medications.

For the purpose of comparing their SAR, toxicity, and metabolic biotransformations, the conventional NSAIDs are further divided into several chemical classes.

ARYL- AND HETEROARYLACETIC ACIDS

This group of NSAIDs has received the most intensive attention for new clinical candidates. As a group, they show high analgesic potency in addition to their potent anti-inflammatory activity, needed for treating inflammatory diseases. Among the members of this class shown in Figure 24.18, ketorolac, indomethacin, and tolmetin have the highest risk of GI complications because of their higher affinity for the COX-1 isozymes, whereas etodolac has the lowest risk because of its COX-2 selective inhibitory action. Both sulindac and nabumetone are prodrugs that require activation, and therefore have lower risk of causing GI irritation than indomethacin.¹³⁰

Indomethacin

From the time of its introduction in 1965, indomethacin (Indocin) has been widely used as an analgesic to relieve inflammatory pain associated with RA, OA and ankylosing spondylitis, and, to a lesser extent, in gout. Although both its analgesic and anti-inflammatory activities are well established, its use is often limited because of frequent GI distress and potential drug interactions, especially with warfarin furosemide, and lithium (i.e., it elevates blood levels of

lithium as a result of reducing renal blood flow and therefore increases lithium toxicities).

Following oral administration, indomethacin is rapidly absorbed and is 90% protein bound at therapeutic plasma concentrations.¹⁷⁵ The drug has a biological half-life of about 5 to 10 hours and a plasma clearance of 1 to 2.5 ml/kg per minute. It is metabolized to its inactive, *O*-desmethyl, *N*-deschlorobenzoyl-, and *O*-desmethyl, *N*-deschlorobenzoylindomethacin metabolites.¹⁷⁵

Sulindac

Sulindac, (*Z*)-5-fluoro-2-methyl-1-([*p*-(methylsulfinyl)phenyl]methylene)-1*H*-indene-3-acetic acid (Clinoril), is an NSAID prodrug that contains a chiral sulfoxide moiety but is marketed as the racemate because it undergoes *in vivo* reduction by the hepatic enzymes into its achiral, active metabolite, methyl sulfide that exhibits potent and nonselective COX inhibition similar to indomethacin.¹⁵¹

The parent sulfoxide has a plasma half-life of 8 hours, and the active methyl sulfide metabolite is 16.4 hours. The more polar and inactive sulfoxide is virtually the only form excreted into the renal tubules, thus sulindac is believed to have minimal nephrotoxicity associated with indomethacin.¹⁷⁶ The long half-life of sulindac is caused by the extensive enterohepatic circulation and reactivation of the inactive sulfoxide excreted. Coadministration of aspirin is contraindicated because it considerably reduces the sulfide blood levels. Careful monitoring of patients with a history of ulcers is recommended. Gastric bleeding, nausea, diarrhea, dizziness, and other adverse effects have been noted with sulindac, but with a lower frequency than with aspirin. Sulindac is recommended for RA, OA, and ankylosing spondylitis.

Tolmetin

Tolmetin sodium (Tolectin), is an arylacetic acid derivative with a pyrrole as the aryl group. This drug is well absorbed

Figure 24.18 • Aryl- and heteroarylacetic acid derivatives.

and has a relatively short plasma half-life (1 hour). It is recommended for use in the management of acute and chronic RA. Its efficacy is similar to aspirin and indomethacin, but with less frequency of the adverse effects and tinnitus associated with aspirin. It does not potentiate coumarin-like drugs nor alter the blood levels of sulfonylureas or insulin. However, tolmetin, and especially its closely related drug, zomepirac (i.e., with a *p*-chlorobenzoyl group and an additional methyl group on the pyrrole ring), can produce a rare but fatal anaphylactic reaction because of irreversible binding of their unstable acyl glucuronides.¹⁷⁷ Zomepirac was withdrawn from market because it is eliminated only via the ester-type, acyl glucuronide.¹⁷⁸ It is possible that tolmetin is less toxic in this regard because it undergoes additional hepatic benzylic hydroxylation via its *p*-methyl group and is excreted as its stable ether glucuronide.

Ketorolac

Ketorolac tromethamine (Toradol), marketed as a mixture of (R)- and (S)-ketorolac enantiomers, is a potent NSAID analgesic indicated for the treatment of moderately severe, acute pain. It should be noted that the pharmacokinetic disposition of ketorolac in humans is subject to marked enantioselectivity. Thus, it is important to monitor the individual blood levels so an accurate assessment of its therapeutic action can be made correctly.¹⁷⁹ However, it should be noted that, being one of the conventional NSAIDs with highest risk of GI complications, its administration should not exceed 5 days.

Nabumetone

Nabumetone (Relafen), a nonacidic NSAID prodrug, is classified as an arylacetic acid, because it undergoes rapid hepatic metabolism to its active metabolite, 6-methoxy-2-naphthylacetic acid.¹⁸⁰ Similar to the other arylacetic acid drugs, it is used in short- or long-term management of RA and OA. Being nonacidic, it does not produce significant primary insult to the GI mucosa lining and also has no effect on prostaglandin synthesis in gastric mucosa, thus producing minimum secondary GI damage when compared with other conventional NSAIDs.

Etodolac

Etodolac (Lodine, Ultradol), a chiral, COX-2 selective NSAID drug that is marketed as a racemate, possesses an indole ring as the aryl portion of this group of NSAID drugs. It shares many similar properties of this group and is indicated for short- and long-term management of pain and OA.

Similar to ketorolac, etodolac exhibits several unique enantioselective pharmacokinetic properties.¹⁸¹ For example, the "inactive" (R)-enantiomer has approximately a 10-fold higher plasma concentration than the active (S)-enantiomer. Furthermore, the active (S)-enantiomer is less protein bound than its (R)-enantiomer and therefore has a very large volume of distribution. It is well absorbed with an elimination half-life of 6 to 8 hours. Etodolac is extensively metabolized into three major inactive metabolites, 6-hydroxy etodolac (via aromatic hydroxylation), 7-hydroxy-etodolac (via aromatic hydroxylation), and 8-(1'-hydroxyethyl) etodolac (via benzylic hydroxylation), which are eliminated as the corresponding ether glucuronides.¹⁸² Its unstable, acyl glucuronide, however, is subject to enterohepatic circulation and reactivation to the parent drug, similar to other NSAIDs in this class.

In a recent study comparing its gastric safety profile with those of meloxicam, diclofenac, and indomethacin, etodolac

was found to have the highest safety index among these NSAIDs in arthritic rats.¹⁸³ Thus, etodolac is an example of a COX-2 selective drug with a much better safety profile among the first generation of NSAIDs developed through the traditional route of using only animal model studies. Its selective COX-2 inhibitory action, which was not realized until much later, explains its much lower risk of the GI side effects among first-generation NSAIDs.

Amfenac, Bromfenac, and Nepafenac

Amfenac (Fenazox), its amide prodrug, nepafenac (Nevanac), and the related analog, bromfenac, are amphoteric because of the presence of an additional aromatic amine group. They are less likely to be absorbed into the general circulation. They are approved for use as topical ocular anti-inflammatory agents for the treatment of postoperative ocular pain, inflammation, and posterior segment edema.¹⁸⁴ The only observed side effects of these drugs are all related to tissues around the eye including abnormal ocular sensation, eye redness and irritation, burning and stinging, and conjunctival or cornea edema.

ARYL- AND HETEROARYLPROPANOIC ACIDS

These are perhaps the most widely used drugs worldwide because three members of this class, ibuprofen, naproxen, and ketoprofen, are now available without a prescription (Fig. 24.19). Their indiscriminate use, however, by the general public without a doctor's prescription, has resulted in an increased incidence of complications in adolescents, including acute and chronic renal failure.¹⁸⁵

All of the members of this class (except oxaprozin) contain a chiral carbon in the α -position of the acetic acid side chain. Even though most are marketed as racemates, only the (S)-enantiomer was found to have any inhibitory activity against the COX isozymes. Thus, the (S)-enantiomer is believed to be solely responsible for the observed therapeutic action as well as the drug-induced GI side effects and nephrotoxicity. Furthermore, in most cases, the inactive (R)-enantiomer is epimerized in vivo, via the 2-arylpropionyl coenzyme-A epimerase to its active (S)-enantiomer.¹⁸⁶

Ibuprofen

Ibuprofen, 2-(4-isobutylphenyl)propionic acid (Motrin, Advil, Nuprin), was introduced into clinical practice following extensive clinical trials. It appears to have comparable efficacy to aspirin in the treatment of RA, but with a lower incidence of side effects. It has also been approved for use in the treatment of primary dysmenorrhea, which is thought to be caused by an excessive concentration of PGs and endoperoxides.¹⁸⁷ However, a recent study indicates that concurrent use of ibuprofen and aspirin may actually interfere with the cardioprotective effects of aspirin, at least in patients with established cardiovascular disease.¹⁶⁹ This is because ibuprofen can reversibly bind to the platelet COX-1 isozymes, thereby blocking aspirin's ability to inhibit TXA₂ synthesis in platelets.

Naproxen

Naproxen (Naprosyn, Anaprox), marketed as the (S)-enantiomer, is well absorbed after oral administration, giving peak plasma levels in 2 to 4 hours and a half-life of 13 hours. Naproxen is highly protein bound and displaces most protein-bound drugs. It is recommended for use in RA, OA,

Figure 24.19 • Aryl- and heteroarylpropionic acids.

acute gouty inflammation, and in primary dysmenorrhea. It shows good analgesic activity (i.e., 400 mg is comparable to 75–150 mg of oral meperidine and superior to 65 mg of propoxyphene and 325 mg of aspirin plus 30 mg of codeine). It is also available OTC as 200-mg tablets (Aleve).

Fenoprofen

Fenoprofen (Nalfon), is rapidly absorbed orally, reaches peak plasma levels within 2 hours, and has a short plasma half-life (3 hours). It is highly protein bound, just like the other NSAIDs, thus caution is needed when it is used concurrently with other medications including hydantoin, sulfonamides, and sulfonyleureas. It is recommended for RA and OA, at an oral dose of 300 to 600 mg for 3 or 4 times per day, but not exceeding 3 g/d to avoid any serious side effects. It should be noted that in a comparison study of all NSAIDs, fenoprofen is the one that has been most closely associated with a rare acute interstitial nephritis.¹⁸⁸ For mild to moderate pain relief, the recommended dosage is 200 mg given every 4 to 6 hours, as needed.

Ketoprofen and Suprofen

Ketoprofen (Orudis, Rhodis) and suprofen (Profenal) are closely related to fenoprofen in their structures, properties, and indications. Even though ketoprofen has been approved for OTC use (Orudis KT, Actron), its GI side effects are similar to indomethacin (Table 24.1), and therefore its use should be closely monitored, especially in patients with GI or renal problems.

Flurbiprofen

Flurbiprofen (Ansaid, Ocufen, Froben), is another drug in this class indicated for both acute and long-term management of RA and OA but with a more complex mechanism of action. Unlike the other drugs in this class, it does not undergo chiral inversion (i.e., the conversion of the “inactive” [R]-enantiomer to the active, [S]-enantiomer). Similar to aspirin and other salicylates, both flurbiprofen enantiomers block COX-2 induction as well as inhibiting the nuclear factor- κ B-mediated polymorphonuclear leukocyte apoptosis

signaling¹⁸⁹; therefore, both enantiomers are believed to contribute equally to its overall anti-inflammatory action.

(R)-flurbiprofen is actually a strong clinical candidate for the treatment of Alzheimer disease, because it has been shown to reduce A β 2 production by human cells.¹⁹⁰

Oxaprozin

Oxaprozin, 4,5-diphenyl-2-oxazolepropionic acid (Daypro), differs from the other members of this group in being an arylpropionic acid derivative. It shares the same properties and side effects of other members in this group. It is indicated for the short- and long-term management of OA and RA, administered as a once-daily dose of 600- to 1,200-mg dose because of its long duration of action.¹⁹¹

N-ARYLANTHRANILIC ACIDS (FENAMATES) AND STRUCTURALLY RELATED ANALOGS

This class of NSAIDs shares one common structural feature that is not present in the other classes discussed earlier. Unlike other classes discussed earlier, the second aromatic ring in this class is connected to the main aromatic carboxylic acid containing ring through a secondary amine linkage (rather than carbonyl group or other nonbasic linker) and at the ortho position rather than at the meta or para position (see their structures in Fig. 24.20). As a result of this structural feature, this class of NSAIDs appears to have a lower risk of causing GI irritation. Recent crystallographic evidence suggests that diclofenac binds to COX isozymes in an inverted conformation with its carboxylate group hydrogen-bonded to Tyr-385 and Ser-530.¹⁹² This finding provides a reason why diclofenac and especially its related analog, lumicoxib, have much greater selectivity toward COX-2 isozymes.

Mefenamic Acid

Mefenamic acid (Ponstel, Ponstan) is one of the oldest NSAIDs, introduced into the market in 1967 for mild to moderate pain and for primary dysmenorrhea. It is rapidly

Figure 24.20 • Fenamates and metabolism of diclofenac.

absorbed with peak plasma levels occurring 2 to 4 hours after oral administration. It undergoes hepatic benzylic hydroxylation of its 3'-methyl group regioselectively into two inactive metabolites, 3'-hydroxymethylmefenamic acid and the 3'-carboxylate metabolite (via further oxidation of the benzylic alcohol group). The parent drugs and these metabolites are conjugated with glucuronic acid and excreted primarily in the urine. Thus, although patients with known liver deficiency may be given lower doses, it is contraindicated in patients with preexisting renal dysfunction.

Common side effects associated with its use include diarrhea, drowsiness, and headache. The possibility of blood disorders has also prompted limitation of its administration to 7 days. It is not recommended for children or during pregnancy.

Meclofenamate

Meclofenamate sodium (Meclomen) is available for use in the treatment of acute and chronic RA, OA, and primary dysmenorrhea. It is metabolized in a similar manner to mefenamic acid discussed above, thus a similar restriction is also applied to meclufenamate. The most significant side effects are GI, including diarrhea.

Diclofenac and Lumiracoxib

Diclofenac sodium (Voltaren), is indicated for short- and long-term treatment of RA, OA, and ankylosing spondylitis. The potassium salt (Cataflam), which is faster acting, is indicated for the management of acute pain and primary dysmenorrhea. Diclofenac was first marketed in Japan in 1974 but was not approved for its use in the United States until 1989, perhaps because of concerns about its hepatotoxicity. Diclofenac is also available in combination with misoprostol (Arthrotec).

Unlike the other NSAIDs, diclofenac appears to be more hepatotoxic and, in rare cases, can cause severe liver damage. This idiosyncratic hepatotoxicity has been attributed to the formation of reactive benzoquinone imines, similar to acetaminophen, which will be discussed later.¹⁹³ Diclofenac undergoes hepatic CYP2C9/3A4 catalyzed aromatic hydroxylations to give 4'-Hydroxy-diclofenac as its major inactive metabolite (~30%) and 5-hydroxy- and 4',5-dihydroxy-diclofenac as its minor metabolites (Fig. 24.20). These hydroxylated metabolites are excreted, normally, such as their glucuronides. Similar to that of acetaminophen, both the 4' and 5-hydroxylated metabolites can be further activated to their reactive quinone imines (not shown in the

Figure), which are normally deactivated by glutathione, the host defensive mechanism, to its inactive glutathione conjugates shown in Figure 24.20. Thus, it is reasonable to assume that patients with low levels of glutathione are more susceptible to diclofenac toxicity, and their use in these patients should be avoided.

Lumiracoxib (Prexige), one of the most COX-2 selective inhibitors marketed in Australia (2004), the United Kingdom (2005), and the United States (2007), was the mainstay of therapy for OA, RA, and acute pain. It differs from diclofenac with an additional methyl substituted onto the 5-position of phenylacetic acid ring. It is extensively metabolized by CYP2C9, just like diclofenac, into three major inactive metabolites, 5-carboxy, 4'-hydroxy, and 4'-hydroxy-5-carboxy derivative, through the oxidation of the 5-methyl group and hydroxylation of the dichloroaromatic ring.¹⁹⁴ Although no evidence of formation of potentially reactive metabolites was reported, the 4'-hydroxy derivatives are the major inactive metabolites eliminated (as the glucuronides), so it is not surprising to learn that lumiracoxib was withdrawn from market in October, 2007 because of several cases of serious adverse liver reactions to the drug, including two deaths and two liver transplants. Thus, patients with low glutathione levels or glucuronyl transferase activity as a result of drug interactions or aging are susceptible for forming reactive metabolites that are not found with healthy individuals, the subjects used in the original metabolic study.¹⁹⁴

OXICAMS

Oxicams, are first-generation NSAIDs that lack a free carboxylic acid side chain but with an acidic enolic 1,2-benzothiazine carboxamide ring (see Fig. 24.16). Only two members of this class, piroxicam and meloxicam, are available in the United States for the management of inflammatory arthritis. Tenoxicam (Mobiflex), a close isosteric analog of piroxicam (i.e., with a 1,2-thiazole ring replacing the benzene ring fused to the thiazine ring), is available in Canada but with a pharmacodynamic and pharmacokinetic profile similar to piroxicam. As discussed earlier, piroxicam and meloxicam have very different affinities for the COX isozymes, and therefore exhibit very different risks for GI complications.

Piroxicam

Piroxicam (Feldene) is the most widely used oxicam because of its once-daily dosing schedule. It is well absorbed after oral administration and has a plasma half-life of 50 hours, thus requiring a dose of only 20 to 30 mg once daily.¹⁹⁵ It undergoes extensive hepatic metabolism, catalyzed by CYP2C9 to give 5-hydroxyiroxicam as its major metabolite (See Fig. 24.16).¹⁵⁴ Several piroxicam prodrugs have been synthesized via derivatization of the enol alcohol group (amipiroxicam, droxicam, and pivoxicam) to reduce piroxicam-induced GI irritation.¹⁹⁵

Meloxicam

Meloxicam (Mobic) is a selective COX-2 inhibitor among oxicams indicated for use in RA and OA. It also has a relatively long half-life of 15 to 20 hours and has a much lower rate of serious GI side effects and a lower than average risk of nephropathy when compared with other conventional NSAIDs.¹⁹⁶ The recommended dose is 7.5 mg once daily with a maximum of 15 mg/d. Meloxicam is metabolized in humans mainly by CYP2C9 (with a minor contribution via

CYP3A4) to 5'-hydroxymethylmeloxicam and 5'-carboxymeloxicam (see Fig. 24.16).¹⁵⁶

In large-scale comparative trials, meloxicam was found to be at least as effective as most conventional NSAIDs in the treatment of rheumatic disease or postoperative pain, but has demonstrated a more favorable GI tolerability profile.¹⁵⁸

The Selective COX-2 Inhibitors

As stated earlier, the development and hasty market introduction of the first selective coxibs drugs, celecoxib (Celebrex), and rofecoxib (Vioxx) in 1999, was based on Vane's^{133,134} hypothesis that blocking an inducible COX-2 isozyme retains all of the therapeutic effects but none of the side effects of the conventional NSAIDs. Shortly after their market introduction, the results of a preliminary Vioxx gastrointestinal outcomes research (VIGOR) trial was reported in 2000 that raised concern and much debate on the cardiovascular safety of all selective COX-2 inhibitors.^{135–137,197} Several additional coxibs drugs including valdecoxib (Bextra), etoricoxib (Arcoxia), and parecoxib sodium (Dynastat), were introduced into the worldwide market during 2002. The potential cardiovascular risk was not taken seriously until late 2004 when rofecoxib (Vioxx) was voluntarily withdrawn from the worldwide market, based on an additional risk assessment from a 3-year randomized, placebo-controlled, double-blind clinical trial.¹⁹⁷ To date, all but the least potent of COX-2 drugs, celecoxib (Celebrex), have been removed from the worldwide market, therefore depriving an otherwise, rational choice of pain medications, especially for arthritic patients who are at higher risk of serious GI complications.¹³⁷

An overexpression of COX-2 was found in multiple cancer types, especially in colorectal cancer,^{198,199} thus future roles of the selective COX-2 inhibitors may be realized in the chemoprevention of cancers and other inflammatory degenerative diseases. The reader should consult several excellent reviews on these latest developments.^{200–202}

CELECOXIB

Celecoxib (Celebrex) was the first selective COX-2 inhibitor drug introduced into the market in 1998 for use in the treatment of RA, OA, acute pain, and menstrual pain. The real benefit is that it has caused fewer GI complications when compared with other conventional NSAIDs. It has also been approved for reducing the number of adenomatous colorectal polyps in familial adenomatous polyposis (FAP).

Celecoxib is well absorbed and undergoes rapid oxidative metabolism via CYP2C9 to give its inactive metabolites (Fig. 24.21).²⁰³ Thus, a potential drug interaction exists between celecoxib and warfarin because the active isomer of warfarin is primarily degraded by CYP2C9.

The Analgesic Antipyretics: Acetaminophen (Paracetamol) and Related Analogs

From a historical perspective, acetaminophen (paracetamol) and the related analgesic antipyretic drugs such as acetanilide, antipyrine, and dipyron were introduced into the market about the same time as aspirin and the other salicylates (i.e., acetanilide, 1886; phenacetin, 1887; and acetaminophen, 1893).²⁰⁴ They were once the most widely used analgesic

Figure 24.21 • Metabolic biotransformation of celecoxib.

antipyretics for relieving pain and reducing fever because, unlike aspirin and salicylates, they do not cause ulceration or increase bleeding time.²⁰⁴ Among these agents, phenacetin was once a very popular analgesic antipyretic drug, more so than acetaminophen, because it was perceived to be safer than acetaminophen toward the stomach (i.e., less acidic in nature). Its use was continued until the late 1970s, even though Brodie and Axelrod had already reported in 1949 that acetaminophen was the active metabolite of acetanilide and phenacetin.²⁰⁵ In their elegant studies, acetanilide was found to undergo hepatic metabolism (i.e., via an aromatic hydroxylation) to acetaminophen, whereas only a small amount of the drug was hydrolyzed to give aniline, which can be further *N*-hydroxylated to phenylhydroxylamine, the compound believed to be responsible for acetanilide toxicity because of methemoglobin formation. Phenacetin, on the other hand, was found to undergo mostly *O*-dealkylation to acetaminophen, whereas a small amount was converted by deacetylation to *p*-phenetidine, also responsible for methemoglobin formation.

Phenacetin only fell out of favor around 1980 when it was found to cause renal and urinary tract tumors in experimental animal models.²⁰⁶ Because of the toxicity described above, both acetanilide and phenacetin are now no longer available, thus acetaminophen is the only drug in this class that is still widely used worldwide because it is a safer and better tolerated pain medication.

MECHANISM OF ACTION: ACETAMINOPHEN AND THE COX-3 PUZZLE

Acetaminophen and other analgesic antipyretics have similar analgesic and antipyretic efficacies to the conventional NSAIDs such as aspirin, ibuprofen, or diclofenac. However, unlike the conventional NSAIDs, they lack the antiplatelet effects of aspirin or the GI side effects associated with NSAIDs. Acetaminophen also has little or no anti-inflammatory properties.^{207–209} Although it has been in use for nearly a century, the mechanism of action of acetaminophen and related analgesic antipyretics remains unknown, but it is generally assumed that they work centrally by blocking a

brain-specific enzyme, perhaps a COX-3 isozyme, responsible for the biosynthesis of prostaglandin.²¹⁰

In 2002, Simmons et al.,²¹¹ through cloning studies, identified a distinct variant of the canine COX-1 isozyme found only in the canine brain, which was designated as the COX-3 isozyme and hypothesized this isozyme as the target for acetaminophen and related analgesic-antipyretic drugs because this isozyme was selectively inhibited by acetaminophen, phenacetin, antipyrine, and dipyrone. This hypothesis was further supported by the findings that acetaminophen produces analgesia and induces hypothermia centrally and that both of these actions are accompanied by a dose-dependent reduction of brain PGE₂ levels that is not observed with diclofenac, a conventional NSAID.²⁰⁹ In addition, the peripheral levels of PGE₂/PGI₂ levels were reduced only by diclofenac but not by acetaminophen.²¹⁰ Moreover, acetaminophen-induced hypothermia was reduced in COX-1 but not COX-2 gene-deleted animal studies.^{209,212} These observations appear to provide additional support for hypothesis that the analgesia and hypothermia of acetaminophen are indeed mediated by inhibition of a distinct COX isozyme present only in the brain. However, most of the recent studies focusing on finding this elusive human COX-3 isozyme have not been successful.^{207,213,214} Moreover, a similar COX-1 variant identified and expressed in humans (this isozyme was designated as COX-1b) was not inhibited by acetaminophen even though it is active in catalyzing PGH₂ synthesis in the brain. Thus, although the COX-3 isozyme may indeed be the molecular target responsible for acetaminophen action in canines, its role in humans is still unproven.^{213,214}

In a recent commentary, Aronoff et al.²⁰⁸ suggested an alternative target (mechanism) by which acetaminophen (APAP) blocks the cyclooxygenase action. Their hypothesis is based on the fact that acetaminophen acts as a reducing co-substrate, thus actively competing with PGG₂ for its conversion to PGH₂, catalyzed by the peroxidase (POX) action of COX enzymes. Figure 24.22 summarizes some of the key mechanism of COX's action suggested by Aronoff et al.²⁰⁸ and includes the additional hypothesis suggested by Gram and Scott²¹⁵ that acetaminophen acts by depleting the stores

Figure 24.22 • Mechanism of action of acetaminophen on PGH₂ synthesis.

of glutathione (GSH), which is a known cofactor for PGE synthase. Thus, with this illustration, it is now possible to see why acetaminophen's action depends on the level of peroxide generated in solution (i.e., PGG₂ and other lipid peroxides, generated by the lipoxygenase pathway), and its effectiveness varies with COX activity.²⁰⁷ At low peroxide concentrations, acetaminophen can compete effectively with the electron transfer mechanism between the Tyr-385 residue and the heme radical, which generates the tyrosine radical in the active site of COX enzymes for the production of PGG₂, it also prevents the regeneration of Fe (IV) (APAP causes the formation of Fe (III), thus ↓ activity of POX), a process that is essential for starting a new POX cycle as shown in Fig. 24.22. However, acetaminophen is ineffective during inflammation because the higher concentration of PGG₂ or other peroxides, produced in the inflamed cells as a consequence of induction of the COX-2 isozyme and lipoxygenase, can overcome the acetaminophen inhibition by degrading acetaminophen in the synovial fluids as depicted in Figure 24.22 (i.e., conversion of APAP to its inactive glutathione conjugate shown).

This mechanism would also explain the recent findings that acetaminophen, unlike NSAIDs, cannot inhibit COX activity in broken cells, and the observation that only the

inhibitory effects of acetaminophen, not indomethacin or diclofenac, were abolished by increasing intracellular oxidation conditions with the addition of cell-permeable hydroperoxide, *t*-butyl-OOH.²¹⁶ This hypothesis would also provide an additional reason why depletion of glutathione is the main cause of acetaminophen toxicity discussed under the next section. In summary, APAP does not compete with AA for the binding site on the COX enzyme. Its mechanism of action is via inhibiting the peroxidase activity of the COX enzyme.

TOXICITY IN ACETAMINOPHEN AND PHENACETIN

Acetanilide and phenacetin can be metabolized to reactive hepatotoxic and renal toxic metabolites by various mechanisms.²¹⁷ Readers should consult a more detailed discussion in the drug metabolism chapter of this text. Figure 24.23 summarizes only the salient features for the purpose of discussing phenacetin/acetaminophen-induced liver and renal toxicities.

Acetanilide and phenacetin are hydroxylated or *O*-dealkylated, respectively via CYP1A2 to their active metabolite, acetaminophen.²⁰⁶ In healthy individuals, acetaminophen is primarily eliminated as its *O*-sulfates and *O*-glucuronides, with only a small amount of the

Figure 24.23 • Metabolic activation of acetaminophen and phenacetin.

N-hydroxylated metabolite (via CYP2E1/CYP3A4 isozymes), which can be sulfated or glucuronidated.^{217,218} Small amounts of these *O*-sulfates, if accumulated in liver or renal tubules, can slowly rearrange to form the reactive *N*-acetyliminoquinone metabolites, shown in Figure 24.23. However, these reactive metabolites, once formed, are immediately deactivated by glutathione, the body's defense mechanism for detoxifying reactive metabolites.

In contrast, a similar *N*-*O*-sulfate of phenacetin will immediately rearrange to this reactive metabolite, *N*-acetyliminoquinone, whereas the corresponding *N*-*O*-glucuronide can also be slowly converted to this reactive metabolite.²¹⁷ Thus, it is not surprising that acetaminophen is a much safer drug than phenacetin with regard to their relative toxicities (i.e., with occasional use, most of acetaminophen is eliminated as its *O*-sulfates and *O*-glucuronides). However, it should be pointed out that acetaminophen-induced toxicity can be greatly increased by concurrent use of alcoholic beverages, especially in alcoholic individuals. This is because both CYP2E1 and CYP3A4 isozymes are induced by alcohol consumption.²¹⁸ Moreover, heavy caffeine use, together with alcohol, would further increase the risk of alcohol-mediated acetaminophen hepatotoxicity.²¹⁹ *N*-acetylcysteine is typically given as an antidote to treat possible acetaminophen poisoning even before plasma levels of acetaminophen are determined. Similar to glutathione, it deactivates the *N*-acetyliminoquinone metabolite before it changes to covalently bind cellular proteins (Fig. 24.23).

ACETAMINOPHEN

Acetaminophen (also known as paracetamol, APAP), a well established analgesic/antipyretic drug, is frequently used by itself OTC (Panado, Tempra, Tylenol) or in combination with codeine (Tylenol 3), hydrocodone (Vicodin), or oxycodone (Percocet) for the treatment of mild to moderate pain and to reduce fever. It is available in several nonprescription forms and is also marketed in combination with aspirin and caffeine (Excedrin, Vanquish).

Unlike aspirin or ibuprofen, acetaminophen is well tolerated with a low incidence of GI side effects. It also has good oral bioavailability, a fast onset and a plasma half-life of approximately 2 hours after dosing. Although it is a relatively safe pain medication, several precautions should be recognized, including not exceeding the recommended maximum dosage of 4 g/d. A lower daily dose of less than 2 g/d is required in patients who are chronic alcoholics or have renal complications.²²⁰

DISEASE-MODIFYING ANTIRHEUMATIC DRUGS

RA is one of the most common chronic, inflammatory autoimmune diseases, affecting approximately 1% of the world's adult population.²²¹ It is characterized by persistent inflammation of the synovial lining of the joints that causes

pain, swelling, and stiffness of the upper and lower extremities. RA, if left untreated, can lead to permanent joint cartilage and bone damage that eventually results in disability and a significant impairment of quality of life.^{221,222} A typical treatment of RA may involve a combination of physical and drug therapy including aspirin, other NSAIDs, or glucocorticoids initially to provide symptomatic relief of pain and swelling, and one or more of the disease-modifying antirheumatic drugs (DMARDs) to slow down the underlying disease progression and to limit further joint damage.^{223,224}

DMARDs, sometime also referred to as the “slow-acting antirheumatic drugs,” include a diverse class of synthetic drugs such as methotrexate, hydroxychloroquine, sulfasalazine, leflunomide, azathioprine, organic gold compounds, or immunobiologicals useful for treating the persistent inflammatory conditions associated with RA. DMARDs have very different mechanisms of action that allow physicians to individualize treatment strategies to slow down the clinical and radiographic progression of RA,

even though it takes between 6 weeks to 6 months to fully realize any of their therapeutic effects.^{222,224–226}

In this chapter, only a few of the commonly used synthetic DMARDs are covered to exemplify different treatment strategies. Readers interested in more detailed information regarding the structure–activity and mechanism of actions of these DMARDs and related analogs should consult other chapters in antimalarials (chloroquine and hydroxychloroquine), anti-infectives (sulfasalazine), and antineoplastic agents (methotrexate, azathioprine, leflunomide). Recent advances in new disease-modifying anti-tumor necrosis factor agents such as etanercept, adalimumab, and infliximab are covered in a separate chapter entitled “Immunobiologicals” in this text as well as in several recent reviews.^{221,222,225–227}

Synthetic Disease-Modifying Antirheumatic Drugs

Figure 24.24 contains the chemical structures of the DMARDs and their metabolites mentioned in this section.

Figure 24.24 • Disease-modifying antirheumatic drugs.

Readers should consult other chapters in this text for additional information regarding these drugs.

METHOTREXATE

Methotrexate (MTX, Rheumatrex), an antifolate drug used in cancer treatment, has also been used in the disease management of RA since the 1950s. Because of its quicker therapeutic onset among all DMARDs and its demonstrated efficacy, tolerability, and low cost, MTX has been the first-line therapy for RA patients who are not responsive to NSAIDs alone.^{224,226,227} Recent findings have indicated that other DMARDs should only be used for patients who are refractory to MTX.^{224,226}

At least four anti-inflammatory mechanisms of action have been suggested for MTX's ability to slow down RA disease progression.^{222,228} First, MTX, being a folate antagonist, prevents antigen-dependent T-cell proliferation by blocking de novo pyrimidine biosynthesis, via a reversible inhibition of dihydrofolate reductase.²²⁸ It also inhibits folate-mediated production of spermine and spermidine in synovial tissue. These polyamines are believed to be the toxic compounds responsible for causing tissue injury in RA. MTX can also reduce intracellular glutathione concentration, thereby altering the cellular redox state that suppresses the formation of reactive oxygen radicals in synovial tissue. Lastly, MTX, similar to sulfasalazine, infliximab, and IL-4, can also inhibit osteoclastogenesis (i.e., bone erosion) in patients with RA, by modulating the interaction of the receptor activator of nuclear factor κ B, its ligand, and osteoprotegerin.²²⁹

Methotrexate is usually administered in a once-weekly dose in the range of 15 to 17.5 mg. Although it has good oral bioavailability (~70%), it is more efficacious via IM or SC routes, because its uptake from the GI tract is mediated by a saturable transporter, known as the reduced folate carrier-1.^{225,228} Most of the administered dose of methotrexate is eliminated in the urine via its 7-hydroxymethotrexate metabolite.

Common side effects of MTX include nausea, anemia, and GI mucosa ulcerations. The use of folinic acid supplement to reduce MTX-mediated toxicities, however, is not recommended for RA patients, because high dosages of folinic acid will compete with MTX for the same transporter for absorption from the GI tract and for cellular uptake. Thus, it may also reverse MTX's anti-inflammatory effects in RA patients.²²⁸ Moreover, MTX can cause birth defects in unborn children, thus it is contraindicated for women during pregnancy.

HYDROXYCHLOROQUINE AND CHLOROQUINE

Hydroxychloroquine (Plaquenil, Quineprox) is an older drug used to treat malaria that is used more often in the treatment of RA and lupus erythematosus. Although its mechanism of action is not known, its ability to interfere with lipopolysaccharide-induced TNF- α gene expression, thereby preventing TNF- α release from mononuclear phagocytes has been suggested.²³⁰ It is usually taken orally with food or milk to prevent stomach irritation and is preferred over chloroquine because of a lower incidence of ocular toxicity. However, long-term use of this medication requires periodic retinal examinations because of rare but potentially preventable retinopathy associated with its use, especially at a daily dose over 6.5 mg/kg.²³¹

SULFASALAZINE

Sulfasalazine (Azufidine) is an azo prodrug that is reduced by the bacterium present in the lower intestine to its active metabolites, sulfapyridine and 5-aminosalicylic acid (5-ASA or mesalamine). It has been used for the treatment of RA or ankylosing spondylitis, and inflammatory bowel diseases (IBDs) such as ulcerative colitis and Crohn disease.

It is generally agreed that the therapeutic effects of sulfasalazine in treating IBDs are due mainly through its active metabolite, 5-ASA. 5-ASA is believed to work, via similar mechanisms of action to the salicylates discussed earlier, by blocking prostaglandin synthesis in the lower intestine.^{165–168} On the other hand, because 5-ASA is completely ionized and very little of this metabolite can enter into systemic circulation, the antirheumatic effects of sulfasalazine have been attributed to its other active metabolite, sulfapyridine.²³² In a more recent study, sulfasalazine and sulfapyridine were found to inhibit 5-aminoimidazole-4-carboxamide ribonucleotide transformylase, an enzyme involved in de novo purine biosynthesis.²³³ Sulfasalazine also inhibits neutrophil function, reduces immunoglobulin levels, and interferes with T-cell function via suppression of NF- κ B activation.²³³ Furthermore, like methotrexate, sulfasalazine has also been shown to inhibit osteoclastogenesis, thereby preventing bone erosion in arthritic patients.^{229,234}

It should be pointed out that approximately one third of the patients treated long term with sulfasalazine discontinued the drug because of dose-related adverse effects including nausea, dyspepsia, vomiting, headache, rash, gastric distress, especially in patients on a daily dosage of greater than 4 g (or a serum sulfapyridine levels above 50 mg/mL).

LEFLUNOMIDE

Leflunomide (Arava), an isoxazole prodrug, is an orally active DMARD marketed in 1998 for the treatment of RA. It is well absorbed and extensively metabolized in vivo to its active metabolite, 2-cyano-3-hydroxy-2-buteneamide (teriflunomide), resulting from a reductive ring opening of the isoxazole ring (see Fig. 24.24). Unlike MTX, teriflunomide blocks T-cell proliferation by inhibiting dihydroorotate dehydrogenase, the rate-limiting enzyme in the de novo biosynthesis of pyrimidine that is believed to be responsible for the immunosuppressive properties of leflunomide.^{235,236} For this reason, it is not surprising that leflunomide has a very comparable therapeutic efficacy to the first-line DMARD, MTX as shown in several extended open clinical trials.²³⁷ However, even though leflunomide is well tolerated like MTX, several cases of toxic neuropathy have been observed during its use, thus careful monitoring of the patient's neurological status during treatment is mandatory.²³⁷ Like MTX, leflunomide is contraindicated in pregnancy or in women considering pregnancy.

THE GOLD COMPOUNDS

The gold salts, gold sodium thiomalate (Aurolate), aurothioglucose (Solganal), and auranofin (Ridaura) have been known to be effective in the treatment of RA for more than 60 years.²²⁵ Recent findings have suggested that, auranofin, an orally active gold salt, inhibits Nuclear factor κ B (NF- κ B) activation TLR4-mediated activation of the signaling pathway that leads to the blocking of the formation of

inflammatory gene product such as cytokines and COX-2.²³⁸ Because zinc is a necessary component of NF- κ B, a transcription factor that is critical for its DNA binding, Yang et al.²³⁹ suggested that auranofin works by oxidizing the zinc containing thiolate anions of NF- κ B into a disulfide, thus abolishing the DNA binding requirement for gene expression. However, few patients take gold salt therapy for longer than 5 years because of their toxicities including mucocutaneous reactions, proteinuria, and cytopenias.²²²

OTHER DISEASE-MODIFYING ANTIRHEUMATIC DRUGS

Other DMARDs that can be used in the treatment of RA include penicillamine (Cuprimine), a metabolite of penicillin, or the cytotoxic anticancer drugs such as chlorambucil (Leukeran), Azathioprine (Imuran) and cyclophosphamide (Cytoxan), or the other immunosuppressants such as cyclosporine (Sandimmune) and mycophenolate mofetil (MMF). However, most of these drugs are less commonly used because of their toxicities.

DRUGS USED IN THE MANAGEMENT OF GOUT AND HYPERURICEMIA

In contrast to RA discussed earlier, gout is somewhat unique, in that its cause is well known, therefore gouty inflammation can be effectively controlled and treated with

medications.^{240,241} Gout is one of the most common causes of acute inflammatory arthritis in men older than 40 years old, characterized by the deposition of monosodium urate crystals in the joints and cartilage.²⁴² Phagocytosis of urate crystals by human neutrophils (and macrophage) induces the synthesis and release of a glycoprotein, the crystal-induced chemotactic factor (CCF), which is believed to be the initial stimulus in the development of acute gouty attacks.²⁴³ Gouty arthritis is also more prevalent in men than in women by a ratio of approximately 6 to 1.

Hyperuricemia

Hyperuricemia is defined as having serum uric acid levels of greater than 7.0 mg/dL in men or more than 6.0 mg/dL in women. Although recurrent attacks of gouty arthritis in a patient are typically associated with hyperuricemia, most people with high serum urate levels are asymptomatic and may never develop gout.^{241,244} Uric acid is a normal metabolic end product of purine nucleotide catabolism (i.e., adenine and guanine), but unlike other mammals, humans lack a critical enzyme, urate oxidase (uricase), needed to further break down uric acid into more water-soluble allantoin (Fig. 24.25).^{241,245,246}

Risk Factors

In addition to hyperuricemia, other factors that may also increase the risk of development of gout include hypertension, renal insufficiency, obesity, and the use of thiazides or loop

Figure 24.25 • Catabolism of purine nucleotides and xanthine oxidase inhibitors.

Figure 24.26 • Colchicine and uricosuric acids.

diuretics, or high intake of alcoholic beverages and purine-rich foods such as meats, liver, bacon, fish, and beans.^{241,242} The prevalence of gout also increases in organ-transplant patients who are treated with cyclosporine. Furthermore, early onset of gout (between 20 and 30 years of age) is most likely a result of hereditary disorders of purine metabolism, especially in those who have a hypoxanthine-guanine phosphoribosyltransferase deficiency, thus it should be evaluated before proper treatment is given.^{245,247}

Treatment of Acute Gouty Arthritis

The main goal of the pharmacotherapy of acute gouty arthritis is a rapid resolution of pain and debility. The treatment of choice in the United States is the use of NSAIDs for patients with an established diagnosis of uncomplicated gout (i.e., those with heart failure, renal insufficiency, or GI disease).^{241,248} For patients who have active peptic ulcers or renal impairment, the choice is either an IM dose of *corticotropin* (ACTH) or an intra-articular injection of glucocorticoids. The chemical aspects of corticosteroids and their therapeutic uses are covered in a separate chapter in this text. Colchicine is generally reserved for prophylaxis of recurrent, acute flare-ups of gouty arthritis or in patients in whom the diagnosis of gout is not yet confirmed.^{245,248}

COLCHICINE

Colchicine is an alkaloid isolated from the dried corms and seeds of *Colchicum autumnale* L., commonly known as autumn crocus or meadow saffron, (see Fig. 24.26 for structure). It is specifically indicated for acute treatment of gouty arthritis because of its ability to block the production and release of the CCF that mediates the inflammatory response because of urate crystals, a mechanism different from colchicine's antimetabolic action, which is being investigated for its anticancer properties.²⁴³ It is often quite effective in aborting an acute gouty attack if given within the first 10 to 12 hours after the onset of arthritis.^{248,249}

Colchicine can be administered orally or intravenously. A low oral dose of 0.6 mg is taken every 1 to 2 hours, until either the resolution of gouty symptoms or the occurrence of GI toxicities such as increased peristalsis, abdominal discomfort, nausea and vomiting, and diarrhea.²⁴⁸ Most of the severe systemic toxicity associated with IV administration of colchicine has been linked to an inappropriate use of the drug.²⁵⁰ Several recent findings comparing the safety and efficacy of colchicine to that of NSAIDs and corticosteroids, have provided strong evidence for eliminating the IV use of colchicine in the treatment of acute gouty arthritis because improper IV dosing can cause severe bone marrow

suppression, renal failure, and death.^{251,252} Moreover, oral colchicine is also recommended only as a second-line therapy for acute gout treatment when NSAIDs or corticosteroids are contraindicated or ineffective.²⁵² Concomitant use of oral colchicine with any of the cholesterol-lowering statins including pravastatin (Pravachol) should also be avoided because of increased risk of axonal neuromyopathy that can progress to rhabdomyolysis with renal failure.²⁵³ This is because most of the statins and colchicine are metabolized in liver primarily by the hepatic CYP3A4 isozymes. Colchicine can also induce acute myopathy in patients when used with pravastatin even though it is not metabolized by CYP3A4, because they share the same P-glycoprotein efflux transporter system.²⁵³

Control of Hyperuricemia

In general, if a patient who has hyperuricemia and the recurrence of gouty arthritis attacks (i.e., less than two attacks/year), their gout can usually be controlled by maintaining serum urate levels below the limit of solubility (i.e., at 6 mg/dL or lower) with drugs that block uric acid synthesis by inhibiting xanthine oxidase or with uricosuric drugs that promote uric acid elimination from the renal tubules.^{244,245,248}

XANTHINE OXIDASE INHIBITORS: ALLOPURINOL, OXYPURINOL, FEBUXOSTAT

Allopurinol (Zyloprim, Progotin) is the only xanthine oxidase inhibitor available in this class. It is rapidly metabolized to its active isomer oxypurinol (Oxyprim), an experimental drug currently in phase III trials, that has a half-life of approximately 15 hours but was found to exhibit a similar side effect profile to that of allopurinol (i.e., 40% of those allergic to allopurinol have similar cross-reactivity to this drug).²⁴⁰ Allopurinol and its active metabolite, oxypurinol, works by effectively competing with the substrate hypoxanthine and xanthine, respectively, because of their structural similarity to xanthine, for xanthine oxidase, thus blocking uric acid formation from purine nucleosides, adenine, and guanine as shown in Figure 24.25. Similarly, allopurinol (or oxypurinol) may also exhibit potential drug interactions with other medications such as didanosine (antiviral agent), azathioprine and mercaptopurine (anticancer drugs), and theophylline (asthma drug). For example, if a patient is given a prescription for allopurinol and azathioprine (Imuran), then the dose of azathioprine should be reduced by at least 50% to avoid the risk of myelosuppression by azathioprine.²⁵⁴

Febuxostat is a novel and selective, nonpurine inhibitor of xanthine oxidase currently awaiting FDA approval for treatment of chronic gout. It is more effective, at a daily dose of 80 or 120 mg, than allopurinol at the commonly recommended daily dose of 300 mg in lowering serum urate levels.^{255,256} Unlike allopurinol, it has minimal effects on other enzymes involved in purine and pyrimidine metabolisms.

URICOSURIC AGENTS: PROBENECID AND SULFINPYRAZONE

Probenecid (Benemid) and sulfinpyrazone (Anturane) are uricosuric agents that work by preventing uric acid reab-

sorption from the renal proximal tubules (see Fig. 24.26 for structures).²⁵⁷ They are only effective in patients with normal renal function who are not taking any medications such as the thiazide diuretics that compete for uric acid excretion via the organic anion transporter system (OATS) at the renal proximal tubules. In addition, patients who are using probenecid should also be counseled to avoid using any salicylates at doses greater than 81 mg/d or sulfonamide-containing diuretics such as furosemide, because concomitant use of any salicylates or diuretics can negate its uricosuric activity.²⁴²

Probenecid

Probenecid (Benemid) is the most widely used uricosuric agent in the United States. It is selectively excreted into the renal tubules by OATS. It is extensively metabolized via *N*-dealkylation or ω -oxidation, followed by phase II conjugation into the active metabolite, *p*-sulfamyl hippurate, which exhibits a high affinity, similar to *p*-aminohippurate, for binding to OATS, thereby preventing uric acid reabsorption from the renal proximal tubules (Fig. 24.26)²⁵⁷

Sulfinpyrazone

Sulfinpyrazone (Anturane) produces its uricosuric action in a similar manner to that of probenecid and is indicated for the treatment of chronic and recurrent gouty arthritis. It is well absorbed with approximately 50% of the administered dose excreted as unchanged drug into the renal tubules. The rest of the drug is primarily metabolized via CYP2C9 into the corresponding sulfide and sulfone metabolites, thus it can potentiate the anticoagulant effect of warfarin.²⁵⁸

TRIPTANS

Triptans are safe and effective drugs for abortive, but not for prophylactic, treatment of moderate to severe migraine and cluster headaches.²⁵⁹ Because of their higher affinity and selectivity for the serotonin 5-HT_{1B/1D} receptors at the trigeminal nerve fibers and dural vasculature, they are able to induce vasoconstrictions at these sites, thereby relieving pain from cranial vasodilatation and reducing neurogenic inflammation associated with these disorders.^{259,260} However, triptans are often contraindicated in patients with uncontrolled hypertension, especially those with coronary vascular diseases, even though there are far fewer 5-HT_{1B} receptors found in coronary blood vessels and in the peripheral vasculatures than in the cranial blood vessels.²⁶¹ Thus, special attention should also be given to assess the safety and tolerability profile of the triptans when choosing among available drugs because of their pharmacokinetic differences.^{261,262}

Pathophysiology of Migraine

Migraine, a recurrent and debilitating headache disorder, affects about 12% of the worldwide population with a higher prevalence in women (~18%) than in men (~6%).²⁵⁹ In the most recent classification and diagnostic criteria for headache disorders published by the Headache Classification Committee of the International Headache Society, the terms, *common* and *classical* migraines have been replaced with *migraine without aura* and *migraine with aura*, respectively.²⁶³ The patients often describe their migraine attack as having an intense pulsating and

throbbing headache lasting from 4 hours to 3 days, if not properly treated.^{259,260} In addition to this excruciating pain, migraine patients often have other symptoms like nausea, vomiting, sensitivity to light (photophobia), sound (phonophobia), or movements that can also severely impact their quality of life.

Although the etiology of migraines remains poorly understood, activation of the meningeal nociceptors at the intracranial trigeminovascular system (TGVS, also referred to as the trigeminal pain pathway) is believed to play a key role in promoting headache and other symptoms associated with migraines.^{264–266} Several theories have been suggested to explain the underlying causes for the symptoms associated with migraines.²⁵⁹ Only two of the most prominent theories are briefly discussed under this section.

THE VASCULAR THEORY OF MIGRAINES

According to the vascular theory, the vasodilatation of cranial carotid arteriovenous anastomoses (sites of many 5-HT_{1B/1D} receptors) and meningeal, dural, cerebral, or pial vessels (primary sites of 5-HT_{1B} receptors) plays an important role in the pathogenesis of migraines and is responsible for the pain associated with migraine headaches.^{259,261} The fact that sumatriptan-induced cranial vasoconstriction is selectively blocked by a selective 5-HT_{1B} antagonist, and not by a 5-HT_{1D} antagonist, lends further support to this vascular theory of migraines.²⁶⁷

THE NEUROGENIC INFLAMMATION THEORY OF MIGRAINES

This theory suggests that migraine headaches occur as a result of an abnormal firing of meningeal nociceptors at the TGVS. Activation of trigeminal neurons releases vasoactive peptides including calcitonin gene-related peptide (CGRP, a vasodilator peptide), substance P, and neurokinin A (both play an important role in pain transmission as well as activation of immune responses and neurogenic inflammation) onto dural tissue where these peptides produce a

local response known as neurogenic inflammation.²⁵⁹ These peptides induce cranial vasodilatation, especially at the dural membranes surrounding the brain (mainly a result of CGRP), thus producing the pain associated with migraine attacks. Further evidence supporting this theory as the underlying cause of migraines can be found from a recent study linking the dural mast cell degranulation to the prolonged activation of the trigeminal pain pathway and neurogenic inflammation.²⁶⁸

The discovery of these vasoactive peptides provides new targets for the future design of nonvasoconstrictors, nontriptan drugs such as CGRP antagonists for the acute and preventive treatment of migraine and cluster headaches.^{259,269}

Structure–Activity Relationship

All clinically available triptans possess comparable pharmacodynamic properties. They all bind and stimulate serotonin 5-HT_{1B/1D} with affinity in the low nanomolar ranges, thus they are equally effective for the acute treatment of migraine.^{262,270} However, they all have different pharmacokinetic properties and side effect profiles that vary in type and severity.²⁶¹ Thus, they are not equally efficacious in preventing migraine recurrence because of the differences in their elimination half-lives.²⁶² They also differ in their potential to induce drug-related CNS side effects, especially somnolence and paresthesia that may lead to a patient's noncompliance of an otherwise effective migraine treatment.²⁷⁰

Table 24.2 summarizes the pharmacokinetic properties of clinically available triptans that contributes to their efficacy, safety, and tolerability.^{259,262,270–274} A quick glance at their chemical structures (see Fig. 24.27) reveals two general structural types, which might provide insights for assessing some of these differences.

The 3-alkylaminoethyl containing triptans (sumatriptan, zolmitriptan, rizatriptan, and almotriptan) are substrates for the hepatic monoamine oxidase type A (MAO-A) because

TABLE 24.2 Pharmacokinetic Properties of the Triptans^a

Drug	Trade Name	Bioavailability Oral (%)	Onset Time (min)	Plasma Half-life (h)	Metabolizing Enzyme ^{a,b}	Drug Interactions	% CNS Side Effects
Sumatriptan	Imitrex Imigrain	14	10–15 (iv) 15–30 (nasal) 30–90 (PO)	2	MAO-A	MAOIs especially MAO-A inhibitors	1.7–6.3
Zolmitriptan	Zomig, Zomig-ZMT	40–48	10–15 (nasal) 45–60 (PO)	3	CYP1A2 MAO-A	MAOIs, SSRIs, Cimetidine	9.9–11.5
Naratriptan	Amerge Naramig	63 (men) 74 (women)	60–180 (PO)	5–6.3	Renal/CYP isozymes		1.9
Rizatriptan	Maxalt Maxalt-MLT	45	30–120 (PO)	2–3	MAO-A	MAOIs especially MAO-A inhibitors, Propranolol	6.1–9.4
Almotriptan	Axert	70–80	60–180 (PO)	3.3	MAO-A CYP3A4		1.5
Frovatriptan	Prova	60	120–180 (PO)	26	CYP1A2	Fluvoxamine, ciprofloxacin, mexiletine	6.0
Eletriptan	Relpax	50	30–60 (PO)	3.6–5.5	CYP3A4	Ketoconazole and other CYP3A4 inhibitors	2.6–14.6

^aCompiled from data reported in the following references (1, 4, 12, and 13).

^bPrimary mode of metabolism listed first.

Figure 24.27 • Triptans.

of their structural resemblance to 5-HT, the preferred substrate for MAO-A. They all have a relatively short duration of action (i.e., 2–3 hours) because of first-pass metabolic inactivation by the MAO-A into an indole acetic acid metabolite that is rapidly eliminated as their corresponding glucuronides. Thus, the use of these triptans requires repeat dosing to prevent the recurrence of migraine attack. They are also contraindicated with concomitant use of any MAO inhibitors, especially inhibitors of MAO-A such as the antidepressant drug, moclobemide (Aurorix, Mauerix).^{261,273}

Eletriptan, frovatriptan, and naratriptan, on the other hand, with their 3-alkylamino side chain fused into a carbocyclic ring structure, all have much longer elimination half-lives and lower incidence of headache recurrence reported.²⁷³ This is because they are not a substrate for MAO-A (amphetamine is not a substrate for MAO because it has an additional methyl group α to the terminal amine function). These triptans are mainly degraded by the hepatic CYP isozymes (CYP1A2, 2D6, 3A4), but their bioavailability may be altered with a drug that inhibits or induces these CYP isozymes.²⁷⁵ For example, eletriptan is primarily metabolized by CYP3A4 isozyme, thus it is not advisable to use eletriptan with a CYP3A4 inhibitor such as ketoconazole, or nefazodone without appropriately adjusting their dosages.²⁷⁵

The highest reported incidences of drug-induced CNS toxicities were found with eletriptan (14% at 80-mg dose), zolmitriptan (11.5% at 5-mg dose) and rizatriptan (9.4% at 10-mg dose). They all have *N*-demethylated, active metabolites that can easily gain entry into the brain because of their

high lipophilicity.²⁷⁰ Thus, the presence of this active metabolite in the brain and the high lipophilicity of the parent triptan have been suggested as a factor for contributing to the observed CNS side effects of the triptans.²⁷⁰ This hypothesis is further supported by the fact that frovatriptan has a much lower CNS toxicity because of the greater water solubility of its *N*-demethylated active metabolite that prevents it from entering the brain, whereas sumatriptan, almotriptan, and naratriptan all have a very low reported incidence of CNS side effects because they have no clinically significant active metabolites.^{270,276}

Donitriptan, a unique high-efficacy and high-selectivity 5-HT_{1B/1D} agonist (i.e., with high-intrinsic activity approaching that of the endogenous agonist 5-HT) currently in late-stage clinical trials, is a novel arylpiperazole derivative with much better consistency of pain relief and a lower incidence of migraine recurrence.²⁷⁷ Furthermore, unlike sumatriptan, it can also block capsaicin-sensitive trigeminal sensory nerves from releasing CGRP, resulting in selective cranial vasodilatation and central nociception.²⁷⁸

Mechanism of Action

Triptans are specifically designed to bind to the 5-HT_{1B/1D} receptors based on the findings that 5-HT_{1B} receptors are present in the cranial blood vessels^{279,280} and 5-HT_{1B/1D} receptors are found in the trigeminal pain pathway.^{280,281} Three distinct mechanisms have been suggested to explain the actions of triptans: (a) Triptans abort migraine headache by its agonist action at the 5-HT_{1B} receptors,

thereby inducing vasoconstriction of the meningeal, dural, or pial blood vessels.²⁷⁹ (b) Triptans also inhibit neurogenic inflammation via its presynaptic stimulation of 5-HT_{1D} receptors and/or through its additional action at the 5-HT_{1B/1D} receptors.²⁸¹ (c) Triptans relieve migraine pain transmission most likely because of its inhibitory action at the trigeminal pain pathway mediated via 5-HT_{1B/1D/1F} receptors.^{259,279,280}

Antimigraine Drugs Acting on 5-HT_{1B/1D} Receptors

SUMATRIPTAN (IMITREX)

Sumatriptan was the first triptan approved (1991) for the acute treatment of migraine headaches. It has the lowest oral bioavailability among all triptans because of its low lipophilicity. The availability of many different dosage forms (i.e., an oral tablet, a SC injection, a nasal spray formulation, and a suppository) allows the flexibility of tailoring therapy to the needs of the individual patients, thus making sumatriptans a very useful drug for an acute treatment of migraine headaches.^{262,282} It also has a very fast onset of action via SC injection or nasal spray administration. However, sumatriptan is contraindicated with monoamine oxidase inhibitors because it is primarily degraded by hepatic MAO-A. Thus, it may require frequent dosing as a result of its short duration of action to prevent migraine recurrence.^{262,282}

ZOLMITRIPTAN (ZOMIG, ZOMIG-ZMT)

Zolmitriptan, the second triptan marketed (approved in 1997), has a much better bioavailability (40%–48%) than sumatriptan. It is rapidly absorbed after oral or nasal spray administration. It also has an orally disintegrating tablet formulation (Zomig ZMT), which can be taken without water. Zolmitriptan undergoes rapid *N*-demethylation via CYP1A2 to a more potent, active metabolite, *N*-desmethylzolmitriptan, which is 2 to 6 times more potent than the parent drug.^{262,283} This active metabolite was detected 5 minutes after dosing and accounts for about two thirds of the plasma concentration of the administered dose of the parent drug.²⁸⁴ Thus, it is reasonable to assume that the therapeutic effects and especially the CNS side effects of zolmitriptan must be in part attributed to the plasma levels of this active metabolite, at least until it is further degraded by hepatic MAO-A to its inactive indole acetic acid derivatives.^{262,283}

NARATRIPTAN (AMERGE, NARAMIG)

Naratriptan, the third triptan approved in 1998, is one of the most lipophilic triptans marketed to date. It has a much improved bioavailability (63% in men and 74% in women), a greater affinity for 5-HT_{1B/1D} receptors (3–6 times), and a lower recurrence rate than sumatriptan because of its much longer elimination half-life.^{262,285} Naratriptan also has a favorable CNS side effect profile when compared with sumatriptan or zolmitriptan because of its metabolic stability, thereby lacking a *N*-demethylated active metabolite and a significant renal excretion (>70% of naratriptan is excreted unchanged and the rest of the administered dose is degraded via several CYP isozymes).^{262,270,286}

RIZATRIPTAN (MAXALT)

Rizatriptan, approved in 1998, is a fast-acting triptan because of its moderate lipophilicity yet has a very short elimination half-life similar to sumatriptan (i.e., like sumatriptan, it is mainly metabolized by MAO-A). The only advantages of this drug when compared with sumatriptan are that it has a slightly faster onset and that it has an orally disintegrating tablet formulation which can be taken without water.²⁶²

ALMOTRIPTAN (AXERT)

Almotriptan, marketed in 2000, has the highest oral bioavailability among all triptans (see Table 24.2). It is metabolized by both MAO-A and CYP3A4, thus has a more favorable side effects profile when compared with sumatriptan. However, it is only available in a 12.5 mg tablet form.

FROVATRIPTAN (FROVA)

Frovatriptan is a newer triptan introduced into the market in 2001. With the incorporation of a 3-alkylamino side chain into a carbazole ring structure, it is not a substrate for MAO-A or CYP3A4. Thus, unlike the other clinically available triptans, it possesses a much longer duration of action with fewer drug–drug interactions with MAO inhibitors or with drugs metabolized by the CYP3A4 isozymes.^{274,276} It is primarily metabolized by CYP1A2 to give its active metabolite, *N*-desmethyl-frovatriptan, which has about one third of the binding affinity for 5-HT_{1D/1B} receptors but with three times longer plasma half-life of the parent drug.^{276,287}

Frovatriptan also has the highest affinity for brain 5-HT_{1B} receptors and the longest elimination half-life among all triptans.^{273,288} The only disadvantage of this drug is its slower onset of action because of its greater water solubility. However, it is a drug of choice for patients with long-lasting migraines or if recurrence is a problem.²⁷³

ELETRIPTAN (RELPAK)

Eletriptan, introduced into the market in 2002, is the newest triptan with highest affinity for 5-HT_{1B}, 5-HT_{1D}, and 5-HT_{1F} receptors. It is one of the most lipophilic triptans marketed to date and is well tolerated and safe across its dosing range of 20 to 80 mg.²⁷⁵ However, it is metabolized primarily (>90%) by CYP3A4 isozyme to its active metabolite, the *N*-desmethyleletriptan, which accounts for approximately 10% to 20% of the plasma concentration of that observed for parent drug.²⁸⁹ Thus, coadministration of eletriptan with potent CYP3A4 inhibitors such as ketoconazole, itraconazole, nefazodone, troleandomycin, clarithromycin, ritonavir, and nelfinavir may require dose reduction and closer monitoring for CNS side effects.^{262,275} Furthermore, because eletriptan and its active metabolite, *N*-desmethyleletriptan, are also substrates for the P-glycoprotein efflux pumps that are responsible for their removal from the brain, coadministration of eletriptan with a known P-glycoprotein inhibitor and/or inducer such as digoxin, diltiazem, verapamil, or St. John's Worth would result in higher brain levels of its active metabolite, and thus a higher rate of the CNS side effects reported for this drug.²⁹⁰

REVIEW QUESTIONS

1. A patient is brought to the emergency room via ambulance. He is unresponsive to questions, has a respiratory rate of 4 breaths per minute, and an arterial oxygen saturation (SpO₂) of 82% measured by finger pulse oximetry. On physical exam, multiple injection (track) marks are identified on his forearms, and the patient also displays a cutaneous rash over his trunk. The suspected diagnosis is a heroin overdose. The nurse calls the pharmacy for 50 mg of diphenhydramine to treat the cutaneous rash. You do not dispense it, why?
2. A new mom comes to your pharmacy to refill her codeine prescription, prescribed for episiotomy pain. She is concerned because her 2-week-old breastfed baby is extremely lethargic, sleeps all day, and seems unresponsive to stimulus. You recommend that she bring the baby to the emergency room immediately. What genetic polymorphism do you suspect the mom has? What danger does this pose to her breastfed infant?
3. A patient presents to your pharmacy with a prescription for Vicodin ES; 2 tablets q 6 hours around the clock; #240; refills = zero. You do not dispense it, why?
4. A 72-year-old man who has been taking the antiarrhythmic drug quinidine for 4 years self treats his diarrhea with Imodium (loperamide). His son calls your pharmacy to report that his father is very sleepy, his pupils are pinpoints, and he is acting “very strange.” You suspect that loperamide is having CNS effects. What is the pharmacological reason behind the quinidine-loperamide drug–drug interaction?
5. Diflunisal is a potent, long acting nonselective COX inhibitor. Explain how this drug binds to the COX-1 enzyme, and how it is eliminated from the body.
6. Provide a biochemical reason why acetaminophen, unlike aspirin and other NSAIDs, is a centrally acting analgesic/antipyretic drug that has no anti-inflammatory activity.
7. Provide a possible rationale for why CYP3A4 inducers can increase the clearance of diclofenac, yet CYP3A4 inhibitors have little or no effect on its pharmacokinetic profile.
8. Sulindac, a potent nonselective COX inhibitor, is said to have a lower risk of stomach bleeding and nephrotoxicity than other aspirin-like NSAIDs such as indomethacin. Explain.
9. Provide a possible chemical/biochemical rationale why frovatriptan has a much lower CNS toxicity than eletriptan.

Steroid Hormones and Therapeutically Related Compounds

PHILIP J. PROTEAU

CHAPTER OVERVIEW

Steroid hormones and related products represent one of the most widely used classes of therapeutic agents. These drugs are used primarily in birth control, hormone-replacement therapy (HRT), inflammatory conditions, and cancer treatment. Most of these agents are chemically based on a common structural backbone, the steroid backbone. Although they share a common structural foundation, the variations in the structures provide specificity for the unique molecular targets. Five general groups of steroid hormones are discussed: estrogens, progestins, androgens, glucocorticoids (GCs), and mineralocorticoids (MCs). The structural bases for the differences in actions and the various therapeutic uses for these compounds are explored. Several review articles and texts provide excellent coverage of the pharmacology and chemistry of steroid hormones.^{1–3}

STEROID NOMENCLATURE, STEREOCHEMISTRY, AND NUMBERING

As shown in Figure 25.1, nearly all steroids are named as derivatives of cholestane, androstane, pregnane, or estrane. The standard system of numbering is illustrated with 5α -cholestane (the H8 and H9 protons have been omitted here for clarity).

The absolute stereochemistry of the molecule and any substituents is shown with solid (β) and dashed (α) bonds. Most carbons have one β bond and one α bond, with the β bond lying closer to the “top” or C18 and C19 methyl side of the molecule. Both α - and β -substituents may be axial or equatorial. This system of designating stereochemistry can best be illustrated by the use of 5α -androstane (Fig. 25.2).

The stereochemistry of the H at C5 is always indicated in the name. The stereochemistry of the other H atoms is not indicated, unless it differs from 5α -cholestane. Changing the stereochemistry of any of the ring juncture or backbone carbons (shown in Fig. 25.1 with a heavy line on 5α -cholestane) greatly changes the shape of the steroid, as seen in the examples of 5α , 8α -androstane and 5β -androstane (Fig. 25.2).

Because of the immense effect that “backbone” stereochemistry has on the shape of the molecule, the International Union of Pure and Applied Chemistry (IUPAC) rules⁴ strongly recommend that the stereochemistry at all backbone carbons be clearly shown. That is, all hydrogens along the

backbone should be drawn. When the stereochemistry is not known, a wavy line is used in the drawing. Methyls are explicitly indicated as CH_3 .

The terms *cis* and *trans* are occasionally used in steroid nomenclature to indicate the backbone stereochemistry among rings. For example, 5α steroids are *A/B trans*, and 5β -steroids are *A/B cis*. The terms *syn* and *anti* are used analogously to *trans* and *cis* for indicating stereochemistry in bonds connecting rings (e.g., the C9:C10 bond that connects rings A and C). The use of these terms is indicated in Figure 25.2.

The position of double bonds can be designated in any of the various ways shown below in Figure 25.3. Double bonds from C8 may go toward C9 or C14, and those from C20 may go toward C21 or C22. In such cases, both carbons are indicated in the name if the double bond is not between sequentially numbered carbons (e.g., 5α -androst-8(14)-ene or 5α - Δ 8(14)-androstene; see Fig. 25.3). These principles of modern steroid nomenclature are applied to naming several common steroid drugs shown in Figure 25.1.

Such common names as *testosterone* and *cortisone* are obviously much easier to use than the long systematic names. Substituents must always have their position and stereochemistry clearly indicated, however, when common names are used (e.g., 17α -methyltestosterone, 9α -fluorocortisone).

Steroid drawings sometimes appear with lines drawn instead of methyls (CH_3), and backbone stereochemistry is not indicated unless it differs from that of 5α -androstane (Fig. 25.4). This manner of representation should be used only when there is no ambiguity in the implied stereochemistry.

STEROID BIOSYNTHESIS

Steroid hormones in mammals are biosynthesized from cholesterol, which in turn is made in vivo from acetyl-coenzyme A (acetyl-CoA) via the mevalonate pathway. Although humans do obtain approximately 300 mg of cholesterol per day in their diets, a greater amount (about 1 g) is biosynthesized per day. A schematic outline of these biosynthetic pathways is shown in Figure 25.5.

Conversion of cholesterol to pregnenolone is the rate-limiting step in steroid hormone biosynthesis. It is not the enzymatic transformation itself that is rate limiting; however, the translocation of cholesterol to the inner mitochondrial membrane of steroid-synthesizing cells is rate limiting.⁵ A key protein involved in the translocation is the

(text continues on page 822)

Numbering and Primary Steroid Names

Examples of Common and Systematic Names

Figure 25.1 • Steroid nomenclature and numbering.

Figure 25.2 • Steroid nomenclature—stereochemistry.

Figure 25.3 • Steroid nomenclature—double bonds.

Figure 25.4 • Alternative representations of steroids.

Figure 25.5 • Outline of the biosynthesis of steroid hormones. (3β-HSD, 3β-hydroxysteroid dehydrogenase/Δ⁵⁻⁴-isomerase; 17β-HSD, 17β-hydroxysteroid dehydrogenase.)

Steroidogenic Acute Regulatory protein (StAR). Defects in the StAR gene lead to congenital lipoid adrenal hyperplasia, a rare condition marked by a deficiency of adrenal and gonadal steroid hormones.⁶ The enzymes involved in the transformation of cholesterol to the hormones are mainly cytochromes P450 and dehydrogenases. The main routes of biosynthesis of the hormones are depicted in Figure 25.5. Estradiol, testosterone, progesterone, aldosterone, and hydrocortisone are representatives of the distinct steroid-receptor ligands that are shown. Further metabolic fates of these compounds are presented under the specific structural class.

An enzyme-denoted cytochrome P450_{sc} (SCC stands for side-chain cleavage) mediates the cleavage of the C17 side chain on the D ring of the sterol to provide pregnenolone, the C21 precursor of the steroids. This enzyme mediates a three-step process involved in the oxidative metabolism of the side chain. Successive hydroxylations at C20 and C22 are followed by oxidative cleavage of the C20–C22 bond, providing pregnenolone. Pregnenolone can be either directly converted into progesterone or modified for synthesis of GCs, estrogens, and androgens. Introduction of unsaturation into the A ring leads to the formation of progesterone. Specifically, oxidation of the alcohol at C3 to the ketone provides a substrate in which isomerization of the $\Delta^{5,6}$ -double bond to the $\Delta^{4,5}$ -double bond is facilitated. This transformation is mediated by a bifunctional enzyme, 3 β -hydroxysteroid dehydrogenase/ $\Delta^{5,4}$ isomerase (3 β -HSD). This enzyme can act on several 3-ol-5-ene steroids in addition to pregnenolone. Hydroxylation at C17 provides the precursor for both sex steroid hormones and GCs. Cytochrome P450c17 hydroxylates pregnenolone and progesterone to provide the corresponding 17 α -hydroxylated compounds. 17 α -Hydroxypregnenolone can be converted to 17 α -hydroxyprogesterone by 3 β -HSD. Cytochrome P450c17 is also a bifunctional enzyme, with lyase activity in addition to the hydroxylase action. The C17,20-lyase activity is crucial for the formation of sex hormones. The lyase oxidatively removes the two carbons at C17, providing the C17 ketone. In the case of 17 α -hydroxypregnenolone, the product is dehydroepiandrosterone (DHEA). If 17 α -hydroxyprogesterone is the substrate for the lyase, androstenedione results. The conversion of 17 α -hydroxyprogesterone to androstenedione is limited in humans, although in other species this is an important pathway. DHEA is converted to androstenedione by the action of 3 β -HSD. Androstenedione can either be converted to testosterone by the action of 17 β -hydroxysteroid dehydrogenase (17 β -HSD) or be transformed into estrone by aromatase, a unique cytochrome P450 that aromatizes the A ring of certain steroid precursors. Testosterone is aromatized to 17 β -estradiol by the same enzyme. 17 β -HSD acts on estrone to form 17 β -estradiol. If testosterone is acted on by 5 α -reductase, 5 α -dihydrotestosterone (DHT), an androgen important in the prostate, is produced.

The major route to GCs diverges at 17 α -hydroxypregnenolone. Instead of oxidative cleavage at C17, 3 β -HSD acts on this substrate to provide 17 α -hydroxyprogesterone. Small amounts of 17 α -hydroxyprogesterone can be produced directly from progesterone, although this is not a major pathway in humans. Sequential action of 21-hydroxylase (Cyp21) and 11 β -hydroxylase (Cyp11B1) provides hydrocortisone, the key GC in humans.

If progesterone is directly acted on by 21-hydroxylase (Cyp21), 11-deoxycorticosterone is produced, a precursor to the MC aldosterone. In tissues where aldosterone is synthesized, aldosterone synthase (Cyp11B2), the multifunctional enzyme, mediates the hydroxylation at C11, as well as the two-step oxidation of C18 to an aldehyde, providing aldosterone, which exists predominantly in the cyclic-hemiacetal form.

CHEMICAL AND PHYSICAL PROPERTIES OF STEROIDS

With few exceptions, the steroids are white crystalline solids. They may be in the form of needles, leaflets, platelets, or amorphous particles, depending on the particular compound, the solvent used in crystallization, and the skill and luck of the chemist. Because the steroids have 17 or more carbon atoms, it is not surprising that they tend to be water insoluble. Addition of hydroxyls or other polar groups (or decreasing carbons) increases water solubility slightly, as expected. Salts are the most water soluble. Examples are shown in Table 25.1. As a class, the 4-en-3-one steroids are light sensitive and should be kept in light-resistant containers.

CHANGES TO MODIFY PHARMACOKINETIC PROPERTIES OF STEROIDS

As with many other compounds described in previous chapters, the steroids can be made more lipid soluble or more water soluble by making suitable ester derivatives of hydroxyl (OH) groups. Derivatives with increased lipid solubility are often made to decrease the release rate of the drug from intramuscular (IM) injection sites (i.e., in depot preparations). More lipid-soluble derivatives also have improved skin absorption properties and thus, are preferred for dermatological preparations. Derivatives with increased water solubility are needed for intravenous preparations. Since hydrolyzing enzymes are found throughout mammalian cells especially in the liver, converting OH groups to esters does not significantly modify the activity of most compounds.

TABLE 25.1 Solubilities of Steroids

	Solubility (g/100 mL)		
	CHCl ₃	EtOH	H ₂ O
Cholesterol	22	1.2	Insoluble
Testosterone	50	15	Insoluble
Testosterone propionate	45	25	Insoluble
Dehydrocholic acid	90	0.33	0.02
Estradiol	1.0	10	Insoluble
Estradiol benzoate	0.8	8	Insoluble
Betamethasone	0.1	2	Insoluble
Betamethasone acetate	10	3	Insoluble
Betamethasone NaPO ₄ salt	Insoluble	15	50
Hydrocortisone	0.5	2.5	0.01
Hydrocortisone acetate	1.0	0.4	Insoluble

Prednisolone	0.4	3	0.01
Prednisolone acetate	1.0	0.7	Insoluble
Prednisolone NaPO ₄ salt	0.8	13	25

Some steroids (e.g., estradiol, progesterone, and testosterone) are particularly susceptible to rapid metabolism after absorption or rapid inactivation in the gastrointestinal tract before absorption. These inactivation processes limit the effectiveness of these hormones as orally available drugs, although micronized forms of estradiol and progesterone are available for oral administration. Sometimes, a simple chemical modification can decrease the rate of inactivation and, thereby, increase the drug's half-life or make it possible to be taken orally.

Examples of common chemical modifications are illustrated in Figure 25.6. Drugs such as testosterone *cyclopentylpropionate* (cypionate) and methylprednisolone

sodium succinate are *prodrugs* that require hydrolysis to release the active hormone in the body.

STEROID HORMONE RECEPTORS

Steroid hormones regulate tissue-specific gene expression. The individual hormones exhibit remarkable tissue selectivity, even though their structural differences are relatively minor. Estrogens such as estradiol increase uterine cell proliferation, for example, but not prostate cell proliferation. Androgens such as testosterone do the reverse, but neither androgens nor estrogens affect stomach epithelium. The

Figure 25.6 • Common steroid modifications to alter therapeutic utility. (*, prodrug.)

basis for this selectivity is the presence of selective steroid hormone receptors in individual tissues. This section provides an overview of steroid hormone receptors and their mode of action.^{1,2}

The steroid receptors themselves are key players in gene expression, but many other proteins are involved in this process. Chaperone proteins, for example, help fold the receptor proteins into the proper three-dimensional shape for binding the steroid ligand. Together, the steroid hormone receptor and associated proteins (Fig. 25.7; details on next page) make up the mature-receptor complex. Transcription (or repression of transcription) occurs when all the necessary associated proteins have been recruited to the DNA–receptor complex. In addition to the major effects on transcription, some effects of steroid hormones are mediated via rapid, nongenomic mech-

Figure 25.7 • Generic structural model of a steroid hormone–receptor complex and its activation for gene transcription. (AT, histone acetyltransferase; CA, coactivator; CC, cochaperone; HSP, heat shock protein; SHR, steroid hormone receptor.)

anisms. Some of these actions appear to involve classical steroid hormone receptors, whereas others rely on novel membrane receptors.^{7–9} This is an active area of study and will help explain all the various actions of steroid hormones.

Structure of Steroid Hormone Receptors

The complementary DNAs (cDNAs) of all the major steroid hormone receptors have been cloned, giving the complete amino acid sequence of each. Although the whole three-dimensional structure of a steroid hormone receptor has not been solved (structures of the ligand-binding domains of the steroid hormone receptors have been elucidated; see next page in this section), the functional role of each part is well known (see Fig. 25.8).¹⁰ The organization of the domains for all types of steroid hormone receptors is the same, but the number of amino acids for each receptor varies:

1. *N*-terminal (*A/B*) domain. Once the steroid–receptor complex has bound to the target gene(s), this domain (also called the *A/B modulator domain*) activates the hormone response elements adjacent to the genes. The hormone response elements are on the DNA adjacent to the target gene. They contain about 12 to 18 base-pair DNA sequences and consist of two “half sites” that are separated by a variable spacer. In the nucleus, steroid hormone–receptor

Figure 25.8 • Functional domains of the steroid hormone receptors. (AR, androgen receptor; ER, estrogen receptor; GR, glucocorticoid receptor; MR, mineralocorticoid receptor; and PR, progesterone receptor.)

complexes exist as dimers; the dimeric structure allows access to both half sites. The nucleotide sequence and spacing between the half sites are essential for the specificity of the various steroid–hormone complexes. After the dimer binds and all accessory proteins have been recruited to the receptor–DNA complex, transcription is initiated.

2. *DNA-binding (C) domain*. This short section is made up of about 65 amino acids, organized into two zinc finger motifs that are important for recognition and binding to the DNA response elements. The zinc fingers are also responsible for dimerization of the receptor.
3. *Hinge (D) domain*. This variable linker region appears to be involved with nuclear localization and transport (translocation) of the steroid–receptor complex into the nucleus.
4. *C-terminal ligand-binding (E) domain (LBD)*. The C-terminal domain includes about 250 amino acids. This section has the steroid hormone–binding site and is also involved with ligand-dependent transcriptional activation, receptor dimerization, binding to chaperone proteins (discussed later), and in some cases, repressing (“silencing”) particular genes.

ESTROGEN RECEPTORS

There are two distinct estrogen receptors (ERs), estrogen receptor α (ER $_{\alpha}$) and estrogen receptor β (ER $_{\beta}$), which are encoded by different genes.¹¹ The ERs have distinct tissue distributions and can have distinct actions on the target genes. ER $_{\alpha}$ can be found in high abundance in the uterus, vagina, and ovaries, as well as in the breast, the hypothalamus, endothelial cells, and vascular smooth muscle. ER $_{\beta}$ is found in greatest abundance in the ovaries and the prostate, with reduced occurrence in the lungs, brain, and vasculature.¹² Although many ligands bind with similar affinities to both receptor subtypes, some ligands are selective for one or the other receptor.^{13–15}

PROGESTERONE RECEPTORS

The progesterone receptor (PR) can also be found in two forms, but these are derived from a single gene. PR_A has had 164 amino acids truncated from the N-terminus of PR_B, providing a receptor that has different interactions with target genes and associated proteins. PR_B mainly mediates the stimulatory actions of progesterone. PR_A acts as a transcriptional inhibitor of ER, androgen receptor (AR), glucocorticoid receptor (GR), mineralocorticoid receptor (MR), and PR_B.¹² These differential actions are believed to be a result of interactions with different coactivators and corepressors. The DNA- and ligand-binding domains for the two receptors are identical.

ANDROGEN, GLUCOCORTICOID, AND MINERALOCORTICOID RECEPTORS

The AR, GR, and MR are present in only a single form. Only one gene and one protein are known for each receptor. Mutant forms of AR¹⁶ and GR¹⁷ are known, and evidence is mounting that some of these mutant receptors are associated with disease states.

