DISCLAIMER

Care has been taken to confirm the accuracy of the information present and to describe generally accepted practices. However, the authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, expressed or implied, with respect to the currency, completeness, or accuracy of the contents of the publication. Application of this information in a particular situation remains the professional responsibility of the practitioner; the clinical treatments described and recommended may not be considered absolute and universal recommendations.

The authors, editors, and publisher have exerted every effort to ensure that drug selection and dosage set forth in this text are in accordance with the current recommendations and practice at the time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package insert for each drug for any change in indications and dosage and for added warnings and precautions. This is particularly important when the recommended agent is a new or infrequently employed drug.

Some drugs and medical devices presented in this publication have Food and Drug Administration (FDA) clearance for limited use in restricted research settings. It is the responsibility of the healthcare provider to ascertain the FDA status of each drug or device planned for use in their clinical practice.

To purchase additional copies of this book, call our customer service department at (800) 638-3030 or fax orders to (301) 223-2320. International customers should call (301) 223-2300.

Visit Lippincott Williams & Wilkins on the Internet: <http://www.lww.com>. Lippincott Williams & Wilkins customer service representatives are available from 8:30 am to 6:00 pm, EST.

The 12th Edition of Wilson and Gisvold's Textbook of Organic Medicinal and Pharmaceutical Chemistry is dedicated to the memory of Robert F. Doerge.

Robert F. Doerge
1915–2006

Robert Doerge—pharmacist, medicinal chemist, and educator—experienced the Depression and served in the Civilian Conservation Corp in Sheridan, AR. Dr. Doerge received his B.S. in pharmacy in 1943 and his PhD in pharmaceutical chemistry, both from the University of Minnesota in 1949. The latter was under the direction of Dr. Charles O. Wilson, who, with Dr. Ole Gisvold, started this well-respected medicinal chemistry textbook. Dr. Doerge began his professional career as an assistant professor in the University of Texas-Austin School of Pharmacy before becoming a research chemist with the former Smith Kline and French Laboratories in Philadelphia. Beginning in 1960, he returned to academia as professor and chair of the pharmaceutical chemistry department in Oregon State University's College of Pharmacy. Prior to his retirement as professor emeritus in 1981, he was the assistant dean.

Dr. Doerge's initial publications were on the topic of synthesis of anticonvulsants. At Smith Kline and French, his work included publications on vitamin stability, and at Oregon State University, his papers focused on the heterocyclic phenylindolizines. Dr. Doerge was a volunteer abstractor for *Chemical Abstracts*. As an educator, Dr. Doerge was an author of chapters in *Wilson and Gisvold's Textbook of Organic Medicinal and Pharmaceutical Chemistry*, coeditor of the 6th and 7th editions, and editor of the 8th edition. His skill and dedication in the classroom were recognized by the students and university with several teaching awards.

We certainly miss this fine gentleman who put the students first and advanced the teaching of medicinal chemistry as a chapter author, coeditor, and editor of the Wilson and Gisvold textbook series.

John H. Block

PREFACE

For 6 decades, *Wilson and Gisvold's Textbook of Organic Medicinal and Pharmaceutical Chemistry* has been a standard in the literature of medicinal chemistry. Generations of students and faculty have depended on this textbook not only for undergraduate courses in medicinal chemistry but also as a supplement for graduate studies. Moreover, students in other health sciences have found certain chapters useful. The current editors and authors worked on the 12th edition with the objective of continuing the tradition of a modern textbook for undergraduate students and also for graduate students who need a general review of medicinal chemistry. Because the chapters include a blend of chemical and pharmacological principles necessary for understanding structure–activity relationships and molecular mechanisms of drug action, the book should be useful in supporting courses in medicinal chemistry and in complementing pharmacology courses.

ABOUT THE 12TH EDITION

The 12th edition follows in the footsteps of the 11th edition by reflecting the dynamic changes occurring in medicinal chemistry. With increased knowledge of the disease process and the identification of the key steps in the biochemical process, the chapters have been updated, expanded, and reorganized. At the same time, to streamline the presentation of the content, some topics were combined into existing chapters. For example, Chapter 2, “Drug Design Strategies,” incorporates material from 11th edition Chapters 2, 3, and 28, and Chapter 3, “Metabolic Changes of Drugs and Related Organic Compounds,” includes the content from 11th edition Chapter 5, “Prodrugs and Drug Latentiation.” In addition, with the newer drugs that have entered the pharmaceutical armamentarium since publication of the 11th edition, coverage of the following topics has been expanded in the 12th edition: Central Dopaminergic Signaling Agents (Chapter 13), Anticonvulsants (Chapter 14), Hormone-Related Disorders: Nonsteroidal Therapies (Chapter 20), Agents Treating Bone Disorders (Chapter 21), and Anesthetics (Chapter 22).

New features of the 12th edition include a chapter overview at the beginning of each chapter to introduce material to be covered in the chapter and review questions at the end of each chapter to reinforce concepts learned in the chapter (answers to these questions are available to students on the book's companion Web site; see next section).

ADDITIONAL RESOURCES

Wilson and Gisvold's Textbook of Organic Medicinal and Pharmaceutical Chemistry, 12th Edition, includes additional resources for both instructors and students that are available on the book's companion Web site at <http://www.thePoint.lww.com/Beale12e>.

Instructors

Approved adopting instructors will be given access to the following additional resources:

- Image bank of all the figures and tables in the book

Students

Students who have purchased *Wilson and Gisvold's Textbook of Organic Medicinal and Pharmaceutical Chemistry*, 12th Edition, have access to the following additional resources:

- The answers to the review questions found in the book

In addition, purchasers of the text can access the searchable Full Text On-line by going to the *Wilson and Gisvold's Textbook of Organic Medicinal and Pharmaceutical Chemistry*, 12th Edition, Web site at <http://www.thePoint.lww.com/Beale12e>. See the inside front cover of this text for more details, including the passcode you will need to gain access to the Web site.

ACKNOWLEDGMENTS

The editors welcome the new contributors to the 12th edition: Jeffrey J. Christoff, A. Michael Crider, Carolyn J. Friel, Ronald A. Hill, Shengquan Liu, Matthias C. Lu, Marcello J. Nieto, and Kenneth A. Witt. The editors extend thanks to all of the authors who have cooperated in the preparation of the current edition. Collectively, the authors represent many years of teaching and research experience in medicinal chemistry. Their chapters include summaries of current research trends that lead the reader to the original literature. Documentation and references continue to be an important feature of the book.

We continue to be indebted to Professors Charles O. Wilson and Ole Gisvold, the originators of the book and editors of five editions, Professor Robert Doerge, who joined Professors Wilson and Gisvold for the 6th and 7th editions and single-handedly edited the 8th edition, and Professors Jaime Delgado and William Remers, who edited the 9th and 10th editions. They and the authors have contributed significantly to the education of countless pharmacists, medicinal chemists, and other pharmaceutical scientists.

CHAPTER 1

Introduction

JOHN M. BEALE, JR. AND JOHN H. BLOCK

The discipline of medicinal chemistry is devoted to the discovery and development of new agents for treating diseases. Most of this activity is directed to new natural or synthetic organic compounds. Paralleling the development of medicinal agents has come a better understanding of the chemistry of the receptor. The latter has been greatly facilitated by low-cost computers running software that calculates molecular properties and structure and pictures it using high-resolution graphics. Development of organic compounds has grown beyond traditional synthetic methods. It now includes the exciting field of biotechnology using the cell's biochemistry to synthesize new compounds. Techniques ranging from recombinant DNA and site-directed mutagenesis to fusion of cell lines have greatly broadened the possibilities for new entities that treat disease. The pharmacist now dispenses modified human insulins that provide more convenient dosing schedules, cell-stimulating factors that have changed the dosing regimens for chemotherapy, humanized monoclonal antibodies that target specific tissues, and fused receptors that intercept immune cell-generated cytokines.

This 12th edition of *Wilson and Gisvold's Textbook of Organic Medicinal and Pharmaceutical Chemistry* continues the philosophy of presenting the scientific basis of medicinal chemistry originally established by Professors Charles Wilson and Ole Gisvold, describing the many aspects of organic medicinals: how they are discovered, how they act, and how they developed into clinical agents. The process of establishing a new pharmaceutical is exceedingly complex and involves the talents of people from various disciplines, including chemistry, biochemistry, molecular biology, physiology, pharmacology, pharmaceuticals, and medicine. Medicinal chemistry, itself, is concerned mainly with the organic, analytical, and biochemical aspects of this process, but the chemist must interact productively with those in other disciplines. Thus, medicinal chemistry occupies a strategic position at the interface of chemistry and biology. All of the principles discussed in this book are based on fundamental organic chemistry, physical chemistry, and biochemistry. To provide an understanding of the principles of medicinal chemistry, it is necessary to consider the physicochemical properties used to develop new pharmacologically active compounds and their mechanisms of action, the drug's metabolism, including possible biological activities of the metabolites, the importance of stereochemistry in drug design, and the methods used to determine what "space" a drug occupies.

The earliest drug discoveries were made by random sampling of higher plants. Some of this sampling, although

based on anecdotal evidence, led to the use of such crude plant drugs as opium, belladonna, and ephedrine that have been important for centuries. With the accidental discovery of penicillin came the screening of microorganisms and the large number of antibiotics from bacterial and fungal sources. Many of these antibiotics provided the prototypical structure that the medicinal chemist modified to obtain antibacterial drugs with better therapeutic profiles. With the changes in federal legislation reducing the efficacy requirement for "nutraceutical," the public increasingly is using so-called nontraditional or alternative medicinals that are sold over the counter, many outside of traditional pharmacy distribution channels. It is important for the pharmacist and the public to understand the rigor that is required for prescription-only and Food and Drug Administration (FDA)-approved nonprescription products to be approved relative to the nontraditional products. It is also important for all people in the healthcare field and the public to realize that whether these nontraditional products are effective as claimed or not, many of the alternate medicines contain pharmacologically active agents that can potentiate or interfere with physician-prescribed therapy.

Hundreds of thousands of new organic chemicals are prepared annually throughout the world, and many of them are entered into pharmacological screens to determine whether they have useful biological activity. This process of random screening has been considered inefficient, but it has resulted in the identification of new lead compounds whose structures have been optimized to produce clinical agents. Sometimes, a lead develops by careful observation of the pharmacological behavior of an existing drug. The discovery that amantadine protects and treats early influenza A came from a general screen for antiviral agents. The use of amantadine in long-term care facilities showed that it also could be used to treat parkinsonian disorders. More recently, automated high-throughput screening systems utilizing cell culture systems with linked enzyme assays and receptor molecules derived from gene cloning have greatly increased the efficiency of random screening. It is now practical to screen enormous libraries of peptides and nucleic acids obtained from combinatorial chemistry procedures.

Rational design, the opposite approach to high-volume screening, is also flourishing. Statistical methods based on the correlation of physicochemical properties with biological potency are used to explain and optimize biological activity. Significant advances in x-ray crystallography and nuclear magnetic resonance have made it possible to obtain detailed representations of enzymes and other drug receptors. The techniques of molecular graphics and computational

chemistry have provided novel chemical structures that have led to new drugs with potent medicinal activities. Development of human immunodeficiency virus (HIV) protease inhibitors and angiotensin-converting enzyme (ACE) inhibitors came from an understanding of the geometry and chemical character of the respective enzyme's active site. Even if the receptor structure is not known in detail, rational approaches based on the physicochemical properties of lead compounds can provide new drugs. For example, the development of cimetidine involved a careful study of the changes

in antagonism of H₂-histamine receptors induced by varying the physical properties of structures based on histamine.

As you proceed through the chapters, think of what problem the medicinal chemist is trying to solve. Why were certain structures selected? What modifications were made to produce more focused activity or reduce adverse reactions or produce better pharmaceutical properties? Was the prototypical molecule discovered from random screens, or did the medicinal chemist have a structural concept of the receptor or an understanding of the disease process that must be interrupted?

CHAPTER 2

Drug Design Strategies

JOHN H. BLOCK

CHAPTER OVERVIEW

Modern drug design as compared with the classical approach—*let's make a change on an existing compound or synthesize a new structure and see what happens*—continues to evolve rapidly as an approach to solving a drug design problem. The combination of increasing power and decreasing cost of desktop computing has had a major impact on solving drug design problems. Although drug design increasingly is based on modern computational chemical techniques, it also uses sophisticated knowledge of disease mechanisms and receptor properties. A good understanding of how the drug is transported into the body, distributed throughout the body compartments, metabolically altered by the liver and other organs, and excreted from the patient is required, along with the structural characteristics of the receptor. Acid–base chemistry is used to aid in formulation and biodistribution. Structural attributes and substituent patterns responsible for optimum pharmacological activity can often be predicted by statistical techniques such as regression analysis. Computerized conformational analysis permits the medicinal chemist to predict the drug's three-dimensional (3D) shape that is *seen* by the receptor. With the isolation and structural determination of specific receptors and the availability of computer software that can estimate the 3D shape of the receptor, it is possible to design molecules that will show an optimum fit to the receptor.

DRUG DISTRIBUTION

A drug is a chemical molecule. Following introduction into the body, a drug must pass through many barriers, survive alternate sites of attachment and storage, and avoid significant metabolic destruction before it reaches the site of action, usually a receptor on or in a cell (Fig. 2.1). At the receptor, the following equilibrium (Rx. 2.1) usually holds:

The ideal drug molecule will show favorable binding characteristics to the receptor, and the equilibrium will lie

to the right. At the same time, the drug will be expected to dissociate from the receptor and reenter the systemic circulation to be excreted. Major exceptions include the alkylating agents used in cancer chemotherapy (see Chapter 10), a few inhibitors of the enzyme acetylcholinesterase (see Chapter 17), suicide inhibitors of monoamine oxidase (see Chapter 16), and the aromatase inhibitors 4-hydroxyandrostenedione and exemestane (see Chapter 25). These pharmacological agents form covalent bonds with the receptor, usually an enzyme's active site. In these cases, the cell must destroy the receptor or enzyme, or, in the case of the alkylating agents, the cell would be replaced, ideally with a normal cell. In other words, the usual use of drugs in medical treatment calls for the drug's effect to last for a finite period of time. Then, if it is to be repeated, the drug will be administered again. If the patient does not tolerate the drug well, it is even more important that the agent dissociate from the receptor and be excreted from the body.

Oral Administration

An examination of the *obstacle course* (Fig. 2.1) faced by the drug will give a better understanding of what is involved in developing a commercially feasible product. Assume that the drug is administered orally. The drug must go into solution to pass through the gastrointestinal mucosa. Even drugs administered as true solutions may not remain in solution as they enter the acidic stomach and then pass into the alkaline intestinal tract. (This is explained further in the discussion on acid–base chemistry.) The ability of the drug to dissolve is governed by several factors, including its chemical structure, variation in particle size and particle surface area, nature of the crystal form, type of tablet coating, and type of tablet matrix. By varying the dosage form and physical characteristics of the drug, it is possible to have a drug dissolve quickly or slowly, with the latter being the situation for many of the sustained-action products. An example is orally administered sodium phenytoin, with which variation of both the crystal form and tablet adjuvants can significantly alter the bioavailability of this drug widely used in the treatment of epilepsy.

Chemical modification is also used to a limited extent to facilitate a drug reaching its desired target (see Chapter 3). An example is olsalazine, used in the treatment of ulcerative colitis. This drug is a dimer of the pharmacologically active mesalamine (5-aminosalicylic acid). The latter is not effective orally because it is metabolized to inactive forms before reaching the colon. The dimeric form passes

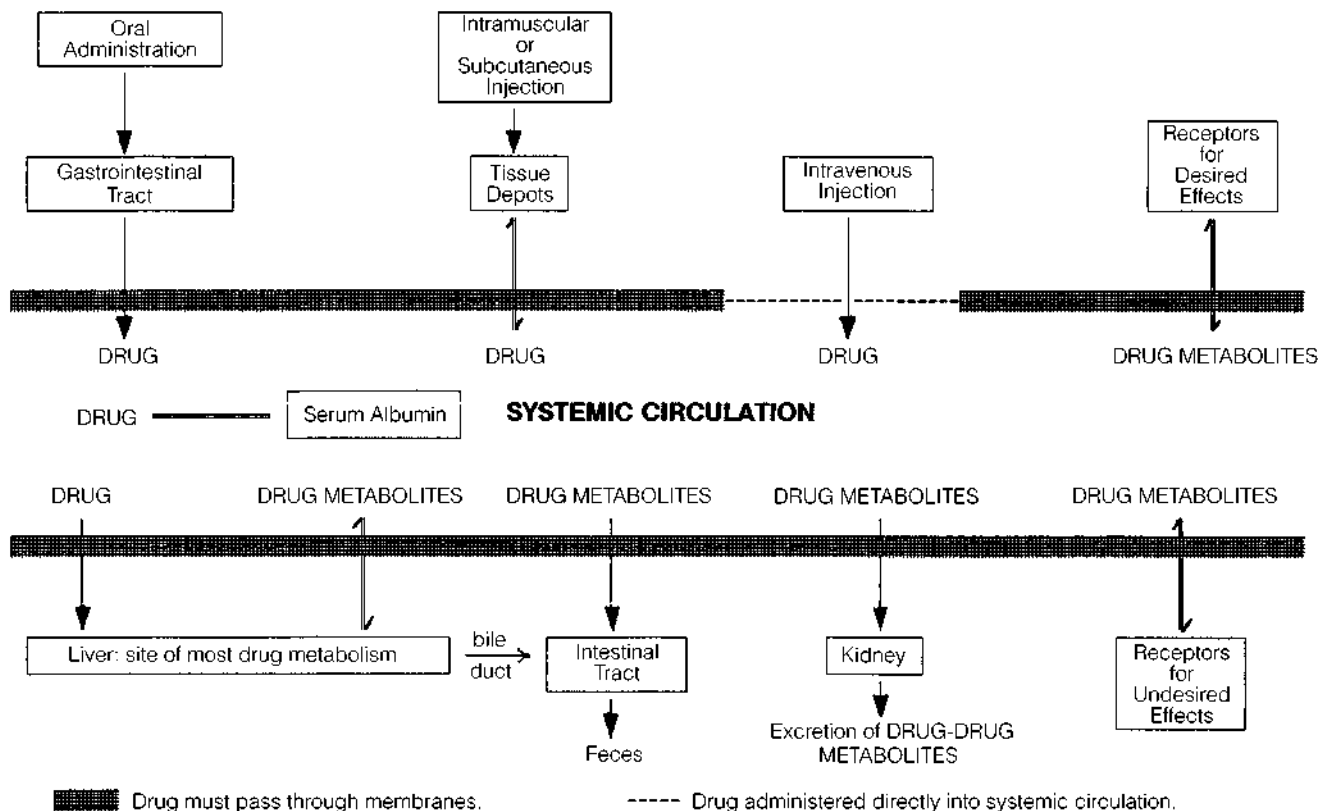

Figure 2.1 • Summary of drug distribution.

through a significant portion of the intestinal tract before being cleaved by the intestinal bacteria to two equivalents of mesalamine.

As illustrated by olsalazine, any compound passing through the gastrointestinal tract will encounter a large number and variety of digestive and bacterial enzymes, which, in theory, can degrade the drug molecule. In practice, a new drug entity under investigation will likely be dropped from further consideration if it cannot survive in the intestinal tract or its oral bioavailability is low, necessitating parenteral dosage forms only. An exception would be a drug for which there is no effective alternative or which is more effective than existing products and can be administered by an alternate route, including parenteral, buccal, or transdermal.

In contrast, these same digestive enzymes can be used to advantage. Chloramphenicol is water soluble enough

(2.5 mg/mL) to come in contact with the taste receptors on the tongue, producing an unpalatable bitterness. To mask this intense bitter taste, the palmitic acid moiety is added as an ester of chloramphenicol's primary alcohol. This reduces the parent drug's water solubility (1.05 mg/mL), enough so that it can be formulated as a suspension that passes over the bitter taste receptors on the tongue. Once in the intestinal tract, the ester linkage is hydrolyzed by the digestive esterases to the active antibiotic chloramphenicol and the very common dietary fatty acid palmitic acid.

Chloramphenicol: R = H

Chloramphenicol Palmitate: R = CO(CH₂)₁₄CH₃

Olsalazine and chloramphenicol palmitate are examples of *prodrugs*. Most prodrugs are compounds that are inactive in their native form but are easily metabolized to the active agent. Olsalazine and chloramphenicol palmitate are examples of prodrugs that are cleaved to smaller compounds, one of which is the active drug. Others are metabolic precursors to the active form. An example of this type of prodrug is menadione, a simple naphthoquinone that is converted in the liver to phytonadione (vitamin K₂₍₂₀₎).

Menadiolone

Phytonadione (Vitamin K₂₍₂₀₎)

Occasionally, the prodrug approach is used to enhance the absorption of a drug that is poorly absorbed from the gastrointestinal tract. Enalapril is the ethyl ester of enalaprilic acid, an active inhibitor of angiotensin-converting enzyme (ACE). The ester prodrug is much more readily absorbed orally than the pharmacologically active carboxylic acid.

Enalapril: R = C₂H₅

Enalaprilic Acid: R = H

Unless the drug is intended to act locally in the gastrointestinal tract, it will have to pass through the gastrointestinal mucosal barrier into venous circulation to reach the site of the receptor. The drug's route involves distribution or partitioning between the aqueous environment of the gastrointestinal tract, the lipid bilayer cell membrane of the mucosal cells, possibly the aqueous interior of the mucosal cells, the lipid bilayer membranes on the venous side of the gastrointestinal tract, and the aqueous environment of venous circulation. Some very lipid-soluble drugs may follow the route of dietary lipids by becoming part of the mixed micelles, incorporating into the chylomicrons in the mucosal cells into the lymph ducts, servicing the intestines, and finally entering venous circulation via the thoracic duct.

The drug's passage through the mucosal cells can be passive or active. As is discussed later in this chapter, the lipid membranes are very complex with a highly ordered structure. Part of this membrane is a series of channels or tunnels that form, disappear, and reform. There are receptors that move compounds into the cell by a process called *pinocytosis*. Drugs that resemble a normal metabolic precursor or intermediate may be actively transported into the cell by the same system that transports the endogenous compound. On the other hand, most drug

molecules are too large to enter the cell by an active transport mechanism through the passages. The latter, many times, pass into the patient's circulatory system by passive diffusion.

Parenteral Administration

Many times, there will be therapeutic advantages in bypassing the intestinal barrier by using parenteral (injectable) dosage forms. This is common in patients who, because of illness, cannot tolerate or are incapable of accepting drugs orally. Some drugs are so rapidly and completely metabolized to inactive products in the liver (first-pass effect) that oral administration is precluded. But that does not mean that the drug administered by injection is not confronted by obstacles (Fig. 2.1). Intravenous administration places the drug directly into the circulatory system, where it will be rapidly distributed throughout the body, including tissue depots and the liver, where most biotransformations occur (see later in this chapter), in addition to the receptors. Subcutaneous and intramuscular injections slow distribution of the drug, because it must diffuse from the site of injection into systemic circulation.

It is possible to inject the drug directly into specific organs or areas of the body. Intraspinal and intracerebral routes will place the drug directly into the spinal fluid or brain, respectively. This bypasses a specialized epithelial tissue, the blood-brain barrier, which protects the brain from exposure to a large number of metabolites and chemicals. The blood-brain barrier is composed of membranes of tightly joined epithelial cells lining the cerebral capillaries. The net result is that the brain is not exposed to the same variety of compounds that other organs are. Local anesthetics are examples of administration of a drug directly onto the desired nerve. A spinal block is a form of anesthesia performed by injecting a local anesthetic directly into the spinal cord at a specific location to block transmission along specific neurons.

Most of the injections a patient will experience in a lifetime will be subcutaneous or intramuscular. These parenteral routes produce a depot in the tissues (Fig. 2.1), from which the drug must reach the blood or lymph. Once in systemic circulation, the drug will undergo the same distributive phenomena as orally and intravenously administered agents before reaching the target receptor. In general, the same factors that control the drug's passage through the gastrointestinal mucosa will also determine the rate of movement out of the tissue depot.

The prodrug approach described previously can also be used to alter the solubility characteristics, which, in turn, can increase the flexibility in formulating dosage forms. The solubility of methylprednisolone can be altered from essentially water-insoluble methylprednisolone acetate to slightly water-insoluble methylprednisolone to water-soluble methylprednisolone sodium succinate. The water-soluble sodium hemisuccinate salt is used in oral, intravenous, and intramuscular dosage forms. Methylprednisolone itself is normally found in tablets. The acetate ester is found in topical ointments and sterile aqueous suspensions for intramuscular injection. Both the succinate and acetate esters are hydrolyzed to the active methylprednisolone by the patient's own systemic hydrolytic enzymes (esterases).

Methylprednisolone: R = H

Methylprednisolone Acetate: R = C(=O)CH₃

Methylprednisolone Sodium Succinate: R = C(=O)CH₂CH₂COO⁻ Na⁺

Another example of how prodrug design can significantly alter biodistribution and biological half-life is illustrated by two drugs based on the retinoic acid structure used systemically to treat psoriasis, a nonmalignant hyperplasia. Etretinate has a 120-day *terminal* half-life after 6 months of therapy. In contrast, the active metabolite, acitretin, has a 33- to 96-hour *terminal* half-life. Both drugs are potentially teratogenic. Women of childbearing age must sign statements that they are aware of the risks and usually are administered a pregnancy test before a prescription is issued. Acitretin, with its shorter half-life, is recommended for a woman who would like to become pregnant, because it can clear her body within a reasonable time frame. When effective, etretinate can keep a patient clear of psoriasis lesions for several months.

Protein Binding

Once the drug enters the systemic circulation (Fig. 2.1), it can undergo several events. It may stay in solution, but many drugs will be bound to the serum proteins, usually albumin (Rx. 2.2). Thus, a new equilibrium must be considered. Depending on the equilibrium constant, the drug can remain in systemic circulation bound to albumin for a considerable period and not be available to the sites of biotransformation, the pharmacological receptors, and excretion.

Protein binding can have a profound effect on the drug's effective solubility, biodistribution, half-life in the body, and interaction with other drugs. A drug with such poor water solubility that therapeutic concentrations of the unbound (active) drug normally cannot be maintained still can be a very effective agent. The albumin–drug complex acts as a reservoir by providing large enough concentrations of free drug to cause a pharmacological response at the receptor.

Protein binding may also limit access to certain body compartments. The placenta is able to block passage of proteins from maternal to fetal circulation. Thus, drugs that normally would be expected to cross the placental barrier and possibly harm the fetus are retained in the maternal circulation, bound to the mother's serum proteins.

Protein binding also can prolong the drug's duration of action. The drug–protein complex is too large to pass through the renal glomerular membranes, preventing rapid excretion of the drug. Protein binding limits the amount of drug available for biotransformation (see later in this chapter and Chapter 3) and for interaction with specific receptor sites. For

example, the large, polar trypanocide suramin remains in the body in the protein-bound form for as long as 3 months ($t_{1/2} = 50$ days). The maintenance dose for this drug is based on weekly administration. At first, this might seem to be an advantage to the patient. It can be, but it also means that, should the patient have serious adverse reactions, a significant length of time will be required before the concentration of drug falls below toxic levels.

The drug-protein binding phenomenon can lead to some clinically significant drug-drug interactions that result when one drug displaces another from the binding site on albumin. A large number of drugs can displace the anticoagulant warfarin from its albumin-binding sites. This increases the effective concentration of warfarin at the receptor, leading to an increased prothrombin time (increased time for clot formation) and potential hemorrhage.

Tissue Depots

The drug can also be stored in tissue depots. Neutral fat constitutes some 20% to 50% of body weight and constitutes a depot of considerable importance. The more lipophilic the drug, the more likely it will concentrate in these pharmacologically inert depots. The ultra-short-acting, lipophilic barbiturate thiopental's concentration rapidly decreases below its effective concentration following administration. It *disappears* into tissue protein, redistributes into body fat, and then slowly diffuses back out of the tissue depots but in concentrations too low for a pharmacological response. Thus, only the initially administered thiopental is present in high enough concentrations to combine with its receptors. The remaining thiopental diffuses out of the tissue depots into systemic circulation in concentrations too small to be effective (Fig. 2.1), is metabolized in the liver, and is excreted.

In general, structural changes in the barbiturate series (see Chapter 12) that favor partitioning into the lipid tissue stores decrease duration of action but increase central nervous system (CNS) depression. Conversely, the barbiturates with the slowest onset of action and longest duration of action contain the more polar side chains. This latter group of barbiturates both enters and leaves the CNS more slowly than the more lipophilic thiopental.

Drug Metabolism

All substances in the circulatory system, including drugs, metabolites, and nutrients, will pass through the liver. Most molecules absorbed from the gastrointestinal tract enter the portal vein and are initially transported to the liver. A significant proportion of a drug will partition or be

transported into the hepatocyte, where it may be metabolized by hepatic enzymes to inactive chemicals during the initial trip through the liver, by what is known as the first-pass effect (see Chapter 3).

Lidocaine is a classic example of the significance of the first-pass effect. Over 60% of this local anesthetic antiarrhythmic agent is metabolized during its initial passage through the liver, resulting in it being impractical to administer orally. When used for cardiac arrhythmias, it is administered intravenously. This rapid metabolism of lidocaine is used to advantage when stabilizing a patient with cardiac arrhythmias. Should too much lidocaine be administered intravenously, toxic responses will tend to decrease because of rapid biotransformation to inactive metabolites. An understanding of the metabolic labile site on lidocaine led to the development of the primary amine analog tocainide. In contrast to lidocaine's half-life of less than 2 hours, tocainide's half-life is approximately 15 hours, with 40% of the drug excreted unchanged. The development of orally active antiarrhythmic agents is discussed in more detail in Chapter 19.

Lidocaine

Tocainide

A study of the metabolic fate of a drug is required for all new drug products. Often it is found that the metabolites are also active. Sometimes the metabolite is the pharmacologically active molecule. These drug metabolites can provide leads for additional investigations of potentially new products. Examples of an inactive parent drug that is converted to an active metabolite include the nonsteroidal anti-inflammatory agent sulindac being reduced to the active sulfide metabolite, the immunosuppressant azathioprine being cleaved to the purine antimetabolite 6-mercaptopurine, and purine and pyrimidine antimetabolites and antiviral

agents being conjugated to their nucleotide form (acyclovir phosphorylated to acyclovir triphosphate). Often both the parent drug and its metabolite are active, which has led to additional commercial products, instead of just one being marketed. About 75% to 80% of phenacetin (now withdrawn from the U.S. market) is converted to acetaminophen. In the tricyclic antidepressant series (see Chapter 12), imipramine and amitriptyline are *N*-demethylated to desipramine and nortriptyline, respectively. All four compounds have been marketed in the United States. Drug metabolism is discussed more fully in Chapter 3.

Sulindac: R = CH₃S(=O)

Active Sulfide Metabolite: R = CH₃S

Azathioprine

6-Mercaptopurine

Acyclovir: R = H

Acyclovir triphosphate: R = O-P-O-P-O-P

Phenacetin: R = OC₂H₅

Acetaminophen: R = OH

Amitriptyline: R = CH₃

Nortriptyline: R = H

Imipramine: R = CH₃

Desipramine: R = H

Although a drug's metabolism can be a source of frustration for the medicinal chemist, pharmacist, and physician and lead to inconvenience and compliance problems with the patient, it is fortunate that the body has the ability to metabolize foreign molecules (xenobiotics). Otherwise, many of these substances could remain in the body for years. This has been the complaint against certain lipophilic chemical pollutants, including the once very popular insecticide dichlorodiphenyltrichloroethane (DDT). After entering the body, these chemicals reside in body tissues, slowly diffusing out of the depots and potentially harming the individual on a chronic basis for several years. They can also reside in tissues of commercial food animals that have been slaughtered before the drug has *washed out* of the body.

Excretion

The main route of excretion of a drug and its metabolites is through the kidney. For some drugs, enterohepatic circulation (Fig. 2.1), in which the drug reenters the intestinal tract from the liver through the bile duct, can be an important part of the agent's distribution in the body and route of excretion. Either the drug or drug metabolite can reenter systemic circulation by passing once again through the intestinal mucosa. A portion of either also may be excreted in the feces. Nursing mothers must be concerned, because drugs and their metabolites can be excreted in human milk and be ingested by the nursing infant.

One should keep a sense of perspective when learning about drug metabolism. As explained in Chapter 3, drug metabolism can be conceptualized as occurring in two stages or phases. Intermediate metabolites that are pharmacologically active usually are produced by phase I reactions. The products from the phase I chemistry are converted into inactive, usually water-soluble end products by phase II reactions. The latter, commonly called *conjugation* reactions, can be thought of as synthetic reactions that involve addition of water-soluble substituents. In human drug metabolism, the main conjugation reactions add glucuronic acid, sulfate, or glutathione. Obviously, drugs that are bound to serum protein or show favorable partitioning into tissue depots are going to be metabolized and excreted more slowly for the reasons discussed previously.

This does not mean that drugs that remain in the body for longer periods of time can be administered in lower doses or be taken fewer times per day by the patient. Several variables determine dosing regimens, of which the affinity of the drug for the receptor is crucial. Reexamine Reaction 2.1 and Figure 2.1. If the equilibrium does not favor formation of the drug-receptor complex, higher and usually more frequent doses must be administered. Further, if partitioning into tissue stores or metabolic degradation and/or excretion is favored, it will take more of the drug and usually more frequent administration to maintain therapeutic concentrations at the receptor.

The Receptor

With the possible exception of general anesthetics (see Chapter 22), the working model for a pharmacological response consists of a drug binding to a specific receptor. Many drug receptors are the same as those used by endogenously produced ligands. Cholinergic agents interact with the same receptors as the neurotransmitter acetylcholine.

Synthetic corticosteroids bind to the same receptors as cortisone and hydrocortisone. Often, receptors for the same ligand are found in various tissues throughout the body. The nonsteroidal anti-inflammatory agents (see Chapter 26) inhibit the prostaglandin-forming enzyme cyclooxygenase, which is found in nearly every tissue. This class of drugs has a long list of side effects with many patient complaints. Note in Figure 2.1 that, depending on which receptors contain bound drug, there may be desired or undesired effects. This is because various receptors with similar structural requirements are found in several organs and tissues. Thus, the nonsteroidal anti-inflammatory drugs combine with the desired cyclooxygenase receptors at the site of the inflammation and the undesired cyclooxygenase receptors in the gastrointestinal mucosa, causing severe discomfort and sometimes ulceration. One of the *second-generation* antihistamines, fexofenadine, is claimed to cause less sedation because it does not readily penetrate the blood-brain barrier. The rationale is that less of this antihistamine is available for the receptors in the CNS, which are responsible for the sedation response characteristic of antihistamines. In contrast, some antihistamines are used for their CNS depressant activity because a significant proportion of the administered dose is crossing the blood-brain barrier relative to binding to the histamine H₁ receptors in the periphery.

Although it is normal to think of side effects as undesirable, they sometimes can be beneficial and lead to new products. The successful development of oral hypoglycemic agents used in the treatment of diabetes began when it was found that certain sulfonamides had a hypoglycemic effect. Nevertheless, a real problem in drug therapy is patient compliance in taking the drug as directed. Drugs that cause serious problems and discomfort tend to be avoided by patients.

At this point, let us assume that the drug has entered the systemic circulation (Fig. 2.1), passed through the lipid barriers, and is now going to make contact with the receptor. As illustrated in Reaction 2.1, this is an equilibrium process. A good ability to fit the receptor favors binding and the desired pharmacological response. In contrast, a poor fit favors the reverse reaction. With only a small amount of drug bound to the receptor, there will be a much smaller pharmacological effect. If the amount of drug bound to the receptor is too small, there may be no discernible response. Many variables contribute to a drug's binding to the receptor. These include the structural class, the 3D shape of the molecule, and the types of chemical bonding involved in the binding of the drug to the receptor.

Most drugs that belong to the same pharmacological class have certain structural features in common. The barbiturates act on specific CNS receptors, causing depressant effects; hydantoins act on CNS receptors, producing an anticonvulsant response; benzodiazepines combine with the γ -aminobutyric acid (GABA) receptors, with resulting anxiolytic activity; steroids can be divided into such classes as corticosteroids, anabolic steroids, progestogens, and estrogens, each acting on specific receptors; nonsteroidal anti-inflammatory agents inhibit enzymes required for the prostaglandin cascade; penicillins and cephalosporins inhibit enzymes required to construct the bacterial cell wall; and tetracyclines act on bacterial ribosomes.

With the isolation and characterization of receptors becoming a common occurrence, it is hard to realize that the concept of receptors began as a postulate. It had been realized

early that molecules with certain structural features would elucidate a specific biological response. Very slight changes in structure could cause significant changes in biological activity. These structural variations could increase or decrease activity or change an agonist into an antagonist. This early and fundamentally correct interpretation called for the drug (ligand) to fit onto some surface (the receptor) that had fairly strict structural requirements for proper binding of the drug. The initial receptor model was based on a rigid lock-and-key concept, with the drug (key) fitting into a receptor (lock). It has been used to explain why certain structural attributes produce a predictable pharmacological action. This model still is useful, although one must realize that both the drug and the receptor can have considerable flexibility. Molecular graphics, using programs that calculate the preferred conformations of drug and receptor, show that the receptor can undergo an adjustment in 3D structure when the drug makes contact. Using space-age language, the drug *docks* with the receptor.

More complex receptors now are being isolated, characterized, and cloned. The first receptors to be isolated and characterized were the reactive and regulatory sites on enzymes. Acetylcholinesterase, dihydrofolate reductase, angiotensin, and human immunodeficiency virus (HIV) protease-converting enzyme are examples of enzymes whose active sites (the receptors) have been modeled. Most drug receptors probably are receptors for natural ligands used to regulate cellular biochemistry and function and to communicate between cells. Receptors include a relatively small region of a macromolecule, which may be an isolatable enzyme, a structural and functional component of a cell membrane, or a specific intracellular substance such as a protein or nucleic acid. Specific regions of these macromolecules are visualized as being oriented in space in a manner that permits their functional groups to interact with the complementary functional groups of the drug. This interaction initiates changes in structure and function of the macromolecule, which lead ultimately to the observable biological response. The concept of spatially oriented functional areas forming a receptor leads directly to specific structural requirements for functional groups of a drug, which must complement the receptor.

It now is possible to isolate membrane-bound receptors, although it still is difficult to elucidate their structural chemistry, because once separated from the cell membranes, these receptors may lose their native shape. This is because the membrane is required to hold the receptor in its correct tertiary structure. One method of receptor isolation is affinity chromatography. In this technique, a ligand, often an altered drug molecule known to combine with the receptor, is attached to a chromatographic support phase. A solution containing the desired receptor is passed over this column. The receptor will combine with the ligand. It is common to add a chemically reactive grouping to the drug, resulting in the receptor and drug covalently binding with each other. The drug-receptor complex is washed from the column and then characterized further.

A more recent technique uses recombinant DNA. The gene for the receptor is located and cloned. It is transferred into a bacterium, yeast, or animal, which then produces the receptor in large enough quantities to permit further study. Sometimes it is possible to determine the DNA sequence of the cloned gene. By using the genetic code for amino acids, the amino acid sequence of the protein component of the receptor can be determined, and the receptor then modeled,

producing an estimated 3D shape. The model for the receptor becomes the template for designing new ligands. Genome mapping has greatly increased the information on receptors. Besides the human genome, the genetic composition of viruses, bacteria, fungi, and parasites has increased the possible sites for drugs to act. The new field of proteomics studies the proteins produced by structural genes.

The earlier discussion in this chapter emphasizes that the cell membrane is a highly organized, dynamic structure that interacts with small molecules in specific ways; its focus is on the lipid bilayer component of this complex structure. The receptor components of the membranes appear to be mainly protein. They constitute a highly organized, intertwined region of the cell membrane. The same type of molecular specificity seen in such proteins as enzymes and antibodies is also a property of drug receptors. The nature of the amide link in proteins provides a unique opportunity for the formation of multiple internal hydrogen bonds, as well as internal formation of hydrophobic, van der Waals, and ionic bonds by side chain groups, leading to such organized structures as the α -helix, which contains about four amino acid residues for each turn of the helix. An organized protein structure would hold the amino acid side chains at relatively fixed positions in space and available for specific interactions with a small molecule.

Proteins can potentially adopt many different conformations in space without breaking their covalent amide linkages. They may shift from highly coiled structures to partially disorganized structures, with parts of the molecule existing in *random chain* or *folded sheet* structures, contingent on the environment. In the monolayer of a cell membrane, the interaction of a small foreign molecule with an organized protein may lead to a significant change in the structural and physical properties of the membrane. Such changes could well be the initiating events in the tissue or organ response to a drug, such as the ion-translocation effects produced by interaction of acetylcholine and the cholinergic receptor.

The large body of information now available on relationships between chemical structure and biological activity strongly supports the concept of flexible receptors. The fit of drugs onto or into macromolecules is rarely an all-or-none

process as pictured by the earlier lock-and-key concept of a receptor. Rather, the binding or partial insertion of groups of moderate size onto or into a macromolecular pouch appears to be a continuous process, at least over a limited range, as indicated by the frequently occurring regular increase and decrease in biological activity as one ascends a homologous series of drugs. A range of productive associations between drug and receptor may be produced, which leads to agonist responses, such as those produced by cholinergic and adrenergic drugs. Similarly, strong associations may lead to unproductive changes in the configuration of the macromolecule, leading to an antagonistic or blocking response, such as that produced by anticholinergic agents and HIV protease inhibitors. Although the fundamental structural unit of the drug receptor is generally considered to be protein, it may be supplemented by its associations with other units, such as mucopolysaccharides and nucleic acids.

Humans (and mammals in general) are very complex organisms that have developed specialized organ systems. It is not surprising that receptors are not distributed equally throughout the body. It now is realized that, depending on the organ in which it is located, the same receptor class may behave differently. This can be advantageous by focusing drug therapy on a specific organ system, but it can also cause adverse drug responses because the drug is exerting two different responses based on the location of the receptors. An example is the selective estrogen receptor modulators (SERMs). They cannot be classified simply as agonists or antagonists. Rather, they can be considered variable agonists and antagonists. Their selectivity is very complex because it depends on the organ in which the receptor is located.

This complexity can be illustrated with tamoxifen and raloxifene (Fig. 2.2). Tamoxifen is used for estrogen-sensitive breast cancer and for reducing bone loss from osteoporosis. Unfortunately, prolonged treatment increases the risk of endometrial cancer because of the response from the uterine estrogen receptors. Thus, tamoxifen is an estrogen antagonist in the mammary gland and an agonist in the uterus and bone. In contrast, raloxifene does not appear to have much agonist property in the uterus but, like tamoxifen, is an antagonist in the breast and agonist in the bone.

Figure 2.2 • Selective SERMs.

Figure 2.3 • Examples of phosphodiesterase type 5 inhibitors.

There are a wide variety of phosphodiesterases throughout the body. These enzymes hydrolyze the cyclic phosphate esters of adenosine monophosphate (cAMP) and guanosine monophosphate (cGMP). Although the substrates for this family of enzymes are cAMP and cGMP, there are differences in the active sites. Figure 2.3 illustrates three drugs used to treat erectile dysfunction (sildenafil, tadalafil, and vardenafil). These three take advantage of the differences in active site structural requirements between phosphodiesterase type 5 and the other phosphodiesterases. They have an important role in maintaining a desired lifestyle: treatment of erectile dysfunction caused by various medical conditions. The drugs approved for this indication were discovered by accident. The goal was to develop a newer treatment of angina. The approach was to develop phosphodiesterase inhibitors that would prolong the activity of cGMP. The end result was drugs that were not effective inhibitors of the phosphodiesterase that would treat angina, but were effective inhibitors of the one found in the corpus cavernosum. The vasodilation in this organ results in penile erection.

Summary

One of the goals is to design drugs that will interact with receptors at specific tissues. There are several ways to do this, including (a) altering the molecule, which, in turn, can change the biodistribution; (b) searching for structures that show in-

creased specificity for the target receptor that will produce the desired pharmacological response while decreasing the affinity for undesired receptors that produce adverse responses; and (c) the still experimental approach of attaching the drug to a monoclonal antibody (see Chapter 5) that will bind to a specific tissue antigenic for the antibody. Biodistribution can be altered by changing the drug's solubility, enhancing its ability to resist being metabolized (usually in the liver), altering the formulation or physical characteristics of the drug, and changing the route of administration. If a drug molecule can be designed so that its binding to the desired receptor is enhanced relative to the undesired receptor and biodistribution remains favorable, smaller doses of the drug can be administered. This, in turn, reduces the amount of drug available for binding to those receptors responsible for its adverse effects.