X-RAY CRYSTALLOGRAPHY AND STEROID FIT AT THE RECEPTOR

The x-ray structures have now been solved for the ligand-binding domains of all the steroid hormone receptors (ER $_{\alpha}$

and ER $_{\beta}$,^{18–20} PR,²¹ AR,²² GR,^{23,24} and MR²⁵). The x-ray crystal structures of the ER, PR, and AR have revealed a key difference that leads to the unique ligand specificity of the ERs.^{19,26} In the region of the ligand-binding domain, where the A ring of steroids binds, are key residues that bind to either the phenolic A ring of estrogens or the enone A ring of progesterone or testosterone. In the case of the ER, glutamate and arginine residues are important in a hydrogen-bonding network that involves the phenolic hydroxyl. In contrast to this structural arrangement, the PR and AR have glutamine and arginine residues that hydrogen bond to the A-ring enones of progesterone and testosterone. The change from glutamate, a hydrogen-bond acceptor, to glutamine, a hydrogen-bond donor, is critical for the discrimination between estrogens and other steroid hormones. The structures of the GR and MR LBDs also reveal the features that provide the specificities for these two receptors. In the LBD of the GR, key proline and glutamine residues are replaced by serine and leucine, respectively, in the MR.²⁵ The proline residue results in a slightly more open-binding pocket, which can accommodate larger residues at the 17 α -position, as seen in many GR ligands, and the glutamine side chain can hydrogen bond with the 17 α -hydroxyl, which is seen in GRs, but is absent in aldosterone.

The x-ray crystal structures of the steroid hormones themselves have also provided important information. Although the conformations of rigid molecules in crystals and their preferred conformations in solution with receptors can differ, it is now clear from x-ray crystallography studies of steroids, prostaglandins, thyroid compounds, and many other drug classes that this technique can be a powerful tool in understanding drug action and in designing new drugs.^{27–29} The relationship is straightforward: steroid drugs usually do not have a charge and, as a result, are held to their receptors by relatively weak forces of attraction. The same is true for steroid molecules as they “pack” into crystals. In both events, the binding energy is too small to hold any but low-energy conformations. In short, the steroid conformation observed in steroid crystals is often the same or very similar to that at the receptor.

Structure of Steroid Hormone–Receptor Complexes

Steroid hormone–receptor complexes include the steroid hormone receptor as well as other proteins, predominantly chaperone (heat shock) proteins, cochaperones, and immunophilins (Fig. 25.7).^{30,31} Their role is to “chaperone” the correct conformation and folding of complex proteins, which is otherwise much more difficult as temperatures increase. At normal physiological temperatures, the chaperone proteins assist the proper folding of large proteins such as steroid hormone receptors. The individual components vary depending on the type of steroid hormone receptor. Without the chaperones, the steroid hormone-binding site on the receptor does not have the proper folding and conformation for optimal steroid binding.

Once the steroid hormone binds to the receptor, a conformational change of the receptor occurs, and the mature receptor complex dissociates (Fig. 25.7). The receptor is dimerized, phosphorylated, and transported into the nucleus, if necessary. There, the zinc fingers on the steroid hormone receptor bind to the target gene(s) in the DNA.

Additional proteins are recruited to the receptor–DNA complex prior to initiation or repression of transcription.³² These additional proteins include coactivators or corepressors and histone acetyltransferases. Typically, the receptor–DNA–coactivator complex displays histone acetyltransferase action, which relaxes the chromatin structure, allowing binding of RNA polymerase II and the subsequent initiation of transcription. If corepressors are recruited to the complex, deacetylation of the histone complex is facilitated, preventing transcription.

GONADOTROPIN-RELEASING HORMONE AND GONADOTROPINS

The gonadotropins are peptides that have a close functional relationship to estrogen, progesterone, and testosterone. They are called *gonadotropins* because of their actions on the gonads. As shown in Figures 25.9 to 25.11, they control ovulation, spermatogenesis, and development of sex organs, and they maintain pregnancy. An additional peptide, gonadotropin-releasing hormone (GnRH), regulates release of the gonadotropins. Included in this group are the following:

- GnRH
- Luteinizing hormone (LH)
- Follicle-stimulating hormone (FSH)
- Chorionic gonadotropin (CG; hCG is human chorionic gonadotropin), a glycopeptide produced by the placenta; its pharmacological actions are essentially the same as those of LH

Gonadotropin-Releasing Hormone

The hypothalamus releases GnRH, a peptide that stimulates the anterior pituitary to secrete LH and FSH in males and females. This peptide controls and regulates both male and female reproduction (Figs. 25.9 and 25.10). GnRH is a modified decapeptide (10 amino acids): PyroGlu-His-Trp-Ser-Tyr-Gly-Leu-Arg-Pro-Gly-NH₂. The pyroglutamate at the N-terminus and the C-terminal amide distinguish this pep-

Figure 25.10 • Regulation of spermatogenesis.

tide from unmodified decapeptides. Analogs of GnRH that are used therapeutically are covered in Chapter 20.

Pituitary Gonadotropins: Luteinizing Hormone and Follicle-Stimulating Hormone

The pituitary gonadotropins LH and FSH, their structures, genes, receptors, biological roles, and their regulation (including by negative feedback actions of steroid hormones) have been studied intensively.^{33,34} FSH, LH, and CG are all glycopeptide dimers with the same α subunit but different β -subunits.

In females, LH and FSH regulate the menstrual cycle (see Figs. 25.9 and 25.11). At the start of the cycle, plasma concentrations of estradiol and other estrogens (Fig. 25.11) and progesterone are low. FSH and LH stimulate several ovarian follicles to enlarge and begin developing more rapidly than others. After a few days, only one follicle continues developing to the release of a mature ovum. The granulosa cells of the maturing follicles begin secreting estrogens, which then cause the uterine endometrium to thicken. Vaginal and cervical secretions increase. Gonadotropins and estrogen reach their

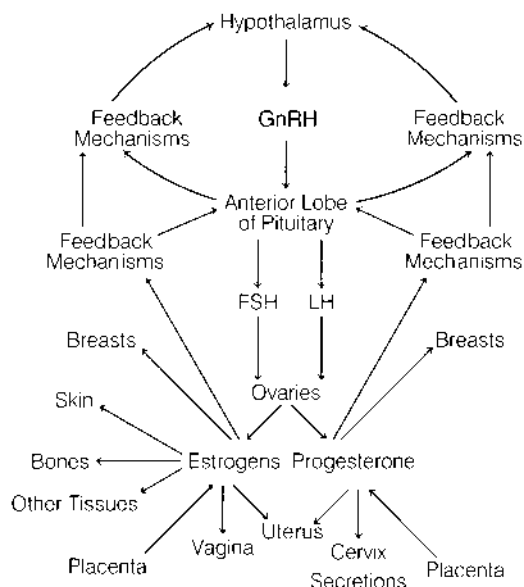

Figure 25.9 • Regulation of ovulation by GnRH.

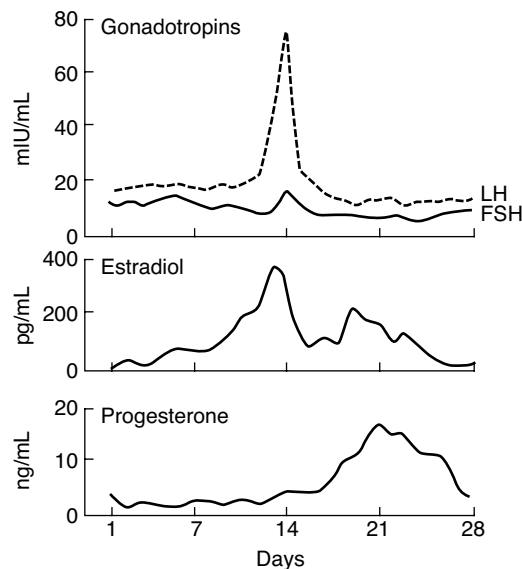

Figure 25.11 • Hormone changes in the normal menstrual cycle.

maximum plasma concentrations at about day 14 of the cycle. The release in LH causes the follicle to break open, releasing a mature ovum. Under the stimulation of LH, the follicle changes into the corpus luteum, which begins secreting progesterone as well as estrogen.

The increased concentrations of estrogens and progesterone regulate the hypothalamus and the anterior pituitary by a feedback inhibition process that decreases GnRH, LH, and FSH production. The result is that further ovulation is inhibited. As described later in this chapter, this is the primary mechanism by which steroid birth control products inhibit ovulation.

If fertilization does not occur by about day 25, the corpus luteum begins to degenerate, slowing down its production of hormones. The concentrations of estrogens and progesterone become too low to maintain the vascularization of the endometrium, and menstruation results.

The pharmacological actions of hCG are essentially the same as those of LH. In females during pregnancy, the hCG secreted by the placenta maintains the corpus luteum to continue secretion of estrogen and progesterone, thus inhibiting ovulation and menstruation.

In males (Fig. 25.10), LH stimulates testosterone synthesis by the testes, and together, testosterone and LH promote spermatogenesis (sperm production) and development of the testes. Testosterone is also essential for the development of secondary sex characteristics in males. FSH stimulates production of proteins and nutrients required for sperm maturation.

SEX HORMONES

Although estrogens and progesterone are usually called female sex hormones and testosterone is called a male sex hormone, all of these steroids are biosynthesized in both males and females. For example, examination of the biosynthetic pathway in Figure 25.5 reveals that progesterone serves as a biosynthetic precursor to hydrocortisone and aldosterone and, to a lesser extent, to testosterone and estrogens. Testosterone is one of the precursors of estrogens. Estrogens and progesterone are produced in much larger amounts in females, however, as is testosterone in males. These hormones play profound roles in reproduction, in the menstrual cycle, and in giving women and men their characteristic physical differences.

Several modified steroidal compounds, as well as some nonsteroidal compounds, have estrogenic activity. A large number of synthetic or semisynthetic steroids with biological activities similar to those of progesterone have been made, and these are commonly called *progestins*. Although the estrogens and progestins have had their most extensive use as chemical contraceptive agents for women and in HRT, their wide spectrum of activity has given them a diversity of therapeutic uses in women, as well as a few uses in men.

Testosterone has two primary kinds of activities: androgenic (promoting male physical characteristics) and anabolic (muscle building). Many synthetic and semisynthetic androgenic and anabolic steroids have been prepared. Despite efforts to prepare selective anabolic agents (e.g., for use in aiding recovery from debilitating illness or surgery), all “anabolic” steroids have androgenic effects. The androgenic

agents are mainly used in males, but they do have some therapeutic usefulness in women (e.g., in the palliation of certain sex organ cancers).

In summary, although many sex hormone products have their greatest therapeutic uses in either women or men, nearly all have some uses in both sexes. Nevertheless, the higher concentrations of estrogens and progesterone in women and of testosterone in men cause the development of the complementary reproductive systems and characteristic physical differences of women and men.

Estrogens³⁵

ENDOGENOUS ESTROGENS

The active endogenous estrogens are estradiol, estrone, and estriol. Estradiol provides the greatest estrogenic activity, with less activity for estrone, and the least activity with estriol. This range of activity parallels the affinity of these estrogens for the ER,³⁶ but the *in vivo* activities of these compounds are also affected by interconversions between active and inactive metabolites.

BIOSYNTHESIS

The estrogens are synthesized by the action of the enzyme aromatase on androstenedione or testosterone (Fig. 25.5). They are normally produced in relatively large quantities in the ovaries and the placenta, in lower amounts in the adrenal glands, and in trace quantities in the testes. In postmenopausal women, most estrogens are synthesized in adipose tissue and other nonovarian sites. About 50 to 350 $\mu\text{g}/\text{d}$ of estradiol are produced by the ovaries (especially the corpus luteum) during the menstrual cycle. During the first months of pregnancy, the corpus luteum produces larger amounts of estradiol and other estrogens; the placenta produces most of the circulating hormone in late pregnancy. During pregnancy, the estrogen blood levels are up to 1,000 times higher than during the menstrual cycle.

METABOLISM OF ESTROGENS

The metabolism of natural estrogens has been reviewed in detail.³⁷ The three primary estrogens in women are 17 β -estradiol, estrone, and estriol (16 α ,17 β -estriol). Although 17 β -estradiol is produced in the greatest amounts, it is quickly oxidized (see Fig. 25.12) to estrone, the estrogen found in highest concentration in the plasma. Estrone, in turn, is converted to estriol, the major estrogen found in human urine, by hydroxylation at C16 (to provide the 16 α -hydroxyl) and reduction of the C17 ketone (17 β -hydroxyl). Estradiol can also be directly converted to estriol. In the human placenta, the most abundant estrogen synthesized is estriol. In both pregnant and nonpregnant women, however, the three primary estrogens are also metabolized to small amounts of other derivatives (e.g., 2-hydroxyestrone, 2-methoxyestrone, 4-hydroxyestrone, and 16 β -hydroxy-17 β -estradiol). Only about 50% of therapeutically administered estrogens (and their various metabolites) are excreted in the urine during the first 24 hours. The remainder are excreted into the bile and reabsorbed; consequently, several days are required for complete excretion of a given dose.

Conjugation appears to be very important in estrogen transport and metabolism. Although the estrogens are unconjugated in the ovaries, significant amounts of conju-

Figure 25.12 • Metabolites of 17β -estradiol and estrone.

gated estrogens may predominate in the plasma and other tissues. Most of the conjugation takes place in the liver. The primary estrogen conjugates found in plasma and urine are glucuronides and sulfates. As sodium salts, they are quite water soluble. The sodium glucuronide of estriol and the sodium sulfate ester of estrone are shown in Figure 25.12.

BIOLOGICAL ACTIVITIES OF ESTROGENS¹²

In addition to having important roles in the menstrual cycle (described previously), the estrogens and, to a lesser extent, progesterone are largely responsible for the development of secondary sex characteristics in women at puberty. The estrogens cause a proliferation of the breast ductile system, and progesterone stimulates development of the alveolar system. The estrogens also stimulate the development of lipid and other tissues that contribute to breast shape and function. Pituitary hormones and other hormones are also involved. Fluid retention in the breasts during the later stages of the menstrual cycle is a common effect of the estrogens.

The estrogens directly stimulate the growth and development of the vagina, uterus, and fallopian tubes and, in combination with other hormones, play a primary role in sexual arousal and in producing the body contours of the mature woman. Pigmentation of the nipples and genital tissues and growth stimulation of pubic and underarm hair (possibly with the help of small amounts of testosterone) are other results of estrogen action.

The physiological changes at menopause emphasize the important roles of estrogens in a young woman. Breast and reproductive tissues atrophy, the skin loses some of its

suppleness, coronary atherosclerosis and gout become potential health problems for the first time, and the bones begin to lose density because of decreased mineral content.

STRUCTURAL CLASSES: ESTROGENS

As shown in Figure 25.13, there are three structural classes of estrogens: steroidal estrogens, diethylstilbestrol and other synthetic compounds, and phytoestrogens (Each class is summarized in the sections that follow). The steroidal estrogens include the naturally occurring estrogens found in humans and other mammals, as well as semisynthetic derivatives of these compounds. Because of rapid metabolism, estradiol itself has poor oral bioavailability. The addition of a 17α -alkyl group to the estradiol structure blocks oxidation to estrone. Ethinyl estradiol is therefore very effective orally, whereas estradiol itself is not. Most of the therapeutically useful steroidal estrogens are produced semisynthetically from natural precursors such as diosgenin, a plant sterol.

Steroidal Estrogens—Conjugated Estrogens, Esterified Estrogens. Conjugated estrogens (sometimes called equine estrogens) are estradiol-related metabolites originally obtained from the urine of horses, especially pregnant mares. Premarin, the major conjugated estrogen product on the market, is a mixture of numerous components that is obtained from mare urine. Equine estrogens are largely mixtures of estrone sodium sulfate and equilin sodium sulfate. Little or no equilin and equilenin are produced in humans. The sulfate groups must be removed metabolically to release the active estrogens. Conjugated estrogens that derive exclusively from

plant precursors are also on the market. Esterified estrogens are also mainly a combination of estrone sodium sulfate and equilin sodium sulfate, but in a different ratio to that in conjugated estrogens. The esterified estrogens are now prepared exclusively from plant sterols.

Diethylstilbestrol. At first glance, it might be surprising that synthetic nonsteroidal molecules such as diethylstilbestrol (DES) could have the same activity as estradiol or other estrogens. DES can be viewed, however, as a form of estradiol with rings B and C open and a six-carbon ring D. The activity of DES analogs was explained in 1946.³⁸ It was proposed that the distance between the two DES phenol OH groups was the same as the 3-OH to 17-OH distance of estradiol; therefore, they could both fit the same receptor. Medicinal chemists have shown the OH-to-OH distance to be actually 12.1 Å in DES and 10.9 Å in estradiol. In aqueous solution, however, estradiol has two water molecules that are hydrogen bonded to the 17-OH. If one of the two water mol-

ecules is included in the distance measurement, there is a perfect fit with the two OH groups of DES (Fig. 25.14). This suggests that water may have an important role for estradiol in its receptor site. It is now generally accepted that the estrogens must have a phenolic moiety for binding, but some investigators propose that the receptor may be flexible enough to accommodate varying distances between the two key hydroxyls. This point about estrogens needing a phenolic ring for high-affinity binding to the ER is critical. Steroids with a phenolic A ring and related phenolic compounds lack high-affinity binding to the other steroid hormone receptors. Although DES was used for many years, it was discovered that the daughters of women who had taken DES during pregnancy (DES babies) had a high risk of vaginal, cervical, and uterine abnormalities, along with a low risk of vaginal clear cell adenocarcinoma.³⁹ Because of the safety concerns associated with DES, it was completely removed from the U.S. market in the late 1990s. DES is still available as an estrogen for use in veterinary medicine, however.

1. Steroidal Estrogens and Derivatives

Figure 25.13 • Natural and synthetic estrogens. (continues on next page)

1. Steroidal Estrogens and Derivatives (cont.)

2. Diethylstilbestrol and Other Synthetic Compounds

3. Estrogens from Plants (Phytoestrogens)

Figure 25.13 • (Continued)

Another synthetic compound, bisphenol A, shares some structural features of DES, in that it has two phenolic groups, but in this case only a single dimethylated carbon separates the two rings, rather than the substituted double bond in DES. As might be expected, the reduced distance between the phenolic hydroxyls and the greater flexibility in the structure lead to an affinity for the ERs several orders of magnitude less than estradiol or DES.⁴⁰ Although bisphenol A is only weakly estrogenic, it is still considered to be an “environmental estrogen” and is present in small quantities in a wide range of plastic products. The low-level exposure of humans to bisphenol A, although currently considered to have minimal health risks, continues to be the focus of numerous studies.⁴¹

Phytoestrogens. Several natural plant substances that have general structural features similar to those of DES and estradiol also have estrogenic effects and have been termed *phytoestrogens*.⁴² These include genistein, from soybeans and a species of clover; daidzein, from soybeans; and coumestrol, found in certain legumes. Genistein and daidzein are examples of isoflavones. These and others have antifertility activity in animals.⁴³ Many claims have been made about the beneficial effects of consuming products containing these phytoestrogens, including preventing and treating cardiovascular disease, reducing postmenopausal symptoms, and preventing osteoporosis. Because of the numerous other components present in many of the commercial products as well as a lack of well-

Figure 25.14 • Computer graphics. Superposition of estradiol (H₂O)₂ (dark lines) with DES (light lines). (Courtesy of Medical Foundation of Buffalo, Inc.)

designed studies to test the effects of the phytoestrogens themselves, however, positive health effects specifically because of direct hormonal action of the phytoestrogens are uncertain. Questions have also been raised about a possible contribution of phytoestrogens to an increased incidence of breast cancer. These concerns, however, are contradicted by studies that suggest a chemoprotective role for soy products containing phytoestrogens (this could well be due to other components of the mixture).⁴⁴ The long history of use of soy products in the world and no global correlations with increased breast cancer risks suggest that any connection between phytoestrogens in general and breast cancer is quite small.⁴⁵

Recent studies have demonstrated that genistein and other phytoestrogens binds preferentially to ER_β over ER_α.^{46,47} The clinical relevance of this difference in binding is unclear, but further research is being vigorously pursued to understand the distinctions between the phytoestrogens and classical estrogens.⁴⁴

THERAPEUTIC USES OF ESTROGENS

Birth Control. A major use of estrogens is for inhibition of ovulation, in combination with progestins. Steroidal birth control agents containing estrogens are discussed in the section on chemical contraception later in this chapter.

Hormone Replacement Therapy. Another major use of estrogens is in HRT for postmenopausal women. For this use, a progestin is often included to oppose the effects of estrogens on endometrial tissue. HRT is covered in more depth later in the chapter.

Treatment of Estrogen Deficiency from Ovarian Failure or after Oophorectomy. Estrogen therapy, usually with a progestin, is common in cases of ovarian failure and after an oophorectomy.

Treatment of Advanced, Inoperable Breast Cancer in Men and Postmenopausal Women and of Advanced, Inoperable Prostate Cancer in Men. Estrogens are used to treat inoperable breast cancer in men and in postmenopausal women, but estrogen therapy can actually stimulate existing breast cancers in premenopausal women. The selective ER modulator tamoxifen is reported to have fewer side effects; hence, it is usually preferred. Estrogens have also been used to treat inoperable prostate cancer, but GnRH analogs are now generally preferred because of fewer unwanted side effects.

Estrogens and Cancer. Many years of study have firmly established an association between estrogen use and increased risk of breast cancer. The risk is associated, however, with the timing of estrogen exposure, the estrogen dose, the length of use, and the type of estrogen used.⁴⁸ A patient should discuss the potential risks of breast cancer with her doctor carefully before starting estrogen therapy. Unopposed estrogens in HRT for postmenopausal women are also linked to an increased risk of endometrial carcinoma, which is the basis for inclusion of a progestin in many forms of HRT.⁴⁹

ESTROGEN PRODUCTS

Estrogens are commercially available in a wide variety of dosage forms: oral tablets, vaginal creams and foams, transdermal patches, and IM dosage preparations.

Estradiol, United States Pharmacopeia (USP). Estradiol, *estra-1,3,5(10)-triene-3,17β-diol*, is the most active of the natural steroid estrogens. Although its 17β-OH group is vulnerable to bacterial and enzymatic oxidation to estrone (Fig. 25.12), it can be temporarily protected as an ester at C3 or C17, or permanently protected by adding a 17α-alkyl group (e.g., 17α-ethinyl estradiol, the most commonly used estrogen in oral contraceptives). The increased oil solubility of the 17β-esters (relative to estradiol) permits the esters to remain in oil at the IM injection site for extended periods. These derivatives illustrate the principles of steroid modification shown in Figure 25.6. Transdermal estradiol products avoid first-pass metabolism, allowing estradiol to be as effective as oral estrogens for treating menopausal symptoms. A new transdermal spray, Evamist, was approved in 2007. Estradiol itself is typically not very effective orally because of rapid metabolism, but an oral formulation of micronized estradiol that allows more rapid absorption of the drug is available (Estrace). In addition to the oral and transdermal products, estradiol is also available in gel, cream, and vaginal ring formulations. The commercially available estradiol esters are the following:

- Estradiol 3-acetate, *USP* (oral; vaginal ring)
- Estradiol 17-valerate, *USP* (IM injection)
- Estradiol 17-cypionate, *USP* (IM injection)

Estrone, USP. Estrone, *3-hydroxyestra-1,3,5(10)-trien-17-one*, is less active than estradiol but more active than its metabolite, estriol. As the salt of its 3-sulfate ester, estrone is the primary ingredient in conjugated estrogens, *USP*, and esterified estrogens, *USP*. Although originally obtained from the urine of pregnant mares (about 10 mg/L), estrone is now prepared synthetically. Estrone itself is not available in commercial oral formulations, but can be obtained at

compounding pharmacies as a topical formulation. Oleoyl-estrone, the C3 ester of estrone with oleic acid, is in phase II clinical trials for the treatment of obesity. This acyl estrone derivative reduces fat stores by a mechanism not involving the ER,⁵⁰ although some of the oleoyl-estrone is hydrolyzed to estrone in vivo.

Piperazine Estrone Sulfate (3-Sulfoxy-Estra-1,3,5(10)-Trien-17-One Piperazine Salt), USP

All the estrone 3-sulfate salts have the obvious pharmaceutical advantage of increased water solubility and better oral availability. Acids convert the salts to the free 3-sulfate esters and cause some hydrolysis of the ester. This does not seem to affect absorption adversely, but precipitation of the free sulfate esters in acidic pharmaceutical preparations should be avoided. The dibasic piperazine molecule acts as a buffer, giving it somewhat greater stability.

Conjugated Estrogens, USP

The term *conjugated estrogens* refers to the mix of sulfate conjugates of estrogenic components isolated from *pregnant mare urine* (Premarin). These compounds are also referred to as CEE (conjugated equine estrogens). Conjugated estrogens contain 50% to 65% sodium estrone sulfate and 20% to 35% sodium equilin sulfate (based on the total estrogen content of the product). Premarin also contains the sulfate esters of 17 α -estradiol, 17 α -dihydroequilin, and 17 β -dihydroequilin, in addition to other minor components. Although most commonly used in HRT to treat postmenopausal symptoms, the conjugated estrogens are used for the entire range of indications described previously, except birth control.

Synthetic Conjugated Estrogens

Cenestin, referred to as “synthetic conjugated estrogens, A” is a mixture of nine estrogenic substances (Fig. 25.13): sodium estrone sulfate, sodium equilin sulfate, sodium equilenin sulfate, sodium 17 α -estradiol sulfate, sodium 17 β -estradiol sulfate, sodium 17 α -dihydroequilin sulfate, sodium 17 β -dihydroequilin sulfate, sodium 17 α -dihydroequilenin sulfate, and sodium 17 β -dihydroequilenin sulfate. These estrogenic substances are synthesized from soy sterols. The term *synthetic* has been added before conjugated estrogens to indicate that this product is distinct from (not equivalent to) the conjugated estrogens derived from mare urine. The “A” following the name indicates that this is the first approved mixture of synthetic conjugated estrogens. Enjuvia is “synthetic conjugated estrogens, B.” Subsequent synthetic conjugated estrogen products will be named in order, with the final descriptors “C, D, E,” etc. Enjuvia contains $\Delta^{8,9}$ -dehydroestrone sulfate, in addition to the nine estrogenic substances listed previously. Cenestin and Enjuvia are both approved for the treatment of moderate-to-severe vasomotor symptoms and vulvar and vaginal atrophy associated with menopause.

Esterified Estrogens, USP

Esterified estrogens (Menest) contain some of the same sulfate conjugates of estrogens present in conjugated estrogens, but the ratios of these components and the composition of minor components of the products differ. These products contain 75% to 85% sodium estrone sulfate and 6% to 15% sodium equilin sulfate, in such proportion that the total of these two components is 90% of the total esterified estrogens content. The esterified estrogens find the same uses as the conjugated estrogens.

Estriol, USP. Estriol, estra-1,3,5(10)-triene-3,16 α ,17 β -triol, is available for compounding into several different formulations for use in HRT. It can be used alone or in combinations with estradiol (Bi-Est) or with estradiol and estrone (Tri-Est).

Ethinyl Estradiol, USP. 17 α -Ethinyl estradiol has the greatest advantage over other estradiol products of being orally active. It is equal to estradiol in potency by injection but is 15 to 20 times more orally active. The primary metabolic path for ethinyl estradiol is 2-hydroxylation by cytochrome P450 isozyme 3A4 (CYP3A4), followed by conversion to the 2- and 3-methyl ethers by catechol-*O*-methyltransferase. The 3-methyl ether of ethinyl estradiol is mestranol, *USP*, used in oral contraceptives. Mestranol is a prodrug that is 3-*O*-demethylated to the active ethinyl estradiol. An oral dose of about 50 μ g of mestranol has an estrogenic action approximately equivalent to 35 μ g of oral ethinyl estradiol. The demethylation is mainly mediated by CYP2C9.⁵¹

SELECTIVE ESTROGEN RECEPTOR MODULATORS AND ANTIESTROGENS

Whereas estrogens have been very important in chemical contraception and HRT, compounds that can antagonize the ER have been of great interest for the treatment of estrogen-dependent breast cancers. Tumor biopsies have shown ER to be present in about 60% of primary breast cancers, and most are responsive to estrogen blockade. Unfortunately, most of these ER-related breast cancers also develop resistance to antiestrogen therapy within 5 years. In contrast, only about 6% of nonmalignant breast tissues have significant ER present. Three compounds that are used clinically for estrogen antagonist action in the treatment of breast cancer are tamoxifen, toremifene, and fulvestrant (Fig. 25.15). Two additional agents that can antagonize ERs are clomiphene, which is used as an ovulation stimulant, and raloxifene, which is used for the prevention and treatment of osteoporosis.

Tamoxifen and clomiphene were traditionally called *ER antagonists* or *antiestrogens*. Referring to these compounds as ER antagonists, however, does not accurately portray how these compounds work in vivo. Although tamoxifen is an ER antagonist in breast tissue, it has agonist actions on endometrium, liver, bone, and cardiovascular system. Because of the differential agonist and antagonist effects of these types of compounds on the ER, depending on the specific tissue, a new term was coined: *selective estrogen receptor modulators* (SERMs). A SERM is a drug that has tissue-specific estrogenic activity. Although many compounds exhibit SERM activity, a few agents are antagonists in all tissues. These compounds are termed *antiestrogens*, and fulvestrant is one example (Fig. 25.15). Tamoxifen and clomiphene are often referred to in older literature as *antiestrogens*.

Tamoxifen has seen extensive use in treating primary breast cancers that are ER dependent.^{52,53} For premenopausal women with metastatic disease, tamoxifen is an alternative and adjuvant with oophorectomy, ovarian irradiation, and mastectomy. Tamoxifen use, however, is not problem free. Tamoxifen increases the incidence of endometrial polyps, hyperplasia and carcinoma, and uterine sarcomas. The risk of endometrial cancer resulting from tamoxifen is, however, much lower than the “modest but highly significant reductions in morbidity and mortality of breast cancer.”⁵⁴ Because

Figure 25.15 • Selective estrogen receptor modulators (SERMs) and antiestrogens.

of the increased risk of endometrial cancer with tamoxifen therapy, tamoxifen should be used to prevent breast cancer only in women at high risk. Women without a family history of breast cancer or other risks should not use tamoxifen in this manner.

Raloxifene is another SERM, but its profile of activity differs from that of tamoxifen. Raloxifene is an ER antagonist in both breast and endometrial tissue, but has agonist action on bone and acts as an estrogen agonist in lowering total cholesterol and low-density lipoprotein (LDL). The subtle structural differences between the two drugs underlie the distinct activity profiles.⁵⁵ The agonist action on bone tissue is the basis for the use of this drug for treating osteoporosis.

A key question is why do compounds like tamoxifen and raloxifene exhibit antagonist action in some tissues, but agonist action in other tissues? Major developments in the past few years are beginning to provide the answer to this question.^{15,56–58} Tamoxifen,⁵⁹ raloxifene, and estradiol¹⁸ all bind to the ER at the same site, but their binding modes are different. In addition, each induces a distinct conformation in the transactivation region of the ligand-binding domain.¹⁸ These unique conformations dictate how the receptor–ligand complex will interact with coregulator proteins (coactivators or corepressors).⁵⁶ In all tissues, the estradiol–ER complex recruits coactivators, so gene transcription is stimulated.

In breast tissue, both raloxifene- and tamoxifen-bound receptors prevent the association with coactivators, but rather recruit corepressors, so antagonist action is observed. In uterine tissue, however, the raloxifene–ER complex recruits corepressors, whereas the tamoxifen–ER complex recruits a coactivator, SRC-1, which leads to agonist action.⁵⁷ An additional factor involved in this agonist action of tamoxifen is the context in which the liganded receptor interacts with the target gene. The liganded ER can interact directly with DNA or can interact indirectly by being tethered to other transcription factors. When the tamoxifen-bound receptor interacts in a tethered manner with the target genes in uterine tissue, the SRC-1 coactivator is recruited, and gene transcription is promoted.^{56,57} A deeper understanding of how the liganded receptors interact with target genes and the mechanisms for recruitment of coregulators may help explain the phenomenon of tamoxifen resistance, which results from increased tamoxifen agonism in breast tissue.⁵⁶

Bazedoxifene is a new SERM that should soon be marketed for the treatment of osteoporosis. Bazedoxifene incorporates an indole ring system in place of the benzothiophene of raloxifene. Bazedoxifene was the result of a screening program that selected for compounds that did not stimulate breast or uterine tissue.⁶⁰ Lasofoxifene, arzoxifene, and ospemifene are the other newer SERMs that are in the late stage of

development (Fig. 25.15).⁶¹ Lasofoxifene can be viewed as a constrained, saturated analog of 4-hydroxytamoxifen. A new drug application (NDA) was filed with the Food and Drug Administration (FDA) in late 2007 and the review is still in progress. Structurally, arzoxifene is most similar to raloxifene, with an ether bridge, rather than a carbonyl bridge, attached to the benzothiophene core. Arzoxifene is being investigated (phase III) for treating osteoporosis and for preventing breast cancer. Ospemifene is an analog of toremifene, which has an OH in place of the *N,N*-dimethyl amino substituent. It is in phase III clinical trials for the treatment of vaginal atrophy in postmenopausal women.

Clomiphene is another drug that exhibits antiestrogen actions, but it is not used for treating breast cancer or osteoporosis; rather, it is used for increasing the odds of a successful pregnancy. Clomiphene's therapeutic application as an ovulation stimulant results from its ability to increase GnRH production by the hypothalamus. The mechanism is presumably a blocking of feedback inhibition of ovary-produced estrogens (via ER antagonism). The hypothalamus and pituitary interpret the false signal that estrogen levels are low and respond by increasing the production of GnRH. The increased GnRH, in turn, leads to increased secretion of LH and FSH, maturation of the ovarian follicle, and ovulation (as described previously in this chapter; see Fig. 25.9). Support for the feedback inhibition mechanism is provided by tests with experimental animals in which clomiphene has no effect in the absence of a functioning pituitary gland.

Multiple births occur about 10% of the time with patients taking clomiphene, and birth defects in 2% to 3% of live newborns. Vasomotor "hot flashes" occur about 10% of the time, and abnormal enlargement of the ovaries about 14%. Abdominal discomfort should be discussed immediately with the physician.

SERM AND ANTIESTROGEN PRODUCTS

Tamoxifen Citrate, USP. Tamoxifen, 2-[4-(1,2-diphenyl-1-butenyl)phenoxy]-*N,N*-dimethylethanamine (Nolvadex), is a triphenylethylene SERM used to treat early and advanced breast carcinoma in postmenopausal women. Tamoxifen is used as adjuvant treatment for breast cancer in women following mastectomy and breast irradiation. It reduces the occurrence of contralateral breast cancer in patients receiving adjuvant tamoxifen therapy. It is also effective in the treatment of metastatic breast cancer in both women and men. In premenopausal women with metastatic breast cancer, tamoxifen is an alternative to oophorectomy or ovarian irradiation. Tamoxifen can be used preventatively to reduce the incidence of breast cancer in women at high risk. Antiestrogenic and estrogenic side effects can include hot flashes, nausea, vomiting, platelet reduction, and (in patients with bone metastases) hypercalcemia. Like all triphenylethylene derivatives, it should be protected from light.

The major metabolite of tamoxifen is *N*-desmethyltamoxifen, which reaches steady-state levels higher than tamoxifen itself. It is believed that *N*-desmethyltamoxifen contributes significantly to the overall antiestrogenic effect. Another metabolite, 4-hydroxytamoxifen, is a more potent antiestrogen than tamoxifen, but because it is only a minor metabolite of tamoxifen, it probably does not contribute significantly to the therapeutic effects. 4-Hydroxytamoxifen, with its greater

affinity for the ERs, however, has been used extensively in pharmacological studies of these receptors. Tamoxifen concentrations are reduced if coadministered with rifampin, a cytochrome P450 inducer.

Toremifene Citrate, USP. Toremifene, 2-[4-[(1*Z*)-4-chloro-1,2-diphenyl-1-butenyl]phenoxy]-*N,N*-dimethylethanamine (Fareston), differs structurally from tamoxifen only by having a chloroethyl group (rather than an ethyl group) attached to the triphenylethylene structure. As might be expected, the pharmacological actions of toremifene and tamoxifen are quite similar. Toremifene is also a SERM, with estrogen antagonist action in breast tissue but agonist action in the endometrium, on bone tissue, and on serum lipid profiles. Recent clinical data indicate that the incidence of endometrial cancer is lower with toremifene use than with tamoxifen.⁶² Toremifene is used in the treatment of metastatic breast cancer in postmenopausal women.

Raloxifene, USP. Raloxifene, [6-hydroxy-2-(4-hydroxyphenyl)benzo[*b*]thien-3-yl][4-[2-(1-piperidinyl)ethoxy]phenyl]methanone (Evista), is a benzothiophene derivative that differs slightly from the triphenylethylene SERMs. A key structural difference is the carbonyl "hinge" that connects the modified phenolic side chain to the benzothiophene ring system. This hinge is the key structural element that leads to the differing actions at the ERs.⁵⁵ Raloxifene, unlike tamoxifen and toremifene, has antagonist properties on the endometrium and breast tissue and agonist properties on bone and the cardiovascular system. The lack of agonist action on endometrial tissue has been suggested as a reason for the lack of endometrial cancer associated with raloxifene use. Raloxifene is approved for the prevention and treatment of osteoporosis in postmenopausal women. It has also been investigated for preventing breast cancer in comparison with tamoxifen. Recent studies indicate that it has similar effectiveness to tamoxifen, but has a preferable side effect profile.⁶³

Bazedoxifene, USP. Bazedoxifene, 1-[[4-[2-(azepan-1-yl)ethoxy]phenyl)methyl]-2-(4-hydroxyphenyl)-3-methylindol-5-ol (Viviant), was declared to be "approvable" by the FDA in 2007 for the prevention of postmenopausal osteoporosis. As of mid-2009, final approval in the United States is still pending. Bazedoxifene was approved in Europe in 2009 for the treatment of postmenopausal osteoporosis.

Fulvestrant, USP. Fulvestrant, 7 α -[9-[(4,4,5,5,5-pentafluoropentyl)sulfinyl]nonyl]estra-1,3,5(10)-triene-3,17 β -diol (Faslodex), is an antagonist structurally based on the estradiol structure, with a long, substituted alkyl chain attached at the 7 α -position of the steroid skeleton. When bound to the ERs, this alkyl chain induces a conformation of the receptor distinctive from that formed upon estradiol or tamoxifen binding, preventing agonist action. Fulvestrant is a pure antagonist at both ER $_{\alpha}$ and ER $_{\beta}$ and an ER downregulator (stimulates degradation of the ER), completely lacking the agonist activity that is seen with tamoxifen or raloxifene. The different pharmacological profile of fulvestrant allows the use of this agent in women who have had disease progression after prior antiestrogen therapy (typically tamoxifen), providing an alternative to aromatase inhibitors.⁶⁴

Figure 25.16 • Conversion of androstenedione to estrone by aromatase.

Clomiphene Citrate, USP. Clomiphene citrate, 2-[4(2-chloro-1,2-diphenylethenyl)phenoxy]-*N,N*-diethylethanamine (Clomid), is used as an ovulation stimulant in women desiring pregnancy. Although early literature refers to clomiphene as an estrogen antagonist, it is more accurately a SERM.⁶⁵ Clomiphene is chemically a mixture of two geometric isomers, zuclomiphene, the *cis*-isomer, and enclomiphene, the *trans*-isomer. In animal studies, these isomers have different estrogenic actions in different tissues. Zuclomiphene appears to have weak agonist actions on all tissues studied, whereas enclomiphene has antagonist actions on uterine tissue, but agonist action on bone tissue.⁶⁶ The actions of clomiphene in humans are likely a composite of the actions of the two isomers.

AROMATASE INHIBITORS

Aromatase is a cytochrome P450 enzyme complex that catalyzes the conversion of androstenedione to estrone and testosterone to estradiol (Figs. 25.5 and 25.16).^{67–69} The complex is made up of reduced nicotinamide adenine dinucleotide phosphate (NADPH)-cytochrome P450 reductase, and cytochrome P450 hemoprotein. In the first two steps, the C19 methyl is hydroxylated to CH₂OH, and then to an aldehyde hydrate form that dehydrates to provide the C19 aldehyde. In the final aromatization step, the C19 carbon is oxidatively cleaved to formate. A hydride shift, proton transfer, and free radical pathways have been proposed, with *cis*-elimination of the 1 β and 2 β hydrogens.⁷⁰ In premenopausal women, aromatase is primarily found in ovaries, but in postmenopausal women, aromatase is largely in muscle and adipose tissue.

As discussed previously with SERMs, some types of breast cancer are estrogen dependent. Because the aromatase reaction is unique in steroid biosynthetic pathways, it would be anticipated that aromatase inhibitors would be very specific in their estrogen biosynthesis blockade. This has proved to be true, and aromatase inhibitors offer a useful approach to decreasing estrogen levels in the treatment of estrogen-dependent breast cancer. Initially, aromatase inhibitors were used as second-line therapy in postmenopausal women who failed on tamoxifen therapy. Recent studies have indicated, however, that the newer aromatase inhibitors can be used as first-line therapy and possibly for cancer prevention in patients at high risk.⁷¹

Aromatase inhibitors include both steroidal and nonsteroidal compounds. Examples of aromatase inhibitors are shown in Fig. 25.17. The first-generation aromatase inhibitors

are shown in Fig. 25.17. The first-generation aromatase inhibitors

Figure 25.17 • Aromatase inhibitors.

were aminoglutethimide, a nonsteroidal compound, and the steroid-based testolactone, two compounds that were developed before it was recognized that their effectiveness in breast cancer treatment was caused by aromatase inhibition.⁷² Aminoglutethimide also inhibits other P450s involved in steroid hormone biosynthesis, which limits its use in breast cancer treatment. The newer drugs are more potent and more specific inhibitors of aromatase than the earlier compounds.

Exemestane is a newer steroidal aromatase inhibitor. It is an enzyme activated irreversible (“suicide”) inhibitor of aromatase. It is orally available and highly selective for aromatase. Its structure reflects only minor structural modifications to the natural substrate, androstenedione.

The nonsteroidal aromatase inhibitors are competitive inhibitors that bind to the enzyme active site by coordinating the iron atom present in the heme group of the P450 protein. Aside from aminoglutethimide, the first selective aromatase inhibitor to be marketed in the United States was anastrozole (Arimidex). Anastrozole incorporates a triazole ring into its structure that can coordinate to the heme iron. Letrozole is another triazole-containing inhibitor that is also effective in the treatment of breast cancer.

Currently available inhibitors suppress plasma estrogen levels (estradiol, estrone, and estrone sulfate) by 80% to 95%. Earlier aromatase inhibitors, such as aminoglutethimide and testolactone, suppressed plasma estrogens to a lesser extent. The side effects often seen with aminoglutethimide because of additional inhibition of other biosynthetic enzymes are avoided with the newest agents. The selectivity of these drugs for aromatase is quite high.

As with the SERMs, these drugs are only effective when the breast cancer cells are “ER positive,” meaning that they respond and proliferate in the presence of estrogen. Aromatase inhibitors can cause fetal harm in pregnant women and are therefore contraindicated.

Additional nonsteroidal inhibitors are based on the flavone structure. Chrysin is a flavonoid natural product that has aromatase inhibitory action in vitro similar to that of aminoglutethimide.⁷³ It is isolated from *Passiflora coerulea* and other plants. While this compound is not used therapeutically as an aromatase inhibitor, it has found questionable use as a nutritional supplement either alone or in combination with anabolic steroids to enhance muscle building and athletic performance. The theory for use is that an aromatase inhibitor allows the estrogenic side effects of androgenic compounds to be reduced. Although various nutritional supplement products containing chrysin are available, it is unclear whether or not significant aromatase inhibition is being achieved in vivo. The oral bioavailability of chrysin is very low, mainly as a result of efficient conversion to the corresponding glucuronide and sulfate conjugates, so the plasma concentration of free chrysin is minimal.⁷⁴

AROMATASE INHIBITOR PRODUCTS

Anastrozole, USP. Anastrozole, $\alpha,\alpha,\alpha',\alpha'$ -tetramethyl-5-(1*H*-1,2,4-triazol-1-ylmethyl)-1,3-benzenediacetonitrile, was the first specific aromatase inhibitor approved in the United States. It is indicated for first-line treatment of postmenopausal women with advanced or metastatic breast cancer, for second-line treatment of postmenopausal patients with advanced breast cancer who have had disease progression following tamoxifen therapy, and for adjuvant treatment

of women with early breast cancer. Patients who did not respond to tamoxifen therapy rarely respond to anastrozole.

Anastrozole reduces serum estradiol approximately 80% after 14 days of daily dosing. Because of an elimination half-life of 50 hours, anastrozole is effective with once-daily dosing (1 mg). Metabolism of anastrozole includes hydroxylation and glucuronidation, as well as *N*-dealkylation to produce triazole. The metabolites of anastrozole are inactive. Although anastrozole can inhibit CYPs 1A2, 2C9, and 3A4 with K_i values in the low micromolar range, the concentrations of anastrozole reached under standard therapeutic dosing are much lower, so anastrozole should lack significant P450 interactions.⁷⁵

Letrozole, USP. Letrozole, 4,4'-(1*H*-1,2,4-triazol-1-ylmethylene)dibenzonitrile (Femara), is used for most of the same indications as anastrozole. It reduces concentrations of estrogens by 75% to 95%, with maximal suppression achieved within 2 to 3 days. Letrozole is specific for aromatase inhibition, with no additional effects on adrenal corticoid biosynthesis. CYPs 3A4 and 2A6 are involved in the metabolism of letrozole to the major carbinol metabolite, which is inactive. The loss of the triazole ring, which is involved in coordination of the heme iron, would explain the loss of activity. Letrozole strongly inhibits CYP2A6 in vitro, with moderate inhibition of CYP2C19. The effect of this in vitro inhibition on the pharmacokinetics of coadministered drugs is unknown. Tamoxifen reduces the levels of letrozole significantly if they are used together, so combination treatment with these agents is not recommended.⁷⁶

Exemestane, USP. Exemestane, 6-methylenandrosta-1,4-diene-3,17-dione (Aromasin), is the first steroid-based aromatase inhibitor approved for the treatment of breast cancer in the United States. It is a mechanism-based inactivator that irreversibly inhibits the enzyme. Plasma estrogen levels are reduced by 85% to 95% within 2 to 3 days, and effects last 4 to 5 days. Exemestane does not inhibit any of the major cytochromes P450 and has essentially no interaction with steroid receptors, with only a very weak affinity for the AR. The 17 β -hydroxyexemestane reduction product, however, has much higher affinity for the AR than the parent (still several fold less than DHT, 0.28% for parent vs. 30% for metabolite). The clinical significance of the affinity is likely minimal because of the low levels of the metabolite produced.

Aminoglutethimide, USP. Aminoglutethimide, 3-(4-aminophenyl)-3-ethyl-2,6-piperidinedione, is mainly used to treat Cushing syndrome, a condition of adrenal steroid excess, a use in which the P450_{sc} inhibition of this compound is exploited rather than its aromatase inhibition. Aminoglutethimide is a weak inhibitor of aromatase and has been used successfully in the treatment of estrogen-dependent breast cancer. Because of the development of more selective aromatase inhibitors, the use of aminoglutethimide for its ability to inhibit aromatase is not supported.

Testolactone, USP. Testolactone, 13-hydroxy-3-oxo-13,17-secoandrost-1,4-dien-17-oic acid Δ -lactone (Teslac), was originally synthesized as a possible anabolic steroid, considering its structural similarity to testosterone. The key structural difference from anabolic steroids is the D-ring

lactone instead of the typical cyclopentyl ring. Although considered in many texts an androgen or anabolic steroid (it is a Schedule III drug because of its classification as an anabolic steroid), testolactone lacks androgenic effects *in vivo*. Its action is believed to be caused by irreversible inhibition of aromatase. It is a relatively weak inhibitor of aromatase, but the irreversible nature of the inhibition can lead to prolonged effects. Its relatively weak inhibition of aromatase and its undesirable dosage schedule (5×50 -mg tablets q.i.d.) give this older agent only limited use in breast cancer treatment because of better available options.

Progestins

ENDOGENOUS PROGESTINS

The key endogenous steroid hormone that acts at the PRs is progesterone. All other endogenous steroids lack significant progestational action.

BIOSYNTHESIS

Progesterone is produced in the ovaries, testes, and adrenal glands. Much of the progesterone that is synthesized from pregnenolone is immediately converted to other hormonal intermediates and is not secreted. See the biosynthetic pathway (Fig. 25.5). The corpus luteum secretes the most progesterone, 20 to 30 mg/d during the last or “luteal” stage of the menstrual cycle. Normal men secrete about 1 to 5 mg of progesterone daily.

METABOLISM OF PROGESTERONE

Progesterone has a half-life of only about 5 minutes when taken orally, because of rapid metabolism. Progesterone can be transformed to many other steroid hormones (Fig. 25.5) and, in that sense, has numerous metabolic products. The principal excretory product of progesterone metabolism, however, is 5β -pregnane- $3\alpha,20\alpha$ -diol and its conjugates (Fig. 25.18). The steps that are involved in the formation of

Figure 25.18 • Progesterone metabolism (timing of the reduction steps can vary). (HSD, hydroxysteroid dehydrogenase.)

this metabolite are reduction of the C4-5 double bond, reduction of the C3 ketone providing the 3α -ol, and reduction of the C20 ketone. The reduction at C5 must precede the reduction of the C3 ketone, but the timing of the C20 can vary, depending on the tissue.^{77,78} Structural features that can block reduction at C5 or C20 have greatly increased the half-lives of progesterone derivatives.

BIOLOGICAL ACTIVITIES OF THE PROGESTINS¹²

Like the estrogens, progesterone has various pharmacological actions, with the main target tissues being the uterus, the breast, and the brain. Progesterone decreases the frequency of the hypothalamic pulse generator and increases the amplitude of LH pulses released from the pituitary. The actions of progesterone in the uterus include development of the secretory endometrium. When release of progesterone from the corpus luteum at the end of the menstrual cycle declines, menstruation begins. Progesterone also acts to thicken cervical secretions, decreasing cervical penetration by sperm. Progesterone is critical for the maintenance of pregnancy by suppressing menstruation and decreasing uterine contractility. Progesterone has important actions in the breasts during pregnancy, acting in conjunction with estrogens to prepare for lactation.

A thermogenic action is also associated with progesterone. During the menstrual cycle, progesterone mediates a slight temperature increase near midcycle and maintains the increased temperature until the onset of menstruation. The exact mechanism for this temperature increase is not known. Progesterone and its metabolites have additional central effects, which are being actively explored (see “Neurosteroids” section at the end of the chapter).⁷⁹

STRUCTURAL CLASSES—PROGESTINS

Progestins are compounds with biological activities similar to those of progesterone. They include three structural classes: (a) progesterone and derivatives, (b) testosterone and 19-nortestosterone derivatives, and (c) miscellaneous synthetic progestins (Fig. 25.19). Progesterone itself has low oral bioavailability because of poor absorption and almost complete metabolism in one passage through the liver. A recently available oral formulation is micronized progesterone in gelatin capsules. The micronized drug is much more readily absorbed, allowing oral delivery of progesterone, even though the dose must be much higher than a parenteral dose to compensate for extensive liver metabolism. Adding 17α -acyl groups slows metabolism of the 20-one, whereas a 6-methyl group enhances activity and reduces metabolism. Medroxyprogesterone acetate (MPA) is a particularly potent example (Table 25.2).

The structural requirements of the PR have been studied in detail.^{27,28} The progesterone 4-en-3-one ring A is a key to binding but only when it is in a conformation quite different from that of testosterone or the GCs. Reviews of this work contain stereo drawings that show the required conformations in three dimensions.^{27,28} Structural features modifying the steroid D ring are also important for optimal interactions with the PR.

Two important discoveries led to the development of the nortestosterone derivatives. One was the discovery that 19-norprogesterone still maintained significant progestational activity. The second was that 17α -alkynyl testosterone

TABLE 25.2 Comparative Progestational Activity of Selected Progestins

	Relative Oral Activity	Activity SC
Progesterone	(nil)	1
17 α -Ethinyltestosterone (ethisterone)	1	0.1
17 α -Ethinyl-19-nortestosterone (norethindrone)	5–10	0.5–1
Norethynodrel	0.5–1	0.05–1

(ethisterone) had greater progestational than androgenic activity. Although the 19-nortestosterones do have androgenic side effects, their primary activity, nevertheless, is progestational. In addition to causing a marked increase in progestational activity, the 17 α -alkynyl group also blocks metabolic or bacterial oxidation to the corresponding 17-ones. Thus, by adding a 17 α -ethinyl group to testosterone, one can simultaneously decrease androgenic activity, promote good progestational activity, and have an orally active compound as well. Table 25.2 illustrates the relative progestational activity of several progestins. A further modification to the nortestosterones yields progestins with minimal androgenic activities. Changing the alkyl group at C13 from a methyl to an ethyl group, as in levonorgestrel, reduces the androgenic effects, while maintaining the progestational effects.

The most exciting new research area relating to progestins is the development of nonsteroidal PR agonists. Tanaproget is the most successful example to date (phase II trials).⁸⁰ As can be seen in Figure 25.19, tanaproget is completely unrelated to progesterone, but it still has high affinity and selectivity for the PR. The nonsteroidal nature of tanaproget offers

the potential for a different side effect profile compared with the other progestins. While there is still a long road before approval of nonsteroidal progestins like tanaproget, there is great enthusiasm that a new class of progestins can be developed.

THERAPEUTIC USES OF PROGESTINS

Progestin therapy may cause menstrual irregularities, such as spotting or amenorrhea. Weight gain and acne have been associated with testosterone and 19-nortestosterone analog, in part because of their slight androgenic effects.

Birth Control. A significant use of the progestins, as of the estrogens, is inhibition of ovulation. Steroidal birth control agents are discussed in the following section on chemical contraception.

Reduction of the Risk of Endometrial Cancer from Postmenopausal Estrogens. As discussed in the section on therapeutic uses of estrogens, several studies have suggested that the combination of a progestin with an estrogen may significantly reduce the risk of endometrial cancer in women taking postmenopausal estrogens. Because of this, a progestin is often included in HRT.

Primary and Secondary Amenorrhea and Functional Uterine Bleeding Caused by Insufficient Progesterone Production or Estrogen–Progesterone Imbalance. Progestins have been used very effectively to treat primary and secondary amenorrhea, functional uterine bleeding, and related menstrual disorders caused by hormonal deficiency or imbalance.

Breast or Endometrial Carcinoma. Progestins can be used for palliative treatment of advanced carcinoma of the breast or endometrium. These agents should not be used in place of surgery, radiation, or chemotherapy.

PROGESTIN PRODUCTS

The progestins are primarily used in oral contraceptive products and in hormone replacement regimens for women. They are also used to treat several gynecological disorders: dysmenorrhea, endometriosis, amenorrhea, and dysfunctional uterine bleeding. Estrogens are given simultaneously in most of these situations.

Progesterone, USP. Progesterone, pregn-4-en-3,20-dione, is so rapidly metabolized that it is not particularly effective orally, being only one twelfth as active as intramuscularly. An oral formulation of micronized progesterone (Prometrium) is available. Progesterone given intramuscularly can be very irritating. A vaginal gel containing 4% or 8% progesterone offers an alternative dosage form. Progesterone was originally obtained from animal ovaries but is now prepared synthetically from plant sterol precursors. The discovery of 19-nortestosterones with progesterone activity made synthetically modified progestins of tremendous therapeutic importance.

Progesterone (and all other steroid 4-ene-3-ones) is light sensitive and should be protected from light.

Hydroxyprogesterone Caproate, USP. Hydroxyprogesterone caproate, 17-hydroxypregn-4-ene-3,20-dione hexanoate, is much more active and longer acting than

progesterone (see Table 25.2), probably because the 17 α ester hinders reduction to the 20-ol. In contrast, hydroxyprogesterone itself lacks progestational activity. The caproate ester is given only intramuscularly. The ester greatly increases oil solubility, allowing it to be slowly released from depot preparations, as one would predict from Figure 25.6. Although only currently available through compounding pharmacies, a new formulation (Gestiva) was deemed approvable by the FDA in late 2006 for the prevention of preterm labor, pending further studies.

Medroxyprogesterone Acetate, USP. MPA, 17-acetyloxy-6 α -methylpregn-4-ene-3,20-dione (Provera), adds a 6 α -methyl group to the basic 17 α -hydroxyprogesterone structure to greatly decrease the rate of reduction of the 4-ene-3-one system. The 17 α -acetate group also decreases reduction of the 20-one, similar to the 17 α -caproate. MPA is very active orally (see Table 25.2) and has such a long duration of action intramuscularly that it cannot be routinely used intramuscularly for treating many menstrual disorders. The IM formulation is useful in the palliative treatment of advanced endometrial, breast, and renal carcinomas. MPA also has an important role in several birth control products (Depo-Provera, Depo-SubQ Provera 104).

Megestrol Acetate, USP. Megestrol acetate, 17-hydroxy-6-methylpregna-4,6-diene-3,20-dione acetate (Megace), is a progestin used primarily for the palliative management of recurrent, inoperable, or metastatic endometrial or breast carcinoma. Megestrol acetate has also been indicated for appetite enhancement in patients with AIDS. The biochemical basis for this use of megestrol is unclear.

Nomegestrol Acetate, USP. Nomegestrol acetate, 17-hydroxy-6-methyl-19-norpregna-4,6-diene-3,20-dione acetate, is being investigated as the progestin component of a new oral contraceptive, in combination with the estrogen estradiol. This new combination, NOMAC/E2, is in phase III trials and would be the first oral contraceptive to utilize estradiol itself as the estrogenic component. Structurally, NOMAC is considered a nor-progesterone derivative that lacks the C19 methyl group in megestrol acetate.

Norethindrone, USP, and Norethynodrel, USP. Norethindrone, 17 α -ethinyl-19-nortestosterone, and its $\Delta^{5(10)}$ -isomer, norethynodrel, might appear at first glance to be subtle copies of each other. One would predict that the $\Delta^{5(10)}$ -double bond would isomerize in the stomach's acid to the Δ^4 -position. However, the two drugs were actually developed simultaneously and independently; hence, neither can be considered a copy of the other. Furthermore, norethindrone is about 10 times more active than norethynodrel (see Table 25.2), indicating that isomerization is not as facile in vivo as one might predict. Although they are less active than progesterone when given subcutaneously, they have the important advantage of being orally active. The discovery of the potent progestin activity of 17 α -ethinyltestosterone (ethisterone) and 19-norprogesterone preceded the development of these potent progestins. Both are orally active, with the 17 α -ethinyl group blocking oxidation to the less active 17-one. The rich electron density of the ethinyl group and the absence of the 19-methyl group greatly enhance progestin activity. Both compounds were of great importance as progestin components of oral contraceptives, although currently, use of norethynodrel is minimal. Norethindrone, USP, and norethindrone acetate,

USP, are widely used for all the usual indications of the progestins, as well as being components of oral contraceptives. Because these compounds retain key features of the testosterone structure, including the 17 β -OH, it is not surprising that they possess some androgenic side effects.

Ethinodiol Diacetate, USP. Ethinodiol diacetate, 19-norpregn-4-en-20-yne-3 β ,17 α -diol diacetate, is a prodrug of norethindrone. A combination of hydrolysis of both esters and oxidation of the C3 alcohol to the ketone is necessary to provide the fully active progestin.⁸¹

Norgestrel, USP, and Levonorgestrel, USP. Norgestrel, (17 α)-(±)-13-ethyl-17-hydroxy-18,19-dinorpregn-4-en-20-yn-3-one, and levonorgestrel, (17 α)-(–)-13-ethyl-17-hydroxy-18,19-dinorpregn-4-en-20-yn-3-one, have a C13 ethyl group instead of the C13 methyl but have progestational properties similar to those of norethindrone, with decreased androgenic effects. The ethyl group apparently provides unfavorable steric interactions with the AR that reduce the affinity compared with that with the PRs. Norgestrel is a racemic mixture, while levonorgestrel is the single active levorotatory enantiomer. Norgestrel is used only in oral contraceptives. Levonorgestrel is used in both oral combination birth control products and polymeric implants that provide contraception for up to 5 years.

Desogestrel, USP. Desogestrel, (17 α)-13-ethyl-11-methylene-18,19-dinorpregn-4-en-20-yn-17-ol, is a 19-nortestosterone analog with good progestin activity. Like the other progestins, it is orally active and used in combination with an estrogen in oral contraceptives. Desogestrel is a prodrug that must be oxidized to the 3-one in vivo to have progestational action. CYPs 2C9 and 2C19 have been implicated in the initial hydroxylation of desogestrel at C3.⁸²

Norgestimate, USP. Norgestimate, (17 α)-17-acetyloxy-13-ethyl-18,19-dinorpregn-4-en-20-yn-3-one oxime, is a 19-nortestosterone, 3-oxime prodrug that is orally active and used with an estrogen in oral contraceptive products. It has minimal androgenic action. Norgestimate is metabolized to 17-deacetylnorgestimate (norelgestromin) and norgestrel, which provide the progestational action.⁸³

Norelgestromin, USP. Norelgestromin, (17 α)-13ethyl-17-hydroxy-18,19-dinorpregn-4-en-20-yn-3-one, oxime, is the progestin component in the contraceptive patch (Ortho-Evra). First-pass metabolism in the liver is avoided by the transdermal application. Hepatic metabolism does occur, however, and norgestrel, an active metabolite, and other hydroxylated and conjugated metabolites are formed.

Etonogestrel, USP. Etonogestrel, 17 α -13-ethyl-17hydroxy-11-methylene-18,19-dinorpregn-4-en-20-yn-3-one, 3-ketodesogestrel, is the active metabolite of desogestrel. It is the progestin component in a newer implantable contraceptive (Implanon) and in the vaginal contraceptive ring (NuvaRing).

Drospirenone, USP. Drospirenone, 3-oxo-6 β ,7 β :15 β ,16 β -dimethylene-17 α -pregn-4-en-21,17-carbolactone, differs structurally from all the other commercially available progestins. Its structure is similar to that of spironolactone, an MR antagonist, and it does have antiminerocorticoid activity as well as progestational activity. It is also reported to have some antiandrogenic effects. The spiro lactone at C17 and the two cyclopropyl groups at C6-

C7 and C15-C16 contribute to these unique actions. Drospirenone is the progestin component in the newer oral contraceptives, Yasmin and Yaz, and in the HRT product, Angeliq.

Trimegestone. Trimegestone, 17 β -(*S*)-lactoyl-17-methyl-estra-4,9-dien-3-one, is a highly modified norprogesterone derivative. The key structural differences are a 17 β -lactoyl group in place of the typical acetyl group, a 17 α -methyl, and a C9-C10 double bond. Trimegestone lacks androgenic action and has little to no affinity for the ER and GR.⁸⁴ Although already approved for treating HRT in Sweden in combination with estradiol, it is still in development in the United States for its use in HRT and as a component of oral contraceptives.

Progesterone Receptor Antagonists and Selective Progesterone Receptor Modulators

Mifepristone (Mifeprex), a PR antagonist, is approved by the FDA to induce abortion in the first 49 days of pregnancy (Fig. 25.20). Mifepristone acts directly by antagonizing the effects of progesterone at PRs, as well as indirectly by causing a decrease in progesterone secretion from the corpus luteum. These combined effects lead to an increase in the level of prostaglandins, which stimulates uterine contractions.

Mifepristone (Mifeprex; RU 486)

CDB-2914

Asoprisnil

Figure 25.20 • Progesterone receptor antagonists and SPRM.

Mifepristone also causes a softening of the cervix, which aids in expulsion of the fertilized ovum. Mifepristone treatment is followed by the use of misoprostol, a prostaglandin E₂ analog, to ensure a complete abortion. Mifepristone also has antagonist action at GR.

Another PR antagonist that is in development is CDB-2914. It is a norprogesterone derivative that has the same 11 β -aryl substituent as seen in mifepristone, although it has less GR antagonism than mifepristone.⁸⁵ CDB-2914 is in phase III trials as an emergency contraceptive.

Compounds that have both agonist and antagonist properties at PRs, depending on the target tissue, have been called selective progesterone receptor modulators (SPRMs), which are analogous to the SERMs. Several are currently in development for various conditions, with asoprisnil being one that has been examined in phase III clinical trials for the treatment of uterine fibroids.⁸⁶ Asoprisnil has antagonist properties in breasts and partial agonist actions in the uterus and vagina.⁸⁷ Structurally, asoprisnil is a nortestosterone derivative with an 11 β -aryl group bearing an oxime in the 4' position. *O*-Demethylation at C-17 β produces a metabolite that also acts an SPRM.

CHEMICAL CONTRACEPTIVE AGENTS

The most notable achievement in chemical contraception came in the late 1950s and early 1960s with the development of oral contraceptive agents—"the pill." Since then, various contraceptive products have been introduced, including hormone-releasing intrauterine devices, polymer implants, injectable formulations, and a transdermal patch. In addition, postcoital contraceptives and abortifacients have been developed. Despite the advances in chemical contraceptive agents for women, no hormonal male contraceptives are currently available, although limited research in this area has been conducted. In the following pages, each of these approaches to chemical contraception is discussed. Individual compounds are discussed previously with the estrogens and progestins.

Ovulation Inhibitors and Related Hormonal Contraceptives

HISTORY⁸⁸⁻⁹¹

In the 1930s, several research groups found that injections of progesterone inhibited ovulation in rats, rabbits, and guinea pigs.⁹²⁻⁹⁴ In the early 1940s, it was discovered that estrogens, progesterone, or both could be used to prevent ovulation in women.^{95,96} In 1965, it was reported that progesterone given from day 5 to day 25 of the menstrual cycle would inhibit ovulation in women.⁹⁷ During this time, Djerassi et al.⁹⁸ of Syntex and Colton⁹⁹ of G. D. Searle and Co. reported the synthesis of norethindrone and norethynodrel. These progestins possessed very high progestational and ovulation-inhibiting activity.

Extensive animal and clinical trials confirmed in 1956 that Searle's norethynodrel and Syntex's norethindrone were effective ovulation inhibitors in women. In 1960, Searle marketed Enovid (a mixture of norethynodrel and mestranol), and in 1962, Ortho marketed Ortho-Novum (a mixture of norethindrone and mestranol) under contract with Syntex. Norethindrone has remained the most extensively used

progestin in oral contraceptives, but several other useful agents have been developed.

THERAPEUTIC CLASSES AND MECHANISM OF ACTION

The modern hormonal contraceptives fall into several major categories (Table 25.3), each with its own mechanism of

contraceptive action. Individual compounds are discussed with the estrogens and progestins in the previous section.

Combination Tablets: Mechanism of Action. Although recognized in the early 1940s that either estrogens or progestins could inhibit ovulation, it was subsequently found that combinations were highly effective. Some problems, such as

TABLE 25.3 Comparison of Steroid Contraceptive Regimens

1. Combination—Monophasic

Products are available in 21- or 28-day dispensers and refills. The 28-day dispensers contain several inert (or Fe21-containing) tablets of a different color, taken daily after the 21 days of active tablets. Doses of active tablets are shown.

Brand	Progestin	Estrogen
Necon 1/50	Norethindrone, 1 mg	Mestranol, 50 μ g
Norinyl 1 + 50	Norethindrone, 1 mg	Mestranol, 50 μ g
Ortho-Novum 1/50	Norethindrone, 1 mg	Mestranol, 50 μ g
Ovcon 50	Norethindrone, 1 mg	Ethinyl estradiol, 50 μ g
Demulen 1/50	Ethinodiol diacetate, 1 mg	Ethinyl estradiol, 50 μ g
Zovia 1/50E	Ethinodiol diacetate, 1 mg	Ethinyl estradiol, 50 μ g
Ovral-28	Norgestrel, 0.5 mg	Ethinyl estradiol, 50 μ g
Ogestrel	Norgestrel, 0.5 mg	Ethinyl estradiol, 50 μ g
Necon 1/35	Norethindrone, 1 mg	Ethinyl estradiol, 35 μ g
Norinyl 1 + 35	Norethindrone, 1 mg	Ethinyl estradiol, 35 μ g
Nortrel 1/35	Norethindrone, 1 mg	Ethinyl estradiol, 35 μ g
Ortho-Novum 1/35	Norethindrone, 1 mg	Ethinyl estradiol, 35 μ g
Modicon	Norethindrone, 0.5 mg	Ethinyl estradiol, 35 μ g
Necon 0.5/35	Norethindrone, 0.5 mg	Ethinyl estradiol, 35 μ g
Nortrel 0.5/35	Norethindrone, 0.5 mg	Ethinyl estradiol, 35 μ g
Ovcon-35	Norethindrone, 0.4 mg	Ethinyl estradiol, 35 μ g
Ortho-Cyclen	Norgestimate, 0.25 mg	Ethinyl estradiol, 35 μ g
Demulen 1/35	Ethinodiol diacetate, 1 mg	Ethinyl estradiol, 35 μ g
Zovia 1/35E	Ethinodiol diacetate, 1 mg	Ethinyl estradiol, 35 μ g
Yasmin	Drospirenone, 3 mg	Ethinyl estradiol, 30 μ g
Loestrin 21 1.5/30	Norethindrone acetate, 1.5 mg	Ethinyl estradiol, 30 μ g
Loestrin Fe 1.5/30	Norethindrone acetate, 1.5 mg	Ethinyl estradiol, 30 μ g
Microgestin Fe 1.5/30	Norethindrone acetate, 1.5 mg	Ethinyl estradiol, 30 μ g
Lo/Ovral	Norgestrel, 0.3 mg	Ethinyl estradiol, 30 μ g
Low-Ogestrel	Norgestrel, 0.3 mg	Ethinyl estradiol, 30 μ g
Desogen	Desogestrel, 0.15 mg	Ethinyl estradiol, 30 μ g
Ortho-Cept	Desogestrel, 0.15 mg	Ethinyl estradiol, 30 μ g
Apri	Desogestrel, 0.15 mg	Ethinyl estradiol, 30 μ g
Levlen	Levonorgestrel, 0.15 mg	Ethinyl estradiol, 30 μ g
Levora	Levonorgestrel, 0.15 mg	Ethinyl estradiol, 30 μ g
Nordette	Levonorgestrel, 0.15 mg	Ethinyl estradiol, 30 μ g
Alesse	Levonorgestrel, 0.1 mg	Ethinyl estradiol, 20 μ g
Aviane	Levonorgestrel, 0.1 mg	Ethinyl estradiol, 20 μ g
Levlite	Levonorgestrel, 0.1 mg	Ethinyl estradiol, 20 μ g
Loestrin 21 1/20	Norethindrone acetate, 1 mg	Ethinyl estradiol, 20 μ g
Loestrin Fe 1/20	Norethindrone acetate, 1 mg	Ethinyl estradiol, 20 μ g
Microgestin Fe 1/20	Norethindrone acetate, 1 mg	Ethinyl estradiol, 20 μ g

2. Combination—Biphasic

Products are available in 21- or 28-day dispensers and refills. They are taken on the same schedule of 21 days plus 7 days of no (or inert) tablets as the monophasics above, except Mircette. Doses of active tablets are shown.

Brand	Progestin and Estrogen
Jenest-28	7 days: Norethindrone, 0.5 mg, and ethinyl estradiol, 35 μ g 14 days: Norethindrone, 1 mg, and ethinyl estradiol, 35 μ g
Necon 10/11	10 days: Norethindrone, 0.5 mg, and ethinyl estradiol, 35 μ g 11 days: Norethindrone, 1 mg, and ethinyl estradiol, 35 μ g
Ortho-Novum 10/11 21	10 days: Norethindrone, 0.5 mg, and ethinyl estradiol, 35 μ g 11 days: Norethindrone, 1 mg, and ethinyl estradiol, 35 μ g
Mircette	21 days: Desogestrel, 0.15 mg, and ethinyl estradiol, 20 μ g 5 days: Ethinyl estradiol, 10 μ g 2 days: Inert

3. Combination—Triphasic

Products are available in 21- or 28-day dispensers and refills. They are taken on the same schedule of 21 days plus 7 days of no (or inert) tablets as the monophasics. Doses of active tablets are shown.

Brand	Progestin and Estrogen
Ortho-Novum 7/7/7	7 days: Norethindrone, 0.5 mg, and ethinyl estradiol, 35 μ g 7 days: Norethindrone, 0.75 mg, and ethinyl estradiol, 35 μ g
Ortho-Tri-Cyclen	7 days: Norethindrone, 1 mg, and ethinyl estradiol, 35 μ g 7 days: Norgestimate, 0.18 mg, and ethinyl estradiol, 35 μ g 7 days: Norgestimate, 0.215 mg, and ethinyl estradiol, 35 μ g
Trinorinyl	7 days: Norgestimate, 0.25 mg, and ethinyl estradiol, 35 μ g 7 days: Norethindrone, 0.5 mg, and ethinyl estradiol, 35 μ g 9 days: Norethindrone, 1 mg, and ethinyl estradiol, 35 μ g
Tri-Levlen	5 days: Norethindrone, 0.5 mg, and ethinyl estradiol, 35 μ g 6 days: Levonorgestrel, 0.05 mg, and ethinyl estradiol, 30 μ g 5 days: Levonorgestrel, 0.075 mg, and ethinyl estradiol, 40 μ g
Tri-Phasil	10 days: Levonorgestrel, 0.125 mg, and ethinyl estradiol, 30 μ g 6 days: Levonorgestrel, 0.05 mg, and ethinyl estradiol, 30 μ g 5 days: Levonorgestrel, 0.075 mg, and ethinyl estradiol, 40 μ g
Trivora	10 days: Levonorgestrel, 0.125 mg, and ethinyl estradiol, 30 μ g 6 days: Levonorgestrel, 0.05 mg, and ethinyl estradiol, 30 μ g 5 days: Levonorgestrel, 0.075 mg, and ethinyl estradiol, 40 μ g
Estrostep	10 days: Levonorgestrel, 0.125 mg, and ethinyl estradiol, 30 μ g 5 days: Norethindrone acetate, 1 mg, and ethinyl estradiol, 20 μ g 7 days: Norethindrone acetate, 1 mg, and ethinyl estradiol, 30 μ g 9 days: Norethindrone acetate, 1 mg, and ethinyl estradiol, 35 μ g

4. Progestin Only

An active tablet is taken each day of the year.

Brand	Progestin	Dose
Micronor	Norethindrone	0.35 mg
Nor-Q.D.	Norethindrone	0.35 mg
Ovrette	Norgestrel	0.075 mg

5. Injectable Depot Hormonal Contraceptives

Brand	Drug	Dosage Cycle
Depo-Provera	Medroxyprogesterone acetate alone	150 mg/month 150 mg every 3 months
Lunelle	Medroxyprogesterone acetate (MPA), 25 mg, and estradiol cypionate (E2C), 5 mg/0.5 mL	0.5-mL IM injection once in deltoid, gluteus maximus, or anterior thigh every 28–30 days

6. Transdermal Contraceptive Patch

Brand	Release Rate	Total Hormone Content	Dosage Cycle
Ortho-Evra	0.15-mg norelgestromin, 0.02 mg, ethinyl estradiol/24 hours	6-mg norelgestromin, 0.075 mg, ethinyl estradiol	One patch each week for 3 weeks, 1 week no patch.

7. Hormone-Releasing Implants, IUDs, and Vaginal Rings

Brand	Drug	Dosage Cycle
Progestasert	Progesterone-releasing IUD	38-mg dose in IUD lasts 1 year
Mirena	Levonorgestrel-releasing intrauterine system (LRIS)	52-mg dose in LRIS provides contraception for up to 5 years
Norplant	6 Silastic capsules with 36-mg levonorgestrel; all 6 capsules are inserted subdermally in the middle upper arm	Contraceptive efficacy lasts for 5 years if the implants are not removed

(table continues on page 844)

TABLE 25.3 Comparison of Steroid Contraceptive Regimens (continued)

Brand	Drug	Dosage Cycle
Implanon	One polymeric rod with 68-mg etonorgestrel, released at a rate of $\sim 40 \mu\text{g/day}$.	Contraceptive efficacy lasts up to 3 years if the implant is not removed
NuvaRing	11.7 mg etonorgestrel, 2.7-mg ethinyl estradiol in a flexible, polymeric vaginal ring	Vaginal ring is inserted for 3 weeks duration, then 1 week off before insertion of a new ring

8. Emergency Contraceptives

Brand	Drug	Dosage
Plan B	0.75-mg levonorgestrel	The first dose (1 tablet) should be taken as soon as possible within 72 hours of intercourse; the second dose (1 tablet) must be taken 12 hours later
Preven	0.25-mg levonorgestrel, 0.05-mg ethinyl estradiol	The first dose (2 tablets) should be taken as soon as possible within 72 hours of intercourse; the second dose (2 tablets) must be taken 12 hours later

breakthrough (midcycle) bleeding, were also reduced by the use of a combination of progestin and estrogen.

It is now believed that the combination tablets suppress the production of LH, FSH, or both by a feedback-inhibition process (see Fig. 25.9). Without FSH or LH, ovulation is prevented. The process is similar to the natural inhibition of ovulation during pregnancy, caused by the release of estrogens and progesterone from the placenta and ovaries. An additional effect comes from the progestin causing the cervical mucus to become very thick, providing a barrier for the passage of sperm through the cervix. Because pregnancy is impossible without ovulation, however, the contraceptive effects of thick cervical mucus or alterations in the lining of the uterus (to decrease the probability of implantation of a fertilized ovum) would appear to be quite secondary. Nevertheless, occasional ovulation may occur, and thus the alterations of the cervical mucus and the endometrium may actually serve an important contraceptive function (especially, perhaps, when the patient forgets to take one of the tablets). During combination drug treatment, the endometrial lining develops enough for withdrawal bleeding to occur about 4 or 5 days after taking the last active tablet of the series (see Table 25.3).

Monophasic (Fixed) Combinations

The monophasic combinations of a progestin and estrogen contain the same amount of drug in each active tablet (see Table 25.3). As discussed later in this chapter, the trend in prescribing has been toward lower doses of estrogen. As estrogen levels are reduced, however, breakthrough bleeding (or spotting) becomes an annoying side effect for some patients at early to midcycle. Spotting after midcycle or amenorrhea appears to be related to too little progestin relative to the estrogen. The biphasic and triphasic combinations were developed to solve these breakthrough-bleeding problems in some patients.

Biphasic and Triphasic (Variable) Combinations

In the natural menstrual cycle, progesterone plasma concentrations peak late in the cycle. The higher estrogen/progesterone ratio early in the cycle is believed to assist in development of the endometrium. The higher progesterone

concentration later contributes to proliferation of the endometrium and a resultant "normal" volume of menstrual flow. The biphasic and triphasic combinations attempt to mimic this variation in estrogen/progestin levels, and thereby reduce the incidence of spotting associated with low-dose monophasic combinations. With proper selection of patients, the goal has been achieved; but in other patients, the incidence of spotting has not decreased appreciably.

Extended Oral Contraceptive Therapy

Several oral contraceptive products that offer women the option to reduce the number of menstrual cycles are now available. Three of these use a 91-day cycle as opposed to the current 28-day cycles typically used for oral contraceptives. The key difference with this approach is that the number of menstrual cycles during the year would be reduced from 12 to 4. The monophasic products, Seasonale and Quasense, have levonorgestrel (0.15 mg) and ethinyl estradiol (30 μg) as the progestin and estrogen, respectively. The dosing regimen has 84 days of hormones, followed by a week of inert tablets. Seasonique is a biphasic contraceptive using the same progestin and estrogen, but with 7 days of 10- μg ethinyl estradiol tablets, instead of inert tablets. The latest addition to extended oral contraceptive therapy is Lybrel, a low-dose product that is dosed continuously, completely eliminating monthly periods. Lybrel uses 90- μg levonorgestrol and 20- μg ethinyl estradiol in each tablet. Although regular menstrual periods will be eliminated, many women in the clinical trials experienced unscheduled breakthrough bleeding.

HOW SAFE?

The safety of the pill has been investigated extensively because of the widespread use of these drugs in healthy young women. Overall, oral contraceptives have an excellent safety profile in healthy, nonsmoking women of child-bearing age.¹⁰⁰ Early studies, based largely on the earlier products that contained high doses of estrogen, showed an alarming incidence of thromboembolic disease (blood clots). More recent studies have shown a greatly reduced risk of cardiovascular

effects with lower estrogen doses. Another concern has been an association between estrogens and increased cancer risk. Recent reanalysis of clinical data supports a slightly increased risk of breast cancer in women taking oral contraceptives, but the risk subsides within 10 years of discontinuation of use.¹⁰¹ This small increase in incidence of breast cancer is not greatly affected by duration of use, dose, age at first use, or progestin component. In addition, use of oral contraceptives has shown a decreased risk for endometrial and ovarian cancers.¹⁰¹

The overall results of these studies have been that (a) the sequential contraceptive products with their high doses of estrogen have been removed from American markets; (b) most combination contraceptives now marketed contain less than 50 μg of estrogen per dose (see Table 25.3); (c) progestin-only or minipill products are available (see Table 25.3); and (d) a few groups of women who should definitely not take oral contraceptives (e.g., women with a history of thromboembolic disease or other cardiovascular disease, women who are heavy smokers over the age of 35, and women with a history of breast cancer in their immediate family) have been identified. The actual incidence of “pill-induced” cardiovascular death for nonsmoking young women is quite small, and there is not a widespread link between oral contraceptive use and cancer. Cigarette smoking increases the risk of thromboembolic disorders associated with oral contraceptive use, so women should be counseled to abstain from smoking while using oral contraceptives.

Progestin Only (Minipill). The estrogen component of sequential and combination oral contraceptive agents has been related to some side effects, with thromboembolism being a concern. One solution to this problem has been to develop new products with decreased estrogen content. The minipill contains no estrogen at all.

Although higher doses of progestin are known to suppress ovulation, minipill doses of progestin do not suffice to suppress ovulation in all women. Some studies have indicated that increased viscosity of the cervical mucus (or sperm barrier) could account for much of the contraceptive effect. Low doses of progestin have also been found to increase the rate of ovum transport and to disrupt implantation. There is a good probability that most, or all, of these factors contribute to the overall contraceptive effect of the minipill. The incidence of pregnancy with the minipill is slightly higher than with combination products, although still very low when the minipill is used as directed.

Depo-Provera. MPA IM injection (Depo-Provera) provides contraception for 3 months after a single 150-mg IM dose. Most women experience some irregular bleeding or spotting and often experience small weight gain. Fertility returns for most women within the first 12 months after discontinuance of Depo-Provera. Contraception typically continues for a few weeks beyond the 3-month term, giving patients a short grace period if the subsequent IM dose is delayed. A related product is Depo-SubQ Provera 104. This is a formulation designed for subcutaneous injection and uses 104 mg of MPA for the same 3-month period of effectiveness.

Transdermal Contraceptives. One transdermal contraceptive patch, Ortho-Evra, is available. The product contains norelgestromin and ethinyl estradiol. A patch is applied once a week for 3 weeks, followed by a week with no patch. The

pregnancy rate for this product is 1 in 100, a rate similar to that often observed with oral contraceptives. Reports of increased risk of blood clots relative to the use of the pill appeared several years after the introduction of Ortho-Evra, which led the FDA to strengthen the warning associated with the use of this product.

Progesterone IUD. The low progestin doses of the minipill seem to have a direct effect on the uterus and associated reproductive tract. Therefore, it would seem possible to lower the progestin dose even more if the drug was released in the reproductive tract itself.

The Progestasert IUD (Progesterone Intrauterine Contraceptive System, USP) has 38 mg of microcrystalline progesterone dispersed in silicone oil. The dispersion is contained in a flexible polymer in the approximate shape of a T. The polymer acts as a membrane to permit 65 μg of progesterone to be released slowly into the uterus each day for 1 year. The progesterone-containing IUD has had some of the therapeutic problems of other IUDs, including a relatively low patient continuation rate, some septic abortions, and some perforations of uterus and cervix.

Levonorgestrel-Releasing Intrauterine System (LRIS). Because the Progestasert system provided evidence that a progestin-releasing intrauterine device was an effective contraceptive, another intrauterine system has been developed with use of a different progestin. Mirena is a plastic T-shaped frame, with the stem of the “T” containing 52 mg of levonorgestrel. The levonorgestrel is released slowly, at a dose lower than in a pill (approximately one-seventh strength), directly to the lining of the uterus. This local release and absorption of the hormone helps to reduce systemic progesterone-type side effects. The contraceptive effectiveness of this device lasts up to 5 years.

Mirena acts as a contraceptive in two ways: it thickens the mucus at the cervix, preventing sperm from getting through, and it also thins the lining of the uterus, preventing implantation. In some women it also prevents ovulation. An additional feature of the LRIS is that menstrual periods are typically lighter than usual. The LRIS may be useful to alleviate the difficulties associated with heavy periods, even in patients who do not need contraception.

There is a small chance that the device may dislodge in the early months of use. Although the LRIS releases a reduced amount of progestin, it does slightly increase progesterone levels in the bloodstream. This increased progesterone can cause side effects including headache, water retention, breast tenderness, or acne, although these are typically mild. Bleeding problems are the most common side effect, but this effect usually ceases after 3 to 6 months of use.

Intrauterine Ring. Another contraceptive option is a flexible polymeric ring, approximately 2.1 inches in diameter, that contains etonogestrel and ethinyl estradiol (NuvaRing). The ring is inserted into the vagina by the woman herself and remains inserted for 3 weeks. The spent ring is removed for 1 week to allow menstrual period. A new ring is inserted 1 week after the removal of the prior ring. The ring contains 11.7 mg of etonogestrel and 2.7 mg of ethinyl estradiol, with a release rate of 0.12-mg etonogestrel per day and 0.015 mg of ethinyl estradiol per day. Unlike a diaphragm, the placement of the vaginal ring contraceptive device is not critical. Clinical trials suggest a 1% to 2% pregnancy rate for women

using the ring as indicated. Like other hormone-based contraceptives, the ring should not be used by women who have cardiovascular disease, blood clots, or hormone-dependent breast cancer. Women should also abstain from smoking while using the ring.

CONTRACEPTIVE IMPLANTS

Norplant. The first implantable contraceptive was Norplant, a set of six flexible Silastic (dimethylsiloxane/methylvinylsiloxane copolymer) capsules that contain levonorgestrel. The capsules implanted in the midportion of the upper arm provided contraception for up to 5 years. Contraceptive efficacy was very high, but the insertion and removal procedures required extra training of physicians, a feature that reduced the desirability of this product. Although Norplant was extremely effective as a contraceptive, various legal issues, public concerns, and production issues led the manufacturers to discontinue production of Norplant. Norplant II, a two-rod implantable system that had reduced problems with insertion and removal, was approved by the FDA but was never marketed in the United States. This system, however, is available as the product Jadelle in various other countries.

The implantable system that has replaced Norplant in the United States is Implanon, a single-rod system (40 × 2 mm) that releases etonogestrel (3-ketodesogestrel) rather than the levonorgestrel. The contraceptive efficacy is up to 3 years. With a single polymer rod and a specially designed applicator system, the insertion/removal difficulties with Norplant should be avoided.

POSTCOITAL CONTRACEPTIVES

Two products specifically designated for postcoital or emergency contraception have been approved. Plan B uses a high-dose, progestin-only approach, whereas Preven combines a progestin and an estrogen (Table 25.3). Both must be taken within 72 hours of unprotected intercourse, followed by another dose 12 hours later. Plan B had its status changed in 2006 to over-the-counter for women 18 years of age or older. Women younger than 18 years old must still obtain a prescription. These treatments are intended only for use in short-term emergency situations.

Combined Estrogen/Progestin Hormone Replacement Therapy

Similar to the combined estrogen and progestin oral contraceptives, combination estrogen/progestin products are

available for use in HRT in women. In contrast to the oral contraceptives, in which the estrogen component is almost always ethinyl estradiol, the estrogen component of HRT products is typically conjugated estrogens or estradiol. The progestin component for HRT is often MPA or norethindrone acetate. Table 25.4 lists the currently available combination products. Both oral tablets and a transdermal patch are used.

TREATMENT OF VASOMOTOR SYMPTOMS OF MENOPAUSE AND ATROPHIC VAGINITIS

Estrogens have been very useful in treating the hot flashes associated with early menopause, as well as atrophic vaginitis and other vaginal symptoms of inadequate estrogen production. The evidence that they result in enhanced mood and improved cognitive function in postmenopausal women is less clear, however, and more studies are needed to sort out the competing claims in these areas.^{102,103} Based on the results of the Women's Health Initiative (WHI) studies of HRT, however, the lowest effective doses should be used for as short of a duration as necessary for the management of postmenopausal symptoms (see below).

OSTEOPOROSIS PREVENTION AND TREATMENT^{104–106}

Osteoporosis is an enormous public health problem, responsible for approximately 1.5 million fractures in the United States each year. Because of the prevalence of osteoporosis, especially in older women, the prevention and treatment of this condition have received much attention. Prior to menopause, a good diet and exercise are essential for young women, to decrease the risk of osteoporosis later in life. After menopause, supplemental estrogens can have a positive effect relative to osteoporosis. Estrogens mainly act by decreasing bone resorption, so estrogens are better at preventing bone loss than restoring bone mass. Estrogens taken after menopause (often with a supplemental progestin) have been unequivocally shown to greatly decrease the incidence and severity of osteoporosis, especially when combined with good nutrition and exercise. The long-term use of estrogens plus a progestin for preventing osteoporosis, however, should be carefully evaluated in light of the WHI studies examining HRT for lowering the risk of heart disease (see next page). Alternatives to estrogens for the prevention of osteoporosis, such as raloxifene and bisphosphonates, should also be considered.

TABLE 25.4 Combined Progestin/Estrogen Hormone Replacement Therapy Products (Available in Tablets or a Transdermal Patch)

Brand	Progestin	Estrogen
Prempro	Medroxyprogesterone acetate, 2.5 or 5 mg	Conjugated estrogens, 0.625 mg
Premphase ^a	Medroxyprogesterone acetate, 5 mg	Conjugated estrogens, 0.625 mg
Femhrt	Norethindrone acetate, 1 mg	Ethinyl estradiol, 5 μg
Activella	Norethindrone acetate, 0.5 mg	Estradiol, 1 mg
Ortho-Prefest ^b	Norgestimate, 0.09 mg	Estradiol, 1 mg
CombiPatch	Norethindrone acetate, 0.14 or 0.25 mg	Estradiol, 50 μg

^aPremphase is dosed 14 days of estrogen-only tablets (0.625-mg conjugated estrogens), followed by 14 days of combined progestin/estrogen.

^bOrtho-Prefest is dosed 15 days of estradiol (1 mg) alone, then 15 days of the combined progestin/estrogen.

HORMONE REPLACEMENT THERAPY, HEART DISEASE, AND CANCER—WOMEN'S HEALTH INITIATIVE TRIALS^{107,108}

After years of general recommendations for the beneficial use of estrogens after menopause for lowering the risk of heart disease, the results of a long-term study with conjugated estrogens supplemented with a progestin have indicated that the risks of this approach outweigh the benefits. The WHI trial, which enrolled over 16,000 postmenopausal women between 1993 and 1998, was terminated early in 2002 because of an unacceptably high level of adverse effects relative to the benefits gained. With long-term use (average follow-up of 5.2 years), there was a slight increase in the incidence of coronary heart disease, as well as an increase in breast cancer risk. Although there was a slight decrease in the risk of colorectal cancer and fewer hip fractures, the effects on the heart and breast argue against the use of estrogens plus a progestin for the prevention of coronary heart disease in postmenopausal women. A second WHI trial with estrogen alone in postmenopausal women without a uterus was halted in 2004. In this study, with an average of 7 years of follow-up, no effect was seen on heart disease, but there was an increase in stroke risk as well as a decrease in hip fractures. In both studies, a single drug regimen was used (0.625 mg of conjugated equine estrogens alone or with 2.5 mg of MPA), so care should be taken in extending these results to other regimens and products. Several years after the studies were stopped, the medical profession is still analyzing and debating the results of the WHI trials.^{108,109} It is fair to say that there are many important health issues associated with HRT and each patient should discuss the costs and benefits of HRT with their physicians and pharmacists. In addition to the WHI studies indicating an increase in breast cancer risk, the Million Women Study conducted in the United Kingdom indicated an additional risk of ovarian cancer for women using HRT, with an increase in risk correlating with the duration of use.¹¹⁰

ANDROGENS¹¹¹

Endogenous Androgens

Testosterone and its more potent reduction product 5α -DHT are produced in significantly greater amounts in males than in females, but females also produce low amounts of these “male” sex hormones. These endogenous compounds have two important activities: androgenic activity (promoting male sex characteristics) and anabolic activity (muscle building).

DHEA and androstenedione are referred to as *adrenal androgens*, although this nomenclature is somewhat misleading. DHEA and androstenedione are biosynthetic precursors to the androgens but have only low affinity for the AR themselves.^{112,113} Therefore, DHEA or androstenedione can have androgenic actions, but only after *in vivo* conversion to testosterone and DHT. DHEA and androstenedione are, however, also precursors to the estrogens, so estrogenic actions may also occur.

Biosynthesis

As shown in Figure 25.5, testosterone can be synthesized through pregnenolone, DHEA, and androstenedione. About

7 mg/d is synthesized by young human adult males. Labeling experiments have also shown that it can be biosynthesized from androst-5-ene- $3\beta,17\beta$ -diol, a reduction product of DHEA.

Testosterone is primarily produced by the interstitial cells of the testes, synthesized largely from cholesterol made in Sertoli cells. DHT is also secreted by the testes, as well as being produced in other tissues. The ovaries and adrenal cortex synthesize androstenedione and DHEA, which can be rapidly converted to testosterone in many tissues. Testosterone levels in the plasma of men are 5 to 100 times higher than those in the plasma of women.

Testosterone is produced in the testes in response to LH release by the anterior pituitary, as shown in Figure 25.10. Testosterone and DHT inhibit the production of LH and FSH by a feedback-inhibition process. This is quite similar to the feedback inhibition by estrogens and progestins in FSH and LH production.

Metabolism of Androgens

Testosterone is rapidly converted to 5α -DHT in many tissues by the action of 5α -reductase. Depending on the tissue, this is either to activate testosterone to the more potent androgen, DHT (e.g., in the prostate), or a step in the metabolic inactivation of this androgen. The primary route for metabolic inactivation of testosterone and DHT is oxidation to the 17-one. The 3-one group is also reduced to the 3α - (major) and 3β -ols (minor). The metabolites are shown in Figure 25.21. Androsterone is the major urinary metabolite and was the first “androgenic” steroid isolated. These metabolites are excreted mainly as the corresponding glucuronides. Other minor metabolites have also been detected.¹¹¹

Biological Activities of Androgens¹¹⁴

Testosterone and DHT cause pronounced masculinizing effects, even in the male fetus. They induce the development of the prostate, penis, and related sexual tissues. At puberty, the secretion of testosterone by the testes increases greatly, leading to an increase in facial and body hair, deepening of the voice, increased protein anabolic activity and muscle mass, rapid growth of long bones, and loss of some subcutaneous fat. Spermatogenesis begins, and the prostate and seminal vesicles increase in activity. Sexual organs increase in size. The skin becomes thicker, and sebaceous glands increase in number, leading to acne in many young people. The androgens also play important roles in male psychology and behavior. In women, testosterone plays a role in libido, mood, muscle mass and strength, as well as bone density.^{115,116}

Structural Classes: Anabolic Androgenic Steroids

The androgens, also known as anabolic androgenic steroids (AAS), include all of the therapeutic agents whose main actions are mediated by the AR. The inclusion of both *anabolic* and *androgenic* in referring to these compounds reflects the fact that no products are currently available in which the anabolic properties of androgens can be separated from the androgenic properties. The commonly used AAS are shown in Figure 25.22. Several recent reviews on AAS have been published.^{111,117}

Figure 25.21 • Metabolism of testosterone and 5 α -DHT (conjugates of the metabolites are also formed). (HSD, hydroxysteroid dehydrogenase.)

SEMISYNTHETIC ANALOGS

Because bacterial and hepatic oxidation of the 17 β -hydroxyl to the 17-one is a key component of metabolic inactivation, 17 α -alkyl groups have been added to prevent oxidation of the alcohol. Even though 17 α -methyltestosterone is only about half as active as testosterone, it can be taken orally because its half-life is longer than that of testosterone. 17 α -ethyltestosterone has greatly reduced activity, as shown in Table 25.5.⁹⁸ As mentioned previously, addition of an α -alkynyl group provides more progestogenic action than androgenic

action, although some activities at AR are retained. A disadvantage of the 17 α -methyl testosterone is hepatotoxicity. Hepatic disturbances, jaundice (occasionally), and death (in rare cases) may occur, particularly in the high doses often used by athletes (see next section).

Table 25.5 illustrates some structure–activity effects of the androgens, such as the greatly decreased activity of the 17 α -ol isomer of testosterone (epitestosterone). A carbonyl group at C3 and a 17 β -OH on a steroid backbone are key structural features required for high affinity at the AR. Hundreds of different AAS have been synthesized and studied. The goal of many synthetic programs was to make a compound that possessed the anabolic properties of testosterone but lacked its androgenic actions. Although numerous compounds were prepared that did display improved anabolic/androgenic ratios in vitro, no compounds completely lacked androgenic action.¹¹⁷ Also, the high anabolic/androgenic ratios did not appear to be maintained when these drugs were used in humans. Despite the inability to prepare a strictly anabolic steroid, several trends were noticed in the structure–activity relationships for the hundreds of AAS that have been prepared.¹¹¹ Removal of the C19 methyl, 5 α -reduction, and replacement of C2 with an oxygen are all structural changes that tend to increase anabolic activity. Although most of the androgens have a carbonyl at C3, stanozolol (Fig. 25.22) represents an “anabolic” steroid that lacks the C3 carbonyl, but still is active. As with other compounds that have been discussed, OH groups in the testosterone are often converted to the corresponding esters to prolong activity or to provide some protection from oxidation.

Therapeutic Uses of Anabolic Androgenic Steroids

The primary use of AAS is in androgen replacement therapy in men, either at maturity or in adolescence. The cause of

TABLE 25.5 Androgenic Activities of Some Androgens

Compound	μg Equivalent to an International Unit
Testosterone (17 β -ol)	15
Epitestosterone (17 α -ol)	400
17 α -Methyltestosterone	25–30
17 α -Ethyltestosterone	70–100
17 α -Methylandrostane-3 α , 17 β -diol	35
17 α -Methylandrostane-3-one-17 β -ol	15
Androsterone	100
Epiandrosterone	700
Androstane-3 α , 17 β -diol	20–25
Androstane-3 α , 17 α -diol	350
Androstane-3 β , 17 β -diol	500
Androstane-17 β -ol-3-one	20
Androstane-17 α -ol-3-one	300
Δ^5 -Androstene-3 α , 17 β -diol	35
Δ^5 -Androstene-3 β , 17 β -diol	500
Androstenedione-3, 17	120–130
Δ^4 -Androstenedione	120

Data are from Djerassi, C., Miramontes, L., Rosenkranz, G., et al.: Steroids. LIV. Synthesis of 19-Nor-17 α -ethynyltestosterone and 19-Nor-17 α -methyltestosterone. J. Am. Chem. Soc. 76:4092–4094, 1954.

Figure 25.22 • Testosterone and synthetic anabolic androgenic steroids.

testosterone deficiency may be either hypogonadism or hypopituitarism.

The use of the AAS for their anabolic activity or for uses other than androgen replacement has been limited because of their masculinizing actions. This has greatly limited their use in women and children. Although anabolic activity is often needed clinically, especially in patients with AIDS, none of the products presently available is free of significant androgenic side effects.

The masculinizing (androgenic) side effects in females include hirsutism, acne, deepening of the voice, clitoral enlargement, and depression of the menstrual cycle. Furthermore, AAS generally alter serum lipid levels and increase the probability of atherosclerosis, characteristically a disease of men and postmenopausal women.

The masculinizing effects of the AAS preclude their use in most circumstances in women. Secondary treatment of advanced or metastatic breast carcinoma in selected patients is generally considered to be the only indication for large-dose, long-term androgen therapy in women. In lower doses, androgen replacement therapy is more often being considered for use in menopausal and postmenopausal women for the positive effects on libido, mood, vasomotor symptoms, and muscle mass, all areas negatively affected by decreased testosterone levels in aging women.¹¹⁸

Androgens are also used to relieve bone pain associated with osteoporosis and to treat certain anemias, although this use has greatly decreased because of the availability of erythropoietin. In all cases, use of these agents requires caution.

Androgens and Sports

The use of androgens for their anabolic effects (hence the term *anabolic steroids*) by athletes began in the late 1940s and has, at times, been widespread.¹¹⁹ Prior to urine testing requirements, it was estimated that up to 80% of competitive weight lifters and about 75% of professional football players used these drugs, along with various other athletes. Despite the growing awareness of the dangers of anabolic steroid use over the past 20 years, abuse of steroids is still a problem in many competitive sports. The recent Bay Area Laboratory Co-Operative (BALCO) scandal involving professional athletes in baseball, football, and track, and the continuing steroid problems seen in cycling illustrate this phenomenon all too well.

Some of the specific risks associated with the use/abuse of AAS are¹²⁰:

In both sexes

Increased risk of coronary heart disease, stroke, or obstructed blood vessels

Increased aggression and antisocial behavior (known as "steroid rage")

Liver tumors, peliosis hepatis (blood-filled cysts), and jaundice (for 17α -alkylated androgens only)

In men

Testicular atrophy with consequent sterility or decreased sperm count and abnormal motility and morphology

Impotence

Enlarged prostate

Breast enlargement (for androgens that can be converted to estrogens)

In women

Clitoral enlargement

Facial and body hair growth

Baldness

Deepened voice

Breast diminution

Because of these risks, the International Olympic Committee, numerous professional sports organizations, and the National Collegiate Athletic Association (NCAA) banned all anabolic drugs. Testing of elite athletes for performance-enhancing drugs of all types, as mentioned previously, is now commonplace.

Although numerous anabolic steroids have been synthesized and used/abused by athletes, most likely all of the androgens have been used by athletes in an attempt to improve strength and increase muscle mass. In the early years, the 17α -alkylated steroids with high anabolic/androgenic ratios in vitro were used with the belief that the anabolic properties of these drugs were greater than those of other androgens such as testosterone. With the ban on the use of steroids in most sports and the prevalence of drug testing, however, the 17α -alkylated steroids have fallen out of favor because of the ease of detecting these compounds by mass spectrometry. This has led to a greater use of testosterone and its esters, as well as the androgen precursors androstenedione ("andro"), androstenediol, androstanediol, and DHEA. The belief is that because these steroids all occur naturally, detecting them will be much more difficult. Although it is true that assays for the endogenous steroids must now discriminate deviations from normal ratios, it is possible to detect the abuse of these compounds. Pharmaceutical testosterone, for example, can be detected by a urine test examining the ratio of testosterone glucuronide to epitestosterone glucuronide and by determining the carbon isotope ratio that can distinguish between synthetic and natural testosterone.¹²¹ Another approach to avoid detection is the synthesis and use of designer steroids, chemicals that have not been previously described and therefore are not actively pursued in drug screens. Tetrahydrogestrinone (THG) (see Figure 25.22) is a designer steroid associated with the BALCO scandal. THG is a derivative of the progestin, gestrinone, that was unknown prior to 2003.¹²² In 2004, THG and the testosterone precursors (except DHEA) were reclassified as Schedule III controlled substances.

Many studies have attempted to determine if taking anabolic steroids improves athletic performance.^{123,124} Some failed to use controls (athletes who trained in an identical manner but did not take anabolic steroids). Others failed to use placebos in at least a single-blind research design (neither the treated nor control groups knowing that they were taking).

An additional problem with many of the studies has been that typical therapeutic doses have been tested for their anabolic properties in clinical settings, whereas athletes typically use much higher doses.¹¹⁷ Although short-term enhancements in strength and increases in muscle mass have been observed, many negative side effects can be expected with long-term steroid use. It would be fair to say, therefore, that the benefit of anabolic steroids to athletic performance is uncertain. The risks of using these drugs appear to outweigh their benefits.

Anabolic Androgenic Steroid Products

Therapeutic uses of the androgens are discussed previously. 17β -Esters and 17α -alkyl products are available for a complete range of therapeutic uses. These drugs are contraindicated in men with prostate cancer; in men or women with heart, kidney, or liver disease; and in pregnancy. Diabetics using the androgens should be carefully monitored. Androgens potentiate the action of oral anticoagulants, causing bleeding in some patients, and they may also interfere with some laboratory tests. Female patients may develop virilization side effects, and doctors should be warned that some of these effects may be irreversible (e.g., voice changes). All the anabolic agents currently commercially available (oxymetholone, oxandrolone, nandrolone decanoate) have significant androgenic activity; hence, virilization is a potential problem for all women patients. Many of the anabolic agents are orally active, as one would predict by noting a 17α -alkyl group in many of them (see Fig. 25.22). Those without the 17α -alkyl (nandrolone decanoate) are active only intramuscularly. The 17α -alkyl products may induce liver toxicity in some patients.

Testosterone, USP. Testosterone, 17β -hydroxyandrost-4-en-3-one, is a naturally occurring androgen in men. In women, it mainly serves as a biosynthetic precursor to estradiol but also has other hormonal effects. It is rapidly metabolized to relatively inactive 17-ones (see Fig. 25.21), however, preventing significant oral activity. Testosterone is available in a transdermal delivery system (patch), a gel formulation, a buccal system, and as implantable pellets. Testosterone 17β -esters are available in long-acting IM depot preparations illustrated in Figure 25.22, including the following:

- Testosterone cypionate, USP: Testosterone 17β -cyclopentylpropionate
- Testosterone enanthate, USP: Testosterone 17β -heptanoate
- Testosterone propionate, USP: Testosterone 17β -propionate

In addition, a NDA for testosterone undecanoate (Nebido) was filed in 2007 for approval as a long-acting preparation for the treatment of male hypogonadism. It is already approved for this use in Europe.

Methyltestosterone, USP. Methyltestosterone, 17β -hydroxy-17-methylandrost-4-en-3-one, is only about half as active as testosterone (intramuscularly), but it has the great advantage of being orally active.

Fluoxymesterone, USP. Fluoxymesterone, 9α -fluoro- $11\beta,17\beta$ -dihydroxy-17-methylandrost-4-en-3-one, is a highly potent, orally active androgen, about 5 to 10 times more potent than testosterone. It can be used for all the indications discussed previously, but its great androgenic activity has made it useful primarily for treatment of the androgen-deficient male.

Oxymetholone, USP. Oxymetholone, 17 β -hydroxy-2-(hydroxymethylene)-17-methylandrostan-3-one, is approved for the treatment of various anemias.

Oxandrolone, USP. Oxandrolone, 17 β -hydroxy-17-methyl-2-oxaandrostan-3-one, is approved to aid in the promotion of weight gain after weight loss following surgery, chronic infections, or severe trauma and to offset protein catabolism associated with long-term corticosteroid use. Oxandrolone is also used to relieve bone pain accompanying osteoporosis. It has been used to treat alcoholic hepatitis and HIV wasting syndrome.

Nandrolone Decanoate, USP. Nandrolone decanoate, 17 β -hydroxyestr-4-en-3-one 17-decanoate, has been used in the management of certain anemias, but the availability of erythropoietin has greatly reduced this use.

Danazol and Endometriosis

Danazol, USP. Danazol, 17 α -pregna-2,4-dien-20-yno-[2,3-*d*]isoxazol-17-ol, is a weak androgen that, in spite of the 17 α -ethinyl group, has little estrogenic or progestogenic activity. Danazol has been called a synthetic steroid with diverse biological effects.¹²⁵ Danazol binds to sex hormone-binding globulin (SHBG) and decreases the hepatic synthesis of this estradiol and testosterone carrier. Free testosterone thus increases. Danazol inhibits FSH and LH production by the hypothalamus and pituitary. It binds to PRs, GRs, ARs, and ERs. Although the exact mechanism of action is unclear, danazol alters endometrial tissue so that it becomes inactive and atrophic, which allows danazol to be an effective treatment for endometriosis. Danazol is also used to treat hereditary angioedema and fibrocystic breast disease.

Antiandrogens

Various compounds (Fig. 25.23) have been intensively studied as AR antagonists, or antiandrogens.^{126,127} Antiandrogens are of therapeutic use in treating conditions of hyperandrogenism (e.g., hirsutism, acute acne, and premature baldness) or androgen-stimulated cancers (e.g., prostatic carcinoma). The ideal antiandrogen would be nontoxic, highly active, and devoid of any hormonal activity. Both steroidal and nonsteroidal antiandrogens have been investigated, but only nonsteroidal antiandrogens have been approved for use

in the United States. Cyproterone acetate, a steroidal antiandrogen, is used in Europe. The steroidal antiandrogens typically have actions at other steroid receptors that limit their use. The nonsteroidal antiandrogens, while lacking hormonal activity, bind with lower affinity to the AR than the endogenous hormones.

FLUTAMIDE, BICALUTAMIDE, AND NILUTAMIDE

Three nonsteroidal antiandrogens are in clinical use in the United States—flutamide, bicalutamide, and nilutamide (Fig. 25.23). They are mainly used in the management of prostate cancer. Flutamide was the first of these compounds approved for use by the FDA, but liver toxicity and thrice-daily dosing offered room for improvement. It was also determined that a metabolite of flutamide, hydroxyflutamide, had greater antiandrogen action than the parent. Bicalutamide, which has greater potency than flutamide, incorporates an OH into its structure at the same relative position as in hydroxyflutamide. Bicalutamide is dosed once a day and has less toxicity than flutamide and nilutamide, making it a preferred choice when initiating therapy.

Prostate cancer is strongly androgen sensitive, so by blocking AR, the cancer can be inhibited or slowed. Studies have shown that these drugs completely inhibit the action of testosterone and other androgens by binding to AR. In clinical trials when given as a single agent for prostate cancer, serum testosterone and estradiol increase. But when given in combination with a GnRH agonist, such as goserelin or leuprolide, bicalutamide and flutamide do not affect testosterone suppression, which is the result of GnRH. GnRH agonists greatly decrease gonadal function—the medical equivalent of castration in men. Thus, the combination of GnRH with bicalutamide or flutamide blocks the production of testosterone in the testes and AR in the prostate.

Antiandrogen Products

Flutamide, USP. Flutamide, 2-methyl-*N*-[4-nitro-3-(trifluoromethyl)phenyl]propanamide, is dosed 3 times daily (250-mg dose; 750-mg total daily dose). A major metabolite of flutamide, hydroxyflutamide, is a more potent AR antagonist than the parent compound. This metabolite, which is present at a much higher steady-state concentration than is flutamide, contributes a significant amount of the

Figure 25.23 • Antiandrogens.

antiandrogen action of this drug. A limiting factor in the use of flutamide is hepatotoxicity in from 1% to 5% of patients. Although the hepatotoxicity usually is reversible following cessation of treatment, rare cases of death associated with hepatic failure have been reported to be associated with flutamide therapy. Diarrhea is also a limiting side effect with flutamide therapy for some patients.

Bicalutamide, USP. Bicalutamide, *N*-4-cyano-3-(trifluoromethyl)phenyl-3-[(4-fluorophenyl)sulfonyl]-2-hydroxy-2-methyl-propanamide (Casodex), is more potent than flutamide and has a much longer half-life (5.9 days vs. 6 hours for hydroxyflutamide). Because of the longer half-life, bicalutamide is used for once-a-day (50 mg) treatment of advanced prostate cancer. Bicalutamide is available as a racemic mixture, but both animal and human studies with the AR show that the R-enantiomer has higher affinity for the AR than the S-enantiomer.¹²⁸

Nilutamide, USP. Nilutamide, 5,5-dimethyl-3-[4-nitro-3-(trifluoromethyl)phenyl]-2,4-imidazolidinedione, is used in combination with surgical castration for the treatment of metastatic prostate cancer. Nilutamide, which has an elimination half-life of approximately 40 hours, can also be used in once-daily dosing, but it has side effects that limit its use—visual disturbances, alcohol intolerance, and allergic pneumonitis.

Inhibition of 5 α -Reductase

5 α -DHT is important for maintaining prostate function in men. The formation of DHT is mediated by 5 α -reductase, an enzyme that has two distinct forms, type I and type II.^{129,130} The type I enzyme is located in the liver and some peripheral tissues and is involved mainly in the metabolism of testosterone and other A-ring enones. The type II enzyme is located in the prostate gland and testes and is responsible for the conversion of testosterone to DHT for androgenic action. Blocking this enzyme is one approach for controlling androgen action. The review by Harris and Kozarich provides an excellent background and details the development of finasteride, the first 5 α -reductase inhibitor approved for use in the United States (Fig. 25.24).¹³¹

DHT also plays a major role in the pathogenesis of benign prostatic hyperplasia (BPH). Finasteride, (5 α ,17 β)-*N*-(1,1-dimethylethyl)-3-oxo-4-azaandrost-1-ene-17-carboxamide (Proscar, Propecia), is a potent, slow, tight-binding inhibitor of 5 α -reductase that functions by a unique mechanism. Finasteride is activated by the enzyme and irreversibly binds to the NADP cofactor, yielding a finasteride–NADP complex that is only slowly released from the enzyme active site, producing essentially irreversible inhibition of the enzyme (Fig. 25.25).¹³² The turnover from the finasteride–5 α -reductase complex is very slow ($t_{1/2}$ ~30 days).

Finasteride is a relatively selective inhibitor of type II 5 α -reductase. This enzyme is present in high levels in the prostate and at lower levels in other tissues. Because of the strong connection to the formation of DHT in the prostate, it was theorized that specific inhibition of this isoform would yield the greatest therapeutic effect. Other studies suggest, however, that the type I isoform may also play a role in the progression of hormone-dependent prostate cancer.¹³³ Because of this, dual 5 α -reductase inhibitors have been developed. Dutasteride, (5 α ,17 β)-*N*-{2,5

Figure 25.24 • Steroid 5 α -reductase inhibitors.

bis(trifluoromethyl)phenyl}-3-oxo-4-azaandrost-1-ene-17-carboxamide (Avodart) a newer drug for treating BPH, inhibits both isoforms of the enzyme (Fig. 25.24). Dutasteride bears an aromatic amide at C17, rather than the *t*-butyl amide seen in finasteride. Both drugs are effective at treating BPH, but a recent retrospective study suggests that rates of acute urinary retention are lower with dutasteride.¹³⁴ It is not yet known, however, if this reduced urinary retention is a result of the dual inhibition nature of dutasteride. Dutasteride inhibits 5 α -reductase by the same mechanism as finasteride and has a long terminal elimination half-life, which is approximately 5 weeks at steady state. In addition to the treatment of BPH, dutasteride is being investigated for its ability to delay the progression of prostate cancer.¹³⁵

A second use of finasteride is in the treatment of male pattern baldness. The conversion of testosterone to DHT in advancing years leads to thinning of hair in men. Inhibition of this conversion was envisioned as a possible baldness treatment. After finasteride was shown to be safe and effective in the treatment of BPH, a lower dose formulation was studied for treating male pattern baldness. The trials were a success, and Propecia (1 mg/d) was the result. Although finasteride preferentially inhibits the type II enzyme, it is believed to be the peripheral type I 5 α -reductase that is being targeted for the baldness treatment. Dutasteride is also being investigated for use as a baldness treatment.

An important warning for the use of both finasteride and dutasteride is that pregnant women should not handle or in any way be exposed to the active ingredients of these drugs. Exposure to either of these 5 α -reductase inhibitors could cause abnormalities of a male baby's external genitalia.

Saw palmetto (*Serenoa repens*) extract is an herbal product used to treat BPH, and it has been suggested that the effects may be attributed to a constituent of the extract with 5 α -reductase inhibition, but other mechanisms have also been proposed.¹³⁶ Further studies and identification of a specific component that inhibits 5 α -reductase are necessary.

Conversion of Testosterone to 5 α -dihydrotestosterone (DHT)

Figure 25.25 • Comparison of 5 α -reductase action on testosterone and finasteride. This scheme is an oversimplification of the exact mechanisms, but it indicates that when finasteride is bound at the active site of 5 α -reductase, NADPH is positioned closer to C1 of finasteride than to the normal C5 of testosterone, leading to essentially irreversible inhibition.

Finasteride - NADPH Complex Formation

**Future Directions: SARMs**^{137,138}

Selective androgen receptor modulators or SARMs are the newest developments among the potential androgen drugs. A parallel to the SERMs and SPRMs, SARMs are molecules that have differential actions at ARs in distinct tissues. The lead compounds furthest along in development are non-steroidal AR ligands that have anabolic properties in muscle and bone, with only partial agonist action in the prostate. Two of these lead compounds, LGD2226 and S4 (Fig. 25.26) are in phase I/II trials, with potential to treat age-related muscle wasting and osteoporosis, in both men and women. As can be seen from Figure 25.26, S4 shares structural similarities with the antiandrogen bicalutamide.

steroids produced by the adrenal cortex, however, are aldosterone and hydrocortisone. Aldosterone is the primary *MC* in humans (i.e., it causes significant salt retention). Hydrocortisone is the primary *GC* in humans (i.e., it has its primary effects on intermediary metabolism). The GCs have

Figure 25.26 • SARMs.

ADRENAL CORTEX HORMONES**Endogenous Corticosteroids**

The adrenal glands (which lie just above the kidneys) secrete over 50 different steroids, including precursors for other steroid hormones. The most important hormonal

become very important in modern medicine, especially for their anti-inflammatory effects.

Aldosterone and, to a lesser extent, other MCs maintain a constant electrolyte balance and blood volume. The GCs have key roles in controlling carbohydrate, protein, and lipid metabolism.

Biosynthesis

As shown in the scheme in Figure 25.27, aldosterone and hydrocortisone are biosynthesized from pregnenolone through a series of steps involving hydroxylations at C17, C11, and C21 that convert pregnenolone to hydrocortisone. Deficiencies in any of the enzymes cause congenital adrenal

hyperplasia. Defects in the gene regulation, as well as the enzymes that catalyze the hydroxylation, have been studied intensively.¹³⁹⁻¹⁴¹ Investigators have linked defects in particular genes or steroid-binding sites to the pathophysiology of patients with the corresponding metabolic diseases.¹⁴¹

These disorders are usually caused by an inability of the adrenal glands to carry out 11 β -, 17 α -, or 21-hydroxylations. The most common is a lack of 21-hydroxylase activity, which will result in decreased production of hydrocortisone and a compensatory increase in adrenocorticotropic hormone (ACTH) production. Furthermore, the resultant buildup of 17 α -hydroxyprogesterone will lead to an increase of testosterone. The 21-hydroxylase is important for the synthesis of both MCs and GCs. When 11 β -hydroxylase activity is low,

Figure 25.27 • Biosynthesis of hydrocortisone and aldosterone.

large amounts of 11-deoxycorticosterone will be produced. Because 11-deoxycorticosterone is a potent MC, there will be symptoms of MC excess, including hypertension. When 17 α -hydroxylase activity is low, there will be decreased production of testosterone and estrogens as well as hydrocortisone.

Although the details are not completely known, the 39-amino acid peptide ACTH (corticotropin) produced by the anterior pituitary is necessary for the conversion of cholesterol to pregnenolone. ACTH acts at the ACTH receptor, a G-protein-coupled receptor that activates adenylyl cyclase, leading to increased cyclic adenosine monophosphate (cAMP) levels. Activation of the ACTH receptors has short- and long-term effects on steroidogenesis. The short-term phase involves an increase in the supply of cholesterol for use by cytochrome P450_{sc} in the formation of pregnenolone. The long-term effects are caused by an increased transcription of steroidogenic enzymes.¹⁴² An overall result of ACTH action is increased synthesis and release of hydrocortisone. Hydrocortisone then acts by feedback inhibition to suppress the formation of additional ACTH (ACTH is discussed in more detail in Chapter 27).

The release of the primary MC aldosterone depends only slightly on ACTH. Aldosterone is an active part of the angiotensin–renin–blood pressure cycle that controls blood volume. A decrease in blood volume stimulates the kidneys to secrete the enzyme renin. Renin, in turn, converts angiotensinogen to angiotensin, which stimulates the adrenal cortex to release aldosterone. Aldosterone then causes the kidneys to retain sodium, and blood volume increases. When the blood volume has increased sufficiently, renin production decreases, until blood volume drops again.

Metabolism of Hydrocortisone

Hydrocortisone and cortisone are enzymatically interconvertible, and thus one finds metabolites with both the 11-keto and the 11 β -hydroxy functionality. Most of the metabolic processes occur in the liver, with the metabolites excreted primarily in the urine. Although many metabolites have been isolated, the primary routes of catabolism are (a) reduction of the C4,5 double bond to yield 5 β -pregnanes, (b) reduction of the 3-one to give 3 α -ols, and (c) reduction of the 20-one to the corresponding 20 α - and 20 β -ols. These are the same steps that are involved in progesterone metabolism. The two primary metabolites are tetrahydrocortisol and tetrahydrocortisone and their conjugates. The cortols (20 α and 20 β), cortolones (20 α and 20 β), and 11 β -hydroxyetiocholanolone are some of the minor metabolites of hydrocortisone (Fig. 25.28).

Biological Activities of Mineralocorticoids and Glucocorticoids¹⁴²

The adrenocortical steroids permit the body to adjust to environmental changes, to stress, and to changes in the diet. Aldosterone and, to a lesser extent, other MCs maintain a constant electrolyte balance and blood volume, and the GCs have key roles in controlling carbohydrate, protein, and lipid metabolism.

Aldosterone increases sodium reabsorption in the kidneys. An increase in plasma sodium concentration, in turn, will lead to increased blood volume, because blood volume and urinary excretion of water are directly related to the plasma sodium

Figure 25.28 • Metabolites of cortisone and hydrocortisone.

concentration. Simultaneously, aldosterone increases potassium ion excretion. 11-Deoxycorticosterone is also quite active as a MC. Similar actions are exhibited with hydrocortisone and corticosterone, but to a much smaller degree.

Aldosterone controls the movement of sodium ions in most epithelial structures involved in active sodium transport. Although aldosterone acts primarily on the distal convoluted tubules of the kidneys, it also acts on the proximal convoluted tubules and collecting ducts. Aldosterone controls the transport of sodium in sweat glands, small intestine, salivary glands, and the colon. In all of these tissues, aldosterone enhances the inward flow of sodium ions and promotes the outward flow of potassium ions.

The GCs have many physiological and pharmacological actions. They control or influence carbohydrate, protein, lipid, and purine metabolism. They also affect the cardiovascular and nervous systems and skeletal muscle. They regulate growth hormone gene expression. In addition, GCs have anti-inflammatory and immunosuppressive actions that arise through complex mechanisms.

GCs stimulate glycogen storage synthesis by inducing the synthesis of glycogen synthase and stimulate gluconeogenesis in the liver. They have a catabolic effect on muscle tissue, stimulating the formation and transamination of amino acids into glucose precursors in the liver. The catabolic actions in Cushing syndrome are demonstrated by wasting of the tissues, osteoporosis, and reduced muscle mass. Lipid metabolism and synthesis increase significantly in the presence of GCs, but the actions usually seem to depend on the presence of other hormones or cofactors. A lack of adrenal cortex steroids also causes depression, irritability, and even psychoses, reflecting significant effects on the central nervous system.

**ANTI-INFLAMMATORY/IMMUNOSUPPRESSIVE
ACTIONS OF GLUCOCORTICOIDS¹⁴³⁻¹⁴⁷**

GR complexes may activate or repress the genes to which they associate. Repression in particular may have an important role in GC anti-inflammatory actions. GCs inhibit the transcription of genes encoding cytokines such as interferon- γ , tumor necrosis factor- α (TNF- α), the interleukins, and granulocyte/monocyte colony-stimulating factor, all factors involved in the immune system and inflammatory responses.¹⁴² GCs inhibit the production and release of other mediators of inflammation, including prostaglandins, leukotrienes, and histamine. In addition, GCs inhibit the expression of the gene encoding collagenase, an important enzyme involved with inflammation.

RESISTANCE TO GLUCOCORTICOIDS¹⁴⁸⁻¹⁵⁰

A few patients with chronic inflammatory illnesses such as asthma, rheumatoid arthritis, and lupus develop resistance to the anti-inflammatory effects of the GCs. The mechanism is not fully understood but appears to be a decrease in the binding or activation ability of GR complexes and their target or "activator" genes. Disruption of the translocation of the GR to the nucleus has also been implicated in GC resistance.¹⁵¹

tion activity is usually undesirable, the drugs are classified by their salt retention activities. As illustrated in Figure 25.29, the adrenal cortex hormones are classified by their biological activities into three major groups.

MINERALOCORTICIDS

The MCs are adrenal cortex steroids and analogs with high salt-retaining activity. They are used mainly for treatment of Addison disease, or primary adrenal insufficiency. The naturally occurring hormone aldosterone has an 11β -OH and an 18-CHO that naturally bridge to form a hemiacetal (as drawn in Fig. 25.27). Aldosterone is too expensive to produce commercially; therefore, other semisynthetic analogs

have taken its place for treatment of Addison disease. Adding a 9α -fluoro group to hydrocortisone greatly increases both salt retention and anti-inflammatory activity. Deoxycorticosterone (11-deoxy), an intermediate in the biosynthesis of aldosterone, has lower MC activity than aldosterone (20-fold) but may play a role if the 11β -hydroxylase is deficient. Deoxycorticosterone is not available for therapeutic uses.

Extensive modifications have been made to the basic hydrocortisone structure to alter the properties of GCs. Modifications at all sites of the steroid backbone have been tried. Aside from addition of a double bond at C1–C2, the most beneficial changes are made to rings B and D of the steroid skeleton and modification of the C17 side chain.

TABLE 25.6 Effects of Substituents on Glucocorticoid/Mineralocorticoid Activity

Functional Group	Glycogen Deposition	Anti-inflammatory Activity	Effects on Urinary Sodium ^a
9 α -Fluoro	10	7–10	+++
9 α -Chloro	3–5	3–4	++
1-Dehydro	3–4	3–4	–
6 α -Methyl	2–3	1–2	---
16 α -Hydroxy	0.4–0.5	0.1–0.2	----
17 α -Hydroxy	1–2	4	–
21-Hydroxy	4–7	25	++

Adapted from Rodig, O.R.: In Burger, A. (ed.). Medicinal Chemistry, Part 2, 3rd ed. New York, Wiley-Interscience, 1970. Used with permission.

^a+, retention; –, excretion.

Table 25.6 summarizes the relative effects of various substituents seen in commercially available products on salt retention and GC activity. The salt-retaining actions are approximately additive. For example, the 3+ increase in salt retention of a 9 α -fluoro group can be eliminated by the 3– decrease of a 6 α -methyl.

GLUCOCORTICOIDS WITH MODERATE-TO-LOW SALT RETENTION

The GCs with moderate-to-low salt retention include cortisone, hydrocortisone, and their 1-enes prednisolone and prednisone. As shown in Table 25.7, an 11 β -OH maintains good topical anti-inflammatory activity, but 11-ones have little or none. The 11 β -hydroxysteroid dehydrogenase in the skin oxidizes an 11 β -hydroxyl to an 11-ketone.¹⁵³ For activation of an 11-one GC for topical action, reduction at C11 would be necessary. The 1-ene of prednisolone and prednisone increases anti-inflammatory activity about fourfold and somewhat decreases salt retention. This increase in activity may be a result of a change in shape of ring A.²⁸ Specifically, analogs more active than hydrocortisone appear to have their ring A bent underneath the molecule to a much greater extent than hydrocortisone.

The 11 β -OH of hydrocortisone is of major importance in binding to the receptors. Cortisone is reduced in vivo to yield hydrocortisone as the active agent. The increased activity of 9 α -halo derivatives may be a result the electron-withdrawing inductive effect on the 11 β -OH, making it more acidic and, therefore, better able to form hydrogen bonds with the receptor. A 9 α -halo substituent also reduces oxidation of the 11 β -OH to the inactive 11-one.

GLUCOCORTICOIDS WITH VERY LITTLE OR NO SALT RETENTION

Cortisone and hydrocortisone, and even prednisone and prednisolone, have too much salt-retaining activity in the doses needed for some therapeutic purposes. Over the past several decades, several substituents have been discovered that greatly decrease salt retention. They include 16 α -hydroxy, 16 α ,17 α -ketal, 6 α -methyl, and 16 α - and 16 β -methyl. Other substituents have been found to increase both GC and MC activities: 9 α -fluoro, 9 α -chloro, and 21-hydroxy.

As a result of the great economic benefit of having a potent anti-inflammatory product on the market, pharmaceutical manufacturers have made numerous combinations of these various substituents. In almost every case, a 16-

TABLE 25.7 Approximate Relative Activities of Corticosteroids^a

	Anti-inflammatory Activity	Topical Activity	Salt-Retaining Activity	Equivalent Dose (mg)
Mineralocorticoids				
Aldosterone	0.2	0.2	800	
Deoxycorticosterone	0	0	40

Dexamethasone	30	10–35	0	0.75

^aThe data in this table are only approximate. Blanks indicate that comparative data are not available to the author or that the product has only one use (e.g., topical). Data were taken from several sources, and there is an inherent risk in comparing such data. The table should, however, serve as a guide to relative activities.

methyl or a modified 16-hydroxy (to eliminate salt retention) has been combined with another substituent to increase GC or anti-inflammatory activity. The number of permutations and combinations has resulted in a redundant array of analogs with very low salt retention and high anti-inflammatory activity.

A primary goal of these highly anti-inflammatory drugs has been to increase topical potency. As shown in Table 25.7, some are as much as 100 times more active topically than hydrocortisone. Relative potency is as follows:

Very high potency

- Augmented betamethasone dipropionate ointment, 0.05%
- Clobetasol propionate, 0.05%
- Diflorasone diacetate ointment, 0.05%

High potency

- Amcinonide, 0.1%
- Betamethasone dipropionate ointment, 0.05%
- Desoximetasone, 0.25%
- Diflorasone diacetate cream, 0.05%
- Fluocinonide, 0.05%
- Halcinonide, 0.1%
- Halobetasol propionate, 0.05%
- Triamcinolone acetonide, 0.5%

Medium potency

- Betamethasone valerate, 0.1%
- Clocortolone pivalate, 0.1%
- Desoximetasone, 0.05%
- Fluocinolone acetonide, 0.025%
- Fluticasone propionate, 0.005%
- Hydrocortisone butyrate, 0.1%
- Hydrocortisone valerate, 0.2%
- Mometasone furoate, 0.1%
- Prednicarbate, 0.1%
- Triamcinolone acetonide, 0.1%

Low potency

- Alclometasone dipropionate, 0.05%
- Desonide, 0.05%
- Fluocinolone acetonide, 0.01%
- Triamcinolone acetonide cream, 0.1%

Lowest potency

- Hydrocortisone, 1.0%
- Hydrocortisone, 2.5%

Although, as shown in Table 25.7, cortisone and prednisone are not active topically, most other GCs are active. Some compounds, such as clobetasol and betamethasone dipropionate, have striking activity topically. Skin absorption is favored by increased lipid solubility of the drug.

Absorption of topical GCs can also be greatly affected by the extent of skin damage, concentration of the GC, cream or ointment base used, and similar factors. One must not assume, therefore, from a study of Table 25.7 that, for example, a 0.25% cream of prednisolone is necessarily exactly equivalent in anti-inflammatory potency to 1% hydrocortisone. Nevertheless, the table can serve as a preliminary guide. Furthermore, particular patients may seem to respond better to one topical anti-inflammatory GC than to another, irrespective of the relative potencies shown in Table 25.7.

RISK OF SYSTEMIC ABSORPTION

The topical corticosteroids do not typically cause significant absorption effects when used on small areas of intact skin.

When these compounds are used on large areas of the body, however, systemic absorption may occur, especially if the skin is damaged or if occlusive dressings are used. Up to 20% to 40% of hydrocortisone given rectally may also be absorbed.

Therapeutic Uses of Adrenal Cortex Hormones

The adrenocortical steroids are used primarily for their GC effects, including immunosuppression, anti-inflammatory activity, and antiallergic activity. The MCs are used only for treatment of Addison disease. Addison disease is caused by chronic adrenocortical insufficiency and may be due to either adrenal or anterior pituitary failure. The GCs are also used in the treatment of congenital adrenal hyperplasias.

The symptoms of Addison disease illustrate the great importance of the adrenocortical steroids in the body and, especially, the importance of aldosterone. These symptoms include increased loss of body sodium, decreased loss of potassium, hypoglycemia, weight loss, hypotension, weakness, increased sensitivity to insulin, and decreased lipolysis.

Hydrocortisone is also used during postoperative recovery after surgery for Cushing syndrome—excessive adrenal secretion of GCs. Cushing syndrome can be caused by bilateral adrenal hyperplasia or adrenal tumors and is treated by surgical removal of the tumors or resection of hyperplastic adrenal gland(s).

The use of GCs during recovery from surgery for Cushing syndrome illustrates a most important principle of GC therapy: abrupt withdrawal of GCs may result in adrenal insufficiency, showing clinical symptoms similar to those of Addison disease. For that reason, patients who have been on long-term GC therapy must have the dose reduced gradually. Furthermore, prolonged treatment with GCs can cause adrenal suppression, especially during times of stress. The symptoms are similar to those of Cushing syndrome, such as rounding of the face, hypertension, edema, hypokalemia, thinning of the skin, osteoporosis, diabetes, and even subcapsular cataracts.

The GCs are used in the treatment of collagen vascular diseases, including rheumatoid arthritis and disseminated lupus erythematosus. Although there is usually prompt remission of redness, swelling, and tenderness by the GCs in rheumatoid arthritis, continued long-term use may lead to serious systemic forms of collagen disease. As a result, the GCs should be used infrequently in rheumatoid arthritis.

The GCs are used extensively topically, orally, and parenterally to treat inflammatory conditions. They also usually relieve the discomforting symptoms of many allergic conditions—intractable hay fever, exfoliative dermatitis, generalized eczema, and others. The GCs are also used to treat asthmatic symptoms unresponsive to bronchodilators. They are especially useful in inhaled formulations (see section on page 863). The GCs' lymphocytopenic actions make them particularly useful for treatment of chronic lymphocytic leukemia in combination with other antineoplastic drugs.

The adrenocortical steroids are contraindicated or should be used with great caution in patients who have (a) peptic ulcer (in which the steroids may cause hemorrhage), (b) heart disease, (c) infections (the GCs suppress the body's normal infection-fighting processes), (d) psychoses (since behavioral disturbances may occur during steroid therapy),

Figure 25.30 • Ophthalmic glucocorticoids.

(e) diabetes (the GCs increase glucose production, so more insulin may be needed), (f) glaucoma, (g) osteoporosis, or (h) herpes simplex involving the cornea.

When administered topically, the GCs present relatively infrequent therapeutic problems, but their anti-inflammatory action can mask symptoms of infection. Many physicians prefer not giving a topical anti-inflammatory steroid until after an infection is controlled with topical antibiotics. The immunosuppressive activity of the topical GCs can also prevent natural processes from curing the infection. Topical steroids actually may also cause dermatoses in some patients.

Finally, as discussed previously with the oral contraceptives, steroid hormones should not be used during pregnancy. If it is absolutely necessary to use GCs topically during pregnancy, they should be limited to small areas of intact skin and used for a limited time.

Mineralocorticoid and Glucocorticoid Products

The corticosteroids used in commercial products are shown in Figures 25.29, 25.30, and 25.31. The structures illustrate the usual changes (see Fig. 25.6) made to modify solubility of the products and, therefore, their therapeutic uses. In particular, the 21-hydroxyl can be converted to an ester to make it less water soluble to modify absorption or to a phosphate ester salt or hemisuccinate ester salt to make it more water soluble and appropriate for intravenous use. The products also reflect the structure–activity relationship changes discussed previously to increase anti-inflammatory activity or potency or decrease salt retention.

Again, patients who have been on long-term GC therapy must have the dose reduced gradually. This “critical rule” and indications are discussed previously under the heading, “Therapeutic Uses of Adrenal Cortex Hormones.” Dosage schedules and gradual dosage reduction can be quite complex and specific for each indication.

Many of the GCs are available in topical dosage forms, including creams, ointments, aerosols, lotions, and solutions. They are usually applied 3 to 4 times a day to well-cleaned areas of affected skin. Ointments are usually prescribed for dry, scaly dermatoses. Lotions are well suited for weeping dermatoses. Creams are of general use for many other

Figure 25.31 • Glucocorticoids used to treat asthma and allergic rhinitis (some are also used topically).

dermatoses. When applied to very large areas of skin or to damaged areas of skin, significant systemic absorption can occur. The use of an occlusive dressing can also greatly increase systemic absorption.

The GCs that are mainly used for inflammation of the eye are shown in Figure 25.30. These compounds differ structurally from other GRs, in that the 21-hydroxyl is missing from medrysone, fluorometholone, and rimexolone, while loteprednol etabonate has a modified ester at C17 that leads to rapid degradation upon systemic absorption.

MINERALOCORTICOIDS

Fludrocortisone Acetate, USP. Fludrocortisone acetate, 21-acetyloxy-9-fluoro-11 β ,17-dihydroxypregn-4-ene-3,20-dione, 9 α -fluorohydrocortisone (Florinef Acetate), is used only for the treatment of Addison disease and for inhibition of endogenous adrenocortical secretions. As shown in Table 25.7, it has up to about 800 times the MC activity of hydrocortisone and about 11 times the GC activity. Its potent activity stimulated the synthesis and study of the many fluorinated steroids shown in Figure 25.29. Although its great salt-retaining activity limits its use to Addison disease, it has sufficient GC activity that in some cases of the disease, additional GCs need not be prescribed.

GLUCOCORTICOIDS WITH MODERATE-TO-LOW SALT RETENTION

Hydrocortisone, USP. Hydrocortisone, 11 β ,17,21-trihydroxypregn-4-ene-3,20-dione, is the primary natural GC in humans. Despite the large number of synthetic GCs, hydrocortisone, its esters, and its salts remain a mainstay of modern adrenocortical steroid therapy and the standard for comparison of all other GCs and MCs (see Table 25.7). It is used for all the indications mentioned previously. Its esters and salts illustrate the principles of chemical modification to modify pharmacokinetic use shown in Figure 25.6. The commercially available salts and esters (see Fig. 25.29) include:

Hydrocortisone acetate, *USP* (21-acetate)
 Hydrocortisone butepirate = hydrocortisone probutate,
USP (17-butyrate, 21-propionate)
 Hydrocortisone butyrate, *USP* (17-butyrate)
 Hydrocortisone sodium phosphate, *USP* (21-sodium phosphate)
 Hydrocortisone sodium succinate, *USP* (21-sodium succinate)
 Hydrocortisone valerate, *USP* (17-valerate)

Cortisone Acetate, USP. Cortisone acetate, 21-(acetyloxy)-17-hydroxypregn-4-ene-3,11,20-trione, is the 21-acetate of naturally occurring cortisone with good systemic anti-inflammatory activity and low-to-moderate salt-retention activity after its *in vivo* conversion to hydrocortisone acetate. This conversion is mediated by 11 β -hydroxysteroid dehydrogenase. It is used for the entire spectrum of uses discussed previously under the heading, “Therapeutic Uses of Adrenal Cortex Hormones”—collagen diseases, Addison disease, severe shock, allergic conditions, chronic lymphocytic leukemia, and many other indications. Cortisone acetate is relatively ineffective topically, mainly because it must be reduced *in vivo* to hydrocortisone. Its plasma half-life is only about 30 minutes, compared with 90 minutes to 3 hours for hydrocortisone.

Prednisolone, USP. Prednisolone, Δ^1 -hydrocortisone, 11 β ,17,21-trihydroxypregna-1,4-diene-3,20-dione, has less salt-retention activity than hydrocortisone (see Table 25.7), but some patients have more frequently experienced complications such as gastric irritation and peptic ulcers. Because of low MC activity, it cannot be used alone for adrenal insufficiency. Prednisolone is available in various salts and esters to maximize its therapeutic utility (see Fig. 25.29):

Prednisolone acetate, *USP* (21-acetate)
 Prednisolone sodium phosphate, *USP* (21-sodium phosphate)
 Prednisolone sodium succinate, *USP* (21-sodium succinate)
 Prednisolone tebutate, *USP* (21-tebutate)

Prednisone, USP. Prednisone, Δ^1 -cortisone, 17,21-dihydroxypregna-1,4-diene-3,11,20-trione, has systemic activity very similar to that of prednisolone, and because of its lower salt-retention activity, it is often preferred over cortisone or hydrocortisone. Prednisone must be reduced *in vivo* to prednisolone to provide the active GC.

GLUCOCORTICOIDS WITH VERY LITTLE OR NO SALT RETENTION

Most of the key differences between the many GCs with minimal salt retention (see Fig. 25.29) have been summarized in Tables 25.6 and 25.7. The tremendous therapeutic and, therefore, commercial importance of these drugs has stimulated the proliferation of new compounds and their products. Many compounds also are available as salts or esters to give the complete range of therapeutic flexibility illustrated in Figure 25.29. When additional pertinent information is available, it is given below the drug name. The systemic name for each drug is provided after the common name.

Alclometasone Dipropionate, USP. Alclometasone dipropionate, 7 α -chloro-11 β -hydroxy-16 α -methyl-17,21-bis(1-oxopropoxy)-pregna-1,4-diene-3,20-dione (Aclovate), is one of the few commercially used GRs that bears a halogen substituent in the 7 α -position.

Amcinonide, USP. Amcinonide, 21-(acetyloxy)-16 α ,17-[cyclopentylidenebis(oxy)]-9-fluoro-11 β -hydroxypregna-1,4-diene-3,20-dione (Cyclocort).

Beclomethasone Dipropionate, USP. Beclomethasone dipropionate, 9-chloro-11 β -hydroxy-16 β -methyl-17,21-bis(1-oxopropoxy)-pregna-1,4-diene-3,20-dione (Beconase, QVAR), is used in nasal sprays and aerosol formulations to treat allergic rhinitis and asthma (see section on page 863).

Betamethasone, USP. Betamethasone, 9-fluoro-11 β ,17,21-trihydroxy-16 β -methylpregna-1,4-diene-3,20-dione, is available as a variety of ester derivatives.

Betamethasone valerate, *USP* (17-valerate)
 Betamethasone acetate, *USP* (21-acetate)
 Betamethasone sodium phosphate, *USP* (21-sodium phosphate)
 Betamethasone dipropionate, *USP* (17-propionate, 21-propionate)

Budesonide, USP. Budesonide, 16 α ,17-[butylidenebis(oxy)]-11 β ,21-dihydroxypregna-1,4-diene-3, 20-dione

(Entocort), in oral capsules is used to treat Crohn disease. The affinity for the GC is approximately 200-fold greater than that of hydrocortisone and 15-fold greater than that of prednisolone. Budesonide is a mixture of epimers, with the 22*R* form having twice the affinity for the GR of the *S* epimer. This GC is metabolized by CYP3A4, and its levels can be increased in the presence of potent CYP3A4 inhibitors. Budesonide is also used in an inhaled formulation for the treatment of asthma (see next page).

Clobetasol Propionate, USP. Clobetasol propionate, 21-chloro-9-fluoro-11 β -hydroxy-16 β -methyl-17-(1-oxopropoxy)-pregna-1,4-diene-3,20-dione (Temovate).

Clocortolone Pivalate, USP. Clocortolone pivalate, 9-chloro-21-(2,2-dimethyl-1-oxopropoxy)-6 α -fluoro-11 β -hydroxy-16 α -methylpregna-1,4-diene-3,20-dione (Cloderm), along with desoximetasone, lacks the C17 α oxygen functionality that is present in other GCs but still retains good GC activity.

Desonide, USP. Desonide, 11 β ,21-dihydroxy-16 α ,17-[(1-methylethylidene)bis(oxy)]pregna-1,4-diene-3,20-dione (DesOwen, Tridesiol).

Desoximetasone, USP. Desoximetasone, 9-fluoro-11 β , 21-dihydroxy-16 α -methylpregna-1,4-diene-3,20-dione, like clocortolone pivalate, lacks a C17 α OH group in its structure.

Dexamethasone, USP. Dexamethasone, 9-fluoro-11 β , 17,21-trihydroxy-16 α -methylpregna-1,4-diene-3,20-dione, is the 16 α -isomer of betamethasone.

Dexamethasone acetate, *USP* (21-acetate)
Dexamethasone sodium phosphate, *USP* (21-sodium phosphate)

Diflorasone Diacetate, USP. Diflorasone diacetate, 17, 21-bis(acetyloxy)-6 α ,9-difluoro-11 β -hydroxy-16 α -methylpregna-1,4-diene-3,20-dione.

Difluprednate. *Difluprednate*, 21-(acetyloxy)-6 α ,9-difluoro-11 β -hydroxy-17-(1-oxobutoxy)pregna-1,4-diene-3,20-dione is being developed (phase III) as a topical ophthalmic emulsion to treat inflammatory eye diseases.

Flunisolide, USP. Flunisolide, 6 α -fluoro-11 β ,21-dihydroxy-16 α ,17-[(1-methylethylidene)bis(oxy)]pregna-1,4-diene-3,20-dione. (See following section for use of flunisolide in the treatment of asthma.)

Fluocinolone Acetonide, USP. Fluocinolone acetonide, 6 α ,9-difluoro-11 β ,21-dihydroxy-16 α ,17-[(1-methylethylidene)bis(oxy)]pregna-1,4-diene-3,20-dione, also known as 6 α -fluorotriamcinolone acetonide, is the 21-acetate derivative of fluocinolone acetonide and is about 5 times more potent than fluocinolone acetonide in at least one topical activity assay.

Fluorometholone, USP. Fluorometholone, 9-fluoro-11 β ,17-dihydroxy-6 α -methylpregn-4-ene-3,20-dione (Fluor-Op, FML), lacks the typical C21 OH group of GCs and is used exclusively in ophthalmic products. The 17-acetate of fluorometholone is also used as an ophthalmic suspension (Flarex).

Flurandrenolide, USP. Flurandrenolide, 6 α -fluoro-11 β ,21-dihydroxy-16 α ,17-[(1-methylethylidene)bis(oxy)]

pregn-4-ene-3,20-dione, although available as a tape product, can stick to and remove damaged skin, so it should be avoided with vesicular or weeping dermatoses.

Fluticasone Propionate, USP. Fluticasone propionate, *S*-(fluoromethyl) 6 α ,9-difluoro-11 β -hydroxy-16 α -methyl-3-oxo-17 α -(1-oxopropoxy)androsta-1,4-diene-17-carbothio-ate (Cutivate), is threefold to fivefold more potent than dexamethasone in receptor binding assays (see also the following section on inhaled corticosteroids).

Halcinonide. Halcinonide, 21-chloro-9-fluoro-11 β -hydroxy-16 α ,17-[(1-methylethylidene)bis(oxy)]pregn-4-ene-3,20-dione, was the first chloroGC marketed. Like many other potent GCs, it is used only topically.

Halobetasol Propionate, USP. Halobetasol propionate, 21-chloro-6 α ,9-difluoro-11 β -hydroxy-16 β -methyl-17-(1-oxopropoxy)pregna-1,4-diene-3,20-dione.

Loteprednol Etabonate, USP. Loteprednol etabonate, chloromethyl 17 α -[(ethoxycarbonyloxy)-11 β -hydroxy-3-oxoandrosta-1,4-diene-17-carboxylate (Alrex, Lotemax), has a modified carboxylate at the C17 position rather than the typical ketone functionality. This modification maintains affinity for the GR but allows facile metabolism to inactive metabolites. This limits the systemic action of the drug. Loteprednol etabonate is used as an ophthalmic suspension that has greatly reduced systemic action because of rapid metabolism to the inactive carboxylate (Fig. 25.30).

Methylprednisolone, USP. Methylprednisolone, 11 β , 17,21-trihydroxy-6 α -methyl-1,4-pregnadiene-3,20-dione, is available unmodified or as ester derivatives.

Methylprednisolone acetate, *USP*
Methylprednisolone sodium succinate, *USP*

Mometasone Furoate, USP. Mometasone furoate, 9,21-dichloro-17 α -[(2-furanylcarbonyloxy)-11 β -hydroxy-16 α -methylpregna-1,4-diene-3,20-dione (Elocon), is a high-potency GC available in cream, lotion, or ointment formulations for topical use. In addition, mometasone furoate monohydrate is formulated for treating allergic rhinitis and asthma (see following section).

Prednicarbate, USP. Prednicarbate, 17-[(ethoxycarbonyloxy)-11 β -hydroxy-21-(1-oxopropoxy)pregna-1,4-diene-3,20-dione, is a prednisolone derivative with a C21 propionate ester and a C17 ethyl carbonate group. It is available for use only in a 0.1% topical cream. Prednicarbate is a medium-potency GC.

Rimexolone, USP. Rimexolone, 11 β -hydroxy-16 α , 17 α -dimethyl-17-(1-oxopropyl)androsta-1,4-diene-3-one, like medrysone and fluorometholone, lacks the C21 OH group. In addition, rimexolone has an additional methyl group in the 17 α -position, a site where an OH group is typically found. Rimexolone is available as a suspension for ophthalmic use (Fig. 25.30).

Triamcinolone, USP. Triamcinolone, 9-fluoro-11 β ,16 α , 17,21-tetrahydroxypregna-1,4-diene-3,20-dione.

Triamcinolone acetonide, *USP*: Triamcinolone-16 α , 17-acetonide
Triamcinolone hexacetonide, *USP*: Triamcinolone acetonide 21-[3-(3,3-dimethyl)butyrate]
Triamcinolone diacetate, *USP*: 16,21-Diacetate

Triamcinolone acetonide is approximately 8 times more potent than prednisone in animal inflammation models. Topically applied triamcinolone acetonide is a potent anti-inflammatory agent (see Table 25.7), about 10 times more so than triamcinolone. The plasma half-life is approximately 90 minutes, although the plasma half-life and biological half-lives for GCs do not correlate well. The hexacetonide is slowly converted to the acetonide *in vivo* and is given only by intra-articular injection. Only triamcinolone and the diacetate are given orally. The acetonide and diacetate may be given by intra-articular or intrasynovial injection. In addition, the acetonide may be given by intrabursal or, sometimes, IM or subcutaneous injection. A single IM dose of the diacetate or acetonide may last up to 3 or 4 weeks. Plasma levels with IM doses of the acetonide are significantly higher than with triamcinolone itself. The acetonide is also used to treat asthma and allergic rhinitis (see following section).

INHALED CORTICOSTEROIDS FOR ASTHMA AND ALLERGIC RHINITIS

The National Asthma Education and Prevention Program has provided recent recommendations on the treatment of asthma, including a strong recommendation for the first-line use of inhaled corticosteroids for severe and moderate persistent asthma in all age groups. The corticosteroids currently used in inhaled formulations are all relatively potent topical corticosteroids that have the advantage of rapid deactivation/inactivation for the portion of the dose that is swallowed. The development of GCs that are efficiently inactivated metabolically when swallowed has greatly reduced the systemic side effects associated with the use of steroids in asthma treatment. The older corticosteroids that are used orally (e.g., methylprednisolone, prednisolone, and prednisone) have much greater systemic side effects, and their use should be limited, if possible. Although systemic side effects are reduced, they are not completely eliminated. The side effects can vary with the steroid used and the frequency of administration.

The six GCs that are currently approved for use in the United States for asthma as inhaled formulations are beclomethasone dipropionate, budesonide, flunisolide, fluticasone propionate, mometasone furoate, and triamcinolone acetonide (Fig. 25.31). Ciclesonide (Alvesco) is the newest GC being pursued for use in the treatment of asthma. Ciclesonide is in phase III clinical trials and may be available in the United States within a few years. It is already approved to treat asthma in Europe and Canada. Clinical trials suggest that it may have better tolerability than some of the currently available inhaled steroids.

The following agents are also available in nasal inhalers for the treatment of allergic rhinitis. Details are provided below for the mode of metabolic inactivation involved for each of these products. Although all of these agents have much lower systemic effects than the oral steroids, some systemic effects, as measured by suppression of the hypothalamic–pituitary–adrenal (HPA) axis, have been observed for these products. Ciclesonide (2006) and fluticasone furoate (Veramyst, 2007), with a 17-furoate in place of the 17-propionate, were both also recently approved for treating allergic rhinitis.

GLUCOCORTICOIDS FOR ASTHMA AND ALLERGIC RHINITIS

Beclomethasone Dipropionate. Beclomethasone dipropionate (Becloment, Beconase, Vanceryl, Vancenase)

(BDP) is rapidly converted in the lungs to beclomethasone 17-monopropionate (17-BMP), the metabolite that provides the bulk of the anti-inflammatory activity. The monopropionate also has higher affinity for the GR than either the dipropionate or beclomethasone. The portion of BDP that is swallowed is rapidly hydrolyzed to 17-BMP, 21-BMP (which arises by a transesterification reaction from 17-BMP), and beclomethasone itself.¹⁵⁴ Beclomethasone has much less GC activity than the monopropionate.¹⁵⁵

Budesonide. Budesonide (Pulmicort Turbhaler, Rhinocort) is extensively metabolized in the liver, with 85% to 95% of the orally absorbed drug metabolized by the first-pass effect. The major metabolites are 6 β -hydroxybudesonide and 16 α -hydroxyprednisolone, both with less than 1% of the activity of the parent compound. Metabolism involves the CYP3A4 enzyme, so coadministration of budesonide with a known CYP3A4 inhibitor should be monitored carefully.

Ciclesonide. Ciclesonide (Omnaris) is a prodrug that requires hydrolysis of the isobutyrate ester at C21 to form the active corticosteroid (des-ciclesonide). It has minimal oral bioavailability due to extensive metabolism, mainly by CYP3A4. The metabolites of ciclesonide have not been fully characterized.

Flunisolide. The portion of a flunisolide (AeroBid, Nasarel) dose that is swallowed is rapidly converted to the 6 β -hydroxy metabolite after first-pass metabolism in the liver. The 6 β -hydroxy metabolite is approximately as active as hydrocortisone itself, but the small amount produced usually has limited systemic effects. Water-soluble conjugates are inactive.

Fluticasone Propionate. The main metabolite of fluticasone propionate (Flovent, Flonase) found in circulation in humans is the 17 β -carboxylate derivative. As expected, a charged carboxylate in place of the normal acetol functionality at C17 greatly reduces affinity for the GR (2,000-fold less than the parent), and this metabolite is essentially inactive. The metabolite is formed via the CYP3A4 system, so care should be taken if fluticasone propionate is coadministered with a CYP3A4 inhibitor such as ketoconazole or ritonavir. Clinically induced Cushing syndrome has been observed when inhaled fluticasone propionate was administered concurrently with ritonavir.¹⁵⁶ Fluticasone is also available in an inhaled formulation in combination with the long-acting β_2 -agonist salmeterol (Advair Diskus).

Mometasone Furoate. Mometasone furoate (Asmanex, Nasonex) undergoes extensive metabolism to multiple metabolites. No major metabolites are detectable in human plasma after oral administration, but the 6 β -hydroxy metabolite is detectable by use of human liver microsomes. This metabolite is formed via the CYP3A4 pathway.

Triamcinolone Acetonide. The three main metabolites of triamcinolone acetonide (Azmacort, Nasacort) are 6 β -hydroxytriamcinolone acetonide, 21-carboxytriamcinolone acetonide, and 6 β -hydroxy-21-carboxytriamcinolone acetonide. All are much less active than the parent compound. The 6 β -hydroxyl group and the 21-carboxy group are both structural features that greatly reduce GC action. The increased water solubility of these metabolites also facilitates more rapid excretion.

Spironolactone (Aldolactone)

Eplerenone (Inspra)

Figure 25.32 • Aldosterone receptor antagonists.

Allopregnanolone
(3 α -Hydroxy-5 α -pregnan-20-one)
(3 α , 5 α -Tetrahydroprogesterone)Allotetrahydrodeoxycorticosterone
(3 α , 21-Dihydroxy-5 α -pregnan-20-one)

Figure 25.33 • Neurosteroid examples.

Mineralocorticoid Receptor Antagonists (Aldosterone Antagonists)

Antagonism of the MR can have profound effects on the renin-angiotensin system, thus having significant cardiac effects. Structurally, these compounds have an A-ring enone, essential for recognition by the receptor, but the 7 α -substituent and the D-ring spiro-lactone provide structural elements that lead to antagonism (Fig. 25.32).

Spironolactone, USP. Spironolactone, 7 α -(acetylthio)-17 α -hydroxy-3-oxopregn-4-ene-3-one-21-carboxylic acid γ -lactone (Aldactone) is an aldosterone antagonist of great medical importance because of its diuretic activity. Spironolactone is discussed in Chapter 18.

Eplerenone, USP. Eplerenone, 9,11 α -epoxy-17 α -hydroxy-3-oxopregn-4-ene-7 α ,21-dicarboxylic acid, γ -lactone, methyl ester (Inspra), is a newer aldosterone antagonist that is used for the treatment of hypertension.

NEUROSTEROIDS^{79,157,158}

Although the main effects of the steroid hormones described in this chapter have been focused on sexual development, maintenance of sexual organ function, and inflammatory processes, steroids also play important roles in the brain. Two terms have been developed to describe the specific steroids that act on the nervous system, neurosteroids and neuroactive steroids. Neurosteroids are synthesized in the brain, either from cholesterol or from other steroid hormones, and have their specific actions in the nervous system. Neuroactive steroids are synthesized in other steroidogenic tissues, but have their actions in the brain after transport from the site of synthesis. Many of the neurosteroids are the same as steroid hormones acting peripherally,

but some have unique roles in the brain. Neurosteroids include pregnenolone, progesterone, and DHEA, as well as their sulfate esters. Metabolites of progesterone and 11-deoxycorticosterone, allopregnanolone and allotetrahydrodeoxycorticosterone (allotetrahydroDOC; Fig. 25.33), respectively, represent neurosteroids with specific central actions.

In addition to the action of neurosteroids/neuroactive steroids via traditional steroid receptors (progesterone, estradiol), many neurosteroids act at different sites, especially the neurosteroids with a 3 α -hydroxyl (Fig. 25.33). Allopregnanolone and allotetrahydroDOC are positive modulators of GABA_A receptors, while pregnenolone sulfate and DHEA sulfate are negative modulators of the GABA_A receptors. DHEA sulfate and pregnenolone sulfate also have actions at NMDA receptors and sigma type 1 receptors, while progesterone interacts with kainite, glycine, 5HT₃, and nicotinic acetylcholine receptors. Although much of the neurosteroid research has been conducted in animal models, the clinical significance of neurosteroids is an area of growing interest.⁷⁹ Neurosteroids have been hypothesized to have neuroprotective effects, anxiolytic effects, and may play roles in modulating seizures. The actions of steroids in the brain will undoubtedly be the focus of much more research in the years to come.

ACKNOWLEDGMENT

I would like to thank Debra Peters for assistance with the illustration of several figures. I would also like to express my appreciation to the authors of various review articles on the steroids and the authors of previous versions of this text. Without the dedication and hard work of these individuals, the assembly of this chapter would have been a much more challenging task.

 R E V I E W Q U E S T I O N S 

1. What is the natural precursor in the human body to all the steroid hormones (estrogens, progestins, androgens, and corticosteroids)? Explain the general steps necessary to convert this precursor to the steroid backbones necessary for the specific steroid hormones. Also indicate the enzyme involved in the key steps.
2. Tamoxifen and raloxifene both mediate their main pharmacological actions via the ERs. Tamoxifen is an antagonist in breast tissue and an agonist in the endometrium and bone. Raloxifene, in contrast, is an antagonist in the breast and the endometrium and an agonist in bone tissue. Explain how these two drugs can have these varied effects in separate tissues, despite both binding at the same site on the ER.

3. Levonorgestrel has several structural differences relative to progesterone, yet still is a drug with useful progestational activity. Describe these structural differences and indicate how they affect the therapeutic properties of this drug.

4. The three structures depicted all illustrate a common structural modification seen in steroid hormone drugs, even though each structure represents a different class of steroid hormone. What is the common structural modification and how does it affect the action of each of these drugs? For each of the structures, provide the specific class of steroid hormone that is represented.

5. Two enzymes involved in steroid hormone biosynthesis are useful therapeutic targets, one for treating breast cancer and the other for treating benign prostatic hypertrophy (BPH). What are these two enzymes and what biosynthetic conversions do they mediate? Provide the name of an inhibitor of each enzyme that is used as a drug.
6. Based on structural features, which of the following represents a corticosteroid that would have strong anti-inflammatory properties, but would have minimal MC (water-retention) action? Explain your choice, specifically identifying key structural features.

Prostaglandins, Leukotrienes, and Essential Fatty Acids

THOMAS J. HOLMES, JR.

CHAPTER OVERVIEW

Lipidomics, which is the quantitative measurement of specifically identified, highly fat-soluble materials found naturally in the human body, is a subset of metabolomics, whose goal is to establish patterns of occurrence or change of intermediary metabolites that might help characterize conditions of health or disease. Prostaglandins, leukotrienes, and essential fatty acids are just three of the many fat-soluble, naturally occurring “targets” or “markers” for such investigations. Other lipids of high interest include cholesterol, steroid hormones, triglycerides, sphingolipids, phospholipids, glycolipids, the fat-soluble vitamins (A, D, E, K, Q), and the myriad derivatives of these compounds. Essential fatty acids are those polyunsaturated fatty acids (PUFA) that must be included in the human diet to maintain health. Various omega-3 and omega-6 fatty acids are included in this group. The prostaglandins (PGA through PGJ) are one group of naturally occurring 20-carbon fatty acid derivatives produced by the oxidative metabolism of 5,8,11,14-eicosatetraenoic acid, an omega-6 fatty acid, which is also called *arachidonic acid*. Other so-called eicosanoids produced in the complex biologic oxidation scheme called the *arachidonic acid cascade* are thromboxane A₂ (TXA₂), the leukotrienes (LKT A–F), and the highly potent antithrombotic agent prostacyclin (PGI₂). Although eicosanoid-derived agents in current human clinical therapy are few, the promise of future contributions from this area is presumed to be very great. This promise stems from the fact that intermediates of arachidonic acid metabolism play an essential modulatory role in many normal and disease-related cellular processes. In fact, much of the pain, fever, swelling, nausea, and vomiting associated with “illness,” in general is probably a result of excessive prostaglandin production in damaged tissues.

ESSENTIAL FATTY ACIDS

The fatty acids that are absolutely necessary to maintain the health of humans are generally polyunsaturated, even-numbered organic acids derived from plants or marine animals. For example, the essential fatty acids linoleic acid (18:2) and alpha-linolenic acid (ALA, 18:3) are respectively omega-6 and omega-3 18-carbon fatty acids, which occur naturally in olive oil as well as other oil-rich plants and seeds. Other PUFA, such as eicosapentaenoic acid (EPA; 20:5) and docosahexaenoic acid (DHA; 22:6) are omega-3

fatty acids that occur in the oils of cold-water ocean fish and have been found to be beneficial to the cardiovascular health of humans. The nomenclature for these PUFA is presented in Table 26.1.

In general, the designation (18:2) indicates that the fatty acid contains 18 carbon atoms and two double bonds, and the omega designation indicates the position of the double bond relative to the last carbon in the fatty acid. Thus, an 18:2 omega-3 fatty acid would have its last double bond terminating at the third carbon from the 18th carbon of the fatty acid (likewise omega-6 indicating the last double bond terminating at the sixth carbon from the end). Omega-9 fatty acids, such as oleic acid (18:1), are not considered essential to the diet but often occur in natural mixtures of unsaturated fatty acids. The omega designation has been transformed to an “n” designation (i.e., n-3, n-6, n-9) in some publications. A delta superscript designation indicates the position of each double bond relative to the carboxylic acid terminus. All double bonds occurring in natural fatty acids are of the *cis*-configuration. The production of harmful *trans*-unsaturated fatty acids (and their triglyceride ester derivatives) occurs as a result of commercial “partial” hydrogenation methods designed to raise the boiling point (cooking temperature) for vegetable oils used in deep-frying popular foods. Partial hydrogenation of vegetable oils was initially considered beneficial in that completely saturated fats (no double bonds) derived from animal fats (i.e., lard) could be replaced in the cooking process.