The medicinal chemist is confronted with several challenges in designing a bioactive molecule. A good fit to a specific receptor is desirable, but the drug would normally be expected to dissociate from the receptor eventually. The specificity for the receptor would minimize side effects. The drug would be expected to clear the body within a reasonable time. Its rate of metabolic degradation should allow reasonable dosing schedules and, ideally, oral administration. Many times, the drug chosen for commercial sales has been selected from hundreds of compounds that have been screened. It usually is a compromise product that meets a medical need while demonstrating good patient acceptance.

ACID-BASE PROPERTIES

Most drugs used today can be classified as acids or bases. As is noted shortly, a large number of drugs can behave as either acids or bases as they begin their journey into the patient in different dosage forms and end up in systemic circulation. A drug's acid-base properties can greatly influence its biodistribution and partitioning characteristics.

Over the years, at least four major definitions of acids and bases have been developed. The model commonly used in pharmacy and biochemistry was developed independently by Lowry and Brønsted. In their definition, an *acid* is defined as a proton donor and a *base* is defined as a proton acceptor. Notice that for a base, *there is no mention of the hydroxide ion*. In the Brønsted-Lowry model, the acid plus base reaction can be expressed as:

Acid/Base-Conjugate Acid/Conjugate Base Pairs

Representative pairings of acids with their conjugate bases and bases with their conjugate acids are shown in Table 2.1. Careful study of this table shows water functioning as a proton acceptor (base) in reactions *a, c, e, g, i, k, and m* and a proton donor (acid) in reactions *b, d, f, h, j, l, and n*. Hence, water is known as an *amphoteric* substance. Water can be either a weak base accepting a proton to form the strongly acidic hydrated proton or hydronium ion H_3O^+ (reactions *a, c, e, g, i, k, and m*), or a weak acid donating a proton to form the strongly basic (proton accepting) hydroxide anion OH^- (reactions *b, d, f, h, j, l, and n*).

Also note the shift between un-ionized and ionized forms in Table 2.1. Examples of un-ionized acids donating their protons forming ionized conjugate bases are acetic acid-acetate (reaction *g*), phenobarbital-phenobarbiturate (reaction *i*), and saccharin-saccharate (reaction *k*). In contrast, examples of ionized acids yielding un-ionized conjugate bases are ammonium chloride-ammonia (reaction *e*) and ephedrine hydrochloride (reaction *m*). A similar shift between un-ionized and ionized forms is seen with bases and their conjugate acids. Examples of un-ionized bases yielding their ionized conjugate acids include ammonia and ammonium (reaction *f*) and ephedrine and protonated ephedrine (reaction *n*). Whereas examples of ionized bases yielding un-ionized conjugate acids are acetate forming acetic acid (reaction *h*), phenobarbiturate yielding phenobarbital (reaction *j*), and saccharate yielding saccharin (reaction *l*). Complicated as it may seem at first, conjugate acids and conjugate bases are nothing more than the products of an acid-base reaction. In other words, they appear to the right of the reaction arrows.

Representative examples of pharmaceutically important acidic drugs are listed in Table 2.1. Each acid, or proton donor, yields a *conjugate base*. The latter is the product after the proton is lost from the acid. Conjugate bases range from the chloride ion (reaction *a*), which does not accept a proton in aqueous media, to ephedrine (reaction *h*), which is an excellent proton acceptor.

Acid Strength

While any acid-base reaction can be written as an equilibrium reaction, an attempt has been made in Table 2.1 to indicate which sequences are unidirectional or show only a small reversal. For hydrochloric acid (reaction *a*), the conjugate base, Cl^- , is such a weak base that it essentially does not function as a proton acceptor. In a similar manner, water is such a weak conjugate acid that there is little reverse reaction involving water donating a proton to the hydroxide anion of sodium hydroxide (reaction *b*).

Two logical questions to ask at this point are how one predicts in which direction an acid-base reaction lies and to what extent the reaction goes to completion. The common physical chemical measurement that contains this information is known as the pK_a . The pK_a is the negative logarithm of the modified equilibrium constant, K_a (Eq. 2.1), for an acid-base reaction written so that water is the base or proton acceptor (reactions *a, c, e, g, i, k, m*, Table 2.1).

$$K_a = \frac{[\text{conj. acid}][\text{conj. base}]}{[\text{acid}]} \quad (\text{Eq. 2.1})$$

Equation 2.1 is based on Rx. 2.3. The square brackets indicate molar concentrations. Because the molar concentration of water (the base in these acid-base reactions) is considered constant in the dilute solutions used in pharmacy and medicine, it is incorporated into the K_a . Rewriting Equation 2.1 by taking the negative logarithm of the K_a , results in the familiar Henderson-Hasselbalch equation (Eq. 2.2).

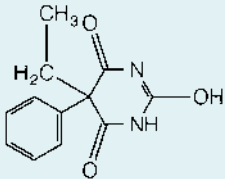

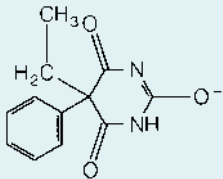

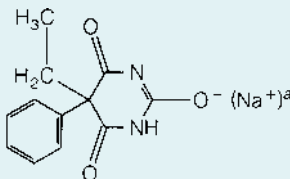

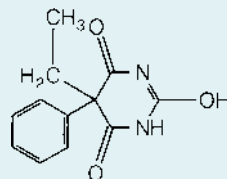

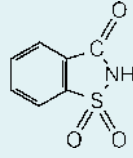

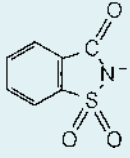

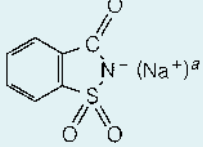

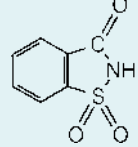

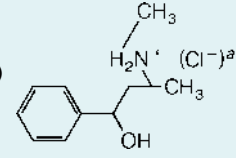

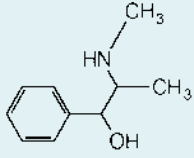

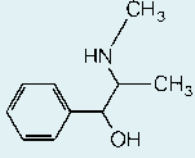

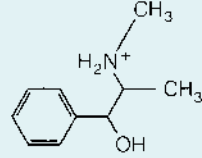

$$\text{pH} = \text{pK}_a + \log \frac{[\text{conj. base}]}{[\text{acid}]} \quad (\text{Eq. 2.2})$$

Warning! It is *important* to recognize that a pK_a for a base is in reality the pK_a of the conjugate acid (acid donor or protonated form, BH^+) of the base. The pK_a is listed in the Appendix as 9.6 for ephedrine and as 9.3 for ammonia. In reality, this is the pK_a of the protonated form, such as ephedrine hydrochloride (reaction *m* in Table 2.1) and ammonium chloride (reaction *e* in Table 2.1), respectively. This is confusing to students, pharmacists, clinicians, and experienced scientists. It is crucial that the chemistry of the drug be understood when interpreting a pK_a value. When reading tables of pK_a values, such as those found in the Appendix, one must realize that the listed value is for the proton donor form of the molecule, no matter what form is indicated by the name. See Table 2.2 for several worked examples of how the pK_a is used to calculate pHs of solutions, required ratios of [conjugate base]/[acid], and percent ionization (discussed later) at specific pHs.

Just how strong or weak are the acids whose reactions in water are illustrated in Table 2.1? Remember that the K_a s or pK_a 's are modified equilibrium constants that indicate the extent to which the acid (proton donor) reacts with water to form conjugate acid and conjugate base. The equilibrium for a strong acid (low pK_a) in water lies to the right, favoring the formation of products (conjugate acid and conjugate base). The equilibrium for a weak acid (high pK_a) in water lies to the left, meaning that the conjugate acid is a better proton donor than the parent acid is or that the conjugate base is a good proton acceptor.

Refer back to Equation 2.1 and, using the K_a values in Table 2.3, substitute the K_a term for each of the acids. For

TABLE 2.1 Examples of Acid–Base Reactions (with the Exception of Hydrochloric Acid, Whose Conjugate Base [Cl⁻] Has No Basic Properties in Water, and Sodium Hydroxide, which Generates Hydroxide, the Reaction of the Conjugate Base in Water Is Shown for Each Acid)

Acid	+ Base	\rightleftharpoons	Conjugate Acid	+ Conjugate Base
Hydrochloric acid (a) HCl	+ H ₂ O	\longrightarrow	H ₃ O ⁺	+ Cl ⁻
Sodium hydroxide (b) H ₂ O	+ NaOH	\longrightarrow	H ₂ O	+ OH ⁻ (Na ⁺) ^a
Sodium dihydrogen phosphate and its conjugate base, sodium monohydrogen phosphate (c) H ₂ PO ₄ ⁻ (Na ⁺) ^a	+ H ₂ O	\rightleftharpoons	H ₃ O ⁺	+ HPO ₄ ²⁻ (Na ⁺) ^a
(d) H ₂ O	+ HPO ₄ ²⁻ (2Na ⁺) ^a	\rightleftharpoons	H ₂ PO ₄ ²⁻ (Na ⁺) ^a	+ OH ⁻ (Na ⁺) ^a
Ammonium chloride and its conjugate base, ammonia (e) NH ₄ ⁺ (Cl ⁻) ^a	+ H ₂ O	\rightleftharpoons	H ₃ O ⁺ (Cl ⁻) ^a	+ NH ₃
(f) H ₂ O	+ NH ₃	\rightleftharpoons	NH ₄ ⁺	+ OH ⁻
Acetic acid and its conjugate base, sodium acetate (g) CH ₃ COOH	+ H ₂ O	\rightleftharpoons	H ₃ O ⁺	+ CH ₃ COO ⁻
(h) H ₂ O	+ CH ₃ COO ⁻ (Na ⁺) ^a	\rightleftharpoons	CH ₃ COOH	+ OH ⁻ (Na ⁺) ^a
Indomethacin and its conjugate base, indomethacin sodium, show the identical acid–base chemistry as acetic acid and sodium acetate, respectively.				
Phenobarbital and its conjugate base, phenobarbital sodium				
(i)		+ H ₂ O	\rightleftharpoons H ₃ O ⁺	+ 
(j) H ₂ O	+ 	\rightleftharpoons		+ OH ⁻ (Na ⁺) ^a
Saccharin and its conjugate base, saccharin sodium				
(k)		+ H ₂ O	\rightleftharpoons H ₃ O ⁺	+ 
(l) H ₂ O	+ 	\rightleftharpoons		+ OH ⁻ (Na ⁺) ^a
Ephedrine HCl and its conjugate base, ephedrine				
(m)		+ H ₂ O	\rightleftharpoons H ₃ O ⁺ (Cl ⁻) ^a	+ 
(n) H ₂ O	+ 	\rightleftharpoons		+ OH ⁻

^aThe chloride anion and sodium cation are present only to maintain charge balance. These anions play no other acid–base role.

TABLE 2.2 Examples of Calculations Requiring the pK_a

1. What is the ratio of ephedrine to ephedrine HCl (pK_a 9.6) in the intestinal tract at pH 8.0? Use Equation 2.2.

$$8.0 = 9.6 + \log \frac{[\text{ephedrine}]}{[\text{ephedrine HCl}]} = -1.6$$

$$\frac{[\text{ephedrine}]}{[\text{ephedrine HCl}]} = 0.025$$

The number whose log is -1.6 is 0.025, meaning that there are 25 parts ephedrine for every 1,000 parts ephedrine HCl in the intestinal tract whose environment is pH 8.0.

2. What is the pH of a buffer containing 0.1-M acetic acid (pK_a 4.8) and 0.08-M sodium acetate? Use Equation 2.2.

$$\text{pH} = 4.8 + \log \frac{0.08}{0.1} = 4.7$$

3. What is the pH of a 0.1-M acetic acid solution? Use the following equation for calculating the pH of a solution containing either an HA or BH⁺ acid.

$$\text{pH} = \frac{\text{pK}_a - \log[\text{acid}]}{2} = 2.9$$

4. What is the pH of a 0.08-M sodium acetate solution? Remember, even though this is the conjugate base of acetic acid, the pK_a is still used. The pK_w term in the following equation corrects for the fact that a proton acceptor (acetate anion) is present in the solution. The equation for calculating the pH of a solution containing either an A⁻ or B base is

$$\text{pH} = \frac{\text{pK}_w + \text{pK}_a + \log[\text{base}]}{2} = 8.9$$

5. What is the pH of an ammonium acetate solution? The pK_a of the ammonium (NH₄⁺) cation is 9.3. Always bear in mind that the pK_a refers to the ability of the proton donor form to release the proton into water to form H₃O⁺. Since this is the salt of a weak acid (NH₄⁺) and the conjugate base of a weak acid (acetate anion), the following equation is used. Note that molar concentration is not a variable in this calculation.

$$\text{pH} = \frac{\text{pK}_{a_1} + \text{pK}_{a_2}}{2} = 7.1$$

6. What is the percentage ionization of ephedrine HCl (pK_a 9.6) in an intestinal tract buffered at pH 8.0 (see example 1)? Use Equation 2.4 because this is a BH⁺ acid.

$$\% \text{ ionization} = \frac{100}{1 + 10^{(8.0-9.6)}} = 97.6\%$$

Only 2.4% of ephedrine is present as the un-ionized conjugate base.

7. What is the percentage ionization of indomethacin (pK_a 4.5) in an intestinal tract buffered at pH 8.0? Use Equation 2.3 because this is an HA acid.

$$\% \text{ ionization} = \frac{100}{1 + 10^{(4.5-8.0)}} = 99.97\%$$

For all practical purposes, indomethacin is present only as the anionic conjugate base in that region of the intestine buffered at pH 8.0.

TABLE 2.3 Representative K_a and pK_a Values from the Reactions Listed in Table 2.1 (See the Appendix)

Hydrochloric acid	1.26×10^6	-6.1
Dihydrogen phosphate	6.31×10^{-8}	7.2
Ammonia (ammonium)	5.01×10^{-10}	9.3
Acetic acid	1.58×10^{-5}	4.8
Phenobarbital	3.16×10^{-8}	7.5
Saccharin	2.51×10^{-2}	1.6
Indomethacin	3.16×10^{-5}	4.5
Ephedrine (as the HCl salt)	2.51×10^{-10}	9.6

hydrochloric acid, a K_a of 1.26×10^6 means that the product of the molar concentrations of the conjugate acid, [H₃O⁺], and the conjugate base, [Cl⁻], is huge relative to the denominator term, [HCl]. In other words, there essentially is no unreacted HCl left in an aqueous solution of hydrochloric acid. At the other extreme is ephedrine HCl with a pK_a of 9.6 or a K_a of 2.51×10^{-10} . Here, the denominator representing the concentration of ephedrine HCl greatly predominates over that of the products, which, in this example, is ephedrine (conjugate base) and H₃O⁺ (conjugate acid). In other words, the protonated form of ephedrine is a very poor proton donor. It holds onto the proton. Free ephedrine (the conjugate base in this reaction) is an excellent proton acceptor.

A general rule for determining whether a chemical is strong or weak acid or base is

- pK_a < 2: strong acid; conjugate base has no meaningful basic properties in water
- pK_a 4 to 6: weak acid; weak conjugate base
- pK_a 8 to 10: very weak acid; conjugate base getting stronger
- pK_a > 12: essentially no acidic properties in water; strong conjugate base

This delineation is only approximate. Other properties also become important when considering cautions in handling acids and bases. Phenol has a pK_a of 9.9, slightly less than that of ephedrine HCl. Why is phenol considered corrosive to the skin, whereas ephedrine HCl or free ephedrine is considered innocuous when applied to the skin? Phenol has the ability to partition through the normally protective lipid layers of the skin. Because of this property, this extremely weak acid has carried the name carbolic acid. Thus, the pK_a simply tells a person the acid properties of the protonated form of the chemical. It does not represent anything else concerning other potential toxicities.

Percent Ionization

Using the drug's pK_a, the formulation or compounding pharmacist can adjust the pH to ensure maximum water solubility (ionic form of the drug) or maximum solubility in nonpolar media (un-ionic form). This is where understanding the drug's acid-base chemistry becomes important. Note Reactions 2.4 and 2.5:

Acids can be divided into two types, HA and BH⁺, on the basis of the ionic form of the acid (or conjugate base). HA acids go from un-ionized acids to ionized conjugate bases (Rx. 2.4). In contrast, BH⁺ acids go from ionized (polar) acids to un-ionized (nonpolar) conjugate bases (Rx. 2.5). In general, pharmaceutically important HA acids include the inorganic acids (e.g., HCl, H₂SO₄), enols (e.g., barbiturates, hydantoin), carboxylic acids (e.g., low-molecular-weight organic acids, arylacetic acids, *N*-aryl anthranilic acids, salicylic acids), and amides and imides (e.g., sulfonamides and saccharin, respectively). The chemistry is simpler for the pharmaceutically important BH⁺ acids: They are all protonated amines. A polyfunctional drug can have several pK_a's (e.g., amoxicillin). The latter's ionic state is based on amoxicillin's ionic state at physiological pH 7.4.

The percent ionization of a drug is calculated by using Equation 2.3 for HA acids and Equation 2.4 for BH⁺ acids.

$$\% \text{ ionization} = \frac{100}{1 + 10^{(pK_a - \text{pH})}} \quad (\text{Eq. 2.3})$$

$$\% \text{ ionization} = \frac{100}{1 + 10^{(\text{pH} - pK_a)}} \quad (\text{Eq. 2.4})$$

A plot of percent ionization versus pH illustrates how the degree of ionization can be shifted significantly with small changes in pH. The curves for an HA acid (indomethacin) and BH⁺ (protonated ephedrine, Table 2.1, reaction *m*) are shown in Figure 2.4. First, note that when pH = pK_a, the compound is 50% ionized (or 50% un-ionized). In other words, when the pK_a is equal to the pH, the molar concentration of the acid equals the molar concentration of its conjugate base. In the Henderson-Hasselbalch equation, pK_a = pH when log [conjugate base]/[acid] = 1. An increase of 1 pH unit from the pK_a (increase in alkalinity) causes an HA acid (indomethacin) to become 90.9% in the

Figure 2.4 • Percent ionized versus pH for indomethacin (pK_a 4.5) and ephedrine (pK_a 9.6).

ionized conjugate base form but results in a BH⁺ acid (ephedrine HCl) decreasing its percent ionization to only 9.1%. An increase of 2 pH units essentially shifts an HA acid to complete ionization (99%) and a BH⁺ acid to the nonionic conjugate base form (0.99%).

Just the opposite is seen when the medium is made more acidic relative to the drug's pK_a value. Increasing the hydrogen ion concentration (decreasing the pH) will shift the equilibrium to the left, thereby increasing the concentration of the acid and decreasing the concentration of conjugate base. In the case of indomethacin, a decrease of 1 pH unit below the pK_a will increase the concentration of un-ionized (protonated) indomethacin to 9.1%. Similarly, a decrease of 2 pH units results in only 0.99% of the indomethacin being present in the ionized conjugate base form. The opposite is seen for the BH⁺ acids. The percentage of ephedrine present as the ionized (protonated) acid is 90.9% at 1 pH unit below the pK_a and is 99.0% at 2 pH units below the pK_a. These results are summarized in Table 2.4.

With this knowledge in mind, return to the drawing of amoxicillin. At physiological pH, the carboxylic acid (HA acid; pK_{a1} 2.4) will be in the ionized carboxylate form, the primary amine (BH⁺ acid; pK_{a2} 7.4) will be 50% protonated and 50% in the free amine form, and the phenol (HA acid; pK_{a3} 9.6) will be in the un-ionized protonated form. Knowledge of percent ionization makes it easier to explain and predict why the use of some preparations can cause

TABLE 2.4 Percentage Ionization Relative to the pK_a

	Ionization (%)	
	HA Acids	BH Acids
$pK_a - 2$ pH units	0.99	99.0
$pK_a - 1$ pH unit	9.1	90.9
$pK_a =$ pH	50.0	50.0
$pK_a + 1$ pH unit	90.9	9.1
$pK_a + 2$ pH units	99.0	0.99

problems and discomfort as a result of pH extremes. Phenytoin (HA acid; pK_a 8.3) injection must be adjusted to pH 12 with sodium hydroxide to ensure complete ionization and maximize water solubility. In theory, a pH of 10.3 will result in 99.0% of the drug being an anionic water-soluble conjugate base. To lower the concentration of phenytoin in the insoluble acid form even further and maintain excess alkalinity, the pH is raised to 12 to obtain 99.98% of the drug in the ionized form. Even then, a cosolvent system of 40% propylene glycol, 10% ethyl alcohol, and 50% water for injection is used to ensure complete solution. This highly alkaline solution is irritating to the patient and generally cannot be administered as an admixture with other intravenous fluids that are buffered more closely at physiological pH 7.4. This decrease in pH would result in the parent unionized phenytoin precipitating out of solution.

Tropicamide is an anticholinergic drug administered as eye drops for its mydriatic response during eye examinations. With a pK_a of 5.2, the drug has to be buffered near pH 4 to obtain more than 90% ionization. The acidic eye drops can sting. Some optometrists and ophthalmologists use local anesthetic eye drops to minimize the patient's discomfort. The only atom with a meaningful pK_a is the pyridine nitrogen. The amide nitrogen has no acid-base properties in aqueous media.

Adjustments in pH to maintain water solubility can sometimes lead to chemical stability problems. An example is indomethacin (HA acid; pK_a 4.5), which is unstable in alkaline media. Therefore, the preferred oral liquid dosage form is a suspension buffered at pH 4 to 5. Because this is

near the drug's pK_a , only 50% will be in the water-soluble form. There is a medical indication requiring intravenous administration of indomethacin to premature infants. The intravenous dosage form is the lyophilized (freeze-dried) sodium salt, which is reconstituted just prior to use.

Drug Distribution and pK_a

The pK_a can have a pronounced effect on the pharmacokinetics of the drug. As discussed previously, drugs are transported in the aqueous environment of the blood. Those drugs in an ionized form will tend to distribute throughout the body more rapidly than will un-ionized (nonpolar) molecules. With few exceptions, the drug must leave the polar environment of the plasma to reach the site of action. In general, drugs pass through the nonpolar membranes of capillary walls, cell membranes, and the blood-brain barrier in the un-ionized (nonpolar) form. For HA acids, it is the parent acid that will readily cross these membranes (Fig. 2.5). The situation is just the opposite for the BH^+ acids. The unionized conjugate base (free amine) is the species most readily crossing the nonpolar membranes (Fig. 2.6).

Consider the changing pH environment experienced by the drug molecule orally administered. The drug first encounters the acidic stomach, where the pH can range from 2 to 6 depending on the presence of food. HA acids with pK_a 's of 4 to 5 will tend to be nonionic and be absorbed partially through the gastric mucosa. (The main reason most acidic drugs are absorbed from the intestinal tract rather than the stomach is that the microvilli of the intestinal mucosa provide a large surface area relative to that found in the gastric mucosa of the stomach.) In contrast, amines (pK_a 9–10) will be protonated (BH^+ acids) in the acidic stomach and usually will not be absorbed until reaching the mildly alkaline intestinal tract (pH 8). Even here, only a portion of the amine-containing drugs will be in their nonpolar conjugate base form (Fig. 2.4). Remember that the reactions shown in Figures 2.3 and 2.4 are equilibrium reactions with K_a values. Therefore, whenever the nonpolar form of either an HA acid (as the acid) or a B base (the conjugate base of the BH^+ acid) passes the lipid barrier, the ratio of conjugate base to acid (percent ionization) will be maintained. Based on Equations 2.3 and 2.4, this ratio depends on the pK_a (a constant) and the pH of the medium.

For example, once in systemic circulation, the plasma pH of 7.4 will be one of the determinants of whether the drug will tend to remain in the aqueous environment of the blood or partition across lipid membranes into hepatic tissue to be metabolized, into the kidney for excretion, into tissue depots, or to the receptor tissue. A useful exercise is to calculate either the [conjugate base]/[acid] ratio using the Henderson-Hasselbalch equation (Eq. 2.2) or percent

Figure 2.5 • Passage of HA acids through lipid barriers.

Figure 2.6 • Passage of BH^+ acids through lipid barriers.

ionization for ephedrine (pK_a 9.6; Eq. 2.4) and indomethacin (pK_a 4.5; Eq. 2.3) at pH 3.5 (stomach), pH 8.0 (intestine), and pH 7.4 (plasma) (see examples 1, 6, and 7 in Table 2.2). Of course, the effect of protein binding, discussed previously, can greatly alter any prediction of biodistribution based solely on pK_a .

COMPUTER-AIDED DRUG DESIGN: EARLY METHODS

Initially, the design of new drugs was based on starting with a prototypical molecule, usually a natural product and making structural modifications. Examples include steroidal hormones based on naturally occurring cortisone, testosterone, progesterone and estrogen; adrenergic drugs based on epinephrine; local anesthetics based on cocaine; opiate analgesics based on morphine; antibiotics based on penicillin, cephalosporin and tetracycline. Examples of prototypical molecules that were not natural in origin include the antipsychotic phenothiazines, bisphosphonates for osteoporosis, benzodiazepines indicated for various CNS treatments. Although prototypical molecules have produced significant advancements in treating diseases, this approach to drug development is limited to the initial discovery of the prototypical molecule. Today, it is more common to take a *holistic* approach that, where possible, involves understanding the etiology of the disease and the structure of the receptor where the ligand (drug) will bind. Increasing computer power coupled with applicable software, both at reasonable cost, has led to more focused approaches for the development of new drugs. Computational methodologies include mathematical equations correlating structure with biological activity, searching chemical databases for leads and rapid docking of ligand to the receptor. The latter requires 3D structure information of the receptor. Originally crystallized enzymes were the common receptors, and their spatial arrangements determined by x-ray crystallography. Today's software can calculate possible 3D structures of protein starting with the amino acid sequence.

Statistical Prediction of Pharmacological Activity

Just as mathematical modeling is used to explain and model many chemical processes, it has been the goal of medicinal chemists to quantify the effect of a structural change on a defined pharmacological response. This would meet three goals in drug design: (a) to predict biological activity in untested compounds, (b) to define the structural requirements required for a good fit between the drug molecule and the receptor, and

(c) to design a test set of compounds to maximize the amount of information concerning structural requirements for activity from a minimum number of compounds tested. This aspect of medicinal chemistry is commonly referred to as quantitative structure–activity relationships (QSAR).

The goals of QSAR studies were first proposed about 1865 to 1870 by Crum-Brown and Fraser, who showed that the gradual chemical modification in the molecular structure of a series of poisons produced some important differences in their action.¹ They postulated that the physiological action, ϕ , of a molecule is a function of its chemical constitution, C . This can be expressed in Equation 2.5:

$$\phi = f(C) \quad (\text{Eq. 2.5})$$

Equation 2.5 states that a defined change in chemical structure results in a predictable change in physiological action. The problem now becomes one of numerically defining chemical structure. It still is a fertile area of research. What has been found is that biological response can be predicted from physical chemical properties such as vapor pressure, water solubility, electronic parameters, steric descriptors, and partition coefficients (Eq. 2.6). Today, the partition coefficient has become the single most important physical chemical measurement for QSAR studies. Note that Equation 2.6 is the equation for a straight line ($Y = mx + b$).

$$\log BR = a(\text{physical chemical property}) + c \quad (\text{Eq. 2.6})$$

where

BR = a defined pharmacological response usually expressed in millimoles such as the inhibitory constant K_i , the effective dose in 50% of the subjects (ED_{50}), the lethal dose in 50% of the subjects (LD_{50}), or the minimum inhibitory concentration (MIC). It is common to express the biological response as a reciprocal, $1/BR$ or $1/C$

a = the regression coefficient or slope of the straight line

c = the intercept term on the y axis (when the physical chemical property equals zero)

To understand the concepts in the next few paragraphs, it is necessary to know how to interpret defined pharmacological concepts such as the ED_{50} , which is the amount of the drug needed to obtain the defined pharmacological response in 50% of the test subjects. Let us assume that drug A's ED_{50} is 1 mmol and drug B's ED_{50} is 2 mmol. Drug A is twice as potent as drug B. In other words, the smaller the ED_{50} (or ED_{90} , LD_{50} , MIC, etc.), the more potent is the substance being tested.

The logarithmic value of the dependent variable (concentration necessary to obtain a defined biological response) is used to linearize the data. As shown later in this chapter, QSARs are not always linear. Nevertheless, using logarithms is an acceptable statistical technique (taking reciprocals obtained from a Michaelis-Menton study produces the linear Lineweaver-Burke plots found in any biochemistry textbook).

Now, why is the biological response usually expressed as a reciprocal? Sometimes, one obtains a statistically more valid relationship. More importantly, expressing the biological response as a reciprocal usually produces a positive slope (Fig. 2.7). Let us examine the following published example (Table 2.5). The BR is the LD_{100} (lethal dose in 100% of the subjects). The mechanism of death is general depression of the CNS.

Figure 2.7 • Plot of $(BR \times 1,000)$ versus $(PC \times 0.01)$.

The most lethal compound in this assay was chlorpromazine, with a BR (LD_{100}) of only 0.00000631 mmol; and the least active was ethanol, with a BR of 0.087096 mmol. In other words, it takes about 13,800 times as many millimoles of ethanol than of chlorpromazine to kill 100% of the test subjects in this particular assay.

Plotting BR versus PC (partition coefficient) produces the nonlinear scatter shown in Figure 2.7. Note that compounds 1 and 11 lie at a considerable distance from the remaining nine compounds. In addition to the 13,800 times difference in activity, there is a 33,900 times difference in the octanol/water partition coefficient. An attempt at obtaining a linear regression equation produces the meaningless Equation. 2.7 whose equation is:

$$BR = -0.0000 PC + 0.0117 \quad (\text{Eq. 2.7})$$

It is meaningless statistically. The slope is 0, meaning that the partition coefficient has no effect on biological activity, and yet from the plot and Table 2.5, it is obvious that the higher the octanol/water partition coefficient, the more toxic the compound. The correlation coefficient (r^2) is 0.05, meaning that there is no significant statistical relationship between activity and partition coefficient.

Now, let us see if the data can be linearized by using the logarithms of the biological activity and partition coefficient. Notice the logarithmic terms. The difference between the LD_{100} of chlorpromazine and ethanol is only 4.14

Figure 2.8 • Plot of $\log BR$ versus $\log PC$.

logarithmic units. Similarly, the difference between chlorpromazine's partition coefficient and that of ethanol is 4.53 logarithmic units. Figure 2.8 shows the plot and regression line for $\log BR$ versus $\log PC$. It is an inverse relationship (Eq. 2.8) between physicochemical property and biological response. Otherwise, the regression equation is excellent with a correlation coefficient of 0.9191.

$$\log BR = -1.1517 \log PC - 1.4888 \quad (\text{Eq. 2.8})$$

Although there is no statistical advantage to using the log of the reciprocal of the biological response, the positive relationship is consistent with common observation that the biological activity increases as the partition coefficient (or other physicochemical parameter) increases. In interpreting plots such as that in Figure 2.9, remember that biological activity is increasing as the amount of compound required to obtain the defined biological response is decreasing. The equation for the line in Figure 2.9 is identical to Equation 2.8, except for the change to positive slope and sign of the intercept. The correlation coefficient also remains the same at 0.9191.

$$\log 1/BR = 1.517 \log PC + 1.4888 \quad (\text{Eq. 2.9})$$

Partition Coefficient

The most common physicochemical descriptor is the molecule's partition coefficient in an octanol/water system. As

TABLE 2.5 Data Used for a Quantitative Structure–Activity Relationship Study

Compound	Log 1/BR	1/BR	BR	BR × 1,000	Log BR	Log PC	PC × 0.01

Source: Hansch, C., Björkroth, J. P., and Leo, A.: J. Pharm. Sci. 76:663, 1987. BR is defined as the LD_{100} , and PC is the octanol/water partition coefficient.

Figure 2.9 • Plot of $\log 1/BR$ versus $\log PC$.

emphasized previously, the drug will go through a series of partitioning steps: (a) leaving the aqueous extracellular fluids, (b) passing through lipid membranes, and (c) entering other aqueous environments before reaching the receptor (Fig. 2.1). In this sense, a drug is undergoing the same partitioning phenomenon that happens to any chemical in a separatory funnel containing water and a nonpolar solvent such as hexane, chloroform, or ether. The partition coefficient (P) is the ratio of the molar concentration of chemical in the nonaqueous phase (usually 1-octanol) versus that in the aqueous phase (Eq. 2.10). For reasons already discussed, it is more common to use the logarithmic expression (Eq. 2.11). The difference between the separatory funnel model and what actually occurs in the body is that the partitioning in the funnel will reach an equilibrium at which the rate of chemical leaving the aqueous phase and entering the organic phase will equal the rate of the chemical moving from the organic phase to the aqueous phase. This is not the physiological situation. Refer to Figure 2.1 and note that dynamic changes are occurring to the drug, such as it being metabolized, bound to serum albumin, excreted from the body, and bound to receptors. The environment for the drug is not static. Upon administration, the drug will be *pushed* through the membranes because of the high concentration of drug in the extracellular fluids relative to the concentration in the intracellular compartments. In an attempt to maintain equilibrium ratios, the flow of the drug will be from systemic circulation through the membranes onto the receptors. As the drug is metabolized and excreted from the body, it will be *pulled* back across the membranes, and the concentration of drug at the receptors will decrease.

$$P = \frac{[\text{chemical}]_{\text{oct}}}{[\text{chemical}]_{\text{aq}}} \quad (\text{Eq. 2.10})$$

$$\log P = \log \left(\frac{[\text{solute}]_{\text{oct}}}{[\text{solute}]_{\text{aq}}} \right) \quad (\text{Eq. 2.11})$$

Equations 2.10 and 2.11 assume that the drug is in the nonpolar state. A large percentage of drugs are amines whose pK_a is such that at physiological pH 7.4, a significant percentage of the drug will be in its protonated, ionized form. A similar statement can be made for the HA acids (carboxyl, sulfonamide, imide) in that at physiological pH, a significant

percentage will be in their anionic forms. An assumption is made that the ionic form is water-soluble and will remain in the water phase of an octanol/water system. This *reality* has led to the use of $\log D$, which is defined as the equilibrium ratio of both the ionized and un-ionized species of the molecule in an octanol/water system (Eq. 2.12). The percent ionization of ionized HA acids and BH protonated amines and acids can be estimated from Equations 2.3 and 2.4 and the $\log D$ from Equations 2.13 and 2.14, respectively.

$$\log D = \log \left(\frac{[\text{solute}]_{\text{oct}}}{[\text{solute}]_{\text{aq}}^{\text{ionized}} + [\text{solute}]_{\text{aq}}^{\text{nonionized}}} \right) \quad (\text{Eq. 2.12})$$

$$\log D_{\text{acids}} = \log P = \log \left[\frac{1}{(1 + 10^{(pH-pK_a)})} \right] \quad (\text{Eq. 2.13})$$

$$\log D_{\text{bases}} = \log P = \log \left[\frac{1}{(1 + 10^{(pK_a-pH)})} \right] \quad (\text{Eq. 2.14})$$

Because much of the time the drug's movement across membranes is a partitioning process, the partition coefficient has become the most common physicochemical property. The question that now must be asked is what immiscible nonpolar solvent system best mimics the water/lipid membrane barriers found in the body? It is now realized that the *n*-octanol/water system is an excellent estimator of drug partitioning in biological systems. One could argue that it was fortuitous that *n*-octanol was available in reasonable purity for the early partition coefficient determinations. To appreciate why this is so, one must understand the chemical nature of the lipid membranes.

These membranes are not exclusively anhydrous fatty or oily structures. As a first approximation, they can be considered bilayers composed of lipids consisting of a polar cap and large hydrophobic tail. Phosphoglycerides are major components of lipid bilayers (Fig. 2.10). Other groups of bifunctional lipids include the sphingomyelins, galactocerebrosides, and plasmalogens. The hydrophobic portion is composed largely of unsaturated fatty acids, mostly with *cis* double bonds. In addition, there are considerable amounts of cholesterol esters, protein, and charged mucopolysaccharides in the lipid membranes. The final result is that these membranes are highly organized structures composed of channels for transport of important molecules such as metabolites, chemical regulators (hormones), amino acids, glucose, and fatty acids into the cell and removal of waste products and biochemically produced products out of the

Figure 2.10 • General structure of a bifunctional phospholipid. Many of the fatty acid esters will be *cis* unsaturated.

Figure 2.11 • Schematic representation of the cell membrane.

cell. The cellular membranes are dynamic, with the channels forming and disappearing depending on the cell's and body's needs (Fig. 2.11). So complex is this system that it is not uncommon to have situations where there is poor correlation between the partition coefficient of a series of molecules and the biological response.²

In addition, the membranes on the surface of nucleated cells have specific antigenic markers, major histocompatibility complex (MHC), by which the immune system monitors the cell's status. There are receptors on the cell surface where hormones such as epinephrine and insulin bind, setting off a series of biochemical events within the cell. Some of these receptors are used by viruses to gain entrance into the cells, where the virus reproduces. As newer instrumental techniques are developed, and genetic cloning permits isolation of the genetic material responsible for forming and regulating the structures on the cell surface, the image of a passive lipid membrane has disappeared to be replaced by a very complex, highly organized, dynamically functioning structure.

For purposes of the partitioning phenomenon, picture the cellular membranes as two layers of lipids (Fig. 2.9). The two outer layers, one facing the interior and the other facing the exterior of the cell, consist of the polar ends of the bifunctional lipids. Keep in mind that these surfaces are exposed to an aqueous polar environment. The polar ends of the charged phospholipids and other bifunctional lipids are solvated by the water molecules. There are also considerable amounts of charged proteins and mucopolysaccharides present on the surface. In contrast, the interior of the membrane is populated by the hydrophobic aliphatic chains from the fatty acid esters.

With this representation in mind, a partial explanation can be presented as to why the *n*-octanol/water partitioning system seems to mimic the lipid membranes/water systems found in the body. It turns out that *n*-octanol is not as nonpolar as initially might be predicted. Water-saturated octanol contains 2.3 M water because the small water molecule easily clusters around octanol's hydroxy moiety. *n*-Octanol-saturated water contains little of the organic phase because of the large hydrophobic 8-carbon chain of octanol. The water in the *n*-octanol phase apparently approximates the polar properties of the lipid bilayer, whereas the lack of octanol in the water phase mimics the physiological aqueous compartments, which are relatively free of nonpolar components. In contrast, partitioning systems such as hexane/water and chloroform/water contain so little water in the organic phase that they are poor models for the lipid bilayer/water system found in the body. At the same time, remember that the *n*-octanol/water system is only an approximation of the actual environment found in the interface between the cellular membranes and the extracellular/intracellular fluids.

Experimental determination of octanol/water partition coefficients is tedious and time consuming. Today, most are calculated. The accuracy of these calculations is only as good as the assumptions made by the writers of the software. These include atomic fragment values, correction factors, spatial properties, effects of resonance and induction, internal secondary bonding forces, etc. There are over 30 different software packages for calculating a molecules partition coefficient, and their accuracy varies widely.^{3,4}

Other Physicochemical and Descriptor Parameters

There is a series of other descriptors that measure the contribution by substituents to the molecule's total physicochemical properties. These include Hammett's ϕ constant; Taft's steric parameter, E_s ; Charton's steric parameter, ν ; Verloop's multidimensional steric parameters, L , B_1 , B_5 ; and molar refractivity, MR, number of hydrogen bond donors and acceptors, pK_a , polar surface area, number of rotatable bonds, connectivity indices, and the list goes into the thousands. Although directories of these have been published, it is common to calculate them. Table 2.6 lists a very small set and illustrates several items that must be kept in mind when selecting substituents to be evaluated in terms of the type of factors that influence a biological response. For electronic parameters such as ϕ , the location on an aromatic ring is important because of resonance versus inductive effects. Notice the twofold differences seen between ϕ_{meta} and ϕ_{para} for the three aliphatic substituents and iodo, and severalfold difference for methoxy, amino, fluoro, and phenolic hydroxyl.

Selection of substituents from a certain chemical class may not really test the influence of a parameter on biological activity. There is little numerical difference among the ϕ_{meta} or ϕ_{para} values for the four aliphatic groups or the four halogens. It is not uncommon to go to the tables and find missing parameters such as the E_s values for acetyl and *N*-acetyl.

Nevertheless, medicinal chemists can use information from extensive tables of physicochemical parameters to minimize the number of substituents required to find out if the biological response is sensitive to electronic, steric, and/or partitioning effects.⁵ This is done by selecting substituents in each of the numerical ranges for the different parameters. In Table 2.6, there are three ranges of B values (-1.23 to -0.55 , -0.28 to 0.56 , and 0.71 to 1.55); three ranges of MR values (0.92 – 2.85 , 5.02 – 8.88 , and 10.30 – 14.96); and two main clusters of ϕ values, one for the aliphatic substituents and the other for the halogens. In the ideal situation, substituents are selected from each of the clusters to determine the dependence of the biological response over the largest possible variable space. Depending on the biological responses obtained from testing the new compounds, it is possible to determine if lipophilicity (partitioning), steric bulk (molar refraction), or electron-withdrawing/donating properties are important determinants of the desired biological response.

With this background in mind, two examples of QSAR equations taken from the medicinal chemistry literature are presented. A study of a group of griseofulvin analogs showed a linear relationship (Eq. 2.15) between the biological response and both lipophilicity ($\log P$) and electronic character (σ).⁶ It was suggested that the antibiotic activity may depend on the enone system facilitating the addition of griseofulvin to a nucleophilic group such as the SH moiety in a fungal enzyme.

Griseofulvin: $R = R_1 = R_2 = \text{OCH}_3$; $R_3 = \text{Cl}$; $X = \text{H}$

$$\log \text{BR} = (0.56)\log P + (2.19)\sigma_x - 1.32 \quad (\text{Eq. 2.15})$$

A parabolic relationship (Eq. 2.16) was reported for a series of substituted acetylated salicylates (substituted aspirins) tested for anti-inflammatory activity.⁷ A nonlinear relationship exists between the biological response and lipophilicity, and a significant detrimental steric effect

is seen with substituents at position 4. The two sterimol parameters used in this equation were L , defined as the length of the substituent along the axis of the bond between the first atom of the substituent and the parent molecule, and B_2 , defined as a width parameter. Steric effects were not considered statistically significant at position 3, as shown by the sterimol parameters for substituents at position 3 not being part of Equation 2.16. The optimal partition coefficient ($\log P_o$) for the substituted aspirins in this assay was 2.6. At the same time, increasing bulk, as measured by the sterimol parameters, decreases activity.

Aspirin: $X = Y = \text{H}$

$$\log 1/\text{ED}_{50} = 1.03 \log P - 0.20(\log P)^2 - 0.05 L_{(4)} - 0.24 B_{2(4)} + 2.29 \quad (\text{Eq. 2.16})$$

At this point, it is appropriate to ask the question, “are all the determinations of partition coefficients and compilation of physical chemical parameters useful only when a statistically valid QSAR model is obtained?” The answer is a firm *no*. One of the most useful spinoffs from the field of QSAR has been the application of experimental design to the selection of new compounds to be synthesized and tested. Let us assume that a new series of drug molecules is to be synthesized based on the following structure. The goal is to test the effect of the 16-substituents in Table 2.6 at each of the three positions on our new series. The number of possible analogs is equal to 16^3 , or 4,096, compounds, assuming that all three positions will always be substituted with one of the substituents from Table 2.7. If hydrogen is included when a position is not substituted, there are 17^3 , or 4,913, different combinations. The problem is to select a small number of substituents that represent the different ranges or clusters of values for lipophilicity, electronic influence, and bulk. An initial design set could include the methyl and propyl from the

TABLE 2.7 Connectivity Table for Hydrogen-Suppressed Phenylalanine

aliphatic cluster, fluorine and chlorine from the halogen cluster, *N*-acetyl and phenol from the substituents showing hydrophilicity, and a range of electronic and bulk values. Including hydrogen, there will be 7^3 , or 343, different combinations. Obviously, that is too many for an initial evaluation. Instead, certain rules have been devised to maximize the information obtained from a minimum number of compounds. These include the following:

1. Each substituent must occur more than once at each position on which it is found.
2. The number of times that each substituent at a particular position appears should be approximately equal.
3. No two substituents should be present in a constant combination.
4. When combinations of substituents are a necessity, they should not occur more frequently than any other combination.

Following these guidelines, the initial test set can be reduced to 24 to 26 compounds. Depending on the precision of the biological tests, it will be possible to see if the data will fit a QSAR model. Even an approximate model usually will indicate the types of substituents to test further and what positions on the molecules are sensitive to substitution and, if sensitive, to what degree variation in lipophilic, electronic, or bulk character is important. Just to ensure that the model is valid, it is a good idea to synthesize a couple of compounds that the model predicts would be inactive. As each group of new compounds is tested, the QSAR model is refined until the investigators have a pretty good idea what substituent patterns are important for the desired activity. These same techniques used to develop potent compounds with desired activity also can be used to evaluate the influence of substituent patterns on undesired toxic effects and pharmacokinetic properties.

Topological Descriptors

An alternate method of describing molecular structure is based on graph theory, in which the bonds connecting the atoms is considered a path that is traversed from one atom to another. Consider Figure 2.12 containing *D*-phenylalanine

and its hydrogen-suppressed graph representation. The numbering is arbitrary and not based on International Union of Pure and Applied Chemistry (IUPAC) or *Chemical Abstracts* nomenclature rules. A connectivity table, Table 2.7, is constructed.

Table 2.7 is a two-dimensional connectivity table for the hydrogen-suppressed phenylalanine molecule. No 3D representation is implied. Further, this type of connectivity table will be the same for molecules with asymmetric atoms (D vs. L) or for those that can exist in more than one conformation (i.e., *chair* vs. *boat* conformation, *anti* vs. *gauche* vs. *eclipsed*).

Graph theory is not limited to the paths followed by chemical bonds. In its purest form, the atoms in the phenyl ring of phenylalanine would have paths connecting atom 7 with atoms 9, 10, 11, and 12; atom 8 with atoms 10, 11, and 12; atom 9 with atoms 11 and 12; and atom 10 with atom 12. Also, the graph itself might differentiate neither single, double, and triple bonds nor the type of atom (C, O, and N in the phenylalanine example). Connectivity tables can be coded to indicate the type of bond.

The most common application of graph theory used by medicinal chemistry is called *molecular connectivity*. It limits the paths to the molecule's actual chemical bonds. Table 2.8 shows several possible paths for phenylalanine, including linear paths and clusters or branching. Numerical values for each path or path-cluster are based on the number of nonhydrogen bonds to each atom. Let us examine oxygen atom 1. There is only one nonhydrogen bond, and it connects oxygen atom 1 to carbon atom 2. The formula is the reciprocal square root of the number of bonds. For oxygen 1, the connectivity value is 1. For carbonyl oxygen 2, it is $2^{-1/2}$, or 0.707. Note that there is no difference between oxygen 1 and nitrogen 5. Both have only one nonhydrogen bond and a connectivity value of 1. Similarly, there is no difference in values for a carbonyl oxygen and a methylene carbon, each having two nonhydrogen bonds. The final connectivity values for a path are the reciprocal square roots of the products of each path. For the second-order path 2C-4C-6C, the reciprocal square root $(3 \times 3 \times 2)^{-1/2}$ is 4.243. The values for each path order are calculated and summed.

As noted previously, the method as described so far cannot distinguish between atoms that have the same number of nonhydrogen bonds. A method to distinguish heteroatoms from each other and carbon atoms is based on the difference between the number of valence electrons and possible hydrogen atoms (which are suppressed in the graph). The *valence* connectivity term for an alcoholic oxygen would be 6 valence electrons minus 1 hydrogen, or 5. The *valence* connectivity term for a primary amine

nitrogen would be 5 valence electrons minus 2 hydrogens, or 3. There are various additional modifications that are done to further differentiate atoms and define their environments within the molecule.

Excellent regression equations using topological indices have been obtained. A problem is interpreting what they mean. Is it lipophilicity, steric bulk, or electronic terms that define activity? The topological indices can be correlated with all of these common physicochemical descriptors. Another problem is that it is difficult to use the equation to decide what molecular modifications can be made to enhance activity further, again because of ambiguities in physicochemical interpretation. Should the medicinal chemist increase or decrease lipophilicity at a particular location on the molecule? Should specific substituents be increased or decreased? On the other hand, topological indices can be very valuable in classification schemes that are described later in this chapter. They do describe the structure in terms of rings, branching, flexibility, etc.

Classification Methods

Besides regression analysis, there are other statistical techniques used in drug design. These fit under the classification of multivariate statistics and include discriminant analysis, principal component analysis, and pattern recognition. The latter can consist of a mixture of statistical and nonstatistical methodologies. The goal usually is to try to ascertain what physicochemical parameters and structural attributes contribute to a class or type of biological activity. Then, the chemicals are classified into groupings such as carcinogenic/noncarcinogenic, sweet/bitter, active/inactive, and depressant/stimulant.

The term *multivariate* is used because of the wide variety and number of independent or descriptor variables that may be used. The same physicochemical parameters seen in QSAR analyses are used, but in addition, the software in the computer programs *breaks* the molecule down into substructures. These structural fragments also become variables. Examples of the typical substructures used include carbonyls, enones, conjugation, rings of different sizes and types, N-substitution patterns, and aliphatic substitution patterns such as 1,3- or 1,2-disubstituted. The end result is that for even a moderate-size molecule typical of most drugs, there can be 50 to 100 variables.

The technique is to develop a large set of chemicals well characterized in terms of the biological activity that is going to be predicted. This is known as the *training set*. Ideally, it should contain hundreds, if not thousands, of compounds, divided into active and inactive types. In reality, sets smaller than 100 are studied. Most of these investigations are retrospective ones in which the investigator locates large data sets from several sources. This means that the biological testing likely followed different protocols. That is why classification techniques tend to avoid using continuous variables such as ED₅₀, LD₅₀, and MIC. Instead, arbitrary end points such as active or inactive, stimulant or depressant, sweet or sour, are used.

Once the training set is established, the multivariate technique is carried out. The algorithms are designed to group the underlying commonalities and select the variables that have the greatest influence on biological activity. The predictive ability is then tested with a test set of compounds that have been put through the same biological tests used for the training set. For the classification model to be valid, the investigator must select data sets whose results are not intuitively obvious and could not be classified by a trained medicinal chemist. Properly done, classification methods can identify structural and physicochemical descriptors that can be powerful predictors and determinants of biological activity.

There are several examples of successful applications of this technique.⁸ One study consisted of a diverse group of 140 tranquilizers and 79 sedatives subjected to a two-way classification study (tranquilizers vs. sedatives). The ring types included phenothiazines, indoles, benzodiazepines, barbiturates, diphenylmethanes, and various heterocyclics. Sixty-nine descriptors were used initially to characterize the molecules. Eleven of these descriptors were crucial to the classification, 54 had intermediate use and depended on the composition of the training set, and 4 were of little use. The overall range of prediction accuracy was 88% to 92%. The results with the 54 descriptors indicate an important limitation when large numbers of descriptors are used. The inclusion or exclusion of descriptors and parameters can depend on the composition of the training set. The training set must be representative of the population of chemicals that are going to be evaluated. Repeating the study on different randomly selected training sets is important.

Classification techniques lend themselves to studies lacking quantitative data. An interesting classification problem

involved olfactory stimulants, in which the goal was to select chemicals that had a musk odor. A group of 300 unique compounds was selected from a group of odorants that included 60 musk odorants plus 49 camphor, 44 floral, 32 ethereal, 41 mint, 51 pungent, and 23 putrid odorants. Initially, 68 descriptors were evaluated. Depending on the approach, the number of descriptors was reduced to 11 to 16, consisting mostly of bond types. Using this small number, the 60 musk odorants could be selected from the remaining 240 compounds, with an accuracy of 95% to 97%.

The use of classification techniques in medicinal chemistry has matured over years of general use. The types of descriptors have expanded to spatial measurements in 3D space similar to those used in 3D-QSAR (see discussion that follows). Increasingly, databases of existing compounds are scanned for molecules that possess what appear to be the desired parameters. If the scan is successful, compounds that are predicted to be active provide the starting point for synthesizing new compounds for testing. One can see parallels between the search of chemical databases and screening plant, animal, and microbial sources for new compounds. Although the statistical and pattern recognition methodologies have been in use for a very long time, there still needs to be considerable research into their proper use, and further testing of their predictive power is needed. The goal of scanning databases of already synthesized compounds to select compounds for pharmacological evaluation will require considerable additional development of the various multivariate techniques.

This chapter is limited to fairly simple computational techniques using readily available, low-cost software. The QSAR approach, including classification methods has at its disposal literally thousands of different descriptors, each with its advocates, and many computational approaches starting with the previously discussed linear regression to neural networks, decision trees and support vector machines. Thus, it is fair to ask if drug discoveries have been made with these computational techniques. The answer is in the ambiguous *yes-and-no* category depending on who is asked. There is general agreement

that QSAR provided the foundation to better understand the relationship between *chemical space* and *pharmacological space*. Consider these two pairs of active molecules. For classification purposes, acetylcholine and nicotine are nicotinic agonists, and dopamine and pergolide are dopaminergic agonists. Using the various measures of similarity and their descriptors, fingerprints, and fragments, these two pairs come up as dissimilar. It is true that the pharmacological profiles of acetylcholine—nicotine and dopamine—pergolide vary so much that nicotine is not used as a nicotinic agonist and pergolide is falling into disuse.^{9,10} Without being trite, computational drug design techniques are not going to replace the medicinal chemist who has an open, inquiring mind.

Has QSAR Been Successful?

The answer to this question depends on what are the expectations.¹¹ In their original development, it was hoped that QSAR equations would lead to commercially successful drugs. This has not occurred. Over the years, methodologies to develop these equations have changed. In the early development of QSAR equations, all of the compounds in a data set were used followed by random holding out of compounds to see if the equation changed. If there are enough compounds, it is now more common to begin with a *training set* and evaluate its validity with a *test set*. This has led to recommendations on the most reliable statistical measurements of validity.^{12–14}

Paralleling the evolution in the use of different statistical measures of validity, deriving these equations has led to the development of a wide variety of descriptors ranging from descriptive, physicochemical and topological. What can be frustrating is that the quality of predictions is dependent on the descriptor set.¹⁵ It must be remembered that most of descriptors are only as good as the algorithms used to calculate them. Further, it can be difficult to interpret exactly what the descriptors are measuring in chemical space. QSAR equations must explain physical reality if predictions for future compounds are to be made.¹⁶

COMPUTER-AIDED DRUG DESIGN: NEWER METHODS

Because powerful computing power, high-resolution computer graphics, and applicable software has reached the desktop, computational drug design methods are widely used in both industrial and academic environments. Through the use of computer graphics, structures of organic molecules can be entered into a computer and manipulated in many ways. Computational chemistry methods are used to calculate molecular properties and generate pharmacophore hypotheses. Once a pharmacophore hypothesis has been developed, structural databases (commercial, corporate, and/or public) of 3D structures can be searched rapidly for *hits* (i.e., existing compounds that are available with the required functional groups and permissible spatial orientations as defined by the search query). It has become popular to carry out *in silico* (computer as opposed to biological) screening of drug–receptor candidate interactions, known as *virtual* high-throughput screening (vHTS), for future development. The realistic goal of vHTS is to identify potential lead compounds. The drug–receptor fit and predicted physicochemical properties are used to *score* and *rank* compounds according to penalty functions and information filters (molecular weight, number of hydrogen bonds, hydrophobicity, etc.). Although medicinal chemists have always been aware of *absorption*, *distribution*, *metabolism*, *elimination*, and *toxicity* (ADMET or ADME/Tox), in recent years, a much more focused approach addresses these issues in the early design stages. Increased efforts to develop computer-based absorption, distribution, metabolism, and elimination (ADME) models are being pursued aggressively. Many of the *predictive* ADME models use QSAR methods described earlier in this chapter. In general, understanding what chemical space descriptors are critical for druglike molecules helps provide insight into the design of chemical libraries for biological evaluation.

Today's computers and software give the medicinal chemist the ability to *design* the molecule on the basis of an estimated fit onto a receptor or have similar spatial characteristics found in the prototypical lead compound. Of course, this assumes that the molecular structure of the receptor is known in enough detail for a reasonable estimation of its 3D shape. When a good understanding of the geometry of the active site is known, databases containing the 3D coordinates of the chemicals in the database can be searched rapidly by computer programs that select candidates likely to fit in the active site. As shown later, there have been some dramatic successes with use of this approach, but first one must have an understanding of ligand (drug)–receptor interactions and conformational analysis.

Forces Involved with Drug–Receptor Interactions

Keep in mind that a biological response is produced by the interaction of a drug with a functional or organized group of molecules. This interaction would be expected to take place by using the same bonding forces as are involved when simple molecules interact. These, together with typical examples, are collected in Table 2.9.

TABLE 2.9 Types of Chemical Bonds

Bond Type	Bond Strength (kcal/mol)	Example
Covalent	40–140	CH ₃ —OH
Reinforced ionic	10	
Ionic	5	R ₄ N [⊕] ⊖I
Hydrogen	1–7	
Ion–dipole	1–7	R ₄ N [⊕] :NR ₃
Dipole–dipole	1–7

Most drugs do not possess functional groups of a type that would lead to ready formation of strong and essentially irreversible covalent bonds between drug and biological receptors. In most cases, it is desirable to have the drug leave the receptor site when the concentration decreases in the extracellular fluids. Therefore, most useful drugs are held to their receptors by ionic or weaker bonds. When relatively long-lasting or irreversible effects are desired (e.g., antibacterial, anticancer), drugs that form covalent bonds with the receptor are effective and useful. The alkylating agents, such as the nitrogen mustards used in cancer chemotherapy, furnish an example of drugs that act by formation of covalent bonds (see Chapter 10).

Covalent bond formation between drug and receptor is the basis of Baker's concept of *active-site-directed irreversible inhibition*.¹⁷ Considerable experimental evidence on the nature of enzyme inhibitors supports this concept. Compounds studied possess appropriate structural features for reversible and highly selective association with an enzyme. If, in addition, the compounds carry reactive groups capable of forming covalent bonds, the substrate may be irreversibly bound to the drug–receptor complex by covalent bond formation with reactive groups adjacent to the active site. The diuretic drug ethacrynic acid (see Chapter 19) is an α,β -unsaturated ketone, thought to act by covalent bond formation with sulfhydryl groups of ion transport systems in the renal tubules. Another example of a drug that covalently binds to the receptor is selegiline (see Chapter 13), an inhibitor of monoamine oxidase-B. Other examples of covalent bond formation between drug and biological receptor site include the reaction of arsenicals and mercurials with cysteine sulfhydryl groups, the acylation of bacterial cell wall constituents by penicillin, and the phosphorylation

of the serine hydroxyl moiety at the active site of cholinesterase by organic phosphates.

Ethacrynic Acid

Selegiline

Keep in mind that it is desirable to have most drug effects reversible. For this to occur, relatively weak forces must be involved in the drug-receptor complex yet be strong enough that other binding sites will not competitively deplete the site of action. Compounds with high structural specificity may orient several weakly binding groups so that the summation of their interactions with specifically oriented complementary groups on the receptor provides total bond strength sufficient for a stable combination. Consequently, most drugs acting by virtue of their structural specificity will bind to the receptor site by hydrogen bonds, ionic bonds, ion-dipole and dipole-dipole interactions, and van der Waals and hydrophobic forces.

Considering the wide variety of functional groups found on a drug molecule and receptor, there will be a variety of secondary bonding forces. Ionization at physiological pH would normally occur with the carboxyl, sulfonamido, and aliphatic amino groups, as well as the quaternary ammonium group at any pH. These sources of potential ionic bonds are frequently found in active drugs. Differences in electronegativity between carbon and other atoms, such as oxygen and nitrogen, lead to an asymmetric distribution of electrons (dipoles) that are also capable of forming weak bonds with regions of high or low electron density, such as ions or other dipoles. Carbonyl, ester, amide, ether, nitrile, and related groups that contain such dipolar functions are frequently found in equivalent locations in structurally specific drugs.

The relative importance of the *hydrogen bond* in the formation of a drug-receptor complex is difficult to assess. Many drugs possess groups such as carbonyl, hydroxyl, amino, and imino, with the structural capabilities of acting as acceptors or donors in the formation of hydrogen bonds. However, such groups would usually be solvated by water, as would the corresponding groups on a biological receptor. Relatively little net change in free energy would be expected in exchanging a hydrogen bond with a water molecule for one between drug and receptor. However, in a drug-receptor combination, several forces could be involved, including the hydrogen bond, which would contribute to the stability of the interaction. Where multiple hydrogen bonds may be formed, the total effect may be sizable, such as that demonstrated by the stability of the protein α -helix and by the stabilizing influence of hydrogen bonds between specific base pairs in the double-helical structure of DNA.

Van der Waals forces are attractive forces created by the polarizability of molecules and are exerted when any two uncharged atoms approach each other very closely. Their strength is inversely proportional to the seventh power of the distance. Although individually weak, the summation of their forces provides a significant bonding factor in higher-molecular-weight compounds. For example, it is not possible to distill normal alkanes with more than 80 carbon atoms, because the energy of 80 kcal/mol required to separate the molecules is approximately equal to the energy required to break a carbon-carbon covalent bond. Flat structures, such as aromatic rings, permit close approach of atoms. The aromatic ring is frequently found in active drugs, and a reasonable explanation for its requirement for many types of biological activity may be derived from the contributions of this flat surface to van der Waals binding to a correspondingly flat receptor area.

The *hydrophobic bond* is a concept used to explain attractive interactions between nonpolar regions of the receptor and the drug. Explanations such as the *isopropyl moiety of the drug fits into a hydrophobic cleft on the receptor composed of the hydrocarbon side chains of the amino acids valine, isoleucine, and leucine* are commonly used to explain why a nonpolar substituent at a particular position on the drug molecule is important for activity. Over the years, the concept of hydrophobic bonds has developed. There has been considerable controversy over whether the bond actually exists. Thermodynamic arguments on the gain in entropy (decrease in ordered state) when hydrophobic groups cause a partial collapse of the ordered water structure on the surface of the receptor have been proposed to validate a hydrophobic bonding model. There are two problems with this concept. First, the term *hydrophobic* implies repulsion. The term for attraction is *hydrophilicity*. Second, and perhaps more important, there is no truly water-free region on the receptor. This is true even in the areas populated by the nonpolar amino acid side chains. An alternate approach is to consider only the concept of hydrophilicity and lipophilicity. The predominating water molecules solvate polar moieties, effectively squeezing the nonpolar residues toward each other.

STERIC FEATURES OF DRUGS

Regardless of the ultimate mechanism by which the drug and the receptor interact, the drug must approach the receptor and fit closely to its surface. Steric factors determined by the stereochemistry of the receptor site surface and that of the drug molecules are, therefore, of primary importance in determining the nature and the efficiency of the drug-receptor interaction. With the possible exception of the general anesthetics, such drugs must possess a high structural specificity to initiate a response at a particular receptor.

Some structural features contribute a high structural rigidity to the molecule. For example, aromatic rings are planar, and the atoms attached directly to these rings are held in the plane of the aromatic ring. Hence, the quaternary

Neostigmine

nitrogen and carbamate oxygen attached directly to the benzene ring in the cholinesterase inhibitor neostigmine are restricted to the plane of the ring, and consequently, the spatial arrangement of at least these atoms is established.

The relative positions of atoms attached directly to multiple bonds are also fixed. For the double bond, *cis*- and *trans*-isomers result. For example, diethylstilbestrol exists in two fixed stereoisomeric forms: *trans*-diethylstilbestrol is estrogenic, whereas the *cis*-isomer is only 7% as active. In *trans*-diethylstilbestrol, resonance interactions and minimal steric interference tend to hold the two aromatic rings and connecting ethylene carbon atoms in the same plane.

Z-Doxepin: $R_1 = \text{CH}_2\text{CH}_2\text{N}(\text{CH}_3)_2$; $R_2 = \text{H}$
E-Doxepin: $R_1 = \text{H}$; $R_2 = \text{CH}_2\text{CH}_2\text{N}(\text{CH}_3)_2$

Z-Cefprozil: $R_1 = \text{H}$; $R_2 = \text{CH}_3$
E-Cefprozil: $R_1 = \text{CH}_3$; $R_2 = \text{H}$

Geometric isomers, such as the *cis*- and the *trans*-isomers, hold structural features at different relative positions in space. These isomers also have significantly different physical and chemical properties. Therefore, their distributions in the biological medium are different, as are their capabilities for interacting with a biological receptor in a structurally specific manner. The *United States Pharmacopeia* recognizes that there are drugs with vinyl groups whose commercial form contains both their *E*- and *Z*-isomers. Figure 2.13 provides four examples of these mixtures.

More subtle differences exist for *conformational isomers*. Like geometric isomers, these exist as different arrangements in space for the atoms or groups in a single classic structure. Rotation about bonds allows interconversion of conformational isomers. However, an energy barrier between isomers is often high enough for their independent existence and reaction. Differences in reactivity of functional groups or interaction with biological receptors may be caused by differences in steric requirements of the receptors. In certain semirigid ring systems, conformational isomers show significant differences in biological activities. Methods for calculating these energy barriers are described next.

Open chains of atoms, which form an important part of many drug molecules, are not equally free to assume all possible conformations; some are sterically preferred. Energy barriers to free rotation of the chains are present because of interactions of nonbonded atoms. For example, the atoms tend to position themselves in space so that they occupy staggered positions, with no two atoms directly facing each other (eclipsed). Nonbonded interactions in polymethylene

Figure 2.13 • Examples of *E*- and *Z*-isomers.

Figure 2.14 • Effect of noncarbon atoms on a molecule's configuration.

chains tend to favor the most extended *anti* conformations, although some of the partially extended *gauche* conformations also exist. Intramolecular bonding between substituent groups can make what might first appear to be an unfavorable conformation favorable.

The introduction of atoms other than carbon into a chain strongly influences the conformation of the chain (Fig. 2.14). Because of resonance contributions of forms in which a double bond occupies the central bonds of esters and amides, a planar configuration is favored in which minimal steric interference of bulky substituents occurs. Hence, an ester may exist mainly in the *anti*, rather than the *gauche*, form. For the same reason, the amide linkage is essentially planar, with the more bulky substituents occupying the *anti* position. Therefore, ester and amide linkages in a chain tend to hold bulky groups in a plane and to separate them as far as possible. As components of the side chains of drugs, ester and amide groups favor fully extended chains and also add polar character to that segment of the chain.

In some cases, *dipole-dipole interactions* appear to influence structure in solution. Methadone may exist partially in a cyclic form in solution because of dipolar attractive forces between the basic nitrogen and carbonyl group or because of hydrogen bonding between the hydrogen on the nitrogen and the carbonyl oxygen (Fig. 2.15). In either conformation, methadone may resemble the conformationally more rigid potent analgesics including morphine, meperidine, and their analogs (see Chapter 24), and it may be this form that interacts with the analgesic receptor. Once the interaction between the drug and its receptor begins, a flexible drug molecule may assume a different conformation than that predicted from solution chemistry.

An intramolecular *hydrogen bond* usually formed between donor hydroxy and amino groups and acceptor oxygen and nitrogen atoms, might be expected to add stability to a particular conformation of a drug in solution. However, in aqueous solution, donor and acceptor groups tend to be bonded to water, and little gain in free energy would be achieved by the formation of an intramolecular hydrogen bond, particularly if unfavorable steric factors involving nonbonded interactions were introduced in the

Figure 2.15 • Stabilization of conformations by secondary bonding forces.

process. Therefore, internal hydrogen bonds likely play only a secondary role to steric factors in determining the conformational distribution of flexible drug molecules.

Conformational Flexibility and Multiple Modes of Action

It has been proposed that the conformational flexibility of most open-chain neurohormones, such as acetylcholine, epinephrine, serotonin, histamine, and related physiologically active biomolecules, permits multiple biological effects to be produced by each molecule, by virtue of their ability to interact in a different and unique conformation with different biological receptors. Thus, it has been suggested that acetylcholine may interact with the muscarinic receptor of postganglionic parasympathetic nerves and with acetylcholinesterase in the fully extended conforma-

tion and, in a different, more folded structure, with the nicotinic receptors at ganglia and at neuromuscular junctions (Fig. 2.16).

Conformationally rigid acetylcholine-like molecules have been used to study the relationships between these various possible conformations of acetylcholine and their biological effects (Fig. 2.16). (+)-*trans*-2-Acetoxypropyl trimethylammonium iodide, in which the quaternary nitrogen atom and acetoxy groups are held apart in a conformation approximating that of the extended conformation of acetylcholine, was about five times more active than acetylcholine in its muscarinic effect on dog blood pressure and was as active as acetylcholine in its muscarinic effect on the guinea pig ileum.¹⁸ The (+)-*trans*-isomer was hydrolyzed by acetylcholinesterase at a rate equal to the rate of hydrolysis of acetylcholine. It was inactive as a nicotinic agonist. In contrast, the (-)-*trans*-isomer and the mixed (\pm)-*cis*-isomers were, respectively, 1/500 and 1/10,000 as active as acetylcholine in muscarinic tests on guinea pig ileum and were inactive as nicotinic agonists. Similarly, the *trans* diaxial relationship between the quaternary nitrogen and acetoxy group led to maximal muscarinic response and rate of hydrolysis by true acetylcholinesterase in a series of isomeric 3-trimethylammonium-2-acetoxydecalins.¹⁹ These results could be interpreted as either that acetylcholine was acting in a *trans* conformation at the muscarinic receptor and not acting in a *cisoid* conformation at the nicotinic receptor or that the nicotinic response is highly sensitive to steric effects of substituents being used to orient the

Figure 2.16 • Acetylcholine conformations (only one each of the two possible *trans*- and *cis*-isomers is represented).

molecule. This approach in studying the cholinergic receptor is covered in more detail in Chapter 17.

Optical Isomerism and Biological Activity

The widespread occurrence of differences in biological activities for *optical activities* has been of particular importance in the development of theories on the nature of drug-receptor interactions. Most commercial drugs are asymmetric, meaning that they cannot be divided into symmetrical halves. Although D- and L-isomers have the same physical properties, a large number of drugs are *diastereomeric*, meaning that they have two or more asymmetric centers. Diastereomers have different physical properties. Examples are the diastereomers ephedrine and pseudoephedrine. The former has a melting point of 79° and is soluble in water, whereas pseudoephedrine's melting

point is 118°, and it is only sparingly soluble in water. Keep in mind that receptors will be asymmetric because they are mostly protein, meaning that they are constructed from L-amino acids. A ligand fitting the hypothetical receptor shown in Figure 2.18 will have to have a positively charged moiety in the upper left corner and a hydrophobic region in the upper right. Therefore, one would predict that optical isomers will also have different biological properties. Well-known examples of this phenomenon include (–)-hyoscyamine, which exhibits 15 to 20 times more mydriatic activity than (+)-hyoscyamine, and (–)-ephedrine, which shows three times more pressor activity than (+)-ephedrine, five times more pressor activity than (+)-pseudoephedrine, and 36 times more pressor activity than (–)-pseudoephedrine. All of ascorbic acid's antiscorbutic properties reside in the (+) isomer. A postulated fit to epinephrine's receptor can explain why (–)-epinephrine exhibits 12 to 15 times more vasoconstrictor activity than (+)-epinephrine. This is the classical three-point attachment model. For epinephrine, the benzene ring, benzylic hydroxyl, and protonated amine must have the stereochemistry seen with the (–) isomer to match up with the hydrophobic or aromatic region, anionic site, and a hydrogen-bonding center on the receptor. The (+) isomer (the mirror image) will not align properly on the receptor.

Frequently, the generic name indicates a specific stereoisomer. Examples include levodopa, dextroamphetamine, dextromethorphan, levamisole, dexmethylphenidate, levobupivacaine, dexlansoprazole, and levothyroxine. Sometimes, the difference in pharmacological activity between stereoisomers is dramatic. The dextrorotatory isomers in the morphine series are cough suppressants with less risk of substance abuse, whereas the levorotatory isomers (Fig. 2.19) contain the analgesic activity and significant risk of substance abuse. Although the direction of optical rotation is opposite to that of the morphine series, dextropropoxyphene contains the analgesic activity, and the *levo*-isomer contains antitussive activity. More recently drugs originally marketed as racemic mixtures are reintroduced using the active isomer. The generic name of the latter does not readily indicate that the *new* product is a specific stereoisomer of a product already in use. Examples include racemic citalopram and its *S*-enantiomer escitalopram; racemic omeprazole and its *S*-enantiomer esomeprazole; and racemic modafinil and its *R*-enantiomer armodafinil.

Figure 2.17 contains examples of drugs with asymmetric carbons. Some were originally approved as racemic mixtures, and later a specific isomer was marketed with claims of having fewer adverse reactions in patients. An example of the latter is the local anesthetic levobupivacaine, which is the *S*-isomer of bupivacaine. Both the *R*- and *S*-isomers have good local anesthetic activity, but the *R*-isomer may cause depression of the myocardium leading to decreased cardiac output, heart block hypotension, bradycardia, and ventricular arrhythmias. In contrast, the *S*-isomer shows less cardiotoxic responses but still good local anesthetic activity. Escitalopram is the *S*-isomer of the antidepressant citalopram. There is some evidence that the *R*-isomer, which contains little of the desired selective serotonin reuptake inhibition, contributes more to the adverse reactions than does the *S*-isomer.

As dramatic as the previous examples of stereoselectivity may be, sometimes it may not be cost-effective to resolve

Figure 2.17 • Examples of drug stereoisomers.

the drug into its stereoisomers. An example is the calcium channel antagonist verapamil, which illustrates why it is difficult to conclude that one isomer is superior to the other. *S*-Verapamil is a more active pharmacological stereoisomer than *R*-verapamil, but the former is more rapidly metabolized by the first-pass effect. First-pass refers to orally administered drugs that are extensively metabolized as they pass through the liver (see Chapter 3). *S*- and *R*-warfarin are metabolized by two different cytochrome P450 isozymes. Drugs that either inhibit or induce these enzymes can significantly affect warfarin's anticoagulation activity.

Because of biotransformations after the drug is administered, it sometimes makes little difference whether a racemic mixture or one isomer is administered. The popular nonsteroidal anti-inflammatory drug (NSAID) ibuprofen is sold as the racemic mixture. The *S*-enantiomer contains the

anti-inflammatory activity by inhibiting cyclooxygenase. The *R*-isomer does have centrally acting analgesic activity, but it is converted to the *S* form in vivo (Fig. 2.18).

In addition to the fact that most receptors are asymmetric, there are other reasons why stereoisomers show different biological responses. Active transport mechanisms involve asymmetric carrier molecules, which means that there will be preferential binding of one stereoisomer over others. When differences in physical properties exist, the distribution of isomers between body fluids and tissues where the receptors are located will differ. The enzymes responsible for drug metabolism are asymmetric, which means that biological half-lives will differ among possible stereoisomers of the same molecule. The latter may be a very important variable because the metabolite may actually be the active molecule.

Figure 2.18 • Metabolic interconversion of *R*- and *S*-ibuprofen.

Calculated Conformations

It should now be obvious that medicinal chemists must obtain an accurate understanding of the active conformation of the drug molecule. Originally, molecular models were constructed from kits containing various atoms of different valence and oxidation states. Thus, there would be carbons suitable for carbon-carbon single, double, and triple bonds; carbon-oxygen bonds for alcohols or ethers and the carbonyl moiety; carbon-nitrogen bonds for amines, amides, imines, and nitrites; and carbons for three-, four-, five-, and larger-member rings. More complete sets include various heteroatoms including nitrogen, oxygen, and sulfur in various oxidation states. These kits might be ball and stick, stick or wire only, or space filling. The latter contained attempts at realistically visualizing the effect of a larger atom such as sulfur relative to the smaller oxygen. The diameters of the atoms in these kits are proportional to the van der Waals radii, usually corrected for overlap effects. In contrast, the wire models usually depict accurate intra-atomic distances between atoms. A skilled chemist using these kits usually can obtain a reasonably accurate 3D representation. This is particularly true if it is a moderately simple molecule with considerable rigidity. An extreme example is a steroid with the relatively inflexible fused-ring system. In contrast, molecules with chains consisting of several atoms can assume many shapes. Yet, there will be a *best* shape or conformation that can be expected to fit onto the receptor. The number of conformers can be estimated from Equation 2.17. Calculating the *global minimum*, the lowest-energy conformation, can be a difficult computational problem. Assume that there are three carbon-carbon freely rotatable single bonds that are rotated in 10-degree increments. Equation 2.17 states that there are 46,656 different conformations.

$$\text{Number of conformers} = \left(\frac{360}{\text{angle increment}} \right)^{\text{No. rotatable bonds}} \quad (\text{Eq. 2.17})$$

There are three common quantitative ways to obtain estimations of preferred molecular shapes required for a good

fit at the receptor. The first, which is the oldest and considered the most accurate, is x-ray crystallography. When properly done, resolution down to a few angstrom units can be obtained. This permits an accurate mathematical description of the molecule, providing atomic coordinates in 3D space that can be drawn by using a chemical graphics program. A serious limitation of this technique is the requirement for a carefully grown crystal. Some chemicals will not form crystals. Others form crystals with mixed symmetries. Nevertheless, with the newer computational techniques, including high-speed computers, large databases of x-ray crystallographic data are now available. These databases can be searched for structures, including substructures, similar to the molecule of interest. Depending on how close is the match, it is possible to obtain a pretty good idea of the low-energy conformation of the drug molecule. This is a common procedure for proteins and nucleic acids after obtaining the amino acid and nucleotide sequences, respectively. Obtaining these sequences is now largely an automated process.

There also is the *debate* that asks if the conformation found in the crystal represents the conformation *seen* by the receptor. For rigid molecules, it probably is. The question is very difficult to answer for flexible molecules. A common technique is to determine the crystal structure of a protein accurately and then *soak* the crystal in a nonaqueous solution of the drug. This allows the drug molecules to diffuse into the active site. The resulting crystal is reanalyzed using different techniques, and the bound conformation of the drug can be determined rapidly without redoing the entire protein. Often, the structure of a bound drug can be determined in a day or less.

Because of the drawbacks to x-ray crystallography, two purely computational methods that require only a knowledge of the molecular structure are used. The two approaches are known as *quantum mechanics* and *molecular mechanics*. Both are based on assumptions that (a) a molecule's 3D geometry is a function of the forces acting on the molecule and (b) these forces can be expressed by a set of equations that pertain to all molecules. For the most part, both computational techniques assume that the molecule is in an isolated system. Solvation effects from water, which are common to any biological system, tend to be ignored, although this is changing with increased computational power. Calculations now can include limited numbers of water molecules, where the number depends on the amount of available computer time. Interestingly, many crystals grown for x-ray analysis can contain water in the crystal lattice. High-resolution nuclear magnetic resonance (NMR) provides another means of obtaining the structures of macromolecules and drugs in solution.

There are fundamental differences between the quantum and molecular mechanics approaches, and they illustrate the dilemma that can confront the medicinal chemist. Quantum mechanics is derived from basic theoretical principles at the atomic level. The model itself is exact, but the equations used in the technique are only approximate. The molecular properties are derived from the electronic structure of the molecule. The assumption is made that the distribution of electrons within a molecule can be described by a linear sum of functions that represent an atomic orbital. (For carbon, this would be *s*, *p_x*, *p_y*, etc.) Quantum mechanics is compu-

tation intensive, with the calculation time for obtaining an approximate solution increasing by approximately N^4 times, where N is the number of such functions. Until the advent of the high-speed supercomputers, quantum mechanics in its *pure* form was restricted to small molecules. In other words, it was not practical to conduct a quantum mechanical analysis of a drug molecule.

To make this technique more practical, simplifying techniques have been developed. Whereas the computing time is decreased, the accuracy of the outcome is also lessened. In general, use of calculations of the quantum mechanics type in medicinal chemistry is a method that is *still waiting to happen*. It is being used by laboratories with access to large-scale computing, but there is considerable debate about its utility, because so many simplifying approximations must be made for larger molecules.

To overcome the limitation of quantum mechanics, there has been motivation to develop alternative approaches to calculation conformations of flexible molecules. The reason is that manipulation of computer models is much superior to the use of traditional physical models. Mathematical models using quantum mechanics or the more common force field methods (see later) better account for the inherent flexibility of molecules than do hard sphere physical models. In addition, it is easy to superimpose one or more molecular models on a computer and to color each structure separately for ease of viewing. Medicinal chemists use the superimposed structures to identify the necessary structural features and the 3D orientation (pharmacophore) responsible for the observed biological activity. The display of the multiple conformations available to a single molecule can provide valuable information about the conformational space available to druglike molecules. Rather than measuring bond distances with a ruler, as was done years ago with handheld models, it is relatively easy to query a computer-generated molecular display. Because the coordinates for each atom are stored in computer memory, rapid data retrieval is achieved. Moreover, the shape and size of a molecular system can be visualized and quantified, unlike the situation with handheld models, when only visual inspections are possible. Exactly how much energy does it cost to rotate torsion angles from one position to the next? Understanding drug volumes and molecular shapes is critically important when defining the complementary (negative volume image) receptor sites needed to accommodate the drug molecule.

High-resolution computer graphics that accompany the conformation calculations have revolutionized the way drug design is carried out. Once a molecular structure has been entered into a molecular modeling software program, the structure can be viewed from any desired perspective. The dihedral angles can be rotated to generate new conformations, and functional groups can be eliminated or modified almost effortlessly. As indicated previously, the molecular features (bond lengths, bond angles, nonbonded distances, etc.) can be calculated readily from the stored 3D coordinates.

Because of ease of calculations relative to quantum mechanics, medicinal chemists are embracing molecular mechanics. Force field calculations rest on the fundamental concept that a ball-and-spring model may be used to approximate a molecule.^{20,21} That is, the stable relative positions of

the atoms in a molecule are a function of through-bond and through-space interactions, which may be described by relatively simple mathematical relationships. The complexity of the mathematical equations used to describe the ball-and-spring model is a function of the nature, size, and shape of the structures. Moreover, the fundamental equations used in force fields are much less complicated than those found in quantum mechanics. For example, small strained organic molecules require greater detail than less strained systems such as peptides and proteins. Furthermore, it is assumed that the total energy of the molecule is a summation of the individual energy components, as outlined in Equation 2.18. In other words, the total energy (E_{total}) is divided into energy components, which are attributed to bond stretching ($E_{\text{stretching}}$), angle bending (E_{bending}), nonbonded interactions ($E_{\text{nonbonded}}$), torsion interactions (E_{torsion}), and coupled energy terms ($E_{\text{cross-terms}}$). The cross-terms combine two interrelated motions (bend–stretch, stretch–stretch, torsion–stretch, etc.). The division of the total energy into terms associated with distortions from equilibrium values is the way most chemists and biological scientists tend to think about molecules.

$$E_{\text{total}} = \sum_{\text{bonds}} E_{\text{stretching}} + \sum_{\text{angles}} E_{\text{bending}} \\ + \sum_{\text{nonbonded}} (E_{\text{VDW}} + E_{\text{electrostatics}}) \\ + \sum_{\text{dihedrals}} E_{\text{torsion}} + \sum E_{\text{cross-terms}} \quad (\text{Eq. 2.18})$$

Each atom is defined (parameterized) in terms of these energy terms. What this means is that the validity of molecular mechanics depends on the accuracy of the parameterization process. Historically, saturated hydrocarbons have proved easy to parameterize, followed by selective heteroatoms such as ether oxygens and amines. Unsaturated systems, including aromaticity, caused problems because of the delocalization of the electrons, but this seems to have been solved. Charged atoms such as the carboxylate anion and protonated amine can prove to be a real problem, particularly if the charge is delocalized. Nevertheless, molecular mechanics is being used increasingly by medicinal chemists to gain a better understanding of the preferred conformation of drug molecules and the macromolecules that compose a receptor. The computer programs are readily available and run on relatively inexpensive, but powerful, desktop computers.

The only way to test the validity of the outcome from either quantum or molecular mechanics calculations is to compare the calculated structure or property with actual experimental data. Obviously, crystallographic data provide a reliable measure of the accuracy of at least one of the low-energy conformers. Because that is not always feasible, other physical chemical measurements are used for comparison. These include comparing calculated vibrational energies, heats of formation, dipole moments, and relative conformational energies with measured values. When results are inconsistent, the parameter values are adjusted. This readjustment of the parameters is analogous to the fragment approach for calculating octanol/water partition coefficients. The values for the fragments and the accompanying correction factors are determined by comparing calculated partition coefficients with a large population of experimentally determined partition coefficients.

Figure 2.19 • Potential energy for butane. The energy (kcal/mol) is plotted on the y-axis versus the torsion angle $C_{sp^3}-C_{sp^3}-C_{sp^3}-C_{sp^3}$, which is plotted on the x-axis. There are three minima. The two *gauche* conformers are higher in energy than the *anti* conformer by approximately 0.9 kcal/mol.

A simplified energy diagram for the hydrocarbon butane is shown in Figure 2.19. It illustrates that the energy rises and falls during rotation around the central $C_{sp^3}-C_{sp^3}$ bond as a function of the relative positions of the methyl groups. The peaks on the curve correspond to energy maxima, whereas the valleys correspond to energy minima. For butane, there are two different types of minima: one is for the *anti* butane conformation and the other two correspond to the *gauche* butane conformations. The *anti* conformation is the global minimum, meaning it has the absolute lowest energy of the three possible low-energy conformations. The differences in the conformational energies cannot be attributed to steric interactions alone. Structures with more than one rotatable bond have multiple minima available. Knowing the permissible conformations available to druglike molecules is important for design purposes.

A more typical energy diagram is shown in Figure 2.20. Notice that some of the minima are nearly equivalent, and it is easy to move from one minimum to another. From energy diagrams alone, it is difficult to answer the question, which of the ligand's low or moderately low conformations fits onto the receptor? This question can be answered partially by assuming that lower-energy conformations are more highly populated and thus more likely to interact with the receptor. Nevertheless, specific interactions such as hydrogen bond formation and dipole-dipole interactions can affect the energy levels of different conformations. Therefore, the bound conformation of a drug is seldom its lowest-energy conformation.

Because looking solely at the molecule can lead to ambiguous conclusions regarding the conformation when docking at the receptor, this has led to calculating conformations of the macromolecule that is the receptor and visualizing the results. A capability that today's graphics software is representing molecular structures in many

Figure 2.20 • Diagram showing the energy maxima and minima as two substituted carbons connected by a single bond are rotated 360 degrees relative to each other.

different ways, depending on the properties one decides to highlight. Dorzolamide is a good example of a drug that involved computer-aided drug design (CADD) methods in its development.²² Figure 2.21 shows a standard representation of dorzolamide from a molecular modeling software package. The atoms can be color coded in various ways according to the different properties that one might want to highlight. As noted previously, however, it is important to know the size and shape of the molecule. Various representations are possible. A convenient visualization technique is to have the atoms and bonds displayed simultaneously with the van der Waals surface represented by an even distribution of dots. These dot surfaces are convenient, in that the atomic connectivity is shown along with the appropriate size and shape of the molecular surface. As computer graphics technology has improved, it has become possible to represent the surface as a translucent volume, shown in Figure 2.22, in which the

Figure 2.21 • A computer-generated representation of dorzolamide. The structure has been energy minimized using Spartan '08.

Figure 2.22 • The ball-and-stick minimized model is displayed with superimposed translucent van der Waals surface showing both atomic connectivity of the molecular structure and its 3D shape and size.

molecular structure appears to be embedded in a clear gelatin material.

Finally, computer graphics images of drug–receptor interactions, whether taken from x-ray crystal data or in silico generated, provide insight into the binding interactions, as shown in Figure 2.23. A full display of all the atomic centers in a protein structure gives too much detail. Most commonly, as shown in Figure 2.23, a ribbon structure traces the backbone of the protein main chain.²³ The Richardson approach is another commonly used display to highlight secondary structural features, in which cylinders denote α -helices, arrows denote β -sheets, and tubes are used for coils and turns.²⁴

Because drug molecules make contact with solvents and receptor sites through surface contacts, it is paramount to have accurate methods to represent molecular surfaces correctly. Algorithms have been developed for such purposes, and they continue to be improved. The most straightforward way to represent a molecular shape is by the so-called van der Waals surface (Fig. 2.22), in which each constituent atom contributes its exposed surface to the overall molecular surface. Each atom is assigned a volume corresponding to its van der Waals radius, and only the union of atomic spheres contributes. These van der Waals surfaces have

Figure 2.23 • A computer-generated representation of a thienothipran-2-sulfonamide bound to the active site of carbonic anhydrase. Note that the ribbon has been traced through the protein backbone. Proteins are commonly displayed this way.

small crevices and pockets that cannot make contact with solvent molecules. Another surface, known as the solvent accessible or Connolly surface, can be generated.²⁵ The algorithm takes the van der Waals surface and rolls a sphere, having the volume of a water molecule with a radius of 1.4 Å, across it. Wherever the sphere makes contact with the original surface, a new surface is created. This expanded surface is a more realistic representation of what water molecules contact. Another similar solvent-accessible surface is known as the Lee and Richards surface.²⁶ This surface is constructed in an analogous way, with a sphere rolled over the van der Waals surface, but the boundary is taken as a line connecting the center of mass of the sphere from point to point. Also, it is possible to calculate the solvent excluded surface. The polar and nonpolar surface areas can be used as QSAR descriptors, and many computer models for solvation use solvent-accessible surface areas (SASA). Commonly, the electrostatic density may be displayed on the surface of a molecular structure, providing an easily recognized color coded grid that may be used to infer the complementary binding functional groups of the putative receptor.