HISTORY OF EICOSANOID DISCOVERY

Early in the past century (1931), it was noted by Kurzrok and Lieb¹ that human seminal fluid could increase or decrease spontaneous muscle contractions of uterine tissue under controlled conditions. This observed effect on uterine musculature was believed to be induced by an acidic vasoactive substance formed in the prostate gland, which was later (1936) termed *prostaglandin* by von Euler.² Much later (1950s), it was found that the acidic extract contained not one but several structurally related prostaglandin substances.³ These materials subsequently were separated, purified, and characterized as the prostaglandins (PGA through PGJ), varying somewhat in degree of oxygenation and dehydrogenation and markedly in biologic activity (see Table 26.2). Specific stereochemical syntheses of the prostaglandins provided access to sufficient quantities of purified materials for wide-scale biologic evaluation and confirmed the structural characterization of these complex substances.⁴

TABLE 26.1 Nomenclature of Unsaturated Fatty Acids

Oleic acid	HOOC—CH ₂ —CH ₂ —CH ₂ —CH ₂ —CH ₂ —CH ₂ —CH ₂ — CH=CH—CH ₂ —CH ₂ —CH ₂ —CH ₂ —CH ₂ —CH ₂ — CH ₂ —CH ₃	18:1 omega-9 n-9 delta-9
Linoleic acid	HOOC—CH ₂ —CH ₂ —CH ₂ —CH ₂ —CH ₂ —CH ₂ —CH ₂ — CH=CH—CH ₂ —CH ₂ —CH=CH—CH ₂ —CH ₂ —CH ₂ — CH ₂ —CH ₃	18:2 omega-6 n-6 delta-9, -12
Alpha-linolenic acid (ALA)	HOOC—CH ₂ —CH ₂ —CH ₂ —CH ₂ —CH ₂ —CH ₂ —CH ₂ — CH=CH—CH ₂ —CH=CH—CH ₂ —CH=CH—CH ₂ —CH ₃	18:3 omega-3 n-3 delta-9, -12, -15
Arachidonic acid	HOOC—CH ₂ —CH ₂ —CH ₂ —CH ₂ —CH=CH—CH ₂ —CH=CH— CH—CH ₂ —CH=CH—CH ₂ —CH=CH—CH ₂ —CH ₂ — CH ₂ —CH ₂ —CH ₃	20:4 omega-6 n-6 delta-5, -8, -11, -14
Eicosapentaenoic acid (EPA)	HOOC—CH ₂ —CH ₂ —CH ₂ —CH=CH—CH ₂ —CH=CH— CH—CH ₂ —CH=CH—CH ₂ —CH=CH—CH ₂ —CH=CH— CH—CH ₂ —CH ₃	20:5 omega-3 n-3 delta-5, -8, -11, -14, -17
Docosahexaenoic acid (DHA)	HOOC—CH ₂ —CH ₂ —CH=CH—CH ₂ —CH=CH—CH ₂ — CH=CH—CH ₂ —CH=CH—CH ₂ —CH=CH—CH ₂ —CH=CH— CH—CH ₂ —CH ₃	22:6 omega-3 n-3 delta-4, -7, -10, -13, -16, -19

TABLE 26.2 Biological Activities Observed with the Eicosanoids

Substance	Observed Biological Activity
PGD ₂	Weak inhibitor of platelet aggregation Mast cell allergic response
PGE ₁	Vasodilation Inhibitor of lipolysis Inhibitor of platelet aggregation Bronchodilatation Stimulates contraction of gastrointestinal smooth muscle
PGE ₂	Stimulates hyperalgesic response Renal vasodilatation Stimulates uterine smooth muscle contraction Protects gastrointestinal epithelia from acid degradation
PGF ₂	Reduces secretion of stomach acid Elevates thermoregulatory set point in anterior hypothalamus Stimulates breakdown of corpus luteum (luteolysis) in animals Stimulates uterine smooth muscle contraction
PGI ₂	Potent inhibitor of platelet aggregation Potent vasodilator Increases cAMP levels in platelets
PGJ ₂	Stimulates osteogenesis Inhibits cell proliferation
TXA ₂	Potent inducer of platelet aggregation Potent vasoconstrictor Decreases cAMP levels in platelets Stimulates release of ADP and serotonin from platelets
LTB ₄	Increases leukocyte chemotaxis and aggregation
LTC/D ₄	Slow-reacting substances of anaphylaxis Potent and prolonged contraction of guinea pig ileum smooth muscle Contracts guinea pig lung parenchymal strips Bronchoconstrictive in humans Increased vascular permeability in guinea pig skin (augmented by PGEs)
5- or 12-HPETE	Vasodilatation of rat and rabbit gastric circulation

Although many scientists have contributed to a refined characterization of the eicosanoid biosynthetic pathways and the biologic consequences of this cascade (currently dubbed “eicosanomics”), the discerning and persistent pioneering efforts of Sune Bergström, Bengt Samuelsson, and John R. Vane were recognized by the award of a shared Nobel Prize in Medicine in 1982. These scientists not only dedicated themselves to the chemical and biologic characterization of the eicosanoid substances, but also were the first to realize the profound significance of the arachidonic acid cascade in disease processes, particularly inflammation. These individuals first proved that the mechanism of the anti-inflammatory action of aspirin and related nonsteroidal anti-inflammatory drugs (NSAIDs) was a direct result of their inhibitory effect on prostaglandin formation. It was shown subsequently that the analgesic and antipyretic effects of these NSAIDs, as well as their proulcerative and anticoagulant side effects, also result from their effect on eicosanoid metabolism (e.g., inhibition of cyclooxygenases 1 and 2 [COX-1 and COX-2]) (see the “Selected Reading” listed at the end of this chapter for comprehensive reviews of the diverse biological roles of the eicosanoids).

EICOSANOID BIOSYNTHESIS

Prostaglandins and other eicosanoids are produced by the oxidative metabolism of free arachidonic acid. Under normal circumstances, arachidonic acid is not available for metabolism as it is present as a conjugated component of the phospholipid matrix of most cellular membranes. Release of free arachidonic acid, which subsequently may be oxidatively metabolized, occurs by stimulation of phospholipase (PLA₂) enzyme activity in response to some traumatic event (e.g., tissue damage, toxin exposure, or hormonal stimulation). It is believed that the clinical anti-inflammatory effect of glucocortical steroids (i.e., hydrocortisone) is a result of their ability to suppress PLA₂ activity via lipocortins and thus prevent the release of free arachidonic acid.⁵ Modulation of PLA₂ activity by alkali metal ions, toxins, and various therapeutic agents has become a major focus of biologic research because of the changes in eicosanoid production and the dramatic

biological effects accompanying PLA₂ stimulation or suppression. Although it was initially believed that the inflammatory response (swelling, redness, pain) was principally a result of PGE₂, recent interest has focused on the interrelationships of PGE-type eicosanoids with the cytokines, such as interleukins-1 and -2, in the modulation of inflammatory reactions.⁶

Two different routes for oxygenation of arachidonic acid have been identified: the cyclooxygenase pathway (Fig. 26.1) and the lipoxygenase pathway (Fig. 26.2). The relative significance of each of these pathways may vary in a particular tissue or disease state. The cyclooxygenase pathway, so named because of the unusual bicyclic endoperoxide (PGG₂) produced in the first step of the sequence, involves the highly stereospecific addition of two molecules of oxygen to the arachidonic acid substrate, followed by subsequent enzyme-controlled rearrangements to produce an

array of oxygenated eicosanoids with diverse biologic activities (see Table 26.2). The first enzyme in this pathway, PGH-synthase, is a hemoprotein that catalyzes both the addition of oxygen (to form PGG₂) and the subsequent reduction (peroxidase activity) of the 15-position hydroperoxide to the 15-(S)-configuration alcohol (PGH₂).⁷ PGH-synthase (also called *cyclooxygenase-1* [COX-1] or -2 [COX-2], and formerly *PG-synthetase*) has been the focus of intense investigation because of its key role as the first enzyme in the arachidonic acid cascade.⁸ It is this enzyme in constitutive (COX-1) or inducible form (COX-2) that is susceptible to inhibition by NSAIDs, leading to relief of pain, fever, and inflammation.^{6,9} This enzyme is also inhibited by the ω-3 (omega-3) fatty acids (EPA and docosahexaenoic acid [DHA]) found in certain cold-water fish, which are provided commercially as nutritional supplements, leading to beneficial cardiovascular effects.¹⁰ Cyclooxygenase will

Figure 26.1 • Cyclooxygenase pathway.

Figure 26.2 • Lipoxygenase pathway.

metabolize 20-carbon fatty acids with one more or one less double bond than arachidonic acid, leading to prostaglandins of varied degrees of unsaturation (e.g., PGE₁ or PGE₃, for which the subscript number indicates the number of double bonds in the molecule).

Prostaglandin H₂ serves as a branch-point substrate for specific enzymes, leading to the production of the various prostaglandins, TXA₂, and PGI₂. Even though most tissues can produce PGH₂, the relative production of each of these derived eicosanoids is highly tissue specific and may be subject to secondary modulation by various cofactors. The complete characterization of enzymes involved in branches of the cyclooxygenase pathway and their genetic origins is currently under way.¹¹

Specific cellular or tissue responses to the eicosanoids are apparently a function of available surface receptor recognition sites.¹² The various tissue responses observed on eicosanoid exposure is outlined in Table 26.2. Nontissue-selective inhibitors of the cyclooxygenase pathway, such as aspirin, thus may exert a diversity of therapeutic effects or side effects (e.g., decreased uterine muscle contraction and platelet aggregation, gastric ulceration, lowering of elevated body temperature, central and peripheral pain relief, and decreased vascular perfusion) based on the inhibitor's tissue distribution profile.

The lipoxygenase pathway of arachidonic acid metabolism (Fig. 26.2) produces various acyclic lipid peroxides

(hydroperoxyeicosatetraenoic acids [HPETEs]) and derived alcohols (hydroxyeicosatetraenoic acids [HETEs]).¹³ Although the specific biologic function of each of these lipoxygenase-derived products is not completely known, they are believed to play a major role as chemotactic factors that promote cellular mobilization toward sites of tissue injury. In addition, the glutathione (GSH) conjugates LKT-C₄ and LKT-D₄ are potent, long-acting bronchoconstrictors that are released in the lungs during severe hypersensitivity episodes (leading to their initial designation as the "slow-reacting substances of anaphylaxis" [SRSAs]). Because of the presumed benefit of preventing formation of LKTs in asthmatic patients, much research effort is being dedicated to the design and discovery of drugs that might selectively inhibit the lipoxygenase pathway of arachidonic acid metabolism, without affecting the cyclooxygenase pathway.¹⁴ Zileuton (Zyflo by Abbott Laboratories) specifically inhibits the 5-lipoxygenase (5-LO) pathway. It has been proposed that aspirin hypersensitivity in susceptible individuals may result from effectively "shutting down" the cyclooxygenase metabolic route, allowing only the biosynthesis of lipoxygenase pathway intermediates, including the bronchoconstrictive LKTs.¹⁴ Other drugs (i.e., Singulair) have been developed, which block the receptors for certain leukotrienes. Considerable effort has also been directed toward discovering inhibitors of 5-LO activating protein (FLAP), which affects this pathway.¹⁵

DRUG ACTION MEDIATED BY EICOSANOIDS

The ubiquitous nature of the eicosanoid-producing enzymes implies their significance in various essential cellular processes. In addition, the sensitivity of these enzymes to structurally varied hydrophobic materials, particularly carboxylic acids and phenolic antioxidants, implies their susceptibility to influence by various exogenously administered agents.

The only group of drugs that has been thoroughly characterized for its effect on arachidonic acid metabolism is the NSAIDs. This large group of acidic, aromatic molecules exerts a diverse spectrum of activities (mentioned previously in this chapter) by inhibition of the first enzyme in the arachidonic acid cascade, PGH-synthase. Such agents as salicylic acid, phenylbutazone, naproxen, sulindac, and ibuprofen presumably act by a competitive, reversible inhibition of arachidonic acid oxygenation.¹⁶ Aspirin and certain halogenated aromatics (including indomethacin, flurbiprofen, and meclomen) appear to inhibit PGH-synthase in a time-dependent, irreversible manner.¹⁷ Since this irreversible inhibition appears critical for aspirin's significant effect on platelet aggregation and, therefore, prolongation of bleeding time,¹⁸ this discovery has led clinicians to recommend the daily consumption of low doses of aspirin (81 mg) in patients at risk for myocardial infarction (MI; heart attack), particularly a second MI.

Interestingly, aspirin's primary competitor in the commercial analgesic marketplace, acetaminophen, is a rather weak inhibitor of arachidonic acid oxygenation *in vitro*.¹⁹ This, in fact, is a characteristic of reversible, noncompetitive, phenolic antioxidant inhibitors in general.²⁰ This determination, in concert with its lack of *in vitro* anti-inflammatory activity (while maintaining analgesic and antipyretic activity equivalent to that of the salicylates), has led to the proposal that acetaminophen is more active as an inhibitor of cyclooxygenases in the brain, where peroxide levels (which stimulate cyclooxygenase activity) are lower, than in inflamed peripheral joints, where lipid peroxide levels are high.¹⁶ In fact, when *in vitro* experimental conditions are modified to reduce the so-called peroxide tone, acetaminophen becomes as effective an inhibitor as aspirin in reducing arachidonic acid metabolism.¹⁹

COX-2 INHIBITORS

The newer anti-inflammatory COX-2 inhibitors were claimed to show greater inhibitory selectivity for the inducible form of cyclooxygenase.²¹ Although not absolute, this selectivity provides a potential therapeutic advantage by reducing side effects, particularly gastric irritation and ulceration.²² Unfortunately, this altered profile of activity is not totally risk free. The manufacturer of rofecoxib (Vioxx) issued a warning (April 2002) regarding the use of this product in patients with a medical history of ischemic heart disease, and this product was removed from the market in 2004. COX-2 inhibitors do not share the same beneficial effects as aspirin in preventing cardiovascular thrombotic events.

DESIGN OF EICOSANOID DRUGS

The ability to capitalize successfully on the highly potent biologic effects of the various eicosanoids to develop new therapeutic agents currently seems an unfulfilled promise to medicinal chemists. Although these natural substances are highly potent effectors of various biologic functions, their use as drugs has been hampered by the following factors: (a) their chemical complexity and relative instability, which have limited, to some extent, their large-scale production and formulation for clinical testing; (b) their susceptibility to rapid degradation *in vivo* (Fig. 26.3), which limits their effective bioactive half-life; and (c) their propensity to affect diverse tissues (particularly the gastrointestinal tract, which may lead to severe nausea and vomiting) if they enter the systemic circulation, even in small amounts. Caution is always recommended with the use of prostaglandin analogs in women of childbearing age because of their potential for inducing dramatic contraction of uterine muscles, possibly leading to miscarriage.

Several approaches have been used to overcome these difficulties. First, structural analogs of particular eicosanoids have been synthesized that are more resistant to chemical and metabolic degradation but maintain, to a large extent, a desirable biologic activity. Although commercial production and formulation may be facilitated by this approach, biological potency of these analogs is usually reduced by several orders of magnitude. Also, systemic side effects may become troublesome because of broader tissue distribution as a result of the increased biological half-life.

Structural alterations of the eicosanoids have been aimed primarily at reducing or eliminating the very rapid metabolism of these potent substances to relatively inactive metabolites (see Fig. 26.3). Several analogs are presented in Table 26.3 to illustrate approaches that have led to potentially useful eicosanoid drugs. Methylation at the 15- or 16-position will eliminate or reduce oxidation of the essential 15-(*S*)-alcohol moiety. Esterification of the carboxylic acid function may affect formulation or absorption characteristics of the eicosanoid, whereas esterase enzymes in the bloodstream or tissues would be expected to quickly regenerate the active therapeutic agent. Somewhat surprisingly, considering the restrictive configurational requirements at the naturally asymmetric centers, various hydrophobic substituents (including phenyl rings) may replace the saturated alkyl chains, with retention of bioactivity.

A second major approach has been aimed at delivering the desired agent, either a natural eicosanoid or a modified analog, to a localized site of action by a controlled delivery method. The exact method of delivery may vary according to the desired site of action (e.g., uterus, stomach, lung) but has included aerosols and locally applied suppository, gel formulations, or cyclodextrin complexes. The recent commercial development of prostaglandin PGF-type derivatives for use in the eye to lower intraocular pressure (IOP) in glaucoma (discussed under "Prostaglandins for Ophthalmic Use") relies on their potent therapeutic effects coupled with their limited distribution from this site of administration.²³

EICOSANOID RECEPTORS

Another approach to developing new therapies based on the known biological activities of the prostaglandins and leukotrienes requires characterization of the naturally occurring tissue receptors for these agents. A thorough knowledge of the tissue distribution (localization) of such receptors and their binding characteristics would allow the design of receptor-specific agonists or antagonists, which might not possess the same limitations as the natural eicosanoids, but could affect tissue function nonetheless.²⁴

An excellent historical description of prostanoid receptor isolation and characterization has been published²⁵; and, a review of developments in this field is available.¹² Basically, prostanoid receptors are identified by their primary eicosanoid agonist (e.g., DP, EP, IP, and TP), although subclassification of PGE receptors has been necessary (e.g., EP₁, EP₂, EP₃, and EP₄), and separate DP₁ and DP₂ have also recently been proposed. In fact, subtypes of the EP₃ receptor (EP_{3A}, EP_{3B}, EP_{3C}, EP_{3D}) and TP receptor (TP_α, TP_β) have also been proposed. Complete characterization of receptors (and subtypes) includes tissue localization, biological effect produced, cellular signal transduction mechanism, inhibitor sensitivity, protein structure, and genetic origin. Not all receptors, or subtypes, have been completely characterized in this way, but significant progress toward this goal has occurred recently. Table 26.4 indicates characteristics of the prostanoid receptors identified thus far.

Although receptor studies have required the use of non-human species (principally, the mouse, but also rat, cow, sheep, and rabbit), a high correlation of structural homology of receptor subtypes between species (approximately 80%–90%) has been observed, whereas structural homology among receptor subtypes is relatively low (30%–50%). All prostanoid receptors, however, are believed to belong to a “rhodopsin-type” superfamily of receptors that function via G-protein-coupled transduction mechanisms. Three general

classes of prostanoid receptors are proposed¹²: (a) *relaxant*, including DP, EP₂, EP₄, and IP, which promote smooth muscle relaxation by raising intracellular cyclic adenosine monophosphate (cAMP) levels; (b) *contractile*, including EP₁, FP, and TP, which promote smooth muscle contraction via calcium ion mobilization; and (c) *inhibitory*, such as EP₃, which prevents smooth muscle contraction by lowering intracellular cAMP levels. Although structural and functional characterization of prostanoid receptors has permitted the identification and differentiation of selective receptor ligands (Table 26.3) (both agonists and antagonists), overlapping tissue distributions and common signal transduction mechanisms present formidable obstacles to the development of specific pharmacological therapies.

COMMERCIALLY AVAILABLE ESSENTIAL FATTY ACID SUPPLEMENTS

Lovaza (omega-3-acid ethyl esters) is available from Reliant Pharmaceuticals by prescription only. Formerly known as Omacar, this mixture of omega-3 fatty acid ethyl esters is recommended to reduce very high (500 mg/dL or above) triglyceride blood levels in adults. This product is administered orally and has similar precautions to usage as the available over-the-counter (OTC) products discussed below.

OTC fatty acid supplements (“fish oil” capsules) are widely available as mixtures of omega-3 PUFA containing predominantly DHA and EPA. The primary therapeutic claim for these products is improved cardiovascular health, however, other health claims for these products are broad and may be unsubstantiated. A comprehensive listing of claims and references to supportive evidence has been published.²⁶ The recommended minimum oral daily dose for these products is 500 mg of combined DHA and EPA. Suggested dosages for specific indications may be 2 to 3 times this level. The natural antioxidant vitamin E may be included in these

products as a “preservative” or cobeneficial nutritional supplement. At lower recommended dosages, side effects are generally minimal (i.e., fishy aftertaste or burping; potential diarrhea), however, caution is recommended for patients on anticoagulant therapy who might experience an exaggerated “blood-thinning” effect caused by displacement of protein-bound anticoagulant in the bloodstream.

ICOSANOIDS APPROVED FOR HUMAN CLINICAL USE

Prostaglandin E₂. PGE₂ Dinoprostone (Prostin E2; Cervidil) is a naturally occurring prostaglandin that is administered in a single dose of 10 mg by controlled-release (0.3 mg/hr) vaginal insert to induce cervical ripening. Use of this agent will potentiate the effects of oxytocin.

Carboprost Tromethamine. Carboprost tromethamine, 15-(S)-methyl-PGF_{2α} (Hemabate), is a prostaglandin derivative that has been modified to prevent metabolic oxidation of the 15-position alcohol function. This derivative may be administered in a hospital setting only in a dose of 250 μg by deep intramuscular injection to induce abortion or to ameliorate severe postpartum hemorrhage.

Prostaglandin E₁, United States Pharmacopeia (USP). PGE₁, Alprostadiol (Prostin VR Pediatric), is a naturally occurring prostaglandin that has found particular use in maintaining a patent (opened) ductus arteriosus in infants with congenital defects that restrict pulmonary or systemic blood flow.

Alprostadiol must be administered intravenously continually at a rate of approximately 0.1 μg/kg/min to temporarily

maintain the patency of the ductus arteriosus until corrective surgery can be performed. Up to 80% of circulating alprostadil may be metabolized in a single pass through the lungs. Because apnea has been observed in 10% to 12% of neonates with congenital heart defects, this product should be administered *only* when ventilatory assistance is immediately available. Other commonly observed side effects include decreased arterial blood pressure, which should be monitored during infusion; inhibited platelet aggregation, which might aggravate bleeding tendencies; and diarrhea. Prostin VR Pediatric is provided as a sterile solution in absolute alcohol (0.5 mg/mL) that must be diluted in saline or dextrose solution before intravenous administration. A liposomal preparation is available (Liposome Company) to extend the biological half-life of the active prostaglandin.

Alprostadil (Caverject) is also available in glass vials for reconstitution to provide 1 mL of solution containing either 10 or 20 $\mu\text{g/mL}$ for intercavernosal penile injection to diagnose or correct erectile dysfunction in certain cases of impotence. The availability of orally administered drugs to treat erectile dysfunction has reduced the therapeutic use of this agent.

Prostaglandin E_1 Cyclodextrin. This cyclic polysaccharide complex of PGE₁ (Vasoprost) is available as an orphan drug for the treatment of severe peripheral arterial occlusive disease when grafts or angioplasty are not indicated. Cyclodextrin complexation is used to enhance water solubility and reduce rapid metabolic inactivation.

Misoprostol. Misoprostol, (16-(*R,S*)-methyl-16-hydroxy)-PGE₁, methyl ester (Cytotec), is a modified prostaglandin analog that shows potent gastric antisecretory and gastro-protective effects when administered orally. Misoprostol is administered orally in tablet form in a dose of 100 to 200 μg 4 times a day to prevent gastric ulceration in susceptible individuals who are taking NSAIDs. Misoprostol is combined with the NSAID diclofenac (Voltaren) in an analgesic product (Arthrotec by Pharmacia), which is potentially safe for long-term antiarthritic therapy. This prostaglandin derivative absolutely should be avoided by pregnant women because of its potential to induce abortion. In fact, the combined use of intramuscular methotrexate and intravaginal misoprostol has been claimed to be a safe and effective, noninvasive method for the termination of early pregnancy.²⁷

Lubiprostone. This product is marketed as Amitiza by Sucampo Pharmaceuticals, Inc. and Takeda Pharmaceuticals America, Inc. to relieve chronic idiopathic constipation in adults. The recommended oral dosage is 24 μg 2 times a day with food. Precautions and side effects are similar to those for other prostaglandin-derived products.

Prostacyclin (PGI₂). Marketed as the sodium salt (epoprostenol; Flolan by GlaxoSmithKline), this product is administered by continuous infusion of a recently prepared solution (within 48 hours) for the treatment of primary pulmonary hypertension (PPH). The chemical stability of this compound in aqueous solution is limited, and the biological half-life is less than 6 minutes. The potent vasodilatory, platelet antiaggregatory effect, and vascular smooth muscle antiproliferatory effect of this naturally occurring eicosanoid produce a dramatic but short-lived therapeutic effect in PPH patients. Because continuous uninterrupted administration of the drug by portable infusion pump is necessary to prevent symptoms of rebound pulmonary hypertension, distribution of this product is restricted.²⁸

Iloprost. This more chemically and biologically stable derivative of prostacyclin is available as a solution (10 $\mu\text{g/mL}$) for nasal inhalation (Ventavis by Actelion) via a precisely calibrated inhalation device for the treatment of pulmonary arterial hypertension (PAH). Patients inhale 6 to 8 puffs of aerosolized iloprost every 2 to 3 hours to produce a direct vasodilatory effect on pulmonary blood vessels, thereby decreasing vascular resistance. Side effects of coughing, flushing, headaches, and jaw pain have been most commonly reported.

PROSTAGLANDINS FOR OPHTHALMIC USE

Several prostaglandin analogs have recently come to market for the treatment of open-angle glaucoma or ocular hypertension in patients who have not benefited from other available therapies. These products are marketed as sterile solutions for use in the eye (as indicated). Each of these agents is presumed to lower IOP by stimulation of FP receptors to open the uveoscleral pathway, thus increasing aqueous humor outflow. Commonly occurring side effects reported for this product group include conjunctival hyperemia, increased pigmentation and growth of eyelashes, ocular pruritus, and increased pigmentation of the iris and eyelid. Contact lenses should be removed during and after (15 minutes) administration of these products.

Bimatoprost (Lumigan) is supplied as a sterile 0.03% ophthalmic solution in 2.5- and 5.0-mL sizes. The recommended dosage of bimatoprost is limited to one drop into the affected eye once daily in the evening. Increased usage may decrease its beneficial effect. If used concurrently with other IOP-lowering drugs, a waiting period of 5 minutes should separate administrations.

Latanoprost (Xalatan) is available as a 0.005% sterile ophthalmic solution in a 2.5-mL dispenser bottle. Latanoprost is also marketed as a combination ophthalmic product with the β -adrenergic blocking agent, timolol, which apparently enhances IOP-lowering by decreasing the production of aqueous humor. Cautions and side effects are similar to those for other ophthalmic prostanoids.

Travoprost (Travatan and Travatan-Z) is supplied as a 2.5- or 5.0-mL sterile 0.004% ophthalmic solution in a 4.0- or 7.5-mL size container. Travoprost is claimed to be the most potent and FP-specific analog in this product category.²⁹ Cautions and side effects are similar to those given previously.

Unoprostone (Rescula) is supplied as a 0.15% sterile ophthalmic solution. Unoprostone is somewhat unusual in that it is a docosanoid (22-carbon atom) PGF_{2 α} analog marketed as the isopropyl ester. The natural 15-position alcohol is oxidized to the ketone as would be expected to occur in vivo. Cautions and side effects are similar to those given previously.

VETERINARY USES OF PROSTANOIDS

Since McCracken and coworkers³⁰ demonstrated that PGF_{2 α} acts as a hormone in sheep to induce disintegration of the corpus luteum (luteolysis), salts of this prostaglandin and various analogs have been marketed to induce or synchronize estrus in breed animals. This procedure allows artificial insemination of many animals during one insemination period. The following two products are currently available for this purpose.

Cloprostenol Sodium. Cloprostenol sodium (Estrumate) is available as the sodium salt from Bayer Agricultural Division or Bayvet Division of Miles Laboratory as an aqueous solution containing 250 mg/mL.

Dinoprost Trimethamine. Dinoprost trimethamine (Lutalyse) marketed by Upjohn Veterinary is a pH-balanced aqueous solution of the trimethylammonium salt of PGF_{2 α} (5 mg/mL).

 **EICOSANOIDS IN CLINICAL DEVELOPMENT FOR HUMAN TREATMENT**

Numerous prostaglandin analogs are under investigation for the treatment of human diseases (see Table 26.3). Efforts are being focused in the areas of gastroprotection as antiulcer therapy, fertility control, the development of thrombolytics (e.g.,

prostacyclin or thromboxane synthetase inhibitors) to treat cerebrovascular or coronary artery diseases, and the development of antiasthmatics through modulation of the lipoxygenase pathway. However, future application of eicosanoids to the treatment of cancer, hypertension, or immune system disorders cannot be ruled out. Thus, although progress in this area has been slow, the expanded use of eicosanoids or eicosanoid analogs as therapeutic agents in the future is almost ensured.

 **R E V I E W Q U E S T I O N S** 

1. Why is the initial enzyme in the arachidonic acid cascade called cyclooxygenase?
2. Name three major categories of highly potent chemical mediators of biological processes produced by the arachidonic acid cascade.
3. What chemical and biological properties of natural prostaglandins cause difficulties in the development of successful commercial drug products derived from this group?
4. Name several classes of therapeutic drug products, which provide their beneficial effects through interference with the arachidonic acid cascade.
5. Why are all prostanoid drug products strictly contraindicated in the treatment of women of childbearing age?
6. What particular birth defect may be successfully treated using PGE₁?
7. Name the two omega-3 fatty acids, which are usually present in the highest concentrations in over-the-counter nutritional supplement formulations?
8. Which eye disease may be successfully treated by local administration of a dilute solution of PGF₂ analogs?
9. Lubiprostone (Amitiza) is recommended for treatment of what condition based on the natural effect of prostaglandins to strongly stimulate contraction of smooth muscles in the GI tract?
10. Why does increased unsaturation (more double bonds) increase the ease of oxidation for long chain fatty acids?

Proteins, Enzymes, and Peptide Hormones

STEPHEN J. CUTLER AND HORACE G. CUTLER

CHAPTER OVERVIEW

This chapter describes the role human proteins, enzymes, and peptides play in regulating the mammalian system. It supports the fact that proteins play a critical role in the mechanisms of molecular biology and the role cellular components play in human physiology. This, in turn, not only serves in the development of natural proteins as therapeutic agents, but also in the development of novel synthetic congeners and genetic derivatives. For pharmacists to be good practitioners, it is necessary that they understand how proteins influence normal physiological function as well as to how they can be used in manipulating diseases.

Proteins are essential to all living matter and perform numerous functions as cellular components. Fundamental cellular events are catalyzed by proteins called *enzymes*, while other proteins serve as architectural constituents of protoplasm and cell membranes. Most important are the classes of hormones that are characterized as proteins or proteinlike compounds because of their polypeptidic structure.

Protein chemistry, essential in understanding the mechanisms of molecular biology and how cellular components participate in physiology, is also key to certain aspects of medicinal chemistry. An examination of the chemical nature of proteins explains the action of those medicinal agents that are proteins, or proteinlike compounds, and elucidates their physicochemical and biochemical properties. This, in turn, relates to their mechanisms of action. Furthermore, in medicinal chemistry, drug–receptor interactions are directly related to structure–activity relationships (SARs) and aid in the process of rational drug design. Drug receptors are considered to be macromolecules, some of which appear to be proteins or proteinlike.

Recombinant DNA (rDNA) technology¹ has had a dramatic impact on our ability to produce complex proteins and polypeptides structurally identical with those found in vivo. Many of the endogenous proteins or polypeptides have exhibited neurotransmitter and hormonal properties that regulate various important physiological processes. rDNA-derived technology products currently being used are discussed in this chapter.

Although this chapter reviews the medicinal chemistry of proteins, it includes some enzymology, not only because many drugs affect enzyme systems and vice versa, but also because basic discoveries in enzymology have been

practically applied to the study of drug–receptor interactions. Hence, a basic introduction to enzymes is included.

PROTEIN HYDROLYSATES

In therapeutics, agents affecting volume and composition of body fluids include various classes of parenteral products. Ideally, it would be desirable to have available parenteral fluids that provide adequate calories and important proteins and lipids to mimic, as closely as possible, an appropriate diet. Unfortunately, this is not the case. Usually, sufficient carbohydrate is administered intravenously to prevent ketosis, and in some cases, it is necessary to give further sources of carbohydrate by vein to reduce protein waste. Sources of protein are made available in the form of protein hydrolysates, and these can be administered to induce a favorable balance.

Protein deficiencies in human nutrition are sometimes treated with protein hydrolysates. The lack of adequate protein may result from several conditions, but the problem is not always easy to diagnose. The deficiency may be caused by insufficient dietary intake, temporarily increased demands (as in pregnancy), impaired digestion or absorption, liver malfunction, increased catabolism, or loss of proteins and amino acids (e.g., in fevers, leukemia, hemorrhage, surgery, burns, fractures, or shock).

Protein Hydrolysate. Protein hydrolysate is a solution of amino acids and short-chain oligopeptides that represent the approximate nutritive equivalent of the casein, lactalbumin, plasma, fibrin, or other suitable protein from which it is derived by acid, enzymatic, or other hydrolytic methods. It may be modified by partial removal, and restoration or addition of one, or more, amino acids. It may contain dextrose, or another carbohydrate suitable for intravenous infusion. Not less than 50% of the total nitrogen present is in the form of α -amino nitrogen. It is a yellowish to red-amber transparent liquid with a pH of 4 to 7.

Parenteral preparations are used to maintain a positive nitrogen balance in patients who exhibit interference with ingestion, digestion, or absorption of food. For such patients, the material to be injected must be nonantigenic and must not contain pyrogens or peptides of high-molecular weight. Injection may result in untoward effects such as nausea, vomiting, fever, vasodilatation, abdominal pain, twitching and convulsions, edema at the site of injection, phlebitis, and thrombosis. Sometimes, these reactions are caused by inadequate cleanliness or too-rapid administration.

AMINO ACID SOLUTIONS

Amino acid solutions contain a mixture of essential and nonessential crystalline amino acids, with or without electrolytes (e.g., Aminosyn, ProcalAmine, Travasol, Novamine). Although oral studies have shown a comparison between protein hydrolysates and free amino acid diets,² protein hydrolysates are being replaced by crystalline amino acid solutions for parenteral administration because the free amino acids are used more efficiently than the peptides produced by the enzymatic cleavage of protein hydrolysates.³

PROTEINS AND PROTEINLIKE COMPOUNDS

The chemistry of proteins is complex, with many facets not completely understood. Protein structure is usually studied in basic organic chemistry and, to a greater extent, in biochemistry, but for the purposes of this chapter, some of the more important topics are summarized, with emphasis on relationships to medicinal chemistry. Much progress has been made in understanding the more sophisticated features of protein structure⁴ and its correlation with physicochemical and biological properties. With the total synthesis of ribonuclease in 1969, new approaches to the study of SARs among proteins have involved the synthesis of modified proteins.

Many types of compounds important in medicinal chemistry are classified structurally as proteins, including enzymes, antigens, and antibodies. Numerous hormones are low-relative-molecular-mass proteins and so are called *simple proteins*. Fundamentally, all proteins are composed of one or more polypeptide chains; that is, the primary organizational level of protein structure is the polypeptide (polyamide) chain composed of naturally occurring amino acids bonded to one another by amide linkages (Fig. 27.1). The specific physicochemical and biological properties of proteins depend not only on the nature of the specific amino acids and their sequence within the polypeptide chain but also on conformational characteristics.

Conformational Features of Protein Structure

As stated, the polypeptide chain is considered to be the primary level of protein structure, and the folding of the polypeptide chains into a specific coiled structure is maintained through hydrogen-bonding interactions (intramolecular) (Fig. 27.2). The folding pattern is the secondary level of protein structure. The intramolecular hydrogen bonds involve the partially negative oxygens of amide carbonyl groups and the partially positive hydrogens of the amide —NH. Additional factors, such as ionic bonding between positively and negatively charged groups and disulfide bonds, help stabilize such folded structures.

The arrangement and interfolding of the coiled chains into layers determine the tertiary and higher levels of protein structure. Such final conformational character is determined by various types of interaction, primarily hydrophobic forces and, to some extent, hydrogen bonding and ion pairing.^{4,5} Hydrophobic forces are implicated in many biological phenomena associated with protein structure and interactions.⁶ The side chains (R groups) of

Figure 27.1 • Diagrammatic representation of a fully extended polypeptide chain with the bond lengths and the bond angles derived from crystal structures and other experimental evidence. (From Corey, R. B., and Pauling, L.: Proc. R. Soc. Lond. Ser. B 141:10, 1953.)

various amino acids have hydrocarbon moieties that are hydrophobic, and they have minimal tendency to associate with water molecules, whereas water molecules are strongly associated through hydrogen bonding. Such hydrophobic R groups tend to get close to one another, with exclusion of water molecules, to form “bonds” between different segments of the chain or between different chains. These are often termed *hydrophobic bonds*, *hydrophobic forces*, or *hydrophobic interactions*.

The study of protein structure has required several physicochemical methods of analysis.⁴ Ultraviolet spectrophotometry has been applied to the assessment of conformational changes that proteins undergo. Conformational changes can be investigated by the direct plotting of the difference in absorption of the protein under various sets of conditions.

Figure 27.2 • Left-handed and right-handed α -helices. The R and H groups on the α -carbon atom are in the correct position corresponding to the known configuration of the L-amino acids in proteins. (From Pauling, L., and Corey, R. B.: unpublished drawings.)

X-ray analysis has been most useful in the elucidation of the structures of several proteins (e.g., myoglobin and lysozyme). Absolute determinations of conformation and helical content can be made by x-ray diffraction analysis. Optical rotation of proteins has also been studied fruitfully. The specific rotations of proteins are always negative, and extreme changes in pH (when the protein is in solution) and conditions that promote denaturation (urea solutions, increased temperatures) tend to augment the negative optical rotation. Accordingly, it is thought that the changes in rotation are caused by conformational changes (i.e., changes in protein structure at the secondary and higher levels of organization). Optical rotatory dispersion has also been used to study conformational alterations and differences among globular proteins. Additionally, circular dichroism methodology has been involved in structural studies. The shape and the magnitude of rotatory dispersion curves and circular dichroism spectra are very sensitive to conformational alterations; thus, the effects of enzyme inhibitors on conformation can be analyzed. Structural studies have included the investigation of the tertiary structures of proteins in high-frequency nuclear magnetic resonance (NMR).^{7,8}

NMR spectroscopy has been of some use in the study of interactions between drug molecules and proteins such as enzymes, proteolipids, and others. NMR has been applied to the study of binding of atropine analogs to acetylcholinesterase⁹ and interactions involving cholinergic ligands and housefly brain and torpedo electroplax.¹⁰ NMR was also used in the determination of the tertiary structure of the capsid protein of the human immunodeficiency virus (HIV).¹¹

Factors Affecting Protein Structure

Conditions that promote the hydrolysis of amide linkages affect protein structure (see under "Protein Hydrolysates" previously in this chapter). The highly ordered conformation of a protein can be disorganized (without hydrolysis of the amide linkages), and in the process, the protein's biological activity is lost. This process, customarily called *denaturation*, involves unfolding of the polypeptide chains, loss of the native conformation of the protein, and disorganization of the uniquely ordered structure, without the cleavage of covalent bonds (e.g., cooked egg albumin). The rupture of native disulfide bonds is usually considered a more

extensive and drastic change than denaturation. Criteria for the detection of denaturation involve detection of previously masked —SH, imidazole, and —NH₂ groups; decreased solubility; increased susceptibility to the action of proteolytic enzymes; decreased diffusion constant and increased viscosity of protein solution; loss of enzymatic activity if the protein is an enzyme; and modification of antigenic properties.

Purification and Classification

It might be said that it is old-fashioned to classify proteins according to the following system, since so much progress has been made in understanding protein structure. Nevertheless, an outline of this system of classification is given because the terms used are still found in the pharmaceutical and medical literature. Table 27.1 includes the classification and characterization of simple proteins. Before classification, the protein material must be purified as much as possible, which is a very challenging task. Several criteria are used to determine homomolecularity, including crystallinity, constant solubility at a given temperature, osmotic pressure in different solvents, diffusion rate, electrophoretic mobility, dielectric constant, chemical assay, spectrophotometry, and quantification of antigenicity. The methodology of purification is complex; procedures can involve various techniques of chromatography (column), electrophoresis, ultracentrifugation, and others. High-performance liquid chromatography (HPLC) has been applied to the separation of peptides (e.g., the purification of some hypothalamic peptides by a combination of chromatographic methods including HPLC).^{12,13}

Conjugated proteins contain a nonprotein structural component in addition to the protein moiety, whereas simple proteins contain only the polypeptide chain of amino acid units. Nucleoproteins are conjugated proteins containing nucleic acids as structural components. Glycoproteins are carbohydrate-containing conjugated proteins (e.g., thyroglobulin). Phosphoproteins contain phosphate moieties (e.g., casein). Lipoproteins are lipid bearing. Metalloproteins have some bound metal. Chromoproteins, such as hemoglobin or cytochrome, have some chromophoric moiety.

Properties of Proteins

The classification in Table 27.1 is based on solubility properties. Fibrous proteins are water insoluble and highly

resistant to hydrolysis by proteolytic enzymes; the collagens, elastins, and keratins are in this class. Globular proteins (albumins, globulins, histones, and protamines) are relatively water soluble; they are also soluble in aqueous solutions containing salts, acids, bases, or ethanol. Enzymes, oxygen-carrying proteins, and protein hormones are globular proteins.

Another important characteristic of proteins is their amphoteric behavior. In solution, proteins migrate in an electric field, and the direction and rate of migration are a function of the net electrical charge of the protein molecule, which in turn depends on the pH of the solution. The isoelectric point is the pH value at which a given protein does not migrate in an electric field; it is a constant for any given protein and can be used as an index of characterization. Proteins differ in rate of migration and in their isoelectric points. Electrophoretic analysis is used to determine purity and for quantitative estimation because proteins differ in electrophoretic mobility at any given pH.⁴

Because they are ionic in solution, proteins bind with cations and anions depending on the pH of the environment. Sometimes, complex salts are formed, and precipitation takes place (e.g., trichloroacetic acid is a precipitating agent for proteins and is used for deproteinizing solutions).

Proteins possess chemical properties characteristic of their component functional groups, but in the native state, some of these groups are “buried” within the tertiary protein structure and may not react readily. Certain denaturation procedures can expose these functions and allow them to respond to the usual chemical reagents (e.g., an exposed —NH₂ group can be acetylated by ketene; —CO₂H can be esterified with diazomethane).

Color Tests and Miscellaneous Separation and Identification Methods

Proteins respond to the following color tests: (a) biuret, pink to purple with an excess of alkali and a small amount of copper sulfate; (b) ninhydrin, a blue color when boiled with ninhydrin (triketohydrindene hydrate), which is intensified by the presence of pyridine; (c) Millon test for tyrosine, a brick-red color or precipitate when boiled with mercuric nitrate in an excess of nitric acid; (d) Hopkins-Cole test for tryptophan, a violet zone with a salt of glyoxylic acid and stratified over sulfuric acid; and (e) xanthoproteic test, a brilliant

TABLE 27.1 Simple (True) Proteins

Class	Characteristics	Occurrence
Albumins	Soluble in water, coagulable by heat and reagents	Egg albumin, lactalbumin, serum albumin, leucosin of wheat, legumelin of legumes
Globulins	Insoluble in water, soluble in dilute salt solution, coagulable	Edestin of plants, vitelline of egg, serum globulin, lactoglobulin, amandin of almonds, myosin of muscles
Prolamines	Insoluble in water or alcohol, soluble in 60%–80% alcohol, not coagulable	Found only in plants (e.g., gliadin of wheat, hordein of barley, zein of corn, and secalin of rye)
Glutelins	Soluble only in dilute acids or bases, coagulable	Found only in plants (e.g., glutenin of wheat and oryzenin of rice)
Protamines	Soluble in water or ammonia, strongly alkaline, not coagulable	Found only in the sperm of fish (e.g., salmine from salmon)
Histones	Soluble in water, but not in ammonia, predominantly basic, not coagulable	Globin of hemoglobin, nucleohistone from nucleoprotein
Albuminoids	Insoluble in all solvents	In keratin of hair, nails, and feathers; collagen of connective tissue; chondrin of cartilage; fibroin of silk; and spongin of sponges

orange zone when a solution in concentrated nitric acid is stratified under ammonia. Almost all so-called alkaloidal reagents will precipitate proteins in slightly acid solution.

The qualitative identification of the amino acids found in proteins and other substances has been simplified greatly by the application of paper chromatographic techniques to the proper hydrolysate of proteins and related substances. End-member degradation techniques for the detection of the sequential arrangements of the amino acid residues in polypeptides (proteins, hormones, enzymes, etc.) have been developed to such a high degree with the aid of paper chromatography that very small samples of the polypeptides can be used. These techniques, together with statistical methods, have led to the elucidation of the amino acid sequences in oxytocin, vasopressin, insulin, hypertensin, glucagon, corticotropins, and others.

Ion exchange chromatography has been applied to protein analysis and to the separation of amino acids. The principles of ion exchange chromatography can be applied to the design of automatic amino acid analyzers with appropriate recording instrumentation.⁴ One- or two-dimensional thin-layer chromatography has been used to accomplish separations not possible with paper chromatography. Another method for separating amino acids and proteins involves a two-dimensional analytical procedure that uses electrophoresis in one dimension and partition chromatography in the other. The applicability of HPLC was noted previously.^{12,13}

Products

Gelatin, NF. Gelatin, NF, is a protein obtained by the partial hydrolysis of collagen, an albuminoid found in bones, skin, tendons, cartilage, hoofs, and other animal tissues. The products seem to be of great variety, and from a technical standpoint, the raw material must be selected according to the purpose intended (Table 27.2). This is because collagen is usually accompanied in nature by elastin and, especially, mucoids such as chondromucoid, which enter into the product in a small amount. The raw materials for official gelatin, and that used generally for food, are skins of calf or swine and bones. The bones are first treated with hydrochloric acid to remove the calcium compounds and then are digested with lime for a prolonged period, which solubilizes most other impurities. The fairly pure collagen is extracted with hot water at a pH of about 5.5, and the aqueous solution of gelatin is concentrated, filtered, and cooled to a stiff gel. Calf skins are treated in about the same way, but those from hogs are not given any lime treatment. The product derived from an acid-treated precursor is known as type A and exhibits an isoelectric point between

pH 7 and 9; that for which alkali is used is known as type B and exhibits an isoelectric point between pH 4.7 and 5. The minimum gel strength officially is that a 1% solution kept at 0°C for 6 hours must show no perceptible flow when the container is inverted.

Gelatin occurs in sheets, shreds, flakes, or coarse powder. It is white or yellowish, has a slight but characteristic odor and taste, and is stable in dry air but subject to microbial decomposition when moist or in solution. It is insoluble in cold water but swells and softens when immersed and gradually absorbs 5 to 10 times its own weight of water. It dissolves in hot water to form a colloidal solution; it also dissolves in acetic acid and in hot dilute glycerin. Gelatin commonly is bleached with sulfur dioxide, but the medicinal product must not have more than 40 parts per million of sulfur dioxide. A proviso is made, however, for the manufacture of capsules or pills, which may have certified colors added, may contain as much as 0.15% sulfur dioxide, and may have a lower gel strength.

Gelatin is used in the preparation of capsules, in the coating of tablets, and, with glycerin, as a vehicle for suppositories. It has also been used as a vehicle when slow absorption is desired for drugs. When dissolved in water, the solution becomes somewhat viscous, and in cases of shock, these solutions may be used to replace the loss in blood volume. Presently, this replacement is accomplished more efficiently with blood plasma, which is safer to use. In hemorrhagic conditions, it is sometimes administered intravenously to increase the clotting of blood or is applied locally for the treatment of wounds.

The most important value in therapy is as an easily digested and adjuvant food. Notably, it fails to provide any tryptophan and is lacking in adequate amounts of other essential amino acids; approximately 60% of the total amino acids consist of glycine and the prolines. Nevertheless, when supplemented, it is very useful in various forms of malnutrition, gastric hyperacidity or ulcer, convalescence, and general diets of the sick. It is especially useful in the preparation of modified milk formulas for feeding infants.

Gelatin Film, Absorbable, United States Pharmacopoeia (USP). Gelatin film, absorbable (Gelfilm), is a sterile, nonantigenic, absorbable, water-insoluble gelatin film. The gelatin films are prepared from a solution of specially prepared gelatin-formaldehyde combination, by spreading on plates and drying under controlled humidity and temperature. The film is available as light yellow, transparent, brittle sheets 0.076 to 0.228 mm thick. Although insoluble in water, they become rubbery after being in water for a few minutes.

Gelatin Sponge, Absorbable, USP. Gelatin sponge absorbable (Gelfoam, Surgifoam) is a sterile, absorbable, water-insoluble, gelatin-based sponge that is a light, nearly white, nonelastic, tough, porous matrix. It is stable to dry heat at 150°C for 4 hours. It absorbs 50 times its own weight of water or 45 times oxalated whole blood.

It is absorbed in 4 to 6 weeks when used as a surgical sponge. When applied topically to control capillary bleeding, it should be moistened with sterile isotonic sodium chloride solution or thrombin solution.

Venoms. Cobra (*Naja*) venom solution, from which the hemotoxic and proteolytic principles have been removed,

TABLE 27.2 Pharmaceutically Important Protein Products

Name Proprietary Name	Category
Gelatin, NF	Pharmaceutical acid (encapsulating agent; suspending agent; tablet binder and coating agent)
Gelatin film, absorbable, USP Gelfilm	Local hemostatic
Gelatin sponge, absorbable, USP Gelfoam, Surgifoam	Local hemostatic

has been credited with virtues because of its toxins and has been injected intramuscularly as a nonnarcotic analgesic in doses of 1 mL/day. Snake venom solution of the water moccasin is used subcutaneously in doses of 0.4 to 1.0 mL as a hemostatic in recurrent epistaxis and thrombocytopenic purpura and as a prophylactic before tooth extraction and minor surgical procedures. Stypven, from the Russell viper, is used topically as a hemostatic and as a thromboplastic agent in Quick's modified clotting-time test. Ven-Apis, the purified and standardized venom from bees, is furnished in graduated strengths of 32, 50, and 100 bee-sting units. It is administered topically in acute and chronic arthritis, myositis, and neuritis.

The frog venom, caerulein, isolated from the red-eyed tree frog *Agalychnis callidryas* mimics the effects of cholecystokinin and has been used in radiography procedures to contract the gallbladder. In addition, sauvagine, an anxiolytic, has been isolated from *A. callidryas*. Finally, bombesin, a 14-amino acid peptide that also possesses anxiolytic properties, has been isolated from the European firebellied frog. Although not a complete list of the peptides isolated from frogs, these provide an insight into the ancient defense mechanisms these reptiles possess and the possibility of exploitation for such uses as analgetics, antimicrobials (especially against resistant organisms), and cardiovascular agents.

Nucleoproteins. The aforementioned nucleoproteins are found in the nuclei and cytoplasm of all cells. They can be deproteinized by several methods. The compounds that occur in yeast are usually treated by grinding with a very dilute solution of potassium hydroxide, adding picric acid in excess, and precipitating the nucleic acids with hydrochloric acid, leaving the protein in solution. The nucleic acids are purified by dissolving in dilute potassium hydroxide, filtering, acidifying with acetic acid, and finally precipitating with a large excess of ethanol.

The nucleoproteins found in the nucleus of eukaryotic cells include various enzymes, such as DNA and RNA polymerases (involved in nucleic acid synthesis), nucleases (involved in the hydrolytic cleavage of nucleotide bonds), isomerases, and others. The nucleus of eukaryotic cells also contains specialized proteins, such as tubulin (involved in the formation of mitotic spindle before mitosis) and histones. Histones are proteins rich in the basic amino acids arginine and lysine, which together make up one fourth of the amino acid residues. Histones combine with negatively charged double-helical DNA to form complexes that are held together by electrostatic interactions. Histones package and order the DNA into structural units called *nucleosomes*. Because of the enormous amount of research on histones, the reader is encouraged to evaluate the "Selected Reading" list provided at the end of this chapter.

ENZYMES

Proteins that have catalytic properties are called *enzymes* (i.e., enzymes are biological catalysts of protein nature). Some enzymes have full catalytic reactivity per se; these are considered simple proteins because they do not have a non-protein moiety. Other enzymes are conjugated proteins, and

the nonprotein structural components are necessary for reactivity. Occasionally, enzymes require metallic ions. Because enzymes are proteins or conjugated proteins, the general review of protein structural studies presented previously in this chapter (e.g., protein conformation and denaturation) is fundamental to the following topics. Conditions that affect denaturation of proteins usually have an adverse effect on the activity of the enzyme.

General enzymology is discussed effectively in numerous standard treatises, and one of the most concise discussions appears in the classic work by Ferdinand,¹⁴ who includes reviews of enzyme structure and function, bioenergetics, and kinetics and appropriate illustrations with a total of 37 enzymes selected from the six major classes. For additional basic studies of enzymology, the reader should refer to this classic monograph and to a comprehensive review of this topic.¹⁵

Relation of Structure and Function

Koshland¹⁶ has reviewed concepts concerning correlations of protein conformation and conformational flexibility of enzymes with enzyme catalysis. Enzymes do not exist initially in a conformation complementary to that of the substrate. The substrate induces the enzyme to assume a complementary conformation. This is the so-called induced-fit theory. There is proof that proteins do possess conformational flexibility and undergo conformational changes under the influence of small molecules. This does not mean that all proteins must be flexible; nor does it mean that conformationally flexible enzymes must undergo conformational changes when interacting with all compounds. Furthermore, a regulatory compound that is not directly involved in the reaction can exert control on the reactivity of the enzyme by inducing conformational changes (i.e., by inducing the enzyme to assume the specific conformation complementary to the substrate). (Conceivably, hormones as regulators function according to the foregoing mechanism of affecting protein structure.) So-called flexible enzymes can be distorted conformationally by molecules classically called *inhibitors*. Such inhibitors can induce the protein to undergo conformational changes, disrupting the catalytic functions or the binding function of the enzyme. In this connection, it is noteworthy how the work of Belleau¹⁷ and the molecular perturbation theory of drug action relate to Koshland's studies presented previously in this textbook.

Evidence continues to support the explanation of enzyme catalysis based on the active site (reactive center) of amino acid residues, which is considered to be that relatively small region of the enzyme's macromolecular surface involved in catalysis. Within this site, the enzyme has strategically positioned functional groups (from the side chains of amino acid units) that participate cooperatively in the catalytic action.¹⁸

Some enzymes have absolute specificity for a single substrate; others catalyze a particular type of reaction that various compounds undergo. In the latter, the enzyme is said to have *relative specificity*. Nevertheless, compared with other catalysts, enzymes are outstanding in their specificity for certain substrates.¹⁹ The physical, chemical, conformational, and configurational properties of the substrate determine its complementarity to the enzyme's reactive center. These factors, therefore, determine whether a given compound satisfies the specificity of a particular

enzyme. Enzyme specificity must be a function of the nature, including conformational and chemical reactivity, of the reactive center, but when the enzyme is a conjugated protein with a coenzyme moiety, the nature of the coenzyme also contributes to specificity characteristics.

In some instances, the active center of the enzyme is apparently complementary to the substrate molecule in a strained configuration, corresponding to the "activated" complex for the reaction catalyzed by the enzyme. The substrate molecule is attracted to the enzyme, and the forces of attraction cause it to assume the strained state, with conformational changes that favor the chemical reaction; that is, the enzyme decreases the activation energy requirement of the reaction to such an extent that the reaction proceeds appreciably faster than it would in the absence of the enzyme. If enzymes were always completely complementary in structure to the substrates, then no other molecule would be expected to compete successfully with the substrate in combination with the enzyme, which, in this respect, would be similar in behavior to antibodies. Occasionally, however, an enzyme complementary to a strained substrate molecule attracts a molecule resembling the strained substrate molecule more strongly; for example, the hydrolysis of benzoyl-L-tyrosylglycineamide is practically inhibited by an equal amount of benzoyl-D-tyrosylglycineamide. This example illustrates a type of antimetabolite activity.

Several types of interaction contribute to the formation of enzyme-substrate complexes: attractions between charged (ionic) groups on the protein and the substrate, hydrogen bonding, hydrophobic forces (the tendency of hydrocarbon moieties of side chains of amino acid residues to associate with the nonpolar groups of the substrate in a water environment), and London forces (induced dipole interactions).

Many studies of enzyme specificity have involved proteolytic enzymes (proteases). Configurational specificity

can be exemplified by the aminopeptidase that cleaves L-leucylglycylglycine but does not affect D-leucylglycylglycine. D-Alanyl-glycylglycine is cleaved slowly by this enzyme. These phenomena illustrate the significance of steric factors; at the active center of aminopeptidase, the closeness of approach affects the kinetics of the reaction.

One can easily imagine how difficult it is to study the reactivity of enzymes on a functional group basis because the mechanism of enzyme action is so complex.¹⁶ Nevertheless, the —SH group probably is found in more enzymes as a functional group than are the other polar groups. In some enzymes (e.g., urease), the less readily available SH groups are necessary for biological activity and cannot be detected by the nitroprusside test, which is used to detect freely reactive SH groups.

A free —OH group of the tyrosyl residue is necessary for the activity of pepsin. Both the —OH of serine and the imidazole portion of histidine appear to be necessary parts of the active center of certain hydrolytic enzymes, such as trypsin and chymotrypsin, and furnish the electrostatic forces involved in a proposed mechanism (Fig. 27.3), in which E denotes enzyme and the other symbols are self-evident. (Alternative mechanisms have been proposed¹⁵; esterification and hydrolysis were studied extensively by M. L. Bender.^{19a-d} D. M. Blow reviewed studies concerning the structure and mechanism of chymotrypsin.^{19c})

These two groups (i.e., —OH and =NH) could be located on separate peptide chains in the enzyme as long as the specific three-dimensional structure formed during activation of the zymogen brought them near enough to form a hydrogen bond. The polarization of the resulting structure would cause the serine oxygen to be the nucleophilic agent that attacks the carbonyl function of the substrate. The complex is stabilized by the simultaneous "exchange" of the hydrogen bond from the serine oxygen to the carbonyl oxygen of the substrate.

Figure 27.3 • Proposed generalized mechanism for enzyme-catalyzed hydrolysis of $\text{R}-\text{C}-\text{X}$.

Figure 27.4 • Generalized mechanism of protease catalysis. (Roberts, J. D.: Chem. Eng. News 57:23, 1979.)

The intermediate acylated enzyme is written with the proton on the imidazole nitrogen. The deacylation reaction involves the loss of this positive charge simultaneously with the attack of the nucleophilic reagent (abbreviated Nu:H).

Roberts²⁰ used nitrogen-15 (¹⁵N) NMR to study the mechanism of protease catalysis. A schematic summary of the generalized mechanism is represented in Figure 27.4. It is concluded that the tertiary N-1 nitrogen of the histidine unit within the reactive center of the enzyme deprotonates the hydroxyl of the neighboring serine unit and simultaneously the hydroxyl oxygen exerts a nucleophilic attack on the carbonyl carbon of the amide substrate, as depicted in the scheme. A tetrahedral intermediate is implicated, and the carboxylate group of the aspartate unit (the third functional group within the reactive center) stabilizes the developing imidazolium ion by hydrogen bonding to the N-3 hydrogen. Finally, decomposition of the anionic tetrahedral intermediate toward product formation (amine and acylated serine) is promoted by prior protonation of the amide nitrogen by the imidazolium group.

A possible alternative route to deacylation would involve the nucleophilic attack of the imidazole nitrogen on the newly formed ester linkage of the postulated acyl intermediate, leading to the formation of the acyl imidazole. The latter is unstable in water, hydrolyzing rapidly to give the product and regenerated active enzyme.

The reaction of an alkyl phosphate in such a scheme may be written in an entirely analogous fashion, except that the resulting phosphorylated enzyme would be less susceptible to deacylation through nucleophilic attack. The diagrammatic scheme in Figure 27.5 has been proposed to explain the function of the active thiol ester site of papain. This ester site is formed and maintained by the folding energy of the enzyme (protein) molecule.

Zymogens (Proenzymes)

Zymogens, also called *proenzymes*, are enzyme precursors. These proenzymes are said to be activated when they are transformed to the enzyme. Activation usually involves catalytic action by some proteolytic enzyme. Occasionally, the activators merely effect a reorganization of the tertiary structure (conformation) of the protein so that the groups involved within the reactive center become functional (i.e., unmasked).

Synthesis and Secretion of Enzymes

Exportable proteins (enzymes), such as amylase, ribonuclease, chymotrypsin(ogen), trypsin(ogen), and insulin, are synthesized on the ribosomes. They pass across the membrane of the endoplasmic reticulum into the cisternae and directly into a smooth vesicular structure, which effects further transportation. They are finally stored in highly concentrated form within membrane-bound granules called *zymogen granules*. The exportable protein content of zymogen granules may reach a value of 40% of the total protein of the gland cell. In these enzyme sequences, the newly synthesized exportable protein (enzyme) is not free in the cell sap. The stored exportable digestive enzymes are released into the extracellular milieu and the hormones into adjacent capillaries. Release of these proteins is initiated by specific inducers. For example, cholinergic agents (but not epinephrine) and Ca^{2+} effect a discharge of amylase, lipase, or others into the medium, increased glucose levels stimulate the secretion of insulin, and so on. This release of the reserve enzymes and hormones is completely independent of the synthetic process, as long as the stores in the granules are not depleted. Energy oxidative phosphorylation does not play an important role in these releases. Electron microscope studies indicate a fusion of the zymogen granule membrane with the cell membrane so that the granule opens directly into the extracellular lumen of the gland.

Classification

There are various systems for the classification of enzymes. The International Union of Biochemistry system includes some of the terminology used in the literature of

Figure 27.5 • Proposed scheme for the action of papain.

medicinal chemistry, and in many instances the terms are self-explanatory. For example, transferases catalyze transfer of a group (e.g., methyltransferase); hydrolases catalyze hydrolysis reactions (e.g., esterases and amidases); and lyases catalyze nonhydrolytic removal of groups, leaving double bonds. There are also oxidoreductases, isomerases, and ligases. Other systems are sometimes used to classify and characterize enzymes, and the following terms are frequently encountered: *lipase*, *peptidase*, *protease*, *phosphatase*, *kinase*, *synthetase*, *dehydrogenase*, *oxidase*, and *reductase*.

Products

Pharmaceutically important enzyme products are listed in Table 27.3.

Pancreatin, USP. Pancreatin (Panteric) is a substance obtained from the fresh pancreas of the hog or the ox and contains a mixture of enzymes, principally pancreatic amylase (amylpsin), protease, and pancreatic lipase (steapsin). It converts not less than 25 times its weight of *USP* Potato Starch Reference Standard into soluble carbohydrates and not less than 25 times its weight of casein into proteoses. Pancreatin of higher digestive power may be brought to this

standard by admixture with lactose, sucrose containing not more than 3.25% of starch, or pancreatin of lower digestive power. Pancreatin is a cream-colored amorphous powder with a faint, characteristic, but not offensive, odor. It dissolves slowly but incompletely in water and is insoluble in alcohol. It acts best in neutral or faintly alkaline media, and excessive acid or alkali renders it inert. Pancreatin can be prepared by extracting the fresh gland with 25% alcohol or with water and subsequently precipitating with alcohol. Besides the enzymes mentioned, it contains some trypsinogen, which can be activated by intestinal enterokinase; chymotrypsinogen, which is converted by trypsin to chymotrypsin; and carboxypeptidase.

Pancreatin is used largely for predigestion of food and for the preparation of hydrolysates. The value of its enzymes orally must be very small because they are digested by pepsin and acid in the stomach, although some of them may escape into the intestines without change. Even if they are protected by enteric coatings, it is doubtful they could be of great assistance in digestion.

Trypsin Crystallized, USP. Trypsin crystallized is a proteolytic enzyme crystallized from an extract of the pancreas gland of the ox, *Bos taurus*. It occurs as a white to yellowish

TABLE 27.3 Pharmaceutically Important Enzyme Products

Name Proprietary Name	Preparations	Category	Application	Usual Adult Dose ^a	Usual Dose Range ^a
Pancreatin, <i>USP</i> <i>Panteric</i>	Pancreatin capsules, <i>USP</i> Pancreatin tablets, <i>USP</i>	Digestive aid		325 mg–1 g	
Trypsin crystallized, <i>USP</i>	Trypsin crystallized for aerosol, <i>USP</i>	Proteolytic enzyme		Aerosol, 125,000 <i>USP</i> units in 3 mL of saline daily	
Pancrelipase, <i>USP</i> <i>Cotazym</i>	Pancrelipase capsules, <i>USP</i> Pancrelipase tablets, <i>USP</i>	Digestive aid			An amount of pancrelipase equivalent to 8,000–24,000 <i>USP</i> units of lipolytic activity before each meal or snack, or to be determined by the practitioner according to the needs of the patient
Chymotrypsin, <i>USP</i> <i>Chymar</i>	Chymotrypsin for ophthalmic solution, <i>USP</i>	Proteolytic enzyme (for zonule lysis)	1–2 mL by irrigation to the posterior chamber of the eye, under the iris, as a solution containing 75–150 U/mL		
Dornase Alfa <i>Pulmozyme</i>	Aerosol	Proteolytic enzyme	Nebulizer		
Hyaluronidase for injection, <i>USP</i> <i>Alidase</i> , <i>Wydase</i>	Hyaluronidase injection, <i>USP</i>	Spreading agent		Hypodermoclysis, 150 <i>USP</i> hyaluronidase units	
Imiglucerase <i>Cerezyme</i>	Injection	Proteolytic enzyme			Dose based on body weight; range is 15–60 U/kg IV over 1–2 hours
Suttilains, <i>USP</i> <i>Travase</i>	Suttilains ointment, <i>USP</i>	Proteolytic enzyme	Topical, ointment, b.i.d. to q.i.d.		

^aSee *USP* DI for complete dosage information.

white, odorless, crystalline or amorphous powder, and 500,000 USP trypsin units are soluble in 10 mL of water or saline TS.

Trypsin has been used for several conditions in which its proteolytic activities relieve certain inflammatory states, liquefy tenacious sputum, and so forth. Many side reactions are encountered, however, particularly when it is used parenterally, which mitigate against its use.

Pancrelipase, USP. Pancrelipase (Cotazym) has a greater lipolytic action than other pancreatic enzyme preparations. Hence, it is used to help control steatorrhea and in other conditions in which pancreatic insufficiency impairs the digestion of fats in the diet.

Chymotrypsin, USP. Chymotrypsin (Chymar) is extracted from mammalian pancreas and is used in cataract surgery. A dilute solution is used to irrigate the posterior chamber of the eye to dissolve the fine filaments that hold the lens.

Dornase Alpha, USP. Dornase alpha (Pulmozyme) is a highly purified solution of recombinant human deoxyribonuclease I (rhDNase). It is indicated for use in cystic fibrosis because of its ability to liquefy secretions from the lung effectively. It accomplishes this by cleaving the extracellular DNA in purulent sputum and reducing the viscosity and elasticity of the secretion.

Hyaluronidase for Injection, USP. Hyaluronidase for injection (Alidase, Wydase) is a sterile, dry, soluble enzyme product prepared from mammalian testes and capable of hydrolyzing the mucopolysaccharide hyaluronic acid. It contains not more than 0.25 μg of tyrosine for each USP hyaluronidase unit. Hyaluronidase in solution must be stored in a refrigerator. Hyaluronic acid, an essential component of tissues, limits the spread of fluids and other extracellular material, and because the enzyme destroys this acid, injected fluids and other substances tend to spread farther and faster than normal when administered with this enzyme. Hyaluronidase may be used to increase the spread and consequent absorption of hypodermoclytic solutions; to diffuse local anesthetics, especially in nerve blocking; and to increase diffusion and absorption of other injected materials, such as penicillin. It also enhances local anesthesia in surgery of the eye and is useful in glaucoma because it causes a temporary drop in intraocular pressure.

Hyaluronidase is practically nontoxic, but caution must be exercised in the presence of infection because the enzyme may cause a local infection to spread, through the same mechanism. It should never be injected in an infected area. Sensitivity to the drug is rare.

The activity of hyaluronidase is determined by measuring the reduction in turbidity of a substrate of native hyaluronidate and certain proteins, or by measuring the reduction in viscosity of a buffered solution of sodium, or potassium hyaluronidate. Each manufacturer defines its product in turbidity or viscosity units, but values are not the same because they measure different properties of the enzyme.

Imiglucerase Injection. Imiglucerase injection (Cerezyme) is a form of human placental glucocerebrosidase from which the terminal mannose residues have been removed. This product is produced through recombinant tech-

nology and is used to treat type 1 Gaucher disease because its ability to hydrolyze glucocerebroside prevents the accumulation of this lipid in organs and tissues.

Sutilains, USP. Sutilains (Travase) is a proteolytic enzyme obtained from cultures of *Bacillus subtilis* and used to dissolve necrotic tissue occurring in second- and third-degree burns as well as bed sores and ulcerated wounds.

Many substances are contraindicated during the topical use of sutilains. These include detergents and anti-infectives that denature the enzyme preparation. The antibiotics penicillin, streptomycin, and neomycin do not inactivate sutilains. Mafenide acetate is also compatible with the enzyme.

Streptokinase. Streptokinase (Kabikinase, Streptase) is a catabolic 47,000-d protein secreted by group C β -hemolytic streptococci. It is a protein with no intrinsic enzymatic activity. Streptokinase activates plasminogen to plasmin, a proteolytic enzyme that hydrolyzes fibrin and promotes the dissolution of thrombi. Plasminogen is activated when streptokinase forms a 1:1 stoichiometric complex with it. Allergic reactions to streptokinase occur commonly because of antibody formation in individuals treated with it. Furthermore, the antibodies inactivate streptokinase and reduce its ability to prolong thrombin time. Streptokinase is indicated for acute myocardial infarction, for local perfusion of an occluded vessel, and before angiography, by intravenous, intra-arterial, and intracoronary administration, respectively.

Urokinase. Urokinase (Abbokinase) is a glycosylated serine protease consisting of 411 amino acid residues, which exists as two polypeptide chains connected by a single disulfide bond. It is isolated from human urine or tissue culture of human kidneys. The only known substrate of urokinase is plasminogen, which is activated to plasmin, a fibrinolytic enzyme. Unlike streptokinase, urokinase is a direct activator of plasminogen. Urokinase is nonantigenic because it is an endogenous enzyme and, therefore, may be used when streptokinase use is impossible because of antibody formation. It is administered intravenously or by the intracoronary route. Its indications are similar to those of streptokinase.

Alteplase. Alteplase (Activase) is a tissue plasminogen activator (t-PA) produced by rDNA technology. It is a single-chain glycoprotein protease consisting of 527 amino acid residues. Native t-PA is isolated from a melanoma cell line. The single-chain molecule is susceptible to enzymatic digestion to a two-chain molecule, in which the two chains remain linked with a disulfide bond. Both forms of the native t-PA are equipotent in fibrinolytic (and plasminogen-activating) properties. It is an extrinsic plasminogen activator associated with vascular endothelial tissue, which preferentially activates plasminogen bound to fibrin. The fibrinolytic action of alteplase (t-PA) is confined to thrombi, with minimal systemic activation of plasminogen. It is produced commercially by rDNA methods by inserting the alteplase gene (acquired from human melanoma cells) into ovarian cells of the Chinese hamster, serving as host cells. The melanoma-derived alteplase is immunologically and chemically identical with the uterine form. Alteplase is indicated for the intravenous management of acute myocardial infarction.

Papain, USP. Papain (Papase), the dried and purified latex of the fruit of *Carica papaya* L. (Caricaceae), can digest protein in either acidic or alkaline media; it is best at a pH between 4 and 7 and at 65°C to 90°C. It occurs as light brownish gray to weakly reddish brown granules, or as a yellowish gray to weakly yellow powder. It has a characteristic odor and taste and is incompletely soluble in water to form an opalescent solution. The commercial material is prepared by evaporating the juice, but the pure enzyme has also been prepared and crystallized. In medicine, it has been used locally in various conditions similar to those for which pepsin is used. It has the advantage of activity over a wider range of conditions, but it is often much less reliable. Intraperitoneal instillation of a weak solution has been recommended to counteract a tendency to develop adhesions after abdominal surgery, and several enthusiastic reports have been made about its value under these conditions. Papain has been reported to cause allergies in persons who handle it, especially those who are exposed to inhalation of the powder.

Bromelains. Bromelains (Ananase) is a mixture of proteolytic enzymes obtained from the pineapple plant. It is proposed for use in the treatment of soft-tissue inflammation and edema associated with traumatic injury, localized inflammation, and postoperative tissue reactions. The swelling that accompanies inflammation may be caused by occlusion of the tissue spaces with fibrin. If this is true, enough Ananase would have to be absorbed and reach the target area after oral administration to act selectively on the fibrin. This is yet to be established, and its efficacy as an anti-inflammatory agent is inconclusive. An apparent inhibition of inflammation, however, has been demonstrated with irritants such as turpentine and croton oil (granuloma pouch technique). Ananase is available in 50,000-U tablets for oral use.

Diastase. Diastase (Taka-Diastase) is derived from the action of a fungus, *Aspergillus oryzae* Cohn (Ahlburg), on rice hulls or wheat bran. It is a yellow, hygroscopic, almost tasteless powder that is freely soluble in water and can solubilize 300 times its weight of starch in 10 minutes. It is used in doses of 0.3 to 1.0 g in the same conditions as malt diastase. Taka-Diastase is combined with alkalis as an antacid in Takazyme, with vitamins in Taka-Combex, and in other preparations.

HORMONES

The hormones discussed in this chapter may be classified structurally as polypeptides, proteins, or glycoproteins. These hormones include metabolites elaborated by the hypothalamus, pituitary gland, pancreas, gastrointestinal tract, parathyroid gland, liver, and kidneys. A comprehensive review of the biochemistry of these polypeptides and other related hormones is beyond the scope of this chapter. For a detailed discussion, the reader should refer to the review by Wallis et al.²¹ and other literature cited throughout this chapter.

Hormones from the Hypothalamus

Spatola provides an excellent, although somewhat dated, review on the physiological and clinical aspects of hypothalamic-releasing hormones.²² Through use of these hormones, the central nervous system regulates other essential

endocrine systems, including the pituitary, which in turn controls still other systems (e.g., the thyroid).

Thyroliberin (thyrotropin-releasing hormone [TRH]) is the hypothalamic hormone responsible for the release of the pituitary's thyrotropin. Thyrotropin stimulates the production of thyroxine and liothyronine by the thyroid. The latter thyroid hormones, by feedback regulation, inhibit the action of TRH on the pituitary. TRH is a relatively simple tripeptide that has been characterized as pyroglutamyl-histidyl-prolinamide. TRH possesses interesting biological properties. In addition to stimulating the release of thyrotropin, it promotes the release of prolactin. It has also some central nervous system effects that have been evaluated for antidepressant therapeutic potential, but the results of clinical studies are not yet considered conclusive.

Gonadoliberin, as the name implies, is the gonadotropin-releasing hormone (Gn-RH), also known as *luteinizing hormone-releasing hormone* (LH-RH). This hypothalamic decapeptide stimulates the release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) by the pituitary. LH-RH is considered to be of potential therapeutic importance in the treatment of hypogonadotropic infertility in both males and females.²³

Luteinizing Hormone-Releasing Hormone (LH-RH)

A hypothalamic growth-releasing factor (GRF), also called somatoliberin, continues to be under intensive investigation. Its identification and biological characterization remain to be completed, but physiological and clinical data support the existence of hypothalamic control of pituitary release of somatotropin.

Somatostatin is another very interesting hypothalamic hormone.²² It is a tetradecapeptide possessing a disulfide bond linking two cysteine residues, 3 and 14, in the form of a 38-member ring. Somatostatin suppresses several endocrine systems. It inhibits the release of somatotropin and thyrotropin by the pituitary. It also inhibits the secretion of insulin and glucagon by the pancreas. Gastrin, pepsin, and secretin are intestinal hormones that are likewise affected by somatostatin. The therapeutic potential of somatostatin is discussed later in relation to the role of glucagon in the pathology of human diabetes.

Other hypothalamic hormones include the luteinizing hormone release-inhibiting factor (LHRIF), prolactin-releasing factor (PRF), corticotropin-releasing factor (CRF), melanocyte-stimulating hormone-releasing factor (MRF), and melanocyte-stimulating hormone release-inhibiting factor (MIF).

As the foregoing discussion illustrates, the hypothalamic endocrine system performs many essential functions affecting other endocrine systems. In turn, the thalamus and cortex exert control on the secretion of these (hypothalamic)

factors. A complete review of this field is beyond the scope of this chapter; the interested reader should refer to the literature cited.^{21–23}

Pituitary Hormones

The pituitary gland, or the hypophysis, is located at the base of the skull and is attached to the hypothalamus by a stalk. The pituitary gland plays a major role²¹ in regulating activity of the endocrine organs, including the adrenal cortex, the gonads, and the thyroid. The neurohypophysis (posterior pituitary), which originates from the brain, and the adenohypophysis (anterior pituitary), which is derived from epithelial tissue, are the two embryologically and functionally different parts of the pituitary gland. The adenohypophysis is under the control of hypothalamic regulatory hormones, and it secretes adrenocorticotropic hormone (ACTH), growth hormone (GH), LH, FSH, prolactin, and others. The neurohypophysis is responsible for the storage and secretion of the hormones vasopressin and oxytocin, controlled by nerve impulses traveling from the hypothalamus.

ADRENOCORTICOTROPIC HORMONE

ACTH (adrenocorticotropic, corticotropin) is a medicinal agent that has been the center of much research. In the late 1950s, its structure was elucidated, and the total synthesis was accomplished in the 1960s. Related peptides also have been synthesized, and some of these possess similar physiological action. Human ACTH has 39 amino acid units within the polypeptide chain.

SAR studies of ACTH²⁴ showed that the COOH-terminal sequence is not particularly important for biological activity. Removal of the NH₂-terminal amino acid results in complete loss of steroidogenic activity. Full activity has been reported for synthetic peptides containing the first 20 amino acids. A peptide containing 24 amino acids has full steroidogenic activity, without allergic reactions. This is of practical importance because natural ACTH preparations sometimes produce clinically dangerous allergic reactions.

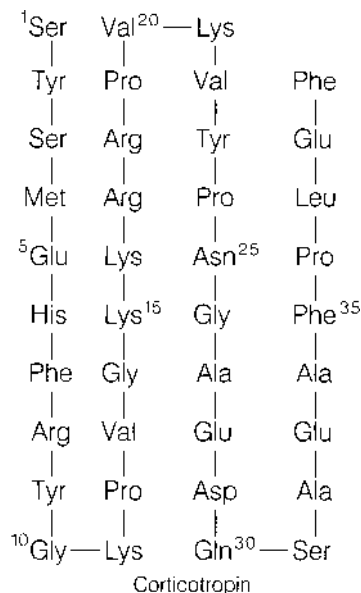

Corticotropin exerts its major action on the adrenal cortex, promoting steroid synthesis by stimulating the formation of pregnenolone from cholesterol.²⁵ An interaction between ACTH and specific receptors is implicated in the mechanism leading to stimulation of adenylate cyclase and acceleration of steroid production. The rate-limiting step in the biosynthesis of steroids from cholesterol is the oxidative cleavage of the side chain of cholesterol, which results in the formation of pregnenolone. This rate-limiting step is regulated by cyclic adenosine monophosphate (cAMP). Corticotropin, through cAMP, stimulates the biosynthesis of steroids from cholesterol by increasing the availability of free cholesterol. This involves activation of cholesterol esterase by phosphorylation. Corticotropin also stimulates the uptake of cholesterol from plasma lipoproteins. Other biochemical effects exerted by ACTH include stimulation of phosphorylase and hydroxylase activities. Glycolysis also is increased by this hormone. Enzyme systems that catalyze processes involving the production of reduced nicotinamide adenine dinucleotide phosphate (NADPH) are also stimulated. (NADPH is required by the steroid hydroxylations that take place in the overall transformation of cholesterol to hydrocortisone, the major glucocorticoid hormone.) Pharmaceutically important ACTH products are listed in Table 27.4.

Corticotropin Injection, USP. Adrenocorticotropic injection (ACTH injection, Acthar) is a sterile preparation of the principle, or principles derived from the anterior lobe of the pituitary of mammals used for food by humans. It occurs as a colorless or light straw-colored liquid, or a soluble, amorphous solid by drying such liquid from the frozen state. It exerts a tropic influence on the adrenal cortex. The solution has a pH range of 3 to 7 and is used for its adrenocorticotropic activity.

Repository Corticotropin Injection, USP. ACTH purified (ACTH-80, corticotropin gel, purified corticotropin) is corticotropin in a solution of partially hydrolyzed gelatin to be used intramuscularly for a more uniform and prolonged maintenance of activity.

Sterile Corticotropin Zinc Hydroxide Suspension, USP. Sterile corticotropin zinc hydroxide suspension is a sterile suspension of corticotropin, adsorbed on zinc hydroxide, which contains no less than 45 and no more than 55 μg of zinc for each 20 USP corticotropin units. Because of its prolonged activity caused by slow release of corticotropin, an initial dose of 40 USP units can be administered intramuscularly, followed by a maintenance dose of 20 U 2 or 3 times a week.