A goal of docking programs is to screen large dataset to locate compounds that appear to have the atomic structure and conformation to dock readily at the receptor. Although there are several software programs available, their ability to differentiate between known ligands and decoys has not reached a level that this approach to searching databases has become standard. In other words, the programs will selected valid ligands and show them docking accordingly with the receptor, but they also docked the decoys and also usually do a poor job of predicting ligand binding affinity.^{27,28} So challenging is this problem that a database of docking decoys has been created.²⁹

Three-Dimensional Quantitative Structure-Activity Relationships

With molecular modeling becoming more common, the QSAR paradigm that traditionally used physicochemical descriptors on a two-dimensional molecule can be adapted to 3D space. Essentially, the method requires knowledge of the 3D shape of the molecule. Accurate modeling of the molecule is crucial. A reference (possibly the prototype molecule) or shape is selected against which all other molecules are compared. The original method called for overlapping the test molecules with the reference molecule and minimizing the differences in overlap. Then, distances were calculated between arbitrary locations on the molecule. These distances were used as variables in QSAR regression equations. Although overlapping rigid ring systems such as tetracyclines, steroids, and penicillins are relatively easy, flexible molecules can prove challenging. Examine the following hypothetical molecule. Depending on the size of the various R groups and the type of atom represented by X , a family of compounds represented by this molecule could have various conformations. Even when the conformations might be known with reasonable certainty, the reference points crucial for activity must be identified. Is the overlap involving the tetrahedral carbon important for activity? Or should the five-membered ring provide the reference points? And which way should it be rotated? Assuming that R_b is an important part of the pharmacophore, should the five-membered ring be rotated so that R_b is pointed down or up? These are not trivial questions, and successful 3D-QSAR studies have depended on just how the investigator positions the molecules relative to each other. There are several instances in which apparently very similar structures have been shown to bind to a given receptor in different orientations.

There are various algorithms for measuring the degree of conformational and shape similarities, including molecular shape analysis (MSA),³⁰ distance geometry,³¹ and molecular similarity matrices.^{32,33} Many of the algorithms use graph theory, in which the bonds that connect the atoms of a molecule can be thought of as paths between specific points on the molecule. Molecular connectivity is a commonly used application of graph theory.³⁴⁻³⁶

Besides comparing how well a family of molecules overlaps with a reference molecule, there are sophisticated software packages that determine the physicochemical parameters located at specific distances from the surface of the molecule. An example of this approach is comparative molecular field analysis (CoMFA).^{37,38} The hypothetical molecule is placed in a grid (Fig. 2.24) and its surface sampled at a specified distance. The parameter types include steric, Lennard-Jones potentials and other quantum chemical parameters, electrostatic and steric parameters, and partition coefficients. The result is thousands of independent variables. Standard regression analysis requires that the dimensionality be reduced and rigorous tests of validity be used. Partial least squares (PLS) has been the most common statistical method used. Elegant as the CoMFA algorithm is for explaining ligand-receptor interactions for a set of molecules, the method alone does not readily point the

Figure 2.24 • Molecule situated in a CoMFA grid.

investigator toward the next molecule that should be synthesized. To get around the problem of strict alignment of one particular conformation with another, there are methods that sample several possible conformations of a set of possible ligands. This is called 4D-QSAR.³⁹

The CoMFA methodology is used in similarity analyses comparing molecular conformers' ability to bind to a receptor. This is called comparative molecular similarity indices analysis or CoMSIA.⁴⁰ It is similar to CoMFA in that the molecules are aligned in a grid, but differs in the type of indices or descriptors with Gaussian functions producing descriptors that describe binding to the receptor being the most useful.

Database Searching and Mining

As pointed out previously, receptors can be isolated and cloned. This means that it is possible to determine their structures. Most are proteins and that means having to determine their amino acid sequence. This can be done either by degrading the protein or by obtaining the nucleotide sequence of the structural gene coding for the receptor and using the triplet genetic code to determine the amino acid sequence. The parts of the receptor that bind the drug (ligand) can be determined by site-directed mutagenesis. This alters the nucleotide sequence at specific points on the gene and, therefore, changes specific amino acids. Also, keep in mind that many enzymes become receptors when the goal is to alter their activity. Examples of the latter include acetylcholinesterase, monoamine oxidase, HIV protease, rennin, ACE, and tetrahydrofolate reductase.

The starting point is a database of chemical structures. They may belong to large pharmaceutical or agrochemical firms that literally have synthesized the compounds in the database and have them *sitting on the shelf*. Alternatively, the database may be constructed so that several different chemical classes and substituent patterns are represented. (See discussion of isosterism in the next section.) The first step is to convert the traditional or historical two-dimensional molecules into 3D structures whose intramolecular distances are known. Keeping in mind the problems of finding the "correct" conformation for flexible molecule, false hits and misses might result from the search. Next, the dimensions of the active site must be determined. Ideally, the receptor has been crystallized, and from the coordinates, the intramolecular distances between what are assumed to be key locations are obtained. If the receptor cannot be crystallized, there are methods for estimating the 3D shape based on searching crystallographic databases and matching amino acid sequences of proteins whose tertiary structure has been determined.

Fortunately, the crystal structures of literally thousands of proteins have been determined, and their structures have been stored in the Brookhaven Protein Databank. It is now known that proteins with similar functions have similar amino acid sequences in various regions of the protein. These sequences tend to show the same shapes in terms of α -helix, parallel and antiparallel β -pleated forms, turns in the chain, etc. Using this information plus molecular mechanics parameters, the shape of the protein and the dimensions of the active site can be estimated. Figure 2.25 contains the significant components of a hypothetical active site. Notice that four amino acid residues at positions

Figure 2.25 • Diagram of a hypothetical receptor site, showing distances between functional groups.

25, 73, 102, and 147 have been identified as important either for binding the ligand to the site or for the receptor's intrinsic activity. Keep in mind that Figure 2.25 is a two-dimensional representation of a 3D image. Therefore, the distances between amino acid residues must take into account the fact that each residue is above or below the planes of the other three residues. For an artificial ligand to "dock," or fit into the site, six distances must be considered: (a) Lys–Glu, (b) Glu–Phe, (c) Phe–Ser, (d) Ser–Lys, (e) Glu–Phe, and (f) Lys–Phe. In reality, not all six distances may be important. In selecting potential ligands, candidates might include a positively charged residue (protonated amine), aromatic ring, hydrogen bond donor or acceptor (hydroxy, phenol, amine, nitro), and hydrogen bond acceptor or a negatively charged residue (carboxylate) that will interact with the aspartate, phenylalanine, serine, and lysine residues, respectively. A template is constructed containing the appropriate residues at the proper distances with correct geometries, and the chemical database is searched for molecules that fit the template. A degree of fit or match is obtained for each "hit." Their biological responses are obtained, and the model for the receptor is further refined. New, better-defined ligands may be synthesized.

In addition to the interatomic distances, the chemical databases will contain important physicochemical values including partition coefficients, electronic terms, molar refractivity, pK_a 's, solubilities, and steric values. Arrangements of atoms may be coded by molecular connectivity or other topological descriptors. The result is a "flood of data" that requires interpretation, large amounts of data storage, and rapid means of analysis. Compounds usually must fit within defined limits that estimate ADME.

Chemical databases can contain hundreds of thousands of molecules that could be suitable ligands for a receptor. But, no matter how good the fit is to the receptor, the candidate molecule is of no use if the absorption is poor or if the drug is excreted too slowly from the body. An analysis of 2,245 drugs has led to a set of "rules" called the *Lipinski*

Rule of Five.^{41,42} A candidate molecule is more likely to have poor absorption or permeability if:

1. The molecular weight exceeds 500.
2. The calculated octanol/water partition coefficient exceeds 5.
3. There are more than 5 H-bond donors expressed as the sum of O–H and N–H groups.
4. There are more than 10 H-bond acceptors expressed as the sum of N and O atoms.

Because of *misses* when searching or mining databases, there have been two suggested changes. The first of these is to take into account the fact that many compounds will be significantly ionized at physiological pH and, therefore, use the distribution coefficient log D with an upper limit of 5.5 rather than a log P of 5.⁴³ Similar results have been found when evaluating herbicides and pesticides.⁴⁴ A second suggested modification of the Rule of Five gives specific ranges for log P, molar refractivity, molecular weight and number of atoms (Table 2.10).⁴⁵

The rapid evaluation of large numbers of molecules is sometimes called *high-throughput screening* (Fig. 2.26). The screening can be *in vitro*, often measuring how well the tested molecules bind to cloned receptors or enzyme active sites. Robotic devices are available for this testing. Based on the results, the search for viable structures is narrowed, and new compounds are synthesized. The criteria for activity will be based on structure and physicochemical values. QSAR, including 3D-QSAR, models can be developed to aid in designing new active ligands.

Alternatively, the search may be virtual. Again starting with the same type of database and the dimensions of the active site, the ability of the compounds in the database to fit or bind is estimated. The virtual receptor will include both its

TABLE 2.10 Suggested Modifications to the Lipinski Rule of Five

	Druglike Range	Preferred Range	Mean
Log P	–0.4–5.6	1.3–4.1	2.3
Molar Refractivity	40–130	70–110	97
Molecular Weight	160–480	230–390	360
No. of Atom	20–70	30–55	48

dimensions and physicochemical characteristic. Keeping in mind that the receptor is a protein, there will be hydrogen bond acceptors and donors (serine, threonine, tyrosine), positively and negatively charged side chains (lysine, histidine, glutamic acid, aspartic acid), nonpolar or hydrophobic side chains (leucine, isoleucine, valine, alanine), and induced dipoles (phenylalanine, tyrosine). The type of groups that will be attracted or repulsed by the type of amino acid side chain is coded into the chemical database. The virtual screening will lead to development of a refined model for good binding, and the search is repeated. When the model is considered valid, it must be tested by actual screening in biological test systems and by synthesizing new compounds to test its validity.

Another approach to searching a database of compounds is the use of the chemical fragments described earlier. There is ongoing debate regarding what type of fragments will result in the most *hits*. Nevertheless, there now are fragment libraries constructed around the range of the fragments' physicochemical properties, solubilities, molecular diversity, and drug likeness based on their presence in existing compounds.⁴⁶

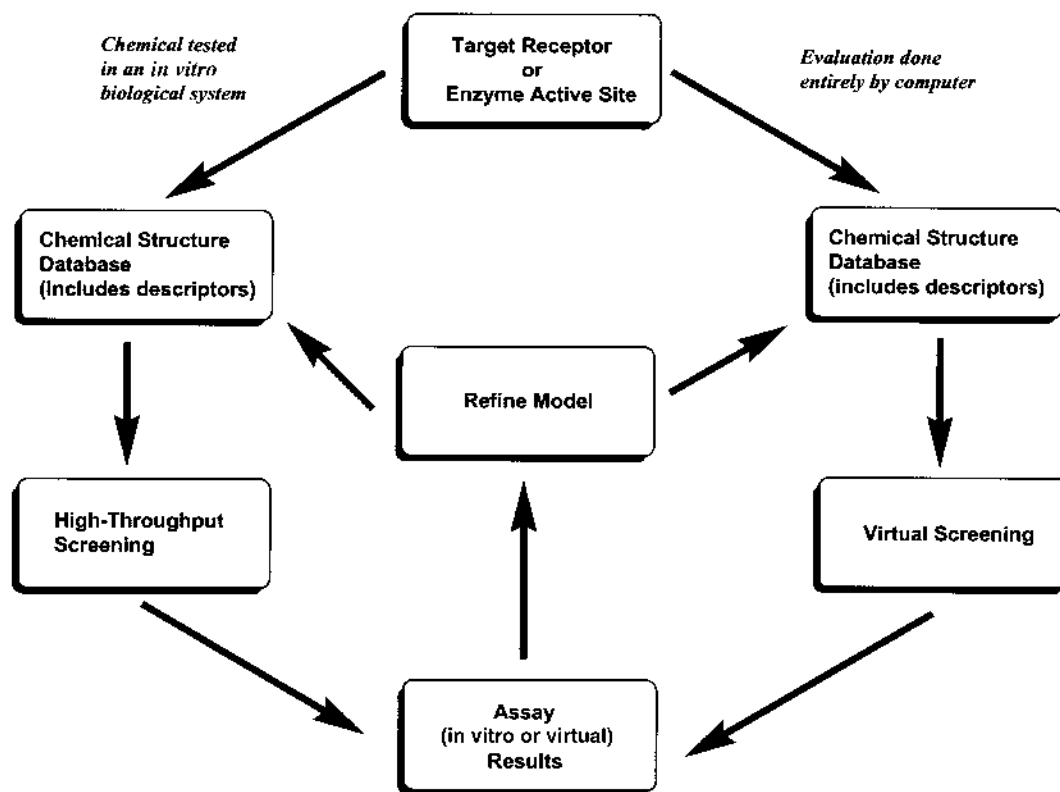

Figure 2.26 • High-throughput screening.

Isosterism

In the process of designing new pharmacologically active compounds or searching databases, it is important to not restrict the definition of the structures to specific atoms. An important concept is *isosterism*, a term that has been used widely to describe the selection of structural components—the steric, electronic, and solubility characteristics that make them interchangeable in drugs of the same pharmacological class. The concept of isosterism has evolved and changed significantly in the years since its introduction by Langmuir in 1919.⁴⁷ Langmuir, while seeking a correlation that would explain similarities in physical properties for nonisomeric molecules, defined *isosteres* as compounds or groups of atoms having the same number and arrangement of electrons. Isosteres that were isoelectric (i.e., with the same total charge as well as the same number of electrons) would possess similar physical properties. For example, the molecules N_2 and CO both possess 14 total electrons and no charge and show similar physical properties. Related examples described by Langmuir were CO_2 , N_2O , N_3^- , and NCO^- (Table 2.11).

With increased understanding of the structures of molecules, less emphasis has been placed on the number of electrons involved, because variations in hybridization during bond formation may lead to considerable differences in the angles, lengths, and polarities of bonds formed by atoms with the same number of peripheral electrons. Even the same atom may vary widely in its structural and electronic characteristics when it forms part of a different functional group. Thus, nitrogen is part of a planar structure in the nitro group but forms the apex of a pyramidal structure in ammonia and amines.

Groups of atoms that impart similar physical or chemical properties to a molecule because of similarities in size, electronegativity, or stereochemistry are now frequently referred to by the general term of *isostere*. The early recognition that benzene and thiophene were alike in many of their properties (Fig. 2.27) led to the term *ring equivalents* for the vinylene group ($-CH=CH-$) and divalent sulfur ($-S-$). This concept has led to replacement of the sulfur atom in the phenothiazine ring system of tranquilizing agents with the vinylene

group to produce the dibenzodiazepine class of antidepressant drugs. The vinylene group in an aromatic ring system may be replaced by other atoms isosteric to sulfur, such as oxygen (furan) or NH (pyrrole); however, in such cases, aromatic character is significantly decreased (Fig. 2.27).

Examples of isosteric pairs that possess similar steric and electronic configurations are the carboxylate (COO^-) and sulfonamide (SO_2NR^-) ions; ketone ($C=O$) and sulfone ($O=S=O$); chloride (Cl^-) and trifluoromethyl (CF_3); hydrogen ($-H$) and fluorine ($-F$); hydroxy ($-OH$) and amine ($-NH_2$); hydroxy ($-OH$) and thiol ($-SH$). Divalent ether ($-O-$), sulfide ($-S-$), amine ($-NH-$), and methylene ($-CH_2-$) groups, although dissimilar electronically, are sufficiently alike in their steric nature to be frequently interchangeable in designing new drugs.⁴⁸

Compounds may be altered by isosteric replacements of atoms or groups, to develop analogs with select biological effects or to act as antagonists to normal metabolites. Each series of compounds showing a specific biological effect must be considered separately, because there are no general rules that predict whether biological activity will be increased or decreased. Some examples of this type follow.

When a group is present in a part of a molecule in which it may be involved in an essential interaction or may influence

Figure 2.27 • Examples of isosteric ring systems.

Figure 2.28 • Examples of how isosterism produces drugs that inhibit the activity of the native metabolite.

the reactions of neighboring groups, isosteric replacement sometimes produces analogs that act as antagonists. The 6-NH₂ and 6-OH groups appear to play essential roles in the hydrogen-bonding interactions of base pairs during nucleic acid replication in cells (Fig. 2.28). Adenine, hypoxanthine and the antineoplastic 6-mercaptopurine illustrate how substitution of the significantly weaker hydrogen-bonding isosteric sulfhydryl groups results in a partial blockage of this interaction and a decrease in the rate of cellular synthesis. Similarly, replacement of the hydroxyl group of pteroylglutamic acid (folic acid) by the isosteric amino group and addition of the methyl group to the *p*-aminobenzoate leads to the widely used methotrexate, a folate antimetabolite. Replacement of the hydrogen at the 5-position of uracil with the isosteric fluorine producing 5-fluorouracil blocks the methylation step leading to thymine.

As a better understanding of the nature of the interactions between drug-metabolizing enzymes and biological receptors develops, selection of isosteric groups with particular electronic, solubility, and steric properties should permit the rational preparation of drugs that act more selectively. At the same time, results obtained by the systematic application of the principles of isosteric replacement are aiding in the understanding of the nature of these receptors.

Are There Drugs Developed Using the Newer Computer-Aided Drug Design Methods?

The same question asked in the discussion of QSAR must be asked regarding the newer CADD methods. Are their commercial products that were discovered using these techniques?

Here, the answer is *yes*. The example of dorzolamide is one. Others include the ACE-inhibitor captopril and HIV protease inhibitors nelfinavir and amprenavir. In reality, modern CADD is used in combination with structure-based drug design and QSAR. These methods permit the medicinal chemist to focus more quickly on the structural components that enhance activity and provide receptor specificity.^{49,50}

SELECTED WEB PAGES

The field of drug design, particularly those aspects that are computer intensive, is increasingly being featured on Web pages. Faculty and students might find it instructive to search the Web at regular intervals. Many university chemistry departments have organized Web pages that provide excellent linkages. Listed are a small number of representative sites that feature drug design linkages. Some have excellent illustrations. These listings should not be considered any type of endorsement by the author, editors, or publisher. Indeed, some of these sites may disappear.

Metabolic Changes of Drugs and Related Organic Compounds

STEPHEN J. CUTLER AND JOHN H. BLOCK

CHAPTER OVERVIEW

Metabolic Changes of Drugs and Related Organic Compounds describes the human metabolic processes of various functional groups found in therapeutic agents. The importance of a chapter on metabolism lies in the fact that drug interactions are based on these processes. For pharmacists to be good practitioners, it is necessary for them to understand why certain drugs are contraindicated with other drugs. This chapter attempts to describe the various phases of drug metabolism, the sites where these biotransformations will occur, the role of specific enzymes, metabolism of specific functional groups, and several examples of the metabolism of currently used therapeutic agents.

Metabolism plays a central role in the elimination of drugs and other foreign compounds (*xenobiotics*) from the body. A solid understanding of drug metabolic pathways is an essential tool for pharmacists in their role of selecting and monitoring appropriate drug therapy for their patients. Most organic compounds entering the body are relatively lipid soluble (*lipophilic*). To be absorbed, they must traverse the lipoprotein membranes of the lumen walls of the gastrointestinal (GI) tract. Then, once in the bloodstream, these molecules can diffuse passively through other membranes and be distributed effectively to reach various target organs to exert their pharmacological actions. Because of reabsorption in the renal tubules, lipophilic compounds are not excreted to any substantial extent in the urine. Xenobiotics then meet their metabolic fate through various enzyme systems that change the parent compound to render it more water soluble (*hydrophilic*). Once the metabolite is sufficiently water soluble, it may be excreted from the body. The previous statements show that a working knowledge of the ADME (absorption, distribution, metabolism, and excretion) principles is vital for successful determination of drug regimens.

If lipophilic drugs, or xenobiotics, were not metabolized to polar, readily excretable water-soluble products, they would remain indefinitely in the body, eliciting their biological effects. Thus, the formation of water-soluble metabolites not only enhances drug elimination, but also leads to compounds that are generally pharmacologically inactive and relatively nontoxic. Consequently, drug metabolism reactions have traditionally been regarded as *detoxication* (or *detoxification*) processes.¹ Unfortunately, it is incorrect to assume that drug metabolism reactions are always detoxifying. Many drugs are biotransformed to pharmacologically active metabolites. These metabolites may have significant

activity that contributes substantially to the pharmacological or toxicological effect(s) ascribed to the parent drug. Occasionally, the parent compound is inactive when administered and must be metabolically converted to a biologically active drug (metabolite).^{2,3} These types of compounds are referred to as *prodrugs*. In addition, it is becoming increasingly clear that not all metabolites are nontoxic. Indeed, many adverse effects (e.g., tissue necrosis, carcinogenicity, teratogenicity) of drugs and environmental contaminants can be attributed directly to the formation of chemically reactive metabolites that are highly detrimental to the body.⁴⁻⁶ This concept is more important when the patient has a disease state that inhibits or expedites xenobiotic metabolism. Also, more and more drug metabolites are being found in our sewage systems. These compounds may be nontoxic to humans but harmful to other animals or the environment.

GENERAL PATHWAYS OF DRUG METABOLISM

Drug metabolism reactions have been divided into two categories: phase I (*functionalization*) and phase II (*conjugation*) reactions.^{1,7} Phase I, or functionalization reactions, include oxidative, reductive, and hydrolytic biotransformations (Table 3.1).⁸ The purpose of these reactions is to introduce a functional polar group(s) (e.g., OH, COOH, NH₂, SH) into the xenobiotic molecule to produce a more water-soluble compound. This can be achieved by direct introduction of the functional group (e.g., aromatic and aliphatic hydroxylation) or by modifying or “unmasking” existing functionalities (e.g., reduction of ketones and aldehydes to alcohols; oxidation of alcohols to acids; hydrolysis of ester and amides to yield COOH, NH₂, and OH groups; reduction of azo and nitro compounds to give NH₂ moieties; oxidative *N*-, *O*-, and *S*-dealkylation to give NH₂, OH, and SH groups). Although phase I reactions may not produce sufficiently hydrophilic or inactive metabolites, they generally tend to provide a functional group or “handle” on the molecule that can undergo subsequent phase II reactions.

The purpose of phase II reactions is to attach small, polar, and ionizable endogenous compounds such as glucuronic acid, sulfate, glycine, and other amino acids to the functional handles of phase I metabolites or parent compounds that already have suitable existing functional groups to form water-soluble conjugated products. Conjugated metabolites are readily excreted in the urine

TABLE 3.1 General Summary of Phase I and Phase II Metabolic Pathways

Phase I or Functionalization Reactions
Oxidative Reactions
Oxidation of aromatic moieties
Oxidation of olefins
Oxidation at benzylic, allylic carbon atoms, and carbon atoms α to carbonyl and imines
Oxidation at aliphatic and alicyclic carbon atoms
Oxidation involving carbon-heteroatom systems:
Carbon-nitrogen systems (aliphatic and aromatic amines; includes <i>N</i> -dealkylation, oxidative deamination, <i>N</i> -oxide formation, <i>N</i> -hydroxylation)
Carbon-oxygen systems (<i>O</i> -dealkylation)
Carbon-sulfur systems (<i>S</i> -dealkylation, <i>S</i> -oxidation, and desulfuration)
Oxidation of alcohols and aldehydes
Other miscellaneous oxidative reactions
Reductive Reactions
Reduction of aldehydes and ketones
Reduction of nitro and azo compounds
Miscellaneous reductive reactions
Hydrolytic Reactions
Hydrolysis of esters and amides
Hydration of epoxides and arene oxides by epoxide hydrase
Phase II or Conjugation Reactions
Glucuronic acid conjugation
Sulfate conjugation
Conjugation with glycine, glutamine, and other amino acids
Glutathione or mercapturic acid conjugation
Acetylation
Methylation

and are generally devoid of pharmacological activity and toxicity in humans. Other phase II pathways, such as methylation and acetylation, terminate or attenuate biological activity, whereas glutathione (GSH) conjugation protects the body against chemically reactive compounds or metabolites. Thus, phase I and phase II reactions comple-

ment one another in detoxifying, and facilitating the elimination of, drugs and xenobiotics.

To illustrate, consider the principal psychoactive constituent of marijuana, Δ^9 -tetrahydrocannabinol (Δ^9 -THC, also known as Δ^1 -THC, depending on the numbering system being used). This lipophilic molecule (octanol/water partition coefficient $\sim 6,000$)⁹ undergoes allylic hydroxylation to give 11-hydroxy- Δ^9 -THC in humans.^{10,11} More polar than its parent compound, the 11-hydroxy metabolite is further oxidized to the corresponding carboxylic acid derivative Δ^9 -THC-11-oic acid, which is ionized (pK_a COOH ~ 5) at physiological pH. Subsequent conjugation of this metabolite (either at the COOH or phenolic OH) with glucuronic acid leads to water-soluble products that are readily eliminated in the urine.¹²

In the series of biotransformations, the parent Δ^9 -THC molecule is made increasingly polar, ionizable, and hydrophilic. The attachment of the glucuronyl moiety (with its ionized carboxylate group and three polar hydroxyl groups; see structure) to the Δ^9 -THC metabolites notably favors partitioning of the conjugated metabolites into an aqueous medium. This is an important point in using urinalysis to identify illegal drugs.

The purpose of this chapter is to provide students with a broad overview of drug metabolism. Various phase I and phase II biotransformation pathways (see Table 3.1) are outlined, and representative drug examples for each pathway are presented. Drug metabolism examples in humans are emphasized, although discussion of metabolism in other mammalian systems is necessary. The central role of the cytochrome P450 (CYP) monooxygenase system in oxidative drug biotransformation is elaborated. Discussion of other enzyme systems involved in phase I and phase II reactions is presented in their respective sections. In addition to stereochemical factors that may affect drug metabolism, biological factors such as age, sex, heredity, disease state, and species variation are considered. The effects of enzyme induction and inhibition on drug metabolism and a section on pharmacologically active metabolites are included.

SITES OF DRUG BIOTRANSFORMATION

Although biotransformation reactions may occur in many tissues, the liver is, by far, the most important organ in drug metabolism and detoxification of endogenous and exogenous compounds.¹³ Another important site, especially for orally administered drugs, is the intestinal mucosa. The latter contains the CYP3A4 isozyme (see discussion on cytochrome nomenclature) and P-glycoprotein that can capture the drug and secrete it back into the intestinal tract. In contrast, the liver, a well-perfused organ, is particularly rich in almost all of the drug-metabolizing enzymes discussed in this chapter. Orally administered drugs that are absorbed into the bloodstream through the GI tract must pass through the liver before being further distributed into body compartments. Therefore, they are susceptible to hepatic metabolism known as the *first-pass effect* before reaching the systemic circulation. Depending on the drug, this metabolism can sometimes be quite significant and results in decreased oral bioavailability. For example, in humans, several drugs are metabolized extensively by the first-pass effect.¹⁴ The following list includes some of those drugs:

Isoproterenol	Morphine	Propoxyphene
Lidocaine	Nitroglycerin	Propranolol
Meperidine	Pentazocine	Salicylamide

Some drugs (e.g., lidocaine) are removed so effectively by first-pass metabolism that they are ineffective when given orally.¹⁵ Nitroglycerin is administered buccally to bypass the liver.

Because most drugs are administered orally, the intestine appears to play an important role in the extrahepatic metabolism of xenobiotics. For example, in humans, orally administered isoproterenol undergoes considerable sulfate conjugation in the intestinal wall.¹⁶ Several other drugs (e.g., levodopa, chlorpromazine, and diethylstilbestrol)¹⁷ are also reportedly metabolized in the GI tract. Esterases and lipases present in the intestine may be particularly¹⁸ important in carrying out hydrolysis of many ester prodrugs (see “Hydrolytic Reactions”). Bacterial flora present in the intestine and colon appear to play an important role in the reduction of many aromatic azo and nitro drugs (e.g., sulfasalazine).^{19,20} Intestinal β -glucuronidase enzymes can hydrolyze glucuronide conjugates excreted in the bile, thereby liberating the free drug or its metabolite for possible reabsorption (enterohepatic circulation or recycling).²¹

Although other tissues, such as kidney, lungs, adrenal glands, placenta, brain, and skin, have some drug-metabolizing capability, the biotransformations that they carry out are often more substrate selective and more limited to particular types of reaction (e.g., oxidation, glucuronidation).²² In many instances, the full metabolic capabilities of these tissues have not been explored fully.

ROLE OF CYTOCHROME P450 MONOOXYGENASES IN OXIDATIVE BIOTRANSFORMATIONS

Of the various phase I reactions that are considered in this chapter, oxidative biotransformation processes are, by far, the most common and important in drug metabolism. The

TABLE 3.2 Cytochrome P450 Enzymes Nomenclature

CYP-Arabic Number-Capital Letter-Arabic Number

1. CYP: Cytochrome P450 enzymes
2. Arabic number: Family (CYP1, CYP2, CYP3, etc.)
Must have more than 40% identical amino acid sequence
3. Capital letter: Subfamily (CYP1A, CYP2C, CYP3A, etc.)
Must have more than 55% identical amino acid sequence
4. Arabic number: Individual enzyme in a subfamily (CYP1A2, CYP2C9, CYP2D6, CYP2E1, CYP3A4, etc.)
Identity of amino acid sequences can exceed 90%

general stoichiometry that describes the oxidation of many xenobiotics (R-H) to their corresponding oxidized metabolites (R-OH) is given by the following equation:²³

The enzyme systems carrying out this biotransformation are referred to as *mixed-function oxidases* or *monooxygenases*.^{24,25} There is a large family that carry out the same basic chemical reactions. Their nomenclature is based on amino acid homology and is summarized in Table 3.2. There are four components to the name. CYP refers to the cytochrome system. This is followed by the Arabic number that specifies the cytochrome family (CYP1, CYP2, CYP3, etc.). Next is a capital letter that represents the subfamily (CYP1A, CYP1B, CYP2A, CYP2B, CYP3A, CYP3B, etc.). Finally, the cytochrome name ends with another Arabic number that specifies the specific enzyme responsible for a particular reaction (CYP1A2, CYP2C9, CYP2C19, CYP3A4, etc.).

The reaction requires both molecular oxygen and the reducing agent NADPH (reduced form of nicotinamide adenine dinucleotide phosphate). During this oxidative process, one atom of molecular oxygen (O_2) is introduced into the substrate R-H to form R-OH and the other oxygen atom is incorporated into water. The mixed-function oxidase system²⁶ is actually made up of several components, the most important being the superfamily of CYP enzymes (currently at 57 genes [<http://drnelson.utmem.edu/CytochromeP450.html>]), which are responsible for transferring an *oxygen atom* to the substrate R-H. Other important components of this system include the NADPH-dependent CYP reductase and the NADH-linked cytochrome b_5 . The latter two components, along with the cofactors NADPH and NADH, supply the reducing equivalents (electrons) needed in the overall metabolic oxidation of foreign compounds. The proposed mechanistic scheme by which the CYP monooxygenase system catalyzes the conversion of molecular oxygen to an “activated oxygen” species is elaborated below.

The CYP enzymes are heme proteins.²⁷ The heme portion is an iron-containing porphyrin called *protoporphyrin IX*, and the protein portion is called the *apoprotein*. CYP is found in high concentrations in the liver, the major organ involved in the metabolism of xenobiotics. The presence of this enzyme in many other tissues (e.g., lung, kidney, intestine, skin, placenta, adrenal cortex) shows that these tissues have drug-oxidizing capability too. The name *cytochrome P450* is derived from the fact that the reduced (Fe^{2+}) form of this enzyme binds with carbon monoxide to form a

complex that has a distinguishing spectroscopic absorption maximum at 450 nm.²⁸

One important feature of the hepatic CYP mixed-function oxidase system is its ability to metabolize an almost unlimited number of diverse substrates by various oxidative transformations.²⁹ This versatility is believed to be a result of the substrate nonspecificity of CYP as well as the presence of multiple forms of the enzyme.³⁰ Some of these P450 enzymes are selectively inducible by various chemicals (e.g., phenobarbital, benzo[α]pyrene, 3-methylcholanthrene).³¹ One of these inducible forms of the enzyme (cytochrome P448)³² is of particular interest and is discussed later in this section.

The CYP monooxygenases are located in the endoplasmic reticulum, a highly organized and complex network of intracellular membranes that is particularly abundant in tissues such as the liver.³³ When these tissues are disrupted by homogenization, the endoplasmic reticulum loses its structure and is converted into small vesicular bodies known as *microsomes*. Mitochondria house many of the cytochrome enzymes that are responsible for the biosynthesis of steroidal hormones and metabolism of certain vitamins.

Microsomes isolated from hepatic tissue appear to retain all of the mixed-function oxidase capabilities of intact hepatocytes; because of this, microsomal preparations (with the necessary cofactors, e.g., NADPH, Mg^{2+}) are used frequently for in vitro drug metabolism studies. Because of its membrane-bound nature, the CYP monooxygenase system appears to be housed in a lipoidal environment. This may explain, in part, why lipophilic

xenobiotics are generally good substrates for the monooxygenase system.³⁴

The catalytic role that the CYP monooxygenase system plays in the oxidation of xenobiotics is summarized in the cycle shown in Figure 3.1.³⁵⁻³⁷ The initial step of this catalytic reaction cycle starts with the binding of the substrate to the oxidized (Fe^{3+}) resting state of CYP to form a P450-substrate complex. The next step involves the transfer of one electron from NADPH-dependent CYP reductase to the P450-substrate complex. This one-electron transfer reduces Fe^{3+} to Fe^{2+} . It is this reduced (Fe^{2+}) P450-substrate complex that is capable of binding dioxygen (O_2). The dioxygen-P450-substrate complex that is formed then undergoes another one-electron reduction (by CYP reductase-NADPH and/or cytochrome b_5 reductase-NADH) to yield what is believed to be a peroxide dianion-P450 (Fe^{3+})-substrate complex. Water (containing one of the oxygen atoms from the original dioxygen molecule) is released from the latter intermediate to form an activated oxygen-P450-substrate complex (Fig. 3.2). The activated oxygen [FeO]³⁺ in this complex is highly electron deficient and a potent oxidizing agent. The activated oxygen is transferred to the substrate (R-H), and the oxidized substrate product (R-OH) is released from the enzyme complex to regenerate the oxidized form of CYP.

The key sequence of events appears to center around the alteration of a dioxygen-P450-substrate complex to an activated oxygen-P450-substrate complex, which can then effect the critical transfer of oxygen from P450 to the substrate.^{37,38} In view of the potent oxidizing nature of the activated oxygen being transferred, it is not surprising CYP

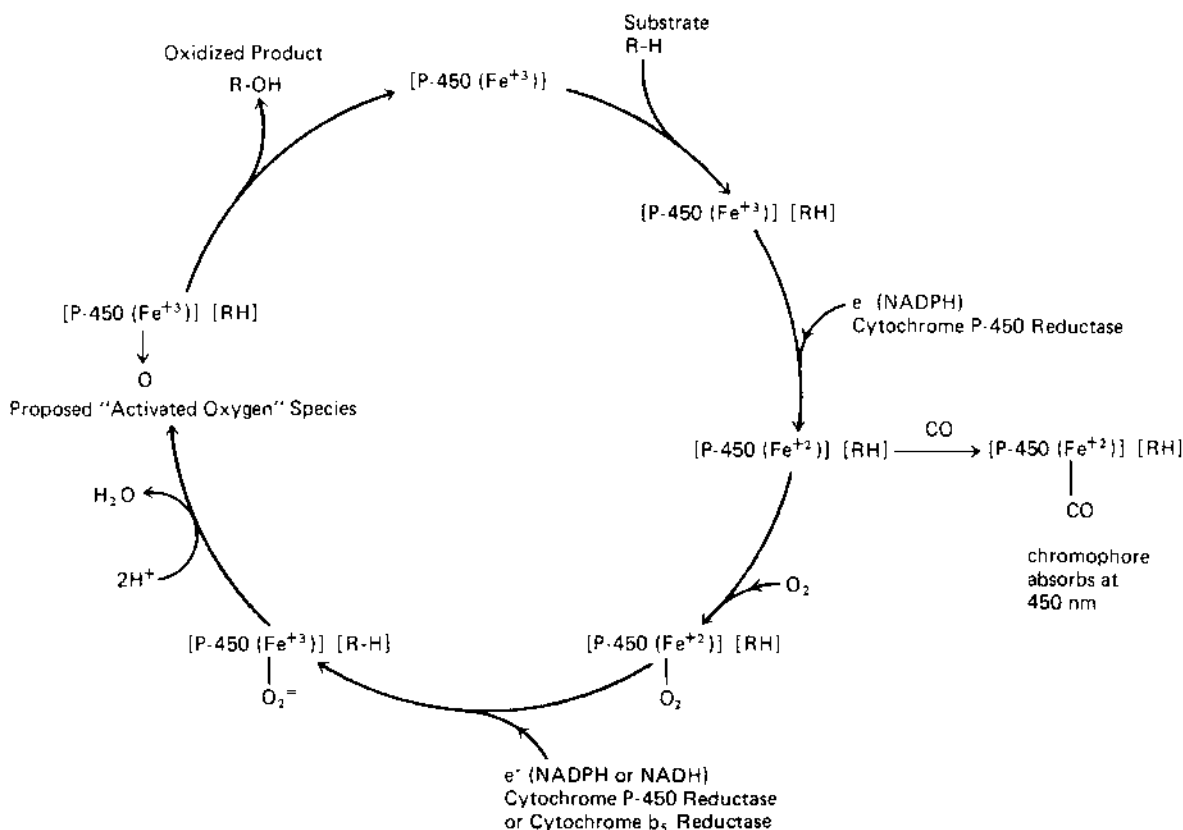

Figure 3.1 • Proposed catalytic reaction cycle involving cytochrome P450 in the oxidation of xenobiotics.

Figure 3.2 • Simplified depiction of the proposed activated oxygen–cytochrome P450-substrate complex. Note the simplified apoprotein portion and the heme (protoporphyrin IX) portion or cytochrome P450 and the proximity of the substrate R-H undergoing oxidation.

can oxidize numerous substrates. The mechanistic details of oxygen activation and transfer in CYP-catalyzed reactions continue to be an active area of research in drug metabolism.³⁴ The many types of oxidative reaction carried out by CYP are enumerated in the sections below. Many of these oxidative pathways are summarized schematically in Figure 3.3 (see also Table 3.1).³⁷

The versatility of CYP in carrying out various oxidation reactions on a multitude of substrates may be attributed to the multiple forms of the enzyme. Consequently, students must realize that the biotransformation of a parent xenobiotic to several oxidized metabolites is carried out not just by one form of P450 but, more likely, by several different forms. Extensive studies indicate that the apoprotein portions of various CYPs differ from one another in their tertiary structure (because of differences in amino acid sequence or the makeup of the polypeptide chain).^{27,30,39–41} Because the apoprotein portion is important in substrate binding and catalytic transfer of activated

oxygen, these structural differences may account for some substrates being preferentially or more efficiently oxidized by one particular form of CYP. Finally, because of the enormous number of uncommon reactions that are catalyzed by P450, the reader is directed to other articles of interest.⁴²

OXIDATIVE REACTIONS

Oxidation of Aromatic Moieties

Aromatic hydroxylation refers to the mixed-function oxidation of aromatic compounds (*arenes*) to their corresponding phenolic metabolites (*arenols*).⁴³ Almost all aromatic hydroxylation reactions are believed to proceed initially through an epoxide intermediate called an “arene oxide,” which rearranges rapidly and spontaneously to the arenol product in most instances. The importance of arene oxides in the formation of arenols and in other metabolic and toxicologic

Figure 3.3 • Schematic summary of cytochrome P450-catalyzed oxidation reactions. (Adapted from Ullrich, V.: *Top. Curr. Chem.* 83:68, 1979.)

reactions is discussed below.^{44,45} Our attention now focuses on the aromatic hydroxylation of several drugs and xenobiotics.

Most foreign compounds containing aromatic moieties are susceptible to aromatic oxidation. In humans, aromatic hydroxylation is a major route of metabolism for many drugs containing phenyl groups. Important therapeutic agents such as propranolol,^{46,47} phenobarbital,⁴⁸ phenytoin,^{49,50} phenylbutazone,^{51,52} atorvastatin,⁵³ 17 α -ethinylestradiol,^{54,55} and (*S*)(-)-warfarin,⁵⁶ among others, undergo extensive aromatic oxidation (Fig. 3.4 shows structure and site of hydroxylation). In most of the drugs just mentioned, hydroxylation occurs at the *para* position.⁵⁷ Most phenolic metabolites formed from aromatic oxidation undergo further conversion to polar and water-soluble glucuronide or sulfate conjugates, which are readily excreted in the urine. For example, the major urinary

metabolite of phenytoin found in humans is the *O*-glucuronide conjugate of *p*-hydroxyphenytoin.^{49,50} Interestingly, the *para*-hydroxylated metabolite of phenylbutazone, oxyphenbutazone, is pharmacologically active and has been marketed itself as an anti-inflammatory agent (Tandearil, Oxalid).^{51,52} Of the two enantiomeric forms of the oral anticoagulant warfarin (Coumadin), only the more active *S*(-) enantiomer has been shown to undergo substantial aromatic hydroxylation to 7-hydroxywarfarin in humans.⁵⁶ In contrast, the (*R*)(+) enantiomer is metabolized by keto reduction⁵⁶ (see "Stereochemical Aspects of Drug Metabolism").

Often, the substituents attached to the aromatic ring may influence the ease of hydroxylation.⁵⁷ As a general rule, microsomal aromatic hydroxylation reactions appear to proceed most readily in activated (electron-rich) rings, whereas deactivated aromatic rings (e.g., those containing electron-withdrawing groups Cl, -N⁺R₃, COOH, SO₂NHR) are generally slow or resistant to hydroxylation. The deactivating groups (Cl, -N⁺H=C) present in the antihypertensive clonidine (Catapres) may explain why this drug undergoes little aromatic hydroxylation in humans.^{58,59} The uricosuric agent probenecid (Benemid), with its electron-withdrawing carboxy and sulfamido groups, has not been reported to undergo any aromatic hydroxylation.⁶⁰

Figure 3.4 • Examples of drugs and xenobiotics that undergo aromatic hydroxylation in humans. Arrow indicates site of aromatic hydroxylation.

In compounds with two aromatic rings, hydroxylation occurs preferentially in the more electron-rich ring. For example, aromatic hydroxylation of diazepam (Valium) occurs primarily in the more activated ring to yield 4'-hydroxydiazepam.⁶¹ A similar situation is seen in the 7-hydroxylation of the antipsychotic agent chlorpromazine (Thorazine)⁶² and in the *para*-hydroxylation of *p*-chlorobiphenyl to *p*-chloro-*p'*-hydroxybiphenyl.⁶³

Recent environmental pollutants, such as polychlorinated biphenyls (PCBs) and 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD), have attracted considerable public concern over their toxicity and health hazards. These compounds appear to be resistant to aromatic oxidation because of the numerous electronegative chlorine atoms in their aromatic rings. The metabolic stability coupled to the lipophilicity of these environmental contaminants probably explains their long persistence in the body once absorbed.^{64–66}

Arene oxide intermediates are formed when a double bond in aromatic moieties is epoxidized. Arene oxides are of significant toxicologic concern because these intermediates are electrophilic and chemically reactive (because of the strained three-membered epoxide ring). Arene oxides are mainly detoxified by spontaneous rearrangement to arenols, but enzymatic hydration to *trans*-dihydrodiols and enzymatic conjugation with GSH also play very important roles (Fig. 3.5).^{43,44} If not effectively detoxified by the first three pathways in Figure 3.5, arene oxides will bind covalently with nucleophilic groups present on proteins, deoxyribonucleic acid (DNA), and ribonucleic acid (RNA), thereby leading to serious cellular damage.^{5,43} This, in part, helps explain why benzene can be so toxic to mammalian systems.

Quantitatively, the most important detoxification reaction for arene oxides is the spontaneous rearrangement to corresponding arenols. Often, this rearrangement is accompanied by a novel intramolecular hydride (deuteride) migration called the “NIH shift.”⁶⁷ It was named after the National Institutes of Health (NIH) laboratory in Bethesda, Maryland, where this process was discovered. The general features of the NIH shift are illustrated with the mixed-function aromatic oxidation of 4-deuterioanisole to 3-deuterio-4-hydroxyanisole in Figure 3.6.⁶⁸

After its metabolic formation, the arene oxide ring opens in the direction that generates the most resonance-stabilized carbocation (positive charge on C-3 carbon is resonance stabilized by the OCH₃ group). The zwitterionic species (positive charge on the C-3 carbon atom and negative charge on the oxygen atom) then undergoes a 1,2-deuteride shift (NIH shift) to form the dienone. Final transformation of the dienone to 3-deuterio-4-hydroxyanisole occurs with the preferential loss of a proton because of the weaker bond energy of the C–H bond (compared with the C–D bond). Thus, the deuterium is retained in the molecule by undergoing this intramolecular NIH shift. The experimental observation of an NIH shift for aromatic hydroxylation of a drug or xenobiotic is taken as indirect evidence for the involvement of an arene oxide.

In addition to the NIH shift, the zwitterionic species may undergo direct loss of D⁺ to generate 4-hydroxyanisole, in which there is no retention of deuterium (Fig. 3.6). The alternative pathway (direct loss of D⁺) may be more favorable than the NIH shift in some aromatic oxidation reactions. Therefore, depending on the substituent group on the arene, some aromatic hydroxylation reactions do not display any NIH shift.

Two extremely important enzymatic reactions also aid in neutralizing the reactivity of arene oxides. The first of these involves the hydration (i.e., nucleophilic attack of water on the

epoxide) of arene oxides to yield inactive *trans*-dihydrodiol metabolites (Fig. 3.5). This reaction is catalyzed by microsomal enzymes called *epoxide hydrases*.^{69,70} Often, epoxide hydrase inhibitors, such as cyclohexene oxide and 1,1,1-trichloropropene-2,3-oxide, have been used to demonstrate the detoxification role of these enzymes. Addition of these inhibitors is accompanied frequently by increased toxicity of the arene oxide being tested, because formation of nontoxic dihydrodiols is blocked. For example, the mutagenicity of benzo[α]pyrene-4,5-oxide, as measured by the Ames *Salmonella typhimurium* test system, is potentiated when cyclohexene oxide is added.⁷¹ Dihydrodiol metabolites have been reported in the metabolism of several aromatic hydrocarbons (e.g., naphthalene, benzo[α]pyrene, and other related polycyclic aromatic hydrocarbons).⁴³ A few drugs (e.g., phenytoin,⁷² phenobarbital,⁷³ glutethimide⁷⁴) also yield dihydrodiol products as minor metabolites in humans. Dihydrodiol products are susceptible to conjugation with glucuronic acid, as well as enzymatic dehydrogenation to the corresponding catechol metabolite, as exemplified by the metabolism of phenytoin.⁷²

A second enzymatic reaction involves nucleophilic ring opening of the arene oxide by the sulfhydryl (SH) group present in GSH to yield the corresponding *trans*-1,2-dihydro-1-*S*-glutathionyl-2-hydroxy adduct, or GSH adduct (Fig. 3.5).⁴⁴ The reaction is catalyzed by various GSH *S*-transferases.⁷⁵ Because GSH is found in practically all mammalian tissues, it plays an important role in the detoxification not only of arene oxides but also of other various chemically reactive and potentially toxic intermediates. Initially, GSH adducts formed from arene oxides are modified in a series of reactions to yield "premercapturic acid" or mercapturic acid metabolites.⁷⁶ Because it is classified as a phase II pathway, GSH conjugation is covered in greater detail later in this chapter.

Because of their electrophilic and reactive nature, arene oxides also may undergo spontaneous reactions with nucleophilic functionalities present on biomacromolecules.^{44,45} Such reactions lead to modified protein, DNA, and RNA structures and often cause dramatic alterations in how these macromolecules function. Much of the cytotoxicity and irreversible lesions caused by arene oxides are presumed to result from their covalent binding to cellular components. Several well-established examples of reactive arene oxides that cause serious toxicity are presented below.

Administration of bromobenzene to rats causes severe liver necrosis.⁷⁷ Extensive *in vivo* and *in vitro* studies indicate that the liver damage results from the interaction of a chemically reactive metabolite, 4-bromobenzene oxide, with hepatocytes.⁷⁸ Extensive covalent binding to hepatic

tissue was confirmed by use of radiolabeled bromobenzene. The severity of necrosis correlated well with the amount of covalent binding to hepatic tissue. Use of diethyl maleate or large doses of bromobenzene in rats showed that the depletion of hepatic GSH led to more severe liver necrosis.

Polycyclic aromatic hydrocarbons are ubiquitous environmental contaminants that are formed from auto emission, refuse burning, industrial processes, cigarette smoke, and other combustion processes. Benzo[α]pyrene, a potent carcinogenic agent, is perhaps the most extensively studied of the polycyclic aromatic hydrocarbons.⁷⁹ Inspection of its structure reveals that aromatic hydroxylation of benzo[α]pyrene can occur at several positions. The identification of several dihydrodiol metabolites is viewed as indirect evidence for the formation and involvement of arene oxides in the metabolism of benzo[α]pyrene. Although certain arene oxides of benzo[α]pyrene (e.g., 4,5-oxide, 7,8-oxide, 9,10-oxide) appear to display some mutagenic and tumorigenic activity, it does not appear that they represent the ultimate reactive species responsible for benzo[α]pyrene's carcinogenicity. In recent years, extensive studies have led to the characterization of a specific sequence of metabolic reactions (Fig. 3.7) that generate a highly reactive intermediate that covalently binds to DNA. Metabolic activation of benzo[α]pyrene to the

ultimate carcinogenic species involves an initial epoxidation reaction to form the 7,8-oxide, which is then converted by epoxide hydrase to (-)-7(*R*),8(*R*)-dihydroxy-7,8-dihydrobenzo[α]pyrene.⁸⁰ The two-step enzymatic formation of this *trans*-dihydrodiol is stereospecific. Subsequent epoxidation at the 9,10-double bond of the latter metabolite generates predominantly (+)-7(*R*),8(*S*)-dihydroxy-9(*R*),10(*R*)-oxy-7,8,9,10-tetrahydrobenzo[α]pyrene or (+)-7,8-diol-9,10-epoxide. It is this key electrophilic diol epoxide metabolite that readily reacts with DNA to form many covalently bound adducts.⁸¹⁻⁸³ Careful degradation studies have shown that the principal adduct involves attack of the C-2 amino group of deoxyguanosine at C-10 of the diol epoxide. Clearly, these reactions are responsible for genetic code alterations that ultimately lead to the malignant transformations. Covalent binding of the diol epoxide metabolite to deoxyadenosine and to deoxycytidine also has been established.⁸⁴

Another carcinogenic polycyclic aromatic hydrocarbon, 7,12-dimethylbenz[α]anthracene, also forms covalent adducts with nucleic acids (RNA).⁸⁵ The ultimate carcinogenic reactive species apparently is the 5,6-oxide that results from epoxidation of the 5,6-double bond in this aromatic hydrocarbon. The arene oxide intermediate binds covalently to guanosine residues of RNA to yield the two adducts.

Oxidation of Olefins

The metabolic oxidation of olefinic carbon-carbon double bonds leads to the corresponding epoxide (or oxirane). Epoxides derived from olefins generally tend to be somewhat more stable than the arene oxides formed from aromatic compounds. A few epoxides are stable enough to be directly measurable in biological fluids (e.g., plasma, urine). Like their arene oxide counterparts, epoxides are susceptible to enzymatic hydration by epoxide hydrase to form *trans*-1,2-dihydrodiols (also called *1,2-diols* or *1,2-dihydroxy*

Figure 3.7 • Metabolic sequence leading to the formation of the ultimate carcinogenic species of benzo[α]pyrene: (+)-7*R*,8*S*-dihydroxy-9*R*,10-*oxy*-7,8,9,10-tetrahydrobenzo[α]pyrene or (+)-7,8-diol-9,10-epoxide.

compounds).^{69,70} In addition, several epoxides undergo GSH conjugation.⁸⁶

A well-known example of olefinic epoxidation is the metabolism, in humans, of the anticonvulsant drug carbamazepine (Tegretol) to carbamazepine-10,11-epoxide.⁸⁷ The epoxide is reasonably stable and can be measured quantitatively in the plasma of patients receiving the parent drug. The epoxide metabolite may have marked anticonvulsant

activity and, therefore, may contribute substantially to the therapeutic effect of the parent drug.⁸⁸ Subsequent hydration of the epoxide produces 10,11-dihydroxycarbamazepine, an important urinary metabolite (10%–30%) in humans.⁸⁷

Epoxidation of the olefinic 10,11-double bond in the antipsychotic agent protriptyline (Vivactil)⁸⁹ and in the H₁-histamine antagonist cyproheptadine (Periactin)⁹⁰

also occurs. Frequently, the epoxides formed from the biotransformation of an olefinic compound are minor products, because of their further conversion to the corresponding 1,2-diols. For instance, dihydroxyalcofenac is a major human urinary metabolite of the once clinically useful anti-inflammatory agent alclofenac.⁹¹ The epoxide metabolite from which it is derived, however, is present in minute amounts. The presence of the dihydroxy metabolite (secodiol) of secobarbital, but not the epoxide product, has been reported in humans.⁹²

Indirect evidence for the formation of epoxides comes also from the isolation of GSH or mercapturic acid metabolites. After administration of styrene to rats, two urinary metabolites were identified as the isomeric mercapturic acid derivatives resulting from nucleophilic attack of GSH on the intermediate epoxide.⁹³ In addition, styrene oxide covalently binds to rat liver microsomal proteins and nucleic acids.⁹⁴ These results indicate that styrene oxide is relatively reactive toward nucleophiles (e.g., GSH and nucleophilic groups on protein and nucleic acids).

There are, apparently, diverse metabolically generated epoxides that display similar chemical reactivity toward nucleophilic functionalities. Accordingly, the toxicity of some olefinic compounds may result from their metabolic conversion to chemically reactive epoxides.⁹⁵ One example that clearly links metabolic epoxidation as a biotransformation pathway involves aflatoxin B₁. This naturally occurring carcinogenic agent contains an olefinic (C2–C3) double bond adjacent to a cyclic ether oxygen. The hepatocarcinogenicity of aflatoxin B₁ has been clearly linked to its metabolic oxidation to the corresponding 2,3-oxide, which is extremely reactive.^{96,97} Extensive *in vitro* and *in vivo* metabolic studies indicate that this 2,3-oxide binds covalently to DNA, RNA, and proteins. A major DNA adduct has been isolated and characterized as 2,3-dihydro-2-(N⁷-guanyl)-3-hydroxyaflatoxin B₁.^{98,99}

Other olefinic compounds, such as vinyl chloride,¹⁰⁰ stilbene,¹⁰¹ and the carcinogenic estrogenic agent diethylstilbestrol (DES),^{102,103} undergo metabolic epoxidation. The corresponding epoxide metabolites may be the reactive

species responsible for the cellular toxicity seen with these compounds.

An interesting group of olefin-containing compounds causes the destruction of CYP.^{104,105} Compounds belonging to this group include allylisopropylacetamide,^{106,107} secobarbital,^{108,109} and the volatile anesthetic agent fluroxene.¹¹⁰ It is believed that the olefinic moiety present in these compounds is activated metabolically by CYP to form a very reactive intermediate that covalently binds to the heme portion of CYP.^{111–113} The abnormal heme derivatives, or “green pigments,” that result from this covalent interaction have been characterized as *N*-alkylated protoporphyrins in which the *N*-alkyl moiety is derived directly from the olefin administered.^{104,105,111–113} Long-term administration of the above-mentioned three agents is expected to lead to inhibition of oxidative drug metabolism, potential drug interactions, and prolonged pharmacological effects.

Oxidation at Benzylic Carbon Atoms

Carbon atoms attached to aromatic rings (benzylic position) are susceptible to oxidation, thereby forming the corresponding alcohol (or carbinol) metabolite.^{114,115} Primary alcohol metabolites are often oxidized further to aldehydes and carboxylic acids ($\text{CH}_2\text{OH} \rightarrow \text{CHO} \rightarrow \text{COOH}$), and secondary alcohols are converted to ketones by soluble alcohol and aldehyde dehydrogenases.¹¹⁶ Alternatively, the alcohol may be conjugated directly with glucuronic acid.¹¹⁷ The benzylic carbon atom present in the oral hypoglycemic agent tolbutamide (Orinase) is oxidized extensively to the corresponding alcohol and carboxylic acid. Both metabolites have been isolated from human urine.¹¹⁸ Similarly, the “benzylic” methyl group in the anti-inflammatory agent tolmetin (Tolectin) undergoes oxidation to yield the dicarboxylic acid product as the major metabolite in humans.^{119,120} The selective cyclooxygenase 2 (COX-2) anti-inflammatory agent celecoxib undergoes benzylic oxidation at its C-5 methyl group to give hydroxycelecoxib as a major metabolite.¹²¹ Significant benzylic hydroxy-

lation occurs in the metabolism of the β -adrenergic blocker metoprolol (Lopressor) to yield α -hydroxymetoprolol.^{122,123} Additional examples of drugs and xenobiotics undergoing benzylic oxidation are shown in Figure 3.8.

Oxidation at Allylic Carbon Atoms

Microsomal hydroxylation at allylic carbon atoms is commonly observed in drug metabolism. An illustrative example of allylic oxidation is given by the psychoactive component of marijuana, Δ^1 -tetrahydrocannabinol Δ^1 -THC. This molecule contains three allylic carbon centers (C-7, C-6, and C-3). Allylic hydroxylation occurs extensively at C-7 to yield 7-hydroxy- Δ^1 -THC as the major plasma metabolite in humans.^{10,11} Pharmacological studies show that this 7-hydroxy metabolite is as active as, or even more active than, Δ^1 -THC per se and may contribute significantly to the overall central nervous system (CNS) psychotomimetic effects of the parent compound.^{124,125} Hydroxylation also occurs to a minor extent at the allylic C-6 position to give both the epimeric 6 α - and 6 β -hydroxy metabolites.^{10,11} Metabolism does not occur at C-3, presumably because of steric hindrance.

The antiarrhythmic agent quinidine is metabolized by allylic hydroxylation to 3-hydroxyquinidine, the principal plasma metabolite found in humans.^{126,127} This metabolite shows significant antiarrhythmic activity in animals and possibly in humans.¹²⁸

Other examples of allylic oxidation include the sedative-hypnotic hexobarbital (Sombulex) and the analgesic pentazocine (Talwin). The 3'-hydroxylated metabolite formed from hexobarbital is susceptible to glucuronide conjugation as well as further oxidation to the 3'-oxo compound.^{129,130} Hexobarbital is a chiral barbiturate derivative that exists in two enantiomeric forms. Studies in humans indicate that the pharmacologically less active (*R*)($-$) enantiomer is metabolized more rapidly than its (*S*)($+$)-isomer.¹³¹ Pentazocine undergoes allylic hydroxylation at the two

(text continues on page 58)

Figure 3.8 • Examples of drugs and xenobiotics undergoing benzylic hydroxylation. Arrow indicates site of hydroxylation.

terminal methyl groups of its *N*-butenyl side chain to yield either the *cis* or *trans* alcohol metabolites shown in the diagrams. In humans, more of the *trans* alcohol is formed.^{132,133}

For the hepatocarcinogenic agent safrole, allylic hydroxylation is involved in a bioactivation pathway leading to the formation of chemically reactive metabolites.¹³⁴ This process involves initial hydroxylation at the C-1' carbon of safrole, which is both allylic and benzylic. The hydroxylated metabolite then undergoes further conjugation to form a sulfate ester. This chemically reactive ester intermediate presumably undergoes nucleophilic displacement reactions with DNA or RNA *in vitro* to form covalently bound adducts.¹³⁵ As shown in the scheme, nucleophilic attack by DNA, RNA, or other nucleophiles is facilitated by a good leaving group (e.g., SO₄²⁻) at the C-1 position. The leaving group tendency of the alcohol OH group itself is not

enough to facilitate displacement reactions. Importantly, allylic hydroxylation generally does not lead to the generation of reactive intermediates. Its involvement in the biotransformation of safrole appears to be an exception.

Oxidation at Carbon Atoms α to Carbonyls and Imines

The mixed-function oxidase system also oxidizes carbon atoms adjacent (i.e., α) to carbonyl and imino (C=N) functionalities. An important class of drugs undergoing this type of oxidation is the benzodiazepines. For example, diazepam (Valium), flurazepam (Dalmane), and nimetazepam are oxidized to their corresponding 3-hydroxy metabolites.¹³⁶⁻¹³⁸ The C-3 carbon atom undergoing hydroxylation is α to both a lactam carbonyl and an imino functionality.

For diazepam, the hydroxylation reaction proceeds with remarkable stereoselectivity to form primarily (90%) 3-hydroxydiazepam (also called *N*-methyloxazepam), with the (*S*) absolute configuration at C-3.¹³⁹ Further *N*-demethylation of the latter metabolite gives rise to the pharmacologically active 3(*S*)(+)-oxazepam.

Hydroxylation of the carbon atom α to carbonyl functionalities generally occurs only to a limited extent in drug metabolism. An illustrative example involves the hydroxylation of the sedative-hypnotic glutethimide (Doriden) to 4-hydroxyglutethimide.^{140,141}

Oxidation at Aliphatic and Alicyclic Carbon Atoms

Alkyl or aliphatic carbon centers are subject to mixed-function oxidation. Metabolic oxidation at the terminal methyl group often is referred to as ω -oxidation, and oxidation of the penultimate carbon atom (i.e., next-to-the-last carbon) is called $\omega-1$ oxidation.^{114,115} The initial alcohol metabolites formed from these enzymatic ω and $\omega-1$ oxidations are susceptible to further oxidation to yield aldehyde, ketones, or carboxylic acids. Alternatively, the alcohol metabolites may undergo glucuronide conjugation.

Aliphatic ω and $\omega-1$ hydroxylations commonly take place in drug molecules with straight or branched alkyl chains. Thus, the antiepileptic agent valproic acid (Depakene) undergoes both ω and $\omega-1$ oxidation to the 5-hydroxy and 4-hydroxy metabolites, respectively.^{142,143} Further oxidation of the 5-hydroxy metabolite yields 2-*n*-propylglutaric acid.

Numerous barbiturates and oral hypoglycemic sulfonylureas also have aliphatic side chains that are susceptible to oxidation. Note that the sedative-hypnotic amobarbital (Amytal) undergoes extensive $\omega-1$ oxidation to the corresponding 3'-hydroxylated metabolite.¹⁴⁴ Other barbiturates, such as pentobarbital,^{145,146} thiamylal,¹⁴⁷ and secobarbital,⁹² reportedly are metabolized by way of ω and $\omega-1$ oxidation. The *n*-propyl side chain attached to the oral hypoglycemic agent chlorpropamide (Diabinese) undergoes extensive $\omega-1$ hydroxylation to yield the secondary alcohol 2'-hydroxychlorpropamide as a major urinary metabolite in humans.¹⁴⁸

Omega and $\omega-1$ oxidation of the isobutyl moiety present in the anti-inflammatory agent ibuprofen (Motrin) yields the corresponding carboxylic acid and tertiary alcohol metabolites.¹⁴⁹ Additional examples of drugs reported to undergo aliphatic hydroxylation include meprobamate,¹⁵⁰ glutethimide,^{140,141} ethosuximide,¹⁵¹ and phenylbutazone.¹⁵²

The cyclohexyl group is commonly found in many medicinal agents, and is also susceptible to mixed-function oxidation (alicyclic hydroxylation).^{114,115} Enzymatic introduction of a hydroxyl group into a monosubstituted cyclohexane ring generally occurs at C-3 or C-4 and can lead to *cis* and *trans* conformational stereoisomers, as shown in the diagrammed scheme.

An example of this hydroxylation pathway is seen in the metabolism of the oral hypoglycemic agent acetohexamide (Dymelor). In humans, the *trans*-4-hydroxycyclohexyl product is reportedly a major metabolite.¹⁵³ Small amounts of the other possible stereoisomers (namely, the *cis*-4-, *cis*-3-, and *trans*-3-hydroxycyclohexyl derivatives) also have been detected. Another related oral hypoglycemic agent, glipizide, is oxidized in humans to the *trans*-4- and *cis*-3-hydroxycyclohexyl metabolites in about a 6:1 ratio.¹⁵⁴

Two human urinary metabolites of phenacyclidine (PCP) have been identified as the 4-hydroxypiperidyl and 4-hydroxycyclohexyl derivatives of the parent compound.^{155,156} Thus, from these results, it appears that "alicyclic" hydroxylation of the six-membered piperidyl moiety may parallel closely the hydroxylation pattern of the cyclohexyl moiety. The stereochemistry of the hydroxylated centers in the two metabolites has not been clearly established. Biotransformation of the antihypertensive agent minoxidil (Loniten) yields the 4'-hydroxypiperidyl metabolite. In dogs, this product is a major urinary metabolite (29%–47%), whereas in humans it is detected in small amounts (~3%).^{157,158}

Oxidation Involving Carbon-Heteroatom Systems

Nitrogen and oxygen functionalities are commonly found in most drugs and foreign compounds; sulfur functionalities occur only occasionally. Metabolic oxidation of

carbon–nitrogen, carbon–oxygen, and carbon–sulfur systems principally involves two basic types of biotransformation processes:

1. Hydroxylation of the α -carbon atom attached directly to the heteroatom (*N*, *O*, *S*). The resulting intermediate is often unstable and decomposes with the cleavage of the carbon–heteroatom bond:

Where X = N, O, S Usually Unstable

Oxidative *N*-, *O*-, and *S*-dealkylation as well as oxidative deamination reactions fall under this mechanistic pathway.

2. Hydroxylation or oxidation of the heteroatom (*N*, *S* only, e.g., *N*-hydroxylation, *N*-oxide formation, sulfoxide, and sulfone formation).

Several structural features frequently determine which pathway will predominate, especially in carbon–nitrogen systems. Metabolism of some nitrogen-containing compounds is complicated by the fact that carbon- or nitrogen-

hydroxylated products may undergo secondary reactions to form other, more complex metabolic products (e.g., oxime, nitron, nitroso, imino). Other oxidative processes that do not fall under these two basic categories are discussed individually in the appropriate carbon–heteroatom section. The metabolism of carbon–nitrogen systems will be discussed first, followed by the metabolism of carbon–oxygen and carbon–sulfur systems.

OXIDATION INVOLVING CARBON-NITROGEN SYSTEMS

Metabolism of nitrogen functionalities (e.g., amines, amides) is important because such functional groups are found in many natural products (e.g., morphine, cocaine, nicotine) and in numerous important drugs (e.g., phenothiazines, antihistamines, tricyclic antidepressants, β -adrenergic agents, sympathomimetic phenylethylamines, benzodiazepines).¹⁵⁹ The following discussion divides nitrogen-containing compounds into three basic classes:

1. Aliphatic (primary, secondary, and tertiary) and alicyclic (secondary and tertiary) amines
2. Aromatic and heterocyclic nitrogen compounds
3. Amides

The susceptibility of each class of these nitrogen compounds to either α -carbon hydroxylation or *N*-oxidation and the metabolic products that are formed are discussed.

The hepatic enzymes responsible for carrying out α -carbon hydroxylation reactions are the CYP mixed-function oxidases. The *N*-hydroxylation or *N*-oxidation reactions, however, appear to be catalyzed not only by CYP but also by a second class of hepatic mixed-function oxidases called

amine oxidases (sometimes called *N-oxidases*).¹⁶⁰ These enzymes are NADPH-dependent flavoproteins and do not contain CYP.^{161,162} They require NADPH and molecular oxygen to carry out *N*-oxidation.

Tertiary Aliphatic and Alicyclic Amines. The oxidative removal of alkyl groups (particularly methyl groups) from tertiary aliphatic and alicyclic amines is carried out by hepatic CYP mixed-function oxidase enzymes. This reaction is commonly referred to as *oxidative N-dealkylation*.¹⁶³ The initial step involves α -carbon hydroxylation to form a carbinolamine intermediate, which is unstable and undergoes spontaneous heterolytic cleavage of the C-N bond to give a secondary amine and a carbonyl moiety (aldehyde or ketone).^{164,165} In general, small alkyl groups, such as methyl, ethyl, and isopropyl, are removed rapidly.¹⁶³ *N*-dealkylation of the *t*-butyl group is not possible by the carbinolamine pathway because α -carbon hydroxylation cannot occur. The first alkyl group from a tertiary amine is removed more rapidly than the second alkyl group. In some instances, bisdealkylation of the tertiary aliphatic amine to the corresponding primary aliphatic amine occurs very slowly.¹⁶³ For example, the tertiary amine imipramine

(Tofranil) is monodemethylated to desmethylimipramine (desipramine).^{166,167} This major plasma metabolite is pharmacologically active in humans and contributes substantially to the antidepressant activity of the parent drug.¹⁶⁸ Very little of the bisdemethylated metabolite of imipramine is detected. In contrast, the local anesthetic and antiarrhythmic agent lidocaine is metabolized extensively by *N*-deethylation to both monoethylglycylxylylidine and glycyl-2,6-xylylidine in humans.^{169,170}

Numerous other tertiary aliphatic amine drugs are metabolized principally by oxidative *N*-dealkylation. Some of these include the antiarrhythmic disopyramide (Norpace),^{171,172} the antiestrogenic agent tamoxifen (Nolvadex),¹⁷³ diphenhydramine (Benadryl),^{174,175} chlorpromazine (Thorazine),^{176,177} and (+)- α -propoxyphene (Darvon).¹⁷⁸ When the tertiary amine contains several different substituents capable of undergoing dealkylation, the smaller alkyl group is removed preferentially and more rapidly. For example, in benzphetamine (Didrex), the methyl group is removed much more rapidly than the benzyl moiety.¹⁷⁹

An interesting cyclization reaction occurs with methadone on *N*-demethylation. The demethylated metabolite normethadone undergoes spontaneous cyclization to form the enamine metabolite 2-ethylidene-1,5-dimethyl-3,3-diphenylpyrrolidine (EDDP).¹⁸⁰ Subsequent *N*-demethylation of EDDP and isomerization of the double bond leads to 2-ethyl-5-methyl-3,3-diphenyl-1-pyrroline (EMDP).

Many times, bisdealkylation of a tertiary amine leads to the corresponding primary aliphatic amine metabolite, which is susceptible to further oxidation. For example, the

bisdemethyl metabolite of the H₁-histamine antagonist brompheniramine (Dimetane) undergoes oxidative deamination and further oxidation to the corresponding propionic acid metabolite.¹⁸¹ Oxidative deamination is discussed in greater detail when we examine the metabolic reactions of secondary and primary amines.

Like their aliphatic counterparts, alicyclic tertiary amines are susceptible to oxidative *N*-dealkylation reactions. For example, the analgesic meperidine (Demerol) is metabolized principally by this pathway to yield normeperidine as a major plasma metabolite in humans.¹⁸² Morphine, *N*-ethylnormorphine, and dextromethorphan also undergo some *N*-dealkylation.¹⁸³

Direct *N*-dealkylation of *t*-butyl groups, as discussed below, is not possible by the α -carbon hydroxylation pathway. In vitro studies indicate, however, that *N*-*t*-butyl-norchlorocyclizine is, indeed, metabolized to significant amounts of norchlorocyclizine, whereby the *t*-butyl group is lost.¹⁸⁴ Careful studies showed that the *t*-butyl group is removed by initial hydroxylation of one of the methyl groups of the *t*-butyl moiety to the carbinol or alcohol product.¹⁸⁵ Further oxidation generates the corresponding carboxylic acid that, on decarboxylation, forms the *N*-isopropyl derivative. The *N*-isopropyl intermediate is dealkylated by the normal α -carbon hydroxylation (i.e., carbinolamine) pathway to give norchlorocyclizine and acetone. Whether this is a general method for the loss of *t*-butyl groups from amines is still unclear. Indirect *N*-dealkylation of *t*-butyl groups is not observed significantly. The *N*-*t*-butyl group present in many β -adrenergic antagonists, such as terbutaline and

salbutamol, remains intact and does not appear to undergo any significant metabolism.¹⁸⁶

Alicyclic tertiary amines often generate lactam metabolites by α -carbon hydroxylation reactions. For example, the tobacco alkaloid nicotine is hydroxylated initially at the ring carbon atom α to the nitrogen to yield a carbinolamine intermediate. Furthermore, enzymatic oxidation of this cyclic carbinolamine generates the lactam metabolite cotinine.^{187,188}

Formation of lactam metabolites also has been reported to occur to a minor extent for the antihistamine cyprohep-

tadine (Periactin)^{189,190} and the antiemetic diphenidol (Vontrol).¹⁹¹

N-oxidation of tertiary amines occurs with several drugs.¹⁹² The true extent of *N*-oxide formation often is complicated by the susceptibility of *N*-oxides to undergo *in vivo* reduction back to the parent tertiary amine. Tertiary amines such as H_1 -histamine antagonists (e.g., orphenadrine, triprolidine), phenothiazines (e.g., chlorpromazine), tricyclic antidepressants (e.g., imipramine), and narcotic analgesics (e.g., morphine, codeine, and meperidine) reportedly form

N-oxide products. In some instances, *N*-oxides possess pharmacological activity.¹⁹³ A comparison of imipramine *N*-oxide with imipramine indicates that the *N*-oxide itself possesses antidepressant and cardiovascular activity similar to that of the parent drug.^{194,195}

Secondary and Primary Amines. Secondary amines (either parent compounds or metabolites) are susceptible to oxidative *N*-dealkylation, oxidative deamination, and *N*-oxidation reactions.^{163,196} As in tertiary amines, *N*-dealkylation of secondary amines proceeds by the carbinolamine pathway. Dealkylation of secondary amines gives rise to the corresponding primary amine metabolite. For example, the α -adrenergic blockers propranolol^{46,47} and

oxprenolol¹⁹⁷ undergo *N*-deisopropylation to the corresponding primary amines. *N*-dealkylation appears to be a significant biotransformation pathway for the secondary amine drugs methamphetamine^{198,199} and ketamine,^{200,201} yielding amphetamine and norketamine, respectively.

The primary amine metabolites formed from oxidative dealkylation are susceptible to *oxidative deamination*. This process is similar to *N*-dealkylation, in that it involves an initial α -carbon hydroxylation reaction to form a carbinolamine intermediate, which then undergoes subsequent carbon–nitrogen cleavage to the carbonyl metabolite and ammonia. If α -carbon hydroxylation cannot occur, then oxidative deamination is not possible. For example, deamination does not occur for norketamine because α -carbon hydroxylation cannot take place.^{200,201} With methamphetamine, oxidative deamination of primary amine metabolite amphetamine produces phenylacetone.^{198,199}

In general, dealkylation of secondary amines is believed to occur before oxidative deamination. Some evidence indicates, however, that this may not always be true. Direct deamination of the secondary amine also has occurred. For example, in addition to undergoing deamination through its desisopropyl primary amine metabolite, propranolol can undergo a direct oxidative deamination reaction (also by α -carbon hydroxylation) to yield the aldehyde metabolite and isopropylamine (Fig. 3.9).²⁰² How much direct oxidative deamination contributes to the metabolism of secondary amines remains unclear.

Some secondary alicyclic amines, like their tertiary amine analogs, are metabolized to their corresponding lactam derivatives. For example, the anorectic agent phenmetrazine (Preludin) is metabolized principally to the lactam product 3-oxophenmetrazine.²⁰³ In humans, this lactam metabolite is a major urinary product. Methylphenidate (Ritalin) also reportedly yields a lactam metabolite, 6-oxori-

Figure 3.9 • Metabolism of propranolol to its aldehyde metabolite by direct deamination of the parent compound and by deamination of its primary amine metabolite, desisopropyl propranolol.

talinic acid, by oxidation of its hydrolyzed metabolite, ritalinic acid, in humans.²⁰⁴

Metabolic *N*-oxidation of secondary aliphatic and alicyclic amines leads to several *N*-oxygenated products.¹⁹⁶ *N*-hydroxylation of secondary amines generates the corresponding *N*-hydroxylamine metabolites. Often, these

hydroxylamine products are susceptible to further oxidation (either spontaneous or enzymatic) to the corresponding nitronne derivatives. *N*-benzylamphetamine undergoes metabolism to both the corresponding *N*-hydroxylamine and the nitronne metabolites.²⁰⁵ In humans, the nitronne metabolite of phenmetrazine (Preludin), found in the urine, is believed to be formed by further oxidation of the *N*-hydroxylamine intermediate *N*-hydroxyphenmetrazine.²⁰³ Importantly, much less *N*-oxidation occurs for secondary amines than oxidative dealkylation and deamination.

Primary aliphatic amines (whether parent drugs or metabolites) are biotransformed by oxidative deamination (through the carbinolamine pathway) or by *N*-oxidation. In general, oxidative deamination of most exogenous primary amines is

carried out by the mixed-function oxidases discussed previously. Endogenous primary amines (e.g., dopamine, norepinephrine, tryptamine, and serotonin) and xenobiotics based on the structures of these endogenous neurotransmitters are metabolized, however, via oxidative deamination by a specialized family of enzymes called *monoamine oxidases* (MAOs).²⁰⁶

MAO is a flavin (FAD)-dependent enzyme found in two isozyme forms, MAO-A and MAO-B, and widely distributed in both the CNS and peripheral organs. In contrast, CYP exists in a wide variety of isozyme forms and is an NADP-dependent system. Also the greatest variety of CYP isozymes, at least the ones associated with the metabolism of xenobiotics, are found mostly in the liver and intestinal mucosa. MAO-A and MAO-B are coded by two genes, both on the X-chromosome and have about 70% amino acid sequence homology. Another difference between the CYP and MAO

families is cellular location. CYP enzymes are found on the endoplasmic reticulum of the cell's cytosol, whereas the MAO enzymes are on the outer mitochondrial membrane. In addition to the xenobiotics illustrated in the reaction schemes, other drugs metabolized by the MAO system include phenylephrine, propranolol, timolol and other β -adrenergic agonists and antagonists, and various phenylethylamines.²⁰⁶

Structural features, especially the α -substituents of the primary amine, often determine whether carbon or nitrogen oxidation will occur. For example, compare amphetamine with its α -methyl homologue phentermine. In amphetamine, α -carbon hydroxylation can occur to form the carbinolamine intermediate, which is converted to the oxidatively deaminated product phenylacetone.⁶⁷ With phentermine, α -carbon hydroxylation is not possible and precludes oxidative deamination for this drug. Consequently, phentermine would be expected to undergo *N*-oxidation readily. In humans, *p*-hydroxylation and *N*-oxidation are the main pathways for biotransformation of phentermine.²⁰⁷

Indeed, *N*-hydroxyphentermine is an important (5%) urinary metabolite in humans.²⁰⁷ As discussed below, *N*-hydroxylamine metabolites are susceptible to further oxidation to yield other *N*-oxygenated products.

Xenobiotics, such as the hallucinogenic agents mescaline^{208,209} and 1-(2,5-dimethoxy-4-methylphenyl)-2-amino propane (DOM or "STP"),^{210,211} are oxidatively deaminated. Primary amine metabolites arising from *N*-dealkylation or decarboxylation reactions also undergo deamination. The example of the bisdesmethyl primary amine metabolite derived from brompheniramine is discussed previously in this chapter (see section on tertiary aliphatic and alicyclic amines).¹⁸¹ In addition, many tertiary aliphatic amines (e.g., antihistamines) and secondary aliphatic amines (e.g., propranolol) are dealkylated to their corresponding primary amine metabolites, which are amenable to oxidative deamination. (*S*)(+)- α -Methyl dopamine resulting from decarboxylation of the antihypertensive agent (*S*)(-)- α -methyl dopa (Aldomet) is deaminated to the corresponding ketone metabolite 3,4-dihydroxyphenylacetone.²¹² In humans, this ketone is a major urinary metabolite.

The *N*-hydroxylation reaction is not restricted to α -substituted primary amines such as phentermine. Amphetamine has been observed to undergo some *N*-hydroxylation *in vitro* to *N*-hydroxyamphetamine.^{213,214} *N*-Hydroxyamphetamine is, however, susceptible to further conversion to the imine or oxidation to the oxime intermediate. Note that the oxime intermediate arising from this *N*-oxidation pathway can undergo hydrolytic cleavage to yield phenylacetone, the same product obtained by the α -carbon hydroxylation (carbinolamine)

pathway.^{215,216} Thus, amphetamine may be converted to phenylacetone through either the α -carbon hydroxylation or the *N*-oxidation pathway. The debate concerning the relative importance of the two pathways is ongoing.²¹⁷⁻²¹⁹ The consensus, however, is that both metabolic pathways (carbon and nitrogen oxidation) are probably operative. Whether α -carbon or nitrogen oxidation predominates in the metabolism of amphetamine appears to be species dependent.

In primary aliphatic amines, such as phentermine,²⁰⁷ chlorphentermine (*p*-chlorphentermine),²¹⁹ and amantadine,²²⁰ *N*-oxidation appears to be the major biotransformation pathway because α -carbon hydroxylation cannot occur. In humans, chlorphentermine is *N*-hydroxylated extensively. About 30% of a dose of chlorphentermine is found in the urine (48 hours) as *N*-hydroxychlorphentermine (free and conjugated) and an additional 18% as other products of *N*-oxidation (presumably the nitroso and nitro metabolites).²¹⁹ In general, *N*-hydroxylamines are chemically unstable and susceptible to spontaneous or enzymatic oxidation to the nitroso and nitro derivatives. For example, the *N*-hydroxylamine metabolite of phentermine undergoes further oxidation to the nitroso and nitro products.²⁰⁷ The antiviral and antiparkinsonian agent amantadine (Symmetrel) reportedly undergoes *N*-oxidation to yield the corresponding *N*-hydroxy and nitroso metabolites *in vitro*.²²⁰

Aromatic Amines and Heterocyclic Nitrogen Compounds. The biotransformation of aromatic amines parallels the carbon and nitrogen oxidation reactions seen for aliphatic amines.^{221–223} For tertiary aromatic amines, such as *N,N*-dimethylaniline, oxidative *N*-dealkylation as well as *N*-oxide formation take place.²²⁴ Secondary aromatic amines may undergo *N*-dealkylation or *N*-hydroxylation to give the corresponding *N*-hydroxylamines. Further oxidation of the *N*-hydroxylamine leads to nitronium products, which in turn may be hydrolyzed to primary hydroxylamines.²²⁵ Tertiary and secondary aromatic amines are encountered rarely in medicinal agents. In contrast, primary aromatic amines are found in many drugs and are often generated from enzymatic reduction of aromatic nitro compounds, reductive cleavage of azo compounds, and hydrolysis of aromatic amides.

N-oxidation of primary aromatic amines generates the *N*-hydroxylamine metabolite. One such case is aniline, which is metabolized to the corresponding *N*-hydroxy product.²²³ Oxidation of the hydroxylamine derivative to the nitroso derivative also can occur. When one considers primary aromatic amine drugs or metabolites, *N*-oxidation constitutes only a minor pathway in comparison with other biotransformation pathways, such as *N*-acetylation and aromatic hydroxylation, in humans. Some *N*-oxygenated metabolites have been reported, however. For example, the antileprotic agent dapsone and its *N*-acetylated metabolite are metabolized significantly to their corresponding *N*-hydroxylamine derivatives.²²⁶ The *N*-hydroxy metabolites are further conjugated with glucuronic acid.

Methemoglobinemia toxicity is caused by several aromatic amines, including aniline and dapsone, and is a result of the bioconversion of the aromatic amine to its *N*-hydroxy derivative. Apparently, the *N*-hydroxylamine oxidizes the Fe²⁺ form of hemoglobin to its Fe³⁺ form. This oxidized (Fe³⁺) state of hemoglobin (called *methemoglobin* or *ferrihemoglobin*) can no longer transport oxygen, which leads to serious hypoxia or anemia, a unique type of chemical suffocation.²²⁷

Diverse aromatic amines (especially azoamino dyes) are known to be carcinogenic. *N*-oxidation plays an important

role in bioactivating these aromatic amines to potentially reactive electrophilic species that covalently bind to cellular protein, DNA, or RNA. A well-studied example is the carcinogenic agent *N*-methyl-4-aminoazobenzene.^{228,229} *N*-oxidation of this compound leads to the corresponding hydroxylamine, which undergoes sulfate conjugation. Because of the good leaving-group ability of the sulfate (SO₄²⁻) anion, this conjugate can ionize spontaneously to form a highly reactive, resonance-stabilized nitrenium species. Covalent adducts between this species and DNA, RNA, and proteins have been characterized.^{230,231} The sulfate ester is believed to be the ultimate carcinogenic species. Thus, the example indicates that certain aromatic amines can be bioactivated to reactive intermediates by *N*-hydroxylation and *O*-sulfate conjugation. Whether primary hydroxylamines can be bioactivated similarly is unclear. In addition, it is not known if this biotransformation pathway plays any substantial role in the toxicity of aromatic amine drugs.

N-oxidation of the nitrogen atoms present in aromatic heterocyclic moieties of many drugs occurs to a minor extent. Clearly, in humans, *N*-oxidation of the folic acid antagonist trimethoprim (Proloprim, Trimplex) has yielded approximately equal amounts of the isomeric 1-*N*-oxide and 3-*N*-oxide as minor metabolites.²³² The pyridinyl nitrogen atom present in nicotine (the major metabolite of nicotine) undergoes oxidation to yield the corresponding *N*-oxide metabolite.²³³ Another therapeutic agent that has been observed to undergo formation of an *N*-oxide metabolite is metronidazole.²³⁴

Amides. Amide functionalities are susceptible to oxidative carbon–nitrogen bond cleavage (via α -carbon hydroxylation) and *N*-hydroxylation reactions. Oxidative dealkylation of many *N*-substituted amide drugs and xenobiotics has been reported. Mechanistically, oxidative dealkylation proceeds via an initially formed carbinolamide, which is unstable and fragments to form the *N*-dealkylated product. For example, diazepam undergoes extensive *N*-demethylation to the pharmacologically active metabolite desmethyldiazepam.²³⁵

Various other *N*-alkyl substituents present in benzodiazepines (e.g., flurazepam)^{136–138} and in barbiturates (e.g., hexobarbital and mephobarbital)¹²⁸ are similarly oxidatively *N*-dealkylated. Alkyl groups attached to the amide moiety of some sulfonylureas, such as the oral hypoglycemic chlorpropamide,²³⁶ also are subject to dealkylation to a minor extent.

In the cyclic amides or lactams, hydroxylation of the alicyclic carbon α to the nitrogen atom also leads to carbinolamides. An example of this pathway is the conversion of cytocine to 5-hydroxycytocine. Interestingly, the latter carbinolamide intermediate is in tautomeric equilibrium with the ring-opened metabolite γ -(3-pyridyl)- γ -oxo-*N*-methylbutyramide.²³⁷

Metabolism of the important cancer chemotherapeutic agent cyclophosphamide (Cytoxan) follows a hydroxylation pathway similar to that just described for cyclic amides. This

drug is a cyclic phosphoramidate derivative and, for the most part, is the phosphorous counterpart of a cyclic amide. Because cyclophosphamide itself is pharmacologically inactive,²³⁸ metabolic bioactivation is required for the drug to mediate its antitumorigenic or cytotoxic effects. The key biotransformation pathway leading to the active metabolite involves an initial carbon hydroxylation reaction at C-4 to form the carbinolamide.^{239,240}

4-Hydroxycyclophosphamide is in equilibrium with the ring-opened dealkylated metabolite aldophosphamide. Although it has potent cytotoxic properties, aldophosphamide undergoes a further elimination reaction (reverse Michael reaction) to generate acrolein and the phosphoramidate mustard *N,N*-bis(2-chloro-ethyl)phosphorodiamidic acid. The latter is the principal species responsible for cyclophosphamide's antitumorigenic properties and

chemotherapeutic effect. Enzymatic oxidation of 4-hydroxycyclophosphamide and aldophosphamide leads to the relatively nontoxic metabolites 4-ketocyclophosphamide and carboxycyclophosphamide, respectively.