Cosyntropin. Cosyntropin (Cortrosyn) is a synthetic peptide containing the first 24 amino acids of natural corticotropin. Cosyntropin is used as a diagnostic agent to test for adrenal cortical deficiency. Plasma hydrocortisone concentration is determined before and 30 minutes after the administration of 250 μg of cosyntropin. Most normal re-

TABLE 27.4 Pharmaceutically Important Adrenocorticotrophic Hormone Products

Preparation Proprietary Name	Category	Usual Adult Dose ^a	Usual Dose Range ^a	Usual Pediatric Dose ^a
Corticotropin injection, USP Corticotropin for injection, USP Acthar	Adrenocorticotrophic hormone; adrenocortical steroid (anti-inflammatory); diagnostic aid (adrenocortical insufficiency)	Adrenocorticotrophic hormone: parenteral, 20 USP units, q.i.d. Adrenocortical steroid (anti-inflammatory): parenteral, 20 USP units q.i.d. Diagnostic aid (adrenocortical insufficiency): rapid test—IM or IV, 25 USP units, with blood sampling in 1 hour; adrenocortical steroid output—IV infusion, 25 U in 500–1,000 mL of 5% dextrose injection over a period of 8 hours on each of 2 successive days, with 24-hour urine collection each day	Adrenocorticotrophic hormone: 40–80 U/day; adrenocortical steroid (anti-inflammatory): 40–80 U/day	Parenteral, 0.4 U/kg of body weight or 12.5 U/m ² of body surface, q.i.d.
Repository corticotropin injection, USP Acthar Gel, Cortrophin Gel	Adrenocorticotrophic hormone; adrenocortical steroid (anti-inflammatory); diagnostic aid (adrenocortical insufficiency)	Adrenocorticotrophic hormone: IM or SC, 40–80 U every 24–72 hours; IV infusion, 40–80 U in 500 mL of 5% dextrose injection given over an 8-hour period, q.d. Adrenocortical steroid (anti-inflammatory): IM or SC, 40–80 U every 24–72 hours; IV infusion, 40–80 U in 500 mL of 5% dextrose injection given over an 8-hour period, q.d. Diagnostic aid (adrenocortical insufficiency): IM, 40 U b.i.d. on each of 2 successive days, with 24-hour urine collection each day		Adrenocorticotrophic hormone: parenteral, 0.8 U/kg of body weight or 25 U/m ² of body surface per dose
Sterile corticotropin zinc hydroxide suspension, USP Cortrophin-Zinc	Adrenocorticotrophic hormone; adrenocortical steroid (anti-inflammatory); diagnostic aid (adrenocortical insufficiency)	Adrenocorticotrophic hormone: IM, initial, 40–60 U/day, increasing interval to 48, then 72 hours; reduce dose per injection thereafter; maintenance, 20 U/day to twice weekly Adrenocortical steroid (anti-inflammatory): IM, initial, 40–60 U/day, increasing interval to 48, then 72 hours; reduce dose per injection thereafter; maintenance, 20 U/day to twice weekly Diagnostic aid (adrenocortical insufficiency): IM, 40 U on each of 2 successive 24-hour periods		
Cosyntropin Cortrosyn	Diagnostic aid (adrenocortical insufficiency)	IM or IV, 250 μg		Children 2 years of age or less, 0.125 mg

^aSee USP DI for complete dosage information.

sponses result in an approximate doubling of the basal hydrocortisone concentration in 30 to 60 minutes. If the response is not normal, adrenal insufficiency is indicated. Such adrenal insufficiency could be a result of either adrenal or pituitary malfunction, and further testing is required to distinguish between the two. Cosyntropin (250 μg infused within 4–8 hours) or corticotropin (80–120 U/day for 3–4 days) is administered. Patients with functional adrenal tissue should respond to this dosage. Patients who respond accordingly are suspected of hypopituitarism, and the diagnosis can be confirmed by other tests for pituitary function. Patients who have Addison disease, however, show little or no response.

Corticotropin. Corticotropin (Acthar) is a synthetic peptide that may be used as an injectable in the determination of

pituitary responsiveness. It possesses the amino acid sequence found in corticotropin-releasing hormone that is responsible for stimulating the release of ACTH.

MELANOTROPINS (MELANOCYTE-STIMULATING HORMONE)

Melanocyte-stimulating hormone (MSH) is elaborated by the intermediate lobe of the pituitary gland and regulates pigmentation of skin in fish, amphibians, and, to a lesser extent, humans. Altered secretion of MSH has been implicated in causing changes in skin pigmentation during the menstrual cycle and pregnancy. The two major types of melanotropin, α -MSH and β -MSH, are derived from ACTH and β -lipotropin, respectively. α -MSH contains the same amino acid sequence as the first 13 amino acids of ACTH; β -MSH

has 18 amino acid residues. A third melanotropin, γ -melanotropin, is derived from a larger peptide precursor, proopiomelanocortin (POMC). Some important endocrinological correlations include inhibitory actions of hydrocortisone on the secretion of MSH and the inhibitory effects of epinephrine and norepinephrine on MSH action.

LIPOTROPINS (ENKEPHALINS AND ENDORPHINS)

Opiates, such as opium and morphine, have been known for centuries as substances that relieve pain and suffering. Neuropharmacologists have theorized that opiates interact with receptors in the brain that are affected by endogenous substances that function as regulators of pain perception. The important breakthrough came in 1975, with the isolation of two peptides with opiatelike activity²⁶ from pig brains. These related pentapeptides, called methionine-enkephalin (metenkephalin) and leucine-enkephalin (leukenkephalin), are abundant in certain nerve terminals and have been found in the pituitary gland.

An examination of the structures of enkephalins revealed that the amino acid sequence of metenkephalin was identical with the sequence of residues 61 to 65 of β -lipotropin (β -LPH), a larger peptide found in the pituitary gland. This discovery suggested that β -LPH might be a precursor for other larger peptides containing the metenkephalin sequence. Soon after the structural relation-

ship between β -LPH and metenkephalin was established, longer peptides, called *endorphins*, were isolated from the intermediate lobe of the pituitary gland. The endorphins (α , β , and γ) contained the metenkephalin amino acid sequence and possessed morphinelike activity.²⁷ The longest of these peptides, β -endorphin, a 31-residue peptide (residues 61–91 of β -LPH), is about 20 to 50 times more potent than morphine as an analgesic and has a considerably longer duration of action than enkephalins. Numerous enkephalin analogs and derivatives have been prepared, and their biological activity has been evaluated. Like morphine, β -endorphin and the enkephalins can induce tolerance and dependence.

In addition to the enkephalins and endorphins, several other opioid peptides have been extracted from pituitary, adrenal, and nervous tissue, including dynorphins and neoenkephalins. The peptides β -LPH, ACTH, and γ -MSH are derived from the same precursor, POMC.

The endorphins and enkephalins have a wide range of biological effects, and most of their actions are in the central nervous system. Their actions include inhibition of release of dopamine in brain tissue and inhibition of release of acetylcholine from neuromuscular junctions. The role of endorphins and enkephalins as inhibitory neurotransmitters agrees well with the observed biological effects of these peptides in lowering response to pain and other stimuli. The role of endorphins and enkephalins as neurotransmitters and neuromodulators, with emphasis on receptor interactions, has been reviewed.²⁸ Also, see Chapter 24 in this textbook.

GROWTH HORMONE (SOMATOTROPIN)

GH is a 191-residue polypeptide elaborated by the anterior pituitary. The amino acid sequence of GH has been determined, and comparison with growth hormones of different species has revealed considerable structural variation.²⁹ In addition, the structure and properties of human GH have been reviewed.³⁰

The major biological action of GH is to promote overall somatic growth. Deficiency in the secretion of this hormone can cause dwarfism, and an overproduction of this hormone can cause acromegaly and gigantism. Secretion of this hormone is stimulated by growth hormone-releasing hormone (GH-RH), a 44-residue polypeptide secreted by the hypothalamus. Secretion of GH is inhibited by somatostatin.

GH stimulates protein synthesis, both in the skeletal muscles and in the liver. In the liver, GH stimulates uptake of amino acids and promotes the synthesis of all forms of RNA. It stimulates glucagon secretion by the pancreas, increases synthesis of glycogen in muscles, augments the release of fatty acids from adipose tissue, and increases osteogenesis. It also causes acute hypoglycemia followed by elevated blood glucose concentration and, perhaps, glycosuria.

GH has been recognized as an effective replacement therapy for GH-deficient children. The supply of GH, however, was very limited because its source was the pituitary glands of human cadavers, and several reports of deaths in children with Creutzfeldt-Jakob disease (caused by viral contamination of GH) halted the distribution of GH in 1977. Both of these problems were solved with the application of rDNA

technology in the commercial production of somatrem and somatotropin.

Somatrem (Systemic). Somatrem (Protropin) is a biosynthetic form of human GH that differs from the pituitary-derived GH and recombinant somatotropin by addition of an extra amino acid, methionine. Because of its structural difference from the natural GH, patients receiving somatrem may develop antibodies, which may result in a decreased response to it. Somatrem is administered intramuscularly or subcutaneously, and the therapy is continued as long as the patient responds, until the patient reaches mature adult height, or until the epiphyses close. The dosage range is 0.05 to 0.1 IU.

Somatropin (rDNA Origin). Somatotropin for injection (Humatrope) is a natural-sequence human GH of rDNA origin. Its composition and sequence of amino acids are identical with those of human GH of pituitary origin. It is administered intramuscularly or subcutaneously. The dosage range is 0.05 to 0.1 IU.

PROLACTIN

Prolactin (PRL), a hormone secreted by the anterior pituitary, was discovered in 1928. It is a 198-residue polypeptide with general structural features similar to those of GH. PRL stimulates lactation of parturition.

Gonadotropic Hormones

The two principal gonadotropins elaborated by the adenohypophysis are FSH and LH. LH is also known as *interstitial cell-stimulating hormone*. The gonadotropins along with thyrotropin form the incomplete glycoprotein group of hormones. FSH and LH may be produced by a single cell, the gonadotroph. The secretion of FSH and LH is controlled by the hypothalamus, which produces LH-RH. LH-RH stimulates the secretion of both FSH and LH, although its effects on the secretion of LH are more pronounced.

FOLLICLE-STIMULATING HORMONE

FSH promotes the development of ovarian follicles to maturity as well as spermatogenesis in testicular tissue. It is a glycoprotein, and the carbohydrate component is considered to be associated with its activity. Urofollitropin (Bravelle) is a highly purified, human-derived FSH that is indicated for ovulation induction.

LUTEINIZING HORMONE

LH is another glycoprotein. It acts after the maturing action of FSH on ovarian follicles, stimulates production of estrogens, and transforms the follicles into *corpora lutea*. LH also acts in the male to stimulate the Leydig cells that produce testosterone.

MENOTROPINS

Pituitary hormones prepared from the urine of postmenopausal women whose ovarian tissue does not respond to gonadotropin are available for medicinal use as the product menotropins (Pergonal). The latter has FSH and LH gonadotropin activity in a 1:1 ratio. Menotropins are useful in the treatment of anovular women whose ovaries

respond to pituitary gonadotropins but who have a gonadotropin deficiency caused by either pituitary or hypothalamus malfunction. Usually, menotropins are administered intramuscularly in an initial dose of 75 IU of FSH and 75 IU of LH daily for 9 to 12 days, followed by 10,000 IU of chorionic gonadotropin 1 day after the last dose of menotropins.

Thyrotropin

The thyrotropic hormone, also called *thyrotropin* and *thyroid-stimulating hormone* (TSH), is a glycoprotein consisting of two polypeptide chains. This hormone promotes production of thyroid hormones by affecting the kinetics of the mechanism by which the thyroid concentrates iodide ions from the bloodstream, thereby promoting incorporation of the halogen into the thyroid hormones and release of hormones by the thyroid.

TSH (Thyropar) appears to be a glycoprotein (relative molecular mass [M_r] 26,000–30,000) containing glucosamine, galactosamine, mannose, and fucose, whose homogeneity is yet to be established. It is produced by the basophil cells of the anterior lobe of the pituitary gland. TSH enters the circulation from the pituitary, presumably traversing cell membranes in the process. After exogenous administration, it is widely distributed and disappears very rapidly from circulation. Some evidence suggests that the thyroid may directly inactivate some of the TSH by an oxidation mechanism that may involve iodine. TSH thus inactivated can be reactivated by certain reducing agents. TSH regulates the production by the thyroid gland of thyroxine, which stimulates the metabolic rate. Thyroxine feedback mechanisms regulate the production of TSH by the pituitary gland.

The decreased secretion of TSH from the pituitary is a part of a generalized hypopituitarism that leads to hypothyroidism. This type of hypothyroidism can be distinguished from primary hypothyroidism by the administration of TSH in doses sufficient to increase the uptake of radioiodine, or to elevate the blood or plasma protein-bound iodine (PBI) as a consequence of enhanced secretion of hormonal iodine (thyroxine). Interestingly, massive doses of vitamin A inhibit the secretion of TSH. Thyrotropin is used as a diagnostic agent to differentiate between primary and secondary hypothyroidism. Its use in hypothyroidism caused by pituitary deficiency has limited application; other forms of treatment are preferable.

Somatostatin

Somatostatin was discovered in the hypothalamus. It is elaborated by the δ -cells of the pancreas and elsewhere in the body. Somatostatin is an oligopeptide (14 amino acid residues) and is referred to as *somatotropin release-inhibiting factor* (SRIF).

Its primary action is inhibiting the release of GH from the pituitary gland. Somatostatin also suppresses the release of both insulin and glucagon. It causes a decrease in both cAMP levels and adenylate cyclase activity. It also inhibits calcium ion influx into the pituitary cells and suppresses glucose-induced pancreatic insulin secretion by activating and deactivating potassium ion and calcium ion permeability, respectively. The chemistry, SARs, and potential clinical applications have been reviewed.^{22,31}

A powerful new synthetic peptide that mimics the action of somatostatin, octreotide acetate (Sandostatin), is approved by the Food and Drug Administration (FDA) for the treatment of certain rare forms of intestinal endocrine cancers, such as malignant carcinoid tumors and vasoactive intestinal peptide-secreting tumors (VIPomas). Octreotide acetate is indicated for long-term treatment of severe diarrhea associated with these carcinomas.

An octaoctotide somatostatin analog, lanreotide acetate (Somatuline Depot), was introduced in 2007 for the long-term treatment of acromegaly. Lanreotide is an inhibitor of various endocrine functions, but its main effects are associated with inhibiting insulin-like growth factor-1 (IGF-1).

Although not an analog of somatostatin but having inhibitory effects on IGF-1 is mecasermin (Increlex). It is designed to replace natural IGF-1 in patients who are deficient in the hormone.

Placental Hormones

HUMAN CHORIONIC GONADOTROPIN

Human chorionic gonadotropin (hCG) is a glycoprotein synthesized by the placenta. Estrogens stimulate the anterior pituitary to produce placentalotropin, which in turn stimulates hCG synthesis and secretion. hCG is produced primarily during the first trimester of pregnancy. It exerts effects that are similar to those of pituitary LH.

hCG is used therapeutically in the management of cryptorchidism in prepubertal boys. It also is used in women in conjunction with menotropins to induce ovulation when the endogenous availability of gonadotropin is not normal.

HUMAN PLACENTAL LACTOGEN

Human placental lactogen (hPL) also is called *human chorionammatotropin* and *chorionic growth-hormone prolactin*. This hormone exerts numerous actions. In addition to mammatropic and lactotropic effects, it exerts somatotropic and luteotropic actions. It is a protein composed of 191 amino acid units in a single-peptide chain with two disulfide bridges.²³ hPL resembles human somatotropin.

Neurohypophyseal Hormones (Oxytocin, Vasopressin)

The posterior pituitary (neurohypophysis) is the source of vasopressin, oxytocin, α - and β -MSH, and coherin. The

synthesis, transport, and release of these hormones have been reviewed by Brownstein.³² Vasopressin and oxytocin are synthesized and released by neurons of the hypothalamic–neurohypophyseal system. These peptide hormones, and their respective neurophysin carrier proteins, are synthesized as structural components of separate precursor proteins, and these proteins appear to be partially degraded into smaller bioactive peptides in the course of transport along the axon.

The structures of vasopressin and oxytocin have been elucidated, and these peptides have been synthesized. Actually, three closely related nonapeptides have been isolated from mammalian posterior pituitary: oxytocin and arginine vasopressin from most mammals and lysine vasopressin from pigs. The vasopressins differ from one another in the nature of the eighth amino acid residue: arginine and lysine, respectively. Oxytocin has leucine at position 8, and its third amino acid is isoleucine instead of phenylalanine. Several analogs of vasopressin have been synthesized and their antidiuretic activity evaluated. Desmopressin, 1-desamino-8-arginine-vasopressin, is a synthetic derivative of vasopressin. It is a longer-acting and more potent antidiuretic than vasopressin, with much less pressor activity. Desmopressin is much more resistant to the actions of peptidases because of the deamination at position 1, which accounts for its longer duration of action. The substitution of D- for L-arginine in position 8 accounts for its sharply lower vasoconstrictive effects.

Vasopressin also is known as the *pituitary antidiuretic hormone* (ADH). This hormone can effect graded changes in the permeability of the distal portion of the mammalian nephron to water, resulting in either conservation or excretion of water; thus, it modulates the renal tubular reabsorption of water. ADH has been shown to increase cAMP production in several tissues. Theophylline, which promotes cAMP by inhibiting the enzyme (phosphodiesterase) that catalyzes its hydrolysis, causes permeability changes similar to those caused by ADH. Cyclic AMP also effects similar permeability changes; hence, it is suggested that cAMP is involved in the mechanism of action of ADH.

The nonrenal actions of vasopressin include its vasoconstrictor effects and neurotransmitter actions in the central nervous system, such as regulation of ACTH secretion, circulation, and body temperature.

ADH is therapeutically useful in the treatment of diabetes insipidus of pituitary origin. It also has been used to relieve intestinal paresis and distention.

Oxytocin is appropriately named because of its oxytocic action. Oxytocin exerts stimulant effects on the smooth muscle of the uterus and mammary gland and has a relaxing ef-

fect on vascular smooth muscle when administered in high doses. It is considered the drug of choice to induce labor, particularly in cases of intrapartum hypotonic inertia. Oxytocin also is used in inevitable or incomplete abortion after the 20th week of gestation. It also may be used to prevent or control hemorrhage and to correct uterine hypotonicity. In some cases, oxytocin is used to promote milk ejection; it acts by contracting the myoepithelium of the mammary glands. Oxytocin is usually administered parenterally by intravenous infusion, intravenous injection, or intramuscular injection. Oxytocin citrate buccal tablets are also available, but the rate of absorption is unpredictable, and buccal administration is less precise. Topical administration (nasal spray) 2 or 3 minutes before nursing to promote milk ejection is sometimes recommended.³³ See Table 27.5 for product listing.

Oxytocin Injection, USP. Oxytocin injection is a sterile solution in water for injection of oxytocic principle prepared by synthesis, or obtained from the posterior lobe of the pituitary of healthy, domestic animals used for food by humans. The pH is 2.5 to 4.5; expiration date, 3 years.

Oxytocin preparations are widely used with or without amniotomy to induce and stimulate labor. Although injection is the usual route of administration, the sublingual route is extremely effective. Sublingual and intranasal spray (Oxytocin Nasal Solution, *USP*) routes of administration also will stimulate milk letdown.

Vasopressin Injection, USP. Vasopressin injection (Pitressin) is a sterile solution of the water-soluble pressor principle of the posterior lobe of the pituitary of healthy, domestic animals used for food by humans; it also may be prepared by synthesis. Each milliliter possesses a pressor activity equal to 20 *USP* posterior pituitary units; expiration date, 3 years.

Vasopressin Tannate. Vasopressin tannate (Pitressin Tannate) is a water-insoluble tannate of vasopressin ad-

ministered intramuscularly (1.5–5.0 pressor units daily) for its prolonged duration of action by the slow release of vasopressin. It is particularly useful for patients who have diabetes insipidus, but it should never be used intravenously.

Felypressin. Felypressin, 2-L-phenylalanine-8-L-lysine vasopressin, has relatively low antidiuretic activity and little oxytocic activity. It has considerable pressor (i.e., vasoconstrictor) activity, which differs from that of epinephrine (i.e., following capillary constriction in the intestine it lowers the pressure in the vena portae, whereas epinephrine raises the portal pressure). Felypressin also causes increased renal blood flow in the cat, whereas epinephrine brings about a fall in renal blood flow. Felypressin is five times more effective as a vasopressor than is lysine vasopressin and is recommended in surgery to minimize blood flow, especially in obstetrics and gynecology.

Lypressin. Lypressin is synthetic 8-L-lysine vasopressin, a polypeptide similar to ADH. The lysine analog is considered more stable, and it is absorbed rapidly from the nasal mucosa. Lypressin (Diapid) is pharmaceutically available as a topical solution, spray, 50 pressor units (185 μg)/mL in 5-mL containers. Usual dosage, topical (intranasal), one or more sprays applied to one or both nostrils one or more times daily.

Desmopressin Acetate. Desmopressin acetate (DDAVP, Stimate) is synthetic 1-desamino-8-D-arginine vasopressin. Its efficacy, ease of administration (intranasal), long duration of action, and lack of side effects make it the drug of choice for the treatment of central diabetes insipidus. It may also be administered intramuscularly or intravenously. It is preferred to vasopressin injection and oral antidiuretics for use in children. It is indicated in the management of temporary polydipsia and polyuria associated with trauma to, or surgery in, the pituitary region.

TABLE 27.5 Neurohypophyseal Hormones: Pharmaceutical Products

Preparation Proprietary Name	Category	Usual Adult Dose ^a	Usual Pediatric Dose ^a
Oxytocin injection, <i>USP</i> <i>Pitocin, Syntocinon</i>	Oxytocic	IM, 3–10 U after delivery of placenta; IV, initially no more than 1–2 mU/ minute, increased every 15–30 minutes in increments of 1–2 mU	
Oxytocin nasal solution, <i>USP</i> <i>Syntocinon</i>	Oxytocic	1 spray or 3 drops in one or both nostrils 2–3 minutes before nursing or pumping of breasts	
Vasopressin injection, <i>USP</i> <i>Pitressin</i>	Antidiuretic posterior pituitary hormone	IM or SC, 2.5–10 U t.i.d. or q.i.d. as necessary	IM or SC, 2.5–10 U t.i.d. or q.i.d. as necessary
Sterile vasopressin tannate oil suspension <i>Pitressin</i>	Antidiuretic posterior pituitary hormone	IM, 1.5–5 U every 1–3 days	IM, 1.25–2.5 U every 1–3 days
Desmopressin acetate nasal solution <i>DDAVP</i>	Antidiuretic posterior pituitary hormone	Maintenance: intranasal, 2–4 μg /day, as a single dose or in 2–3 divided doses	Maintenance: intranasal, 2–4 μg /kg of body weight per day or 5–30 mg/day or in 2–3 divided doses
Desmopressin acetate injection <i>DDAVP, Stimate</i>	Antidiuretic posterior pituitary hormone	IV or SC, 2–4 μg /day usually in 2 divided doses in the morning or evening	IV, 3 μg /kg of body weight diluted in 0.9% sodium chloride injection <i>USP</i>

^aSee *USP* DI for complete dosage information.

Pancreatic Hormones

Relationships between lipid and glucose levels in the blood and the general disorders of lipid metabolism found in diabetic subjects have received the attention of many chemists and clinicians. To understand diabetes mellitus, its complications, and its treatment, one has to begin with the basic biochemistry of the pancreas and the way carbohydrates are correlated with lipid and protein metabolism. The pancreas produces insulin, as well as glucagon; β -cells secrete insulin, and α -cells secrete glucagon. Insulin is considered first.

INSULIN

One of the major triumphs of the 20th century occurred in 1922, when Banting and Best³⁴ extracted insulin from dog pancreas. Advances in the biochemistry of insulin have been reviewed with emphasis on proinsulin biosynthesis, conversion of proinsulin to insulin, insulin secretion, insulin receptors, metabolism, effects by sulfonylureas, and so on.^{35–38}

Insulin is synthesized by the islet β -cells from a single-chain, 86-amino-acid polypeptide precursor, proinsulin.³⁹ Proinsulin itself is synthesized in the polyribosomes of the rough endoplasmic reticulum of the β -cells from an even larger polypeptide precursor, preproinsulin. The B chain of preproinsulin is extended at the NH_2 -terminus by at least 23 amino acids. Proinsulin then traverses the Golgi appara-

tus and enters the storage granules, where the conversion to insulin occurs.

The subsequent proteolytic conversion of proinsulin to insulin is accomplished by the removal of the Arg–Arg residue at positions 31 and 32 and the Arg–Lys residue at positions 64 and 65 by an endopeptidase that resembles trypsin in its specificity and a thiol-activated carboxypeptidase B-like enzyme.⁴⁰

The actions of these proteolytic enzymes on proinsulin result in the formation of equimolar quantities of insulin and the connecting C-peptide. The resulting insulin molecule consists of chains A and B, with 21 and 31 amino acid residues, respectively. The chains are connected by two disulfide linkages, with an additional disulfide linkage within chain A (Fig. 27.6).

The three-dimensional structure of insulin was determined by x-ray analysis of single crystals. These studies demonstrated that the high bioactivity of insulin depends on the integrity of the overall conformation. The biologically active form of the hormone is thought to be the monomer. The receptor-binding region consists of A-1 Gly, A-4 Glu, A-5 Gln, A-19 Tyr, A-21 Asn, B-12 Val, B-16 Tyr, B-24 Phe, and B-26 Tyr. The three-dimensional crystal structure appears to be conserved in solution and during its receptor interaction.

The amino acid sequence of insulins from various animal species has been examined.³⁵ Details of these are shown in

Figure 27.6 • Conversion of proinsulin to insulin.

TABLE 27.6 Some Sequence Differences in Insulins of Various Species

Species	A Chain				B Chain			
	1	8	9	10	-1	1	29	30
Human	Gly.	Thr.	Ser.	Ile.		Phe.	Lys.	Thr.
Pork	Gly.	Thr.	Ser.	Ile.		Phe.	Lys.	Ala.
Beef	Gly.	Ala.	Ser.	Val.		Phe.	Lys.	Ala.
Sheep	Gly.	Ala.	Gly.	Val.		Phe.	Lys.	Ala.
Horse	Gly.	Thr.	Gly.	Ile.		Phe.	Lys.	Ala.
Rabbit	Gly.	Thr.	Ser.	Ile.		Phe.	Lys.	Ser.
Chicken	Gly.	His.	Asn.	Thr.		Ala.	Lys.	Ala.
Cod	Gly.	His.	Arg.	Pro.	Met.	Ala.	Lys.	—
Rat I ^a	Gly.	Thr.	Ser.	Ile.		Phe.	Lys.	Ser.
Rat II ^a	Gly.	Thr.	Ser.	Ile.		Phe.	Met.	Ser.

See Reference 55 for details.

^aAsp substitution for Glu at position 4 on A chain.

Table 27.6. It is apparent from the analysis that frequent changes in sequence occur within the interchain disulfide ring (positions 8, 9, and 10). The hormonal sequence for porcine insulin is the closest to that of humans, differing only by the substitution of an alanine residue at the COOH-terminus of the B chain. Porcine insulin, therefore, is a good starting material for the synthesis of human insulin.

Insulin composes 1% of pancreatic tissue, and secretory protein granules contain about 10% insulin. These granules fuse with the cell membrane with simultaneous liberation of equimolar amounts of insulin and the C-peptide. Insulin enters the portal vein, and about 50% is removed in its first passage through the liver. The plasma half-life of insulin is approximately 4 minutes, compared with 30 minutes for the C-peptide.

Usually, exogenous insulin is weakly antigenic. Insulin antibodies have been observed to neutralize the hypoglycemic effect of injected insulin. The antibody-binding sites on insulin are quite different from the sites involved in binding of insulin with its receptors.⁴¹

Regulation of insulin secretion is affected by numerous factors, such as food, hormonal and neuronal stimuli, and ionic mechanisms.⁴² In humans, the principal substrate that stimulates the release of insulin from the islet β -cells is glucose. In addition to glucose, other substrates (e.g., amino acids, free fatty acids, and ketone bodies) also can stimulate insulin secretion directly. Secretin and ACTH can directly stimulate insulin secretion. Glucagon and other related peptides can increase the secretion of insulin, whereas somatostatin inhibits its secretion.

Autonomic neuronal mechanisms also play an important role in regulating insulin release. In the sympathetic nervous system, α -adrenergic agonists inhibit insulin release, whereas β -adrenergic agonists stimulate the release of insulin. In the parasympathetic nervous system, cholinomimetic drugs stimulate insulin release.

“Clinical” insulin that has been crystallized five times and then subjected to countercurrent distribution (2-butanol:1% dichloroacetic acid in water) yields about 90% insulin A, with varying amounts of insulin B together with other minor components. A and B differ by an amide group and have the same activity. End-member analysis, sedimentation, and diffusion studies indicate an M_r of about 6,000. The value of 12,000 M_r for insulin containing trace amounts of zinc (obtained by physical methods) is probably a bimolecular

association product through the aid of zinc. Insulin was the first protein for which a complete amino acid sequence was determined. The extensive studies of Sanger⁴³ and others elucidated the amino acid sequence and structure of insulin. Katsoyannis⁴⁴ and others followed with the synthesis of A and B chains of human, bovine, and sheep insulin. The A and B chains were combined to form insulin in 60% to 80% yields, with a specific activity comparable to that of the natural hormone.

The total synthesis of human insulin was reported by Rittel et al.⁴⁵ These workers selectively synthesized the final molecule appropriately cross-linked by disulfide (-S-S-) groups in yields ranging between 40% and 50%, whereas earlier synthetic methods involved random combination of separately prepared A and B chains of the molecule.

rDNA technology has been applied successfully in the production of human insulin on a commercial scale. Human insulin is produced in genetically engineered *Escherichia coli*.⁴⁶ Eli Lilly and Co., in cooperation with Genentech, began marketing rDNA-derived human insulin (Humulin) in 1982. There are two available methods of applying rDNA technology in the production of human insulin. The earlier method involved insertion of genes, for production of either the A or the B chain of the insulin molecule, into a special strain of *E. coli* (KI2) and subsequently combining the two chains chemically to produce an insulin that is structurally and chemically identical with pancreatic human insulin. The second, and more recent, method involves the insertion of genes for the entire proinsulin molecule into special *E. coli* cells that are then grown via fermentation. The connecting C-peptide is then enzymatically cleaved from proinsulin to produce human insulin.⁴⁷ Human insulin produced by rDNA technology is less antigenic than that from animal sources.

Although insulin is readily available from natural sources (e.g., porcine and bovine pancreatic tissue), partial syntheses and molecular modifications have been developed as the basis for SAR studies. Such studies have shown that amino acid units cannot be removed from the insulin peptide chain A without significant loss of hormonal activity. Several amino acids of chain B, however, are not considered essential for activity. Up to the first six and the last three amino acid units can be removed without significant decrease in activity.²³

Two insulin analogs, which differ from the parent hormone in that the NH_2 -terminus of chain A (A^1) glycine has been replaced by L- and D-alanine, respectively, have been

synthesized by Cosmatos et al.⁴⁸ for SAR studies. The relative potencies of the L and D analogs reveal interesting SARs. The L- and D-alanine analogs are 9.4% and 95%, respectively, as potent as insulin in glucose oxidation. The relative binding affinity to isolated fat cells is reported to be approximately 10% for the L and 100% for the D analog. Apparently, substitution on the α carbon of A¹ glycine of insulin, with a methyl in a particular configuration, interferes with the binding; hence, the resulting analog (that of L-alanine) is much less active. Methyl substitution in the opposite configuration affects neither the binding nor the bioactivity.

Molecular modifications of insulin on the amino groups appear to reduce bioactivity, but modifications of the ϵ -amino group of lysine number 29 on chain B (B-29) may yield active analogs. Accordingly, May et al.⁴⁹ synthesized N- ϵ -(+)-biotinyl insulin, which was equipotent with natural insulin. Complexes of this biotinyl-insulin derivative with avidin also were prepared and evaluated biologically; these complexes showed a potency decrease to 5% of that of insulin. Such complexes conjugated with ferritin are expected to be useful in the development of electron microscope stains of insulin receptors.

Alteration in the tertiary structure of insulin appears to drastically reduce biological activity as well as receptor binding. The three-dimensional structure provided by x-ray crystallography of the insulin monomer has revealed an exposed hydrophobic face that is thought to be involved directly in interacting with the receptor.⁵⁰ Thus, loss of biological activity in insulin derivatives, produced by chemical modification, can be interpreted in terms of adversely affecting this hydrophobic region. Also, species variation in this hydrophobic region is very unusual.

Insulin is inactivated *in vivo* by (a) an immunochemical system in the blood of insulin-treated patients, (b) reduction of disulfide bonds (probably by glutathione), and (c) insulinase (a proteolytic enzyme) that occurs in liver. Pepsin and chymotrypsin hydrolyze some peptide bonds that lead to inactivation. Insulin is inactivated by reducing agents such as sodium bisulfite, sulfurous acid, and hydrogen.

Advances in the area of insulin's molecular mechanisms have been reviewed^{36–38,51} with emphasis on receptor interactions, effect on membrane structure and functions, effects on enzymes, and the role of second messengers. The insulin receptor is believed to be a glycoprotein complex with a high M_r . The receptor is thought to consist of four subunits: two identical α units with an M_r of about 130,000 d and two identical β units with an M_r of 95,000 d, joined together by disulfide bonds. The α subunits are primarily responsible for binding insulin to its receptor, and the β subunits are thought to possess intrinsic protein kinase activity that is stimulated by insulin. The primary effect of insulin may be a kinase stimulation leading to phosphorylation of the receptor as well as other intracellular proteins.^{52,53} Additionally, insulin binding to its receptors may result in the generation of a soluble intracellular second messenger (possibly a peptide) that may mediate some insulin activity relating to activation of enzymes such as pyruvate dehydrogenase and glycogen synthetase. The insulin-receptor complex becomes internalized and may serve as a vehicle for translocating insulin to the lysosomes, in which it may be broken down and recycled back to the plasma membrane. The half-life of insulin is about 10 hours.

The binding of insulin to its target tissue is determined by several factors. The number of receptors in the target tissue and their affinity for insulin are two important determinants. These factors vary substantially from tissue to tissue. Another important consideration is the concentration of insulin itself. Elevated levels of circulating insulin decrease the number of insulin receptors on target cell surfaces and vice versa. Other factors that affect insulin binding to its receptors include pH, temperature, membrane lipid composition, and ionic strength.⁵³ It is conceivable, therefore, that conditions associated with insulin resistance, such as obesity and type 1 and type 2 diabetes mellitus, could be caused by altered receptor kinase activity, or impaired generation of second messengers (low- M_r peptides), increased degradation of the messenger, or fewer substrates (enzymes involved in metabolic activity) for the messenger or receptor kinase.⁵⁴

Metabolic Effects of Insulin. Insulin has pronounced effects on the metabolism of carbohydrates, lipids, and proteins.⁵⁵ The major tissues affected by insulin are muscle (cardiac and skeletal), adipose tissue, and liver. The kidney is much less responsive, and others (e.g., brain tissue and red blood cells) do not respond at all. The actions of insulin are highly complex and diverse. Because many of the actions of insulin are mediated by second messengers, it is difficult to distinguish between its primary and secondary actions.

In muscle and adipose tissue, insulin promotes transport of glucose and other monosaccharides across cell membranes; it also facilitates transport of amino acids, potassium ions, nucleosides, and ionic phosphate. Insulin also activates certain enzymes—kinases and glycogen synthetase in muscle and adipose tissue. In adipose tissue, insulin decreases the release of fatty acids induced by epinephrine or glucagon. cAMP promotes fatty acid release from adipose tissue; therefore, it is possible that insulin decreases fatty acid release by reducing tissue levels of cAMP. Insulin also facilitates the incorporation of intracellular amino acids into protein.

Insulin is believed to influence protein synthesis at the ribosomal level in various tissues.⁵⁶ In skeletal muscles, insulin predominantly stimulates translation by increasing the rate of initiation of protein synthesis and the number of ribosomes. In the liver, the predominant effect is on transcription. In cardiac muscles, insulin is believed to decrease the rate of protein degradation.

In the liver, there is no barrier to the transport of glucose into cells; nevertheless, insulin influences liver metabolism, decreasing glucose output, decreasing urea production, lowering cAMP levels, and increasing potassium and phosphate uptake. The lower cAMP levels result in decreased activity of glycogen phosphorylase, leading to diminished glycogen breakdown and increased activity of glycogen synthetase. It appears that insulin induces specific hepatic enzymes involved in glycolysis while inhibiting gluconeogenic enzymes. Thus, insulin promotes glucose use through glycolysis by increasing the synthesis of glucokinase, phosphofructokinase, and pyruvate kinase. Insulin decreases the availability of glucose from gluconeogenesis by suppressing pyruvate carboxylase, phosphoenolpyruvate carboxykinase, fructose-1,6-diphosphatase, and glucose-6-phosphatase.

Insulin's effects on lipid metabolism also are important. In adipose tissue, it has an antilipolytic action (i.e., an effect opposing the breakdown of fatty acid triglycerides). It also

decreases the supply of glycerol to the liver. Thus, at these two sites, insulin decreases the availability of precursors for the formation of triglycerides. Insulin is necessary for the activation and synthesis of lipoprotein lipases, enzymes responsible for lowering very low-density lipoprotein (VLDL) and chylomicrons in peripheral tissue. Other effects include stimulation of the synthesis of fatty acids (lipogenesis) in the liver.

Diabetes mellitus is a systemic disease caused by a decrease in the secretion of insulin or reduced sensitivity or responsiveness to insulin by target tissue (insulin receptor activity). The disease is characterized by hyperglycemia, hyperlipidemia, and hyperaminoacidemia. Diabetes mellitus frequently is associated with the development of microvascular and macrovascular diseases, neuropathy, and atherosclerosis. Various types of diabetes have been recognized and classified and their pathophysiology discussed.⁵⁷

The two major types of diabetes are type 1, insulin-dependent diabetes mellitus (IDDM), and type 2, non-insulin-dependent diabetes mellitus (NIDDM). Type 1 diabetes (also known as juvenile-onset diabetes) is characterized by a destruction of pancreatic β -cells, resulting in a deficiency of insulin secretion. Autoimmune complexes and viruses have been mentioned as two possible causes of β -cell destruction. Generally, in type 1 diabetes, receptor sensitivity to insulin is not decreased. Type 2 diabetes, also known as adult-onset diabetes, is characterized primarily by insulin receptor defects or postinsulin receptor defects. There is no destruction of β -cells, and insulin secretion is relatively normal. In reality, however, the two types of diabetes show a considerable overlap of clinical features.⁵⁷

Diabetes mellitus is associated with both microangiopathy (damage to smaller vessels, e.g., the eyes and kidney) and macroangiopathy (damage to larger vessels, e.g., atherosclerosis). Hyperlipidemia (characterized by an increase in the concentration of lipoproteins such as VLDL, intermediate density lipoprotein [IDL], and LDL) has been implicated in the development of atherosclerosis and is known to occur in diabetes. Severe hyperlipidemia may lead to life-threatening attacks of acute pancreatitis. It also seems that severe hyperlipidemia causes xanthoma. Considering the effects of insulin on lipid metabolism, as summarized previously, one can rationalize that in type 2 diabetes, in which the patient may actually have an absolute excess of insulin, in spite of the evidence of glucose tolerance tests, the effect of the excessive insulin on lipogenesis in the liver may suffice to increase the levels of circulating triglycerides and VLDL. In type 1 diabetes, with a deficiency of insulin, the circulating level of lipids may rise because too much precursor is available, with fatty acids and carbohydrates going to the liver.

The relationship between the carbohydrate metabolic manifestations of diabetes and the development of microvascular and macrovascular diseases has been studied extensively.^{58,59} It is becoming increasingly clear that hyperglycemia plays a major role in the development of vascular complications of diabetes, including intercapillary glomerulosclerosis, premature atherosclerosis, retinopathy with its specific microaneurysms and retinitis proliferans, leg ulcers, and limb gangrene. First, hyperglycemia causes an increase in the activity of lysine hydroxylase and galactosyl transferase, two important enzymes involved in glycoprotein synthesis. Increased glycoprotein synthesis in the collagen of kidney basement membrane may lead to the de-

velopment of diabetic glomerulosclerosis. Second, increased uptake of glucose by noninsulin-sensitive tissues (e.g., nerve Schwann cells and ocular lens cells) occurs during hyperglycemia. Intracellular glucose is converted enzymatically first to sorbitol and then to fructose. The buildup of these sugars inside the cells increases the osmotic pressure in ocular lens cells and Schwann cells, resulting in increased water uptake and impairing cell functions. Some forms of diabetic cataracts and diabetic neuropathy are believed to be caused by this pathway. Third, hyperglycemia may precipitate nonenzymatic glycosylation of various proteins in the body, including hemoglobin, serum albumin, lipoprotein, fibrinogen, and basement membrane protein. Glycosylation is believed to alter the tertiary structures of proteins and possibly their rate of metabolism. The rate of glycosylation is a function of plasma glucose concentration and the duration of hyperglycemia. Needless to say, this mechanism might play an important role in both macrovascular and microvascular lesions. Finally, hyperglycemia increases the rate of aggregation and agglutination of circulating platelets. Platelets play an important role in promoting atherogenesis. The increase in the rate of platelet aggregation and agglutination leads to the development of microemboli, which can cause transient cerebral ischemic attacks, strokes, and heart attacks.⁵⁷

Concepts of the therapeutics of diabetes mellitus have been reviewed by Maurer.⁶⁰ This review emphasizes that insulin therapy does not always prevent serious complications. Even diabetic patients considered under insulin therapeutic control experience wide fluctuations in blood glucose concentration, and it is hypothesized that these fluctuations eventually cause the serious complications of diabetes (e.g., kidney damage, retinal degeneration, premature atherosclerosis, cataracts, neurological dysfunction, and a predisposition to gangrene).

Insulin Preparations. The various commercially available insulin preparations are listed in Table 27.7. Amorphous insulin was the first form made available for clinical use. Further purification afforded crystalline insulin, which is now commonly called "regular insulin." Insulin injection, USP, is made from zinc insulin crystals. For some time, regular insulin solutions have been prepared at a pH of 2.8 to 3.5; if the pH were increased above the acidic range, particles would be formed. More highly purified insulin, however, can be maintained in solution over a wider pH range, even when unbuffered. Neutral insulin solutions have greater stability than acidic solutions; neutral insulin solutions maintain nearly full potency when stored up to 18 months at 5°C and 25°C. As noted in Table 27.7, the various preparations differ in onset and duration of action. A major disadvantage of regular insulin is its short duration of action (5–7 hours), which necessitates its administration several times daily.

Many attempts have been made to prolong the duration of action of insulin, for example, development of insulin forms less water soluble than the highly soluble (in body fluids) regular insulin. Protamine insulin preparations proved to be less soluble and less readily absorbed from body tissue. Protamine zinc insulin (PZI) suspensions were even longer acting (36 hours) than protamine insulin; these are prepared by mixing insulin, protamine, and zinc chloride with a buffered solution. The regular insulin/PZI ratios in clinically useful preparations range from 2:1 to 4:1.

TABLE 27.7 Insulin Preparations

Name	Particle Size (μm)	Action	Composition	pH	Duration (hours)
Insulin injection, ^a USP		Prompt	Insulin + ZnCl ₂	2.5–3.5	5–7
Prompt insulin zinc suspension, ^a USP	2 ^b	Rapid	Insulin + ZnCl ₂ + buffer	7.2–7.5	12
Insulin zinc suspension, ^a USP	10–40 (70%) 2 (30%) ^b	Intermediate	Insulin + ZnCl ₂ + buffer	7.2–7.5	18–24
Extended insulin zinc suspension, ^a USP	10–40	Long acting	Insulin + ZnCl ₂ + buffer	7.2–7.5	24–36
Globin zinc insulin injection ^a USP		Intermediate	Globin ^c + ZnCl ₂ + insulin	3.4–3.8	12–18
Protamine zinc insulin suspension, ^d USP		Long acting	Protamine ^e + insulin + Zn	7.1–7.4	24–36
Isophane insulin suspension, ^a USP	30	Intermediate	Protamine ^f ZnCl ₂ insulin buffer	7.1–7.4	18–24

^aClear or almost clear.

^bAmorphous.

^cGlobin (3.6–4.0 mg/100 USP units of insulin) prepared from beef blood.

^dTurbid.

^eProtamine (1.0–1.5 mg/100 USP units of insulin) from the sperm or the mature testes of fish belonging to the genus *Oncorhynchus* or *Salmo*.

^fProtamine (0.3–0.6 mg/100 USP units of insulin).

Isophane insulin suspension incorporates some of the qualities of regular insulin injection and is usually long acting enough (although not as much as PZI) to protect the patient from first day to the next (the term *isophane* is derived from the Greek *iso* and *phane*, meaning equal and appearance, respectively). Isophane insulin is prepared by careful control of the protamine/insulin ratio and the formation of a crystalline entity containing stoichiometric amounts of insulin and protamine. (Isophane insulin also is known as *NPH*; the *N* indicates neutral pH, the *P* stands for protamine, and the *H* for Hegedorn, the developer of the product.) NPH insulin has a quicker onset and a shorter duration of action (28 hours) than PZI. NPH is given in single morning doses and normally exhibits greater activity during the day than at night. NPH and regular insulin can be combined conveniently and effectively for many patients with diabetes.

The posology of various insulin preparations is summarized in Table 27.7.

A major concern with PZI and NPH insulins is the potential antigenicity of protamine (obtained from fish). This concern led to the development of lente insulins. By varying the amounts of excess zinc, by using an acetate buffer (instead of phosphate), and by adjusting the pH, two types of lente insulin were prepared. At high concentrations of zinc, a microcrystalline form precipitates and is called *ultralente*. Ultralente insulin is relatively insoluble and has a slower onset and a longer duration of action than PZI. At a relatively low zinc concentration, an amorphous form precipitates and is called *semilente insulin*. The latter is more soluble and has a quicker onset and a shorter duration of action than regular insulins. A third type of insulin suspension, lente insulin, is a 70:30 mixture of ultralente and semilente insulins. Lente insulin has a rapid onset and an intermediate duration of action (comparable to that of NPH insulin). Lente insulins are chemically incompatible with the PZI and NPH insulins because of the different buffer system used in the preparation of these insulins (an acetate buffer is used in lente insulins and a phosphate buffer is used in PZI and NPH insulins). Dosage and sources are summarized in Table 27.8.

Additionally, regular insulin will remain fast acting when combined with NPH but not when added to lente. The rapid action of regular insulin is neutralized by the excess zinc present in lente insulin.⁵⁴ Similar products⁶¹ containing rDNA-derived human insulin (instead of the bovine- and porcine-derived insulin) are available.

Progress in alternative routes of delivery of insulin has been prompted by problems associated with conventional insulin therapy, mentioned previously. First, various types of electromechanical devices (infusion pumps) have been developed with the aim of reducing fluctuations in blood glucose levels associated with conventional insulin therapy (subcutaneous injections). These continuous-infusion pumps are either close-loop or open-loop systems. The ultimate goal of research in this area is to develop a reliable implantable (miniature) device for long-term use that would eliminate the need for daily administration and monitoring of blood glucose levels. The second area of research studies alternative routes of administration such as oral, nasal, and rectal. Preliminary results indicate that absorption of insulin at these sites is not uniform and is unpredictable. The third approach to correcting the problems of conventional insulin therapy is to supplement the defective pancreas by transplantation with a normally functioning pancreas from an appropriate donor. The major problem with this approach is rejection of the donor pancreas by the recipient, as well as problems associated with the draining of exocrine enzymes. A modified procedure transplants only viable pancreatic islet cells or fetal or neonatal pancreas. The possibility remains, however, that in type 1 diabetes, the newly transplanted pancreatic β -cells could be destroyed by the same autoimmune process that caused the disease in the first place.

GLUCAGON

Glucagon, USP. The hyperglycemic–glycogenolytic hormone elaborated by the α -cells of the pancreas is known as glucagon. It contains 29 amino acid residues in the sequence shown. Glucagon has been isolated from the amorphous fraction of a commercial insulin sample (4% glucagon).

TABLE 27.8 Dosage and Source of Insulin Preparations

USP Insulin Type	Strengths and Sources	Usual Adult Dose ^a
Insulin injection (regular insulin, crystalline zinc insulin, Cispro)	U-40 mixed, U-100 mixed: purified beef, pork; purified pork; biosynthetic human; semisynthetic human	Diabetic hyperglycemia: SC, as directed by physician 15–30 minutes before meals up to t.i.d. or q.i.d.
Isophane insulin suspension (NPH insulin)	U-500: purified pork U-40 mixed, U-400 mixed: beef; purified beef, pork; purified pork; biosynthetic human; semisynthetic human	SC, as directed by physician, q.d. 30–60 minutes before breakfast; an additional dose before breakfast may be necessary for some patients about 30 minutes before a meal or at bedtime
Isophane insulin suspension (70%) and insulin injection (30%)	U-100: purified pork; semisynthetic human	SC, as directed by physician, q.d. 15–30 minutes before breakfast, or as directed
Insulin zinc suspension (Lente insulin)	U-40 mixed, U-100 mixed: beef; purified beef; purified pork; biosynthetic human; semisynthetic human	SC, as directed by physician, q.d. 30–60 minutes before breakfast; an additional dose may be necessary for some patients about 30 minutes before a meal or at bedtime
Extended insulin zinc suspension (Ultralente insulin)	U-40 mixed, U-100 mixed: beef; purified beef	SC, as directed by physician, q.d. 30–60 minutes before breakfast
Prompt insulin zinc suspension (Semilente insulin)	U-40 mixed, U-100 mixed: beef; purified pork	SC, as directed by physician, q.d. 30–60 minutes before breakfast; an additional dose may be necessary for some patients about 30 minutes before a meal or at bedtime
Protamine zinc insulin suspension (PZI Insulin)	U-40 mixed, U-100 mixed: purified pork	SC, as directed by physician, q.d. 30–60 minutes before breakfast

^aSee USP DI for complete dosage information.
SC, subcutaneously.

Attention has been focused on glucagon as a factor in the pathology of human diabetes. According to Unger et al.,⁶² the following observations support this implication of glucagon: elevated glucagon blood levels (hyperglucagonemia) have been observed in association with every type of hyperglycemia; when secretion of both glucagon and insulin is suppressed, hyperglycemia is not observed unless the glucagon levels are restored to normal by the administration of glucagon; the somatostatin-induced suppression of glucagon release in diabetic animals and humans restores blood sugar levels to normal and alleviates certain other symptoms of diabetes.

Unger et al.⁶² propose that although the major role of insulin is regulation of the transfer of glucose from the blood to storage in insulin-responsive tissues (e.g., liver, fat, and muscle), the role of glucagon is regulation of the liver-mediated mobilization of stored glucose. The principal consequence of high concentrations of glucagon is liver-mediated release into the blood of abnormally high concen-

trations of glucose, thereby causing persistent hyperglycemia. This indicates that a relative excess of glucagon is an essential factor in the development of diabetes.

Glucagon's solubility is 50 $\mu\text{g}/\text{mL}$ in most buffers between pH 3.5 and 8.5. It is soluble, 1 to 10 mg/mL , in the pH ranges 2.5 to 3.0 and 9.0 to 9.5. Solutions of 200 $\mu\text{g}/\text{mL}$ at pH 2.5 to 3.0 are stable for at least several months at 4°C if sterile. Loss of activity by fibril formation occurs readily at high concentrations of glucagon at room temperature, or above, at pH 2.5. The isoelectric point appears to be at pH 7.5 to 8.5. Because it has been isolated from commercial insulin, its stability properties should be comparable to those of insulin.

As with insulin and some of the other polypeptide hormones, glucagon-sensitive receptor sites in target cells bind glucagon. This hormone-receptor interaction leads to activation of membrane adenylate cyclase, which catalyzes cAMP formation. Thus, intracellular cAMP levels are elevated. The mode of action of glucagon in glycogenolysis is basically the same as the mechanism of epinephrine (i.e., stimulation of adenylate cyclase). Subsequently, the increase in cAMP activates the protein kinase that catalyzes phosphorylation of phosphorylase kinase to phosphophosphorylase kinase. The latter is necessary for the activation of phosphorylase to form phosphorylase *a*. Finally, phosphorylase *a* catalyzes glycogenolysis, which is the basis for the hyperglycemic action of glucagon. Although both glucagon and epinephrine exert hyperglycemic action through cAMP, glucagon affects liver cells and epinephrine affects both muscle and liver cells.

Fain⁶³ reviewed the many phenomena associated with hormones, membranes, and cyclic nucleotides, including several factors that activate glycogen phosphorylase in rat liver. These factors involve not only glucagon but also vasopressin and the catecholamines. Glucagon and β -catecholamines mediate their effects on glycogen phosphorylase through cAMP, but may involve other factors as well.

Glucagon exerts other biochemical effects. Gluconeogenesis in the liver is stimulated by glucagon, and this is accompanied by enhanced urea formation. Glucagon inhibits the

incorporation of amino acids into liver proteins. Fatty acid synthesis is decreased by glucagon. Cholesterol formation is also reduced. Glucagon activates liver lipases, however, and stimulates ketogenesis. Ultimately, the availability of fatty acids from liver triglycerides is elevated, fatty acid oxidation increases acetyl-CoA and other acyl-CoAs, and ketogenesis is promoted. As glucagon effects elevation of cAMP levels, release of glycerol and free fatty acids from adipose tissue also is increased.

Glucagon, whose regulatory effect on carbohydrate and fatty acid metabolism is well understood, is therapeutically important. It is recommended for the treatment of severe hypoglycemic reactions caused by the administration of insulin to diabetic or psychiatric patients. Of course, this treatment is effective only when hepatic glycogen is available. Nausea and vomiting are the most frequently encountered reactions to glucagon.

Usual dose: parenteral, adults, 500 μg to 1 mg (0.5–1.0 U), repeated in 20 minutes if necessary; pediatric, 25 $\mu\text{g}/\text{kg}$ of body weight, repeated in 20 minutes if necessary.

Gastrointestinal Hormones

There is a formidable array of polypeptide hormones of the gastrointestinal tract that includes secretin, pancreaticocholecystokinin, gastrin, motilin, neurotensin, vasoactive intestinal peptide, somatostatin, and others. The biosynthesis, chemistry, secretion, and actions of these hormones have been reviewed.⁶⁴

GASTRIN

Gastrin is a 17-residue polypeptide isolated from the antral mucosa. It was isolated originally in two different forms. In one of the forms, the tyrosine residue in position 12 is sulfated. Both forms are biologically active. Cholinergic response to the presence of food in the gastrointestinal tract provides the stimulus for gastrin secretion. The lowering of pH in the stomach inhibits the secretion of gastrin. The effects of structural modification of gastrin on gastric acid secretion have been reviewed.⁶⁵ These studies revealed that the four residues at the COOH terminus retain significant biological activity and that the aspartate residue is the most critical for activity. The most important action of gastrin is to stimulate the secretion of gastric acid and pepsin. Other actions of gastrin include increased secretion of pancreatic enzymes; contraction of smooth muscles; water and electrolyte secretion by the stomach and pancreas; water and electrolyte absorption by the small intestine; and secretion of insulin, glucagon, and somatostatin. A synthetic pentapeptide derivative, pentagastrin, is currently used as a gastric acid secretagogue.

Pentagastrin. Pentagastrin (Peptavlon), a physiological gastric acid secretagogue, is the synthetic pentapeptide derivative: N-*t*-butyloxycarbonyl- β -alanyl-L-tryptophyl-L-methionyl-L-aspartyl-L-phenylalanyl amide. It contains the COOH-terminal tetrapeptide amide (H · Try · Met · Asp · Phe · NH₂), which is considered to be the active center of the natural gastrins. Accordingly, pentagastrin appears to have the physiological and pharmacological properties of the gastrins, including stimulation of gastric secretion, pepsin secretion, gastric motility, pancreatic secretion of water and bicarbonate, pancreatic enzyme secretion, biliary flow and bicarbonate output, intrinsic factor secretion, and contraction of the gallbladder.

Pentagastrin is indicated as a diagnostic agent to evaluate gastric acid secretory function, and it is useful in testing for an acidity in patients with suspected pernicious anemia, atrophic gastritis or gastric carcinoma, hypersecretion in suspected duodenal ulcer or postoperative stomal ulcers, and Zollinger-Ellison tumor.

Pentagastrin is usually administered subcutaneously; the optimal dose is 6 $\mu\text{g}/\text{kg}$. Gastric acid secretion begins approximately 10 minutes after administration, and peak responses usually occur within 20 to 30 minutes. The usual duration of action is from 60 to 80 minutes. Pentagastrin has a relatively short plasma half-life, perhaps less than 10 minutes. The available data from metabolic studies indicate that pentagastrin is inactivated by the liver, kidney, and tissues of the upper intestine.

Contraindications include hypersensitivity or idiosyncrasy to pentagastrin. It should be used with caution in patients with pancreatic, hepatic, or biliary disease.

SECRETIN

Secretin is a 27-amino-acid polypeptide that is structurally similar to glucagon. The presence of acid in the small intestine is the most important physiological stimulus for the secretion of secretin. The primary action of secretin is on pancreatic acinar cells that regulate the secretion of water and bicarbonate. Secretin also promotes the secretion of pancreatic enzymes, to a lesser extent. Secretin inhibits the release of gastrin and, therefore, gastric acid. It also increases stomach-emptying time by reducing the contraction of the pyloric sphincter.⁶⁴

CHOLECYSTOKININ-PANCREOZYMIN

It was thought originally that cholecystokinin and pancreozymin were two different hormones. Cholecystokinin was thought to be responsible for contraction of the gallbladder, whereas pancreozymin was believed to induce secretion of pancreatic enzymes. It is now clear that both actions are caused by a single 33-residue polypeptide, referred to as *cholecystokinin-pancreozymin* (CCK-PZ). CCK-PZ is secreted in the blood in response to the presence of food in the duodenum, especially long-chain fatty acids. The five COOH-terminal amino acid residues are identical with those in gastrin. The COOH-terminal octapeptide retains full activity of the parent hormone.

The octapeptide is found in the gut as well as the central nervous system. SARs of cholecystokinin have been reviewed.⁶⁴ The COOH-terminal octapeptide is present in significant concentrations in the central nervous system. Its possible actions here, the therapeutic implications in the treatment of Parkinson disease and schizophrenia, and its SAR have been reviewed.⁶⁵

VASOACTIVE INTESTINAL PEPTIDE

Vasoactive intestinal peptide (VIP) is widely distributed in the body and is believed to occur throughout the gastrointestinal tract. It is a 28-residue polypeptide with structural similarities to secretin and glucagon. It causes vasodilation and increases cardiac contractibility. VIP stimulates bicarbonate secretion, relaxes gastrointestinal and other smooth muscles, stimulates glycogenesis, inhibits gastric acid secretion, and stimulates insulin secretion. Its hormonal and neurotransmitter role has been investigated.⁶⁶

GASTRIC INHIBITORY PEPTIDE

Gastric inhibitory peptide (GIP) is a 43-amino-acid polypeptide isolated from the duodenum. Secretion of GIP into the blood is stimulated by food. The primary action of GIP is inhibition of gastric acid secretion. Other actions include stimulation of insulin and glucagon secretion and stimulation of intestinal secretion.⁶⁴

MOTILIN

Motilin is a 22-residue polypeptide isolated from the duodenum. Its secretion is stimulated by the presence of acid in the duodenum. Motilin inhibits gastric motor activity and delays gastric emptying.

NEUROTENSIN

Neurotensin is a 13-amino-acid peptide, first isolated from bovine hypothalamus. It has now been identified in the intestinal tract. The ileal mucosa contains 90% of the total neurotensin of the body. It is implicated as a releasing factor for several adenohipophyseal hormones. It causes vasodilation, increases vascular permeability, and increases gastrin secretion. It decreases secretion of gastric acid and secretin.

Parathyroid Hormone

This hormone is a linear polypeptide containing 84 amino acid residues. SAR studies⁶⁷ of bovine parathyroid hormone revealed that the biological activity is retained by an NH₂-terminal fragment consisting of eight amino acid residues. It regulates the concentration of calcium ion in the plasma within the normal range, in spite of variations in calcium intake, excretion, and anabolism into bone. In addition, for this hormone, cAMP is implicated as a second messenger. Parathyroid hormone activates adenylate cyclase in renal and skeletal cells, and this effect promotes formation of cAMP from ATP. The cAMP increases the synthesis and release of the lysosomal enzymes necessary for the mobilization of calcium from bone.

Parathyroid Injection, USP. Parathyroid injection has been used therapeutically as an antihypocalcemic agent for the temporary control of tetany in acute hypoparathyroidism.

Teriparatide (Forteo). Teriparatide is a recombinant form of parathyroid hormone, which is used for the treatment of osteoporosis in men and postmenopausal women. The N-terminal region possesses 34 amino acids, which are identical to the biologically active region of the 84-amino acid sequence of human parathyroid hormone. It has been shown to act on osteoblasts to stimulate new bone growth and improve bone density.

CALCITONIN

Calcitonin (thyrocalcitonin) is a 32-amino-acid polypeptide hormone secreted by parafollicular cells of the thyroid glands in response to hypocalcemia. The entire 32-residue peptide appears to be required for activity, because smaller fragments are totally inactive. Common structural features of calcitonin isolated from different species are a COOH-terminal prolinamide, a disulfide bond between residues 1 and 7 at the NH₂ terminus, and a chain length of 32 residues. Calcitonin inhibits calcium resorption from bone, causing hypocalcemia, with parallel changes in plasma phosphate concentration. In general, calcitonin negates the osteolytic effects of parathyroid hormone.

The potential therapeutic uses of calcitonin are in the treatment of hyperparathyroidism, osteoporosis and other bone disorders, hypercalcemia of malignancy, and idiopathic hypercalcemia.

Angiotensins

The synthesis of angiotensins in the plasma is initiated by the catalytic action of renin (a peptidase elaborated by the kidneys) on angiotensinogen, an α -globulin produced by the liver and found in the plasma. The hydrolytic action of renin on angiotensinogen yields angiotensin I, a decapeptide consisting of the first 10 residues of the NH₂-terminal segment of angiotensinogen. Angiotensin I has weak pharmacological activity. It is converted to angiotensin II, an octapeptide, by the catalytic actions of angiotensin-converting enzyme (ACE). Angiotensin II is a highly active peptide and is hydrolyzed to angiotensin III, a heptapeptide, by an aminopeptidase. Angiotensin III retains most of the pharmacological activity of its precursor. Further degradation of angiotensin III leads to pharmacologically inactive peptide fragments.

Angiotensin II is the most active form; hence, it is the most investigated angiotensin for pharmacological action and SARs. The two primary actions of angiotensin II are vasoconstriction and stimulation of synthesis and secretion of aldosterone by the adrenal cortex. Both of these actions lead to hypertension.

Mechanisms and sites of action of angiotensin agonists and antagonists in terms of biological activity and receptor interactions have been reviewed.⁶⁸ Additionally, com-

pounds that inhibit ACE have found therapeutic use as anti-hypertensive agents (e.g., captopril). The synthesis and the biological activity of several ACE inhibitors have been reviewed.⁶⁹ Further, the agents used to target this enzyme are discussed in the cardiovascular section of this textbook.

Angiotensin Amide. Angiotensin amide (Hypertensin) is a synthetic polypeptide (1-L-aspariginyl-5-L-valine angiotensin octapeptide) and has twice the pressor activity of angiotensin II. It is pharmaceutically available as a lyophilized powder for injection (0.5–2.5 mg diluted in 500 mL of sodium chloride injection or 5% dextrose for injection) to be administered by continuous infusion. The pressor effect of angiotensin is due to an increase in peripheral resistance; it constricts resistance vessels but has little or no stimulating action on the heart and little effect on the capacitance vessels. Angiotensin has been used as an adjunct in various hypotensive states. It is mainly useful in controlling acute hypotension during administration of general anesthetics that sensitize the heart to the effects of catecholamines.

Plasmakinins

Bradykinin and kallidin are potent vasodilators and hypotensive agents that have different peptide structures: bradykinin is a nonapeptide, whereas kallidin is a decapeptide. Kallidin is lysyl-bradykinin; that is, it has an additional lysine at the NH₂ terminus of the chain. These two compounds are made available from kininogen, a blood globulin, on hydrolysis. Trypsin, plasmin, or the proteases of certain snake venoms can catalyze the hydrolysis of kininogen.

Bradykinin is one of the most powerful vasodilators known; 0.05 to 0.5 $\mu\text{g}/\text{kg}$ intravenously can decrease blood pressure in all mammals investigated so far.

Although the kinins per se are not used as medicinals, kallikrein enzyme preparations that release bradykinin from the inactive precursor have been used in the treatment of Raynaud disease, claudication, and circulatory diseases of the eyegrounds. (*Kallikreins* is the term used to designate the group of proteolytic enzymes that catalyze the hydrolysis of kininogen, forming bradykinin.)

SUBSTANCE P

Substance P is a polypeptide consisting of 11 amino acid residues. It has been implicated in the transmission of "painful" sensory information through the spinal cord to higher centers in the central nervous system.⁷⁰⁻⁷² Substance P is localized in the primary afferent sensory fibers. Other pharmacological effects are vasodilatation, stimulation of smooth muscles, stimulation of salivary secretion, and diuresis. In addition, this neuropeptide contributes to some inflammatory responses. Approximately 50% of the known neuropeptides are synthesized as biologically inactive glycine extended precursors that require a carboxy-terminal posttranslational amidation for biological activity. Amidation enzymes are responsible for the conversion of the carboxyl group of the neuropeptide to the corresponding amide group and include the two amidating enzymes peptidylglycine α -monooxygenase (PAM) and peptidylamidoglycolate lyase (PGL), which work sequentially to produce the inflammatory neuropeptide Substance P from an inactive precursor peptide. Much research is being performed to exploit this mechanism of inflammation.

Thyroglobulin

Thyroglobulin, a glycoprotein, is composed of several peptide chains; it also contains 0.5% to 1% iodine and 8% to 10% carbohydrate in the form of two types of polysaccharide. The formation of thyroglobulin is regulated by TSH. Thyroglobulin has no hormonal properties. It must be hydrolyzed to release the hormonal iodothyronines thyroxine and liothyronine (see "Thyroid Hormones" in Chapter 19).

BLOOD PROTEINS

The blood is the transport system of the organism and thus performs important distributive functions. Considering the multitude of materials transported by the blood (e.g., nutrients, oxygen, carbon dioxide, waste products of metabolism, buffer systems, antibodies, enzymes, and hormones), its chemistry is very complex. Grossly, approximately 45% consists of the formed elements that can be separated by centrifugation, and of these, only 0.2% is other than erythrocytes. The 55% of removed plasma contains approximately 8% solids, of which a small portion (less than 1%) can be removed by clotting to produce defibrinated plasma, called *serum*. Serum contains inorganic and organic compounds, but the total solids are chiefly protein, mostly albumin, and the rest nearly all globulin. The plasma contains the protein fibrinogen, which is converted by coagulation to insoluble fibrin. The separated serum has an excess of the clotting agent thrombin.

Serum globulins can be separated by electrophoresis into α -, β -, and γ -globulins, which contain most of the antibodies. The immunological importance of globulins is well-known. Many classes and groups of immunoglobulins are produced in response to antigens or even to a single antigen. The specificity of antibodies has been studied from various points of view, and Richards et al.⁷³ have suggested that even though immune sera appear to be highly specific for antigen binding, individual immunoglobulins may not only interact with several structurally diverse determinants, but may bind such diverse determinants to different sites within the combining region.

The importance of the blood coagulation process has been obvious for a long time. Coagulation mechanisms are covered in several biochemistry texts (see under "Selected Reading"), so a brief summary suffices here. The required time for blood clotting is normally 5 minutes, and any prolongation beyond 10 minutes is considered abnormal. Thrombin, the enzyme responsible for the catalysis of fibrin formation, originates from the inactive zymogen prothrombin; the prothrombin-thrombin transformation depends on calcium ions and thromboplastin. The fibrinogen-fibrin reaction catalyzed by thrombin involves proteolytic cleavage (partial hydrolysis), polymerization of the fibrin monomers from the preceding step, and actual clotting (hard clot formation). The final process forming the hard clot occurs in the presence of calcium ions and the enzyme fibrinase.

Thrombin, USP. Thrombin is a sterile protein substance prepared from prothrombin of bovine origin. It is used as a topical hemostatic because it can clot blood, plasma, or a solution of fibrinogen without addition of other substances. Thrombin also may initiate clotting when combined with gelatin sponge or fibrin foam.

For external use it is applied topically to the wound, as a solution containing 100 to 2,000 National Institutes of Health (NIH) units/mL in sodium chloride irrigation or sterile water for injection or as a dry powder.

Hemoglobin

Erythrocytes contain 32% to 55% hemoglobin, about 60% water, and the rest as stroma. Stroma can be obtained, after hemolysis of the corpuscles by dilution, through the process of centrifuging and consists of lecithin, cholesterol, inorganic salts, and a protein, stromatin. Hemolysis of the corpuscles,

or “laking” as it is sometimes called, may be brought about by hypotonic solution, by fat solvents, by bile salts that dissolve the lecithin, by soaps or alkalis, by saponins, by immune hemolysins, and by hemolytic sera, such as those from snake venom and numerous bacterial products.

Hemoglobin (Hb) is a conjugated protein; the prosthetic group heme (hematin) and the protein (globin), which is composed of four polypeptide chains, are usually in identical pairs. The total M_r is about 66,000, including four heme molecules. The molecule has an axis of symmetry and, therefore, is composed of identical halves with an overall ellipsoid shape of the dimensions $55 \times 55 \times 70 \text{ \AA}$.

Iron in the heme of hemoglobin (ferrohemoglobin), is in the ferrous state and can combine reversibly with oxygen to function as a transporter of oxygen.

In this process, the formation of a stable oxygen complex, the iron remains in the ferrous form because the heme moiety lies within a cover of hydrophobic groups of the globin. Both Hb and O_2 are magnetic, whereas HbO_2 is diamagnetic because the unpaired electrons in both molecules have become paired. When oxidized to the ferric state (methemoglobin or ferrihemoglobin), this function is lost. Carbon monoxide combines with hemoglobin to form carboxyhemoglobin (carbonmonoxyhemoglobin) to inactivate it.

The stereochemistry of the oxygenation of hemoglobin is very complex, and it has been investigated to some extent. Some evidence from x-ray crystallographic studies reveals that the conformations of the α and β chains are altered when their heme moieties complex with oxygen, thus promoting complexation with oxygen. It is assumed that hemoglobin can exist in two forms, the relative position of the subunits in each form being different. In the deoxy form, α and β subunits are bound to each other by ionic bonds in a compact structure that is less reactive toward oxygen than is the oxy form. Some ionic bonds are cleaved in the oxy form, relaxing the conformation. The latter conformation is more reactive to oxygen.

IMPACT OF BIOTECHNOLOGY ON THE DEVELOPMENT AND COMMERCIAL PRODUCTION OF PROTEINS AND PEPTIDES AS PHARMACEUTICAL PRODUCTS

Over the past decade and a half, far-reaching and revolutionary breakthroughs in molecular biology, especially research involving gene manipulations (i.e., genetic engineering), have led the way in the development of new biotechnology-derived products for the treatment of diseases. The term *biotherapy* has been coined to describe the clinical and diagnostic use of biotechnology-derived products. Generally, these products are proteins, peptides, or nucleic acids that are structurally and/or functionally similar to naturally occurring biomolecules. The large-scale production of these complex biomolecules was beyond the capabilities of traditional pharmaceutical technologies. According to the 1995 survey⁷⁴ conducted by the Pharmaceutical Research and Manufacturers of America, there are currently more than 230 biotechnology-derived products in various stages of development and 24 approved biotechnology-derived products available in the market. The currently approved biotechnology products are listed

in Table 27.9. There are 14 approval applications pending at the FDA and 49 in the third and final stage of clinical testing. A detailed discussion of the various processes and methodologies involved in biotechnology and the wide array of biotechnology-derived pharmaceutical products is beyond the scope of this chapter and is covered in Chapter 4. There are several reference sources^{72,75–77} available.

Since the emphasis in this chapter is on proteins, peptides, and enzymes, the discussion of biotechnology processes and products is limited to these topics. The various biotechnology-derived products⁷⁴ include enzymes, receptors, hormones and growth factors, cytokines, vaccines, monoclonal antibodies, and nucleic acids (genes and anti-sense RNA).

Biotechnology techniques are constantly changing and expanding; however, the two primary techniques responsible for the development of most of the products are rDNA technology and monoclonal antibody technology. The emphasis in this chapter is on rDNA technology and products derived from this technology. The monoclonal antibody technology and resulting products are discussed elsewhere in this book. Excellent references^{78,79} are available for review. The following discussion of rDNA technology assumes that the reader has thorough comprehension of the normal process of genetic expression in human cells (i.e., replication, transcription, and translation). Several biochemistry textbooks are available for review.

rDNA Technology

rDNA technology frequently has been referred to as *genetic engineering* or *gene cloning*. A comprehensive discussion of the process and application of rDNA technology is available in several good reviews.^{72,75–77} The concept of genetic engineering is based on the fact that the genetic material (DNA) in all living organisms is made of the same four building blocks, that is, four different deoxymononucleotides. Therefore, genetic material from one organism or cell may be combined with the genetic material of another organism or cell. Because every single protein, regardless of its source, is produced as a result of expression of a specific gene coding for it, the application of this technology in the mass production of desired human proteins is obvious. A number of human diseases are caused by deficiencies of desired proteins or peptides. For example, insulin deficiency is a major cause of diabetes, and human growth hormone deficiency causes dwarfism. If a human gene coding for a deficient protein is identified and isolated, then it may be combined with fast-replicating, nonchromosomal bacterial DNA (i.e., plasmids). The recombinant DNA is placed back into the bacteria, which then are grown in ideal media. The plasmids replicate and the genes within the plasmid are expressed, including the human gene, resulting in large quantities of the desired human protein.

The major steps in a typical rDNA process used in commercial-scale synthesis of human proteins are summarized in Figure 27.7 and discussed in the following:

1. Identification and isolation of the desired gene: The possible nucleotide sequence of a desired gene can be ascertained by (a) isolating and determining the amino acid sequence of the protein expressed by the gene and then determining the possible nucleotide sequences for the corresponding mRNA and the DNA (gene), (b) isolating

TABLE 27.9 Approved Biotechnology of Drugs and Vaccines

Product Name	Company	Indication (Date of U.S. Approval)
Actimmune Interferon gamma-1b	Genentech ^a (San Francisco, CA)	Management of chronic granulomatous disease (December 1990)
Activase Alteplase, recombinant	Genentech ^a (San Francisco, CA)	Acute myocardial infarction (November 1987); acute massive pulmonary embolism (June 1990)
Aldurazyme Laronidase	Genzyme	Mucopolysaccharidosis I (May 2003)
Alferon N Interferon alfa-n3 (injection)	Interferon Sciences (New Brunswick, NJ)	Genital warts (October 1989)
Betaseron Interferon beta-1b, recombinant	Berlex Laboratories ^a (Wayne, NJ) Chiron ^a (Emeryville, CA)	Relapsing, remitting multiple sclerosis (July 1993)
Cerezyme Imiglucerase for injection (recombinant glucocerebrosidase)	Genzyme (Cambridge, MA)	Treatment of Gaucher disease (May 1994)
Engerix-B Hepatitis B vaccine (recombinant)	SmithKline Beecham ^a (Philadelphia, PA)	Hepatitis B (September 1989)
Epogen Epoetin alfa (rEPO)	Amgen ^a (Thousand Oaks, CA)	Treatment of anemia associated with chronic renal failure, including patients on dialysis and not on dialysis, and anemia in Retrovir-treated, HIV-infected patients (June 1989); treatment of anemia caused by chemotherapy in patients with nonmyeloid malignancies (April 1993)
Fabrazyme Agalsidase beta	Genzyme	Fabry disease (April 2003)
Procrit ^c Epoetin alfa (rEPO)	Ortho Biotech ^a (Raritan, NJ)	Treatment of anemia associated with chronic renal failure, including patients on dialysis and not on dialysis, and anemia in Retrovir-treated, HIV-infected patients (December 1990); treatment of anemia caused by chemotherapy in patients with nonmyeloid malignancies (April 1993)
Humatrope Somatotropin (rDNA origin) for injection	Eli Lilly ^a (Indianapolis, IN)	Human growth hormone deficiency in children (March 1987)
Humulin Human insulin (rDNA origin)	Eli Lilly ^a (Indianapolis, IN)	Diabetes (October 1982)
Intron A Interferon alfa-2b (recombinant)	Schering-Plough ^a (Madison, NJ)	Hairy cell leukemia (June 1986); genital warts (June 1988); AIDS-related Kaposi sarcoma (November 1988); hepatitis C (February 1991); hepatitis B (July 1992)
KoGENate Antihemophilic factor (recombinant)	Miles ^a (West Haven, CT)	Treatment of hemophilia A (February 1993)
Leukine Sargramostim (yeast-derived GM-CSF)	Immunex ^a (Seattle, WA)	Autologous bone marrow transplantation (March 1991)
Myozyme Alglucosidase alfa	Genzyme	Treatment of Pompe disease (April 2006)
Naglazyme Galsulfase	BioMarin	Mucopolysaccharidosis VI (May 2005)
Neupogen Filgrastim (rG-CSF)	Amgen ^a (Thousand Oaks, CA)	Chemotherapy-induced neutropenia (February 1991); autologous or allogeneic bone marrow transplantation (June 1994); chronic severe neutropenia (December 1994)
Nutropin Somatotropin for injection	Genentech ^a (San Francisco, CA)	Growth failure in children due to chronic renal insufficiency, growth hormone inadequacy in children (March 1994)
OncoScint CR/OV Satumomab pendetide	CYTOGEN ^a (Princeton, NJ)	Detection, staging, and follow-up of colorectal and ovarian cancers (December 1992)
Orencia Abatacept	Bristol-Myers	Treatment of rheumatoid arthritis (December 2005)
ORTHOCLONE OKT 3 Muromonab-CD3	Ortho Biotech ^a (Raritan, NJ)	Reversal of acute kidney transplant rejection (June 1986); reversal of heart and liver transplant rejection (June 1993)

Product Name	Company	Indication (Date of U.S. Approval)
Proleukin Aldesleukin (interleukin-2)	Chiron ^a (Emeryville, CA)	Renal cell carcinoma (May 1992)
Protropin Somatrem for injection	Genentech ^a (San Francisco, CA)	Human growth hormone deficiency in children (October 1985)
Pulmozyme DNAse (dornase alpha)	Genentech ^a (San Francisco, CA)	Cystic fibrosis (December 1993)
Rebif Interferon beta-1a	Serono Labs	Treatment of multiple sclerosis (March 2002)
RECOMBINATE Antihemophilic factor recombinant (rAHF)	Baxter Healthcare/Hyland Division (Glendale, CA) Genetics Institute ^b (Cambridge, MA)	Hemophilia A (December 1992)
RECOMBIVAX HB Hepatitis B vaccine (recombinant), MSD	Merck ^a (Whitehouse Station, NJ)	Hepatitis B prevention (July 1986)
ReoPro Abciximab	Centocor (Malvern, PA) Eli Lilly ^a (Indianapolis, IN)	Antiplatelet prevention of blood clots (December 1994)
Roferon-A Interferon alfa-2a, recombinant	Hoffmann-La Roche ^a (Nutley, NJ)	Hairy cell leukemia (June 1986); AIDS-related Kaposi sarcoma (November 1988)

^aPhRMA member company.

^bPhRMA research affiliate.

^cProcrit was approved for marketing under Amgen's epoetin alfa PLA. Amgen manufactures the product for Ortho Biotech. Under an agreement between the two companies, Amgen licensed to Ortho Pharmaceuticals the U.S. rights to epoetin for indications in human use excluding dialysis and diagnostics.

the mRNA and determining its nucleotide sequence, and (c) using DNA probes to “fish out” the desired gene from the genomic library (cellular DNA chopped up into segments 10,000–20,000 nucleotides long).

2. Constructing rDNA: Once the desired human gene is identified and isolated, it is recombined with genes of microbial cells that are known to have rapid rates of cell division. To accomplish this task, bacterial enzymes known as *restriction endonucleases* are used. More than 100 different variations of these hydrolytic enzymes, which act like scissors in hydrolyzing the phosphodiester bonds of DNA at specific sites (i.e., nucleotide sequences), are available. The use of a specific restriction endonuclease both to obtain the human gene and to open a site on the microbial gene allows easy formation of the hybrid (recombined) DNA molecule because of the “sticky” ends on both genes. The ends of the human gene and the microbial DNA vector are “glued” together by enzymes known as *DNA ligases*. The human genes are placed in specific locations on the microbial DNA vectors to ensure expression of the human gene when the microbial cells divide. Plasmids are the most commonly used microbial DNA. These extrachromosomal circular DNAs replicate independently of the chromosomes and are much smaller than chromosomal DNA. Plasmids are easy to manipulate and are considered excellent vectors to carry human genes. Other microbial cells used as hosts are yeast cells. Mammalian cells, such as Chinese hamster ovary cells, are used when glycosylation of the rDNA-derived protein is essential for biological activity (e.g., erythropoietin). Nonmammalian cells cannot glycosylate proteins.

3. Cloning: The cells carrying the recombined human gene are then allowed to grow in appropriate media. As the cells divide, the rDNA replicates and expresses its products, including the desired human protein as well as the normal bacterial proteins.

4. Isolation and purification of rDNA-derived protein: From this complex mixture containing bacterial proteins, cell components, chemicals used in preparing the media, etc., isolating and purifying the desired human protein is a daunting task indeed. This requires sophisticated isolation techniques, such as complex filtrations, precipitations, and HPLC. The primary goal of the purification process is to ensure that the protein isolated will retain the biological activity of the native protein in the body. The rDNA-derived protein is then formulated into a pharmaceutical product that is stable during transportation, storage, and administration to a patient.

BIOTECHNOLOGY-DERIVED PHARMACEUTICAL PRODUCTS

More than 2 dozen FDA-approved biotechnology-derived pharmaceutical products are listed in Table 27.9. There are more than 200 other products in various stages of development.⁷⁴ The FDA-approved products fall loosely into five major categories: enzymes, hormones, lymphokines, hematopoietic factors, and biologicals. A detailed discussion of all of these products is beyond the scope of this chapter. Because most of these products are proteins or peptides, a cursory evaluation of them and their uses⁸⁰ follows.