N-hydroxylation of aromatic amides, which occurs to a minor extent, is of some toxicological interest, because this biotransformation pathway may lead to the formation of chemically reactive intermediates. Several examples of cytotoxicity or carcinogenicity associated with metabolic *N*-hydroxylation of the parent aromatic amide have been reported. For example, the well-known hepatocarcinogenic 2-acetylaminofluorene (AAF) undergoes an *N*-hydroxylation reaction catalyzed by CYP to form the corresponding *N*-hydroxy metabolite (also called a *hydroxamic acid*).²⁴¹ Further conjugation of this hydroxamic acid produces the corresponding *O*-sulfate ester, which ionizes to generate the electrophilic nitrenium species. Covalent binding of this reactive intermediate to DNA is known to occur and is likely to be the initial event that ultimately leads to malignant tumor formation.²⁴² Sulfate conjugation plays an important role in this biotransformation pathway (see “Sulfate Conjugation,” for further discussion).

Acetaminophen is a relatively safe and nontoxic analgesic agent if used at therapeutic doses. Its metabolism illustrates the fact that a xenobiotic commonly produces more than one metabolite. Its metabolism also illustrates the effect of age, because infants and young children carry out sulfation rather than glucuronidation (see discussion at the end of this chapter). New pharmacists must realize that at one time acetanilide and phenacetin were more widely used than acetaminophen, even though both are considered more toxic because they pro-

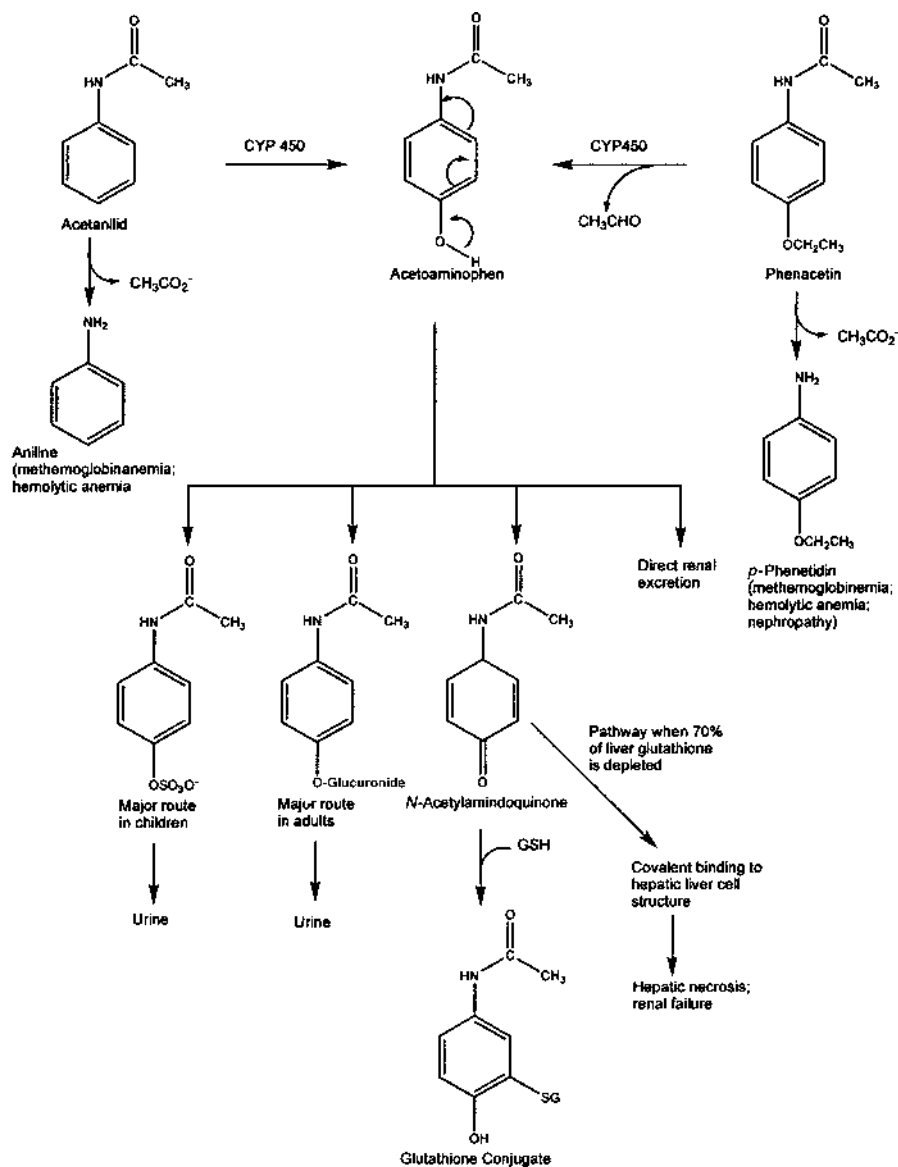

duce aniline derivatives. Besides producing toxic aniline and *p*-phenetidin, these two analgesics also produce acetaminophen. When large doses of the latter drug are ingested, extensive liver necrosis is produced in humans and animals.^{243,244} Considerable evidence argues that this hepatotoxicity depends on the formation of a metabolically generated reactive intermediate.²⁴⁵ Until recently,^{246,247} the accepted bioactivation pathway was believed to involve an initial *N*-hydroxylation reaction to form *N*-hydroxyacetaminophen.²⁴⁸

Spontaneous dehydration of this *N*-hydroxyamide produces *N*-acetylimidoquinone, the proposed reactive metabolite. Usually, the GSH present in the liver combines with this reactive metabolite to form the corresponding GSH conjugate. If GSH levels are sufficiently depleted by large doses of acetaminophen, covalent binding of the reactive intermediate occurs with macromolecules present in the liver, thereby leading to cellular necrosis. Studies indicate, however, that the reactive *N*-acetylimidoquinone intermediate is not formed from *N*-hydroxyacetaminophen.^{245–247} It probably arises through some other oxidative process. Therefore, the mechanistic formation of the reactive metabolite of acetaminophen remains unclear.

OXIDATION INVOLVING CARBON–OXYGEN SYSTEMS

Oxidative *O*-dealkylation of carbon–oxygen systems (principally ethers) is catalyzed by microsomal mixed function oxidases.¹⁶³ Mechanistically, the biotransformation involves an initial α -carbon hydroxylation to form either a hemiacetal or a hemiketal, which undergoes spontaneous carbon–oxygen

bond cleavage to yield the dealkylated oxygen species (phenol or alcohol) and a carbon moiety (aldehyde or ketone). Small alkyl groups (e.g., methyl or ethyl) attached to oxygen are *O*-dealkylated rapidly. For example, morphine is the metabolic product of *O*-demethylation of codeine.²⁴⁹ The antipyretic and analgesic activities of phenacetin (see drawing of acetaminophen metabolism) in humans appear to be a consequence of *O*-deethylation to the active metabolite acetaminophen.²⁵⁰ Several other drugs containing ether groups, such as indomethacin (Indocin),^{251,252} prazosin (Minipress),^{253,254} and metoprolol (Lopressor),^{122,123} have reportedly undergone significant *O*-demethylation to their corresponding phenolic or alcoholic metabolites, which are further conjugated. In many drugs that have several nonequivalent methoxy groups, one particular methoxy group often appears to be *O*-demethylated selectively or preferentially. For example, the 3,4,5-trimethoxyphenyl moiety in both mescaline²⁵⁵ and trimethoprim²³² undergoes *O*-demethylation to yield predominantly the corresponding 3-*O*-demethylated metabolites. 4-*O*-demethylation also occurs to a minor extent for both drugs. The phenolic and alcoholic metabolites formed from oxidative *O*-demethylation are susceptible to conjugation, particularly glucuronidation.

OXIDATION INVOLVING CARBON-SULFUR SYSTEMS

Carbon-sulfur functional groups are susceptible to metabolic *S*-dealkylation, desulfuration, and *S*-oxidation reactions. The first two processes involve oxidative

carbon-sulfur bond cleavage. *S*-dealkylation is analogous to *O*- and *N*-dealkylation mechanistically (i.e., it involves α -carbon hydroxylation) and has been observed for various sulfur xenobiotics.^{163,256} For example, 6-(methylthio)purine is demethylated oxidatively in rats to 6-mercaptapurine.^{257,258} *S*-demethylation of methitural²⁵⁹ and *S*-debenzylation of 2-benzylthio-5-trifluoromethylbenzoic acid also have been reported. In contrast to *O*- and *N*-dealkylation, examples of drugs undergoing *S*-dealkylation in humans are limited because of the small number of sulfur-containing medicinals and the competing metabolic *S*-oxidation processes (see diagram).

Oxidative conversion of carbon-sulfur double bonds (C=S) (thiono) to the corresponding carbon-oxygen double bond (C=O) is called *desulfuration*. A well-known drug example of this metabolic process is the biotransformation of thiopental to its corresponding oxygen analog pentobarbital.^{260,261} An analogous desulfuration reaction also occurs with the P=S moiety present in several organophosphate insecticides, such as parathion.^{262,263} Desulfuration of parathion leads to the formation of paraoxon, which is the active metabolite responsible for the anticholinesterase activity of the parent drug. The mechanistic details of desulfuration are poorly understood, but it appears to involve microsomal oxidation of the C=S or P=S double bond.²⁶⁴

Organosulfur xenobiotics commonly undergo *S*-oxidation to yield sulfoxide derivatives. Several phenothiazine derivatives are metabolized by this pathway. For example, both sulfur atoms present in thioridazine (Mellaril)^{265,266} are susceptible to *S*-oxidation. Oxidation of the 2-methylthio

group yields the active sulfoxide metabolite mesoridazine. Interestingly, mesoridazine is twice as potent an antipsychotic agent as thioridazine in humans and has been introduced into clinical use as Serentil.²⁶⁷

S-oxidation constitutes an important pathway in the metabolism of the H₂-histamine antagonists cimetidine (Tagamet)²⁶⁸ and metiamide.²⁶⁹ The corresponding sulfoxide derivatives are the major human urinary metabolites.

Sulfoxide drugs and metabolites may be further oxidized to sulfones (-SO₂-). The sulfoxide group present in the immunosuppressive agent oxisuran is metabolized to a sulfone moiety.²⁷⁰ In humans, dimethylsulfoxide (DMSO) is found primarily in the urine as the oxidized product dimethylsulfone. Sulfoxide metabolites, such as those of thioridazine, reportedly undergo further oxidation to their sulfone -SO₂-derivatives.^{265,266}

Oxidation of Alcohols and Aldehydes

Many oxidative processes (e.g., benzylic, allylic, alicyclic, or aliphatic hydroxylation) generate alcohol or carbinol metabolites as intermediate products. If not conjugated, these alcohol products are further oxidized to aldehydes (if primary alcohols) or to ketones (if secondary alcohols). Aldehyde metabolites resulting from oxidation of primary alcohols or from oxidative deamination of primary aliphatic

amines often undergo facile oxidation to generate polar carboxylic acid derivatives.¹¹⁶ As a general rule, primary alcoholic groups and aldehyde functionalities are quite vulnerable to oxidation. Several drug examples in which primary alcohol metabolites and aldehyde metabolites are oxidized to carboxylic acid products are cited in previous sections.

Although secondary alcohols are susceptible to oxidation, this reaction is not often important because the reverse reaction, namely, reduction of the ketone back to the secondary alcohol, occurs quite readily. In addition, the secondary alcohol group, being polar and functionalized, is more likely to be conjugated than the ketone moiety.

The bioconversion of alcohols to aldehydes and ketones is catalyzed by soluble alcohol dehydrogenases present in the liver and other tissues. NAD⁺ is required as a coenzyme, although NADP⁺ also may serve as a coenzyme. The reaction catalyzed by alcohol dehydrogenase is reversible but often proceeds to the right because the aldehyde formed

is further oxidized to the acid. Several aldehyde dehydrogenases, including aldehyde oxidase and xanthine oxidase, carry out the oxidation of aldehydes to their corresponding acids.^{116,271–273}

Metabolism of cyclic amines to their lactam metabolites has been observed for various drugs (e.g., nicotine, phenmetrazine, and methylphenidate). It appears that soluble or microsomal dehydrogenase and oxidases are involved in oxidizing the carbinol group of the intermediate carbinolamine to a carbonyl moiety.²⁷³ For example, in the metabolism of medazepam to diazepam, the intermediate carbinolamine (2-hydroxymedazepam) undergoes oxidation of its 2-hydroxy group to a carbonyl moiety. A microsomal dehydrogenase carries out this oxidation.²⁷⁴

Other Oxidative Biotransformation Pathways

In addition to the many oxidative biotransformations discussed previously in this chapter, oxidative aromatization or dehydrogenation and oxidative dehalogenation reactions also occur. Metabolic aromatization has been reported for norgestrel. Aromatization or dehydrogenation of the A ring present in this steroid leads to the corresponding phenolic product 17 α -ethinyl-18-homoestradiol as a minor metabolite in women.²⁷⁵ In mice, the terpene ring of Δ^1 -THC or $\Delta^{1,6}$ -THC undergoes aromatization to give cannabinol.^{276,277}

Many halogen-containing drugs and xenobiotics are metabolized by oxidative dehalogenation. For example, the volatile anesthetic agent halothane is metabolized principally to trifluoroacetic acid in humans.^{278,279} It has been postulated that this metabolite arises from CYP-mediated hydroxylation of halothane to form an initial carbinol intermediate that spontaneously eliminates hydrogen bromide (dehalogenation) to yield trifluoroacetyl

chloride. The latter acyl chloride is chemically reactive and reacts rapidly with water to form trifluoroacetic acid. Alternatively, it can acylate tissue nucleophiles. Indeed, *in vitro* studies indicate that halothane is metabolized to a reactive intermediate (presumably trifluoroacetyl chloride), which covalently binds to liver microsomal proteins.^{280,281} Chloroform also appears to be metabolized oxidatively by a similar dehalogenation pathway to yield the chemically reactive species phosgene. Phosgene may be responsible for the hepatotoxicity and nephrotoxicity associated with chloroform.²⁸²

A final example of oxidative dehalogenation concerns the antibiotic chloramphenicol. *In vitro* studies have shown that the dichloroacetamide portion of the molecule undergoes oxidative dechlorination to yield a chemically reactive oxamyl chloride intermediate that can react with water to form the corresponding oxamic acid metabolite or can acylate microsomal proteins.^{283,284} Thus, it appears that in several instances, oxidative dehalogenation can lead to the formation of toxic and reactive acyl halide intermediates.

REDUCTIVE REACTIONS

Reductive processes play an important role in the metabolism of many compounds containing carbonyl, nitro, and azo groups. Bioreduction of carbonyl compounds generates alcohol derivatives,^{116,285} whereas nitro and azo reductions lead to amino derivatives.²⁸⁶ The hydroxyl and amino moieties of the metabolites are much more susceptible to conjugation than the functional groups of the parent compounds. Hence, reductive processes, as such, facilitate drug elimination.

Reductive pathways that are encountered less frequently in drug metabolism include reduction of *N*-oxides to their corresponding tertiary amines and reduction of sulfoxides to sulfides. Reductive cleavage of disulfide linkages and reduction of carbon-carbon double bonds also occur, but constitute only minor pathways in drug metabolism.

Reduction of Aldehyde and Ketone Carbonyls

The carbonyl moiety, particularly the ketone group, is encountered frequently in many drugs. In addition, metabolites containing ketone and aldehyde functionalities often arise from oxidative deamination of xenobiotics (e.g., propranolol, chlorpheniramine, amphetamine). Because of their ease of oxidation, aldehydes are metabolized mainly to carboxylic acids. Occasionally, aldehydes are reduced to primary alcohols. Ketones, however, are generally resistant to oxidation and are reduced mainly to secondary alcohols. Alcohol metabolites arising from reduction of carbonyl compounds generally undergo further conjugation (e.g., glucuronidation).

Diverse soluble enzymes, called *aldo-keto reductases*, carry out bioreduction of aldehydes and ketones.^{116,287} They are found in the liver and other tissues (e.g., kidney). As a general class, these soluble enzymes have similar physicochemical properties and broad substrate specificities and require NADPH as a cofactor. Oxidoreductase enzymes that carry out both oxidation and reduction reactions also can reduce aldehydes and ketones.²⁸⁷ For example, the important liver alcohol dehydrogenase is an NAD⁺-dependent-oxidoreductase that oxidizes ethanol and other aliphatic alcohols to aldehydes and ketones. In the presence of NADH or NADPH, however, the same enzyme system can reduce carbonyl derivatives to their corresponding alcohols.¹¹⁶

Few aldehydes undergo bioreduction because of the relative ease of oxidation of aldehydes to carboxylic acids. However, one frequently cited example of a parent aldehyde drug undergoing extensive enzymatic reduction is the sedative-hypnotic chloral hydrate. Bioreduction of this hydrated aldehyde yields trichloroethanol as the major metabolite in humans.²⁸⁸ Interestingly, this alcohol metabolite is pharmacologically active. Further glucuronidation of the alcohol leads to an inactive conjugated product that is readily excreted in the urine.

Aldehyde metabolites resulting from oxidative deamination of drugs also undergo reduction to a minor extent. For example, in humans the β -adrenergic blocker propranolol is converted to an intermediate aldehyde by *N*-dealkylation and oxidative deamination. Although the aldehyde is oxidized primarily to the corresponding carboxylic acid (naphthoxylactic acid), a small fraction is also reduced to the alcohol derivative (propranolol glycol).²⁸⁹

Two major polar urinary metabolites of the histamine H₁-antagonist chlorpheniramine have been identified in dogs as the alcohol and carboxylic acid products (conjugated) derived, respectively, by reduction and oxidation of an aldehyde metabolite. The aldehyde precursor arises from bis-*N*-demethylation and oxidative deamination of chlorpheniramine.²⁹⁰

Bioreduction of ketones often leads to the creation of an asymmetric center and, thereby, two possible stereoisomeric alcohols.^{116,291} For example, reduction of acetophenone by a soluble rabbit kidney reductase leads to the enantiomeric alcohols (*S*)(-)- and (*R*)(+)-methylphenylcarbinol, with the (*S*)(-)-isomer predominating (3:1 ratio).²⁹² The preferential formation of one stereoisomer over the other is termed *product stereoselectivity* in drug metabolism.²⁹¹ Mechanistically, ketone reduction involves a "hydride" transfer from the reduced nicotinamide moiety of the cofactor NADPH or NADH to the carbonyl carbon atom of the ketone. It is generally agreed that this step proceeds with considerable *stereoselectivity*.^{116,291} Consequently, it is not surprising to find many reports of xenobiotic ketones that are reduced preferentially to a predominant stereoisomer. Often, ketone reduction yields alcohol metabolites that are pharmacologically active.

Although many ketone-containing drugs undergo significant reduction, only a few selected examples are presented in detail here. The xenobiotics that are not discussed in the text have been structurally tabulated in Figure 3.10. The keto group undergoing reduction is designated with an arrow.

Ketones lacking asymmetric centers in their molecules, such as acetophenone or the oral hypoglycemic acetohehexamide, usually give rise to predominantly one enantiomer on reduction. In humans, acetohehexamide is metabolized rapidly in the liver to give principally (*S*)(-)-hydroxyhexamide.^{293,294} This metabolite is as active a hypoglycemic agent as its parent compound and is eliminated through the kidneys.²⁹⁵ Acetohehexamide usually is not recommended in diabetic patients with renal failure, because of the possible accumulation of its active metabolite, hydroxyhexamide.

When chiral ketones are reduced, they yield two possible diastereomeric or epimeric alcohols. For example, the (*R*)(+) enantiomer of the oral anticoagulant warfarin undergoes extensive reduction of its side chain keto group to generate the (*R,S*)(+) alcohol as the major plasma metabolite in humans.^{56,296} Small amounts of the (*R,R*)(+) diastereomer are also formed. In contrast, the (*S*)(-) enantiomer undergoes little ketone reduction and is primarily 7-hydroxylated (i.e., aromatic hydroxylation) in humans.

Reduction of the 6-keto functionality in the narcotic antagonist naltrexone can lead to either the epimeric 6 α - or 6 β -hydroxy metabolites, depending on the animal species.^{297,298} In humans and rabbits, bioreduction of naltrexone is highly stereoselective and generates only 6 β -naltrexol, whereas in chickens, reduction yields only 6 α -

Figure 3.10 • Additional examples of xenobiotics that undergo extensive ketone reduction, not covered in the text. Arrow indicates the keto group undergoing reduction.

naltrexol.^{297–299} In monkeys and guinea pigs, however, both epimeric alcohols are formed (predominantly 6 β -naltrexol).^{300,301} Apparently, in the latter two species, reduction of naltrexone to the epimeric 6 α - and 6 β -alcohols is carried out by two distinctly different reductases found in the liver.^{299–301}

Reduction of oxisuran appears not to be an important pathway by which the parent drug mediates its immunosuppressive effects. Studies indicate that oxisuran has its greatest immunosuppressive effects in those species that form alcohols as their major metabolic products (e.g., human, rat).^{302–306} In species in which reduction is a minor pathway (e.g., dog), oxisuran shows little immunosuppressive activity.^{304–306} These findings indicate that the oxisuran alcohols (oxisuranols) are pharmacologically active and contribute substantially to the overall immunosuppressive effect of the parent drug. The sulfoxide group in oxisuran is chiral, by virtue of the lone pair of electrons on sulfur. Therefore, reduction of oxisuran leads to diastereomeric alcohols.

Reduction of α,β -unsaturated ketones results in reduction not only of the ketone group but of the carbon–carbon double bond as well. Steroidal drugs often fall into this class, including norethindrone, a synthetic progestin found in many oral contraceptive drug combinations. In women, the major plasma and urinary metabolite of norethindrone is the 3 $\beta,5\beta$ -tetrahydro derivative.³⁰⁷

Ketones resulting from metabolic oxidative deamination processes are also susceptible to reduction. For instance, rabbit liver microsomal preparations metabolize amphetamine to phenylacetone, which is reduced subsequently to 1-phenyl-2-propanol.³⁰⁸ In humans, a minor urinary metabolite of (-)-ephedrine has been identified as the diol derivative formed from keto reduction of the oxidatively deaminated product 1-hydroxy-1-phenylpropan-2-one.³⁰⁹

Reduction of Nitro and Azo Compounds

The reduction of aromatic nitro and azo xenobiotics leads to aromatic primary amine metabolites.²⁸⁶ Aromatic nitro compounds are reduced initially to the nitroso and hydroxylamine intermediates, as shown in the following metabolic sequence:

Azo reduction, however, is believed to proceed via a hydrazo intermediate (-NH-NH-) that subsequently is cleaved reductively to yield the corresponding aromatic amines:

Bioreduction of nitro compounds is carried out by NADPH-dependent microsomal and soluble nitro reductases present in the liver. A multicomponent hepatic microsomal

reductase system requiring NADPH appears to be responsible for azo reduction.^{310–312} In addition, bacterial reductases present in the intestine can reduce nitro and azo compounds, especially those that are absorbed poorly or excreted mainly in the bile.^{313,314}

Various aromatic nitro drugs undergo enzymatic reduction to the corresponding aromatic amines. For example, the 7-nitro benzodiazepine derivatives clonazepam and nitrazepam are metabolized extensively to their respective 7-amino metabolites in humans.^{315,316} The skeletal muscle relaxant dantrolene (Dantrium) also reportedly undergoes reduction to aminodantrolene in humans.^{317,318}

For some nitro xenobiotics, bioreduction appears to be a minor metabolic pathway *in vivo*, because of competing oxidative and conjugative reactions. Under artificial anaerobic *in vitro* incubation conditions, however, these same nitro xenobiotics are enzymatically reduced rapidly. For example, most of the urinary metabolites of metronidazole found in humans are either oxidation or conjugation products. Reduced metabolites of metronidazole have not been detected.³¹⁹ When incubated anaerobically with guinea pig liver preparations, however, metronidazole undergoes considerable nitro reduction.³²⁰

Bacterial reductase present in the intestine also tends to complicate *in vivo* interpretations of nitro reduction. For example, in rats, the antibiotic chloramphenicol is not reduced *in vivo* by the liver but is excreted in the bile and, subsequently, reduced by intestinal flora to form the amino metabolite.^{321,322}

The enzymatic reduction of azo compounds is best exemplified by the conversion of sulfamido-chrysoidine (Prontosil) to the active sulfanilamide metabolite in the liver.³²³ This reaction has historical significance, for it led to

the discovery of sulfanilamide as an antibiotic and eventually to the development of many of the therapeutic sulfonamide drugs. Bacterial reductases present in the intestine play a significant role in reducing azo xenobiotics, particularly those that are absorbed poorly.^{313,314} Accordingly, the two azo dyes tartrazine^{324,325} and amaranth³²⁶ have poor oral absorption because of the many polar and ionized zulfonic acid groups present in their structures.

Therefore, these two azo compounds are metabolized primarily by bacterial reductases present in the intestine. The importance of intestinal reduction is further revealed in the metabolism of sulfasalazine (formerly salicylazosulfapyridine, Azulfidine), a drug used in the treatment of ulcerative colitis. The drug is absorbed poorly and undergoes reductive cleavage of the azo linkage to yield sulfapyridine and 5-aminosalicylic acid.^{327,328} The reaction occurs primarily in the colon and is carried out principally by intestinal bacteria. Studies in germfree rats, lacking intestinal flora, have demonstrated that sulfasalazine is not reduced to any appreciable extent.³²⁹

Miscellaneous Reductions

Several minor reductive reactions also occur. Reduction of *N*-oxides to the corresponding tertiary amine occurs to some extent. This reductive pathway is of interest because several tertiary amines are oxidized to form polar and water-soluble *N*-oxide metabolites. If reduction of *N*-oxide metabolites occurs to a significant extent, drug elimination of the parent tertiary amine is impeded. *N*-Oxide reduction often is assessed by administering the pure synthetic *N*-oxide *in vitro* or *in vivo* and then attempting to detect the formation of the tertiary amine. For example, imipramine *N*-oxide undergoes reduction in rat liver preparations.³³⁰

Reduction of sulfur-containing functional groups, such as the disulfide and sulfoxide moieties, also constitutes a minor reductive pathway. Reductive cleavage of the disulfide bond in disulfiram (Antabuse) yields *N,N*-diethyldithiocarbamic acid (free or glucuronidated) as a major metabolite in humans.^{331,332} Although sulfoxide functionalities are oxidized mainly to sulfones ($-\text{SO}_2-$), they sometimes undergo reduction to sulfides. The

importance of this reductive pathway is seen in the metabolism of the anti-inflammatory agent sulindac (Clinoril). Studies in humans show that sulindac undergoes reduction to an active sulfide that is responsible for the overall anti-inflammatory effect of the parent drug.^{333,334} Sulindac or its sulfone metabolite exhibits little anti-inflammatory activity. Another example of sulfide formation involves the reduction of DMSO to dimethyl sulfide. In humans, DMSO is metabolized to a minor extent by this pathway. The characteristic unpleasant odor of dimethyl sulfide is evident on the breath of patients who use this agent.³³⁵

(Atromid-S) yields *p*-chlorophenoxyisobutyric acid (CPIB) as the major plasma metabolite in humans.³⁴⁴ Studies in rats indicate that the free acid CPIB is responsible for clofibrate's hypolipidemic effect.³⁴⁵

Many parent drugs have been chemically modified or derivatized to generate so-called prodrugs to overcome some undesirable property (e.g., bitter taste, poor absorption, poor solubility, irritation at site of injection). The rationale behind the prodrug concept was to develop an agent that, once inside the biological system, would be biotransformed to the active parent drug.¹⁸ The presence of esterases in many tissues and plasma makes ester derivatives logical prodrug candidates, because hydrolysis would cause the ester prodrug to revert to the parent compound. Accordingly, antibiotics such as chloramphenicol and clindamycin have been derivatized as their palmitate esters to minimize their bitter taste and to improve their palatability in pediatric liquid suspensions.^{346,347} After oral administration, intestinal esterases and lipases hydrolyze the palmitate esters to the free antibiotics. To improve the poor oral absorption of carbenicillin, a lipophilic indanyl ester has been formulated (Geocillin).³⁴⁸ Once orally absorbed, the ester is hydrolyzed rapidly to the parent drug. A final example involves derivatization of prednisolone to its C-21 hemisuccinate sodium salt. This water-soluble derivative is extremely useful for parenteral administration and is metabolized to the parent steroid drug by plasma and tissue esterases.³⁴⁹

Amides are hydrolyzed slowly in comparison to esters.³³⁷ Consequently, hydrolysis of the amide bond of procainamide is relatively slow compared with hydrolysis of the ester linkage in procaine.^{336,350} Drugs in which amide cleavage has been reported to occur, to some extent, include lidocaine,³⁵¹ carbamazepine,⁸⁷ indomethacin,^{251,252} and prazosin (Minipress).^{253,254} Amide linkages present in barbiturates (e.g., hexobarbital)^{352,353} as well as in hydantoins (e.g., 5-phenylhydantoin)^{354,355} and succinimides (phensuximide)^{354,355} are also susceptible to hydrolysis.

HYDROLYTIC REACTIONS

Hydrolysis of Esters and Amides

The metabolism of ester and amide linkages in many drugs is catalyzed by hydrolytic enzymes present in various tissues and in plasma. The metabolic products formed (carboxylic acids, alcohols, phenols, and amines) generally are polar and functionally more susceptible to conjugation and excretion than the parent ester or amide drugs. The enzymes carrying out ester hydrolysis include several nonspecific esterases found in the liver, kidney, and intestine as well as the pseudocholinesterases present in plasma.^{336,337} Amide hydrolysis appears to be mediated by liver microsomal amidases, esterases, and deacylases.³³⁷

Hydrolysis is a major biotransformation pathway for drugs containing an ester functionality. This is because of the relative ease of hydrolyzing the ester linkage. A classic example of ester hydrolysis is the metabolic conversion of aspirin (acetylsalicylic acid) to salicylic acid.³³⁸ Of the two ester moieties present in cocaine, it appears that, in general, the methyl group is hydrolyzed preferentially to yield benzoylcegonine as the major human urinary metabolite.³³⁹ The hydrolysis of cocaine to methylcegonine, however, also occurs in plasma and, to a minor extent, blood.^{340,341} Methylphenidate (Ritalin) is biotransformed rapidly by hydrolysis to yield ritalinic acid as the major urinary metabolite in humans.³⁴² Often, ester hydrolysis of the parent drug leads to pharmacologically active metabolites. For example, hydrolysis of diphenoxylate in humans leads to diphenoxylate acid (difenoxin), which is, apparently, 5 times more potent an antiarrhythmic agent than the parent ester.³⁴³ The rapid metabolism of clofibrate

Miscellaneous Hydrolytic Reactions

Hydrolysis of recombinant human peptide drugs and hormones at the N- or C-terminal amino acids by carboxypeptidase and aminopeptidase and proteases in blood and other

tissues is a well-recognized hydrolytic reaction.^{356,357} Examples of peptides or protein hormones undergoing hydrolysis include human insulin, growth hormone (GH), prolactin, parathyroid hormone (PTH), and atrial natriuretic factor (ANF).³⁵⁸

In addition to hydrolysis of amides and esters, hydrolytic cleavage of other moieties occurs to a minor extent in drug metabolism,⁸ including the hydrolysis of phosphate esters (e.g., diethylstilbestrol diphosphate), sulfonyleureas, cardiac glycosides, carbamate esters, and organophosphate compounds. Glucuronide and sulfate conjugates also can undergo hydrolytic cleavage by β -glucuronidase and sulfatase enzymes. These hydrolytic reactions are discussed in the following section. Finally, the hydration or hydrolytic cleavage of epoxides and arene oxides by epoxide hydrase is considered a hydrolytic reaction.

Miscellaneous Bioactivation of Prodrugs

Throughout this chapter, the metabolism of prodrugs to an active form is presented. However, in the cases presented earlier, there was a chemical functional group that was subject to phase I metabolism to release the active drug molecule.

The metabolic reactions included oxidative activation, reductive activation, hydrolytic activation, etc. One reaction that is of particular interest involves chemical activation as seen with the proton pump inhibitors, which are clinically used to treat gastric ulceration. When administered to a patient, the drug is dosed orally, allowing for systemic distribution. When the proton pump inhibitor arrives at an acidic region of the body, such as the parietal cells of the stomach, chemical activation occurs. The highly acidic environment in and around the parietal cell allows for protonation of nitrogen on the benzimidazole ring, followed by attachment of the pyridine nitrogen. Ring opening of the intermediate then yields the sulfenic acid that subsequently cyclizes with the loss of water. This intermediate is highly susceptible to nucleophilic attack by the SH moieties of the cysteine residues associated with proteins, including the proton pump of the parietal cells. This pump is responsible for exchange of K⁺ with H⁺ from parietal cell into gastric lumen, and through this inhibition, there is regulation of the acidic environment of stomach.

PHASE II OR CONJUGATION REACTIONS

Phase I or functionalization reactions do not always produce hydrophilic or pharmacologically inactive metabolites. Various phase II or conjugation reactions, however,

can convert these metabolites to more polar and water-soluble products. Many conjugative enzymes accomplish this objective by attaching small, polar, and ionizable endogenous molecules, such as glucuronic acid, sulfate, glycine, and glutamine, to the phase I metabolite or parent xenobiotic. The resulting conjugated products are relatively water soluble and readily excretable. In addition, they generally are biologically inactive and nontoxic. Other phase II reactions, such as methylation and acetylation, do not generally increase water solubility but mainly serve to terminate or attenuate pharmacological activity. The role of GSH is to combine with chemically reactive compounds to prevent damage to important biomacromolecules, such as DNA, RNA, and proteins. Thus, phase II reactions can be regarded as truly detoxifying pathways in drug metabolism, with a few exceptions.

A distinguishing feature of most phase II reactions is that the conjugating group (glucuronic acid, sulfate, methyl, and acetyl) is activated initially in the form of a coenzyme before transfer or attachment of the group to the accepting substrate by the appropriate transferase enzyme. In other cases, such as glycine and glutamine conjugation, the substrate is activated initially. Many endogenous compounds, such as bilirubin, steroids, catecholamines, and histamine, also undergo conjugation reactions and use the same coenzymes, although they appear to be mediated by more specific transferase enzymes. The phase II conjugative pathways

Figure 3.11 • Formation of UDPGA and β -glucuronide conjugates.

discussed include those previously listed in this chapter. Although other conjugative pathways exist (e.g., conjugation with glycosides, phosphate, and other amino acids and conversion of cyanide to thiocyanate), they are of minor importance in drug metabolism and are not covered in this chapter.

Glucuronic Acid Conjugation

Glucuronidation is the most common conjugative pathway in drug metabolism for several reasons: (a) a readily available supply of D-glucuronic acid (derived from D-glucose), (b) numerous functional groups that can combine enzymatically with glucuronic acid, and (c) the glucuronyl moiety (with its ionized carboxylate [pK_a 3.2] and polar hydroxyl groups), which, when attached to xenobiotic substrates, greatly increases the water solubility of the conjugated product.^{117,359–361} Formation of β -glucuronides involves two steps: synthesis of an activated coenzyme, uridine-5'-diphospho- α -D-glucuronic acid (UDPGA), and subsequent transfer of the glucuronyl group from UDPGA to an appropriate substrate.^{117,360,361} The transfer step is catalyzed by microsomal enzymes called *UDP-glucuronyltransferases*. They are found primarily in the liver but also occur in many other tissues, including kidney, intestine, skin, lung, and brain.^{360,361} The sequence of events involved in glucuronidation is summarized in Figure 3.11.^{117,360,361} The synthesis of the coenzyme UDPGA uses α -D-glucose-1-phosphate as its initial precursor. Note that all glucuronide conjugates have the β -configuration or β -linkage at C-1 (hence, the term *β -glucuronides*). In contrast, the coenzyme UDPGA has an α -linkage. In the enzymatic transfer step, it appears that nucleophilic displacement of the α -linked UDP moiety from UDPGA by the substrate RXH proceeds with complete inversion of configuration at C-1 to give the β -glucuronide. Glucuronidation of one functional group usually suffices to effect excretion of the conjugated metabolite; diglucuronide conjugates do not usually occur.

The diversity of functional groups undergoing glucuronidation is illustrated in Table 3.3 and Figure 3.12.

Metabolic products are classified as oxygen-, nitrogen-, sulfur-, or carbon-glucuronide, according to the heteroatom attached to the C-1 atom of the glucuronyl group. Two important functionalities, the hydroxy and carboxy, form *O*-glucuronides. Phenolic and alcoholic hydroxyls are the most common functional groups undergoing glucuronidation in drug metabolism. As we have seen, phenolic and alcoholic hydroxyl groups are present in many parent compounds and arise through various phase I metabolic pathways. Morphine,^{362,363} acetaminophen,³⁶⁴ and *p*-hydroxyphenytoin (the major metabolite of phenytoin)^{49,50} are a few examples of phenolic compounds that undergo considerable glucuronidation. Alcoholic

TABLE 3.3 Types of Compounds Forming Oxygen, Nitrogen, Sulfur, and Carbon Glucuronides^a

Oxygen Glucuronides
Hydroxyl compounds
Phenols: morphine, acetaminophen, <i>p</i> -hydroxyphenytoin
Alcohols: trichloroethanol, chloramphenicol, propranolol
Enols: 4-hydroxycoumarin
<i>N</i> -Hydroxyamines: <i>N</i> -hydroxydapsone
<i>N</i> -Hydroxyamides: <i>N</i> -hydroxy-2-acetylaminofluorene
Carboxyl compounds
Aryl acids: benzoic acid, salicylic acid
Arylalkyl acids: naproxen, fenoprofen
Nitrogen Glucuronides
Arylamines: 7-amino-5-nitroindazole
Alkylamines: desipramine
Amides: meprobamate
Sulfonamides: sulfisoxazole
Tertiary amines: cyproheptadine, tripeleminamine
Sulfur Glucuronides
Sulfhydryl groups: methimazole, propylthiouracil, diethylthiocarbamic acid
Carbon Glucuronides
3,5-Pyrazolidinedione: phenylbutazone, sulfipyrazone

^aFor structures and site of β -glucuronide attachment, see Figure 4.12.

Figure 3.12 • Structure of compounds that undergo glucuronidation. Arrows indicate sites of β -glucuronide attachment.

hydroxyls, such as those present in trichloroethanol (major metabolite of chloral hydrate),²⁸⁸ chloramphenicol,³⁶⁵ and propranolol,^{366,367} are also commonly glucuronidated. Less frequent is glucuronidation of other hydroxyl groups, such as enols,³⁶⁸ *N*-hydroxylamines,²²⁶ and *N*-hydroxylamides.²⁴¹ For examples, refer to the list of glucuronides in Table 3.3.

The carboxy group is also subject to conjugation with glucuronic acid. For example, arylaliphatic acids, such as the anti-inflammatory agents naproxen³⁶⁹ and fenpropfen,^{370,371} are excreted primarily as their *O*-glucuronide derivatives in humans. Carboxylic acid metabolites such as those arising from chlorpheniramine²⁹⁰ and propranolol²⁸⁹ (see "Reduction of Aldehyde and Ketone Carbonyls,") form *O*-glucuronide conjugates. Aryl acids (e.g., benzoic acid,³⁷² salicylic acid^{373,374}) also undergo conjugation with glucuronic acid, but conjugation with glycine appears to be a more important pathway for these compounds.

Occasionally, *N*-glucuronides are formed with aromatic amines, aliphatic amines, amides, and sulfonamides. Representative examples are found in the list of glucuronides in Table 3.3. Glucuronidation of aromatic and aliphatic amines is generally a minor pathway in comparison with *N*-acetylation or oxidative processes (e.g., oxidative deamination). Tertiary amines, such as the antihistaminic agents cyproheptadine (Periactin)³⁷⁵ and tripeleminamine,³⁷⁶ form interesting quaternary ammonium glucuronide metabolites.

Because the thiol group (SH) does not commonly occur in xenobiotics, *S*-glucuronide products have been reported for only a few drugs. For instance, the thiol groups present in methimazole (Tapazole),³⁷⁷ propylthiouracil,^{378,379} and *N,N*-diethyldithiocarbamic acid (major reduced metabolite of disulfiram, Antabuse)³⁸⁰ undergo conjugation with glucuronic acid.

The formation of glucuronides attached directly to a carbon atom is relatively novel in drug metabolism. Studies in humans have shown that conjugation of phenylbutazone (Butazoludin)^{381,382} and sulfinpyrazone (Anturane)³⁸³ yield the corresponding *C*-glucuronide metabolites:

Phenylbutazone, R = CH₂CH₂CH₂CH₃

Sulfinpyrazone, R = CH₂CH₂SC(=O)C₆H₅

Besides xenobiotics, several endogenous substrates, notably bilirubin³⁸⁴ and steroids,³⁸⁵ are eliminated as glucu-

ronide conjugates, which are excreted primarily in the urine. As the relative molecular mass of the conjugate exceeds 300 Da, however, biliary excretion may become an important route of elimination.³⁸⁶ Glucuronides that are excreted in the bile are susceptible to hydrolysis by β -glucuronidase enzymes present in the intestine. The hydrolyzed product may be reabsorbed in the intestine, thus leading to enterohepatic recycling.²² β -Glucuronidases are also present in many other tissues, including the liver, the endocrine system, and the reproductive organs. Although the function of these hydrolytic enzymes in drug metabolism is unclear, it appears that, in terms of hormonal and endocrine regulation, β -glucuronidases may liberate active hormones (e.g., steroids) from their inactive glucuronide conjugates.²²

In neonates and children, glucuronidating processes are often not developed fully. In such subjects, drugs and endogenous compounds (e.g., bilirubin) that are metabolized normally by glucuronidation may accumulate and cause serious toxicity. For example, neonatal hyperbilirubinemia may be attributable to the inability of newborns to conjugate bilirubin with glucuronic acid.³⁸⁷ Similarly, the inability of infants to glucuronidate chloramphenicol has been suggested to be responsible for the *gray baby syndrome*, which results from accumulation of toxic levels of the free antibiotic.³⁸⁸

Sulfate Conjugation

Conjugation of xenobiotics with sulfate occurs primarily with phenols and, occasionally, with alcohols, aromatic amines, and *N*-hydroxy compounds.³⁸⁹⁻³⁹¹ In contrast to glucuronic acid, the amount of available sulfate is rather limited. The body uses a significant portion of the sulfate pool to conjugate numerous endogenous compounds such as steroids, heparin, chondroitin, catecholamines, and thyroxine. The sulfate conjugation process involves activation of inorganic sulfate to the coenzyme 3'-phosphoadenosine-5'-phosphosulfate (PAPS). Subsequent transfer of the sulfate group from PAPS to the accepting substrate is catalyzed by various soluble sulfotransferases present in the liver and other tissues (e.g., kidney, intestine).³⁹² The sequence of events involved in sulfoconjugation is depicted in Figure 3.13. Sulfate conjugation generally leads to water-soluble and inactive metabolites. It appears, however, that the *O*-sulfate conjugates of some *N*-hydroxy compounds give rise to chemically reactive intermediates that are toxic.²⁴¹

Phenols compose the main group of substrates undergoing sulfate conjugation. Thus, drugs containing phenolic moieties are often susceptible to sulfate formation. For example, the antihypertensive agent α -methyldopa (Aldomet) is metabolized extensively to its 3-*O*-sulfate ester in humans.^{393,394} The β -adrenergic bronchodilators salbutamol (albuterol)³⁹⁵ and terbutaline (Brethine, Bricanyl)³⁹⁶ also undergo sulfate conjugation as their

Figure 3.13 • Formation of PAPS and sulfate conjugates.

principal route of metabolism in humans. For many phenols, however, sulfoconjugation may represent only a minor pathway. Glucuronidation of phenols is frequently a competing reaction and may predominate as the conjugative route for some phenolic drugs. In adults, the major urinary metabolite of the analgesic acetaminophen is the *O*-glucuronide conjugate, with the concomitant *O*-sulfate conjugate being formed in small amounts.³⁶⁴ Interestingly, infants and young children (ages 3–9 years) exhibit a different urinary excretion pattern: the *O*-sulfate conjugate is the main urinary product.^{397,398} The explanation for this reversal stems from the fact that neonates and young children have a decreased glucuronidating capacity because of undeveloped glucuronyltransferases or low levels of these enzymes. Sulfate conjugation, however, is well developed and becomes the main route of acetaminophen conjugation in this pediatric group.

Other functionalities, such as alcohols (e.g., aliphatic C₁ to C₅ alcohols, diethylene glycol)^{399,400} and aromatic amines (e.g., aniline, 2-naphthylamine),^{401,402} can also form sulfate conjugates. These reactions, however, have only minor importance in drug metabolism. The sulfate conjugation of

N-hydroxylamines and *N*-hydroxylamides takes place as well, occasionally. *O*-Sulfate ester conjugates of *N*-hydroxy compounds are of considerable toxicological concern because they can lead to reactive intermediates that are responsible for cellular toxicity. The carcinogenic agents *N*-methyl-4-aminoazobenzene and 2-AAF are believed to mediate their toxicity through *N*-hydroxylation to the corresponding *N*-hydroxy compounds (see earlier section on *N*-hydroxylation of amines and amides). Sulfoconjugation of the *N*-hydroxy metabolites yields *O*-sulfate esters, which presumably are the ultimate carcinogenic species. Loss of SO₄²⁻ from the foregoing sulfate conjugates generates electrophilic nitrenium species, which may react with nucleophilic groups (e.g., NH₂, OH, SH) present in proteins, DNA, and RNA to form covalent linkages that lead to structural and functional alteration of these crucial biomacromolecules.⁴⁰³ The consequences of this are cellular toxicity (tissue necrosis) or alteration of the genetic code, eventually leading to cancer. Some evidence supporting the role of sulfate conjugation in the metabolic activation of *N*-hydroxy compounds to reactive intermediates comes from the observation that the degree of hepatotoxicity and hepatocarcinogenicity of *N*-hydroxy-2-acetylaminofluorene depends markedly on the level of sulfo-transferase activity in the liver.^{404,405}

The discontinued analgesic phenacetin is metabolized to *N*-hydroxyphenacetin and subsequently conjugated with sulfate.⁴⁰⁶ The *O*-sulfate conjugate of *N*-hydroxyphenacetin binds covalently to microsomal proteins.⁴⁰⁷

This pathway may represent one route leading to reactive intermediates that are responsible for the hepatotoxicity and nephrotoxicity associated with phenacetin. Other pathways (e.g., arene oxides) leading to reactive electrophilic intermediates are also possible.⁶

Conjugation with Glycine, Glutamine, and Other Amino Acids

The amino acids glycine and glutamine are used by mammalian systems to conjugate carboxylic acids, particularly aromatic acids and arylalkyl acids.^{408,409} Glycine conjugation is common to most mammals, whereas glutamine conjugation appears to be confined mainly to humans and other primates. The quantity of amino acid conjugates formed from xenobiotics is minute because of the limited availability of amino acids in the body and competition with glucuronidation for carboxylic acid substrates. In contrast with glucuronic acid and sulfate, glycine and glutamine are not converted to activated coenzymes. Instead, the carboxylic acid substrate is activated with adenosine triphosphate (ATP) and coenzyme A (CoA) to form an acyl-CoA complex. The latter intermediate, in turn, acylates glycine or glutamine under the influence of specific glycine or glutamine *N*-acyltransferase enzymes. The activation and acylation steps take place in the mitochondria of liver and kidney cells. The sequence of metabolic events associated with glycine and glutamine conjugation of phenylacetic acid is summarized in Figure 3.14. Amino acid conju-

Figure 3.14 • Formation of glycine and glutamine conjugates of phenylacetic acid.

gates, being polar and water soluble, are excreted mainly renally and, sometimes, in the bile.

Aromatic acids and arylalkyl acids are the major substrates undergoing glycine conjugation. The conversion of benzoic acid to its glycine conjugate, hippuric acid, is a well-known metabolic reaction in many mammalian systems.⁴¹⁰ The extensive metabolism of salicylic acid (75% of dose) to salicyluric acid in humans is another illustrative example.^{411,412} Carboxylic acid metabolites resulting from oxidation or hydrolysis of many drugs are also susceptible to glycine conjugation. For example, the H₁-histamine antagonist brompheniramine is oxidized to a propionic acid metabolite that is conjugated with glycine in both human and dog.¹⁸¹ Similarly, *p*-fluorophenylacetic acid, derived from the metabolism of the antipsychotic agent haloperidol (Haldol), is found as the glycine conjugate in the urine of rats.⁴¹³ Phenylacetic acid and isonicotinic acid, resulting from the hydrolysis of, respectively, the anticonvulsant phenacemide (Phenurone)⁴¹⁴ and the antituberculosis agent isoniazid,⁴¹⁵ also are conjugated with glycine to some extent.

Glutamine conjugation occurs mainly with arylacetic acids, including endogenous phenylacetic⁴¹⁶ and 3-indolylacetic acid.⁴¹⁷ A few glutamine conjugates of drug metabolites have been reported. For example, in humans, the 3,4-dihydroxy-5-methoxyphenylacetic acid metabolite of mescaline is found as a conjugate of glutamine.⁴¹⁸ Diphenylmethoxyacetic acid, a metabolite of the antihistamine diphenhydramine (Benadryl), is biotransformed further to the corresponding glutamine derivative in the rhesus monkey.⁴¹⁹

Several other amino acids are involved in the conjugation of carboxylic acids, but these reactions occur only occasionally and appear to be highly substrate and species dependent.^{409,420} Ornithine (in birds), aspartic acid and serine (in rats), alanine (in mouse and hamster), taurine (H₂NCH₂CH₂SO₃H) (in mammals and pigeons), and histidine (in African bats) are among these amino acids.⁴²⁰

GSH or Mercapturic Acid Conjugates

GSH conjugation is an important pathway for detoxifying chemically reactive electrophilic compounds.^{421–428} It is now

generally accepted that reactive electrophilic species manifest their toxicity (e.g., tissue necrosis, carcinogenicity, mutagenicity, teratogenicity) by combining covalently with nucleophilic groups present in vital cellular proteins and nucleic acids.^{4,429} Many serious drug toxicities may be explained also in terms of covalent interaction of metabolically generated electrophilic intermediates with cellular nucleophiles.^{5,6} GSH protects vital cellular constituents against chemically reactive species by virtue of its nucleophilic SH group. The SH group reacts with electron-deficient compounds to form *S*-substituted GSH adducts (Fig. 3.15).^{421–428}

GSH is a tripeptide (γ -glutamyl-cysteinylglycine) found in most tissues. Xenobiotics conjugated with GSH usually are not excreted as such, but undergo further biotransformation to give *S*-substituted *N*-acetylcysteine products called mercapturic acids.^{76,86,424–428} This process involves enzymatic cleavage of two amino acids (namely, glutamic acid and glycine) from the initially formed GSH adduct and subsequent *N*-acetylation of the remaining *S*-substituted cysteine residue. The formation of GSH conjugates and their conversion to mercapturic acid derivatives are outlined in Figure 3.15.

Conjugation of a wide spectrum of substrates with GSH is catalyzed by a family of cytoplasmic enzymes known as GSH *S*-transferases.⁷⁵ These enzymes are found in most tissues, particularly the liver and kidney. Degradation of GSH conjugates to mercapturic acids is carried out principally by renal and hepatic microsomal enzymes (Fig. 3.15).⁷⁶ Unlike other conjugative phase II reactions, GSH conjugation does not require the initial formation of an activated coenzyme or substrate. The inherent reactivity of the nucleophilic GSH toward an electrophilic substrate usually provides sufficient driving force. The substrates susceptible to GSH conjugation are quite varied and encompass many chemically different classes of compounds. A major prerequisite is that the substrate be sufficiently electrophilic. Compounds that react with GSH do so by two general mechanisms: (a) nucleophilic displacement at an electron-deficient carbon or heteroatom or (b) nucleophilic addition to an electron-deficient double bond.^{421–423}

Many aliphatic and arylalkyl halides (Cl, Br, I), sulfates (OSO₃⁻), sulfonates (OSO₂R), nitrates (NO₂), and organophosphates (O-P[OR]₂) possess electron-deficient carbon atoms that react with GSH (by aliphatic nucleophilic displacement) to form GSH conjugates, as shown:

Figure 3.15 • Formation of GSH conjugates of electrophilic xenobiotics or metabolites (*E*) and their conversion to mercapturic acids.

The carbon center is rendered electrophilic as a result of the electron-withdrawing group (e.g., halide, sulfate, phosphate) attached to it. Nucleophilic displacement often is facilitated when the carbon atom is benzylic or allylic or when X is a good leaving group (e.g., halide, sulfate). Many industrial chemicals, such as benzyl chloride ($C_6H_5CH_2Cl$), allyl chloride ($CH_2=CHCH_2Cl$), and methyl iodide, are

known to be toxic and carcinogenic. The reactivity of these three halides toward GSH conjugation in mammalian systems is demonstrated by the formation of the corresponding mercapturic acid derivatives.⁴²⁴⁻⁴²⁸ Organophosphate insecticides, such as methyl parathion, are detoxified by two different GSH pathways.^{430,431} Pathway “a” involves aliphatic nucleophilic substitution and yields *S*-methylglu-

2,4-Dichloronitrobenzene

tathione. Pathway "b" involves aromatic nucleophilic substitution and produces *S-p*-nitrophenylglutathione. Aromatic or heteroaromatic nucleophilic substitution reactions with GSH occur only when the ring is rendered sufficiently electron-deficient by the presence of one or more strongly electron-withdrawing substituents (e.g., NO₂, Cl). For example, 2,4-dichloronitrobenzene is susceptible to nucleophilic substitution by GSH, whereas chlorobenzene is not.⁴³²

The metabolism of the immunosuppressive drug azathioprine (Imuran) to 1-methyl-4-nitro-5-(*S*-glutathionyl)imidazole and 6-mercaptopurine is an example of heteroaromatic nucleophilic substitution involving GSH.⁴³³⁻⁴³⁵ Interestingly, 6-mercaptopurine formed in this reaction appears to be responsible for azathioprine's immunosuppressive activity.⁴³⁶

Arene oxides and aliphatic epoxides (or oxiranes) represent a very important class of substrates that are conjugated and detoxified by GSH.⁴³⁷ The three-membered oxygen-containing ring in these compounds is highly strained and, therefore, reactive toward ring cleavage by nucleophiles (e.g., GSH, H₂O, or nucleophilic groups present on cellular

macromolecules). As discussed previously, arene oxides and epoxides are intermediary products formed from CYP oxidation of aromatic compounds (arenes) and olefins, respectively. If reactive arene oxides (e.g., benzo[α]pyrene-4,5-oxide, 4-bromobenzene oxide) and aliphatic epoxides (e.g., styrene oxide) are not “neutralized” or detoxified by GSH *S*-transferase, epoxide hydrase, or other pathways, they ultimately covalently bind to cellular macromolecules and cause serious cytotoxicity and carcinogenicity. The isolation of GSH or mercapturic acid adducts from benzo[α]pyrene, bromobenzene, and styrene clearly demonstrates the importance of GSH in reacting with the reactive epoxide metabolites generated from these compounds.

GSH conjugation involving substitution at heteroatoms, such as oxygen, is seen often with organic nitrates. For example, nitroglycerin (Nitrostat) and isosorbide dinitrate (Isordil) are metabolized by a pathway involving an initial GSH conjugation reaction. The GSH conjugate products, however, are not metabolized to mercapturic acids but instead are converted enzymatically to the corresponding alcohol derivatives and glutathione disulfide (GSSG).⁴³⁸

The nucleophilic addition of GSH to electron-deficient carbon-carbon double bonds occurs mainly in compounds with α,β -unsaturated double bonds. In most instances, the double bond is rendered electron deficient by resonance or conjugation with a carbonyl group (ketone or aldehyde), ester, nitrile, or other. Such α,β -unsaturated systems undergo so-called Michael addition reactions with GSH to yield the corresponding GSH adduct.⁴²¹⁻⁴²⁸ For example, in rats and dogs, the diuretic agent ethacrynic acid (Edecrin) reacts with GSH to form the corresponding GSH or mercapturic acid derivatives.⁴³⁹ Not all α,β -unsaturated compounds are conjugated with GSH. Many steroidal agents with α,β -unsaturated carbonyl moieties, such as prednisone and digitoxigenin, have evinced no significant conjugation with GSH. Steric factors, decreased reactivity of the double bond, and other factors (e.g., susceptibility to metabolic reduction of the ketone or the C=C double bond) may account for these observations.

Occasionally, metabolic oxidative biotransformation reactions may generate chemically reactive α,β -unsaturated systems that react with GSH. For example, metabolic oxidation of acetaminophen presumably generates the chemically reactive intermediate *N*-acetyl-imidoquinone. Michael addition of GSH to the imidoquinone leads to the corresponding mercapturic acid derivative in both animals and humans.^{245,248} 2-Hydroxyestrogens, such as 2-hydroxy-17 β -estradiol, undergo conjugation with GSH to yield the two isomeric mercapturic acid or GSH derivatives. Although the exact mechanism is unclear, it appears that 2-hydroxyestrogen is oxidized to a chemically reactive orthoquinone or semiquinone intermediate that reacts with GSH at either the electrophilic C-1 or C-4 position.^{440,441}

In most instances, GSH conjugation is regarded as a detoxifying pathway that protects cellular macromolecules such as protein and DNA against harmful electrophiles. In a few cases, GSH conjugation has been implicated in causing toxicity. Often, this is because the GSH conjugates are themselves electrophilic (e.g., vicinal dihaloethanes) or give rise to metabolic intermediates (e.g., cysteine metabolites of haloalkenes) that are electrophilic.⁴²⁴⁻⁴²⁸ 1,2-Dichloroethane, for example, reacts with GSH to produce *S*-(2-chloroethyl)glutathione; the nucleophilic sulfur group in this conjugate can internally dis-

place the chlorine group to give rise to an electrophilic three-membered ring episulfonium ion. The covalent interaction of the episulfonium intermediate with the guanosine moiety of DNA may contribute to the mutagenic and carcinogenic effects observed for 1,2-dichloroethane.⁴²⁵⁻⁴²⁷ The metabolic conversion of GSH conjugates to reactive cysteine metabolites is responsible for the nephrotoxicity associated with some halogenated alkanes and alkenes.⁴²⁸ The activation pathway appears to involve γ -glutamyl transpeptidase and cysteine conjugate β -lyase, two enzymes that apparently target the conjugates to the kidney.

Acetylation

Acetylation constitutes an important metabolic route for drugs containing primary amino groups.^{408,442,443} This encompasses primary aromatic amines (ArNH₂), sulfonamides (H₂NC₆H₄SO₂NHR), hydrazines (—NHNH₂), hydrazides (—CONHNH₂), and primary aliphatic amines. The amide derivatives formed from acetylation of these amino functionalities are generally inactive and nontoxic. Because water solubility is not enhanced greatly by *N*-acetylation, it appears that the primary function of acetylation is to terminate pharmacological activity and detoxification. A few reports indicate, however, that acetylated metabolites may be as active as (e.g., *N*-acetylprocainamide),^{444,445} or more toxic than (e.g., *N*-acetylisoniazid),^{446,447} their corresponding parent compounds.

The acetyl group used in *N*-acetylation of xenobiotics is supplied by acetyl-CoA.⁴⁰⁸ Transfer of the acetyl group from this cofactor to the accepting amino substrate is carried out by soluble *N*-acetyltransferases present in hepatic reticuloendothelial cells. Other extrahepatic tissues, such as the lung, spleen, gastric mucosa, red blood cells, and lymphocytes, also show acetylation capability. *N*-Acetyltransferase enzymes display broad substrate specificity and catalyze the acetylation of several drugs and xenobiotics (Fig. 3.16).^{442,443} Aromatic compounds with a primary amino group, such as aniline,⁴⁰⁸ *p*-aminobenzoic acid,^{448,449} *p*-aminosalicylic acid,⁴¹⁸ procainamide (Pronestyl),^{444,445,448,449} and dapsone (Avlosulfon),⁴⁵⁰ are especially susceptible to *N*-acetylation. Aromatic amine metabolites resulting from the reduction of aryl nitro compounds also are *N*-acetylated. For example, the anticonvulsant clonazepam (Klonopin) undergoes nitro reduction to its 7-amino metabolite, which in turn is *N*-acetylated.³¹⁵ Another related benzodiazepam analog, nitrzapem, follows a similar pathway.³¹⁶

The metabolism of several sulfonamides, such as sulfanilamide,⁴⁵¹ sulfamethoxazole (Gantanol),⁴⁵² sulfoxazole (Gantrisin),⁴⁵² sulfapyridine⁴⁵³ (major metabolite from azo reduction of sulfasalazine, Azulfidine), and sulfamethazine,⁴⁰⁸ occurs mainly by acetylation at the N-4 position. With sulfanilamide, acetylation also takes place at the sulfamido N-1 position.⁴⁵¹ *N*-Acetylated metabolites of sulfonamides tend to be less water soluble than their parent compounds and have the potential of crystallizing out in renal tubules (*crystalluria*), thereby causing kidney damage. The frequency of crystalluria and renal toxicity is especially high with older sulfonamide derivatives, such as sulfathiazole.^{1,420} Newer sulfonamides, such as sulfoxazole and sulfamethoxazole, however, are metabolized to relatively water-soluble acetylated derivatives, which are less likely to precipitate out.

Hydrazines and Hydrazides

Aliphatic Amines

Figure 3.16 • Examples of different types of compound undergoing *N*-acetylation. Arrows indicate sites of *N*-acetylation.

The biotransformation of hydrazine and hydrazide derivatives also proceeds by acetylation. The antihypertensive hydralazine (Apresoline)^{454,455} and the MAO inhibitor phenelzine (Nardil)⁴⁵⁶ are two representative hydrazine compounds that are metabolized by this pathway. The initially formed *N*-acetyl derivative of hydralazine is unstable and cyclizes intramolecularly to form 3-methyl-*s*-triazolo[3,4- α]phthalazine as the major isolable hydralazine metabolite in humans.^{454,455} The antituberculosis drug isoniazid or isonicotinic acid hydrazide (INH) is metabolized extensively to *N*-acetylisoniazid.^{446,447}

The acetylation of some primary aliphatic amines such as histamine,⁴⁵⁷ mescaline,^{208,209} and the bis-*N*-demethylated metabolite of α (-)-methadol⁴⁵⁸⁻⁴⁶⁰ also has been reported. In comparison with oxidative deamination processes, *N*-acetylation is only a minor pathway in the metabolism of this class of compounds.

The acetylation pattern of several drugs (e.g., isoniazid, hydralazine, procainamide) in the human population displays a bimodal character in which the drug is conjugated either rapidly or slowly with acetyl-CoA.^{461,462} This phenomenon is termed *acetylation polymorphism*. Individuals are classified as having either slow or rapid acetylator phenotypes. This variation in acetylating ability is genetic and is caused mainly by differences in *N*-acetyltransferase activity. The proportion of rapid and slow acetylators varies widely among different ethnic groups throughout the world. Oddly, a high proportion of Eskimos and Asians are rapid acetylators, whereas Egyptians and some Western European groups are mainly slow acetylators.⁴⁶² Other populations are intermediate between these two

extremes. Because of the bimodal distribution of the human population into rapid and slow acetylators, there appears to be significant individual variation in therapeutic and toxicological responses to drugs displaying acetylation polymorphism.^{408,461,462} Slow acetylators seem more likely to develop adverse reactions, whereas rapid acetylators are more likely to show an inadequate therapeutic response to standard drug doses.

The antituberculosis drug isoniazid illustrates many of these points. The plasma half-life of isoniazid in rapid acetylators ranges from 45 to 80 minutes; in slow acetylators, the half-life is about 140 to 200 minutes.⁴⁶³ Thus, for a given fixed-dosing regimen, slow acetylators tend to accumulate higher plasma concentrations of isoniazid than do rapid acetylators. Higher concentrations of isoniazid may explain the greater therapeutic response (i.e., higher cure rate) among slow acetylators, but they probably also account for the greater incidence of adverse effects (e.g., peripheral neuritis and drug-induced systemic lupus erythematosus syndrome) observed among slow acetylators.⁴⁶² Slow acetylators of isoniazid apparently are also more susceptible to certain drug interactions involving drug metabolism. For example, phenytoin toxicity associated with concomitant use with isoniazid appears to be more prevalent in slow acetylators than in rapid acetylators.⁴⁶⁴ Isoniazid inhibits the metabolism of phenytoin, thereby leading to an accumulation of high and toxic plasma levels of phenytoin.

Interestingly, patients who are rapid acetylators appear to be more likely to develop isoniazid-associated hepatitis.^{446,447} This liver toxicity presumably arises from initial hydrolysis of the *N*-acetylated metabolite *N*-acetylisoniazid to acetylhy-

drazine. The latter metabolite is further converted (by CYP enzyme systems) to chemically reactive acylating intermediates that covalently bind to hepatic tissue, causing necrosis. Pathological and biochemical studies in experimental animals appear to support this hypothesis. Therefore, rapid acetylators run a greater risk of incurring liver injury by virtue of producing more acetylhydrazine.

The tendency of drugs such as hydralazine and procainamide to cause lupus erythematosus syndrome and to elicit formation of antinuclear antibodies (ANAs) appears related to acetylator phenotype, with greater prevalence in slow acetylators.^{465,466} Rapid acetylation may prevent the immunological triggering of ANA formation and the lupus syndrome. Interestingly, the *N*-acetylated metabolite of procainamide is as active an antiarrhythmic agent as the parent drug^{444,445} and has a half-life twice as long in humans.⁴⁶⁷ These findings indicate that *N*-acetylprocainamide may be a promising alternative to procainamide as an antiarrhythmic agent with less lupus-inducing potential.

Methylation

Methylation reactions play an important role in the biosynthesis of many endogenous compounds (e.g., epinephrine and melatonin) and in the inactivation of numerous physiologically active biogenic amines (e.g., norepinephrine, dopamine, serotonin, and histamine).⁴⁶⁸ Methylation, however, constitutes only a minor pathway for conjugating drugs and xenobiotics. Methylation generally does not lead to polar or water-soluble metabolites, except when it creates a quaternary ammonium derivative. Most methylated products tend to be pharmacologically inactive, although there are a few exceptions.

The coenzyme involved in methylation reactions is *S*-adenosylmethionine (SAM). The transfer of the activated

methyl group from this coenzyme to the acceptor substrate is catalyzed by various cytoplasmic and microsomal methyltransferases (Fig. 3.17).^{468,469} Methyltransferases of particular importance in the metabolism of foreign compounds include catechol-*O*-methyltransferase (COMT), phenol-*O*-methyltransferase, and nonspecific *N*-methyltransferases and *S*-methyltransferases.³⁵⁸ One of these enzymes, COMT, should be familiar because it carries out *O*-methylation of such important neurotransmitters as norepinephrine and dopamine and thus terminates their activity. Besides being present in the central and peripheral nerves, COMT is distributed widely in other mammalian tissues, particularly the liver and kidney. The other methyltransferases mentioned are located primarily in the liver, kidney, or lungs. Transferases that specifically methylate histamine, serotonin, and epinephrine are not usually involved in the metabolism of xenobiotics.⁴⁶⁸

Foreign compounds that undergo methylation include catechols, phenols, amines, and *N*-heterocyclic and thiol compounds. Catechol and catecholamine-like drugs are metabolized by COMT to inactive monomethylated catechol products. Examples of drugs that undergo significant *O*-methylation by COMT in humans include the anti-hypertensive (*S*)(-)- α -methyldopa (Aldomet),^{470,471} the antiparkinsonism agent (*S*)(-)-dopa (Levodopa),⁴⁷² isoproterenol (Isuprel),⁴⁷³ and dobutamine (Dobutrex).⁴⁷⁴ The student should note the marked structural similarities between these drugs and the endogenous catecholamines such as norepinephrine and dopamine. In the foregoing four drugs, COMT selectively *O*-methylates only the phenolic OH at C-3. Bismethylation does not occur. Catechol metabolites arising from aromatic hydroxylation of phenols (e.g., 2-hydroxylation of 17 α -ethinylestradiol)^{54,55} and from the arene oxide dihydrodiol-catechol pathway (see section on oxidation of aromatic moieties, e.g., the catechol metabolite of phenytoin)⁴⁷⁵ also undergo *O*-methylation. Substrates undergoing *O*-methylation by COMT must contain an aromatic 1,2-dihydroxy group (i.e., catechol group). Resorcinol (1,3-dihydroxybenzene) or *p*-hydroquinone (1,4-dihydroxybenzene) derivatives are not substrates for COMT. This explains why isoproterenol undergoes extensive *O*-methylation⁴⁷³ but terbutaline (which contains a resorcinol moiety) does not.³⁹⁶

Occasionally, phenols have been reported to undergo *O*-methylation but only to a minor extent.⁴⁶⁸ One interesting

Figure 3.17 • Conjugation of exogenous and endogenous substrates (RXH) by methylation.

example involves the conversion of morphine to its *O*-methylated derivative, codeine, in humans. This metabolite is formed in significant amounts in tolerant subjects and may account for up to 10% of the morphine dose.⁴⁷⁶

Although *N*-methylation of endogenous amines (e.g., histamine, norepinephrine) occurs commonly, biotransformation of nitrogen-containing xenobiotics to *N*-methylated metabolites occurs to only a limited extent. Some examples reported include the *N*-methylation of the antiviral and antiparkinsonism agent amantadine (Symmetrel) in dogs⁴⁷⁷ and the *in vitro* *N*-methylation of norephedrine in rabbit lung preparations.⁴⁶⁸ *N*-methylation of nitrogen atoms present in heterocyclic compounds (e.g., pyridine derivatives) also takes place. For example, the pyridinyl nitrogens of nicotine^{187,188} and nicotinic acid⁴⁷⁸ are *N*-methylated to yield quaternary ammonium products.

Thiol-containing drugs, such as propylthiouracil,⁴⁷⁹ 2,3-dimercapto-1-propanol (BAL),⁴⁸⁰ and 6-mercaptopurine,^{481,482} also have been reported to undergo *S*-methylation.

FACTORS AFFECTING DRUG METABOLISM

Drugs and xenobiotics often are metabolized by several different phase I and phase II pathways to give several metabolites. The relative amount of any particular metabolite is determined by the concentration and activity of the enzyme(s) responsible for the biotransformation. The rate of metabolism of a drug is particularly important for its pharmacological action as well as its toxicity. For example, if the rate of metabolism of a drug is decreased, this generally increases the intensity and duration of the drug action. In addition, decreased metabolic elimination may lead to accumulation of toxic levels of the drug. Conversely, an increased rate of metabolism decreases the intensity and duration of action as well as the drug's efficacy. Many factors may affect drug metabolism, and they are discussed in the following sections. These include age, species and strain, genetic or hereditary factors, sex, enzyme induction, and enzyme inhibition.^{32,483-486}

Age Differences

Age-related differences in drug metabolism are generally quite apparent in the newborn.^{487,488} In most fetal and newborn animals, undeveloped or deficient oxidative and conjugative enzymes are chiefly responsible for the reduced metabolic capability seen. In general, the ability to carry out metabolic reactions increases rapidly after birth and approaches adult levels in about 1 to 2 months. An illustration of the influence of age on drug metabolism is seen in the duration of action (sleep time) of hexobarbital in newborn and adult mice.⁴⁸⁹ When given a dose of 10 mg/kg of body weight, the newborn mouse sleeps more than 6 hours. In contrast, the adult mouse sleeps for fewer than 5 minutes when given the same dose.

In humans, oxidative and conjugative (e.g., glucuronidation) capabilities of newborns are also low compared with those of adults. For example, the oxidative (CYP) metabolism of tolbutamide appears to be markedly lower in newborns.⁴⁹⁰ Compared with the half-life of 8 hours in adults, the plasma half-life of tolbutamide in infants is more than 40 hours. As

discussed previously, infants possess poor glucuronidating ability because of a deficiency in glucuronyltransferase activity. The inability of infants to conjugate chloramphenicol with glucuronic acid appears to be responsible for the accumulation of toxic levels of this antibiotic, resulting in the so-called gray baby syndrome.³⁸⁸ Similarly, neonatal hyperbilirubinemia (or kernicterus) results from the inability of newborn babies to glucuronidate bilirubin.³⁸⁷

The effect of old age on drug metabolism has not been as well studied. There is some evidence in animals and humans that drug metabolism diminishes with old age.^{491,492} Much of the evidence, however, is based on prolonged plasma half-lives of drugs that are metabolized totally or mainly by hepatic microsomal enzymes (e.g., antipyrine, phenobarbital, acetaminophen). In evaluating the effect of age on drug metabolism, one must differentiate between "normal" loss of enzymatic activity with aging and the effect of a diseased liver from hepatitis, cirrhosis, etc., plus decreased renal function, because much of the water-soluble conjugation products are excreted in the liver.

Species and Strain Differences

The metabolism of many drugs and foreign compounds is often species dependent. Different animal species may biotransform a particular xenobiotic by similar or markedly different metabolic pathways. Even within the same species, individual variations (strain differences) may result in significant differences in a specific metabolic pathway.^{493,494} This is a problem when a new drug is under development. A new drug application requires the developer to account for the product as it moves from the site of administration to final elimination from the body. It is difficult enough to find appropriate animal models for a disease. It is even harder to find animal models that mimic human drug metabolism.

Species variation has been observed in many oxidative biotransformation reactions. For example, metabolism of amphetamine occurs by two main pathways: oxidative deamination or aromatic hydroxylation. In human, rabbit, and guinea pig, oxidative deamination appears to be the predominant pathway; in the rat, aromatic hydroxylation appears to be the more important route.⁴⁹⁵ Phenytoin is another drug that shows marked species differences in metabolism. In the human, phenytoin undergoes aromatic oxidation to yield primarily (*S*)(-)-*p*-hydroxyphenytoin; in the dog, oxidation occurs to give mainly (*R*)(+)-*m*-hydroxyphenytoin.⁴⁹⁶ There is a dramatic difference not only in the position (i.e., *meta* or *para*) of aromatic hydroxylation but also in which of the two phenyl rings (at C-5 of phenytoin) undergoes aromatic oxidation.

Species differences in many conjugation reactions also have been observed. Often, these differences are caused by the presence or absence of transferase enzymes involved in the conjugative process. For example, cats lack glucuronyltransferase enzymes and, therefore, tend to conjugate phenolic xenobiotics by sulfation instead.⁴⁹⁷ In pigs, the situation is reversed: pigs are not able to conjugate phenols with sulfate (because of lack of sulfotransferase enzymes) but appear to have good glucuronidation capability.⁴⁹⁷ The conjugation of aromatic acids with amino acids (e.g., glycine, glutamine) depends on the animal species as well as on the substrate. For example, glycine conjugation is a common conjugation pathway for benzoic acid in many animals. In certain birds (e.g., duck, goose, turkey), however, glycine

is replaced by the amino acid ornithine.⁴⁹⁸ Phenylacetic acid is a substrate for both glycine and glutamine conjugation in humans and other primates. However, nonprimates, such as rabbit and rat, excrete phenylacetic acid only as the glycine conjugate.⁴⁹⁹ The metabolism of the urinary antiseptic, phenazopyridine (Pyridium) depends strongly on the animal. The diazo linkage remains intact in over half of the metabolites in humans, whereas 40% of the metabolites in the guinea pig result from its cleavage. The metabolic product pattern in human or guinea pig does not correlate with that of either rat or mouse (Fig. 3.18).⁵⁰⁰

Strain differences in drug metabolism exist, particularly in inbred mice and rabbits. These differences apparently are caused by genetic variations in the amount of metabolizing enzyme present among the different strains. For example, *in vitro* studies indicate that cottontail rabbit liver microsomes metabolize hexobarbital about 10 times faster than New Zealand rabbit liver microsomes.⁵⁰¹ Interindividual differences in drug metabolism in humans are considered in the section that follows.

Hereditary or Genetic Factors

Marked individual differences in the metabolism of several drugs exist in humans.⁴⁶³ Many of these genetic or heredi-

tary factors are responsible for the large differences seen in the rate of metabolism of these drugs. The frequently cited example of the biotransformation of the antituberculosis agent isoniazid is discussed previously under acylation. Genetic factors also appear to influence the rate of oxidation of drugs such as phenytoin, phenylbutazone, dicumarol, and nortriptyline.^{502,503} The rate of oxidation of these drugs varies widely among different individuals; however, these differences do not appear to be distributed bimodally, as in acetylation. In general, individuals who tend to oxidize one drug rapidly are also likely to oxidize other drugs rapidly. Numerous studies in twins (identical and fraternal) and in families indicate that oxidation of these drugs is under genetic control.⁵⁰³

Many patients state that they do not respond to codeine and codeine analogs. It now is realized that their CYP2D6 isozyme does not readily *O*-demethylate codeine to form morphine. This genetic polymorphism is seen in about 8% of Caucasians, 4% of African Americans, and less than 1% of Asians.⁵⁰⁴ Genetic polymorphism with CYP isozymes is well documented as evidenced by the many examples in this chapter. There is limited evidence of polymorphism involving MAO-A and MAO-B. The chemical imbalances seen with some mental diseases may be the cause.²⁰⁶

Figure 3.18 • Phenazopyridine metabolism in humans, guinea pigs, rats, and mice.

Sex Differences

The rate of metabolism of xenobiotics also varies according to gender in some animal species. A marked difference is observed between female and male rats. Adult male rats metabolize several foreign compounds at a much faster rate than female rats (e.g., *N*-demethylation of aminopyrine, hexobarbital oxidation, glucuronidation of *o*-aminophenol). Apparently, this sex difference also depends on the substrate, because some xenobiotics are metabolized at the same rate in both female and male rats. Differences in microsomal oxidation are under the control of sex hormones, particularly androgens; the anabolic action of androgens seems to increase metabolism.⁵⁰⁵

Sex differences in drug metabolism appear to be species dependent. Rabbits and mice, for example, do not show a significant sex difference in drug metabolism.⁵⁰⁵ In humans, there have been a few reports of sex differences in metabolism. For instance, nicotine and aspirin seem to be metabolized differently in women and men.^{506,507} On the other hand, gender differences can become significant in terms of drug–drug interactions based on the drug's metabolism. For women, the focus is on drugs used for contraception. Note in Table 3.4 that the antibiotic rifampin, a CYP3A4 inducer, can shorten the half-life of oral contraceptives.

Enzyme Induction

The activity of hepatic microsomal enzymes, such as the CYP mixed-function oxidase system, can be increased

markedly by exposure to diverse drugs, pesticides, polycyclic aromatic hydrocarbons, and environmental xenobiotics. The process by which the activity of these drug-metabolizing enzymes is increased is termed *enzyme induction*.^{508–511} The increased activity is apparently caused by an increased amount of newly synthesized enzyme. Enzyme induction often increases the rate of drug metabolism and decreases the duration of drug action. (See Table 3.4 for a list of clinically significant drug–drug interactions based on one drug inducing the metabolism of a second drug.)

Inducing agents may increase the rate of their own metabolism as well as those of other unrelated drugs or foreign compounds (Table 3.4).³² Concomitant administration of two or more drugs often may lead to serious drug interactions as a result of enzyme induction. For instance, a clinically critical drug interaction occurs with phenobarbital and warfarin.⁵¹² Induction of microsomal enzymes by phenobarbital increases the metabolism of warfarin and, consequently, markedly decreases the anticoagulant effect. Therefore, if a patient is receiving warfarin anticoagulant therapy and begins taking phenobarbital, careful attention must be paid to readjustment of the warfarin dose. Dosage readjustment is also needed if a patient receiving both warfarin and phenobarbital therapy suddenly stops taking the barbiturate. The ineffectiveness of oral contraceptives in women on concurrent phenobarbital or rifampin therapy has been attributed to the enhanced metabolism of estrogens (e.g., 17α -ethinylestradiol) caused by phenobarbital⁵¹³ and rifampin⁵¹⁴ induction.

TABLE 3.4 Clinically Significant Cytochrome P450-Based Drug–Drug Interactions

Agent	Substrates	Inhibitors	Inducers	Agent	Substrates	Inhibitors	Inducers
CYP 1A2	Amitriptyline	Cimetidine	Carbamazepine	CYP 3A4	Imipramine		
	Clomipramine	Ciprofloxacin	Phenobarbital		Meperidine		
	Clozapine	Clarithromycin	Phenytoin		Methadone		
	Desipramine	Enoxacin	Primidone		Mexiletine		
	Fluvoxamine	Erythromycin	Rifampin		Nortriptyline		
	Haloperidol	Fluvoxamine	Ritonavir		Oxycodone		
	Imipramine	Isoniazid	Smoking		Propafenone		
	Ropinirole	Nalidixic acid	St. John's wort		Propoxyphene		
	Tacrine	Norfloxacin			Thioridazine		
	Theophylline	Troleandomycin			Tramadol		
	(R)-Warfarin	Zileuton			Trazodone		
CYP 2C9	Diazepam	Amiodarone	Carbamazepine	Alfentanil	Amiodarone	Carbamazepine	
	Phenytoin	Chloramphenicol	Phenobarbital	Alprazolam	Cimetidine	Efavirenz	
	(S)-Warfarin	Cimetidine	Phenytoin	Amlodipine	Ciprofloxacin	Ethosuximide	
		Fluconazole	Primidone	Atorvastatin	Clarithromycin	Garlic supplements	
		Fluoxetine	Rifampin		Busulfan	Cyclosporine	Modafinil
		Fluvoxamine	Rifapentine		Carbamazepine	Delavirdine	Nevirapine
		Isoniazid			Cisapride	Diltiazem	Oxcarbazepine
		Metronidazole			Clarithromycin	Efavirenz	Phenobarbital
		Voriconazole			Cyclosporine	Erythromycin	Phenytoin
		Zafirlukast			Dihydroergotamine	Fluconazole	Primidone
	CYP 2C19	Phenytoin	Fluoxetine	Carbamazepine	Disopyramide	Fluoxetine	Rifabutin
Thioridazine		Fluvoxamine	Phenobarbital	Doxorubicin	Fluvoxamine	Rifampin	
		Modafinil	Phenytoin	Dronabinol	Grapefruit	Rifapentine	
		Omeprazole		Ergotamine	Indinavir	St. John's wort	
		Topiramate		Erythromycin	Isoniazid		
CYP 2D6	Amitriptyline	Amiodarone	St. John's wort	Estrogens, oral contraceptives	Itraconazole		
	Atomoxetine	Cimetidine		Ethinyl estradiol	Ketoconazole		
	Codeine	Fluoxetine		Ethosuximide	Metronidazole		
	Desipramine	Paroxetine		Etoposide	Nefazodone		
	Dextromethorphan	Quinidine		Felodipine	Nelfinavir		
	Donepezil	Ritonavir		Fentanyl	Nifedipine		
	Doxepin	Sertraline		Indinavir	Norfloxacin		
	Fentanyl			Isradipine	Quinine		
	Flecainide			Itraconazole	Ritonavir		
	Haloperidol						
	Hydrocodone						

Abstracted from Levien, T. L., and Baker, D. E.: Pharmacist's Letter, December 2002, Detail-Document #150400. (Pharmacist's Letter used as sources: Hansten, P. D., and Horn, J. R.: Drug Interactions Analysis and Management. Vancouver, WA, Applied Therapeutics, 2002; and Tatro, D. S. [ed.]: Drug Interaction Facts. St. Louis, Facts & Comparisons, 2002.)

Inducers of microsomal enzymes also may enhance the metabolism of endogenous compounds, such as steroidal hormones and bilirubin. For instance, phenobarbital can increase the metabolism of cortisol, testosterone, vitamin D, and bilirubin in humans.^{508,509} The enhanced metabolism of vitamin D₃ induced by phenobarbital and phenytoin appears to be responsible for the osteomalacia seen in patients on long-term therapy with these two anticonvulsant drugs.⁵¹⁵ Interestingly, phenobarbital induces glucuronyltransferase enzymes, thereby enhancing the conjugation of bilirubin with glucuronic acid. Phenobarbital has been used occasionally to treat hyperbilirubinemia in neonates.⁵¹⁶

In addition to drugs, other chemicals, such as polycyclic aromatic hydrocarbons (e.g., benzo[*a*]pyrene, 3-methylcholanthrene) and environmental pollutants (e.g., pesticides, PCBs, TCDD), may induce certain oxidative pathways and, thereby, alter drug response.^{508,509,511} Cigarette smoke contains minute amounts of polycyclic aromatic hydrocarbons, such as benzo[*a*]pyrene, which are potent inducers of microsomal CYP enzymes. This induction increases the oxidation of some drugs in smokers. For example, theophylline is metabolized more rapidly in smokers than in nonsmokers. This difference is reflected in the marked difference in the plasma half-life of theophylline between smokers ($t_{1/2}$ 4.1 hours) and

nonsmokers ($t_{1/2}$ 7.2 hours).⁵¹⁷ Other drugs, such as phenacetin, pentazocine, and propoxyphene, also reportedly undergo more rapid metabolism in smokers than in nonsmokers.^{518–520}

Occupational and accidental exposure to chlorinated pesticides and insecticides can also stimulate drug metabolism. For instance, the half-life of antipyrine in workers occupationally exposed to the insecticides lindane and dichlorodiphenyltrichloroethane (DDT) is reportedly significantly shorter (7.7 vs. 11.7 hours) than in control subjects.⁵²¹ A case was reported in which a worker exposed to chlorinated insecticides failed to respond (i.e., decreased anticoagulant effect) to a therapeutic dose of warfarin.⁵²²

As discussed previously in this chapter, multiple forms (isozymes) of CYP have been demonstrated.^{31,40–42} Many chemicals selectively induce one or more distinct forms of CYP³¹ (see Table 3.4.) Enzyme induction also may affect toxicity of some drugs by enhancing the metabolic formation of chemically reactive metabolites. Particularly important is the induction of CYP enzymes involved in the oxidation of drugs to reactive intermediates. For example, the oxidation of acetaminophen to a reactive imidoquinone metabolite appears to be carried out by a phenobarbital-inducible form of CYP in rats and mice. Numerous studies in these two animals indicate that phenobarbital pretreatment increases in vivo hepatotoxicity and covalent binding as well as increases formation of reactive metabolite in microsomal incubation mixtures.^{243–245,248} Induction of cytochrome P448 is of toxicological concern because this particular enzyme is involved in the metabolism of polycyclic aromatic hydrocarbons to reactive and carcinogenic intermediates.^{80,523} Consequently, the metabolic bioactivation of benzo[α]pyrene to its ultimate carcinogenic diol epoxide intermediate is carried out by cytochrome P448 (see section on aromatic oxidation for the bioactivation pathway of benzo[α]pyrene to its diol epoxide).⁵²³ Thus, it is becoming increasingly apparent that enzyme induction may enhance the toxicity of some xenobiotics by increasing the rate of formation of reactive metabolites.

Enzyme Inhibition

Several drugs, other xenobiotics including grapefruit, and possibly other foods can inhibit drug metabolism (Table 3.5).^{32,483–486} With decreased metabolism, a drug often accumulates, leading to prolonged drug action and serious adverse effects. Enzyme inhibition can occur by diverse mechanisms, including substrate competition, interference with protein synthesis, inactivation of drug-metabolizing enzymes, and hepatotoxicity leading to impairment of enzyme activity. Some drug interactions resulting from enzyme inhibition have been reported in humans.^{524,525} For example, phenylbutazone (limited to veterinary use) stereoselectively inhibits the metabolism of the more potent (*S*)(–) enantiomer of warfarin. This inhibition may explain the excessive hypoprothrombinemia (increased anticoagulant effect) and many instances of hemorrhaging seen in patients on both warfarin and phenylbutazone therapy.⁵⁶ The metabolism of phenytoin is inhibited by drugs such as chloramphenicol, disulfiram, and isoniazid.⁵¹² Interestingly, phenytoin toxicity as a result of enzyme inhibition by isoniazid appears to occur primarily in slow acetylators.⁴⁶⁴ Several drugs, such as dicumarol, chlorampheni-

TABLE 3.5 Potential Drug–Grapefruit Interactions Based on Grapefruit Inhibition of CYP 3A4

Drug	Result
Amiodarone	Increased bioavailability
Diazepam	Increased AUC
Carbamazepine	Increased AUC, peak and trough plasma concentrations
Cisapride	Increased AUC
Cyclosporine, tacrolimus	Increased AUC and serum concentrations
Atorvastatin, simvastatin	Increased absorption and plasma concentrations
Saquinavir	Increased absorption and plasma concentrations

Abstracted from Kehoe, W. A.: Pharmacist's Letter, 18, September 2002, Detail Document #180905. AUC, area under the curve.

col, and phenylbutazone,⁵¹² inhibit the biotransformation of tolbutamide, which may lead to a hypoglycemic response.