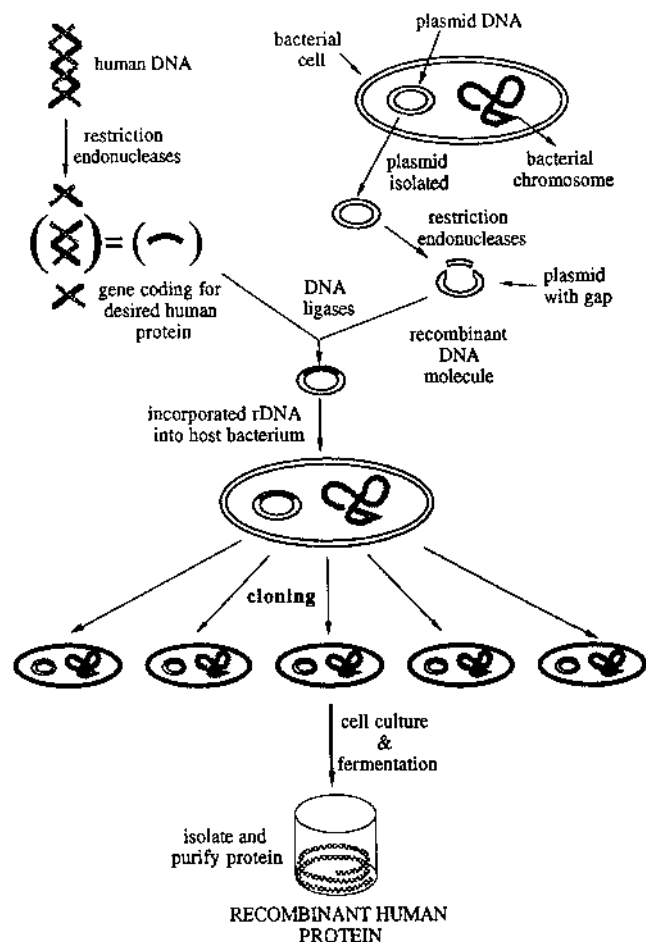

Figure 27.7 • Summary of a typical rDNA process used in the commercial-scale production of human proteins.

rDNA-DERIVED ENZYMES

Alteplase, Recombinant. Alteplase (Activase) was discussed previously.

Dornase Alpha. Dornase alpha, rhDNAse (Pulmozyme), is a mucolytic enzyme identical with the natural human DNAse and is used in the treatment of cystic fibrosis. Patients with cystic fibrosis suffer from decreased pulmonary function and infections caused by the secretion of thick mucus. Proteins contained in the mucus are bound to extracellular DNA, produced as a result of disintegration of bacteria in the lungs. This enzyme is involved in cleaving extracellular DNA and separates DNA from proteins, allowing proteolytic enzymes to break down proteins and thus decrease the viscosity of mucus in the lungs.⁸¹ Proteins bound to extracellular DNA are not susceptible to proteolytic enzymes.⁸² Dornase alpha is a glycoprotein containing 260 amino acids that is commercially produced in genetically engineered Chinese hamster ovary cells.

Dornase alpha is indicated for the treatment of cystic fibrosis in conjunction with other available therapies, such as antibiotics, bronchodilators, and corticosteroids. Adult dosage is 2.5 mg inhaled once daily, administered via a recommended nebulizer. Dornase alpha should not be mixed or diluted with other agents in the nebulizer because of the possibility of adverse physicochemical changes that may affect

activity. Common adverse effects include sore throat, hoarseness, and facial edema.

Imiglucerase. Imiglucerase (Cerezyme)⁸⁰ is a glycoprotein containing 497 amino acid residues and is *N*-glycosylated at four different positions. It is an analog of the natural human enzyme β -glucocerebrosidase and contains arginine at position 495 instead of the histidine in the natural enzyme. It is commercially produced in genetically engineered Chinese hamster ovary cells.

Like the natural enzyme, imiglucerase catalyzes the hydrolysis of glucocerebroside, a glycolipid, to glucose and ceramide within the lysosomes of phagocytic cells. Gaucher disease is caused by a deficiency of this enzyme, which results in the accumulation of glucocerebroside within tissue macrophages. The glycolipid-engorged macrophages are known as *Gaucher cells* and are responsible for the numerous clinical manifestations of Gaucher disease. The common clinical manifestations of Gaucher disease are severe anemia, thrombocytopenia, and skeletal complications that include osteonecrosis and osteopenia.

Imiglucerase is indicated for the long-term replacement therapy of Gaucher disease. It is administered intravenously at an initial dose of 2.5 to 60 U/kg, infused over 1 to 2 hours. This dose is usually repeated every 2 weeks. Both the dose and the frequency of administration may be varied, however, depending on the response.⁸³ Common adverse effects include dizziness, headache, abdominal discomfort, nausea, and rash.

rDNA-DERIVED HORMONES

The rDNA-derived hormones include insulin human injection *USP* (Humulin R, Novolin R, Velosulin Human), growth hormone (somatotropin; Humatrope), and somatrem (Protropin). All of these products, as well as other products containing human insulin, have been discussed in this chapter.

rDNA-DERIVED CYTOKINES

Interferons.⁸⁰ Interferons are natural glycoproteins produced by virtually all eukaryotic cells; they possess immunomodulating, antiviral, and cytotoxic activities. This family of glycoproteins is produced by cells in response to a wide range of stimuli.⁸⁴ In humans, interferons bind to cellular receptors, which leads to the synthesis of more than a dozen proteins that contribute to viral resistance. The antiviral effects of interferons may be caused by inhibition of the synthesis of viral mRNA or proteins or prevention of viral penetration or uncoating.^{85,86} Based on their antigenic subtypes, the interferons are classified into three major groups: α , β , and γ . α -Interferon and β -interferon are produced by virtually all cells in response to a viral infection and various other stimuli. γ -Interferon is produced specifically by the T lymphocytes and the natural killer (NK) cells. γ -Interferons have greater immunoregulatory, but lower antiviral, effects than α - or β -interferons.⁸⁶ More than 12 subspecies of α -interferons, 1 β -interferon, and 2 γ -interferons are known to exist. In general, the interferons are glycoproteins consisting of 165 to 166 amino acid residues. There are four rDNA-derived α -interferons available for clinical use around the world and three available in the United States (described next). All α -interferons exhibit antiviral and antiproliferative activity, enhance phagocytic activity, and augment specific

cytotoxicity of lymphocytes for certain target cells.⁸⁷ The most common adverse effects of α - and β -interferons include flulike symptoms, bone marrow suppression, neurotoxic effects, hypocalcemia, anorexia and other gastrointestinal symptoms, and weight loss.

Interferon Alfa-2a, Recombinant. Interferon alfa-2a, recombinant (Roferon), is produced from genetically engineered *E. coli* and contains 165 amino acid residues. At position 23, interferon alfa-2a has a lysine residue. The pharmaceutical product contains a single α -interferon subtype. A murine monoclonal antibody is used during purification by affinity chromatography. Interferon alfa-2a is used in the treatment of hairy cell leukemia and acquired immunodeficiency syndrome (AIDS)-related Kaposi sarcoma. It is absorbed well after intramuscular or intravenous administration and has a half-life of 5 to 7 hours when administered by the intramuscular route. The solution should be stored in the refrigerator at 36°F to 46°F and should not be frozen or shaken.

Peginterferon Alfa-2a, Recombinant. Interferon alfa-2a, recombinant (Roferon), is produced from genetically engineered *E. coli*. It is interferon, alfa-2a utilizing a 40 kd polyethylene glycol (PEG) strand to allow for stable therapeutic serum levels of alfa-2a for up to 168 hours on a single dose. This process is known as PEGylation and involves the process of attaching strands of the polymer PEG to molecules in an attempt to make them safer and more effective as therapeutic agents. The physiochemical changes in the drug increase systemic retention as well as influence the binding affinity to the cell receptors. The therapeutic usefulness of peginterferon alfa-2a is in the treatment of hepatitis C.

Interferon Alfa-2b, Recombinant. Interferon alfa-2b, recombinant (Intron A), also contains a single subtype of α -interferon. It is a glycoprotein containing 165 amino acid residues and is commercially produced from genetically engineered *E. coli*. It differs from interferon alfa-2b in possessing an arginine residue at position 23. It is used in the treatment of hairy cell leukemia, condyloma acuminata (genital warts), AIDS-related Kaposi sarcoma, hepatitis C, and hepatitis B. It is administered intramuscularly or subcutaneously with a half-life of 2 to 3 hours and via intravenous infusion with a half-life of 8 hours. The reconstituted solution is stable for 1 month when stored at a temperature of 36°F to 46°F.

Interferon Alfa-n3 (Injection). Interferon alfa-n3 (Alferon N) is a polyclonal mixture of up to 14 natural α -interferon subtypes and contains 166 amino acid residues. Its commercial production involves induction of pooled units of human leukocytes with an avian virus (Sendai virus). The purification process involves immunoaffinity and filtration chromatography. It is indicated primarily by intralesional injection for the treatment of genital warts. The solution should be stored at a temperature of 36°F to 46°F and should not be shaken.

Interferon Beta-1a. Interferon beta-1a (Rebif, Avonex), has biological effects similar to those of natural β -interferon and α -interferons. Unlike beta-1b, which is produced in modified *E. coli*, beta-1a is produced in mammalian cells. It has been shown to slow the progression of multiple sclerosis as well as reduce the rate of relapse of this disease.

Interferon Beta-1b, Recombinant. Interferon beta-1b, recombinant (Betaseron), has biological effects similar to

those of natural β -interferon and α -interferons. The natural β -interferon is a glycoprotein containing 166 amino acid residues. The rDNA product differs from the natural form, in that it is not glycosylated, it lacks the amino-terminal methionine, and it has serine in the place of methionine at position 17.⁸⁸ It is used for a wide variety of indications via intravenous, intramuscular, subcutaneous, intrathecal, and intraleSIONAL routes. Its primary indication is for the prevention of exacerbations in patients suffering from relapsing/remitting multiple sclerosis. Recommended dosage is 8 million units, administered subcutaneously, every other day. It also is indicated in the treatment of malignant glioma and malignant melanoma. Recommended temperature for storage is 36°F to 46°F, and unused reconstituted solution should be discarded.

Aldesleukin. Aldesleukin, interleukin-2 (Proleukin),⁸⁹ is an rDNA-derived lymphokine that differs structurally from native interleukin-2 (IL-2) but has biological activity similar to that of the natural lymphokine.⁸⁹ Natural IL-2 is produced primarily by the peripheral blood lymphocytes and contains 133 amino acid residues. The immunoregulatory effects of aldesleukin include enhancing mitogenesis of lymphocytes, stimulating the growth of IL-2-dependent cell lines, enhancing cytotoxicity of lymphocytes, inducing lymphokine-activated killer (LAK) cells and NK cells, and inducing interferon- γ production. The exact mechanism of the antitumor activity of aldesleukin in humans is unknown.

The rDNA process involves genetically engineered *E. coli* (pBR 322 plasmids). The gene for IL-2 was synthesized after first isolating and identifying the mRNA from the human Jurkat cell line and then preparing the complementary DNA (cDNA). The IL-2 gene was genetically engineered before it was hybridized into pBR 322 plasmid. Further manipulation of the hybridized plasmid resulted in the production of a modified IL-2, aldesleukin.⁹⁰ Aldesleukin differs structurally from the native IL-2 in that the former is not glycosylated, it lacks the N-terminal alanine residue, and it has serine in the place of cysteine at position 125. Noncovalent, molecular aggregation of aldesleukin is different from IL-2, and the former exists as a microaggregate of 27 molecules.

The primary indication for aldesleukin is in the treatment of adult metastatic renal carcinoma. It is administered via intravenous infusion in doses of 10,000 to 50,000 U/kg every 8 hours for 12 days. It is primarily metabolized by the kidneys, with no active form found in the urine. Aldesleukin causes serious adverse effects in patients, including fever, hypotension, pulmonary congestion and dyspnea, coma, gastrointestinal bleeding, respiratory failure, renal failure, arrhythmias, seizures, and death.

rDNA-DERIVED HEMATOPOIETIC FACTORS

Hematopoietic growth factors are glycoproteins produced by a number of peripheral and marrow cells. More than 200 billion blood cells are produced each day; and the hematopoietic factors, along with other lymphopoietic factors such as the stem cell factor and the interleukins, are involved in the proliferation, differentiation, and maturation of various types of blood cells derived from the pluripotent stem cells.

Erythropoietin.⁸⁰ Erythropoietin is a heavily glycosylated protein containing 166 amino acid residues. It is pro-

duced primarily by the peritubular cells in the cortex of the kidney, and up to 15% is produced in the liver. It is the principal hormone responsible for stimulating the production of red blood cells from erythroid progenitor cells, erythrocyte burst-forming units, and erythrocyte colony-forming units.⁹¹ Small amounts of erythropoietin are detectable in the plasma; however, most of the hormone is secreted by the kidneys in response to hypoxia or anemia, when levels of the hormone can rise more than 100-fold.

Decreased erythropoietin production is one of several potential causes of anemia of chronic renal disease. Other causes of anemia of chronic renal disease include infection or inflammatory condition in the kidneys, iron deficiency, marrow damage, and vitamin or mineral deficiency. Regardless of the underlying disease causing renal failure, erythropoietin levels decrease in patients with renal failure. Until rDNA technology was used to produce commercial quantities of erythropoietin, it was obtained from the urine of patients suffering from severe aplastic anemia. This process of obtaining natural hormone was costly and time-consuming and produced only small quantities of the hormone.

Epoetin Alfa. Epoetin alfa, rEPO (Epogen, Procrit), is the recombinant human erythropoietin produced in Chinese hamster ovary cells into which the human erythropoietin gene has been inserted. These mammalian cells glycosylate the protein in a manner similar to that observed in human cells.⁹²

Epoetin alfa is indicated in anemic patients with chronic renal failure, including both those who require regular dialysis and those who do not. Epoetin alfa is also indicated in anemia associated with AIDS, treatment of AIDS with zidovudine, frequent blood donations, and neoplastic diseases. It is indicated to prevent anemia in patients who donate blood prior to surgery for future autologous transfusions and to reduce the need for repeated maintenance transfusions.⁹³ The hormone is available as an isotonic buffered solution, which is administered by the intravenous route. The solution should not be frozen or shaken and is stored at 36°F to 46°F.

Colony-Stimulating Factors.⁸⁰ Colony-stimulating factors are natural glycoproteins produced in lymphocytes and monocytes. These factors bind to cell-surface receptors of hematopoietic progenitor cells and stimulate proliferation, differentiation, and maturation of these cells into recognizable mature blood cells.⁹³ Colony-stimulating factors produced by rDNA technology have the same biological activity as the natural hormones. Currently, there are two colony-stimulating factors commercially produced by rDNA technology. These products are discussed next.

Filgrastim. Filgrastim, rG-CSF (Neupogen), is a 175-amino acid polypeptide produced in genetically engineered *E. coli* cells containing the human granulocyte colony-stimulating factor (G-CSF) gene. Filgrastim differs from the natural hormone in that the former is not glycosylated and contains an additional methionine group at the N-terminus, which is deemed necessary for expression of the gene in *E. coli*.

Filgrastim specifically stimulates the proliferation and maturation of neutrophil granulocytes and, hence, is considered lineage specific. Accepted indications for filgrastim include the following: (a) to decrease the incidence of febrile neutropenia in patients with nonmyeloid malignancies who receive myelosuppressive chemotherapeutic agents, thus

lowering the incidence of infections in these patients; (b) to accelerate myeloid recovery in patients undergoing autologous bone marrow transplantation; and (c) in AIDS patients, to decrease the incidence of neutropenia caused by the disease itself, or by drugs used to treat the disease. The usual starting dose for filgrastim is 5 $\mu\text{g}/\text{kg}$ per day in patients with nonmyeloid cancer who receive myelosuppressive chemotherapy.

Filgrastim solution should be stored at 36°F to 46°F and used within 24 hours of preparation. The solution should not be shaken or allowed to freeze. Any solution left at room temperature for more than 6 hours should be discarded. The most frequent adverse effects of filgrastim are medullary bone pain, arthralgia, and myalgia.

Sargramostim. Sargramostim, rGM-CSF (Leukine), is a glycoprotein commercially produced in genetically engineered yeast cells. Its polypeptide chain contains 127 amino acids. It differs from the natural hormone by substitution of leucine at position 23 and variations in the glycosylation.⁹⁴ Sargramostim is a lineage-nonspecific hematopoietic factor, because it promotes the proliferation and maturation of granulocytes (neutrophils and eosinophils) and monocytes (macrophages and megakaryocytes).

The primary indication for sargramostim is in myeloid engraftment following autologous bone marrow transplantation and hematopoietic stem cell transplantation. Handling, storage precautions, and adverse effects are similar to those for filgrastim.

RDNA-DERIVED MISCELLANEOUS PRODUCTS

Antihemophilic Factor. Antihemophilic factor (factor VIII) (Humate-P, Hemophil M, Koate HP, Monoclate-P) is a glycoprotein found in human plasma and a necessary cofactor in the blood-clotting mechanism. This high-molecular-weight glycoprotein has a complex structure with several components (subcofactors).⁹⁵ The commercially available concentrates derived from blood collected from volunteer donors by the American Red Cross Blood Services are used primarily for the treatment of patients with hemophilia A. Because the commercially available products are purified concentrates derived from blood pooled from millions of donors, the major precautions in using the products relate to transmission of viruses, such as hepatitis virus, herpesvirus, and HIV. This major problem has been alleviated, mostly because of the development and marketing of rDNA-derived antihemophilic factors.

Antihemophilic Factor (Recombinant). Antihemophilic factor (recombinant), rAHF (KoGENate, Helixate), is an rDNA-derived factor VIII expressed in genetically engineered baby hamster kidney cells.⁹⁶ KoGENate has the same biological activity as the human plasma-derived antihemophilic factor (pdAHF). The purification process for rAHF includes monoclonal antibody immunoaffinity chromatography to remove any protein contaminants.

rAHF is indicated for the treatment of hemophilia A and is administered by the intravenous route. Patients suffering from hemophilia A exhibit a decrease in the activity of plasma clotting factor VIII. This product temporarily prevents bleeding episodes in hemophiliacs and may be used to prevent excessive bleeding during surgical procedures in these patients. A major advantage of the rAHF over the

natural factor VIII is the lack of virus in the product. rAHF does not contain von Willebrand factor; therefore, it is not indicated in the treatment of von Willebrand disease. Patients receiving rAHF should be monitored carefully for the development of antibodies.

Bioclote is an rDNA-derived factor VIII expressed in genetically engineered Chinese hamster ovary cells. It has the same biological activity as pdAHF and is structurally similar. Its indications and adverse effects are similar to those for KoGENate.

REVIEW QUESTIONS

- The rennin–angiotensin system plays an important role in regulation of blood pressure. As such, this pathway encompasses the conversion of an approximately 400-amino acid sequence to a decapeptide, then to the biologically active octapeptide and is an excellent target for drug therapy to manage hypertension. Describe the starting protein and its conversion to the biologically active metabolite. Be sure to include the enzymes involved in the conversion of the protein and peptides.
- In the digestion and absorption of dietary protein:
 - pepsinogen is converted to pepsin by gastrin via a proteolysis reaction.
 - chymotrypsinogen is activated by trypsin.
 - carboxypeptidase activates pepsinogen in the stomach.
 - hydrochloric acid activates aminopeptidase.
- Clinically, which of the following is used to dissolve necrotic tissue of second- and third-degree burn patients?
 - streptokinase
 - sutilains
 - trypsin
 - dornase
 - lypressin
- While working in your basement you discover a method of producing proteins and peptides that has never been described in the literature. What is the significance of being able to produce cytokines such as interferons?
- You have discovered a protein that is capable of blocking the progression of Alzheimer disease. The sources of this protein are very limited, and you need additional material to complete a phase II clinical trial. Describe how you would use rDNA technology to produce more of this wonder drug.

CHAPTER 28

Vitamins

MICHAEL J. DEIMLING, M. O. FARUK KHAN, AND GUSTAVO R. ORTEGA

CHAPTER OVERVIEW

The medicinal chemistry of vitamins is fundamental not only to the therapeutics of nutritional problems but also to the understanding of the biochemical actions of other medicinal agents that directly or indirectly affect the metabolic functions of vitamins and coenzymes. Notable in this regard is the interrelationship between folic acid and vitamin B₁₂ in the development of megaloblastic anemia, as well as the efficacy of warfarin in relation to vitamin K status. In addition, vitamins may rarely be used in treatments unrelated to their role as a vitamin. The use of retinoic acid in acne, niacin in hyperlipidemias, and hydroxocobalamin in the treatment of cyanide poisoning are a few that are discussed within this chapter. Accordingly, this chapter includes a brief summary of the history, chemistry, kinetics, biochemistry, therapeutic use, adverse effects (hypervitaminosis), and available vitamin products that can assist the clinician in a better understanding of the role vitamins play in both health and disease.

The use of vitamins, especially as multivitamins, has increased significantly as a result of a move toward the practice of healthier lifestyles. There are two approaches to the use of vitamins that are not always clearly distinct. The first is in the treatment of known or suspected deficiencies, or to prevent deficiencies as bodily needs change as seen during pregnancy, disease, or aging. In this approach, health consequences are caused by vitamin deficiency, and the vitamins restore health by resolving the deficiency. There are numerous studies that prove the efficacy of using vitamins to treat their known deficiency syndromes or to prevent deficiencies. However, there is evidence that vitamin deficiencies may cause more health problems than are currently known. The role of vitamin deficiencies in cancer, cardiovascular disease, bone health, and immune disorders, among others, continue to be examined although the results are often conflicting. Certainly, the maintenance of adequate vitamin intake, either through diet or a multivitamin supplement, is to be encouraged.

The second approach is the use of a vitamin or group of vitamins in doses above that required for prevention of deficiency, to provide an overall health benefit, or to prevent or treat disease. Study results are even more controversial in this area because of conflicting results and, more importantly, the gathered evidence that excessive use of certain vitamins, under some circumstances, may actually be harmful. It remains controversial whether there is clear and convincing evidence to suggest that the use of vitamins in doses above their recommended dietary allowance (RDA), singly

or in combination, provides any health benefit or can prevent or treat disease.

One difficulty in assessing the role of vitamins, and other nutrients, in health and disease is the finding that often more than one is involved in a physiological or disease process. This is seen in studies on bone mineralization where administering calcium in the presence of vitamin D deficiency, or vitamin D in the presence of a calcium-deficient diet, may miss the importance of calcium and/or vitamin D supplementation. We now realize that vitamin K is also involved in bone formation and this third factor, among others, must be considered. However, studies examining multiple factors are complex and not easily performed. Another complicating factor comes from the continually expanding use of fortification. Total vitamin intake is often unknown, even in the absence of supplementation, as a result of intake from multiple sources unnaturally high in vitamin content. For a summary, refer to the National Institutes of Health (NIH) State-of-the-Science Conference on Multivitamin/Mineral Supplements and Chronic Disease Prevention.¹

INTRODUCTION

A complete history of the vitamins would have to begin with the earliest written historical records. For millennia, different cultures have recorded the use of dietary substances to successfully treat disease; some of which we now know are a result of vitamin deficiency. Patients afflicted with one of these deficiencies were successfully treated as a result of the empirical or fortuitous selection of dietary substances rich in the deficient vitamin(s). However, the basis for these deficiency diseases and why these treatments were successful was not systematically examined until the late 1800s to early 1900s.

The search for vitamins began in earnest in the early 1900s when researchers first began to realize that synthetic diets consisting of sufficient amounts of purified carbohydrates, proteins, fats, minerals, water, and calories failed to sustain growth in animals. Although there were many important contributors to the eventual discovery of the concept of vitamins and the individual chemicals that comprise them, only a few key papers are presented here. These help explain the terminology of vitamins in general; more detail is included with the individual vitamins. In 1911, Funk² described a substance that could cure polyneuritis in birds that was found in the aqueous phase of an extract of rice polishings. Later in 1912, Funk³ published an excellent summary of the state of vitamin discovery, and for the first time proposed the use of the word *vitamine*, which has been often stated to be derived from a

combination of the latin, *vita* (life) or alternatively from *vital*, and *amine*, which comes from the chemical term *am* (from ammonia) for nitrogen and the suffix *-ine*, which means basic in the chemical sense. Early work of Funk indicated that the curative substance for bird polyneuritis found in rice polishings was necessary for life, contained nitrogen, and was basic, hence the name.

Also in 1912, Sir Frederick Gowland Hopkins⁴ clearly demonstrated that growth retardation found in rats fed purified diets could be reversed by the addition of small amounts of milk. The amount added was not sufficient to be quantitatively important with respect to its caloric value or nutritive value as a source of protein, carbohydrate, fat, or minerals. Therefore, Hopkins suggested that there must be some, yet unidentified, factors in the milk that are required for growth, but only in very small amounts. He referred to these substances as *accessory factors*. McCollum and Davis⁵⁻⁸ in a series of papers showed that rats fed a diet of purified milk sugar, protein, minerals, and lard or olive oil, which provided sufficient calories, also failed to grow. Furthermore, they found that addition of small amounts of butterfat, egg yolk, or lipid extracts of either of these two substances would quickly restore growth. In 1916, McCollum and Kennedy⁹ suggested that the term *vitamine* be dropped for two reasons. First, the use of the prefix *vita* implied that these were the only substances vital for life; however, other dietary substances were known to be required for life, such as essential amino acids. Second, the ending *amine* implied they contained basic nitrogen, proof of which was lacking. Because the substance they were examining was fat soluble and the accessory factor described by Funk was water soluble, the suggestion was made to refer to these as *fat-soluble A* and *water-soluble B*. Deficiency of an *antiscorbutic substance* in the diet was thought to result in scurvy, and Drummond¹⁰ proposed the term *water-soluble C* in 1919.

In 1920, Drummond¹¹ proposed an alternative. He noted that the ending *-ine* was used in chemical nomenclature to denote a basic substance, and there was no evidence that any of the dietary factors was basic, much less amines. Nor was there an expectation that future discoveries would be basic. He therefore suggested dropping the final “-e” and using the term *vitamin*, which would be acceptable under the rules of chemical nomenclature. He further suggested using the terms vitamin A and vitamin B for the fat-soluble A and water-soluble B, which had been suggested by McCollum and Kennedy, and continuing with subsequent letters, such as C, as new vitamins were discovered. Other names were also proposed, but none as historically important as these.

This terminology continued for the most part, through the discovery of many of the remaining vitamins. The only alteration is that, except for vitamin C, the water-soluble vitamins were grouped into the *vitamin B complex*, instead of, or in addition to, using alphabetic letters as originally suggested, and they were then numbered as vitamin B₁, vitamin B₂, etc. This terminology was a result of the early crude extracts of water-soluble B vitamin actually containing several vitamins, not just one as originally thought, and as the extracts were resolved into individual vitamins, the series B₁, B₂, etc. developed. Jansen¹² noted in 1935 that there were no similarities in the structure or action of the B vitamins and that assigning letters was prone to error. He suggested using their proper names, for example *ascorbic acid* instead of *vitamin C*, and this practice has, for the most part, been adopted by the major

chemistry standards organization, the International Union of Pure and Applied Chemistry (IUPAC).

It continues to be traditional to classify these compounds as either lipid-soluble or water-soluble vitamins. This classification is convenient because members of each category possess important properties in common although they are much more diverse than this simple division suggests. Some designations were later proved to be duplicates, or shown not to be vitamins; hence, we are left with A, B, C, D, E, and K as the only letters to commonly designate the vitamins. Currently, there are 13 substances recognized as vitamins.

The vitamins are arranged in this chapter in the traditional groupings of the fat-soluble vitamins, vitamin A, D, E, and K, followed by the water-soluble vitamins, using their historical B-complex vitamin number such as vitamin B₁, vitamin B₂, etc., with vitamin C at the end. Because the preferred names of many of the water-soluble vitamins no longer follow this convention, Table 28.1 lists the designation and order used in this chapter, followed by the preferred name(s) and other known names.

Two organizations provide guidelines for daily vitamin intake in the United States. The first, the Food and Drug Administration (FDA), regulates the labeling of foods and dietary supplements with respect to their nutritional content, including vitamins. The current labeling requirements for vitamins, established following the Dietary Supplement Health and Education Act (DSHEA) of 1994 and published in the Code of Federal Regulations¹³ (CFR) under Title 21, Section 101.9, requires that the vitamin content of food and dietary supplements be listed as a percentage of the daily value (DV). The DV for nutrients is determined by using the daily reference value (DRV) if the nutrient is a source of energy, such as protein, carbohydrates, and fats, or by using the reference daily intake (RDI) for vitamins and minerals. The RDI replaces the previously used term, USRDA (United States Recommended Daily Allowance), to prevent confusion with the RDAs (see later) published by the National Academy of Sciences. The RDI for each of the vitamins as published in 21CFR101.9 is listed in Table 28.2, and the percent DV that is placed on the food or dietary supplement label is determined by dividing the content of one serving of the food by the RDI and multiplying by 100.

The second organization that provides nutritional guidelines is the Nutrition Board of the National Academy of

TABLE 28.1 Nomenclature of Water-Soluble Vitamins

Historical Name	Preferred Name(s)	Other Names
Vitamin B ₁	Thiamine	Thiamin, aneurine, aneurin
Vitamin B ₂	Riboflavin	Vitamin G, riboflavine, lactoflavin
Vitamin B ₃	Niacin, niacinamide	Nicotinic acid, nicotinamide, vitamin PP
Vitamin B ₅	Pantothenic acid	
Vitamin B ₆	Vitamin B ₆	Pyridoxine, pyridoxin
Vitamin B ₇	Biotin	Vitamin H
Vitamin B ₉	Folate, folic acid	Vitamin M, vitamin B _c , folacin
Vitamin B ₁₂	Cobalamins	Cyanocobalamin, extrinsic factor (EF)
Vitamin C	Ascorbic acid	Antiscorbutic substance

TABLE 28.2 Reference Daily Intakes for Vitamins Used in Food Labeling

Vitamin	Reference Daily Intake
Vitamin A	5,000 IU ^a
Vitamin C	60 mg
Vitamin D	400 IU
Vitamin E	30 IU
Vitamin K	80 μg
Thiamin	1.5 mg
Riboflavin	1.7 mg
Niacin	20 mg
Vitamin B ₆	2 mg
Folate	400 μg
Vitamin B ₁₂	6 μg
Biotin	300 μg
Pantothenic acid	10 mg

^aInternational Units.

Sciences, Institute of Medicine.¹⁴ Its guidelines are published in the form of dietary reference intakes (DRIs), which include several ways of evaluating the proper intake of vitamins and minerals. The estimated average requirement (EAR) is defined as the “average daily nutrient intake level that is estimated to meet the nutrient needs of half of the healthy individuals in a life stage or gender group.” If an EAR can be determined for a vitamin, then the RDA is calculated using statistical methods and is defined as an “estimate of the daily average dietary intake that meets the needs of nearly all (97%–98%) healthy members of a particular life stage and gender group.” Generally, the RDA is the most specific guide for daily vitamin intake available. However, when there is not enough data to support determination of an EAR, and thus an RDA, the nutrition board sets a level known as the adequate intake (AI), which is defined as the “recommended average daily nutrient intake level based on observed or experimentally determined approximations of estimates of nutrient intake by a group (or groups) of apparently healthy people who are assumed to be maintaining an adequate nutritional state.” Finally, the tolerable upper intake level (UL) is defined as the “highest average nutrient intake level likely to pose no risk of adverse health effects for nearly all people in a particular group.” Table 28.3 contains the current DRIs, in terms of the RDA (when available) or the AI (when the RDA is not available) for the vitamins covered in this chapter.

Finally, the World Health Organization¹⁵ (WHO) is in the process of *harmonizing* (WHO term for standardizing) nutrient values so that they can be useful internationally. This is necessary because of the wide variety of terms and corresponding approaches to defining dietary standards seen across the globe. WHO recommends using the term *nutrient intake value* (NIV) to encompass all nutrient-based dietary standards, not just vitamins. In order to simplify terminology, WHO recommends only two NIVs. First, the average nutrient requirement (ANR) represents the mean requirement in a healthy population required to achieve a specific outcome. Second, the upper nutrient level (UNL) is defined as “the highest level of habitual nutrient intake that is likely to pose no risk of adverse health effects in almost all individuals in the general population.”

Another important distinction is the difference between the natural vitamin content of foods and the vitamin content

following enrichment or fortification. A good example would be vitamins in whole grain products. These naturally serve as an excellent source of certain vitamins; however, when they are processed as is the case with the production of white flour, much of the vitamin content is lost. To effectively prevent vitamin deficiencies, many developed countries, including the United States, require that the lost vitamins be added to approximate the natural levels. This process is called *enrichment*. *Fortification* is the addition of vitamins above the levels found naturally in the food. For example, many ready-to-eat cereals are fortified with vitamins, which can then become an excellent source of a vitamin, although the grain used in the cereal is not a natural source of the vitamin. We try to distinguish between foods that are good natural sources and those that have become significant sources through fortification.

FAT-SOLUBLE VITAMINS

The fat-soluble vitamins include vitamins A, D, E, and K. These compounds possess other characteristics in common besides solubility. They are usually associated with the lipids in foods and are absorbed from the intestine with these dietary lipids. Other than vitamin K, the fat-soluble vitamins are stored in the liver and, thus, conserved by the organism; whereas storage of the water-soluble vitamins is usually not significant. This leads to a greater potential for toxicity associated with long-term accumulation of the fat-soluble vitamins following ingestion of large doses that is not generally seen with the water-soluble vitamins.

Vitamin A

The discovery of vitamin A is often attributed to the original paper by McCollum and Davis⁵ in 1912 demonstrating that dietary fats contained substances, other than the fats themselves, necessary for proper growth. In 1931, vitamin A was isolated from fish oil¹⁶ and the structure was confirmed the next year.¹⁷ Vitamin A was first synthesized in 1947,¹⁸ but studies of the molecular mechanism of action in the visual process were not significantly productive until the 1960s. One of the major contributors in elucidating the visual function of vitamin A was George Wald,¹⁹ a corecipient of the Nobel Prize for Physiology or Medicine in 1967 for his work that is summarized in a 1968 paper. Since the original isolation of the substance referred to as vitamin A, several compounds have been found naturally or synthesized to have biological activity similar to vitamin A. Of particular dietary importance in this regard are the provitamin A carotenoids which are converted into active forms of vitamin A in vivo.

Dietary vitamin A is obtained naturally from foods of animal origin, either as free vitamin A or combined as the biologically active esters, chiefly of palmitic and some myristic and dodecanoic acids. The highest sources of natural vitamin A are livers of animals, especially herbivorous, poultry, and fish. Vitamin A is also found in egg yolk; however, the whites are not a good source. Vitamin A can also be obtained from foods fortified with this vitamin such as ready-to-eat breakfast cereals, milk, butter, and margarine.

The provitamin A carotenoids are obtained from plant sources and comprise some of the best sources of this vitamin. The provitamin As are found in deep green, yellow,

CHEMISTRY

Vitamin A belongs to a class of compounds referred to as the *retinoids*, which consist of four isoprenoid units joined in a head-to-tail manner.²⁰ All double bonds in the isoprenoid units are implied to be in the *E* (*trans*) configuration unless stated otherwise. Currently, the term *retinoid* is applied to retinol and its naturally occurring derivatives plus synthetic analogs, which need not have vitamin A activity. *Vitamin A* is currently used as a generic descriptor for all retinoids that exhibit the biological activity of retinol, the original substance identified as vitamin A. The term *vitamin A₁* and *all-trans* retinol have been used to refer to retinol whereas *vitamin A₂*

was used to refer to 3,4-dehydroretinol. *Retinoate analogs* are used to refer to “compounds that control epithelial differentiation and prevent metaplasia, without possessing the full range of activities of vitamin A.”²¹ Retinal (formerly *all-trans* retinal), the form of vitamin A that takes part in the visual cycle, and retinoic acid (formerly *all-trans* retinoic acid), the form that takes part in cell differentiation, are the two active forms of vitamin A (Fig. 28.1). About 60 β -carotenes, out of 700 carotenoids that have been identified, exhibit vitamin A activity in the body and are termed the provitamin As or provitamin A carotenoids. The important carotenoids regarded as the provitamin As are α -, β -, and γ -carotenes and cryptoxanthin (Fig. 28.2). β -Carotene is the most important provitamin A carotenoid. The transformations of preformed vitamin As and β -carotene are shown in Figure 28.1.

Vitamin A activity has been historically expressed as *United States Pharmacopeia (USP)* units, international units (IU), retinol equivalents (RE), or β -carotene equivalents. The USP units and IU are equivalent. Each unit expresses the activity of 0.3 μg of retinol. Thus, 1 mg of retinol has the activity of 3,333 units. Other equivalents are listed in Table 28.4. This system does not take into account the incomplete absorption and rate-limited bioconversion of the provitamin A carotenoids into the active form, retinol. One RE represents the biological activity of 1 μg of retinol, 6 μg of β -carotene, or 12 μg of α -carotene or β -cryptoxanthin. The RE was used

to convert all dietary sources of vitamin A into a single unit for easy comparison and accounts for inefficiencies in absorption and rate-limited bioconversion of the provitamin A carotenoids.²² The current unit used to express vitamin A activity is the retinol activity equivalents (RAE). This came about from the finding that the absorption of the provitamin A carotenoids is 50% less than originally thought. The only difference in this system is that the provitamin A carotenoids are one half the activity assumed when using REs (see Table 28.5).

The stereochemistry of vitamin A and related compounds is complex, and the study of the structural relationships among vitamin A and its stereoisomers has been complicated by the common use of several numbering systems (Fig. 28.3). The first numbering system (A) is the one currently recommended by IUPAC and is used throughout this text. The second system (B) places emphasis on the conjugated π system, whereas the third (C) is used by the *USP Dictionary of USAN and International Drug Names*.

The conjugated double-bond systems found in vitamin A and β -carotene, as well as the attached ring in the form of β -ionone or dehydro- β -ionone found in 3,4-dehydroretinol, are essential for activity. When any of these is saturated, activity is lost. The ester and methyl ethers of vitamin A have a biological activity on a molar basis equal to that of vitamin A. Retinoic acid (vitamin A acid) is biologically active but is not stored in the liver.

For steric reasons, the number of isomers of vitamin A most likely to occur is limited. These are all-*trans*, 9-*cis*, 13-*cis*, and the 9,13-di-*cis*. A *cis* linkage at double bond 7 or 11 encounters steric hindrance. The 11-*cis* isomer is twisted as well as bent at this linkage; nevertheless, this is

**Figure 28.3** • Vitamin A numbering systems.

the only isomer that is active in vision and is synthesized in retinyl pigmented epithelial cells from all-*trans*-retinyl esters by the action of isomerase followed by hydrolysis.

KINETICS

Vitamin A is absorbed in the intestine via the same pathway used for dietary lipids, requiring bile salts, dietary fat, and pancreatic juice. Retinyl esters are hydrolyzed in the intestinal lumen to retinol by pancreatic triacylglycerol lipase (EC 3.1.1.3) and the brush border enzyme lysophospholipase (EC 3.1.1.5). The retinol is absorbed into the enterocytes by facilitated diffusion at normal concentrations. At pharmacological doses, however, retinol can be absorbed by passive diffusion.^{23,24} Bioavailability for most forms of preformed vitamin A is 70% to 90%. Upon cellular entry, retinol associates with a retinol binding protein (RBP), most likely RBP2. RBPs represent a group of proteins involved in intracellular and intercellular binding and transport of vitamin A. These intracellular proteins function in the transport and metabolism of retinol and retinoic acid by solubilizing them in aqueous media and presenting them to the appropriate enzymes while protecting them from catabolizing enzymes.²⁵ These proteins also limit the concentration of free retinoids within the cell.

Provitamin A carotenoids are absorbed by passive diffusion and also depend on absorbable fats and bile. It is currently assumed that one twelfth of normal dietary β -carotene but only one twenty-fourth of the other provitamin A carotenoids is absorbed and bioconverted. This explains the low activity of the provitamin A carotenoids in relation to retinol as shown in Table 28.5. The enterocytes are the main site of β -carotene transformation to retinal,²⁶ but the enzymes that catalyze the transformation also occur in hepatic and other tissue. Up to 20% to 30% of provitamin A carotenoids are absorbed unchanged. Following absorption by the enterocytes, β -carotene is symmetrically cleaved into retinal by β -carotene 15,15'-monooxygenase (EC 1.14.99.36), which requires molecular oxygen.²⁷ β -Carotene can give rise to two molecules of retinal; whereas with the other three carotenoids, only one molecule is possible by this transformation. This is a result of the composition of β -carotene, which has a structure identical to retinal in both halves of the molecule, whereas the other provitamin As have a structure identical to retinal in one half of the molecule (see Fig. 28.2). Asymmetric cleavage of the carotenoids by β -carotene-9,10-monooxygenase has also been reported,^{26,28,29} but its role in humans is not fully resolved. The retinal formed from the provitamin As is then reduced to retinol by retinol dehydrogenase (EC 1.1.1.105) or alcohol dehydrogenase (EC 1.1.1.1).

Within the enterocytes, the retinol is esterified by three enzymes, diacylglycerol *O*-acyltransferase (DGAT, EC 2.3.1.20), retinol *O*-fatty-acyltransferase (EC 2.3.1.76), also known as acyl-coenzyme A (CoA):retinol acyltransferase (ARAT), and phosphatidylcholine-retinol *O*-acyltransferase (EC 2.3.1.135), also known as lecithin:retinol acyltransferase (LRAT). LRAT esterifies retinol bound to RBP2, whereas ARAT can esterify unbound retinol. It has been proposed that LRAT esterifies retinol at normal doses, while ARAT esterifies excess retinol.³⁰ It has also been suggested that high doses of retinol may increase retinoic acid formation in the enterocytes through a retinoic acid responsive element (RARE) that promotes RBP2 expression.³¹

The retinyl esters are incorporated into chylomicrons, which in turn enter the lymph. Once in the general circula-

tion, chylomicrons are converted into chylomicron remnants, which are cleared primarily by the liver but possibly other tissues.³⁰ As the esters enter the hepatocytes, they are hydrolyzed to retinol which is then bound to RBP1 or RBP4. These are released into the blood or transferred to liver stellate cells for storage. Within the stellate cells, the retinol bound to RBP is esterified for storage by LRAT and ARAT. Stellate cells contain up to 80% of the body's vitamin A stores.³² The RBP-retinol complex released into the general circulation from hepatocytes or stellate cells is extensively bound to transthyretin (TTR), which protects RBP-retinol from glomerular filtration and subsequent renal excretion.³³ Retinol alone is taken up by target cells, probably by passive diffusion, from circulating RBP-retinol and once inside, is bound to RBP1 and possibly RBP2. Other retinoids may also circulate in plasma in low amounts, such as free retinol and 13-*cis* retinoic acid, but these are most likely bound to albumin.

Elimination of vitamin A generally involves the glucuronidation of retinol or retinoic acid followed by renal or biliary excretion that may result in enterohepatic cycling. Other pathways for oxidizing retinoids to more polar substances also exist. Normally, no unchanged retinol is excreted. Retinal, retinoic acid, and other metabolites are, however, found in the urine and feces.

BIOCHEMISTRY

Vitamin A is involved in numerous biochemical functions. The best-known action of vitamin A is in its function in the chemistry of vision. The requirement for vitamin A for proper visual response to light in the retina has been well characterized. However, its role in cellular growth and differentiation continues to expand.

The molecular mechanism of action of vitamin A, in the form of 11-*cis* retinal, in the visual process has been under investigation for many years.^{34,35} Figure 28.4 represents the

Figure 28.4 • Retinol and the visual cycle.

chemical changes that take place in the visual cycle involving the rhodopsin system in the rod cells of the retina. Uptake of retinol from blood by the epithelial cells of the retina is followed by re-esterification and conversion to the 11-*cis* retinol form. This is converted to the aldehyde, 11-*cis* retinal, which is the form used in the visual pathway. In contrast to the cone cells of the retina, which are responsible for color vision and only function well in the presence of ample light, the vitamin A-dependent rods are essential for vision over a wide range of light intensity, especially low levels. This system is responsible for vision in the dark, which explains the night blindness seen in vitamin A-deficient individuals.

Vitamin A is also intimately involved in cellular differentiation during embryonic development and the maintenance of cellular differentiation in various tissues in the adult. The molecular mechanism of vitamin A, in the form of retinoic acid, in this area is more complex.^{36,37} This form of vitamin A acts through retinoic acid receptors (RARs) which are a member of the steroid/thyroid hormone superfamily of receptors. These act as ligand-dependent transcription factors that regulate gene expression. Several RARs have been identified: RAR α (RARA), RAR β (RARB), and RAR γ (RARG). These differ in their tissue distribution and the level of expression during cell development and differentiation. Following cytoplasmic RAR-retinoic acid binding, the complex forms a heterodimer with the retinoid X receptor (RXR). The heterodimer translocates to the nucleus and binds to a RARE or retinoid X response element (RXRE) on DNA associated with the promoter region of target genes and, together with coactivators, regulates target gene transcription. Several RXR receptors have also been identified including RXR α (RXRA), RXR β (RXRB), and RXR γ (RXRG), and they have been shown to be also involved in the intracellular action of vitamin D. They have a different tissue distribution from the RARs. A specific ligand for RXR has been identified as 9-*cis*-retinoic acid, which can also bind to RARs; however, the physiological role of this retinoid is not known. Retinoic acid can bind only to RARs. 9-*cis* retinoic acid may, therefore, represent a third active form of vitamin A.^{38,39} Several synthetic retinoids have been synthesized that bind selectively to RXR receptors, and these are referred to as *retinoids*.

The biological effects of retinoic acid are mediated through various proteins, numbering in the hundreds, which are controlled at the nuclear level by this form of the vitamin. Ultimately, effects are seen in cell differentiation, both during embryonic development and in the adult. Effects on reproduction, growth, immune function, hematopoiesis, epithelium, central nervous system (CNS) function, and cancer have also been observed, among others. This widespread involvement in biological function explains the myriad of effects seen in deficiency and overdoses of this vitamin.

Deficiency of this vitamin leads to several disorders collectively referred to as vitamin A deficiency disorders (VADD). Preschool-age children are especially susceptible to and develop more serious forms of VADD leading to increased mortality which may approach 50% in poor societies.⁴⁰ A deficiency of vitamin A is manifested chiefly by keratinization of the mucous membranes throughout the body. This degeneration is more pronounced in the eye than in any other part of the body and gives rise to a condition known as xerophthalmia which results in drying and thickening of the conjunctiva and cornea. This may ultimately lead to corneal destruction and permanent blindness.

Vitamin A deficiency also results in poor dark adaptation of the eyes referred to as night blindness (*nyctalopia*). Immune insufficiency develops resulting in a tendency to infection. Anemia results from hematopoietic failure in the marrow. In children, growth failure and wasting also occurs. Deficiency of vitamin A can also give rise to dryness and scaliness of the skin in adults.

THERAPEUTIC USES

Vitamin A is used in the treatment of known or suspected vitamin A deficiency. Vitamin A deficiency in developed countries such as the United States is not likely of dietary origin but is more likely caused by malabsorption as is seen in sprue, hepatic cirrhosis, biliary, or pancreatic diseases. Interestingly, vitamin A levels decrease during infection with the measles virus (*rubeola*) resulting in increased morbidity and mortality, especially in children with preexisting vitamin A deficiency. Vitamin A supplementation has been shown to decrease mortality by 50% and prevent blindness in children developing measles if given at the time of diagnosis. Of course, vaccination is of prime importance; however, in underdeveloped countries where the rate of vaccination is low, vitamin A supplementation is a beneficial alternative.⁴¹ Retinoate analogs have been developed for use in the treatment of dermatological conditions such as psoriasis and acne. Some therapies for cancer by retinoate analogs have also been established, and newer therapies against various cancers are under investigation.³⁷

Both natural and synthetic carotenoids decrease acute photosensitivity in porphyria in a manner unrelated to its vitamin activity.⁴² Most β -carotene is converted to retinol during absorption, but the fraction that is absorbed unchanged is distributed widely and accumulates in the skin. This can provide protection against sun exposure in patients with erythropoietic protoporphyria. It does not provide total protection against the sun, but patients who respond to its treatment can remain in the sun the same as normal individuals. Discontinuance of the drug results in a return of hypersensitivity. β -Carotene does not function as a sunscreen in normal patients and should not be used as such. Carotenodermia, a result of accumulation in the skin, is the major side effect. Tanning capsules containing β -carotene and/or the carotenoid and canthaxanthin, uses this effect.

β -Carotene has also been investigated for possible protective effects in cancer. Early studies suggested a protective effect in lung cancer, but recent studies of lung, prostate, colon, breast, or nonmelanoma skin cancer did not show a protective effect.⁴³ Surprisingly, the results of several later studies suggest that increased intake of β -carotene might increase the risk of lung cancer in smokers.^{1,44} Studies also do not show any protective effects in cardiovascular disease.^{1,43}

HYPERVITAMINOSIS

The toxicities of vitamin A have been known since before the vitamin was discovered,⁴⁵ and can lead to both short- and long-term effects.⁴⁶⁻⁴⁸ Short-term doses of 0.5 to 4 million IU can lead, within hours to several days, to CNS effects including increased intracranial pressure, headache, irritability, and seizures; gastrointestinal effects including nausea, vomiting, and pain; dermatological effects such as desquamation; ophthalmic effects such as papilledema, scotoma, and photophobia; and liver damage. Most of these reactions

have been reported in infants following treatment with large doses of vitamin A, but some have resulted from ingestion of food rich in vitamin A, such as liver, especially from polar bears.

Long-term intake of doses of vitamin A lower than the intake required for short-term toxicity but still above that required by the body can lead to long-term effects, including effects on the skin, liver, CNS, and bone. Although the amount required varies, doses as low as 15,000 IU/day have led to some adverse effects. Higher doses, generally above 100,000 IU/day, are required to see all the reported adverse effects. In patients with low body weight, malnutrition, or liver or renal disease, the doses required for long-term adverse effects may be still lower.

Dermatological adverse effects include drying of the skin and mucosa, dermatitis, pruritus, swelling and fissuring of the lips, and rarely loss of body hair. Hepatic effects include hypertrophy and hyperplasia of the hepatic stellate cells, hepatomegaly, fibrosis, and cirrhosis, which can lead to portal hypertension, ascites, and jaundice. Splenomegaly is also seen. CNS effects include increased intracranial pressure (pseudotumor cerebri) leading to headache, visual disturbances (e.g., diplopia), drowsiness, vomiting, seizures, and a bulging fontanel in infants. Finally, pain in the bone and joints, with accompanying tenderness and reduced bone mineralization⁴⁹ have also been reported.

The teratogenic effects of vitamin A are also well-known.⁵⁰ Intake of as little as 10,000 IU/day during pregnancy may increase the risk of birth defects, and the risk increases with increasing intake of vitamin A.^{51,52} Birth defects include cardiovascular, craniofacial, neural tube, and urogenital and musculoskeletal abnormalities.

β -Carotene, in contrast, is relatively nontoxic as are the other provitamin A carotenoids.^{47,53} After long-term exposure to high levels of β -carotene (30–180 mg/day for 15 years), patients have not developed any problems other than skin discoloration and asymptomatic hypercarotemia. Furthermore, β -carotene is not teratogenic. The most likely mechanism is the incomplete absorption and slow rate of conversion of β -carotene to retinol in the intestinal cells.⁵⁴ However, a recent systematic review and meta-analysis found an increase in overall mortality in studies using β -carotene.^{43,55} This, coupled with the finding that β -carotene may increase the risk of lung cancer in smokers, as discussed previously, suggests that it may not be as nontoxic as originally thought when used chronically.

PRODUCTS

Vitamin A contains retinol (vitamin A alcohol) or its esters from edible fatty acids (chiefly acetic and palmitic acids). It is available from various manufacturers under many names. Dosage forms vary from oral tablets, capsules, and solutions to topical ointments and creams. It is also available as an injectable in the form of vitamin A palmitate (Aquasol A) that is intended for intramuscular (IM) injection. Vitamin A is also available as a component of multivitamins from many different sources.

The provitamin A carotenoids are also widely available, primarily β -carotene, from various sources under many names. Oral liquids, tablets, and capsules are available, containing β -carotene, either singly or in combination as multivitamin preparations.

Retinoate analogs are also available for the treatment of dermatological conditions and cancer. Table 28.6 lists the current products on the market and their approved uses, whereas Figure 28.5 shows their corresponding structure.

Vitamin D

The recognition in 1919 that rickets was the result of a nutritional deficiency led to the isolation of antirachitic compounds from food products.⁵⁶ The role of sunlight in the prevention of rickets was noted at the same time.⁵⁷ Early studies showed that vitamin A preparations available at the time, in addition to their growth-promoting properties, could also cure xerophthalmia and rickets. Thus, the early assumption was that all of these were because of the deficiency of vitamin A. A preliminary report by Funk and Dubin⁵⁸ in 1921 was the first to suggest the presence of a vitamin in yeast extracts that was distinctly different from vitamin A and vitamin B, which the authors named vitamin D. It is interesting that the authors believed the new vitamin D was another of the B vitamins, which at that point in history was known to consist of at least two different vitamins. McCollum et al.⁵⁹ clearly showed in 1922 that vitamin A and the antirachitic factor were, in fact, two separate vitamins. The synthesis of both major forms of vitamin D, ergocalciferol and cholecalciferol, was accomplished in 1977.⁶⁰

The highest natural source of vitamin D is fatty fish such as herring, catfish, salmon, mackerel, and tuna or oils derived from fish such as cod liver oil. Eggs, from hens fed vitamin D, and butter also contain small amounts of vitamin D. The most common source of vitamin D in developed countries, such as the United States, is fortified foods such as milk, ready-to-eat cereals, and some fruit juices. Cholecalciferol or ergocalciferol is usually used in fortification or supplementation.

CHEMISTRY

Chemically, the various forms of vitamin D are broken-open steroids referred to as *secosteroids*. The term vitamin D is currently applied to all steroids possessing biological activity like that of cholecalciferol.⁶¹ Irradiation of yeast ergosterol yields a 1:1 mixture of ergocalciferol and lumisterol known as vitamin D₁. Because all the activities reside in the ergocalciferol, the term vitamin D₁ is no longer used. The photoconversion of ergocalciferol (ercalciol, previously calciferol, vitamin D₂) from ergosterol is shown in Figure 28.6. Cholecalciferol (calciol, previously vitamin D₃) is the form produced in vivo from the action of sunlight on 7-dehydrocholesterol (Fig. 28.7) in the skin. 22,23-Dihydroergocalciferol was known as Vitamin D₄. (24S)-Ethylcalciol (formerly sitocalciferol), made from 7-dehydrositosterol, was known as vitamin D₅. Note the structural differences between ergocalciferol and cholecalciferol shown in Figure 28.6 and Figure 28.7. The ergocalciferol side chain contains a double bond between C²² and C²³ and a methyl group on C²⁴.

KINETICS

The gastrointestinal absorption of the vitamin Ds requires bile, pancreatic juice, and dietary fat. Following formation

TABLE 28.6 Clinically Used Retinoate Analogs

Generic Name	Trade Name	Dosage Form	Use
Acitretin	Soriatane	Capsule	Psoriasis
Adapalene	Differin	Cream or gel	Acne vulgaris
Alitretinoin	Panretin	Gel	Kaposi sarcoma
Bexarotene	Targretin	Capsule	T-cell lymphomas

Tazarotene	Tazorac, Avage	Cream or gel	Psoriasis
Tretinoin	Retin-A, Renova, Avita, Altinac, Atralin, Vesanoid	Cream or gel Capsule	Acne vulgaris Leukemia

of micelles in the intestinal lumen, vitamin D esters are hydrolyzed, and free vitamin D, usually as cholecalciferol or ergocalciferol, is absorbed by passive diffusion into the enterocytes. There, it is incorporated into chylomicrons and secreted into the lymph where it enters the circulation.⁶² Cholecalciferol and ergocalciferol were once thought to be the active forms of vitamin D; however, they have now been identified as provitamins because they require hydroxylation by the liver and the kidney to be fully active.

As shown in Figure 28.8, the first step occurs in the liver, following uptake from chylomicron remnants, by the enzyme vitamin D₃ 25-hydroxylase (EC 1.14.15.-). This enzyme converts the provitamin to calcidiol (previously 25-hydroxyvitamin D₃, 25(OH)D₃) and requires both molecular

oxygen and reduced NADPH. The enzyme is found on the inner mitochondrial membrane,⁶³ and the rate correlates with substrate concentration. Following secretion into the blood, calcidiol and other forms of vitamin D are associated with group-specific component (vitamin D-binding protein [GC]) formerly referred to as vitamin D-binding protein (VDBP). The calcidiol bound to GC is the major circulating form of the vitamin and may be stored in fats and muscle for prolonged periods. GC binding helps in the transport of vitamin Ds in blood and also prolongs the circulatory half-lives by making them less susceptible to hepatic metabolism and biliary excretion.⁶⁴ Albumin and lipoproteins also bind vitamin Ds but with lower affinity than GC. The circulating levels of calcidiol are proportional to vitamin D intake and synthesis; thus, plasma levels of calcidiol have been used to indicate vitamin D status.⁶⁵

The epithelial cells of the proximal convoluted tubules in the kidneys convert calcidiol to calcitriol [previously 1 α ,25-dihydroxyvitamin D₃, 1 α ,25(OH)₂D₃] by the enzyme calcidiol 1-monooxygenase (EC 1.14.13.13) also known previously as 25(OH)D₃ 1 α -hydroxylase. The activity of this mitochondrial, cytochrome P450 enzyme is increased by parathyroid hormone and hypophosphatemia and decreased by calcitriol and Ca²⁺.⁶⁶ Understanding this final step is crucial because renal disease can lead to deficiency of the active calcitriol and subsequent derangements in calcium and bone metabolism. Treatment is only effective if a vitamin D preparation that already has the 1 α -hydroxy is used. Similar to cholecalciferol, ergocalciferol also requires hydroxylation in the liver and kidney to become fully active as shown in Figure 28.9.

In a classical sense, cholecalciferol, the form produced in animals, is not a true vitamin because it is produced in the

Figure 28.5 • Structures of clinically used retinoate analogs.

Figure 28.6 • Photoactivation of ergosterol to ergocalciferol.

skin from 7-dehydrocholesterol by UV radiation (Fig. 28.7) in the range of 290 to 300 nm.⁶⁶ 7-Dehydrocholesterol is produced from cholesterol by the enzyme 7-dehydrocholesterol reductase (EC 1.3.1.21). Only when exposure to sunlight is inadequate does cholecalciferol become a vitamin in the historical sense. As shown in Figure 28.7, upon exposure to UV irradiation, 7-dehydrocholesterol is converted rapidly to previtamin D₃. Previtamin D₃ undergoes slow thermal conversion to cholecalciferol and the biologically inactive lumisterol and tacalcinol (formerly tachysterol₃). Excess exposure increases production of the inactive compounds. The slow conversion of previtamin D₃ to cholecalciferol ensures adequate supplies when the exposure is brief. Further, lumisterol and tacalcinol can be converted back to previtamin D₃ and thus serve as a reservoir.⁶⁶ It has been estimated that a 10-minute exposure of just the uncovered hands and face will produce sufficient cholecalciferol.⁶⁷ Inadequate photo conversion to cholecalciferol is most likely to occur in northern latitudes during the winter months, in people with dark-colored skin or in people who routinely use clothing or sunscreens to reduce their sun exposure, such as the elderly.

The mechanism responsible for the movement of cholecalciferol from the skin to the blood is not known. In the blood, cholecalciferol is bound primarily to GC. This protein selectively removes cholecalciferol from the skin

because it has low affinity for 7-dehydrocholesterol, previtamin D₃, lumisterol, and tacalcinol.

Catabolism of vitamin D is initiated by the enzyme 1,25-dihydroxyvitamin D₃ 24-hydroxylase (EC 1.14.13.-), whose expression is stimulated by calcitriol, itself. 24-Hydroxylation is followed by oxidation to the ketone. Subsequent hydroxylation at C²³ leads to cleavage of the side chain, resulting in the biologically inactive product calcitronic acid.^{68,69} The 24-hydroxy metabolites are excreted primarily in the bile.

BIOCHEMISTRY

Similar to retinoic acid, the vitamin D receptor (VDR) is a member of the steroid/thyroid hormone superfamily of receptors. These act as ligand-dependent transcription factors that regulate gene expression. In intestine, bone, kidney, and other tissues, calcitriol binds to VDR localized in the cytoplasm, and the complex forms a heterodimer with a retinoid RXR. RXRs are also involved in vitamin A action and the reader is referred to that section for more information. This complex translocates to the nucleus and binds to vitamin D response elements (VDREs) associated with the promoter region of target genes and, together with coactivators, regulates target gene transcription. Over 50 genes have been identified that are controlled by calcitriol.

Figure 28.7 • Photoactivation of 7-dehydrocholesterol to cholecalciferol.

Figure 28.8 • Cholecalciferol bioactivation.

One of the most well-known effects of calcitriol is to maintain calcium homeostasis. Phosphate metabolism is also affected. The mechanism of action promoting Ca^{2+} transport in the intestine involves calcitriol-mediated formation of a calcium-binding protein, calbindin, which is known to exist in at least two forms in humans, calbindin 1, 28kDa (CALB1) and S100 calcium binding protein G (S100G), also known as calbindin-D9k. A calcium-dependent ATPase, Na^+ , and calbindin are necessary for intestinal Ca^{2+} transport and act to enhance the transcellular movement resulting in increased absorption of dietary Ca^{2+} . Transient receptor potential cation channel, subfamily V, member 6 (TRPV6), which controls the rate of cellular entry of Ca^{2+} , is also found to be increased in intestinal cells under the control of calcitriol. Calcitriol also promotes intestinal phosphate absorption, mobilization of Ca^{2+} and phosphate from bone, and renal reabsorption of Ca^{2+} and phosphate. Also involved are parathyroid hormone and calcitonin.

VDRs have also been identified in tissues not normally associated with bone mineral homeostasis. Besides the intestines, kidneys, and osteoblasts, vitamin D receptors have been located in the parathyroid gland, the pancreatic islet cells, the mammary epithelium, the skin keratinocytes, muscle, and the immune cells. Activation in the latter has potent antiproliferative and immunomodulatory functions. Thus, calcitriol and its analogous VDR ligands have therapeutic potential in the treatment of inflammatory diseases (rheumatoid and psoriatic arthritis), dermatological conditions (psoriasis, keratosis), osteoporosis, suppression of parathyroid hormone, cancers (including colon, prostate, and breast), and autoimmune diseases.⁷⁰ It has been suggested that vitamin D exerts its anticancer effects through its role as a nuclear transcription factor that regulates cell growth, dif-

ferentiation, apoptosis, and other cancer-developing cellular mechanisms.⁷¹

The classic form of vitamin D deficiency universally recognized is rickets. In young infants, the entire skull is soft (craniotabes), and problems in bone development lead to delays in sitting, crawling, and walking. Osteomalacia (evident on x-rays) and deformities of the bones eventually lead to deformities in the rib cage, bowlegs or knock-knees, bone pain, and a predisposition to fractures. Bone deformities may become permanent if not treated with vitamin D at an early stage. Vitamin D deficiency in children and adults also leads to myopathies, which can lead to weakness, and hypocalcemia, which can lead to paresthesia, muscle spasms, and tetany. Recent studies conclude that an increased rate of overall mortality in the general population is associated with low levels of vitamin D.⁷² The same study also demonstrated that vitamin D deficiency increases the risk of cancer, diabetes, and hypertension.

THERAPEUTIC USES

Cholecalciferol and ergocalciferol are used in the treatment of known or suspected vitamin D deficiency or the prevention of vitamin D deficiency when bodily needs are increased as seen in pregnancy. Calcitriol can also be used, especially when an immediate effect is desired as in severe deficiencies because it is the active form of vitamin D found in the body. This would involve treatment of rickets, osteomalacia, muscle pain, and hypocalcemia that can result from vitamin D deficiency. Vitamin D is also useful, particularly when used with calcium supplementation, to treat osteoporosis.^{44,73} Vitamin D can also be used to treat hypophosphatemia or hypocalcemia because of other causes, such as hypoparathyroidism.

Figure 28.9 • Ergocalciferol bioactivation.

TABLE 28.7 Vitamin D Products

Generic Name	Trade Name	Dosage Form	Use
Calcifediol	Calderol	Capsule	Vitamin D therapy
Calcipotriene	Dovonex	Ointment, cream, or scalp solution	Plaque psoriasis
Calcitriol	Rocaltrol, Calcijex	Capsule, oral solution, injection	Vitamin D therapy, renal osteodystrophy, hypocalcemia, hypoparathyroidism
Cholecalciferol	Delta-D, various	Capsules, tablet, injection, cream, ointment	Vitamin D therapy, hypoparathyroidism, hypophosphatemia
Dihydroxycholecalciferol	DHT	Capsule, oral solution, tablet	Hypoparathyroidism
Doxercalciferol	Hectorol	Capsule	Renal osteodystrophy
Ergocalciferol	Drisdol, various	Oral softgel, capsule, oral solution, tablet	Vitamin D therapy, hypoparathyroidism, hypophosphatemia
Paricalcitol	Zemlar	Injection, capsule	Renal osteodystrophy

Uremia associated with renal failure can result in hypocalcemia and secondary hyperparathyroidism as a result of insufficient conversion of calcidiol to calcitriol by the diseased kidneys. This results in renal osteodystrophy, a metabolic bone disease involving abnormal mineralization. Patients are often on dialysis by the time these problems occur. Treatment with calcitriol, or other active analogs of vitamin D with a 1α -hydroxy group (see Table 28.7) helps to increase Ca^{2+} levels, as well as decrease parathyroid hormone levels essentially controlling these effects. Doses used do not result in extraskelatal calcification or increase the rate of decline in renal function as can be seen with excessive doses of vitamin D.

Beneficial effects have been shown for high levels of calcitriol in patients with advanced prostate cancer⁷⁴ and colorectal cancer⁷⁵ although this is not a proven therapy. These investigational treatments require high doses of vitamin D and the resultant hypercalcemia limits the usefulness. Vitamin D analogs with a decreased tendency to cause hypercalcemia and hypercalciuria are being developed and investigated. Although the issue of vitamin D in heart health is not resolved yet, an inverse correlation was found between cardiovascular events and serum vitamin D (as calcidiol or calcitriol) levels—low vitamin D levels are associated with hypertension, elevated very low-density lipoprotein (VLDL) triglycerides, and impaired insulin metabolism.^{76,77} Calcipotriene represents a vitamin D analog used for its antiproliferative effects and the ability to promote cellular differentiation in the epidermis and is effective in the treatment of psoriasis.⁷⁸

HYPERVITAMINOSIS

Hypervitaminosis D apparently cannot arise from excessive exposure to sunlight⁷⁹ but only occurs following ingestion of large quantities of synthetic vitamin D. The precise amount to produce toxicity would depend on the dose and duration of exposure, however, doses of 100,000 IU daily for 4 days have not resulted in toxicity.⁸⁰ Toxicity involves derangements of calcium metabolism, resulting in hypercalcemia and metastatic calcification of soft tissue. Most problems result from the hypercalcemia, which typically causes muscular weakness, anorexia, nausea, vomiting, and depression of the CNS (which can result in coma and death). In addition, deposition of calcium salts in the kidneys (nephrocalcinosis) and the tubules (nephrolithiasis) can lead to potentially irreversible renal damage. Early signs are polyuria and nocturia because of damage to the renal concentrating mechanism.

PRODUCTS

Table 28.7 is a list of the currently available products, and Figure 28.10 shows their structures. Most vitamin supplements containing vitamin D singly, or in combination with other vitamins as multivitamin preparations, contain cholecalciferol. However, ergocalciferol can also be used. These are available in various preparations under many different names as oral capsules, tablets, solutions, and powders. Table 28.7 also shows the vitamin D analogs used in the treatment of renal osteodystrophy that occurs as a result of secondary hyperparathyroidism in patients unable to convert calcidiol to the active calcitriol. This is most often seen in severe renal failure, especially in patients on dialysis. Each of these products already has the 1α -hydroxy, so the need for bioactivation by the kidney is circumvented. Finally, calcipotriene is available for the treatment of psoriasis.

Vitamin E

Since the early 1920s, it was known that rats fed only cow's milk cannot produce offspring. In 1922, Evans and Bishop⁸¹ discovered an unrecognized dietary factor essential for reproduction. In 1924, Sure⁸² named the principle that could rectify this deficiency vitamin E. When the compound known as vitamin E was isolated from wheat germ oil in 1936 by Evans et al.,⁸³ it was named α -tocopherol, from the Greek words *tokos* meaning "childbirth," *phero* meaning "to bear," and "-ol" indicating an alcohol. The structure⁸⁴ and synthesis⁸⁵ of α -tocopherol were reported in 1938. Since then, several other closely related compounds have been discovered from natural sources, and this family of natural products took the generic name tocopherols.

The tocopherols are especially abundant in wheat germ, rice germ, corn germ, other seed germs, lettuce, soya, and cottonseed oil. All green plants contain some tocopherols, and there is evidence that some green leafy vegetables and rose hips contain more than wheat germ. It is probably synthesized by leaves and translocated to the seeds. All four tocopherols have been found in wheat germ oil; α -, β -, and γ -tocopherols have been found in cottonseed oil. Corn oil contains predominantly γ -tocopherol and thus furnishes a convenient source for the isolation of this difficult member of the tocopherols. δ -Tocopherol is 30% of the mixed tocopherols of soya bean oil. Palm oil contains about 30% of tocopherols and 70% of tocotrienols. Cereals like oat, rye, and barley contain small amounts of tocotrienols.

Figure 28.10 • Structures of vitamin D products.

CHEMISTRY

Several tocopherols have been isolated. Some have the 4',8',12'-trimethyltridecyl-saturated side chain; others have unsaturation in the side chain. It has been suggested that these polyunsaturated tocols be named tocotrienols. The best-known tocopherol is α -tocopherol, which has the greatest biological activity. The base structure, represented in Figure 28.11, shows that the tocopherols are methyl-substituted tocol derivatives: α -tocopherol is 5,7,8-trimethyltol; β -tocopherol is 5,8-dimethyltol; the γ -compound is 7,8-dimethyltol; and δ -tocopherol is 8-methyltol. The tocotrienols have similar substituents. Vitamin E is a generic descriptor for all tocol and tocotrienol derivatives that have biological activity similar to α -tocopherol.⁸⁶ Currently, eight of these tocols, four tocopherols and four tocotrienols, are considered the vitamin E family. These tocols possess two important structural components, the chromanol ring and the side chain, and differ by the methylation patterns of the chromanol ring (α -, β -, γ -, and δ -) and presence or absence of double bonds in the side chain (no double bond in tocopherols whereas three double bonds in tocotrienols).

Natural (+)- α -tocopherol has the configuration 2*R*,4'*R*,8'*R*. The natural tocotrienol has a 2*R*,3'*E*,7'*E* configuration. The tocopherols are diterpenoid natural products biosynthesized from a combination of four isoprenoid units; geranylgeranyl pyrophosphate is the key intermediate that leads to these compounds.

(+)- α -Tocopherol is about 1.36 times as effective as (\pm)- α -tocopherol in rat antisterility bioassays. As mentioned previously, (+)- α -tocopherol is the naturally occurring form of α -tocopherol with 2*R*,4'*R*,8'*R* configuration. (\pm)- α -Tocopherol is synthetic, and is called all-*rac*- α -tocopherol. The configuration at C² is critical and the Nutrition Board of the National Academy of Sciences, Institute of Medicine recognized in 2000 that 2*R*-forms of α -tocopherol meet the human requirements. β -Tocopherol is about half as active as α -tocopherol, and the γ - and δ -tocopherols are only 0.01 times as active as α -tocopherol.

The esters of tocopherol (e.g., acetate, propionate, and butyrate) are more active than the parent compound because of better bioavailability.⁸⁷ This is also true of the phosphoric acid ester of (\pm)- δ -tocopherol when it is administered

Figure 28.11 • Tocopherols and tocotrienols.

parenterally.⁸⁸ The ethers of the tocopherols are inactive, because unlike esters that are readily hydrolyzed to the active antioxidant chromanol form by esterases, ethers are relatively metabolically more stable and as such do not possess antioxidant property.

Oxidation of the tocopherols to their corresponding quinones also leads to inactive compounds. Replacement of the methyl groups on the chromanol ring by ethyl groups decreases activity. The introduction of a double bond in the 3,4-position of α -tocopherol reduces its activity by about two thirds. Reduction of the size of the long alkyl side chain or the introduction of double bonds in this side chain markedly reduces activity.

KINETICS

Bile salts and dietary lipids play critical roles in the absorption of vitamin E and their esters into intestinal epithelial cells through micellization. Pancreatic lipases facilitate the micellization of vitamin E as a consequence of hydrolysis of non-vitamin E lipids by forming mixed micells. The vitamin E esters (e.g., α -tocopherol acetate), on the other hand, require hydrolysis by the pancreatic lipases prior to micellization and uptake into the enterocytes. The uptake of vitamin E from the mixed micells is thought to be a passive diffusion process; however, the role of a scavenger receptor class B type I (SR-BI) has also been suggested.

The intracellular trafficking of vitamin E may involve its incorporation into chylomicrons. Both α - and γ -tocopherols are equally incorporated into chylomicrons, which are then secreted into the lymphatic system. An ATP-binding cassette, subfamily A, member 1 (ABCA1) transport protein-directed efflux of vitamin E from epithelial cells into HDL followed by direct transport into the portal vein has also been suggested as an important alternative pathway for vitamin E absorption. Dietary fats increase chylomicron-mediated absorption while a low-fat diet increases HDL-mediated absorption of vitamin E.⁸⁹ The absence of dietary

fat results in little absorption of vitamin E.⁹⁰ Despite a low-fat diet, high bioavailability was reported when vitamin E was added with emulsifier onto fortified breakfast cereal, suggestive of micellization as a critical factor for its absorption.⁹¹ No apparent differences in intestinal absorption of various forms of vitamin E (e.g., α - and γ -tocopherols or *RRR*- and *SRR*- α -tocopherols) have been observed.⁹² Overall, 20% to 80% of vitamin E is absorbed from the intestinal lumen into the bloodstream. The liver is an important storage site. γ -Tocopherol is secreted primarily into the bile while α -tocopherol enters the circulation, where it is found in much higher levels than γ -tocopherol, even though the latter predominates in the diet. This difference is attributed to a liver cytosolic binding protein, α -tocopherol transfer protein (α -TTP) that is selective for α -tocopherol.

The tocopherols in lymph are associated with chylomicrons and VLDLs. Circulating tocopherols are also carried by α -TTP, which preferentially incorporates them into blood low-density lipoproteins (LDLs). The tocopherols are readily and reversibly bound to most tissues, including adipose tissue, and the vitamin is thus stored. The vitamin is concentrated in membrane structures, such as mitochondria, endoplasmic reticulum, and nuclear and plasma membranes.

Although “Simon metabolites” (tocopheronic acid and its γ -lactone) were first identified as the primary vitamin E metabolites by *in vitro* sample oxidation, the biologically relevant are the 2-carboxyethyl-6-hydroxychroman (CEHC) products (Fig. 28.12). Thus α -, β -, γ -, and δ -CEHCs are identified as metabolites of the respective tocopherols. The terminal methyl group is oxidized to a carboxylic acid and shortened by several steps of β -oxidation to produce CEHC. The CEHC metabolites undergo glucuronide and sulfate conjugations, and most of the CEHC metabolites are found in urine as these conjugates. These metabolites are also excreted in the bile and vitamin E may undergo some enterohepatic circulation.⁹²

BIOCHEMISTRY

For decades, there has been significant interest in investigating the biochemical functions of vitamin E, but it is still difficult to explain many of the biochemical derangements caused by vitamin E deficiency in animals. There seems to be general agreement that one of the primary metabolic

Figure 28.12 • Vitamin E metabolites.

Figure 28.13 • Antioxidant mechanisms of α - and γ -tocopherols. (R_1 , H, or CH_3 ; R_2 , Phytyl.)

functions of the vitamin is preventing the oxidation of lipids, particularly unsaturated fatty acids. Through this antioxidant effect, α -tocopherol plays an important role in protecting cell membranes made of lipids and LDLs. The α -tocopherol donates its electrons to the free radicals to neutralize them, thus protecting the cellular lipids from oxidative damage. In this process, α -tocopherol loses its antioxidant capacity by forming the α -tocopherol radical (Fig. 28.13). It is generally accepted that other antioxidants like vitamin C or glutathione can restore vitamin E from its single electron oxidation state, tocopherol radical. Although several reports suggested that once it is fully oxidized to the tocoquinone form, it will not be regenerated back to vitamin E, reports are also available showing that it can be regenerated back in presence of glutathione according to the mechanism shown in Figure 28.14.^{93,94}

Figure 28.14 • Interconversion of α -tocopherol and α -tocopherol quinone.

Because of the methylation level, which enhances the nucleophilicity and reactivity of the 6-OH group, the α -isoforms of both tocopherol and tocotrienol are the most potent antioxidants among all the vitamin E family. Although α -tocotrienol is believed to be a more potent antioxidant than the α -tocopherol for many factors (e.g., higher recycling efficiency, more uniform distribution within the microsomal membrane bilayer and more efficient interaction with lipid free radicals) misleading results have been demonstrated because of the high affinity of α -TTP for α -tocopherol. α -Tocopherol is biologically the most important isoform because of its high affinity for α -TTP, which results in high bioavailability and bioactivity.⁹⁵

Biochemical functions of the vitamin E family are diverse and may include actions other than their well-documented antioxidant activities. α -Tocopherol not only strongly inhibits platelet and other cell adhesion but also inhibits cell proliferation, protein kinase C, 5-lipoxygenase, and phospholipase A₂ and activates protein phosphatase 2A and diacylglycerol kinase, which are unrelated to its antioxidant activity. These actions reflect the specific interactions of α -tocopherol with enzymes, structural proteins, lipids, and transcription factors. γ -Tocopherol and CEHC metabolic products of vitamin E exhibit many other functions including anti-inflammatory, anti-neoplastic, natriuretic, and also cardioprotective functions.⁹⁶

During the last 5 years, interest in the action of tocotrienols has increased with the inclusion of a substantial amount of vitamin E research directed toward that of α -tocotrienol. Numerous unique biochemical functions of α -tocotrienol have been discovered that include prevention of inducible neurodegeneration by regulating specific mediators of cell death, hypocholesterolemic effects by suppressing 3-hydroxy-3-methyl-glutaryl-CoA (HMG-CoA) reductase activity, and protection against stroke. It has also been reported that tocotrienols, but not tocopherols, suppress the growth of breast cancer cells.⁹⁶

The diseases caused by vitamin E deficiency in animals are not well correlated with that in human. The sterility in rats and nutritional muscular dystrophies in other lower animal including monkeys, rabbits, lambs, and chicks are well documented. Reversible neurological disorders in humans and hemolytic anemia in premature infants because of vitamin E deficiency have been seen.

The antioxidant function does not explain all the biochemical abnormalities caused by vitamin E deficiency. Moreover, vitamin E is not the only *in vivo* antioxidant. Two enzyme systems, glutathione reductase and *o*-phenylenediamine peroxidase, also function in this capacity.⁹⁷ It has been postulated that vitamin E has a role in the regulation of protein synthesis. Other actions of this vitamin have also been investigated, for example, effects on muscle creatine kinase and liver xanthine oxidase. Vitamin E deficiency leads to an increase in the turnover of creatine kinase. Vitamin E-deficient animals also exhibit increased liver xanthine oxidase activity, which is because of increased *de novo* synthesis.⁹⁷

Although it has been difficult to establish clinical correlates of vitamin E deficiency in humans, Bieri and Farrell⁹⁷ have summarized some useful generalizations and conclusions. These workers noted that the infant, especially the premature infant, is susceptible to tocopherol deficiency because of ineffective transfer of the vitamin from placenta to fetus and that growth in infants requires greater availability of the vitamin. In adults, the tocopherol storage depots provide adequate availability that is not readily depleted, but intestinal malabsorption syndromes, when persistent, can lead to depletion of the storage depots. Children with cystic fibrosis suffer from severe vitamin E deficiency caused by malabsorption. Tropical sprue, celiac disease, gastrointestinal resections, hepatic cirrhosis, biliary obstruction, and excessive ingestion of mineral oil may also cause long-term malabsorption.

THERAPEUTIC USES

Vitamin E is used in the treatment of known or suspected vitamin E deficiency. The use of vitamin E to prevent or treat a wide variety of diseases has been examined quite extensively and in some cases has been found to be of some benefit, although the effect is frequently minimal. Vitamin E may help in Alzheimer disease, dysmenorrhea, nonalcoholic fatty liver, and tardive dyskinesias, to name a few. However, in most cases, and especially for common diseases, there is often no proven benefit or the studies are contradictory.

Vitamin E has been extensively studied for the prevention of cardiovascular disease, but evidence against any benefit continues to accumulate.^{44,98} Indeed, some studies show that vitamin E supplementation may actually increase stroke risk⁹⁸ or all cause mortality.⁵⁵ It has also been suggested that megadoses of tocopherol be used in the treatment of peripheral vascular disease. Although some studies support this proposal, experts in the field state that further clinical studies are necessary to make a definitive recommendation. Nevertheless, it continues to be popular and controversial to consider the beneficial effects, and investigations of megavitamin E therapy for cardiovascular disease continue to appear in the literature.⁹⁷

The failure to demonstrate the protective effects against heart diseases by vitamin E supplements may be because they contain only α -tocopherol. To effectively remove the

Figure 28.15 • α -Tocopheryl succinate.

peroxide damage in these cells by electrophilic peroxy-nitrites or other mutagens, γ -tocopherol is also needed that, in addition to forming the orthoquinone, acts *in vivo* as a trap for these membrane-soluble electrophilic mutagens forming stable adducts through the nucleophilic C⁵, which is blocked in α -tocopherol (Fig. 28.13). It has been suggested that because α -tocopherol supplementation suppresses γ -tocopherol levels, a combination of the two tocopherols in the ratios found in the diet may be more useful than α -tocopherol, alone.⁹⁹

The well-documented antioxidant property of the tocopherols led to their examination for anticancer activity without any consistent success;^{43,100} although some studies have shown a reduction in prostate cancer in smokers.⁴⁴ It is interesting that the ethers (RO-), esters (RCOO-), and amides (RCONH-) at C⁶ of the chromanol ring (α -tocopheryl succinate ester is the prototype, Fig. 28.15) have shown to be potent antineoplastic agents. The antineoplastic potency of the tocopherol analogs is not related to their antioxidant property, which was proven by synthesizing a series of “redox-silent” analogs and testing them against various neoplastic cell lines. The detailed molecular biology studies revealed that these are mainly mitocans (mitochondrially targeted anticancer drugs) that selectively destabilize the mitochondria in malignant cells and suppressed cancer in preclinical models. Although they are fully recognized as potent anticancer agents, detailed clinical studies for their therapeutic application are yet to be completed.¹⁰¹

HYPERVITAMINOSIS

Vitamin E used in high doses, as high as 3,200 mg/day, has a proven record of safety.⁴⁷ Various reports, many single case reports, or uncontrolled studies have suggested adverse effects such as interference with clotting, weakness, decreased thyroid hormone levels, and gastrointestinal upset. The importance of these is unknown. The only notable adverse effects have occurred in premature infants given large doses of this vitamin. Hepatotoxicities have been seen in premature infants of less than 1,500 g birth weight given vitamin E intravenously, and the incidence of necrotizing enterocolitis and sepsis increased under similar conditions following oral or intravenous (IV) dosing.

PRODUCTS

Vitamin E is available from numerous sources as oral capsules, liquids, and tablets under various names. Vitamin E is also available as a component of numerous multivitamin preparations. The forms of vitamin E used in these products are shown in Table 28.8. Vitamin E activity is currently expressed in terms of the (+)- α -tocopherol equivalents based on the former *USP* units and mass. One former *USP* unit is equal to one former IU.

TABLE 28.8 Relative Potencies of Various Commercial Forms of Vitamin E

Form of Vitamin E	Potency
Potency (in former <i>USP</i> units) of 1 mg	
(±)- α -Tocopherol	1.1
(±)- α -Tocopherol acetate	1
(±)- α -Tocopherol acid succinate	0.89
(+)- α -Tocopherol	1.49
(+)- α -Tocopherol acetate	1.36
(+)- α -Tocopherol acid succinate	1.21

Vitamin K

Lipid-free diet research by Henrik Dam¹⁰² starting in 1929 and culminating in 1935¹⁰³ resulted in the discovery of an antihemorrhagic factor that Dam named *vitamin K* (from the German word *Koagulation*). Along with the work of Edward A. Doisy, the structure of vitamin K was determined in 1939¹⁰⁴ and synthesis accomplished in 1965.¹⁰⁵ For their work, Dam and Doisy shared the 1943 Nobel Prize in Medicine. Originally, the term vitamin K was applied to the vitamin isolated from alfalfa, and a similar principle from putrified fish meal was named *vitamin K₂*. The original vitamin K was thereafter referred to as vitamin *K₁*. In 1960, IUPAC recommended the terms phyloquinone for vitamin *K₁* with the official abbreviation of "K" and menaquinone for the originally isolated vitamin *K₂*.¹⁰⁶ Several compounds chemically related to vitamin *K₂*, differing only in the number of 5-carbon prenyl (isoprenoid) units attached, were subsequently discovered, and in 1973, IUPAC adopted the term *menaquinones* (MK) to refer to this group of substances.¹⁰⁷ The menaquinones differ in the number of prenyl units attached and specific compounds are designated menaquinone-*n* (MK-*n*) where *n* represents the number of prenyl side chains. The original vitamin *K₂* is now known as MK-6. For this discussion, the term vitamin K will be used to denote both phyloquinone and menaquinones when appropriate. Also of note, the *USP* generic name for phyloquinone in pharmaceutical preparations is phytonadione, and this is the preferred term among medical practitioners. Throughout this text, these two terms will be used in their best context.

Naturally occurring vitamin K is found in two forms depending on whether the source is plants or bacteria. Plants produce phyloquinone whereas bacteria produce

menaquinones. Dietary sources from plants include leafy green vegetables; such as collard greens, spinach, and salad greens; soy and canola oils; and margarine. Broccoli, brussels sprouts, cabbage, and olive oil also contain appreciable quantities. The major bacterial source is the intestinal flora, especially Gram-positive organisms; however, their contribution to overall vitamin K intake is unknown.

CHEMISTRY

Chemically, all vitamin Ks are 2-methyl 1,4-naphthoquinone derivatives containing variable aliphatic side chains at C³. Phyloquinone (Fig. 28.16) invariably contains a phytyl side chain. Menaquinones (Fig. 28.17) are a series of compounds that have a longer side chain with more unsaturation. This side chain may be composed of 1 to 13 prenyl (isoprenyl) units.

Many other closely related compounds possess vitamin K activity. Of particular historical note are the water-soluble menadione (2-methyl-1,4-naphthoquinone; vitamin *K₃*), which is no longer marketed because of toxicities, and menadiol (2-methylnaphthalene-1,4-diol; vitamin *K₄*). Menadione contains the naphthoquinone ring without any attached prenyls and can be thought of as MK-0 (see Fig. 28.17). Menadiol is menadione with the two keto groups reduced to hydroxyls. Both compounds are bioactivated to the active form through alkylation. Phyloquinone naturally occurs as a *trans*-isomer and has an *R,R,E* configuration. The synthetic, commercially available form is a mixture of *cis*- and *trans*-isomers, with no more than 20% *cis*.

KINETICS

Phyloquinone is absorbed in the proximal intestine¹⁰⁸ via the same pathway used for dietary lipids, requiring bile salts, dietary fat, and pancreatic juice. The extent of absorption depends on the dietary source. Pharmaceutical preparations of purified phyloquinone may have bioavailabilities as high as 80%, whereas the bioavailability from plant sources, although rich in phyloquinone, may be lower than 10%.¹⁰⁹ This is thought to be because of the inefficiency in extracting the vitamin K from the plant cells during the digestive process. Still, these plant sources are likely the most important natural source of vitamin K in the diet. An additional source of vitamin K is the menaquinones, which are synthesized by the gut flora. These are likely absorbed from the ileum similar to phyloquinone. The contribution to

Naphthoquinone

Naphthoquinone

Figure 28.17 • Menaquinone general structure. Menaquinone-4 ($n = 4$) and menaquinone-6 ($n = 6$) are the most common forms.

overall dietary intake is unresolved¹¹⁰ but these help explain the high level of vitamin K activity in feces.

Following absorption by the enterocytes, and similar to other dietary fats, phylloquinone and menaquinones are found in the newly formed chylomicrons, which are released into the lymph and bloodstream. The primary form of circulating vitamin K activity is phylloquinone. Conversion of the chylomicrons into chylomicron remnants and their subsequent association with apolipoprotein E result in receptor-mediated uptake by cells through pinocytosis. Historically, phylloquinone uptake by hepatic cells was thought to be the predominant process; however, it is now recognized that uptake by osteoblast precursor cells also occurs and explains the ultimate delivery to osteoblasts inside bone tissue.¹¹¹ Approximately 90% of the vitamin K found in the liver is in the form of menaquinones and the remainder is phylloquinone.¹¹⁰ In contrast to other fat-soluble vitamins, no significant storage occurs. The major urinary metabolites are glucuronide conjugates of carboxylic acids derived from shortening of the side chain.

BIOCHEMISTRY

The accepted mechanism for vitamin K is to function as a cofactor in the posttranslational synthesis of γ -carboxyglutamic acid (Gla) from glutamic acid (Glu) residues.¹¹² The discovery of Gla in 1974^{113,114} clarified the mechanism of vitamin K and led to the identification of additional vitamin K-dependent proteins. All vitamin K-dependent proteins contain propeptide possessing Glu residues. Vitamin K participates in the carboxylation of several specific Glu residues to form Gla residues, which function as Ca^{+2} -binding sites on the vitamin K-dependent proteins (see Fig. 28.18). Further, the Gla residues are found in essentially the same region, near the amino terminus, and this region is called the *Gla domain*.¹¹⁵ Of the 14 known vitamin K-dependent proteins, four function as procoagulants, three function as anticoagulants, two are involved in bone and extracellular matrix homeostasis, one in cell proliferation, and four represent transmembrane proteins whose function has not been identified. All of these proteins have considerable structural homology. All contain 10 to 12 Gla residues, which are important for their proper activity.¹¹⁶ For example, prothrombin has 10 Gla residues; loss of just two residues decreases its coagulation activity by 80%.

This synthesis of Gla residues from Glu residues requires reduced vitamin K (a hydroquinone, KH_2), carbon dioxide, and molecular oxygen. Although the reaction does not require ATP, it uses the energy from the oxidation of KH_2 to execute the carboxylation of glutamic acid.¹¹⁷ The enzyme, γ -glutamyl carboxylase (GGCX; EC 6.4.-.-), must

create a carbanion by extracting a proton from the glutamate γ -carbon. This requires a base with a pK_a of 26 to 28. The anion of the hydroquinone, however, has a pK_a of only about 9.

A proposed mechanism (Fig. 28.19) for this carboxylation creates such a base from vitamin K.^{118,119} Vitamin K is reduced to its hydroquinone form (vitamin KH_2). Molecular oxygen is incorporated into the conjugate acid form of vitamin KH_2 to form a peroxy anion, which subsequently forms a dioxetane intermediate. The peroxy bond is cleaved by the adjacent enolate anion to produce an intermediate sufficiently basic to deprotonate the α -carbon. Extraction of the proton allows the carboxylase to carboxylate the Glu residue. The vitamin K intermediate is converted to vitamin K oxide, which must be reduced back to vitamin K. Vitamin K oxide is recycled back to vitamin K by vitamin K-epoxide reductase (VKOR; EC 1.1.4.1) and NAD(P)H dehydrogenase (quinone) (EC 1.6.5.2), also known as vitamin K reductase. Both of these enzymes are dithiol dependent and are inhibited by the 4-hydroxycoumarin anticoagulants such as warfarin.

Historically, the most well-known function of vitamin K is in the formation of four of the procoagulation factors, specifically factors VII, IX, X, and prothrombin. The Gla residues function as Ca^{2+} ion bridges linking the blood-clotting protein to phospholipids on endothelial cells and platelets. Binding to membrane surfaces is critical in the activation of these proteins.¹²⁰ Prothrombin and factors VII, IX, and X participate in the cascade of reactions leading to fibrin clot formation.

Vitamin K in mammals also maintains adequate levels of the vitamin K-dependent proteins C (PROC), S (PROS1), and Z (PROZ), which have anticoagulant activity. PROC exerts its anticoagulant effect by inactivating activated factors V_a and VIII_a .¹²¹ PROC is first activated by prothrombin. This activation requires a cell surface receptor, thrombomodulin (THBD), and also Ca^{2+} and PROS1. PROC also increases fibrinolysis by inactivating the major inhibitor of tissue plasminogen activator.¹²² PROS1 is found in the plasma and is bound to complement component 4 binding protein, alpha (C4BPA) and functions as a cofactor in the PROC inactivation of activated factor V_a . PROS1 also acts as a cofactor in the downregulation of factor X activation.¹²³ PROZ binds to serpin peptidase inhibitor, clade A (alpha-1 antiproteinase, antitrypsin), member 10 (SERPINA10) and downregulates coagulation by inhibiting activated factor X_a .¹²⁴

There are two vitamin K-dependent proteins involved in bone structure, bone Gla protein (BGLAP, osteocalcin) and matrix Gla protein (MGP). BGLAP is present in the highest amounts in bone, dentin, and other mineralized tissue and contains three Gla residues. MGP is found in bone

Figure 28.18 • Calcium binding to Gla residues on vitamin K-dependent proteins.

Figure 28.19 • The vitamin K cycle showing its role in γ -carboxylation of glutamate by GG CX. (R, phytyl side chain.)

and cartilage, but is probably widely distributed in the body, and contains five Gla residues.¹²⁵ Both of these are important in regulating bone mineralization, in conjunction with vitamin D, calcium and other hormones. Specifically, vitamin D increases the synthesis of BGLAP propeptide whereas vitamin K is required for its activation through formation of Gla residues. Deficiency of vitamin K or the use of vitamin K antagonists, such as warfarin, can result in mineral loss and bone malformation. Although maintenance of adequate vitamin K intake is important for bone maintenance, high doses of vitamin K may not lead to remineralization. It is important to note that proper maintenance of bone structure is multifaceted with at least two key vitamins, K and D, involved and several other factors. Studies of individual vitamins and their role in bone health may be misleading because increasing intake of a single vitamin may not be sufficient to offset deficiencies in other biomolecules involved in overall bone homeostasis. The promotion of bone formation by vitamin K₂ is not solely mediated through its action on Gla proteins; however, it can also directly stimulate messenger ribonucleic acid (mRNA) production of osteoblast mRNA markers and regulate transcription of bone-specific genes.¹²⁶

Another vitamin K-dependent Gla protein, growth arrest-specific 6 (GAS6), was the most recently discovered which contains 10 to 11 Gla residues.¹²⁷ GAS6 is a protein initially found to increase approximately 30-fold during the G₀ phase of the cell cycle suggesting a role in cell proliferation. Several biological roles related to this function have been elucidated since then, including effects on apoptosis,

immune function, inflammation, and cell differentiation, among others.¹²⁸ Of particular interest is the possible role in diabetic nephropathy.¹²⁹ Current studies are underway to define the function of this protein, with particular interest in the possible role in cancer. Early evidence indicates a possibility of the menaquinones in decreasing the occurrence of hepatocellular carcinoma.¹³⁰ The menaquinone analog, menatetrenone, has also been shown to reduce the recurrence rate of hepatocellular carcinoma.¹³¹ This work may ultimately lead to an understanding of any value that vitamin K may have in the prevention or treatment of other cancers.

The latest Gla-containing proteins with unknown functions have wide tissue distribution and are rich in proline residues; thus they have been named proline rich Gla 1 (PRRG1) and proline rich Gla 2 (PRRG2)¹³² and transmembrane Gla proteins 3 and 4 (TGP3 and TGP4).¹³³

Vitamin K deficiency typically results in an increased clotting time and hemorrhagic disorders. This can manifest as easy bruising, continual bleeding from puncture wounds, mucosal hemorrhage such as gastrointestinal or urinary tract bleeding and intracranial hemorrhaging can occur in infants. Dietary deficiency of vitamin K is rare; most cases are caused by decreased absorption (e.g., intestinal polyposis, chronic ulcerative colitis, intestinal fistula, intestinal obstruction, and sprue), liver disease (e.g., atrophy, cirrhosis, or chronic hepatitis), or biliary disease (e.g., obstructive jaundice, biliary fistulas, insufficient or abnormal bile). Vitamin K deficiency can also lead to decreased bone mineralization.

THERAPEUTIC USES

Phytonadione is indicated in the treatment of known or suspected vitamin K deficiency that may result from dietary deficiency, malabsorption, hepatic, or biliary disease. Phytonadione is also used in the prophylactic treatment of vitamin K deficiency bleeding (VKDB) of the newborn, previously known as hemorrhagic disease of the newborn. In the average infant, the birth values of prothrombin content are adequate, but during the first few days of life, they appear to fall rapidly, even dangerously low, and then slowly recover spontaneously. This transition period was and is critical because of the numerous sites of hemorrhagic manifestations, traumatic or spontaneous, that may prove serious, if not fatal. Several controversial studies linked IM phytonadione administration to newborns with an increased risk of the development of childhood cancer. However, the current position of the American Academy of Pediatrics (AAP) is that these studies were flawed and later large-scale studies showed no association. Therefore, the 2003 policy statement of the AAP recommended 0.5 mg to 1 mg of vitamin K₁ (phytonadione) intramuscularly at birth as a prophylactic measure.¹³⁴ This was reaffirmed in 2006.¹³⁵

Phytonadione, or other vitamin K products, should not be administered to patients receiving coumarin anticoagulants, such as warfarin, during routine therapy as these can antagonize their effects. However, phytonadione is indicated in the treatment of overdoses of vitamin K–epoxide reductase inhibitors, such as warfarin, or other drugs that can interfere with vitamin K utilization in the clotting process. Of particular note is the requirement in this one use for an active form of vitamin K. Specifically, the only marketed product is phytonadione. Inactive forms, such as menadiol, are not bioactivated with sufficient rapidity to be used as antidotes in this situation. Finally, vitamin K may also have some utility in preventing bone loss as is seen in osteoporosis.¹²⁵

HYPERVITAMINOSIS

Phytonadione is considered relatively nontoxic even at high doses. Rare cases of hemolytic anemia have been reported, and the manufacturer has reported anaphylactic reactions following use of the injectable product. Menadiol is also considered relatively nontoxic. Menadione, in contrast, can produce hemolytic anemia, hyperbilirubinemia, and kernicterus in newborns, especially premature infants. In addition, menadione can cause hemolytic anemia in patients with glucose-6-phosphate dehydrogenase deficiency.⁴⁵ For these reasons, it is no longer marketed in the United States.

PRODUCTS

Phytonadione is available as oral tablets and capsules from numerous sources under various names. A popular prescription product for oral tablets is Mephyton. Phytonadione is also available as an injectable for IM use. It is also available in numerous multivitamin preparations under various names. Menadiol is also available in some markets.

WATER-SOLUBLE VITAMINS

Although the water-soluble vitamins are structurally diverse, they are put in a general class to distinguish them from the

lipid-soluble vitamins. This class includes the B-complex vitamins and ascorbic acid (vitamin C). The term *B-complex* refers to combinations including all eight B vitamins: thiamine (B₁), riboflavin (B₂), niacin (B₃), pantothenic acid (B₅), pyridoxine (B₆), biotin (B₇), folic acid (B₉), and cyanocobalamin (B₁₂). Dietary deficiencies of any of the B vitamins commonly are complicated by deficiencies of other members of the group, so treatment with B-complex preparations is usually indicated.

Vitamin B₁

Thiamine, the preferred name for vitamin B₁, holds a prominent place in the history of vitamin discovery because beriberi, the disease resulting from insufficient thiamine intake, was one of the earliest recognized deficiency diseases. Its relationship to polyneuritis in birds was noted in the early work of Funk,³ and his work with pigeons led to the discovery that a water-soluble substance in rice polishings was curative. The early designation of water-soluble B was replaced with vitamin B by Drummond¹¹ when suggesting the use of *vitamin* instead of *vitamine*. Complicating early animal studies was the inconsistency in the deficiency syndromes observed by the various investigators. Early work on vitamin B using crude extracts showed that this vitamin also had growth-promoting properties in rats fed vitamin B–deficient diets. In addition, vitamin B–deficient diets could also result in dermatitis, which at that time appeared similar to human pellagra. Oftentimes, the source used for vitamin B and the animal model studied determined the experimental results observed.

The antineuritic water-soluble B vitamin that cured polyneuritis in birds and the growth-promoting water-soluble B vitamin were proposed to be two different vitamins by Emmett and Luros¹³⁶ in 1920. This was later confirmed by other investigators.¹³⁷ In 1927, the British Accessory Food Factors Committee recommended vitamin B₁ for the antineuritic water-soluble B and vitamin B₂ for the growth-promoting, also called the antipellegra, water-soluble B. The American Society of Biological Chemists recommended the name vitamin B for the antineuritic factor and vitamin G for the growth-promoting factor. Eventually, the British system became the standard. In 1960, the IUPAC Commission on the Nomenclature of Biological Chemistry¹⁰⁶ adopted the name *thiamine*. In 1966, IUPAC¹³⁸ proposed the name *thiamin*, and in 2004, reverted once again to *thiamine* although *thiamin* is still in common use. Thiamine has also been referred to as aneurine.¹² The isolation of thiamine was elusive; however, it was finally isolated and crystallized from rice polishings by Jansen and Donath¹³⁹ in 1926. The structure and synthesis was published 10 years later in 1936.¹⁴⁰

One of the richest natural sources of thiamine is pork. Whole grain and whole-grain products, such as yeast, beans, and peas, are also excellent sources. Beef and chicken as well as some fish are also good sources. In developed countries, including the United States, fortified products, especially ready-to-eat cereals, are a significant dietary source of thiamine.

CHEMISTRY

The chemical structures of thiamine and its coenzyme form, thiamine diphosphate (ThDP), are shown in Figure 28.20. ThDP is composed of a diphosphate terminated side chain, a five-membered thiazolium ring, and a six-membered aminopyrimidine ring. Thiamine hydrochloride (Fig. 28.21),

Figure 28.20 • Thiamine and thiamine diphosphate.

a common form available for vitamin supplementation, is stable in acid but unstable in aqueous solutions with a pH above 5. Under these conditions, it undergoes decomposition of the thiazolium ring forming an inactive product (Fig. 28.22). Exposure of thiamine to air or to oxidizing agents such as hydrogen peroxide, permanganate, or alkaline potassium ferricyanide oxidizes it readily to thiochrome (Fig. 28.23). Thiochrome exhibits a vivid blue fluorescence; hence, this reaction is the basis for the quantitative fluorometric assay of thiamine in the *USP*.

KINETICS

ThDP, either from the diet or from production by the intestinal microflora of the colon, is hydrolyzed in the intestinal lumen to free thiamine. Movement of thiamine into and through cells is primarily through transport carriers because it has a quaternary nitrogen, which limits diffusion. Thiamine is transported into the intestinal enterocytes via the human thiamine transporters, (hTHTR)-1 and hTHTR-2.¹⁴¹ These transporters are now known as solute carrier family 19, member 2 (SLC19A2) and member 3 (SLC19A3), respectively, and are related to the reduced folate carrier (RFC) for folates, which is member 1 (SLC19A1). This carrier-mediated process is saturable at relatively low micromolar concentrations, and higher concentrations can be absorbed through passive diffusion.¹⁴² Once inside the cell, some thiamine is phosphorylated to form ThDP, and the rest is transported across the basolateral membrane into the blood where it freely distributes to other tissues. Phosphorylation of thi-

Figure 28.21 • Thiamine hydrochloride.

amine in the cell is thought to be the driving force behind the transport mechanism. Tissues requiring thiamine use SLC19A2 and SLC19A3 to transport thiamine into the cell where it is then phosphorylated. These same transporters also explain entry of thiamine into the CNS. Excess thiamine is readily excreted by the kidneys.

BIOCHEMISTRY

Thiamine is converted to the active ThDP by direct pyrophosphate transfer from ATP using thiamine diphosphokinase (EC 2.7.6.2), which is regulated through a riboswitch; a conformational transition in the RNA transcripts encoding the synthetic enzyme that is induced by the binding of the ThDP itself.¹⁴³ ThDP performs important metabolic functions by assisting in making or breaking bonds between carbon and sulfur, oxygen, hydrogen, nitrogen, and carbon. Thus, it plays the central role in several important anabolic and catabolic intermediary pathways (see Table 28.9), such as glycolysis, the citric acid cycle, and amino acid metabolism. Broadly all these enzymes are categorized as decarboxylase- or transferase-type enzymes based on their mechanism of action; all share certain mechanistic similarities as shown in Figure 28.24.¹⁴³

The whole catalytic cycle can be divided into three steps: activation, first half-reaction, and the second half-reaction. The C² carbon of ThDP is first activated by deprotonation forming a nucleophilic ylide. ThDP first tautomerizes into an unusual imino form, and the nitrogen atom of the imine then abstracts the proton. Overall, the conformation of ThDP is maintained by the enzymes so as to favor activation by positioning N^{4'} of the amino pyrimidine group in close proximity to the C² of the thiazolium ring. The first half-reaction involves nucleophilic attack on a substrate carbonyl cleaving the substrate (e.g., pyruvate for decarboxylase and a ketose sugar for transketolase) to release the first product—CO₂ for decarboxylases, and an aldose with two less carbons for transketolase—leaving behind an enamine complex. This is common to all types of ThDP-dependent enzymatic reactions. The second half-reaction is specialized for each category of ThDP-dependent enzyme, which involves the nucleophilic attack of the enamine intermediate on the incoming second substrate to release the final product. In case of pyruvate or paralogous decarboxylases, this second substrate is a proton producing an aldehyde and releasing the ThDP, whereas in the case of transketolase, this second substrate is an aldose sugar producing a ketose sugar with two more carbon atoms and releasing the ThDP.¹⁴³

Figure 28.22 • Alkaline decomposition of thiamine.

Figure 28.23 • Oxidation of thiamine to thiochrome.

TABLE 28.9 Thiamine Diphosphate–Dependent Enzymes

Enzyme	EC Number	Function
Pyruvate dehydrogenase (acetyl-transferring)	1.2.4.1	Glycolysis, gluconeogenesis, amino acid synthesis
Oxoglutarate dehydrogenase (succinyl-transferring)	1.2.4.2	Citric acid cycle (TCA cycle)
3-Methyl-2-oxobutanoate dehydrogenase (2-methylpropanoyl-transferring)	1.2.4.4	Valine, leucine, and isoleucine degradation
Transketolase	2.2.1.1	Pentose phosphate pathway
Branched-chain-2-oxoacid decarboxylase	4.1.1.72	Decarboxylation of α -keto acids

Figure 28.24 • Catalytic cycle of thiamine diphosphate.

All ThDP-dependent enzymes need a proton donor to initiate the first half-reaction and a proton acceptor to complete the second half-reaction. In most cases, the aminopyrimidine N^4 in concert with an invariant glutamate is the proton donor-acceptor in the first half-reaction, although there are no universally conserved residues for the second half-reaction, and differ according to the enzyme class.¹⁴³

In the decarboxylation of pyruvate, the coenzyme interacts with pyruvic acid to form the so-called active aldehyde. This active aldehyde intermediates then interacts with thioctic acid to form acetyl-thioctate, which is responsible for acetylating CoA-SH to form acetyl-CoA. In deficiency states, the oxidation of α -keto acids is decreased, resulting in increased pyruvate levels in the blood.

THERAPEUTIC USES

Thiamine, as the base or as the hydrochloride salt, is indicated in the treatment or prophylaxis of known or suspected thiamine deficiencies. Severe thiamine deficiency is called *beriberi*, which is very rare in developed countries. The most likely cause of thiamine deficiency in the United States is the result of chronic alcoholism, which leads to multiple vitamin deficiencies as a result of poor dietary intake. The major organs affected are the nervous system (dry beriberi), which manifests as neurological damage, the cardiovascular system (wet beriberi), which manifests as heart failure and edema, and the gastrointestinal tract. Thiamine administration reverses the gastrointestinal, cardiovascular, and neurological symptoms; however, if the deficiency has been severe or of prolonged duration, the neurological damage may be permanent. A severe form of neurological damage seen in alcoholics, Wernicke encephalopathy or Wernicke-Korsakoff syndrome, has a high fatality rate and requires immediate therapy with thiamine.

Very high doses of thiamine (30–90 mg/day) are required in the treatment of thiamine-responsive megaloblastic anemia (TRMA), which is a rare genetic disorder resulting from a single point mutation in the thiamine transporter gene.¹⁴⁴ Thiamine antagonists have been examined for their antineoplastic activity; however, there are no current treatments based on this strategy.

HYPERVITAMINOSIS

Thiamine doses of 5 mg/day for 4 to 5 weeks has resulted in headache, insomnia, irritability, increased heart rate, and weakness. In addition, thiamine can cause anaphylactic reactions following parenteral use.

PRODUCTS

Thiamine, as thiamine hydrochloride or thiamine mononitrate, is available from numerous sources as oral capsules, liquids, and tablets under various names. Thiamine hydrochloride is also available in injectable form. Thiamine is also available as a component of numerous multivitamin preparations. Thiamine mononitrate is more stable than the hydrochloride in the dry state and is less hygroscopic.

Vitamin B₂

The discovery of the vitamin we now call riboflavin developed from an early work with vitamin B before the knowledge that it was more than one vitamin. The reader is referred to the history of vitamin B₁ because the histories are identical

until the discovery that vitamin B was actually two vitamins leading to the designation of vitamin B₁ and vitamin B₂. The discovery of vitamin B₂ was also complicated by the inconsistent experimental results seen among researchers as they focused on the dermatological effects of vitamin B₂-deficient diets. The conflicting results were eventually found to be due, in part, to deficiencies in study animals not just of vitamin B₂, but also vitamin B₃ (niacin), the cause of human forms of pellagra, and/or vitamin B₆ (pyridoxine), another cause of dermatitis. Likewise, treatments with vitamin B₂ were inconsistent because the early sources of this vitamin contained other B vitamins. Vitamin B₂ was eventually isolated from egg whites in 1933¹⁴⁶ and produced synthetically in 1935.¹⁴⁷ The name *riboflavine* was officially accepted in 1960¹⁰⁶; although the term was in common use before then. In 1966, IUPAC¹³⁸ changed it to *riboflavin*, which is in common use today.

Riboflavin is synthesized by all green plants and by most bacteria and fungi. Therefore, riboflavin is found, at least in small amounts, in most foods. Foods that are naturally high in riboflavin include milk and other dairy products, meat, eggs, fatty fish, and dark green vegetables. Fortified cereals have become an important source of riboflavin in the western diet including the United States.

CHEMISTRY

Chemically, riboflavin is an *N*-glycoside of flavin, also known as lumichrome, and the sugar, ribitol (Fig. 28.25). Flavins are derived from the Latin word *flavus* for “yellow” because of the yellow color of its crystals and yellow fluorescence under UV light. Riboflavin is heat stable but easily degraded by light. Its systematic names are 7,8-dimethyl-10-ribitylisalloxazine and 7,8-dimethyl-10-(D-ribo-2,3,4,5-tetrahydroxypentyl)isalloxazine.

KINETICS

Dietary riboflavin must be liberated as free riboflavin prior to absorption; therefore, covalently bound forms are unavailable for absorption. Most dietary riboflavin is in the form of noncovalently bound coenzymes, primarily flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD), and free riboflavin is liberated following the action of the digestive enzymes. Riboflavin is absorbed in the upper ileum by an active, saturable carrier; although passive diffusion may also occur at high concentrations. The number of carriers appears to be regulated in direct proportion to the need for riboflavin. Following absorption, riboflavin is phosphorylated in the mucosal cell, which aids active transport through a trapping mechanism, followed by release of free riboflavin into the bloodstream.^{148,149}

Riboflavin is also synthesized by the microflora of the large intestine, and small amounts are absorbed by an active carrier present in the colonic cells. Excess riboflavin is excreted by the kidney, primarily unchanged, although small amounts may appear as metabolites. Fecal levels are usually high because of synthesis by the microflora of the colon and are not an indicator of increased excretion or decreased absorption.

BIOCHEMISTRY

Riboflavin is the precursor in the biosynthesis of the prosthetic groups of the coenzymes FMN and FAD as shown in

Figure 28.25 • Bioactivation of riboflavin to FMN and FAD.

Figure 28.25. FMN is actually named incorrectly because it is not a nucleotide. The metabolic functions of this vitamin involve these two enzyme cofactors, which participate in numerous, vital oxidation–reduction processes. FMN (riboflavin 5′-phosphate) is produced from the vitamin and ATP

by riboflavin kinase (EC 2.7.1.26). Amitriptyline, imipramine, and chlorpromazine can inhibit riboflavin kinase resulting in a functional riboflavin deficiency. FAD originates from an FMN and ATP reaction that involves reversible dinucleotide formation catalyzed by FAD synthetase (EC 2.7.7.2). FMN and FAD function in combination with many enzymes, often characterized as flavoproteins, as the prosthetic groups of their coenzymes and rarely as the actual coenzyme. In some instances, the FAD or FMN is found covalently bound to the enzyme.

Flavoproteins function under aerobic or anaerobic conditions as oxidases and dehydrogenases. Examples include glucose oxidase, xanthine oxidase, cytochrome reductase, and acyl-CoA dehydrogenase. The riboflavin moiety of the complex is considered a hydrogen-transporting agent functioning as a hydrogen acceptor. The hydrogen donors may be NADH, NADPH, or other suitable substrate. The isoalloxazine rings accept two hydrides stepwise to form the dihydroriboflavin derivative (Fig. 28.26).

THERAPEUTIC USES

Severe riboflavin deficiency is known as *ariboflavinosis*, and treatment or prevention of this condition is the only proven use of riboflavin. Ariboflavinosis is most commonly associated with multiple vitamin deficiency as a result of alcoholism in developed countries. Because of the large number of enzymes requiring riboflavin as a coenzyme, deficiencies can lead to a wide range of abnormalities. In adults seborrheic dermatitis, photophobia, peripheral neuropathy, anemia, and oropharyngeal changes including angular stomatitis, glossitis, and cheilosis, are often the first signs of riboflavin deficiency. In children, cessation of growth can also occur. As the deficiency progresses, more severe pathologies develop until death ensues. Riboflavin deficiency may also produce teratogenic effects and alter iron handling leading to anemia.¹⁵⁰

HYPERVITAMINOSIS

There are no known toxicities associated with large doses of riboflavin. This is most likely because of the capacity-limited uptake that, in the presence of high doses, down regulates, thereby limiting absorption from the intestines. Renal filtration and excretion of riboflavin can also increase significantly in the presence of high plasma levels.¹⁴⁹

PRODUCTS

Riboflavin or riboflavin 5′-monophosphate is available from numerous sources as oral capsules, liquids, and tablets under various names. Riboflavin is also available as a component of numerous multivitamin preparations.

Vitamin B₃

Vitamin B₃ was formerly called nicotinic acid; however, the term niacin is now preferred to avoid any confusion with the

Figure 28.26 • Oxidation and reduction of the isoalloxazine rings.

alkaloid, nicotine. Niacinamide, also known as nicotinamide, refers to the amide derivative of niacin that is equivalent in vitamin activity. Some texts use niacin to refer to nicotinic acid, niacinamide, and any derivatives with vitamin activity comparable to niacin. Furthermore, research and chemistry-based resources use the terms nicotinic acid and nicotinamide; whereas pharmacy resources use niacin and niacinamide. For example, enzyme nomenclature uses the former, whereas facts and comparisons uses the latter. This section uses each term in its best context.

The synthesis and structural identification of niacin actually predated its discovery as a vitamin. Niacin had been prepared from nicotine since at least 1898. Niacin had also been purified and identified in 1913 as a component of yeast and rice polishings by Funk¹⁵¹ in his quest to discover the vitamin later called thiamine. The discovery of niacin as a vitamin was complicated, as discussed under vitamin B₂, by the early misconception that animal forms of pellagra and the human form were caused by the same vitamin deficiency. Ultimately, it was the study of human pellagra and black tongue disease in dogs, also caused by niacin deficiency,¹⁵² that led to the discovery of niacin as a vitamin. In September of 1937, Elvehjem et al.¹⁵³ were the first to prove the link between niacin and black tongue disease in dogs. Clinical studies using niacin in human pellagra patients followed, and the first published report of success was in November of 1937.¹⁵⁴

Niacin can be synthesized by humans into its active forms, nicotinamide adenine dinucleotide (NAD⁺) and nicotinamide adenine dinucleotide phosphate (NADP⁺), from the amino acid, tryptophan. Consequently, and analogous to vitamin D, niacin is not a true vitamin by the classic definition of the term. However, because of inherent inefficiencies in the conversion, the use of dietary tryptophan as a replacement for niacin can result in tryptophan deficiency for protein synthesis. This results in a requirement for niacin in the diet as a vitamin or a diet abnormally high in tryptophan. To compensate for this conversion, the DRIs for niacin are expressed in niacin equivalents (NE) that allows for 60 mg of dietary tryptophan to equal 1-mg niacin. Niacin or niacin derived nucleotides can also be synthesized using aspartic acid in plants and microorganisms

Natural sources of niacin include meat (beef, pork, chicken, lamb), fish, and whole grains. As with other B vitamins, fortified ready-to-eat cereals are an important source in developed countries such as the United States.

CHEMISTRY

Niacin is chemically pyridine-3-carboxylic acid (Fig. 28.27). Its coenzyme forms are NADH/NAD⁺ or NADPH/NADP⁺ as shown in Figure 28.28.

KINETICS

Niacin appears in the diet in various forms.¹⁵⁵ Some niacin is relatively unavailable for absorption unless the

Figure 28.28 • Structures of niacin-derived cofactors.

food is treated in a manner that releases the niacin. For example, some grains (i.e., corn) may contain predominantly niacin esterified to polysaccharides or peptides, referred to as niacytin. This form has a relatively low bioavailability unless treated with alkali in cooking or processing. Coffee beans have a high niacin content in the form of trigonellin (1-methyl nicotinic acid) that is converted to niacin upon roasting. Most dietary niacin from natural sources is in the form of the nucleotide derivatives, NAD⁺ and NADP⁺, which are digested by NAD⁺ diphosphatase (EC 3.6.1.22), followed by hydrolases in the intestine to release nicotinamide. Free nicotinamide and niacin are absorbed through a facilitated diffusion process in the intestine.¹⁵⁶ At physiological doses, little niacin is excreted unchanged. Most is excreted as *N*-methylniacin or the glycine conjugate (nicotinuric acid). After administration of large doses, niacin can be found in the urine unchanged.

BIOCHEMISTRY

Niacin synthesis into the active cofactors, NAD⁺ and NADP⁺, is shown in Figure 28.29. Both niacin and niacinamide react with 5-phosphoribosyl-1-pyrophosphate (PRPP) to form the respective mononucleotide derivative, which then reacts with ATP to produce the corresponding dinucleotide product. For niacinamide, this is NAD⁺; however, for niacin this product is converted to NAD⁺ by transformation of the carboxyl of the nicotinic acid moiety to the amide using free ammonia. An alternative pathway is to use glutamine through NAD⁺ synthase (glutamine-hydrolysing) (EC 6.3.5.1); however, this pathway is slower and is most likely not as important. NADP⁺ is produced from NAD⁺ by ATP through kinase catalysis.

Figure 28.29 • Biosynthesis of NAD⁺ and NADP⁺ from niacin, nicotinamide, or tryptophan.

NAD⁺ and NADP⁺ are oxidizing coenzymes for many (>200) dehydrogenases. Some dehydrogenases require NAD⁺, others require NADP⁺, and some function with either. The generalized representation in Figure 28.30 illustrates the function of these coenzymes in metabolic oxidations and reductions. The abbreviation NAD⁺ emphasizes the electrophilicity of the pyridine C⁴ moiety (which is the center of reactivity), and the substrate designated could be a

Figure 28.30 • Generalized representation of the hydride transfer reaction.

primary or secondary alcohol. *Arrow a* in Figure 28.30 symbolizes the function of NAD⁺ as oxidant in the hydride transfer from the substrate to the coenzyme, forming NADH, reduced coenzyme. The hydroxyl of the substrate is visualized as undergoing deprotonation concertedly by either water or the pyridine nitrogen of NADH. *Arrow b* shows concerted formation of the carbonyl π -bond of the oxidation product. *Arrow c* symbolizes the reverse hydride transfer from reduced coenzyme, NADH, to the carbonyl carbon, and concertedly, as the carbonyl oxygen undergoes protonation, the reduction of the carbonyl group forms the corresponding alcohol. Thus, NAD⁺ and NADP⁺ are hydride acceptors, and NADH and NADPH are hydride donors. Although this is a simplistic representation, it shows the dynamism of the oxidation–reduction reactions effected by these coenzymes under appropriate dehydrogenase catalysis. Alternatively, the reduced coenzymes may be used in ATP production through the electron-transport system.

THERAPEUTIC USES

Niacin is used in the treatment of niacin deficiency, which is referred to as pellagra (from the Italian, *pelle* for “skin” and *agra* for “dry”). The major systems affected are the gastrointestinal tract (diarrhea, enteritis and stomatitis), the skin (dermatitis), and the CNS (generalized neurological deficits including dementia). Pellagra has become a rare condition in the United States and other countries that require or encourage enrichment of wheat flour or fortification of cereals with niacin. Because the nucleotide form can be synthesized *in vivo* from tryptophan, pellagra is most often seen in areas where the diet is deficient in both niacin and tryptophan. Typically, maize (corn)-based diets meet this criteria. Niacin deficiency can also result from diarrhea, cirrhosis, alcoholism, or Hartnup disease. It is interesting that niacin deficiency can also, rarely, result from vitamin B₆ deficiency (see Vitamin B₆ section).

Niacin, but not niacinamide, is also one of the few vitamins that are useful in the treatment of diseases unrelated to deficiencies. In 1955, Altschul et al.¹⁵⁷ reported that niacin doses of 1 to 4 g/day could lower serum cholesterol levels in humans. Currently, niacin doses of 2 to 4.5 g/day are used in the treatment of hypercholesterolemia and hypertriglyceridemia. Triglycerides, VLDL, and LDL are reduced; HDL is increased. The mechanisms underlying these effects have recently been reviewed.^{158,159}

HYPERVITAMINOSIS

Niacin, in doses that range above the DRI but below that required for dyslipidemias, is unlikely to produce adverse effects. However, adverse effects of niacin are seen when this vitamin is used at pharmacological doses above 1 g/day in the treatment of dyslipidemia. Notable adverse effects include flushing because of vasodilation; dermatological effects including dry skin, pruritus and hyperkeratosis; gastrointestinal effects including peptic ulcer, stomach pain, nausea, and diarrhea; elevations in serum uric acid and glucose (in Type 2 diabetics); and rare hepatotoxicity.^{159–161} Traditionally, hepatotoxicity has been more associated with the sustained release as compared to the immediate release formulations; however, recent analysis of niacin-ER adverse events suggests the opposite may be true for this formulation.¹⁶²

Of particular note is that niacinamide, even in high doses, is not effective in hyperlipidemias and only rarely produces the vascular, dermatological and hepatotoxicity associated with high doses of niacin. Even gastrointestinal upset is less common with niacinamide. For this reason, niacinamide would be the preferred form for vitamin supplementation, especially if taken in high doses.

PRODUCTS

Niacin is available, in immediate-release form, from numerous sources as oral capsules, liquids, and tablets under various names. Timed-release products of niacin are also available primarily for the treatment of hyperlipidemias. Niacin is also available as a fixed-dose combination with one of the HMG-CoA reductase inhibitors or *statin* antihyperlipidemics (Advicor, Simcor). Niacin is also available as a component of numerous multivitamin preparations. Niacinamide is available from numerous sources as oral capsules, liquids, and tablets under various names. Niacinamide is also available as a component of numerous multivitamin preparations.

Vitamin B₅

The first suggestion for the existence of vitamin B₅ came from Carter et al.¹⁶³ in 1930; although it was never characterized or isolated. In 1933, R. J. Williams¹⁶⁴ and his collaborators found a “growth determinant of universal occurrence” and named it, according to the authors, “*pantothenic acid*, the name being derived from the Greek, meaning *from everywhere*” (probably from the Greek *pantothēn*). Pantothenic acid, the preferred term, later became associated with the name *vitamin B₅*. The synthesis and structure were reported in 1940.¹⁶⁵ This vitamin is synthesized by most green plants and microorganisms. Excellent sources of the vitamin are liver, egg yolk, whole grains, and fortified ready-to-eat cereals. However, as the original name implies, many foods contain sufficient pantothenic acid to supply dietary needs.

CHEMISTRY

Chemically, pantothenic acid is considered to be a β -alanine derivative of the asymmetric pantoic acid and thus shows asymmetry (Fig. 28.31). Only the naturally occurring D(+)-stereoisomer (with *R* configuration) is biologically active and the L(–)-stereoisomer (with *S* configuration) is inactive. When its carboxylate functional group is attached through an amide linkage with β -mercaptoethylamine, it is known as pantetheine (also spelled *pantotheine*). The biologically active form of pantothenic acid, CoA, is formed when the terminal alcoholic function of pantetheine is attached to ADP 3'-phosphate as shown in Figure 28.32.

Figure 28.31 • Pantothenic acid.

Coenzyme A (CoA-SH)

Figure 28.32 • Coenzyme A structure.

KINETICS

Dietary pantothenic acid occurs primarily in the form of acyl proteins, CoA or pantotheine 4'-phosphate, which are converted into pantetheine in the intestinal lumen. Pantetheine is converted to pantothenic acid by pantetheine hydrolase (EC 3.5.1.92) also found in the intestinal lumen.¹⁶⁶ Enteric bacteria can also provide a source of CoA and pantetheine 4'-phosphate; however, the importance of this source is not known. Pantothenic acid is absorbed from the intestine, more in the jejunum than the ileum, through the sodium-dependent multivitamin transporter (SMVT), which also transports biotin and lipoic acid.^{141,148} This explains the ability of these three substances to competitively inhibit absorption of each other. The transporter is driven by the Na^+ gradient that exists from the extracellular fluid to the intracellular fluid, transporting 2 Na^+ for each monovalent anion of pantothenate, biotin, or lipoate.¹⁶⁷ In addition,

the inside-negative membrane potential may also act as a driving force because a net charge of +1 enters the cell. This same carrier is ubiquitous throughout bodily tissues and probably also accounts for cellular uptake from the blood. Conversion to the active form, acetyl-CoA, most likely occurs inside the cell.

BIOCHEMISTRY

The metabolic functions of pantothenic acid in human biochemistry are mediated through the synthesis of CoA (Fig. 28.33). Pantothenic acid is a structural component of CoA, which is necessary for many important metabolic processes. Pantothenic acid is incorporated into CoA by a series of five enzyme-catalyzed reactions. CoA is involved in the activation of fatty acids before β -oxidation, which requires ATP to form the respective fatty acyl-CoA derivatives. Pantothenic acid also participates in fatty acid β -oxidation in the final step, forming acetyl-CoA. Acetyl-CoA is also formed from pyruvate decarboxylation, in which CoA participates with thiamine diphosphate and lipoic acid, two other important coenzymes. Thiamine diphosphate is the actual decarboxylating coenzyme that functions with lipoic acid to form acetyldihydrolipoic acid from pyruvate decarboxylation. CoA then accepts the acetyl group from acetyldihydrolipoic acid to form acetyl-CoA. Acetyl-CoA is an acetyl donor in many processes and is the precursor in important biosyntheses (e.g., those of fatty acids, steroids, acyl proteins, porphyrins, and acetylcholine). CoA is also intimately involved in the growth of microorganisms, including those pathogenic to humans. This has led to the novel strategy of developing pantothenic acid analogs that selectively inhibit pantothenic acid utilization and/or

Figure 28.33 • Biosynthesis of coenzyme A.

biosynthesis in these organisms leading to antibacterial, antifungal, or antimalarial effects.¹⁶⁸

THERAPEUTIC USES

The only therapeutic indication for pantothenic acid is in treatment of a known or suspected deficiency of this vitamin. Because of the ubiquitous nature of pantothenic acid, deficiency states of this vitamin are only seen experimentally by use of synthetic diets devoid of the vitamin,¹⁶⁹ by use of the vitamin antagonist, ω -methylpantothenic, or both. In a 1991 review, Tahiliani and Beinlich¹⁷⁰ described that the most common symptoms associated with pantothenic acid deficiency were headache, fatigue, and a sensation of weakness. Sleep disturbances and gastrointestinal disturbances, among others, were also noted. The most likely setting for pantothenic acid deficiency is in the setting of alcoholism where a multiple vitamin deficiency exists confounding the exact role of the pantothenic acid deficiency as compared to the other vitamins. Because a deficiency of a single B vitamin is rare, pantothenic acid is commonly formulated in multivitamin or B-complex preparations.

HYPERVITAMINOSIS

Pantothenic acid is considered to be relatively safe. Doses of 10 to 20 g/day have caused diarrhea and water retention.¹⁶¹

PRODUCTS

Pantothenic acid is available from numerous sources as oral capsules, liquids, and tablets under various names. The calcium salt of pantothenic acid or the alcohol derivative pantothenol is commonly used in pharmaceutical preparations because it is more stable than the parent compound. Pantothenic acid, or one of its derivative or salt forms, is also available as a component of numerous multivitamin preparations.

Vitamin B₆

The discovery of vitamin B₆ is generally ascribed to Paul György¹⁷¹ who first realized there was a vitamin that was distinctly different from vitamin B₂ in 1934. Four years later (1938), Lepkovsky¹⁷² was the first to report the isolation of vitamin B₆ in crystalline form although others, including György, followed by just a few months.^{173,174} The structure^{175,176} and synthesis¹⁷⁷ were published simultaneously in 1939. György¹⁷⁸ proposed the term *pyridoxin*, derived from two of the chemical constituents, *pyrid* of pyridine and *oxo* of methoxy, as a name for the new vitamin in 1939, but *pyridoxine* came into general use thereafter. Other active forms of vitamin B₆ were found,¹⁷⁹ and in 1960, IUPAC¹⁰⁶ used the descriptor *pyridoxine* to refer to all "naturally occurring pyridine derivatives with vitamin B₆ activity." IUPAC¹⁸⁰ terminology was again revised in 1973, and the term *vitamin B₆*, instead of pyridoxine, is the approved generic descriptor for all active forms of the vitamin. *Pyridoxine* is used specifically to refer to 4,5-bis(hydroxymethyl)-2-methylpyridin-3-ol. The term *pyridoxol* is no longer recommended. All active forms of vitamin B₆ and their recommended names are shown in Figure 28.34, along with their interconversions.

Pyridoxine is naturally found in whole grains, meat, poultry, cereals, peanuts, corn, and fish. However, up to 40% of the vitamin may be destroyed during cooking. Food sources

contain all three forms, either in their free form or phosphorylated. Plants contain primarily pyridoxine and pyridoxamine, whereas animal sources provide chiefly pyridoxal.

CHEMISTRY

Pyridoxine (PN) is the C⁴ hydroxymethyl derivative, pyridoxal (PL) is the C⁴ formyl derivative and pyridoxamine (PM) is the C⁴ aminomethyl derivative of 5-(hydroxymethyl)-2-methylpyridin-3-ol). Each of these are also converted to their corresponding 5'-phosphate derivatives referred to as pyridoxine 5'-phosphate (PNP), pyridoxal 5'-phosphate (PLP), and pyridoxamine 5'-phosphate (PMP), respectively (see Fig. 28.34). Because of their ability to interconvert, all are considered active forms of vitamin B₆ in vivo. Although PLP is the major coenzyme form, PMP can also function as a coenzyme primarily in aminotransferases. The major metabolite is 4-pyridoxic acid, which is excreted in the urine.

KINETICS

PNP, PLP, and PMP are enzymatically hydrolyzed in the small intestine to PN, PL, and PM prior to absorption. The intestinal absorption of dietary vitamin B₆, in the form of PN, PL, and PM, has historically been ascribed to passive diffusion.¹⁸¹ Recent evidence suggests that a carrier-mediated process may also be involved.¹⁸² One additional form of vitamin B₆, pyridoxine-5'- β -D-glucoside (Fig. 28.35), is the predominate form in some plants (grains, fruits, and vegetables), and this form has a significantly lower bioavailability than other forms because of incomplete hydrolysis of the glycosidic bond in the intestines.

In the liver, all three forms are interconverted; however, the major form of vitamin B₆ in the liver is PLP.¹⁸¹ PLP (60%), PN (15%), and PL (14%) circulate in the blood bound to albumin. Vitamin B₆ traverses cell membranes, upon entry or exit, only in the dephosphorylated form. Plasma alkaline phosphatase (EC 3.1.3.1) is responsible for the removal of the phosphate group prior to cellular uptake from the blood.¹⁸³ Upon cellular entry via facilitated transport, phosphorylation acts to trap the vitamin and drive the overall process of cellular uptake.¹⁸⁴ Total body stores of vitamin B₆ approximate 170 mg with 75% to 80% found in muscle, primarily as phosphorylase (EC 2.4.1.1), and 5% to 10% in the liver¹⁸⁵ with the remaining portion distributed among the remaining tissues. The muscle pool is thought to be very stable, relatively unavailable to other tissues and highly conserved during deficient intake. Therefore, deficiency of this vitamin is more likely to affect tissues other than muscle, especially newly formed tissues.¹⁸⁵ Excess vitamin B₆ is eventually converted to PL, which is oxidized to 4-pyridoxic acid. This acid is the primary form found in the urine, accounting for essentially all excess dietary vitamin B₆.

BIOCHEMISTRY

PLP functions as a coenzyme¹⁸⁶ that performs many vital functions in human metabolism. More than 140 distinct PLP-dependent enzymes have been cataloged by the Enzyme Commission (EC).¹⁸⁷ It functions in the transaminations and decarboxylations that amino acids generally undergo, and about half of all the PLP-dependent enzymes function as aminotransferases. For example, it functions as

Figure 28.34 • Active forms of vitamin B₆ and the major metabolite pyridoxic acid.

a cotransaminase in the transamination of alanine to form pyruvic acid and as a codecarboxylase in the decarboxylation of dihydroxyphenylalanine (DOPA) to form dopamine. Other biological transformations of amino acids in which pyridoxal can function are racemization, elimination of the α -hydrogen together with a β -substituent (i.e., OH or SH) or a γ -substituent, and probably the reversible cleavage of β -hydroxyamino acids to glycine and carbonyl compounds.

An electromeric displacement of electrons from bonds with the α -carbon (see Fig. 28.36) results in the release of a cation (H, R', or COOH) and, subsequently, leads to various reactions observed with pyridoxal. The extent to which one of these displacements predominates over others depends on the structure of the amino acid and the environment (pH, solvent, catalysts, enzymes, etc.). When this mechanism applies *in vivo*, the pyridoxal component is linked to the enzyme through the phosphate of the hydroxymethyl group by hydrogen bond networks and/or ionic interactions.

Figure 28.37 shows the role of PLP in the transamination reaction. The first half-reaction involves the initial

proton abstraction from the external aldimine at C α by the active site lysine, yielding a quinonoid intermediate. Lysin ammonium, thus formed, protonates the C α' of the quinonoid intermediate to generate a ketimine, which is subsequently hydrolyzed to release α -ketoglutarate and enzyme-PMP complex (E-PMP).

Diacylglycine decarboxylase (DGD) is an unusual PLP-dependent enzyme that performs both decarboxylation, in the first half-reaction, and transamination, in the second half-reaction (Fig. 28.38). In the first half-reaction, a dialkylamino acid is decarboxylated producing a ketone and releasing the E-PMP form, which in the second half-reaction catalyzes transamination to convert an α -keto acid (e.g., pyruvic acid) into an amino acid (e.g., alanine), regenerating the DGD-PLP form.

Figure 28.35 • Pyridoxine-5'- β -D-glucoside.

Figure 28.36 • Generalized vitamin B₆ reactions.

Figure 28.37 • Transamination reactions of pyridoxine.

THERAPEUTIC USES

Pyridoxine is indicated in the treatment and prevention of known or suspected vitamin B₆ deficiency, which is most likely to occur in the setting of alcoholism in developed countries. Vitamin B₆ deficiency-related conditions have been reviewed by Spinneker et al.¹⁸⁴ A hypochromic, microcytic, iron-refractory anemia, a form of sideroblastic anemia, develops because of decreased hemoglobin synthesis. Cognitive defects also develop with impairment in memory function, especially in the elderly. Convulsive seizures occur, and these are particularly problematic in vitamin B₆-deficient infants. Peripheral neuropathy with paresthesia, and burning and thermal sensations is also common. The conversion of tryptophan to niacin is also PLP-dependent and vitamin B₆ deficiency may, rarely, lead to pellagra.¹⁸³ All of these conditions respond to increased dietary intake or administration of vitamin B₆.

At least seven genetic disorders that result in a vitamin B₆ deficiency syndrome in the presence of an adequate dietary intake have been identified. These result from defects in enzymes that are responsible for the bioactivation or uti-

lization of vitamin B₆. Chronic use of estrogen-containing oral contraceptives may lead to derangements in tryptophan metabolism, a phenomenon also seen during pregnancy that is thought to result from inhibition of kinureninase (EC 3.7.1.3) by metabolites of estrogenic agents.¹⁸⁸ Vitamin B₆ levels may also be lower in these same groups. All of these conditions respond, at least partially, to treatment with large doses of pyridoxine; although the use of high doses of pyridoxine in pregnancy may not be warranted and its use with contraceptives may lead to failure.¹⁸³

Certain hydrazine derivatives, when administered therapeutically (e.g., isoniazid and hydralazine), can induce a deficiency of the coenzyme PLP by direct inactivation through the mechanism of hydrazone formation with the aldehyde functional group. Cycloserine and penicillamine may act through a similar mechanism.¹⁸⁴ Concurrent administration of pyridoxine can avoid or resolve the relative vitamin B₆ deficiency seen in each of these conditions. Administration of high doses of vitamin B₆ with levodopa, alone, is not recommended because of enhanced conversion of levodopa to dopamine in the periphery resulting in decreased levodopa

Figure 28.38 • Vitamin B₆-catalyzed decarboxylation and transamination by diacylglycine decarboxylase.

availability to the CNS. The concurrent use of a DOPA decarboxylase inhibitor mitigates this interaction and high doses of vitamin B₆ are without effect on peripheral levodopa conversion. RDA amounts of vitamin B₆ have not been shown to be problematic in either case.

HYPERVITAMINOSIS

Interestingly, peripheral neuropathy, a symptom of vitamin B₆ deficiency, can also occur following ingestion of high doses of pyridoxine. Doses of 2 g/day can produce paresthesia and alter proprioception.¹⁸⁹ Some studies suggest the dose required may be as low as 50 to 500 mg/day. Symptoms may actually increase for several weeks after discontinuing pyridoxine, a phenomenon called *coasting*.¹⁹⁰

PRODUCTS

Pyridoxine is available from numerous sources under various names as oral formulations in tablet, capsule, powder, lozenge, and solution form. Pyridoxine HCl is available for IM or IV injection. Pyridoxine is also available as a component of numerous multivitamin preparations.

Vitamin B₇

Vitamin B₇ is now referred to as *biotin*. Biotin was first isolated in 1936¹⁹¹ and identified structurally in 1942.¹⁹² Although this vitamin is known to perform essential metabolic functions in the human, the biotin content of foods, and thus the necessary dietary intake, has not been well established. Good dietary sources of biotin include liver (beef and chicken), meat (beef, pork, chicken), fish, eggs, nuts, and some fruits and vegetables.¹⁹³ Enteric microorganisms synthesize biotin from pimeloyl-CoA¹⁹⁴ in the diet and thereby become an additional source of biotin.

CHEMISTRY

Biotin is composed of a tetrahydroimidazolidone (ureido) ring fused with a tetrahydrothiophene ring. A pentanoic acid substituent (at C⁵ of pentanoic acid) is attached to the tetrahydrothiophene ring at C⁴. The D-isomer (all *cis*) possesses all the activity and the N¹ position is the attachment point for the carboxyl group involved in carboxylation reactions (see Fig. 28.39).

KINETICS

Dietary biotin occurs primarily in the form of protein-bound biotin, which is converted into biotin in the intestinal lumen. Enteric bacteria can also provide a source of protein-bound biotin; however, the importance of this source is not known. Biotin is absorbed from the intestine, more in the jejunum than the ileum, through the SMVT, which also transports

pantothenic acid and lipoic acid.^{141,148} This explains the ability of these three substances to competitively inhibit absorption of each other and the ability of some drugs, such as carbamazepine and primidone, to produce biotin deficiency through competitive inhibition of absorption. The transporter is driven by the Na⁺ gradient that exists from the extracellular fluid to the intracellular fluid, transporting 2 Na⁺ for each monovalent anion of pantothenate, biotin, or lipoate.¹⁶⁷ In addition, the inside-negative membrane potential may also act as a driving force because a net charge of +1 enters the cell. This same carrier is ubiquitous throughout bodily tissues and probably also accounts for cellular uptake from the blood. Conversion to the active form most likely occurs inside the cell. Greater than 50% of a dose is excreted in the urine as intact biotin. The body appears unable to break the fused imidazolidone and tetrahydrothiophene ring system. The metabolites bisnorbiotin, biotin-*d*, *l*-sulfoxide, bisnorbiotin methyl ketone, and biotin sulfone have been identified in the urine.^{141,195}

BIOCHEMISTRY

Biotin is required for enzymatic activity of several important carboxylases (Table 28.10). Biotin is first attached to a lysine residue of biotin carboxyl carrier protein (BCCP) by biotin-[propionyl-CoA-carboxylase (ATP-hydrolyzing)] ligase (holocarboxylase [HCS], EC 6.3.4.10), which forms the biotinyl domain of the enzyme or separate subunit. The N¹ position is subsequently carboxylated to form carboxybiotin (Fig. 28.40), which is then able to transfer the carboxyl group to other substrates. The source of the carboxyl is either bicarbonate or decarboxylation of another substrate as is seen in transcarboxylation reactions.¹⁹⁶ A typical carboxylation reaction mediated by biotin-BCCP is shown in Figure 28.41. The source of the carboxyl is bicarbonate with ATP supplying energy for the reaction. This is followed by the subsequent transfer of the carboxyl to the substrate with regeneration of the biotin-BCCP complex.

An interesting recent development is the finding that biotin is also attached to histones in the nucleus by the same enzyme involved in attachment to BCCP.¹⁹⁷ The suggestion is that biotin may be involved in genetic regulation; although the exact role remains unknown at this time.

Deficiency states may rarely develop as a result of a biotin-deficient diet, as was observed in early, biotin-deficient TPN solutions,¹⁹⁸ or as a result of prolonged feeding of large quantities of raw egg white.¹⁹⁹ Raw egg white contains avidin, a protein that complexes biotin and interferes with its absorption from the gastrointestinal tract. A relative biotin deficiency has also been shown to occur in

Figure 28.39 • Biotin.

TABLE 28.10 Biotin-Dependent Enzymes

Enzyme	EC Number	Function

the case of two identified genetic disorders. Holocarboxylase deficiency is a genetic disorder of biotin-(propionyl-CoA-carboxylase [ATP-hydrolysing]) ligase, the enzyme responsible for the terminal step incorporating biotin into the apoenzyme. Biotinidase (EC 3.5.1.12) deficiency is a genetic disorder of the amidase that releases biotin from the apoenzyme and allows it to be recycled. Both of these lead to multiple carboxylase deficiency (MCD), a condition marked by decreased activity of all biotin-dependent carboxylases and both respond, at least partially, to large doses of biotin.¹⁹⁷ The symptoms of biotin deficiency include dermatitis, conjunctivitis, alopecia, and CNS abnormalities including behavioral, developmental, and psychological effects.¹⁹⁸

HYPERVITAMINOSIS

There are no known documented cases of toxicity resulting from excessive intake of biotin.

PRODUCTS

Biotin is available as oral tablets, capsules, and lozenges from numerous sources under various names. Biotin content ranges from approximately 300 to 1,000 μg , some-

times higher. Biotin is also found in a host of multivitamin preparations.

Vitamin B₉

Vitamin B₉ is now known officially as *folic acid* or *folate*, which is preferred because it is shorter.²⁰⁰ The term *folic acid* is derived from the Latin word *folium* meaning “leaf” and was coined by Mitchell et al.²⁰¹ in 1941 to refer to a substance isolated from spinach leaves that was an essential growth factor in *Streptococcus lactis* R (now classified as *Enterococcus hirae*). Folate crystals were isolated in 1943²⁰² and the structure reported in 1946.²⁰³

Natural sources of dietary folate are fruits, vegetables, beans, and peas as well as beef and chicken liver. However, since January 1998, the Federal Government²⁰⁴ has required folic acid fortification of all enriched cereal-grain products (flour, rice, bread, rolls, buns, pasta, corn, grits, corn meal, farina, macaroni, and noodle products), and these have now become important dietary sources of folate in the United States.^{205,206}

CHEMISTRY

The chemical structure of folic acid (Fig. 28.42) was found to be composed of a pteridine heterocyclic system (rings A and B), *p*-aminobenzoic acid (PABA) and Glu; hence the name pteroylglutamate (PteGlu). In plants and bacteria, folic acid is synthesized by converting guanosine triphosphate (GTP) through a multistep sequence into the pteridine heterocycle. This is followed by dihydropteroate synthase (EC 2.5.1.15), which adds the PABA moiety and finally the glutamate residue is added by dihydrofolate synthase (EC 6.3.2.12). It is of note that the antibacterial sulfonamides compete with PABA for the bacterial form of dihydropteroate synthase and, thereby, interfere with bacterial folic acid synthesis. This

Figure 28.41 • Biotin-mediated carboxylation reaction.

Figure 28.42 • Folic acid.

results in a selective antibacterial effect because susceptible bacteria cannot utilize preformed folate from the environment.

It was soon noted that PteGlu and naturally occurring folates differed in that the natural forms had a reduced ring B of the pteridine moiety; more than one Glu attached, which is referred to as *pteroylpolyglutamates* (PteGlu_n); and a single carbon unit attached to the nitrogen at position 5 or 10. As a result, it was first recommended that folic acid be used to denote the fully oxidized, monoglutamate form without the single carbon unit and folate was used to denote all forms that possess biological activity as the vitamin. Currently, folate (the preferred term) specifically refers to pteroylglutamate and folic acid refers to pteroylglutamic acid.²⁰⁰ Folate can also be used generically to refer to any of the members of the group of pteroylglutamates, their mixtures, differing one-carbon substituents, level of reduction, or number of glutamate residues. Because of this dual use of the term folate, the authors have chosen to use the term folate only in its generic sense throughout this chapter. This will avoid confusion with the fully oxidized form, folic acid, which is the major form available for vitamin supplementation.

KINETICS

Folates occur in the diet as PteGlu_n that must be hydrolyzed to the monoglutamate form (PteGlu) before absorption. The hydrolysis is catalyzed by gamma-glutamyl hydrolase (EC 3.4.19.9) found in the brush border of the intestinal mucosa. The PteGlu is primarily absorbed by active transport by reduced folate carrier (RFC) in the jejunum and upper duodenum.^{141,148} RFC is now known as solute carrier family 19, member 1 (SLC19A1) and is related to the thiamine transporters SLC10A2 and SLC19A3 that were discussed previously. This absorption is saturable and facilitated by the slightly acidic conditions found in these regions. Although the mucosa in these regions possesses dihydrofolate reductase (DHFR, EC 1.5.1.3), most reduction to dihydrofolate (H₂PteGlu, formerly called dihydrofolic acid or DHFA) and then to tetrahydrofolate (H₄PteGlu, formerly called tetrahydrofolic acid or THFA) and methylation occur in the liver. H₄PteGlu is distributed to all tissues, where it is stored as polyglutamates, primarily pentaglutamates or heptaglutamates (H₄PteGlu₅ or H₄PteGlu₇). The 5-methyl derivative (5-methyl-PteGlu_n) is the main transport and storage form in the body. The body stores 5 to 10 mg with approximately 50% in the liver. The major elimination pathway for the vitamin is biliary excretion as the 5-methyl derivative. Extensive enterohepatic cycling occurs. Only trace amounts are found in the urine. Large doses that exceed the tubular

reabsorption limit, however, result in substantial amounts in the urine.

BIOCHEMISTRY

Folic acid, and dietary forms of folate that are not in the reduced state, must undergo reduction of ring B for biological activity. Folic acid is first reduced to H₂PteGlu by dihydrofolate reductase (DHFR; EC 1.5.1.3) using NADPH as a cofactor and then to H₄PteGlu by the same enzyme. These key steps are important in the understanding of the folate antagonists, such as methotrexate, that inhibit DHFR and, thereby, interfere with the utilization of all folates that are not in the reduced (H₄PteGlu) state. Upon cellular uptake, several glutamate residues are attached via tetrahydrofolate synthase (EC 6.3.2.17) to form H₄PteGlu_n, effectively trapping the folate in the cell (Fig. 28.43).

In its reduced, polyglutamate form (H₄PteGlu_n), folic acid functions in the transfer of single carbon groups (see Fig. 28.44). H₄PteGlu_n is required for several important methylation reactions (Table 28.11) including the biosynthesis of methionine, serine, purine bases, transfer RNA (tRNA), and deoxythymidine triphosphate (dTTP), which is required for DNA synthesis. The most notable methylation reaction involves 5,10-methylene-H₄PteGlu_n in the conversion of deoxyuridine monophosphate (dUMP) to deoxythymidine monophosphate (dTMP), the first step in dTTP synthesis, by the enzyme thymidylate synthase (EC 2.1.1.45). Inhibition of DHFR and the resulting depletion of 5,10-methylene-H₄PteGlu_n by H₄PteGlu analogs, such as methotrexate, is thought to produce an antineoplastic effect by depleting the cellular dTTP, which is required for DNA replication.²⁰⁷ Likewise, trimethoprim and related drugs produce their antimicrobial effect through high specificity for the bacterial form of the same enzyme.

There is a fundamental relationship between folate and cobalamin in the regulation of active forms of H₄PteGlu_n. Most of the active forms of H₄PteGlu_n are interconvertible through reversible reactions (Fig. 28.44); however, the reduction of 5,10-methylene-H₄PteGlu_n to form 5-methyl-H₄PteGlu_n is not reversible. The only pathway for conversion of 5-methyl-H₄PteGlu_n back to H₄PteGlu_n for further utilization is through methionine synthase (EC 2.1.1.13), which converts homocysteine to methionine utilizing methylcobalamin as a cofactor (also see Vitamin B₁₂). A deficiency of cobalamin can result in abnormal accumulation of 5-methyl-H₄PteGlu_n with a subsequent relative depletion of all other active forms of H₄PteGlu_n. Depletion of available 5,10-methylene-H₄PteGlu_n, either through folate deficiency or through cobalamin deficiency, leads to impaired DNA synthesis resulting in the characteristic megaloblastic anemia commonly seen in a deficiency of either of these vitamins. Of great importance for the clinician to remember, administering folic acid to a cobalamin-deficient patient will correct the megaloblastic anemia because it provides a renewed source of reduced H₄PteGlu_n; however, the neurological damage from the cobalamin deficiency continues unabated.

THERAPEUTIC USES

Folic acid is used in the treatment of known or suspected folate deficiency or increased need as occurs during

Figure 28.43 • Bioactivation of folic acid to tetrahydrofolate polyglutamates.

Figure 28.44 • Interconversion of active folates.

TABLE 28.11 Folic Acid–Dependent Enzymes

Enzyme	EC Number	Function
Methionine synthase	2.1.1.13	Conversion of L-homocysteine to L-methionine
Glycine hydroxymethyltransferase	2.1.2.1	Interconversion of serine and glycine
Phosphoribosylglycinamide formyltransferase	2.1.2.2	Purine synthesis
Phosphoribosylaminoimidazolecarboxamide formyltransferase	2.1.2.3	Purine synthesis
Glutamate formimidoyltransferase	2.1.2.5	Histidine metabolism
Methionyl-tRNA formyltransferase	2.1.2.9	tRNA synthesis
Thymidylate synthase	2.1.1.45	Conversion of dUMP to dTMP in DNA synthesis

pregnancy. The most likely cause of folate deficiency in developed countries is alcoholism. The resulting megaloblastic anemia, thought to result from a deficiency in DNA synthesis, as noted previously, is indistinguishable from that caused by vitamin B₁₂ because both vitamins are involved in the same critical biochemical step. Unlike vitamin B₁₂, no neurological abnormalities are associated with folate deficiency. Because folate requirements increase during pregnancy, and maternal folate deficiency has been associated with a risk of neural tube defects in the fetus, folic acid supplementation is recommended, at a minimum, periconceptually.^{208,209} Because of the potentially beneficial effects in reducing these birth defects, the FDA has mandated fortification of all enriched cereal-grain products in the United States with folic acid since 1998.²⁰⁴

Folic acid has also been shown to reduce homocysteine levels, which is a risk factor for cardiovascular disease independent of other risk factors. However, although there is some evidence that folic acid supplementation may reduce the risk of stroke,²¹⁰ the risk of other cardiovascular disease has not been proven to be affected.²¹¹ Some studies suggest that multivitamin preparations with folic acid taken prior to, and during pregnancy, may protect against congenital heart defects. Folate may also decrease the risk of colorectal cancer; however, once colorectal cancer develops it may act as a promoting agent.²¹²

One of the biologically active forms of folic acid, leucovorin (5-formyl-H₄PteGlu), is used in the treatment of accidental overdoses of DHFR inhibitors, such as methotrexate, because it does not require bioactivation by DHFR as does folic acid. Leucovorin is also used concomitantly with, or shortly following, methotrexate, trimetrexate, pyrimethamine, trimethoprim, and related drug therapy to decrease the toxicity in sensitive cells. Finally, although leucovorin can be used in place of folic acid in all other uses, there is no therapeutic advantage.

HYPERVITAMINOSIS

High doses of folic acid are rather nontoxic; however, at least one study has shown that 15 mg/day for 1 month can result in gastrointestinal disturbances (including anorexia, nausea, and pain) and CNS effects (including sleep disturbances, vivid dreams, malaise, irritability, and increased excitability).²¹³ The primary danger of excessive folate intake is the masking of vitamin B₁₂ deficiency. Folic acid can correct the anemia caused by vitamin B₁₂ deficiency, but it has no effect on the neurological damage. The potential for high doses of folic acid to mask B₁₂ deficiency explains why large daily doses of folic acid are best avoided in the general population.

PRODUCTS

Folic acid is available alone in tablet and injectable form, or in combination with other vitamins, in various multivitamin preparations. Leucovorin is a racemic mixture of 6*S* and 6*R* 5-formyl-H₄PteGlu and is available as the calcium salt for use in treatment of accidental overdoses of DHFR inhibitors, such as methotrexate, or to decrease their toxicity in sensitive cells. The active 6*S*-isomer of leucovorin is also available as levoleucovorin calcium (Fusilev) and is dosed at one-half the rate of leucovorin with the same uses. L-Methylfolate (Deplin) is the 6*S*-isomer of 5-methyl-H₄PteGlu. This is the biologically active isomer of 5-methyl-H₄PteGlu, which is the main transport and storage form (as 5-methyl-H₄PteGlu_n) of folates in the body. It is used in tablet form as a *medical food* for the treatment of methylenetetrahydrofolate reductase [NAD(P)H] (EC 1.5.1.20) deficiency (MTHFR deficiency). Medical foods are substances that are regulated by the FDA and are administered enterally under the supervision of a physician intended for the dietary management of a disease that has distinctive nutritional needs.

Vitamin B₁₂

Vitamin B₁₂ specifically refers to cyanocobalamin, the form typically found in dietary supplements because of its high stability.²¹⁴ However, the immediate precursor to the vitamin B₁₂-derived coenzymes is hydroxocobalamin (vitamin B_{12b}), which is formed in vivo from cyanocobalamin. Cobalamin is used to refer to any of the related cobalt-containing compounds that serve as coenzymes or their biologically active precursors as shown in Figure 28.45.

The discovery of vitamin B₁₂ began with the unwitting description by Dr. Thomas Addison in 1855 of patients suffering from an anemia that was later identified as *pernicious anemia*.²¹⁵ Following the rapid developments in vitamin discovery in the early 1900s, it was soon determined that a diet high in liver could reverse the effects of pernicious anemia as was clearly shown in 1926 by Minot and Murphy.²¹⁶ However, concentration and identification of the vitamin was slow because the only known assay for vitamin B₁₂ activity was the reversal of pernicious anemia in human patients. Almost 30 years had passed before Shorb²¹⁷ reported in 1947 that liver extract was required for the growth of *Lactobacillus lactis* in similar proportions to that found to treat pernicious anemia. With an inexpensive, rapid assay for vitamin B₁₂ activity, the crystalline form was isolated and reported simultaneously just 1 year later by Smith²¹⁸ and Ricks et al.²¹⁹ who suggested the name vitamin B₁₂. Interestingly, the conversion to cyanocobalamin occurs during the purification process and is not the natural form of

Figure 28.45 • Biologically active forms of cobalamin.

the vitamin. The structure of cyanocobalamin was announced simultaneously by Hodgkin et al.²²⁰ and Bonnett et al.²²¹ in 1955 and the complete synthesis completed in 1972.²²²

De novo synthesis of cobalamin is only found in microorganisms. Therefore, cobalamin is found naturally in commercial fermentation processes of antibiotics, such as those of *Streptomyces griseus*, *Streptomyces olivaceus*, and *Streptomyces aureofaciens* as well as sewage, Milorganite and others. Some of these fermentations furnish a commercial source of vitamin B_{12} . Animals depend on synthesis by the intestinal flora or, as in humans, foods from animals that have already consumed cobalamin. Excellent dietary sources are meats, eggs, dairy, fish, and shellfish. The only dietary plant products containing the vitamin are legumes, because of their symbiosis with microorganisms, or those that have been fortified with the vitamin.

CHEMISTRY

These are the most complex group of vitamins consisting of a corrin core with a central cobalt atom with +1, +2, or +3 oxidation state. The corrin core has four pyrrole units, two of which are attached directly whereas the others are joined by methylene bridges. Out of six coordination bonds of cobalt, four are bonded to pyrrole nitrogens and the fifth is bound to one of the nitrogen atoms of the dimethylbenzimidazole derivative containing ribose 3-phosphate and aminoisopropanol linked through an amide bond to the side chain of the corrin core. The sixth substituent of the cobalt atom can be $-CN$, $-OH$, $-CH_3$, or a 5'-deoxyadenosyl unit (Fig. 28.45). In hydroxocobalamin, the cobalt atom is in the +3 oxidation state and called vitamin B_{12b} (Co^{3+}), which is reduced by flavo-protein reductase to the vitamin B_{12r} (Co^{2+}) form and then to the vitamin B_{12s} (Co^+) form, which is converted to the methyl coenzyme form. Vitamin B_{12r} (Co^{2+}) is believed to be converted to the adenosylcoenzyme form by cob(I)yrinic acid a, c-diamide adenosyltransferase (EC 2.5.1.17) using ATP.

KINETICS

Dietary cobalamin is protein bound but is released in the stomach through the action of acid and gastric proteases. The primary natural forms are methylcobalamin, deoxyadenosylcobalamin, and hydroxocobalamin with only

trace amounts of cyanocobalamin, which is processed similarly except for the initial liberation from protein. Free cobalamin then binds to transcobalamin (TC) I, also called *haptocorrin*, which is a high-affinity cobalamin-binding protein found in all bodily fluids including saliva. As the bound cobalamin enters the small intestine, pancreatic proteases digest TC I releasing free cobalamin, which then binds to intrinsic factor (IF), secreted primarily by parietal cells of the gastric mucosa, forming an intrinsic factor-cobalamin (IF-CBL) complex. In the distal ileum, IF-CBL binds to cubilin, also known as the intrinsic factor cobalamin receptor (IFCR), on the luminal surface and undergoes receptor-mediated endocytosis. Intracellularly, IF is cleaved by the lysozymal enzyme, cathepsin L (EC 3.4.22.15), and the free cobalamin binds to TC II to form TC II-CBL, which is then released into the bloodstream completing the process of transcytosis.^{223–225} Dietary supplements that contain cyanocobalamin undergo an additional conversion in the plasma by cyanocobalamin reductase (cyanide-eliminating) (EC 1.16.1.6) to hydroxocobalamin, which serves as the immediate precursor to the cobalamin derived coenzymes.

The average dietary intake of cobalamin is 5 to 30 μg ; however, only 1 to 2 μg /meal is absorbed most likely because of saturation of the IF-dependent transport. Small amounts of cobalamin can also be absorbed through passive diffusion; however, this is normally insufficient to prevent deficiency unless the diet consists of abnormally large quantities of foods rich in cobalamin, such as liver. Only 1% of an oral dose of cobalamin is absorbed in patients that lack gastric acid and IF, which explains the large doses, 1,000 to 2,000 μg (1–2 mg) per day, of vitamin B_{12} required in the oral treatment of pernicious anemia.

In the bloodstream, cobalamin is bound not only to TC II but also to plasma haptocorrin, which may function primarily as a storage form of cobalamin. Uptake into cells that need cobalamin is receptor mediated through TC II-CBL receptors (TC II-R). Half of the body stores of cobalamin are in the liver primarily as adenosylcobalamin. Cobalamin is excreted into the bile and undergoes enterohepatic cycling utilizing IF for reabsorption. This explains why deficiency will occur more rapidly in patients with malabsorption of cobalamin than inadequate dietary intake. Excess cobalamin is eliminated unchanged in the feces and urine.

BIOCHEMISTRY

In the biosynthesis of the coenzymes derived from cobalamin, cobalt is reduced from a trivalent to a monovalent state before the organic anionic ligands are attached to the structure. The two types of cobalamins that participate as coenzymes in human metabolism are adenosylcobalamin and methylcobalamin. These coenzymes perform vital functions in methylmalonate–succinate isomerization and in methylation of homocysteine to methionine (Fig. 28.46).

Two enzymes have been shown to be cobalamin dependent in humans. Methylmalonyl-CoA mutase (EC 5.4.99.2) requires 5'-deoxyadenosylcobalamin; this enzyme system catalyzes the methylmalonyl-CoA transformation to succinyl-CoA, which is the major pathway of propionyl-CoA metabolism (Fig. 28.46). This is a free radical mediated rearrangement reaction where cobalamin's role is to serve as the source of free radicals, through homolytic cleavage of the weak Co-C bond, for the abstraction of hydrogen atoms. Propionyl-CoA from odd-chain fatty acid metabolism must be processed through this pathway to succinyl-CoA to enter the Krebs (citric acid) cycle to be either converted to γ -oxaloacetate, leading to gluconeogenesis, or oxidized aerobically to CO_2 , with production of ATP. The methylation of homocysteine to form methionine requires methylcobalamin and is catalyzed by methionine synthase (EC 2.1.1.13), a transmethylase that also requires 5-methyl-PteGlu_n and reduced FAD. This lat-

ter reaction forms the basis for the megaloblastic anemia that results from either folic acid or cobalamin deficiency and the masking of cobalamin deficiency by folic acid. The reader is referred to the section on vitamin B₉ for a related discussion.

THERAPEUTIC USES

The most common form of cobalamin deficiency, known as pernicious anemia, is now known to be an autoimmune disorder that results from parietal cell destruction. This results in insufficient production of gastric acid and IF and the ensuing malabsorption of cobalamin. Other less common causes of insufficient absorption are hypochlorhydria, gastrectomy, ileocecal resection, celiac disease, and chemical incompatibilities with drugs in the gastric milieu. A deficiency of cobalamin can also result from nutritional deficiencies, increased requirements as is seen in pregnancy, as well as a strict vegetarian diet without adequate supplementation. The symptoms of cobalamin deficiency primarily result from potentially irreversible nerve damage, involving sensory, motor, and cognitive functioning, and the megaloblastic anemia that can be confused with that seen in folate deficiency. The ability of folic acid to reverse megaloblastic anemia seen in cobalamin deficiency, without affecting nerve damage, is discussed in the Vitamin B₉ section.

Cyanocobalamin is the form most commonly used in the treatment of cobalamin deficiency; however, hydroxo-

Figure 28.46 • Coenzymes of vitamin B₁₂.

cobalamin is equally efficacious. A rare genetic disorder that results in an inability to convert cyanocobalamin to hydroxocobalamin is the only known instance where hydroxocobalamin would be the preferred treatment.²²⁶ Hydroxocobalamin, but not cyanocobalamin, is also used in the treatment of cyanide toxicity. Administration of large doses results in the conversion of hydroxocobalamin to the nontoxic cyanocobalamin effectively reducing plasma levels of cyanide. In this case, 5 to 10 g of IV hydroxocobalamin may be needed as compared to 1 mg/day in severe pernicious anemia.

HYPERVITAMINOSIS

Milligram doses of cyanocobalamin are generally not associated with toxicity although rare allergic²²⁷ and anaphylactic reactions^{228,229} and mild diarrhea have occurred. As further evidence of the safety of vitamin B₁₂, the adverse effects following the use of hydroxocobalamin in the treatment of cyanide poisoning, where the typical dose is 5 to 10 g, have been relatively mild.²³⁰

PRODUCTS

Cyanocobalamin, the most common form used, is available as oral and sublingual tablets as well as oral lozenges from numerous sources under various names. These products contain anywhere from approximately 50 to 1,000 μg of cyanocobalamin. Cyanocobalamin is also available as a nasal spray for daily use (CaloMist 25 μg /actuation) or weekly use (Nascobal 500 μg /actuation) and as an injectable for intramuscular (IM) or deep subcutaneous (SQ) administration. Hydroxocobalamin is available as two, 2.5-g vials (Cyanokit) for the treatment of cyanide poisoning. Hydroxocobalamin is also available in oral and injectable dosage forms from numerous sources under various names. The only advantage for hydroxocobalamin in the treatment of pernicious anemia would be in patients unable to convert cyanocobalamin to hydroxocobalamin as the result of a rare genetic disorder as discussed previously. Cyanocobalamin and hydroxocobalamin are also available in a host of multi-vitamin preparations.

Vitamin C

Scurvy (from the French word *scorbutus*) has been recognized as a disease afflicting mankind for thousands of years.²³¹ However, it was not until the early 1500s that natives of North America used teas brewed from pine needles to treat or prevent the symptoms of scurvy without understanding the basis for their curative properties. Citrus fruits such as oranges, lemons, and limes were later identified as equally effective treatments. Only within the last 100 years has a deficiency in vitamin C been definitively identified as the cause of scurvy. In 1932, Waugh and King^{232,233} isolated crystalline vitamin C from lemon juice and showed it to be the antiscorbutic factor present in each of these treatments. Interestingly, in a series of papers published at approximately the same time,^{234,235} Svirbely and Szent-Györgyi²³⁶ showed that the substance the latter had crystallized from peppers and reported 4 years earlier was the same as vitamin C and not a hexuronic acid as originally proposed. The structure and chemical formula of vitamin C was identified in 1933 by Hirst et al.²³⁷ as one of a series of possible

Figure 28.47 • L-Ascorbic acid.

tautomeric isomers. The first synthesis of vitamin C was announced almost simultaneously by Ault et al.²³⁸ and Reichstein²³⁹ in 1933. Since that time, it has been synthesized in several different ways.

Vitamin C can be synthesized by nearly all living organisms, plants, and animals; but primates, guinea pigs, bats, and a few other species cannot produce this vitamin. The consensus is that organisms that cannot synthesize vitamin C lack the liver microsomal enzyme L-gulonolactone oxidase (1.1.3.8), which catalyzes the terminal step of the biosynthetic process. Sato and Udenfriend²⁴⁰ summarized studies of the biosynthesis of vitamin C in mammals and the biochemical and genetic basis for the incapability of some species to synthesize the vitamin. Because humans are one of the few animal species that cannot synthesize vitamin C, it has to be available as a dietary component.

Dietary sources of ascorbic acid include fruits (especially citrus fruits), vegetables (especially peppers), and potatoes. Although the sources of some commercial products are rose hips and citrus fruits, most ascorbic acid is prepared synthetically.

CHEMISTRY

Vitamin C is now commonly referred to as *ascorbic acid* because of its acidic character and its effectiveness in the treatment and prevention of scorbutus (scurvy). The acidic character is because of the two enolic hydroxyls; the C³ hydroxyl has a pK_a value of 4.1, and the C² hydroxyl has a pK_a of 11.6. All biological activities reside in L-ascorbic acid (Fig. 28.47); therefore, all references to vitamin C, ascorbic acid, ascorbate, and their derivatives refer to this form. The monobasic sodium salt (Fig. 28.48) is the usual salt form.

KINETICS

Dietary ascorbic acid is readily absorbed as ascorbate and dehydroascorbate by facilitated diffusion while ascorbate can also be absorbed by active transport. Large doses can saturate these systems, limiting the amounts absorbed. Once absorbed, it is distributed to all tissues and transported into cells via the same mechanisms.^{241,242} Excess ascorbate is metabolized to oxalic acid and excreted by the kidneys (Fig. 28.49), which

Figure 28.48 • Ascorbate sodium.

Figure 28.49 • Oxidation of ascorbic acid.

may form the basis for the formation of kidney stones following ingestion of large doses. Although oxalate is the major urinary metabolite (44%), unchanged ascorbate (20%) and the intermediate metabolite 2,3 diketo-L-gulonic acid (20%) are also found in appreciable quantities.²⁴²

BIOCHEMISTRY

Ascorbic acid is a required cofactor for several important dioxygenases, functioning as an electron donor in each of these reactions (Table 28.12). These dioxygenases are involved in the hydroxylation of many important biomolecules during their synthetic sequence including collagen, peptide hormones, steroids, and norepinephrine. The resulting oxidized product, semidehydroascorbate (Fig. 28.50), can be reduced back to ascorbic acid through cytochrome-*b*₅ reductase (EC 1.6.2.2) or thioredoxin-disulfide reductase (EC 1.8.1.9). Alternatively, two molecules of semidehydroascorbate can undergo a disproportionation reaction yielding one molecule of ascorbic acid and one molecule of dehydroascorbate. The latter can also be converted to ascorbic acid by thioredoxin-disulfide reductase (EC 1.8.1.9) or reduction by glutathione that may be enzymatically or nonenzymatically mediated.²⁴²

THERAPEUTIC USES

Vitamin C is indicated for the treatment and prevention of known or suspect deficiency. Although scurvy occurs infrequently, it is seen in the elderly, infants, alcoholics, and drug users. The array of symptoms associated with scurvy is thought to result from inadequate formation of the products of the key enzymatic reactions for which ascorbate is a

cofactor. Especially notable are the derangements in connective tissue formation as a result of the effects on collagen synthesis leading to hemorrhaging, poor wound healing, and defects in bone and dentin. Ascorbate can also be used to enhance absorption of dietary nonheme iron or iron supplements. Ascorbic acid (but not the sodium salt) was historically used to acidify the urine as a result of excretion of unchanged ascorbic acid, although this use has fallen into disfavor. Ascorbate also increases iron chelation by deferoxamine, explaining its use in the treatment of iron toxicity. However, use of ascorbate can also enhance iron absorption, which could aggravate the original iron toxicity and so caution is advised. It is also a useful adjunct in the treatment of methemoglobinemia.

Ascorbic acid is an effective reducing agent and antioxidant; although the daily doses required to produce significant *in vivo* activity (>1 g) are much higher than the RDA (<100 mg). Because oxidative stress is thought to underly many disease processes, there has been intense interest in utilizing high doses of the antioxidant vitamins to prevent or treat diseases unrelated to their role as vitamins. There are numerous studies that have examined the effects of vitamin C supplementation alone, or in combination with other vitamins and minerals, yet the only conclusion to be drawn is that there is no clear and convincing evidence that vitamin C is useful in the treatment or prevention of most major disease states. Systematic reviews have not found evidence for general use in the common cold, cardiovascular disease in general, hypertension, atherosclerosis, cancer, preeclampsia, or overall mortality.^{43,55,243,244}

HYPERVITAMINOSIS

High doses of vitamin C can lead to renal, bone, hematological, and gastrointestinal effects.⁴⁶ Renal calculi because of oxalate or urate result from enhanced renal excretion of these compounds in the presence of high doses of vitamin C. Increased release of calcium and phosphorus from bone have been observed. Hematological effects include increased absorption of nonheme iron without significant increases in total body iron stores. Diarrhea, likely resulting from an osmotic effect, has been reported following large doses, and ascorbic acid tablets that lodge in the esophagus can cause local erosion. Finally, ascorbic acid has been shown to interfere with several colorimetric redox assays because of its ability to act as a reducing agent.

PRODUCTS

Ascorbic acid is available as oral tablets, capsules, lozenges, crystals, and solutions from various manufacturers. It is also available as an injectable solution and as part

TABLE 28.12 Ascorbate-Dependent Enzymes

Enzyme	EC Number	Function
Gamma-butyrobetaine dioxygenase	1.14.11.1	Lysine degradation
Procollagen-proline dioxygenase	1.14.11.2	Collagen synthesis
Procollagen-lysine 5-dioxygenase	1.14.11.4	Collagen synthesis
Procollagen-proline 3-dioxygenase	1.14.11.7	Collagen synthesis
Trimethyllysine dioxygenase	1.14.11.8	Lysine degradation
Phytanoyl-CoA dioxygenase	1.14.11.18	Fatty acid metabolism
Dopamine beta-monooxygenase	1.14.17.1	Norepinephrine synthesis
Peptidylglycine monooxygenase	1.14.17.3	Peptide hormone synthesis

of innumerable multivitamin combinations under various names. Ascorbic acid is also available as the sodium salt in an injectable solution and as calcium ascorbate in oral tablets, granules, and powder. These two salts are also formulated into an assortment of multivitamin combinations sold under various names. Several other micronutrient salts of ascorbic acid, such as the potassium salt, are available. Ascorbyl palmitate (ascorbic acid 6 palmitate) is the C^6 palmitic acid ester of ascorbic acid (see Fig. 28.51). This ester of ascorbic acid is a fat-soluble form that releases ascorbic acid in the digestive tract following hydrolysis of the ester bond. Ascorbyl palmitate has also been used in topical preparations designed to protect the skin from UV radiation under the premise that the antioxidant properties,

in a manner similar to the oral use of ascorbic acid, would add to the protectant effects. However, there is evidence that its use in these preparations may actually lead to enhanced skin damage.²⁴⁵

Figure 28.51 • Ascorbyl palmitate.

REVIEW QUESTIONS

- List the fat-soluble vitamins, the water-soluble vitamins, and the B-complex vitamins.
- Explain the difference between enrichment and fortification.
- How do most of the vitamins function? How else might some vitamins function?
- Which vitamin is involved in proper function of the eye and how is it involved? Would you recommend retinoic acid (Tretinoin) for treatment of a deficiency of this vitamin? Explain your reasoning.
- Vitamin A is very toxic in high doses but the provitamin A carotenoids are not. Explain this difference.
- Which vitamins can be made in humans and how are they synthesized?
- Explain the sunlight-mediated production of vitamin D in the skin using structures when appropriate. Does excessive sunlight produce toxic levels of vitamin D?
- What are tocopherols? Researchers have shown that all forms of tocopherols are absorbed from the intestine equally, yet

- α -tocopherol is found in the circulation in the highest amounts. Why?
- Which two vitamins are absorbed via the SMVT and can competitively inhibit each other?
 - What is a severe form of central neurological damage, with a high fatality rate, seen in alcoholics because of a severe vitamin deficiency? Name the vitamin.
 - Controversial results have been found with vitamin E use in cardiovascular diseases. Explain at least one possible chemical reason for this controversy.
 - Vitamin C is an antioxidant vitamin. Explain how the indiscriminate use of large doses may lead to renal, bone, hematological, and gastrointestinal effects.
 - Explain the role of vitamin K in the formation of Gla proteins. List the known biochemical roles of the Gla proteins.
 - Which vitamins have a role in bone mineralization?
 - Explain how leucovorin can treat overdoses of methotrexate, and other DHFR inhibitors, while folic acid is ineffective.
 - What is the danger of treating megaloblastic anemia empirically with folic acid?
 - What is the purpose of fortification of food with folic acid and what foods require fortification?
 - Niacin is used unrelated to its vitamin activity for what cardiovascular disorder? Would you recommend niacinamide instead of niacin for this use because it causes less side effects?
 - What is the major form of vitamin B₆ that takes part in enzymatic reactions? Which form is excreted in the urine? Which other forms of vitamin B₆ are known as active forms because they can be interconverted to the major form used in enzymatic reactions? List the types of reactions cocatalyzed by vitamin B₆.
 - What is pernicious anemia and what is the cause? What chemical form of the deficiency vitamin is most commonly given to treat pernicious anemia? When is this the form to use?

An Introduction to the Medicinal Chemistry of Herbs

JOHN M. BEALE, JR.

CHAPTER OVERVIEW

According to the World Health Organization, approximately 80% of the world's population uses herbal drugs as part of their normal healthcare routine.¹ The United States is no exception. In the United States, herbal medicines represent the fastest-growing segment of pharmacy trade.² Self-medication with herbs cuts across all educational and affluence levels. Senior citizens as well as young, health-conscious persons are using herbs at an incredible rate. The reasons for herbal use are many and certainly cannot be fully enumerated here. Possibly, herbal users desire to assume control over their own healthcare needs. Perhaps the large, "impersonal" healthcare system is unpalatable to many, and they turn to herbal medicines as an alternative. Patients may feel alienated by increasingly busy physicians who have less time to spend with them, and they may turn to herbal drugs because they feel that they can gain some control.

Obviously, if people are going to use herbals as part of their healthcare routine, they must find out about the herbs and what they do. There is no doubt that a definite major factor affecting herbal use is advertising targeted very successfully to specific populations, such as the young professional or the senior citizen. Such advertising is mere pseudoscience, but its flamboyance is a big drawing factor. Herbal ads often convey an attitude that self-medication is safe and effective, and this makes people feel good and as if they do not need the physician who just saw them for 5 minutes. People also tend to believe that natural products are inherently better than synthetic drugs. The natural drugs somehow contain the "vital force" that is going to improve their health. This is actually a belief in the vitalism principle, which Wöhler disproved in 1828.³ Tyler puts this issue into clear terms: "If it comes in a shrinkwrap, safety-sealed box, or a bottle with a childproof lid, it is not harvested freshly from the earth. It is a manufactured industrial product, no matter how many flowers adorn the wrapper, no matter how many times the label invokes the word 'nature.'"⁴

Certainly, the cost of medical care cannot be overlooked when considering the reasons for interest in alternative forms of medicine. Most herbal medicines are far less expensive than prescription drugs. There is danger, however, in self-medicating with herbal drugs. The old adage that "he who tries to diagnose himself has a fool for a physician" becomes very apropos with herbal medicine. When prescription drugs are dispensed, a patient has access to the information that is available from the physician or pharmacist. This is often not the case with herbal medicinals. In the United

States, training of healthcare professionals in the use of herbal drugs has been nearly nonexistent for years. Hence, herbal users are left to their own devices regarding choice, safety, and quality of the herb chosen.

HISTORICAL ASPECTS

Until 1882,⁵ several drugs were monographed and described in the *United States Pharmacopoeia (USP)*. Ginseng, for example, was clearly characterized as a drug and could be labeled and described to patients as such. Today, the Food and Drug Administration (FDA) calls ginseng, legally, a "food for beverage use." Outside the United States, it is common to find ginseng recommended for many different medical conditions.⁶ At the time of the 1882 *USP* and into the early 1900s, pharmacists were well trained in the use, preparation, and dispensing of herbals and could advise patients on their herbal selection. This is not always the case today.

The convoluted regulatory efforts that began in 1906 and continue today are well described by Tyler.⁷ A group of herbs had been grandfathered against the Federal Food, Drug, and Cosmetic Act of 1938 and the Kefauver-Harris Amendments of 1962. Most purveyors of herbs assumed that these herbs would continue to be salable with the indications on the label—in other words, marketed as drugs. The FDA declared that all of these grandfathered drugs would be considered misbranded and subject to confiscation if any claims of efficacy were not in accordance with the evaluations of 1 of 17 over-the-counter (OTC) drug evaluation panels that had operated between 1972 and 1990. The net result was that it became possible to sell herbal drugs only if no statements regarding prevention or treatment of a disease state were on the label. The FDA assigned three categories into which herbs were placed. Category I⁸ (effective) contains only a select few herbal drugs. These are mostly laxatives such as cascara bark and senna leaf (although as Tyler points out, prune juice is excluded). Category II (unsafe or ineffective) contained 142 herbs, and category III (insufficient evidence to judge) contains 116. As applied to herbs and, in fact, the entire OTC classification, the judgments of the FDA have been harmful and non-scientific.

For the most part, herbal manufacturers decided not to fight the FDA and merely removed the disease- or condition-specific information from the labels and continued to sell the herbs as foods or nutritional supplements. With regard to using herbs as food additives, the FDA has

maintained a list of substances “generally recognized as safe” (the GRAS list).⁹ The list contains about 250 herbs, primarily relating to their use in beverages and cooking and as food additives. The list, of course, contains no references to herbs as drugs.

In 1990, the Nutrition Labeling and Education Act required consistent, scientifically based labeling on all processed foods. Herbal medicines were still left in limbo. Finally, in 1994, the Dietary Safety Health and Education Act included herbal medicines in the definition of dietary supplements. The act ensures consumers' access to supplements on the market as long as they are safe, and it allows structure and function claims on the label. Despite all of these legislative efforts, herbal drugs have been relegated to the grocery shelf as dietary supplements. They are sold with little or no instruction, and the public has no way of ascertaining purity, standardization, or legitimacy of the use for which the product is sold. Indeed, there is more information on the label of a tube of toothpaste than on a bottle of an herbal drug. Herbal manufacturing companies are making efforts to improve products along these lines, but there is a long way to go. Until testing can be done to prove that herbs are safe and effective, they will probably remain in their present circumstances.

For many years, medicinal chemistry was paired with a science called *pharmacognosy*,¹⁰ a course of study of plants with medicinal uses and analytical techniques for detecting active ingredients. Pharmacognosy was an important science, because many of the pharmaceuticals used in the treatment of disease are discovered through the study of ethnobotanical leads and laboratory research. This course of study gave pharmacists the training required to understand, recommend, and counsel on herbs. Today, pharmacognosy is no longer required in most schools, and most practicing pharmacists and physicians have little understanding of herbs.

Medicinal herbs are unlike anything else that appears in the chapters of this book. Although they are unquestionably drugs (a fact that many sellers of herbs will dispute), they are not pure substances. Indeed, most herbal preparations contain many different constituents. Ephedra complex, or *ma huang*, is a sympathomimetic that contains five or six different β -phenethylamine derivatives. At least one of these, (+)-norpseudoephedrine, is a Schedule IV compound. The alkaloid content^{11–13} varies widely in commercial ephedra-containing preparations. In one study, for one single product, lot-to-lot variations in the content of (–)-ephedrine, (+)-pseudoephedrine, and (–)-methylephedrine exceeded 180%, 250%, and 1,000%, respectively.¹¹ Total alkaloid content among 20 products ranged from 0.0 to 18.5 mg/dosage unit, and discrepancies were exhibited between the labeled contents and actual measurements.¹² Another study assayed nine products and found that total alkaloid levels ranged from 0.3 to 56 mg/g of ephedra.¹³

Unlike the situation with ephedra, in many cases, we simply have no idea what the components do. The constituents of some herbal drugs seem to work synergistically and cannot be separated without loss of activity of the preparation. Herbal preparations are most often used as crude mixtures and are not standardized or analyzed for the content of the active principle(s). Hence, the chemistry of medicinal herbs cannot be treated in the same way as that of, say, a pure antibiotic or a calcium channel blocker. The medicinal chemistry of the actions, interactions, and side effects of herbal

products is complex and difficult to assess clinically and chemically. Frequently, some of the compounds present in a given herb can be identified, but there may be no obvious way to correlate chemical structure with function. Often, assessment of structure–function relationships with herbal products involves a lot of guessing.

WHAT IS AN HERB?

An herb is a substance of plant origin that, according to one's desires, can be used for culinary or medicinal purposes.¹⁴ Obviously, some are more suited to culinary than medicinal uses, but most herbal substances have some identifiable medicinal use. As mentioned in the previous section, a typical herb may contain dozens of different compounds, so it has rarely been advantageous to separate an herb into its component parts. In fact, doing so may completely inactivate the drug. In an herbal mixture, some compounds can reinforce others and vice versa. It is impossible to predict what will happen. In relatively few cases has the active ingredient of an herb been isolated, characterized thoroughly, and tested for activity. We are left with a situation in which herbs are used in crude form as powders, fluidextracts, and teas. This should not be misconstrued to mean that analysis of herb components is useless. On the contrary, it is essential but just is not done often enough.

HERBAL PURITY AND STANDARDIZATION

In the United States, the issues of herbal purity and adulteration have been neglected for years. Because herbs are not regulated in the United States the same way they are in other countries, the pressure to ensure lot-to-lot standardization and to screen out plant adulterants has been less than optimal. Instances have been reported in the literature¹¹ in which several bottles of an herb purchased in the same location possessed different concentrations of active ingredient. Ephedra and ginseng are notable examples. Another example is echinacea. This herb is occasionally adulterated with a plant that looks very similar to *Echinacea angustifolia* but has none of the activity of echinacea. Plant parts, insect parts, soil, etc. can all be adulterants. Fortunately, pressure on the herb-producing industry has caused a markedly increased effort to screen and standardize herbs for trade. Possibly, simple high-performance liquid chromatography (HPLC) methods could be used to verify the herb's quality if the time were taken to obtain them. A chromatogram could be supplied to the purchaser to show the purity of the herb. Nevertheless, remember that an herb is a crude material containing multiple pharmacologically active compounds.

AN HERB IS A DRUG

Despite the regulations, an herbal preparation possesses the properties of a drug, albeit a mild one in many cases, and should be treated as such. It is pharmacologically active. It interacts with prescription drugs. It affects the health of the person taking it. Advertisers often tout herbs as “nondrugs” in an attempt to lure consumers. Pharmacists should be cog-

nizant of the truth that herbs are real drugs and that their patients may be self-medicating with them. This practice may affect the outcome of therapy with prescription drugs. For example, suppose a patient is stabilized on Coumadin and starts to take ginkgo. Ginkgo affects platelet-activating factor (PAF)¹⁵ and can effectively cause an overdose effect with Coumadin, and the patient can bleed. Or, suppose a patient taking a monoamine oxidase inhibitor (MAOI) decides to take St. John's wort; the patient may have a toxic reaction.¹⁶ Because pharmacists often do not see what their patients are buying, this is a complex problem.

The herbal drugs available to consumers are far too numerous to discuss in this chapter. This section presents a few of the more commonly used herbs along with their chemistry. Information on other herbs can easily be found in the literature.

TYPES OF HERBS

Echinacea

The medicinal herb that we call *echinacea*, or the purple coneflower, is indigenous to the Great Plains of the United States and, indeed, can be found in much of the Western Hemisphere. The plant gets its name (coneflower) from the narrow florets, which project downward in a conical array from a prominent center toward a substantial stem that bears one flower. Today, the herb is used as an immunostimulant,¹⁷ as a means of lessening the symptoms and duration of a cold or the flu, and sometimes as a wound healer. Recent reports show that echinacea is the best-selling herb in the United States.³ Folklore¹⁸ tells us that Native Americans used *E. angustifolia* to treat superficial wounds, snakebite, and the common cold. In the latter part of the 19th century, settlers exchanged information about medicines with the Indians and added echinacea to their own "pharmacopoeia." Echinacea even became one of the first patent medicines, sold by a huckster in Missouri at midcentury. In the early 1900s, echinacea was introduced to the European continent, where it occupies a special place in medical therapy. One estimate stated that, in Germany alone, there are 800 echinacea-containing drugs, including several homeopathic preparations.¹⁹

Three species are identified as echinacea²⁰: *E. angustifolia*, *Echinacea pallida*, and *Echinacea purpurea*. All are used for medicinal purposes, and they have similar properties. There are slight differences among the species with regard to the anatomical distribution of active constituents.

CHEMISTRY

There is no doubt that echinacea has immunomodulating properties. The chemistry of the constituents of the plant has been studied extensively, but it is difficult to correlate a major activity with any plant fraction. Indeed, no single component appears to be responsible for the activity of echinacea. Standardization of echinacea preparations has also proved to be a problem. The consumer is presented with three potential preparations sold under the name "echinacea": *E. purpurea*, *E. angustifolia*, and *E. pallida*. Some medicinal preparations are from the roots (all three species), some from the aerial parts (*E. purpurea*), and some from the whole plant (homeopathic mother tinctures of *E. angustifolia* and *E. pallida*).²⁰ Another factor that affects the compo-

sition of echinacea preparations is the way in which they are extracted. Expressed juices, teas, hydroalcoholic extracts, and tinctures in alcohol are used, as well as solids. It is rarely possible to obtain reproducibility in these preparations.

In 1916, the National Formulary of the United States listed the roots of both *E. angustifolia* and *E. pallida* as official, and the distinction between the two began to be forgotten. In about 1950, *E. purpurea* was introduced as the primary medicinal plant in Europe. Of the three species, *E. pallida* is the most widely cultivated, the tallest, and has the largest flowers. This is considered the official preparation in the United States. *E. purpurea* root preparations are sometimes adulterated with a similar-looking plant called *Parthenium integrifolium*. HPLC analysis can easily detect the adulteration.²¹ This shows how difficult it is to standardize echinacea preparations. Additionally, opinions differ about which plant component is the best for analytical standardization of the drug. Echinacea contains a series of phenylpropanoid glycosides, echinacoside, verbascoside, and 6-*O*-caffeoyl echinacoside (Fig. 29.1).^{22,23} These compounds possess no immunostimulating activity. Some argue that the caffeoyl glycoside echinacoside should be the standard, because it is easy to detect and quantitate; others feel that it makes little sense to standardize the echinacea preparation to a compound that has no medicinal activity.

Several fractions of echinacea have been isolated according to polarity and studied for pharmacological activity. The most polar components, the polysaccharides, yielded two immunostimulatory polysaccharides, PS1 and PS2.²⁴ These stimulate phagocytosis in vivo and in vitro and cause a burst of production of oxygen radicals by macrophages in a dose-dependent way. PS1 is a 4-*O*-methylglucuronoarabinxylin with a molecular weight (MW) of 35,000. PS2 is an acidic arabinorhamnogalactan with an average MW of 45,000. Luettig et al.²⁵ have shown that different concentrations of polysaccharides from *E. purpurea* could stimulate macrophages to release tumor necrosis factor- α (TNF- α). These constituents also activate B cells and stimulate the production of interleukin-1. Three glycoproteins have also been isolated that exhibit B-cell-stimulating activity and induce the release of interleukin-1, TNF- α , and interferon (IFN) from macrophages, both in vitro and in vivo.²²

Alcoholic tinctures of the aerial parts and roots of echinacea contain caffeic acid derivatives (Fig. 29.2) and

Echinacoside	R=Glucose (1,6-)	R'=Rhamnose (1,3)-
Verbascoside	R=H	R'=Rhamnose (1,3)-
6- <i>O</i> -Caffeoylglycoside	R=6- <i>O</i> -caffeoylglucose	R'=Rhamnose (1,3)-

Figure 29.1 • Chemical constituents of *Echinacea*.

Figure 29.2 • Caffeic acid derivatives in *Echinacea*.

lipophilic, polyacetylenic compounds (Fig. 29.3). The roots of *E. angustifolia* and *E. pallida* contain 0.3% to 1.7% echinacoside²⁶ as the principal conjugate in the plant. *E. angustifolia* contains 1,5-*O*-dicafeoyl quinic acids (quinic, chlorogenic, and cynarin)²⁷ in the root tissue, allowing distinction by HPLC. Echinacoside has low bacterial and viral activity but does not stimulate the immune system. The most important set of compounds that seem to be found throughout the tissues of all of the echinacea species are the 2,3-*O*-dicafeoyl tartaric acids, caftaric acid, and chicoric acid.²⁸ Chicoric acid possesses phagocytic stimulatory activity in vitro and in vivo, whereas echinacoside lacks this activity. Chicoric acid also inhibits hyaluronidase and protects collagen type III from free-radical degradation.

The alkamides²⁹ (Fig. 29.3) from the roots and flowers of *E. angustifolia* and *E. purpurea* stimulate phagocytosis in model animal systems. There are a host of these compounds distributed throughout the aerial parts of some *Echinacea* species and the roots of most. One such compound, echinacein,²⁸ displays sialogogue and insect repellent properties and is believed to be the main immunostimulant in echinacea. The alkamides and ketoalkynes^{29,30} may very well possess activity. One notable effect is the anti-inflammatory effect of a high-molecular-weight arabinogalactan that is about as potent as indomethacin.²⁵ The lipophilic fractions, the alkamides, stimulate phagocytosis and inhibit 5-lipoxygenase and cyclooxygenase (COX), blocking the inflammatory process.

It is clear that echinacea can stimulate components of the innate immune system, but no single component seems to be responsible for the effect. Echinacea, if taken at the onset of symptoms of a cold or flu, will lessen the severity of the disease. It is not recommended that one use echinacea longer than 10 to 14 days, however, and persons younger than the age of 12 and those who are immunocompromised should never use this herb.

Feverfew

Feverfew, *Tanacetum parthenium* (L.) Schultz Bip,³¹ is an herb that was used in antiquity to reduce fever and pain. The

literature is replete with anecdotal evidence of the usefulness of the herb, and recent clinical studies have added more support. Feverfew is a member of the aster/daisy family. The plant tissues have a pungent smell and very bitter taste. The medicinal principle of feverfew is concentrated in hairy trichomes on the chrysanthemum-like leaves.³² The plant displays clusters of daisylike flowers with yellow centers and radiating white florets. Recent uses of feverfew are for migraine and arthritis, although the indication for arthritis is disputable. The anecdotal evidence that an herb could successfully treat a condition such as migraine headache, naturally begged for some scientific proof.

Figure 29.3 • Lipophilic, polyacetylenic constituents of *Echinacea*.

Two prospective clinical studies using dried whole feverfew leaf have been performed^{33,34} to assess the value of the herb in migraine. The two leaf studies on migraine provided good supportive evidence for activity of the herb against migraine. Both studies were double-blinded, placebo-controlled, and standardized on 0.54-mg parthenolide per capsule. In both studies, the feverfew group demonstrated significant decreases in frequency, severity of attacks, and nausea and vomiting. No adverse effects were observed of the nonsteroidal anti-inflammatory drug (NSAID) type.

MECHANISM OF ACTION

Feverfew inhibits prostaglandin synthesis, but not through an effect on COX.³⁵ The herb also inhibits the synthesis of thromboxane, again by a COX-independent mechanism. Additionally, feverfew inhibits the synthesis of phospholipase A₂ in platelets,^{36,37} preventing the liberation of arachidonic acid from membrane phospholipids for subsequent conversion to prostaglandins and thromboxane. Feverfew also inhibits the adenosine diphosphate (ADP)-, collagen-, and thrombin-induced aggregation of platelets, suggesting that the herb has a greater thrombotic effect. In another similar study, dried leaves of feverfew inhibited prostaglandin and thromboxane synthesis in platelets and inhibited platelet aggregation initiated by ADP and collagen.³⁸ Surprisingly, this study showed that feverfew inhibited the platelet-release reaction by which intracellular storage granules are released.³⁹ These storage granules contain serotonin, a positive effector in migraine headache. Some of the more surprising findings for feverfew are that it appears to be a selective inhibitor of inducible COX-2,⁴⁰ and it has clear effects on vascular tone in animal models.

The pharmacologically active constituent in feverfew has typically been considered to be parthenolide,⁴¹ an amphiphilic sesquiterpene lactone that is biosynthesized from the germacranolide cation. Parthenolide is present in much

3- β -Hydroxy parthenolide

Figure 29.5 • Chemical constituents of feverfew.

greater quantities than any of the other constituents, and its presence does seem to correlate with activity, at least in dried leaves. Parthenolide is an α -methylene lactone,⁴² an α,β -unsaturated molecule that can serve as an acceptor in the Michael reaction. In the Michael reaction, a donor nucleophile such as a thiol can attack the acceptor to form a covalent adduct. If parthenolide functions this way, a biological nucleophile such as a thiol on an enzyme could be bound, inactivating that enzyme. The likelihood of this mechanism has been shown by successfully forming adducts with parthenolide itself *in vivo*.^{43,44} The other components—canin, artemican, secotanapthenolide, and 3- β -hydroxy parthenolide (Figs. 29.4 and 29.5) are present in lower concentrations.⁴⁵ Their effects may be important to the activity of feverfew, but this is impossible to judge at present. One study that used an extract of the leaf with known parthenolide content failed to show activity, so questions still remain.

Saint John's Wort

Saint John's wort (*Hypericum perforatum*) is a medicinal herb that has been used since the time of Paracelsus (1493–1541) to treat various psychiatric disorders. Today, the herb remains one of the most important psychotropic drugs in Germany and Western Europe for the treatment of depression, anxiety, and nervousness.⁴⁶ The drug has recently become popular among consumers in the United States. The demand for the drug in the United States has been fueled by German studies that reported that St. John's wort was equipotent with fluoxetine in the treatment of depression.

Some interesting circumstances give the herb its name. The plant is a low-growing shrub that grows wild in Europe and Western Asia with yellow flowers that bloom around June 24, the traditional birthdate of St. John. If the flowers are rubbed, a red pigment is released. This red substance has traditionally been associated with the blood of St. John released at his beheading.

The medicinal components of St. John's wort are derived from the flowering tops. A 2001 study in *Journal of the American Medical Association*, however, negates about 30 previously published trials and showed that St. John's wort failed to improve major depressive disorder in the first large-scale, multicenter, randomized, placebo-controlled trial in patients diagnosed with major depressive disorder. The herb has a definite mild sedative effect, and in 10 years of controlled clinical trials, it has proved effective in the treatment of *mild* depression.

CHEMISTRY⁴⁷

The red components of Saint John's wort are the anthracene derivatives hypericin, present in about 0.15%,

Figure 29.4 • Chemical constituents of feverfew.

Figure 29.6 • Chemical components of St. John's wort.

and pseudohypericin. (Fig. 29.6) Flavonoids present are quercetin, hyperoside, quercitrin, isoquercitrin, and rutin. (Fig. 29.6) Two C–C-linked biflavins, amentoflavone and biapigenin, are present, as is the acylphloroglucinol derivative hyperforin. Procyanidin, a chiral flavone dimer, adds to the list of flavones. Some terpenes and *n*-alkanes are present as minor components. The primary active ingredients have traditionally been held to be the hypericins and the flavone/flavonols, especially the hypericins. In fact, the German Commission E Monograph specifies that the herb should be standardized to hypericin content.

Despite the evidence of efficacy, the mechanism of action of St. John's wort remains unclear. Several possibilities have been put forth. Probably, the most popular one is

the MAOI/COMT hypothesis. According to this hypothesis, St. John's wort increases the levels of catecholamines at the brain synapses by inhibiting their inactivation by oxidative deamination (MAOI) and by catechol functionalization (catechol-*O*-methyltransferase [COMT]).⁴⁷ Recent studies have shown that hypericins possess such activities only at pharmacologically excessive concentrations. If true, these effects at normal doses are small and do nothing to alleviate depression. Other hypotheses suggest hormonal effects or effects on the dopaminergic system. Hyperforin has become a candidate for the major antidepressant constituent of St. John's wort, supposedly inhibiting serotonin reuptake by elevating free intracellular sodium.

Figure 29.7 • Capsaicin derivatives of *Capsicum*.

St. John's wort also exhibits anti-inflammatory and antibacterial activity. Reports of antiviral activity are unsubstantiated. The main adverse effect with St. John's wort is severe phototoxicity. A sunburnlike condition may occur at normal dosages. St. John's wort should never be taken with MAOIs because of the risk of potentiation of the effects. Selective serotonin reuptake inhibitors (SSRIs) likewise should not be taken with St. John's wort because of the risk of serotonergic syndrome.

Dose (capsules standardized to 0.3% hypericin): 300 mg of standardized extract 3 times daily.

The FDA considers St. John's wort to be unsafe.

Capsicum (Capsaicin, Chili Pepper, Hot Pepper)

Pepper plants have been used for years as herbal remedies for pain.⁴⁸ The therapeutically useful pepper plants are members of the Solanaceae family. There are two primary species whose dried fruit is commonly used: *Capsicum frutescens* and *Capsicum annum*. The actual active ingredient, capsaicin, is extracted from an oleoresin that represents up to 1.5% of the plant. Two major components in the oleoresin (among several) are capsaicin and 6,7-dihydrocapsaicin. (Fig. 29.7) Volatile oils and vitamins A and C occur in large quantities. The amount of ascorbic acid in the capsaicin oleoresin is reportedly 4 to 6 times that in an orange.⁴⁹

Capsaicin is supplied pharmaceutically as a cream, gel, or lotion. The first application of the preparation produces intense pain and irritation at the site of application, but usually no skin reaction occurs. Repeated applications cause desensitization, and eventually analgesic and anti-inflammatory effects occur. Stimulation of afferent nerve tracts causes a heat sensation.

There are several potential explanations for the alleviation of pain by capsaicin. There is believed to be a compound called *substance P* that mediates pain stimuli from the periphery to the spinal cord. One theory is that capsaicin depletes the neuronal supply of substance P so that pain stimuli cannot reach the brain.⁵⁰ Additionally, the methoxyphenol portion of the capsaicin molecule may fit

the COX receptor site and inhibit the lipoxygenase and COX pathways.⁴⁹

Capsaicin is extremely potent, so topical preparations are compounded in percentage strengths of 0.025% to 0.25%. The preparations deplete substance P most effectively if used 3 to 4 times a day. Capsaicin has been suggested as a remedy for postsurgical pain (postamputation and postmastectomy), postherpetic neuralgia, and a variety of other complex pain situations. Relief of pain may occur as quickly as 3 days or may require up to 28 days.

Patients should be instructed to wash their hands well after applying capsaicin. Contact with mucous membranes and the eyes should be avoided. If contact occurs, one should wash with cool running water.

Capsaicin as the oleoresin is used as a "pepper spray" for self-defense. Spraying into the eyes causes immediate blepharospasm, blindness, and incapacitation for up to 30 minutes.

Garlic

Garlic (*Allium sativum*)⁵¹ is an herbal drug with references to medicinal properties that date back thousands of years. Of all the herbal remedies available to consumers, garlic is probably the most extensively researched.⁵² Publications about the effects and benefits of garlic occur with great frequency. Garlic is a bulb. It may be used as such, but it is typically dried, powdered, and compressed into a tablet. Usually, the tablets are enteric coated.

CHEMISTRY

Garlic⁵³ contains a key component, alliin or *S*-methyl-L-cysteine sulfoxide. Additionally, methiin (methylcysteine sulfoxide), cycloalliin, several γ -L-glutamyl-*S*-alkyl-L-cysteines, and alkyl alkanethiosulfonates are present (Fig. 29.8). The tissues also contain enzymes (alliinase, peroxidase, myrosinase), as well as additional sulfur-containing compounds, ajoene, and other minor components. Garlic itself has the highest sulfur content of all of the *Allium* species. When the garlic clove is crushed, the enzyme

Figure 29.8 • Chemical components of garlic.

alliinase is released, and alliin is converted to allicin. Allicin gives garlic its characteristic odor and is believed to be the pharmacologically active ingredient from the herb. Alliinase will not survive the acidic environment of the stomach, so enteric-coated tablets are used.

Garlic is most often studied for its lipid-lowering and antithrombotic⁵⁴ effects. A cholesterol-lowering effect is well documented in both animals and humans. Garlic lowers serum cholesterol, triglycerides, and low-density lipoprotein (LDL) while increasing high-density lipoprotein (HDL). Jain reported mean reductions of 6% in total serum cholesterol and 11% in LDL. Methylallyltrisulfide in garlic oil potentially inhibits ADP-induced platelet aggregation, and ajoene inhibits platelet aggregation for short periods.

Compared with the statin drugs, there is a paucity of human research data for garlic. There have been no morbidity and mortality studies for garlic, for instance. All that we can really gather from the literature is that there *may* be an effect on patient lipid profiles, but for every positive response, a negative one can be found. Garlic is certainly not harmful and can be used safely as part of a lipid-reduction program, but this should be done under a physician's supervision.

Chamomile

The herb known as chamomile⁵⁵ is derived from the plants *Matricaria chamomilla* (German, Hungarian, or genuine chamomile) and *Anthemis nobilis* (English, Roman, or common chamomile). Plants from the two genera have similar activities. The medicinal components are obtained from the flowering tops. The flowers are dried and used for chamomile teas and extracts. Chamomile has been used medicinally for at least 2,000 years. The Romans used the herb for its medicinal properties, which they knew were antispasmodic and sedative. The herb also has a long history in the treatment of digestive and rheumatic disorders.

The activity of chamomile is found in a light blue essential oil that composes only 0.5% of the flower. The blue color is caused by chamazulene, 7-ethyl-1,4-dimethylazulene (Fig. 29.9). This compound is actually a byproduct of processing the herb. The major component of the oil is the sesquiterpene (–)- α -bisabolol. Also present are apigenin, angelic acid, tiglic acid, the terpene precursors (farnesol, nerolidol, and germacranolide) coumarin, scopoletin-7-glucoside, umbelliferone, and herniarin. Much of the effect of chamomile is caused by bisabolol (Fig. 29.9). Bisabolol is a highly active anti-inflammatory agent in various rodent inflammation and arthritis tests. In addition, bisabolol shortens the healing time of burns and ulcers in animal models.

The gastrointestinal (GI) antispasmodic properties of bisabolol and its oxides are well-known. In fact, bisabolol is said to be as potent as papaverine in tests of muscle spasticity. Besides bisabolol, the flavone and coumarin components

Figure 29.9 • Bisabolol, a key component of chamomile.

Figure 29.10 • Anti-inflammatory components of chamomile.

have antispasmodic activities. The blue compound chamazulene possesses both anti-inflammatory and antiallergenic activities, as do the water-soluble components (the flavonoids). Apigenin and luteolin (Fig. 29.10) possess anti-inflammatory potencies similar to that of indomethacin. These flavonoids possess acidic phenolic groups, a spacer, and an aromatic moiety that could fit into the COX receptor. None of these effects has been unequivocally documented in humans. The essential oil possesses low-water solubility, but teas used over a long period of time provide a cumulative medicinal effect. Typically, 1 teaspoon (3 g) of flower head is boiled in hot water for 15 minutes, 4 times a day.

DRUG INTERACTIONS

Chamomile contains coumarins and may enhance the effect of prescription anticoagulants. The herb is an antispasmodic and slows the motility of the GI tract. This action might decrease the absorption of drugs. Chamomile preparations may be adulterated with chamomile pollen. This may cause allergy, anaphylaxis, and atopic dermatitis.

Ephedra

The varieties of ephedra (*Ephedra sinica*, *Ephedra nevadensis*, *Ephedra trifurca*, *ma huang*, natural ecstasy, ephedrine, *Herba Ephedrae*) that possess medicinal activity grow in Mongolia or along the Mongolian border region with China. The plant itself, an evergreen with a pine odor, consists of green canelike structures with small, reddish brown basal leaves. In the fall, the canes, root, and rhizome are harvested and dried in the sun. The dried material furnishes the active ingredients.

ACTIVITY

Ma huang is a sympathomimetic agent. The active principles are β -phenethylamines (Fig. 29.11).^{11–13} These agents can stimulate the release of epinephrine and norepinephrine from nerve endings. Ma huang is a sympathomimetic stimulant in the periphery as well as in the central nervous system (CNS). It has positive inotropic and positive chronotropic effects on

Figure 29.11 • Beta-phenethylamines in ma huang.

the heart; hence, the herb may be dangerous to people with cardiac disease. The amounts of ephedra-type compounds and the relative composition differ so widely that it is difficult to be certain what one is getting in any given preparation. Ma huang's main active ingredient is the β -phenethylamine compound (–)-ephedrine. Plants grown in China may contain 0.5% to 2.5% of this compound. Many ephedrine congeners are represented in the plant,¹¹ and many of these possess considerable pharmacological activity. Some are as follows: (–)-ephedrine, (+)-pseudoephedrine, norephedrine, norpseudoephedrine, ephedroxane, and pseudoephedroxane (Fig. 29.11).

Ma huang's principal active ingredient is (–)-ephedrine. This compound is the *erythro*-D(–)-isomer with the 2(*S*),3(*R*) configuration. The less potent (+)-pseudoephedrine has the *threo* 2(*S*),3(*S*) structure. Ephedrine acts as a mixed agonist on both α - and β -receptors.

PHARMACOLOGICAL EFFECTS

Ephedrine's actions occur through mixed stimulation of the α - and β -adrenergic receptors. The drug is a CNS stimulant that increases the strength and rate of cardiac contraction. Additionally, ephedrine decreases gastric motility, causes bronchodilation, and stimulates peripheral vasoconstriction with the predicted increase in blood pressure. The *threo* isomer (+)-pseudoephedrine causes similar effects but is much less potent than (–)-ephedrine. The claims that ephedra causes increased metabolism and “fat burning” are certainly false, and ephedra lacks anorectic effects. Any reports of successful use of ephedra preparations in weight loss probably reflect the stimulant or “energizing” effect and increased physical activity. In the United States, ephedra has been used as a recreational CNS stimulant (natural ecstasy).

E. nevadensis and *E. trifurca* are typically used in teas. The FDA prohibits preparations with more than 8 mg/dose and advises that one should not take an ephedra product more often than every 6 hours and no more than 24 mg/day. Ephedra should not be used for more than 7 days. Dosages

over the recommended amount may cause stroke, myocardial infarction, seizures, and death.

Ephedra has been closely linked to methamphetamine production. There are movements in many localities to outlaw the herb. There are many drug interactions with ma huang. β -Blockers may enhance the sympathetic effect and cause hypertension. MAOIs may interact with ephedra to cause hypertensive crisis. Phenothiazines might block the α -effects of ephedra, causing hypotension and tachycardia. Simultaneous use of theophylline may cause GI and CNS effects. In pregnancy, ephedra is absolutely contraindicated (uterine stimulation). Persons with heart disease, hypertension, and diabetes should not take ephedra.

Cranberry

The cranberry plant (*Vaccinium macrocarpon*, *Vaccinium oxycoccus*, and *Vaccinium erythrocarpum*) is a trailing evergreen that grows primarily in acidic swamp areas. The whole berries are divested of seeds and skins, and the rest of the fruit is used as a drink or in capsule form. Cranberry juice has been used, for many years, as a urinary tract disinfectant. In 1923,⁵⁶ a report said that the urine of persons who consumed cranberry juice became more acidic. Because an acidic medium hinders the growth of bacteria, it was thought that acidification of the urine inhibited bacterial growth.

An analysis of cranberry juice shows that it contains many different compounds. Citric, malic, benzoic, and quinic acids are present as carboxylic acid components. With pK_a 's of 3.5 to 5, these compounds should exist in the ionized form in the urine at pH 5.5, thus lowering the pH. We now know that acidification of the urine is not the entire story. In fact, drinking the cocktail does not appreciably acidify the urine. Two other constituents exist in the juice: mannose and a high-molecular-weight polysaccharide.^{57–59} With bacteria that use fimbrial adhesins in infecting the urinary tract, mannose binds and inhibits adhesion of the type 1 mannose-sensitive fimbriae, whereas the high-molecular-weight polysaccharide inhibits binding of the P-type fimbriae. Hence, adhesion of many *Escherichia coli* strains, which cause over half of all urinary tract infections, is inhibited. This inhibition has the effect of blocking infection.

Dosage: Drink between 10 and 16 oz of juice daily.

Ginkgo Biloba

Ginkgo biloba (L.), also known as the maidenhair or Kew tree, has survived essentially unchanged in China for 200 million years.⁶⁰ There is a Chinese monograph, describing the use of ginkgo leaves, dating from 2800 BC. Today, ginkgo is extracted by an extremely complex multistep process that concentrates the active constituents and removes the toxic ginkgolic acid.⁶¹

The ginkgo extract is a complex mixture of both polar and nonpolar components (Fig. 29.12). The more polar fractions contain flavonol and flavone glycosides. The more nonpolar fractions contain some diterpene lactones, known as ginkgetin, ginkgolic acid, and isoginkgetin, and some interesting caged diterpenes known as ginkgolide A, B, C, J, and M.⁶² There is also a 15-carbon sesquiterpene (bilobalide) and other minor components. *G. biloba* extract is prepared by picking the leaves, drying them, and constituting them into an acetone-water extract that is standardized to contain 24% flavone glycosides and 6% terpenes.⁶⁰

Figure 29.12 • Chemical components of ginkgo extract.

G. biloba produces vasodilating effects on both the arterial and venous circulation.^{60,61} The result is increased tissue perfusion (i.e., in the peripheral circulation) and cerebral blood flow. The extract produces arterial vasodilatation (rodent models), dampens arterial spasticity, and decreases capillary permeability, capillary fragility,⁶⁰ erythrocyte aggregation, and blood viscosity. There are several possible explanations for these effects. One possibility is that the compounds in *G. biloba* extract inhibit prostaglandin and thromboxane biosynthesis. It has also been speculated that *G. biloba* extract has an indirect regulatory effect on catecholamines. Ginkgolide B is reportedly a potent inhibitor of PAF.¹⁵ In any case, the effects are caused by a mixture of the constituents, not a single one.

G. biloba has become popular because of its putative abilities to increase peripheral and cerebral circulation. The herb is called an *adaptogen*,⁶³ a drug that helps persons handle stress. In the periphery, the herb has been compared to pentoxifylline. If the properties are true, the herb could be used for intermittent claudication. If cerebral blood flow can be increased with *G. biloba*, the herb might be useful for disorders of memory that occur with age and Alzheimer disease. The popular use for the herb is to help people think better under stress and to increase the length of time that someone (e.g., a student) can handle mental stress.

Ginseng

Ginseng is the root of the species *Panax quinquefolius*. This form is commonly known as American, or Western, ginseng. The shape of the root is important to many and may make it highly prized. *Panax* means “all” or “man.” Sometimes, the root is shaped like the figure of a human. The doctrine of signatures would say that this root would benefit the whole person. Another species of ginseng, *Panax ginseng*, is commonly called Asian, or Korean, ginseng. Chemically, the two species are very similar. Major components are named the *ginsenosides* (Figs. 29.13, 29.14).⁶⁴

The chemical constituents of ginseng are called ginsenosides or *panaxosides*. A total of 12 of these have been isolated but are present in such small quantities that purification is difficult. Sterols, flavonoids, proteins, and vitamins (B₁, B₂, B₁₂, pantothenic acid, niacin, and biotin) are also components with pharmacological activity. The chemistry of ginseng gives a good example of how different compounds in

Figure 29.13 • Structures of ginsenosides.

Figure 29.14 • Structures of ginsenosides.

20 (R) Ginsenoside

one herb can have opposing pharmacological effects.⁶⁵ Ginsenoside Rb-1 acts as a CNS depressant, anticonvulsant, analgesic, and antipsychotic, prevents stress ulcers, and accelerates glycolysis and nuclear RNA synthesis. Ginsenoside Rg-1 stimulates the CNS, combats fatigue, is hypertensive, and aggravates stress ulcers. Additionally, ginsenosides Rg and Rg-1 enhance cardiac performance, whereas Rb depresses that function. Some of the other ginsenosides display antiarrhythmic activity similar to that of the calcium channel blocker verapamil and amiodarone.

Ginseng is popularly believed to enhance concentration, stamina, alertness, and the ability to do work. Longer-term use in elderly patients is claimed to enhance “well-being.” There are few data from human studies. Clinical studies comparing ginseng with placebo on cognitive function tests showed statistically insignificant improvement. Nevertheless, ginseng is a popular herbal product recommended by the German Commission E.

Milk Thistle

Milk thistle (*Silybum marianum*) is a member of the Asteraceae, a family that includes daisies, asters, and thistles. The plant has a wide range around the world and is found in the Mediterranean, Europe, North America, South America, and Australia. The seeds of the milk thistle plant have been used for 2,000 years as a hepatoprotectant.^{66,67} This usage can be traced to the writings of Pliny the Elder (AD 23–79) in Rome, who reported that the juice of the plant could be used for “carrying off bile.” Culpepper in England reported that milk thistle was useful in “removing obstructions of the liver and spleen and against jaundice.”

CHEMISTRY

Milk thistle contains as an active constituent silymarin (Fig. 29.15),⁶⁶ which is actually a mixture of three isomeric flavanolignans: silybin (silibinin), silychristin, and silydianin. Silybin is the most active hepatoprotectant and antioxidant compound of the mixture. Also present in the plant are the flavanolignans dehydrosilybin, silyandrin, silybinome, and silyhermin. Other lipid-soluble components are apigenin, silybonol, and linoleic, oleic, myristic, stearic, and palmitic acids.

MECHANISM OF ACTION

The silymarin complex is aptly suited for its hepatoprotective actions.⁶⁸ Silymarin undergoes enterohepatic cycling,

moving from intestine to liver and concentrating in liver cells. Protein synthesis is induced in the liver by silybin, whose steroid structure stimulates both DNA and RNA synthesis. Through these activities, the regenerative capacity of the liver is activated. Silymarin is reported to alter the outer cell membrane structure of liver cells, blocking entrance of toxic substances into the cell. This blockage is so pronounced that it can reduce the death rate from *Amanita phalloides* poisoning. Silymarin’s effect can be explained by its antioxidant properties; it scavenges free radicals. By this effect, the level of intracellular glutathione rises, becoming available for other detoxification reactions. Silybin inhibits enzymes such as lipoxygenase,⁶⁶ blocking peroxidation of fatty acids and membrane lipid damage. Studies also show that silymarin protects the liver from amitriptyline, nortriptyline, carbon tetrachloride, and cisplatin. When treated, patients with alcoholic cirrhosis showed increased liver function as measured by enzymes. In patients with acute viral hepatitis, silymarin shortened treatment time and improved aspartate aminotransferase (AST) and alanine aminotransferase (ALT) levels.

In liver disease, silymarin appears to have an immunomodulatory effect. The activities of superoxide dismutase (SOD) and glutathione peroxidase are increased, which probably accounts for the effect on free radicals. Silymarin, however, has an anti-inflammatory effect on human platelets. Silybin retards release of histamine from human mast cells and inhibits activation of T lymphocytes. The chemical appears capable of reducing the levels of all immunoglobulin classes and enhances the motility of lymphocytes. Milk thistle extract and its components have shown efficacy in treating hepatotoxin poisoning, cirrhosis, and hepatitis. It also plays a role in blood and

Silymarin

Figure 29.15 • Silymarin from milk thistle.

immunomodulation and in lipids and biliary function. The overall effect is caused by the electron-scavenging properties of flavanolignans, the enhanced regenerative capacity of the liver, and the alteration of liver cell membranes that blocks toxin entry.

Valerian

Valerian (*Valeriana officinalis*) is found in temperate regions of North America, Europe, and Asia. The dried rhizome of valerian contains an unpleasant-smelling volatile oil that is attributed to isovaleric acid. Despite the odor, valerian is a safe and effective sleep aid.

CHEMISTRY

Three classes of compounds have been linked to the sedative properties of valerian. The rhizome contains monoterpenes and sesquiterpenes (valerenic acid and its acetoxy derivative), iridoids (valepotriates), and pyridine alkaloids (Fig. 29.16).^{69,70} At present, it is not possible to state which class of compound is responsible for the sedative activity. Most researchers believe that the valepotriate is the active component, but some studies have shown that valerenic acid is more potent.

Aqueous and hydroalcoholic extracts of valerian induce the release of [³H]γ-aminobutyric acid (GABA) from synaptosome preparations. The extracts appear to have much the same effects as benzodiazepines, except that valerian does not act on the Na⁺/K⁺-ATPase. Valerenic acid inhibits the GABA transaminase. This effect would increase the inhibitory effect of GABA in the CNS.

There is no doubt that valerian is safe and effective as a sleep aid. Used properly, it is one of the more recommendable herbs.

Dose: 400 to 900 mg standardized extract 0.5 to 1 hour before bedtime.

Pennyroyal

Pennyroyal (*Hedeoma pulegeoides*, *Mentha pulegium*) is an example of an extremely toxic herb. The plant is a member

Figure 29.16 • Chemical constituents of valerian.

Figure 29.17 • Pulegone in pennyroyal.

of the mint family, Labiatae. The dried leaves and flowering tops of the plant contain from 16% to 30% oil, consisting of the monoterpene pulegone (Fig. 29.17).⁷¹ The oil also contains tannins, α- and β-pinenes, other terpenes, long-chain alcohols, piperitenones, and paraffin.

The toxicity of pennyroyal is believed to be a result of the pulegone⁷¹ in the oil. Cytochrome P450 catalyzes the metabolism of pulegone to yield the toxic metabolite menthofuran (Fig. 29.17). Possibly, some of the other terpenes undergo oxidation to active metabolites as well. Menthofuran, metabolites of other terpenes, and pulegone itself deplete hepatic glutathione, resulting in liver failure. This mechanistic hypothesis is supported by the fact that administration of acetylcysteine reverses the toxicity.

Pennyroyal has been used as an abortifacient since the time of Pliny the Elder,⁷² an insect repellent (the terpenes in the oil have citronellal-like properties), an aid to induce menstruation, and a treatment for the symptoms of premenstrual syndrome. It has also been used as a flea repellent on dogs and cats.

When used as an abortifacient, the drug often causes liver failure and hemorrhage, leading to death. Pennyroyal is sometimes used with black cohosh to accelerate the abortifacient effect. Coma and death have been reported. Pennyroyal is an example of an herb that has no safe uses. It should not be sold.

Herbal Drugs Used in the Treatment of Cancer

Anticancer drugs derived from biological sources are fairly common and are among the most important in the therapeutic armamentarium. Drugs such as doxorubicin, mitomycin C, mithramycin, and bleomycin have been around for a long time and have shed much light on the treatment of cancer. Three plant-derived drugs that have found their way through clinical trials deserve mention here. Two of the most famous are vincristine and vinblastine (Fig. 29.18). These are compounds isolated from the periwinkle plant *Catharanthus roseus*. The Vinca alkaloids bind tightly to tubulin in cells and interfere with its normal function in spindle formation. The Vinca alkaloids make the tubulin less stable. The net result is metaphase arrest of cell division. Paclitaxel (Taxol, Fig. 29.18) was originally isolated from the needles or bark of the Pacific yew. Because it occurs in vanishingly small concentration in the plant, a semisynthetic method for its production was developed. Taxol binds to tubulin like the Vinca alkaloids, but it makes the tubulin structure hyperstable so that it cannot function. Again, the net result is metaphase arrest.

Figure 29.18 • Vincristine and vinblastine.

Licorice

When we think of licorice, we typically think of the popular candy. Licorice, however, has an important history in herbal medicine. Licorice is a perennial shrub that is indigenous to the Mediterranean and is cultivated in the Middle East, Spain, northern Asia, and the United States. The most common variety used for medicinal purposes is *Glycyrrhiza glabra* var. *typica*. Licorice has been used since Roman times and was described in early Chinese writings.

CHEMISTRY

The root and rhizomes of the licorice plant contain ~5% to 9% of a steroidal glycoside called *glycyrrhizin* (Fig. 29.19). In the glycoside form, glycyrrhizin is 150 times sweeter than sugar. Also present are triterpenoids, glucose, mannose, and sucrose. Concentrated aqueous extracts may contain 10% to 20% glycyrrhizin. When the herb is ingested, the intestinal flora catalyze the conversion of glycyrrhizin into glycyrrhetic acid (Fig. 29.19), the pharmacologically active

Figure 29.19 • Chemical components of licorice.

Glycyrrhetic Acid $R_1 = H$
Glycyrrhizin $R_1 = R'$

compound. Glycyrrhizin and glycyrrhetic acid possess mild anti-inflammatory properties. Glycyrrhizin appears to stimulate gastric mucus secretion. This may be the origin of the antiulcer properties of licorice. Glycyrrhizin and glycyrrhetic acid do not act directly as steroids. Instead, they potentiate, rather than mimic, endogenous compounds.

There is some interesting folklore relating to the use of licorice. During World War II, a Dutch physician⁷³ noticed that patients with peptic ulcer disease improved dramatically when treated with a paste containing 40% licorice extract. The physician treated many patients in this way, but during the course of his work, he noticed that there was a serious side effect from the herbal drug. About 20% of his ulcer patients developed a reversible edema of the face and extremities. Since these original observations, many studies have been conducted with licorice root. The findings have remained the same; licorice is useful for peptic ulcer disease, but potentially serious mineralocorticoid side effects are possible (lethargy, edema, headache, sodium and water retention, excess excretion of potassium, and increased blood pressure).

Licorice exerts its protective effects on the gastric mucosa by inhibiting two enzymes, 15-hydroxyprostaglandin

dehydrogenase and Δ^{13} -prostaglandin reductase. Inhibition of these enzymes causes their substrates to increase in concentration, increasing the levels of prostaglandins in the gastric mucosa and causing a cytoprotective effect. The acid also inhibits 11- β -hydroxysteroid dehydrogenase,⁷⁴ thus increasing the glucocorticoid concentration in mineralocorticoid-responsive tissues, causing increased sodium retention, potassium excretion, and blood pressure.

In the 1960s, a semisynthetic compound based on glycyrrhetic acid, 4-*O*-succinylglycyrrhetic acid (carbenoxolone), was introduced in Europe. It proved effective against peptic ulcer disease, but it was later shown to be inferior to the H₂-receptor antagonists.

Licorice is also an effective demulcent, soothing a sore throat, and is an expectorant and cough suppressant.

Licorice can cause serious adverse reactions. These are mineralocorticoid effects (pseudoprimary aldosteronism), muscle weakness, rhabdomyolysis, and heart failure. Poisoning by licorice is insidious. Long-term high doses are extremely toxic. Licorice can potentiate the digitalis glycosides and cause toxicity. With cardiovascular agents that prolong the QT interval, the effects may be additive.

REVIEW QUESTIONS

1. What did the Durham-Humphrey Amendment do to drug commerce?
2. What enzyme is induced by St. John's wort and is responsible for prescription drug interactions with this herb?
3. What drug interaction is commonly observed with *G. biloba* use?
4. What is the most problematic aspect of herbal manufacture in the United States?
5. What is the constituent of St. John's wort that is now believed to be responsible for the antidepressant effect of the herb?
6. What herbal drug has been shown to be an effective hepatoprotectant?
7. What herbal drug is an effective treatment for peptic ulcers, albeit with unfortunate side effects?
8. What is a rhizome?

A P P E N D I X

Calculated Log P, Log D, and pK_a

The log P, log D at pH 7, and pK_a values are from Chemical Abstracts Service, American Chemical Society, Columbus, OH, 2009, and were calculated using Advanced Chemistry Development (ACD/Labs) Software V8.14 for Solaris (©1994–2009 ACD/Labs). The pK_a values are for the most acidic HA acid and most weakly acidic BH⁺ groups. The latter represent the most basic nitrogen. Keep in mind that pK_a values for HA acids that exceed 10 to 11 mean that there

will be little, if any, anionic contribution in the pH ranges used in pharmaceutical formulations and in physiological pH ranges. Similarly, for BH⁺ acids, there will be little, if any, cationic contribution for pK_a values below 2 to 3. Because *Chemical Abstracts* does not report calculated physicochemical values for ionized compounds, including salts and quaternary ammonium compounds, the log P values in this appendix are for the un-ionized form.

Name of Compound	Log P	Log D at pH 7	pK _a		Name of Compound	Log P	Log D at pH 7	pK _a

α-Tocopherol	11.86	11.86	11.40		Valsartan	4.38	-0.57	3.69	
Tolazamide	1.71	0.47			Vardenafil	3.03	2.97	9.11	6.11
Tolbutamide	2.34	0.80			Varenicline	0.74	-1.74		9.60
Tolcapone	4.15	1.98	4.78		Venlafaxine HCl	2.91	0.70		9.26
Tolmetin	1.55	-0.98	4.46		Verapamil	4.91	2.91		9.03
Tolnaftate	5.48	5.48			Vidarabine	-1.46	-1.46	13.11	3.25
Tolterodine	5.77	2.80	10.00	10.78	Vinblastine	4.22	3.45	11.36	7.64
Tolvaptan	4.33	4.33			Vincristine	2.84	2.10	11.07	7.64
Topotecan	0.79	0.55	7.20	2.28	Vinorelbine	5.42	5.03	11.34	7.09
Toremifene	7.96	6.32		8.63	Voriconazole	0.72	0.72	12.00	4.98
Torseamide	3.17	0.53	3.08	4.80	Vorinostat	0.86	0.86	9.48	
Tramadol	2.51	0.40		9.16	Warfarin	3.47	0.98	4.50	
Trandolapril	4.53	1.41	3.72	5.51	Xylometazoline	4.91	1.92		10.62
Tranexamic acid	0.32	-2.19	4.77	10.39	Yohimbine	1.91	0.47		8.44
Tranlycypromine	1.21	-0.56		8.78	Zafirlukast	6.15	2.65	3.37	
Travoprost	4.06	4.06	13.50		Zalcitabine	-1.51	-1.51		4.47
Trazodone	1.66	1.52		6.59	Zaleplon	1.00	1.00		
Treprostinil	4.09	0.47	3.19		Zanamivir	-3.75	-6.25	3.92	11.65
Tretinoin	6.83	4.62	4.79		Zileuton	3.74	3.74	9.99	
Triacetin	-0.24	-0.24			Ziprasidone	4.02	2.75	13.34	8.24
Triamcinolone	1.03	1.03	11.58		Zoledronic acid	-2.28	-7.04	0.32	6.78
Triamcinolone acetonide	2.60	2.60	12.69		Zolmitriptan	1.64	-0.78	12.57	9.52
Triamcinolone diacetate	1.82	1.82	11.21		Zolpidem	2.61	2.35		6.91
					Zonisamide	-0.10	-0.10	9.56	

INDEX

Note: Page numbers followed by “f” indicate figures; those followed by “t” indicate tables. Drugs are listed under the generic name.

- A**
AAS. *See* Androgen(s)
Abacavir, 345
Abarelix acetate, 699t, 700–701, 700f
Abbokinase. *See* Urokinase
Abciximab, 149, 629
Ablify. *See* Aripiprazole
Abitrexate. *See* Methotrexate
Abmoclolin. *See* Chlorambucil
Absolute ethanol, 182
Absolute specificity, 885
Absorption, distribution, metabolism, and elimination (ADME) models, for computer-aided drug design, 25
Acarbose, 662–663, 687–688, 687f–688f
Accuretic. *See* Quinapril hydrochloride
ACE. *See* Angiotensin-converting enzyme
Acebutolol, 552–553, 553f–554f
Acetaldehyde, in alcohol metabolism, 182
Acetaminophen
 as antipyretic, 803–806, 804f–806f
 conjugation of, 89–90, 92, 97, 99
 metabolism of, 8, 73–74
 toxicity in, 805–806, 806f
Acetanilide, 803–804
Acetohexamide, 660, 671f, 673t, 676, 677f, 680
 metabolism of, 59, 61, 80, 82
Acetophenone, metabolism of, 80–82
(+)-*trans*-(1S,2S)-acetoxycyclopropyltrimethylammonium, 565, 566f
Acetoxyethyl onium salts, 567t
2-Acetylaminofluorene, metabolism of, 73–74
Acetylation, 97–102
Acetylation polymorphism, 101
Acetylcholine (ACh), 24, 558
 conformational flexibility of, 29–30, 29f
 conformation of, 564–565, 565f
 ganglionic stimulation by, 596–597, 597f
 hydrolysis of, 570–571, 572f
 neuromuscular junction transmission and, 599–600
 as neurotransmitter, 558–559, 563–564, 563f–564f, 596–597, 597f
 nicotinic effect of, 597–598
 pharmaceutical, 568
 release of, 563–564, 563f
 storage of, 563, 563f
 structure–activity relationships of, 566–567, 566f–567f, 567t
 structure of, 558
 synthesis of, 563–564, 563f–564f
Acetylcholine chloride, 568
Acetylcholine receptors, 559–563
 activation of, 562–563, 562f
 muscarinic, 560–563, 561f–562f, 566–567, 566f
 nicotinic, 559–560, 559f–560f, 559t
Acetylcholinesterase (AChE), 558, 563–564, 563f
 action of, 570–572, 572f
 inhibition of, 570–572, 571t–572t, 572f
 phosphorylation of, 577–578, 577f–578f
 reactivation of, 577–578, 577f
Acetylcholinesterase inhibitors, 570–572, 571t–572t, 572f
 irreversible, 572t, 577–581, 577f–578f, 580f
 reversible, 572–576, 572t, 573f
Acetyl-CoA, 563–564, 563f–564f
Acetylmethadol (LAAM), 788f, 789
Acetylsalicylic acid. *See* Aspirin
ACh. *See* Acetylcholine
AChE. *See* Acetylcholinesterase
Acidosis, antiarrhythmic activity and, 632
Acids, 12–17
 conjugate, 12, 13t
 definition of, 12
 percent ionization, 14–16, 15f–16f
 reactions, 12, 13t
 strength of, 12, 14, 14t
AcipHex. *See* Rabeprazole sodium
Acitretin, half-life of, 6
Aclovate. *See* Alclometasone dipropionate
Acquired immunity, 159t, 161–165
 innate vs., 159, 159t
Acrivastine, 741t, 756–757
ACT-D. *See* Dactinomycin-D
ACTH. *See* Adrenocorticotropic hormone; Corticotropin
Acthar. *See* Corticotropin injection
Acthar Gel. *See* Repository corticotropin injection
Acthrel. *See* Corticorelin
Actidil. *See* Triprolidine hydrochloride
Actinomycin, 260t, 384, 384f, 388
Actinomycin-D. *See* Dactinomycin-D
Actinospectocin. *See* Spectinomycin hydrochloride
Action potentials, neuronal membrane permeability during, 719–720
Actiq. *See* Fentanyl
Activase. *See* Alteplase; Alteplase, recombinant
Activella, 846t
Active-site-directed irreversible inhibition, 25
Actonel. *See* Risedronate sodium
Actoplus Met. *See* Metformin; Pioglitazone
Actos. *See* Pioglitazone
Actron. *See* Ketoprofen
Acute gouty arthritis, 810–811, 810f
Acute pain, 776–777
Acute phase factors, 160, 160t
Acyclovir, 341
 metabolism of, 7–8
Aclases, penicillin resistance and, 266
AD 32. *See* Valrubicin
Adalat. *See* Nifedipine
Adamantanamines, 336
Adapin. *See* Doxepin hydrochloride
Adaptogen, 970
Addison disease, 857, 859–860
Adefovir dipivoxil, 340–341
Adenine arabinoside, 40, 40f, 340, 378
Adenosine monophosphate (AMP), 561–563
 in platelet aggregation, 657, 657f
 in smooth muscle relaxation, 618–619, 619f
Adenosine monophosphate-activated protein kinase (AMPK), metformin activation by, 686
Adenylate cyclase, 562–563, 562f
 gastric acid secretion and, 760, 761f
ADH. *See* Vasopressin
Adjuvants, vaccines and, 176–177
ADM. *See* Doxorubicin hydrochloride
ADME models. *See* Absorption, distribution, metabolism, and elimination
ADR. *See* Doxorubicin hydrochloride
Adrenal cortex hormones, 853–864, 854f–857f, 858t, 860f, 864f
 biological activities of, 855–856
 biosynthesis of, 854–855, 854f
 endogenous, 853–854
 metabolism of, 855, 855f
 mineralocorticoid receptor antagonists, 615, 864
 structural classes of, 856–859, 856f–857f, 858t
 therapeutic uses of, 859–860
Adrenalin. *See* Epinephrine
Adrenergic agents, 519–555, 520t
 adrenergic receptor antagonists, 545–555
 neurotransmitters, 519–524
 drugs affecting, 528–531
 receptors, 524–528
 sympathomimetic agents, 531–545
 α -Adrenergic antagonists, 641
 Adrenergic-blocking agents, 519
 Adrenergic drugs, 558
 centrally active, 641–642
 Adrenergic neurotransmitters, 519–524, 520t
 biosynthesis of, 519, 521f, 522
 drugs affecting, 528–531
 metabolism of, 523–524, 523t, 524f
 storage and release of, 522
 structure and physicochemical properties of, 519, 520f
 uptake of, 522–523
 Adrenergic receptors, 524–528
 α , 525–526, 525t–526t, 527f
 antagonists, 545–555
 β , 525t, 526–527, 526t, 528f–529f
 subtypes of, 524–525, 525t–526t
 Adrenergic stimulants, 519
 Adrenergic system inhibitors, 639
 Adrenocorticotropic hormone (ACTH), 810, 855, 891, 892t
 Adrenocorticotropic hormone injection, 891, 892t
 Adria. *See* Doxorubicin hydrochloride
 Adriamycin. *See* Doxorubicin hydrochloride
 Adrucil. *See* 5-Fluorouracil
 Adsorbed diphtheria and tetanus toxoid, 173
 Adsorbed tetanus and diphtheria toxoid for adults, 174
 Adsorbed tetanus toxoid, 173
 Adsorption, of virus, 333
 Advil. *See* Ibuprofen
 AeroBid. *See* Flunisolide
 Aerosporin. *See* Polymyxin B sulfate
 AF-DX 116, 567, 568f
 Aflatoxin B₁, metabolism of, 54, 56
 African sleeping sickness, 221
 Afrin. *See* Oxymetazoline
 Afrinol. *See* L-(+)-Pseudoephedrine
 Aftate. *See* Tolnaftate
 Age, drug metabolism and, 104
 Agenerase. *See* Amprenavir
 Agglutination, immunological, 164
 Aggregation, of recombinant proteins, 134
 Aggrenox. *See* Dipyridamole
 Aging, of cholinesterases, 578, 578f
 α -Agonists, 534–535, 540
 α_1 -Agonists, 525, 525t–526t
 α_2 -Agonists, 525, 525t–526t
 β -Agonists, 540–543
 β_2 -Agonists, 525, 525t–526t
 β_3 -Agonists, 543
 Akineton. *See* Biperiden
 Akineton hydrochloride. *See* Biperiden hydrochloride
 Alamast. *See* Pemirolast potassium ophthalmic solution
 Albamylin. *See* Novobiocin sodium
 Albendazole, 226
 Albiglutide, 690f, 691
 Albuminoids, 883t
 Albumins, 883t
 Albuterol. *See* Salbutamol
 Alclometasone, 861
 Alclometasone dipropionate, 857f
 Alcofenac, metabolism of, 53
 Alcohol(s)
 as anti-infective agents, 181–182
 metabolism of, 181–182
 as sedative–hypnotics, 455–456
 Alcohol intolerance, cephalosporins and, 285
 Aldactone. *See* Spironolactone
 Aldehyde oxidase, 78

- Aldehydes
 as anti-infective agents, 182–183
 as sedative-hypnotics, 456–457
- Aldesleukin, 141, 909r, 911
- Aldomet. *See* Methyldopa
- Aldomet ester hydrochloride. *See* Methyldopate hydrochloride
- Aldosterone, 821f, 853–857, 854f, 856f, 858r
- Aldosterone antagonists, 615, 864
- Aleglitazar, 682, 683f
- Alemtizumab, 148
- Alendronate sodium, 707r, 708
- Aleve. *See* Naproxen
- Alfenta. *See* Alfentanil
- Alfentanil, 787f, 788
- Alferon N. *See* Interferon alfa-n3
- Alfuzosin, 548
- Alidase. *See* Hyaluronidase for injection
- Alimta. *See* Pemetrexed
- Aliskiren, 614–615
- Alkalosis, antiarrhythmic activity and, 632
- Alkane anesthetics, structure–activity relationships of, 712–713, 712f
- Alkanol anesthetics, 713
- Alkeran. *See* Melphalan
- Alkylamine antihistamines. *See* Propylamine antihistamines
- Alkylating agents, 358–372
 busulfan, 362, 364f, 369–370
 dacarbazine, 366–367, 367f–368f, 371
 individual agents, 368–372
 mechanism of action of, 358–359, 358f–359f
 nitrogen mustards, 359–361
 nitrosoureas, 365, 366f–367f
 organoplatinum compounds, 362–365, 365f
 procarbazine, 366–367, 367f–368f, 371
 resistance to, 359
 temozolomide, 366–367, 367f–368f
 thiotepea, 361–362, 364f, 369
- Alkylation
 monoalkylation, 361–362
 process of, 358–359, 358f–359f
- Alkylbenzyltrimethylammonium chloride, 187–188
- Allegra. *See* Fexofenadine hydrochloride
- Allergic reactions
 to cephalosporins, 285
 glucocorticoids for, 859, 860f, 863
 histamine role in, 736, 739–740
 to local anesthetics, 724–726
 to penicillins, 268–269
- Allucin, 967f, 968
- Alliin, 967–968, 967f
- Allopurinol, 809f, 811
- All-trans-retinoic acid. *See* Tretinoin
- Allylamines antifungals, 199–200
- Allylic carbon atoms, oxidative reactions at, 55–58
- Allylisopropylacetamide, metabolism of, 55–56
- Almotriptan, 812–814, 812r, 813f
- Alogliptin, 692, 694f
- Alomide. *See* Lodoxamide tromethamine
- Alphagan. *See* Brimonidine
- Alpha-particle emission, 414
- Alprazolam, 449–450
- Alprostadil, 876–877
- Alex. *See* Loteprednol etabonate
- Altace. *See* Ramipril
- Alteplase, 889
 recombinant, 908r, 910
- Alternative complement pathway, 160–161, 160f
- Altretamine, 371–372
- Alupent. *See* Metaproterenol
- Amantadine, 336, 478
 metabolism of, 69–70
 methylation, 103–104
- Amaranth, metabolism of, 84–85
- Amaryl. *See* Glimepiride
- Amibenonium, 572r
- Amibenonium chloride, 575
- Ambien. *See* Zolpidem
- Ambodryl Hydrochloride. *See* Bromodiphenhydramine hydrochloride
- Ambrisentan, 638
- Amcill. *See* Ampicillin
- Amcinonide, 857f, 861
- AMD-3100, 351
- Amebiasis, 220
- Amenorrhea, progestins for, 839
- Amerge. *See* Naratriptan
- Amfenac, 799f, 800
- Amigestic. *See* Salsalate
- Amikacin, 294, 299–300
 inactivation of, 296
- Amikin. *See* Amikacin
- 7-Amino-5-nitroindazole, conjugation of, 90–91
- Amino acid solutions, 881
- Aminoalcohols, 592–594
- Aminoalcohol esters, 588–591
- Aminoalcohol ethers, 591–592
- Aminoalkyl ethers. *See* Ethanolamine antihistamines
- Amino amide local anesthetics, 726–729, 727f–728f
- Aminoamides, 594–595
- p-Aminobenzoic acid (PABA), 217
 acetylation of, 97, 100
 in allergic reactions to local anesthetics, 724–726
- Aminoglutethimide, 835f, 836
- Aminoglycosides, 260r, 294–301
 chemistry of, 294–295
 discovery of, 294
 mechanism of action of, 295
 microbial resistance to, 295–296
 spectrum of activity of, 295
 structure–activity relationships of, 296–297
 types of, 297–301
- β-Aminoketones, 467–468
- 4-Aminoquinolines, 246r–247t, 248–250, 249f
- 8-Aminoquinolines, 246r–247t, 250–251, 250f
- Aminosalicylate sodium, 217
- 5-Aminosalicylic acid, 807f
- p-Aminosalicylic acid (PAS), 215, 217
 acetylation of, 97, 100
- Amiodarone, 636
- Amitiza. *See* Lubiprostone
- Amitriptyline hydrochloride, 512
 metabolism of, 8, 55f
 metabolites of, 111
- Amlodipine, 623r, 626
- Amobarbital, 454, 454f
 metabolism of, 59–60
- Amodiaquine, 248, 249f, 250
- Amoxapine, 513
- Amoxicillin, 15, 268, 269r, 272–273
- Amoxicillin-clavulanate potassium, 275
- Amoxil. *See* Amoxicillin
- AMP. *See* Adenosine monophosphate
- Amphetamine sulfate, 506r, 507, 533
 metabolism of, 48, 68–69, 83, 104–105
- Amphicol. *See* Chloramphenicol
- Amphotericin B, 197–198, 260r
- Amphotericins, chemical classification of, 260
- Ampicillin, 268–269, 269r, 272
- Ampicillin-sulbactam, 276
- AMPK. *See* Adenosine monophosphate-activated protein kinase
- Amprénovir, 349–350
- Amrinone, 646–647
- Amylin analogs, 689–690, 689f