The grapefruit–drug interaction is complex. It may be caused by the bioflavonoids or the furanocoumarins. Grapefruit's main bioflavonoid, naringin, is a weak CYP inhibitor, but the product of the intestinal flora, naringenin, does inhibit CYP3A4. The literature is very confusing because many of the studies were done in vitro, and they cannot always be substantiated under in vivo conditions. In addition, components in grapefruit also activate P-glycoprotein, which would activate the efflux pump in the gastric mucosa and thus interfere with oral absorption of the certain drugs. The combination of CYP enzyme inhibition and P-glycoprotein activation can lead to inconclusive results.⁵²⁶ The general recommendation when a drug interaction is suspected is that the patient avoid grapefruit and its juice.

Miscellaneous Factors Affecting Drug Metabolism^{32,483–486}

Other factors also may influence drug metabolism. Dietary factors, such as the protein-to-carbohydrate ratio, affect the metabolism of a few drugs. Indoles present in vegetables such as Brussels sprouts, cabbage, and cauliflower, and polycyclic aromatic hydrocarbons present in charcoal-broiled beef induce enzymes and stimulate the metabolism of some drugs. Vitamins, minerals, starvation, and malnutrition also apparently influence drug metabolism. Finally, physiological factors, such as the pathological state of the liver (e.g., hepatic cancer, cirrhosis, hepatitis), pregnancy, hormonal disturbances (e.g., thyroxine, steroids), and circadian rhythm, may markedly affect drug metabolism.

Stereochemical Aspects of Drug Metabolism

Many drugs (e.g., warfarin, propranolol, hexobarbital, glutethimide, cyclophosphamide, ketamine, and ibuprofen) often are administered as racemic mixtures in humans. The two enantiomers present in a racemic mixture may differ in pharmacological activity. Usually, one enantiomer tends to be much more active than the other. For example, the (*S*)(–)

enantiomer of warfarin is 5 times more potent as an oral anticoagulant than the (*R*)(+) enantiomer.⁵²⁷ In some instances, the two enantiomers may have totally different pharmacological activities. For example, (+)- α -propoxyphene (Darvon) is an analgesic, whereas (–)- α -propoxyphene (Novrad) is an antitussive.⁵²⁸ Such differences in activity between stereoisomers should not be surprising, because Chapter 2 explains that stereochemical factors generally have a dramatic influence on how the drug molecule interacts with the target receptors to elicit its pharmacological response. By the same token, the preferential interaction of one stereoisomer with drug-metabolizing enzymes may lead one to anticipate differences in metabolism for the two enantiomers of a racemic mixture. Indeed, individual enantiomers of a racemic drug often are metabolized at different rates. For instance, studies in humans indicate that the less active (+) enantiomer of propranolol undergoes more rapid metabolism than the corresponding (–) enantiomer.⁵²⁹ Allylic hydroxylation of hexobarbital occurs more rapidly with the *R*(–) enantiomer in humans.⁵³⁰ The term *substrate stereoselectivity* is used frequently to denote a preference for one stereoisomer as a substrate for a metabolizing enzyme or metabolic process.²⁹¹

Individual enantiomers of a racemic mixture also may be metabolized by different pathways. For instance, in dogs, the (+) enantiomer of the sedative-hypnotic glutethimide (Doriden) is hydroxylated primarily α to the carbonyl to yield 4-hydroxyglutethimide, whereas the (–) enantiomer undergoes aliphatic ω -1 hydroxylation of its C-2 ethyl

group.^{140,141} Dramatic differences in the metabolic profile of two enantiomers of warfarin also have been noted. In humans, the more active (*S*)(–)-isomer is 7-hydroxylated (aromatic hydroxylation), whereas the (*R*)(+) isomer undergoes keto reduction to yield primarily the (*R,S*) warfarin alcohol as the major plasma metabolite.^{56,296} Although numerous other examples of substrate stereoselectivity or enantioselectivity in drug metabolism exist, the examples presented should suffice to emphasize the point.^{291,531}

Drug biotransformation processes often lead to the creation of a new asymmetric center in the metabolite (i.e., stereoisomeric or enantiomeric products). The preferential

metabolic formation of a stereoisomeric product is called *product stereoselectivity*.²⁹¹ Thus, bioreduction of ketone xenobiotics, as a general rule, produces predominantly one stereoisomeric alcohol (see "Reduction of Ketone Carbonyls").^{116,291} The preferential formation of (*S*)(-)-hydroxyhexamide from the hypoglycemic agent acetohexamide^{293,294} and the exclusive generation of 6 β -naltrexol from naltrexone^{297,298} (see "Reduction of Ketone Carbonyls" for structure) are two examples of highly stereoselective bioreduction processes in humans.

Oxidative biotransformations display product stereoselectivity, too. For example, phenytoin contains two phenyl rings in its structure, both of which a priori should be susceptible to aromatic hydroxylation. In humans, however, *p*-hydroxylation occurs preferentially (~90%) at the pro-(*S*)-phenyl ring to give primarily (*S*)(-)-5-(4-hydroxyphenyl)-5-phenylhydantoin. Although the other phenyl ring also is *p*-hydroxylated, it occurs only to a minor extent (10%).⁴⁹⁶ Microsomal hydroxylation of the C-3 carbon of diazepam and desmethyldiazepam (using mouse liver preparations) has been reported to proceed with remarkable stereoselectivity to yield optically active metabolites with the 3(*S*) absolute configuration.¹³⁹ Interestingly, these two metabolites are pharmacologically active and one of them, oxazepam, is marketed as a drug (Serax). The allylic hydroxylation of the *N*-butenyl side group of the analgesic pentazocine (Talwin) leads to two possible alcohols (*cis* and *trans* alcohols). In human, mouse, and monkey, pentazocine is metabolized predominantly to the *trans* alcohol metabolite, whereas the rat primarily tends to form the *cis* alcohol.^{129,130} The product stereoselectivity observed in this biotransformation involves *cis* and *trans* geometric stereoisomers.

The term *regioselectivity*⁵³² has been introduced in drug metabolism to denote the selective metabolism of two or more similar functional groups (e.g., OCH₃, OH, NO₂) or two or more similar atoms that are positioned in different regions of a molecule. For example, of the four methoxy groups present in papaverine, the 4-OCH₃ group is regioselectively *O*-demethylated in several species

(e.g., rat, guinea pig, rabbit, and dog).⁵³³ Trimethoprim (Trimplex, Proloprim) has two heterocyclic sp² nitrogen atoms (N¹ and N³) in its structure. In dogs, it appears that oxidation occurs regioselectively at N³ to give the corresponding 3-*N*-oxide.²³² Nitroreduction of the 7-nitro group in 5,7-dinitroindazole to yield the 7-amino derivative in the mouse and rat occurs with high regioselectivity.⁵³⁴ Substrates amenable to *O*-methylation by COMT appear to proceed with remarkable regioselectivity, as typified by the cardiotoxic agent dobutamine (Dobutrex). *O*-methylation occurs exclusively with the phenolic hydroxy group at C-3.⁴⁷⁴

Pharmacologically Active Metabolites

The traditional notion that drug metabolites are inactive and insignificant in drug therapy has changed dramatically in recent years. Increasing evidence indicates that many drugs are biotransformed to pharmacologically active metabolites that contribute to the therapeutic as well as toxic effects of the parent compound. Metabolites shown to have significant therapeutic activity in humans are listed in Table 3.4.^{2,535} The parent drug from which the metabolite is derived and the biotransformation process involved also are given.

How significantly an active metabolite contributes to the therapeutic or toxic effects ascribed to the parent drug depend on its relative activity and quantitative importance (e.g., plasma concentration). In addition, whether the metabolite accumulates after repeated administration (e.g., desmethyldiazepam in geriatric patients) or in patients with renal failure is determinant.

From a clinical standpoint, active metabolites are especially important in patients with decreased renal function. If renal excretion is the major pathway for elimination of the active metabolite, then accumulation is likely to occur in patients with renal failure. Especially with drugs such as procainamide, clofibrate, and digitoxin, caution should be exercised in treating patients with renal failure.^{2,413}

Many of the toxic effects seen for these drugs have been attributed to high-plasma levels of their active metabolites. For example, the combination of severe muscle weakness and tenderness (myopathy) seen with clofibrate in renal failure patients is believed to be caused by high levels of the active metabolite chlorophenoxyisobutyric acid.^{536,537} Cardiovascular toxicity owing to digitoxin and procainamide in anephric subjects has been attributed to high plasma levels of digoxin and *N*-acetylprocainamide, respectively. In such situations, appropriate reduction in dosage and careful monitoring of plasma levels of the parent drug and its active metabolite often are recommended.

The pharmacological activity of some metabolites has led many manufacturers to synthesize these metabolites and to market them as separate drug entities (Table 3.6). For example, oxyphenbutazone (Tandearil, Oxalid) is the *p*-hydroxylated metabolite of the anti-inflammatory agent phenylbutazone (Butazolidin, Azolid), nortriptyline (Aventyl) is the *N*-demethylated metabolite of the tricyclic antidepressant amitriptyline (Elavil), oxazepam (Serax) is the *N*-demethylated and 3-hydroxylated metabolite of diazepam (Valium), and mesoridazine (Serentil) is the sulfoxide metabolite of the antipsychotic agent thioridazine (Mellaril).

Antivirals that are used in treating herpes simplex virus, varicella-zoster virus, and/or human cytomegalovirus must be bioactivated.⁵³⁸ These include acyclovir, valacyclovir, penciclovir, famciclovir, and ganciclovir, which must be phosphorylated on the pentoselike side chain to the triphosphate derivative to be effective in inhibiting the enzyme DNA polymerase. The antiviral cidovir is dispensed as a monophosphate and only needs to be diphosphorylated for conversion to the active triphosphate metabolite. The nucleoside antivirals that are used in treating acquired immunodeficiency syndrome/human immunodeficiency virus (AIDS/HIV) must also undergo a similar metabolic conversion to the triphosphate metabolite.⁵³⁹ The triphosphate derivative acts as a competitive inhibitor of the enzyme, reverse transcriptase, which normally uses the triphosphorylated form of

TABLE 3.6 Pharmacologically Active Metabolites in Humans

Parent Drug	Metabolite	Biotransformation Process
Acetohexamide	Hydroxyhexamide	Ketone reduction
Acetylmethadol	Noracetylmethadol	<i>N</i> -Demethylation
Amitriptyline	Nortriptyline	<i>N</i> -Demethylation
Azathioprine	6-Mercaptopurine	Glutathione conjugation
Carbamazepine	Carbamazepine-9,10-epoxide	Epoxidation
Chloral hydrate	Trichloroethanol	Aldehyde reduction
Chlorpromazine	7-Hydroxychlorpromazine	Aromatic hydroxylation
Clofibrate	Chlorophenoxyisobutyric acid	Ester hydrolysis
Cortisone	Hydrocortisone	Ketone reduction
Diazepam	Desmethyldiazepam and oxazepam	<i>N</i> -Demethylation and 3-hydroxylation
Digitoxin	Digoxin	Alicyclic hydroxylation
Diphenoxylate	Diphenoxylate acid	Ester hydrolysis
Imipramine	Desipramine	<i>N</i> -Demethylation
Mephobarbital	Phenobarbital	<i>N</i> -Demethylation
Metoprolol	α -Hydroxymethylmetoprolol	Benzylic hydroxylation
Phenacetin	Acetaminophen	<i>O</i> -Deethylation
Phenylbutazone	Oxybutazone	Aromatic hydroxylation
Prednisone	Prednisolone	Ketone reduction
Primidone	Phenobarbital	Hydroxylation and oxidation to ketone
Procainamide	<i>N</i> -Acetylprocainamide	<i>N</i> -Acetylation
Propranolol	4-Hydroxypropranolol	Aromatic hydroxylation
Quinidine	3-Hydroxyquinidine	Allylic hydroxylation
Sulindac	Sulfide metabolite of sulindac	Sulfoxide reduction
Thioridazine	Mesoridazine	<i>S</i> -oxidation
Warfarin	Warfarin alcohols	Ketone reduction

nucleic acids. Examples include zidovudine, stavudine, zalcitabine, lamivudine, and didanosine.

One of the more recent uses of drug metabolism in the development of a novel agent includes the example of oseltamivir, a neuraminidase inhibitor used in treating influenza. Ro-64-0802, the lead drug, showed promise against both influenza A and B viruses *in vitro* but was not very ef-

fective when used *in vivo*. To improve the oral bioavailability, the ethyl ester, oseltamivir, was developed as a prodrug. Administration of the more lipophilic oseltamivir allowed good penetration of the active metabolite in various tissues, especially in the lower respiratory tract. The metabolism proceeds via a simple ester hydrolysis to yield the active free carboxylic acid.⁵⁴⁰

R E V I E W Q U E S T I O N S

1. What would be the logical primary metabolite of a phase I reaction for the following drug molecule?

norepinephrine

2. Using the agent represented, identify which of the following metabolic pathways might occur.

Atenolol (Tenormin)

- hydrolysis by amidase enzymes
- oxidative *N*-dealkylation
- oxidative *O*-dealkylation
- All of the above are possible.
- Only a and b are correct.

3. Using the structure for Esmolol (Brevibloc), an antiarrhythmic beta-blocking agent, identify which of the following is/are true:

- The agent has a very short $t_{1/2}$ because of its susceptibility of hydrolysis by esterases.
- The agent is compatible with sodium bicarbonate.
- The agent should not be "pushed" in an iv line that is supplying a drug to a patient that is buffered with bicarbonate.
- All of the above are true.
- Only a and c are true.

4. Explain your answer(s) for question number 3.
5. A patient you are monitoring has been on Telmisartan (Cozaar), an angiotensin receptor blocker for the management of their hypertension. The drug must be metab-

olized by CYP2C9 or CYP3A4 from a 5-methanol to a 5-carboxylic acid to exhibit its effects. After 2 years of successful therapy, their blood pressure suddenly increases. Why might this occur and what would you suggest as a substitute?

CHAPTER 4

Biotechnology and Drug Discovery

JOHN M. BEALE, JR.

CHAPTER OVERVIEW

Developments in biotechnology in recent times have been quite dramatic. The years between 1999 and 2001 witnessed a tremendous increase in the number of biotechnology-related pharmaceutical products in development, and a number of important new drugs progressed through trials and into the clinic. A good reflection of the impact of biotechnology is the GenBank database. GenBank is an electronic repository of gene sequence information, specifically the nucleotide sequences of complementary DNA (cDNA), representing the messenger RNA (mRNA), and genomic clones that have been isolated and sequenced by scientists worldwide.^{1,2} The growth of the GenBank database has been rapid, and it has been increasing steadily since about 1992.³ Figures 4.1 and 4.2 graphically depict these growth rates.

In October 2008, the Pharmaceutical Research and Manufacturers Association (PhRMA) reported that 633 biotechnology-derived medicines were in testing at various stages and that nearly 100 diseases are being targeted by research conducted by 144 companies and the National Cancer Institute. Of these—all of which are in human trials or awaiting Food and Drug Administration (FDA) approval—244 are new drugs for cancer, 162 are new drugs for infectious diseases, 59 are new drugs for autoimmune diseases, 18 are new drugs for neurological disorders, and 34 are new drugs for human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome (AIDS) and related conditions.⁴ PhRMA also reported nearly 200 new medicines targeted for pediatric use.⁵ Approved drugs derived from biotechnology also treat or help prevent myocardial infarction, stroke, multiple sclerosis (MS), leukemia, hepatitis, rheumatoid arthritis, breast cancer, diabetes, congestive heart failure, lymphoma, renal cancer, cystic fibrosis (CF), and other diseases. The number of biotechnology products under development for a wide variety of diseases are illustrated in Figure 4.3.

The Human Genome Project, an international effort to obtain complete genetic maps, including nucleotide sequences, of each of the 24 human chromosomes, has spawned much new knowledge and technology. It is awesome to consider that in the mere 30 years since 1972, the science has reached the stage of attempting genetic cures for some diseases, such as CF and immune deficiency disorders.

BIOTECHNOLOGY AND PHARMACEUTICAL CARE

As it affects medicine and pharmaceutical care, biotechnology has forever altered the drug discovery process and the thinking about patient care. Extensive screening programs once drove drug discovery on natural or synthetic compounds. Now, the recombinant DNA (rDNA)-driven drug discovery process is beginning to yield new avenues for the preparation of some old drugs. For example, insulin, once prepared by isolation from pancreatic tissue of bovine or porcine species, can now be prepared in a pure form identical with human insulin. Likewise, human growth hormone (hGH), once isolated from the pituitary glands of the deceased, can now be prepared in pure form. Recombinant systems, such as these, provide high-yielding, reproducible batches of the drug and uniform dosing for patients.

LITERATURE OF BIOTECHNOLOGY

Many good literature sources on biotechnology exist for the pharmacist and medicinal chemist. These cover topics such as management issues in biotechnology,^{6–14} implementation of instruction on biotechnology in education,^{15–22} costs of biotechnology drugs,^{23–26} implementation in a practice setting,^{27–42} regulatory issues,^{43–46} product evaluation and formulation,^{47,48} patient compliance,^{49,50} and finding information.^{51–53} Additionally, there are a number of general texts,^{54–60} review articles,^{61–65} and a general resource reference catalogue.⁶⁶ Any good biochemistry textbook is also a useful resource.

BIOTECHNOLOGY AND NEW DRUG DEVELOPMENT

The tools of biotechnology are also being brought to bear in the search for new biological targets for presently available drugs as well as for the discovery of new biological molecules with therapeutic utility. Molecular cloning of novel receptors can provide access to tremendous tools for the testing of drugs (e.g., the adrenergic receptors), whereas cloning of a novel growth factor might potentially provide a new therapeutic agent. Biotechnology is also being used to screen compounds for biological activity. By using cloned and

Figure 4.1 • Yearly growth of GenBank in base pairs.

Figure 4.2 • Yearly growth of GenBank in terms of gene sequences.

Figure 4.3 • Yearly approvals of biotechnology-derived drugs and vaccines.

expressed genes, it is possible to generate receptor proteins to facilitate high-throughput screening of drugs in vitro or in cell culture systems rather than in animals or tissues. Biotechnology is being investigated in completely novel approaches to the battle against human disease, including the use of antisense oligonucleotides and gene replacement therapies for the treatment of diseases such as CF and the use of monoclonal antibodies (MAbs) for the treatment of cancer.

Biotechnology encompasses many subdisciplines, including genomics, proteomics, gene therapy, made-to-order molecules, computer-assisted drug design, and pharmacogenomics. A goal of biotechnology in the early 21st century is to eliminate the “one-drug-fits-all” paradigm for pharmaceutical care.⁵⁸

The drugs that are elaborated by biotechnological methods are proteins and, hence, require special handling. There are some basic requirements of pharmaceutical care for the pharmacist working with biotechnologically derived products⁴¹:

- An understanding of how the handling and stability of biopharmaceuticals differs from other drugs that pharmacists dispense
- Knowledge of preparation of the product for patient use, including reconstitution or compounding if required
- Patient education on the disease, benefits of the prescribed biopharmaceutical, potential side effects or drug interactions to be aware of, and the techniques of self-administration
- Patient counseling on reimbursement issues involving an expensive product
- Monitoring of the patient for compliance

The pharmacist must maintain an adequate knowledge of agents produced through the methods of biotechnology and remain “in the loop” for new developments. The language of biotechnology encompasses organic chemistry, biochemistry, physiology, pharmacology, medicinal chemistry, immunology, molecular biology, and microbiology. A pharmacist has studied in all of these areas and is uniquely

poised to use these skills to provide pharmaceutical care with biotechnological agents when needed.

The key techniques that unlocked the door to the biotechnology arena are those of rDNA, also known as *genetic engineering*. rDNA techniques allow scientists to manipulate genetic programming, create new genomes, and extract genetic material (genes) from one organism and insert it into another to produce proteins.

THE BIOTECHNOLOGY OF RECOMBINANT DNA

Since its inception in the mid-1970s, recombinant DNA (rDNA)⁶⁷⁻⁷⁴ (genetic engineering) technology has driven much of the fundamental research and practical development of novel drug molecules and proteins. rDNA technology provides the ability to isolate genetic material from any source and insert it into cells (plant, fungal, bacterial, animal) and even live animals and plants, where it is expressed as part of the receiving organism’s genome. Before discussing techniques of genetic engineering, a review of some of the basics of cellular nucleic acid and protein chemistry is relevant.⁷⁵⁻⁷⁷

Most of the components that contribute to cellular homeostasis are proteins—so much so that more than half of the dry weight of a cell is protein. Histones, cellular enzymes, membrane transport systems, and immunoglobulins are just a few examples of the proteins that carry out the biological functions of a living human cell. Proteins are hydrated three-dimensional structures, but at their most basic level, they are composed of linear sequences of amino acids that fold to create the spatial characteristics of the protein. These linear sequences are called the *primary structure* of the protein, and they are encoded from DNA through RNA. The information flow sequence DNA → RNA → protein has, for many years, been called the biological “Central Dogma.”^{78,79} The

specific sequence of amino acids is encoded in genes. Genes are discrete segments of linear DNA that compose the chromosomes in the nucleus of a cell. The Human Genome Project has revealed that there are between 30,000 and 35,000 functional genes in a human, encompassing about 3,400,000,000 base pairs (bp).⁸⁰

As depicted in Figure 4.4, in the nucleus of the cell, double-stranded DNA undergoes a process of transcription (catalyzed by RNA polymerase) to yield a single-stranded molecule of pre-mRNA. Endonucleases then excise non-functional RNA sequences called *introns*, from the pre-mRNA, to yield functional mRNA. In the cytoplasm, mRNA complexes with the ribosomes and the codons are read and translated into proteins. The process of protein synthesis in *Escherichia coli* begins with the activation of amino acids as aminoacyl-transfer RNA (tRNA) derivatives. All 20 of the amino acids undergo this activation, an adenosine

triphosphate (ATP)-dependent step catalyzed by aminoacyl-tRNA synthetase. Initiation involves the mRNA template, *N*-formylmethionyl tRNA, the initiation codon (AUG), initiation factors, and the ribosomal subunits. Elongation occurs (using several elongation factors) with the aminoacyl-tRNAs being selected by recognition of their specific codons and forming new peptide bonds with neighboring amino acids. When biosynthesis of the specific protein is finished, a termination codon in the mRNA is recognized, and release factors disengage the protein from the elongation complex. Finally, the protein is folded and post-translational processing occurs.^{81,82} Processes that might be used in this step include removal of initiating residues and signaling sequences, proteolysis, modification of terminal residues, and attachment of phosphate, methyl, carboxyl, sulfate, carbohydrate, or prosthetic groups that help the protein achieve its final three-dimensional shape. Specialized

Figure 4.4 • Path from DNA to protein.

chaperone proteins can also direct the three-dimensional formation. Posttranslational modifications occur in mammalian cells in the endoplasmic reticulum or the Golgi apparatus before the protein is transported out of the cell. Most posttranslational modifications occur only in higher organisms, not in bacteria. The three-base genetic codon system is well known and has been conserved among all organisms. This allows rDNA procedures to work and facilitates the development of a model for the amino acid sequence of a protein by correlation with the codon sequence of the genome.

Recombinant DNA Technology

The fundamental techniques involved in working with rDNA include isolating or copying a gene; inserting the precise gene into a transmissible vector that can be transcribed, amplified, and propagated by a host cell's biochemical machinery; transferring it to that host cell; and facilitating the transcription into mRNA and translation into proteins. Cloned DNA can also be removed or altered by using an appropriate restriction endonuclease. Because genes encode the language of proteins, in theory, it is possible to create any protein if one can obtain a copy of the corresponding gene. rDNA methods require the following⁸³:

- An efficient method for cleaving and rejoining phosphodiester bonds on fragments of DNA (genes) derived from an array of different sources
- Suitable vectors or carriers capable of replicating both themselves and the foreign DNA linked to them
- A means of introducing the rDNA into a bacterial, yeast, plant, or mammalian cell
- Procedures for screening and selecting a clone of cells that has acquired the rDNA molecule from a large population of cells

There are two primary methods for cloning DNA⁸⁴ using genomic and cDNA libraries as the primary sources of DNA fragments, which, respectively, represent either the chromosomal DNA of a particular organism or the cDNA prepared from mRNA present in a given cell, tissue, or organ. In the first method, a library of DNA fragments is created from a cell's genome, which represents all of the genes present. The library is then screened against special DNA probes. Lysing the genomic contents to generate fragments of different sizes and compositions, some of which should contain the genetic sequences that encode the specific activity that one is seeking, creates the library. With knowledge of the protein sequence that the gene specifies, DNA probes can be synthesized that should hybridize with corresponding fragments in the library. By labeling the probes with fluorescent or radioactive tags, probe molecules that hybridize and form double-helical DNA can be identified and isolated electrophoretically. The DNA from the library can then be amplified by a technique such as the polymerase chain reaction (PCR), inserted into a vector, and transferred into a host cell. A comparison of these methods is given in Table 4.1.

The second major method for cloning DNA represents only genes that are being expressed⁸⁴ at a given time and involves first the isolation of the mRNA that encodes the amino acid sequence of the protein of interest. Treating the mRNA with the viral enzyme reverse transcriptase in the presence of nucleoside triphosphates (NTPs) causes a strand of DNA to be synthesized complementary to the mRNA matrix, affording

TABLE 4.1 Characteristics of Genomic versus cDNA Libraries

Characteristic	Genomic	cDNA
Source of genetic material	Genomic DNA	Cell or tissue mRNA
Complexity (independent recombinants)	>100,000	5,000–20,000
Size range of recombinants (bp ^a)	1,000–50,000	30–10,000
Presence of introns	Yes	No
Presence of regulatory elements	Yes	Maybe
Suitable for heterologous expression	Maybe	Yes

^abp, base pairs.

an RNA–DNA hybrid. The RNA strand is broken down in alkaline conditions, yielding a single-stranded molecule of DNA. The DNA polymerase reaction affords a complementary or copy strand of DNA (cDNA), which on fusion of a promotor sequence can be attached to a transport vector. Figure 4.5 depicts these reactions.

If the amino acid sequence of a protein (and, hence, the codon sequence) is known, automated synthesis of DNA through chemical or enzymatic means represents a third way that genes can be engineered. This method is useful only for relatively small proteins. In principle, for the preparation of a genomic library, the cellular origin of the DNA is not an issue, whereas the cellular origin of mRNA is central to the preparation of a cDNA library. Therefore, genomic libraries vary from species to species but not from tissue to tissue within that species. cDNA varies with tissue and the developmental stages of cells, tissues, or species. Another important distinction is that the fragment of DNA from eukaryotic chromosomes will contain exons (protein-coding segments) and introns (noncoding segments between exons), whereas in cDNA, the introns are spliced out.

Figure 4.5 • Method for preparation of cDNA from an mRNA transcript.

Figure 4.6 • Mechanism of a restriction endonuclease reaction.

Restriction Endonucleases^{84,85}

The restriction endonuclease (or restriction enzyme) is probably best described as a set of “molecular scissors” in nature. Restriction endonucleases are bacterial enzymes that, as the name implies, cleave internal phosphodiester bonds of a DNA molecule. The cleavage site on a segment of DNA lies within a specific nucleotide sequence of about 6 to 8 bp. More than 500 restriction endonucleases have been discovered, and these react with more than 100 different cleavage sites. The chemical reaction of the restriction endonuclease releases the 3' end of one base as an alcohol and the 5' end as a monophosphate. The general reaction is shown in Figure 4.6.

The recognition sites for restriction endonucleases are specific palindromic sequences of DNA⁸⁵ not more than 8 bp long. A number of these palindromes are listed in Table 4.2. A *palindrome* is a sequence of letters that reads the same way forward and backward, for instance: “A man, a plan, a canal: Panama!,” “DNA-land,” “Did Hannah see bees? Hannah did.” Restriction endonucleases cleave DNA at palindromic sites to yield several types of cuts:

These cuts yields an overhanging C/C “sticky” end that is relatively easy to ligate with complementary ends of other DNA molecules. A cut from an endonuclease like *HaeIII*:

requires more complicated methods to ligate into vector DNA. Palindromic cleavage sites for some selected restriction enzymes are given in Table 4.2. The *arrow* shows the cleavage site. The restriction endonucleases are a robust group of enzymes that form a toolbox for investigators working in the field of genetic engineering. About the only caveat to their use is an obvious one: They must be chosen not to make their cut inside the gene of interest.

DNA Ligases⁸⁶

When the gene of interest has been excised from its flanking DNA by the appropriate restriction endonucleases and the vector DNA has been opened (using the same restriction endonuclease to break phosphodiester bonds), the two different DNA molecules are brought together by annealing. In the first step of this process, heating unwinds the double-stranded DNA of the vector. The insert or passenger DNA is added to the heated mixture, and subsequent cooling facilitates pairing of complementary strands. Then, phosphodiester bonds are regenerated, linking the two DNA molecules, vector and insert. A total of four such bonds must be reformed, two on each strand at the 5' and 3' sites. This process is termed *ligation*, and the enzymes that catalyze the reaction are named *DNA ligases*. Typically, ATP or another energy source is required to drive the ligation reaction, and linker fragments of DNA are used to facilitate coupling. There are several different types of ligation reactions that are used, depending on the type of restriction endonuclease product that was formed. The sticky-ended DNA, using complementary vector and insert ends that easily base pair at the cuts, is probably the easiest to accomplish, although methods exist to ligate the blunt-ended varieties, using DNA ligase.

The Vector⁸⁴

There are several methods available for introducing DNA into host cells. DNA molecules that can maintain themselves by replication are called *replicons*. Vectors are subsets of replicons. In genetic engineering, the vector (carrier) is the most widely used method for the insertion of foreign, or passenger, genetic material into a cell. *Vectors* are genetic elements such as plasmids or viruses that can be propagated and that have been engineered so that they can accept fragments of foreign DNA. Depending on the vector, they may have many other features, including multiple cloning sites

TABLE 4.2 Palindromic Cleavage Sites

<i>AluI</i> AG↓CT	<i>AsuII</i> TT↓CGAA	<i>BalI</i> TGG↓CCA	<i>BamHI</i> G↓GATCC	<i>BglII</i> A↓GATCT	<i>ClaI</i> AT↓CGAT	<i>EcoRI</i> G↓AATTC

(a region containing multiple restriction enzyme sites into which an insert can be installed or removed), selection markers, and transcriptional promoters. The passenger DNA must integrate into the host cell's DNA or be carried into the cell as part of a biologically active molecule that can replicate independently. If this result is not achieved, the inserted gene will not be successfully transcribed. The most commonly used biological agent for transporting genes into bacterial and yeast cells is the plasmid, such as the *E. coli* bacterial plasmid pBR322. A plasmid is a small, double-stranded, closed circular extrachromosomal DNA molecule. This plasmid contains 4,361 bp and can transport relatively small amounts of DNA. Plasmids occur in many species of bacteria and yeasts. Sometimes, plasmids carry their own genes (e.g., the highly transmissible genes for antibiotic resistance in some bacterial species). An important feature of a plasmid is that it has an origin of replication (*ori*) site that allows it to multiply independently of a host cell's DNA. Although there can be more than one copy of a plasmid in a cell, the copy number is controlled by the plasmid itself.

Another type of cloning vector is the bacteriophage (Fig. 4.7). Bacteriophage λ (lambda) possesses a genome of approximately 4.9×10^5 bp and can package large amounts of genetic material without affecting the infectivity of the phage. A large DNA library can be created, packaged in bacteriophage λ , and, when the virus infects, inserted into cells. Hybridization is then detected by screening with DNA probes.⁸⁷ In addition, there are special vectors called *phagemids*, vaccinia and adenovirus for cloning into mammalian cells, and yeast artificial chromosomes (YACs) that facilitate cloning in yeasts.⁸⁸ Differences among these vectors concern the size of the insert that they will accept, the methods used in the selection of the clones, and the procedures for propagation.

Once the passenger DNA has been created and the plasmid vector cut (both with the same restriction enzyme), the insert is ligated into the plasmid along with a promoter (a short DNA sequence that enhances the transcription of the adjacent gene). Often, a gene imparting antibiotic resistance linked to the desired gene is inserted as a selection tool. The idea behind this is that if the gene is inserted in the proper location, the bacterial cell will grow on a medium containing the antibiotic. Bacteria that do not contain the resistance gene and, hence, lack the required gene will not grow. This makes the task of screening for integration of the desired gene easier. After the molecule is ligated, the vector is finally an rDNA molecule that can be inserted into a host cell.

Host cells can be bacteria (e.g., *E. coli*), eukaryotic yeast (*Saccharomyces cerevisiae*), or mammalian cell lines, including Chinese hamster ovary (CHO), African green monkey kidney (VERO), and baby hamster kidney (BHK). It is easy to grow high concentrations of bacteria and yeast cells in fermenters to yield high protein concentrations. Mammalian cell culture systems typically give poorer protein yields, but sometimes this is acceptable, especially when the product demands the key posttranslational modifications that do not occur in bacteria. Host cells containing the vector are grown in small-scale cultures and screened for the desired gene.⁸⁹ When the clone providing the best protein yield is located, the organism is grown under carefully controlled conditions and used to inoculate pilot-scale fermentations. Parameters such as production medium composition, pH, aeration, agitation, and temperature are investigated at this stage to optimize the fermentation. The host cells divide, and the plasmids in them replicate, producing the desired "new" protein. The fermentation is scaled up into larger bioreactors for large-scale isolation of the recombinant protein. Obviously, the cultures secrete

Figure 4.7 • Types of cloning vectors: a bacteriophage and a plasmid.

their own natural proteins along with the cloned protein. Purification steps are required before the recombinant protein is suitable for testing as a new, genetically engineered pharmaceutical agent. Once the host cell line expressing the recombinant gene is isolated, it is essential to maintain selection pressure on it so that it does not spontaneously lose the plasmid. Typically, this pressure is applied by maintaining the cells on medium containing an antibiotic to which they bear a resistance gene.

SOME TYPES OF CLONING

A listing of some types of cloning is given in Table 4.3.

Functional Expression Cloning⁹⁰

Functional expression cloning focuses on obtaining a specific cDNA of known function. There are many variations on this approach, but they all rely on the ability to search for and isolate cDNAs based on some functional activity that can be measured (e.g., the electrophysiological measurement of ion conductances following expression of cDNAs in frog oocytes). By incrementally subdividing the cDNAs into pools and following the activity, it is possible to obtain a single cDNA clone that encodes the functionality. The advantage of functional expression cloning is that it does not rely on knowledge of the primary amino acid sequence. This is a definite advantage when attempting to clone proteins of low abundance.

Positional Cloning⁹⁰

Positional cloning can be used to localize fragments of DNA representing genes prior to isolating the DNA. An example of the use of positional cloning is the cloning of the gene responsible for CF. By studying the patterns of inheritance of

the disease and then comparing these with known chromosomal markers (linkage analysis), it was possible, without knowing the function of the gene, to locate the gene on human chromosome 7. Then, by using a technique known as *chromosome walking*, the gene was localized to a DNA sequence that encodes a protein now known as the cystic fibrosis transmembrane conductance regulator (CFTR). This protein, previously unknown, was shown to be defective in CF patients and could account for many of the symptoms of the disease. Like functional cloning, positional cloning has the advantage that specific knowledge of the protein is not required. It is also directly relevant to the understanding of human disease, and it can provide important new biological targets for drug development and the treatment of disease.

Homology-Based Cloning

Another cloning strategy involves the use of previously cloned genes to guide identification and cloning of evolutionarily related genes. This approach, referred to as *homology-based cloning*, takes advantage of the fact that nucleotide sequences encoding important functional domains of proteins tend to be conserved during the process of evolution. Thus, nucleotide sequences encoding regions involved with ligand binding or enzymatic activity can be used as probes that will hybridize to complementary nucleotide sequences that may be present on other genes that bind similar ligands or have similar enzymatic activity. This approach can be combined with PCR^{91,92} to amplify the DNA sequences. The use of homology-based cloning has the advantages that it can be used to identify families of related genes, does not rely on the purification or functional activity of a given protein, and can provide novel targets for drug discovery. Its usefulness is offset by the possibility that the isolated fragment may not encode a complete or functional protein or that, in spite of knowledge of the shared sequence, the actual function of the clone may be difficult to identify.

TABLE 4.3 Cloning Strategies

Strategy	Advantages	Disadvantages	Example
Positional	Provides information underlying the genetic basis of known diseases	3.3×10^9 bp, difficult to use with diseases caused by multiple interacting alleles	Cystic fibrosis gene product
Protein purification	Yields genetic information encoding proteins of known structure and function	Protein purification, especially for low-abundance proteins, is exacting; availability of appropriate libraries, incomplete coding sequences	β_2 -Adrenergic receptor
Antibody based	Yields genetic information encoding proteins of known structure and function	Involves protein purification, unrecognized cross-reactivity, incomplete coding sequences	Vitamin D receptor
Functional expression	Yields genetic information encoding a functionally active protein; does not require protein purification	Function must be compatible with existing library-screening technology	Substance K receptor
Homology based	Identification of related genes or gene families; relatively simple	Depends on preexisting gene sequence; can yield incomplete genes or genes of unknown function	Muscarinic receptor
Expressed sequence tagging	High throughput; identification of novel cDNAs	Incomplete coding sequences or genes of unknown function	
Total genomic sequencing	Knowledge of total genome; identification of all potential gene products	3.3×10^9 bp, labor intensive; genes of unknown function	<i>Haemophilus influenzae</i>

EXPRESSION OF CLONED DNA

Once cloned, there are many different possibilities for the expression and manipulation of DNA sequences. Because it concerns the use of cloned genes in the process of drug discovery and development, there are many obvious ways in which the expression of DNA sequences can be applied. One of the most obvious is in replacement of older technologies that involve the purification of proteins for human use from either animal sources or human byproducts, such as blood. An example of this is factor VIII, a clotting cascade protein used for the treatment of the genetically linked bleeding disorder hemophilia. Until recently, the only source of purified factor VIII was human blood, and tragically, before the impact of AIDS was fully appreciated, stocks of factor VIII had become contaminated with HIV-1, resulting in the infection of as many as 75% of the patients receiving this product. The gene encoding factor VIII has since been cloned, and recombinant factor VIII is now available as a product purified from cultured mammalian cells. Other recombinant clotting factors, including factors VIIa and IX, are under development and, together with recombinant factor VIII, will eliminate the risk of exposure to human pathogens.

Other examples in which the expression of cloned human genes offers alternatives to previously existing products include human insulin, which is now a viable replacement for purified bovine and porcine insulin for the treatment of diabetes, and hGH, which is used for the treatment of growth hormone deficiency in children (dwarfism). Unlike insulin, growth hormones from other animal species are ineffective in humans; thus, until human recombinant growth hormone became available, the only source of hGH was the pituitary glands of cadavers. This obviously limited the supply of hGH and, like factor VIII, exposed patients to potential contamination by human pathogens. Recombinant hGH (rhGH) can now be produced by expression in bacterial cells.

The expression of cloned genes can be integrated into rational drug design by providing detailed information about the structure and function of the sites of drug action. With the cloning of a gene comes knowledge of the primary amino acid sequence of an encoded receptor protein. This information can be used to model its secondary structure and in an initial attempt to define the protein's functional domains, such as its ligand-binding site. Such a model can then serve as a basis for the design of experiments that can be used to test the model and facilitate further refinement. Of particular use are mutagenesis experiments that use rDNA techniques to change a primary amino acid sequence so that the consequences can be studied. In addition, expression of a cloned target protein can be used to generate samples for various biophysical determinations, such as x-ray crystallography. This technique, which can provide detailed information about the three-dimensional molecular structure of a protein, frequently requires large amounts of protein, which, in some cases, is only available with the use of recombinant expression systems.

Like the many strategies used to clone genes, there are many strategies for their expression, involving the use of either bacterial or eukaryotic cells and specialized vectors compatible with expression in host cells. Since these cells do not normally express the protein of interest, this methodology

is often referred to as *heterologous expression*. It is also possible to prepare cRNA from rDNA, which can then be used for either *in vitro* expression or injection directly into cells. In the former situation, purified ribosomes are used in the test tube to convert cRNA into protein; for the latter situation, the endogenous cellular ribosomes make the protein. A relatively new development for the expression of cloned genes is the use of animals that have the cloned gene stably integrated into their genome. Such transgenic animals can potentially make very large amounts of recombinant protein, which can be harvested from the milk, blood, and ascites fluid.

The choice of a particular expression system depends on several factors. Protein yield, requirements for biological activity, and compatibility of the expressed protein with the host organism are a few. An example of the compatibility issue is that bacteria do not process proteins in exactly the same way as do mammalian cells, so that the expression of human proteins in bacteria will not always yield an active product or any product at all. Cases like these may require expression in mammalian cell cultures. The choice of an expression system also reflects the available vectors and corresponding host organisms. A basic requirement for the heterologous expression of a cloned gene is the presence of a promoter that can function in the host organism and a mechanism for introducing the cloned gene into the organism. The promoter is the specific site at which DNA polymerase binds to initiate transcription and is usually specific for the host organism. As in gene cloning, the vectors are either plasmids or viruses that have been engineered to accept rDNA and that contain promoters that direct the expression of the rDNA. The techniques for introducing the vector into the organism vary widely and depend on whether one is interested in transient expression of the cloned gene or in stable expression. In the latter case, integration into the host genome is usually required; transient expression simply requires getting the vector into the host cell.

MANIPULATION OF DNA SEQUENCE INFORMATION

Perhaps the greatest impact of rDNA technology lies in its ability to alter a DNA sequence and create entirely new molecules that, if reintroduced into the genome, can be inherited and propagated in perpetuity. The ability to alter a DNA sequence, literally in a test tube, at the discretion of an individual, corporation, or nation, brings with it important questions about ownership, ethics, and social responsibility. There is no question, however, that potential benefits to the treatment of human disease are great.

There are three principal reasons for using rDNA technology to alter DNA sequences. The first is simply to clone the DNA to facilitate subsequent manipulation. The second is to intentionally introduce mutations so that the site-specific effect on protein structure and function can be studied.^{93,94} The third reason is to add or remove sequences to obtain some desired attribute in the recombinant protein. For example, recent studies with factor VIII show that the protein contains a small region of amino acids that are the major determinant for the generation of anti-factor VIII antibodies in a human immune system. This autoimmune response of the patient inhibits the activity of factor VIII, which is

obviously a serious therapeutic complication for patients who are using factor VIII for the treatment of hemophilia. By altering the DNA sequence encoding, this determinant, however, the amino acid sequence can be changed both to reduce the antigenicity of the factor VIII molecule and to make it transparent to any existing anti-factor VIII antibodies (i.e., changing the epitope eliminates the existing antibody recognition sites).

It is possible to combine elements of two proteins into one new recombinant protein. The resulting protein, referred to as a *chimeric* or *fusion protein*, may then have some of the functional properties of both of the original proteins. This is illustrated in Figure 4.8 for two receptors labeled A and B. Each receptor has functional domains that are responsible for ligand binding, integration into the plasma membrane, and activation of intracellular signaling pathways. Using rDNA techniques, one can exchange these functional domains to create chimeric receptors that, for example, contain the ligand-binding domain of receptor B but the transmembrane and intracellular signaling domains of receptor A. The application of the fusion protein strategy is discussed further in connection with the hGH receptor (under "Novel Drug-Screening Strategies") and with denileukin diftiox.

Another reason for combining elements of two proteins into one recombinant protein is to facilitate its expression and purification. For example, recombinant glutathione S-transferase (GST), cloned from the parasitic worm *Schistosoma japonicum*, is strongly expressed in *E. coli* and has a binding site for glutathione. Heterologous sequences encoding the functional domains from other proteins can be fused, in frame, to the carboxy terminus of GST, and the resulting fusion protein is often expressed at the same levels as GST itself. In addition, the resulting fusion protein retains the ability to bind glutathione, which means that affinity chromatography, using glutathione that has been covalently bonded to agarose, can be used for a single-step purification of the fusion protein. The functional activity of the heterologous domains that have been fused to GST can then be

studied either as part of the fusion protein or separately following treatment of the fusion protein with specific proteases that cleave at the junction between GST and the heterologous domain. Purified fusion proteins can also be used to generate antibodies to the heterologous domains and for other biochemical studies. Sometimes, fusion proteins are made to provide a recombinant protein that can be easily identified. An example of this is a technique called *epitope tagging*, in which well-characterized antibody recognition sites are fused with recombinant proteins. The resulting recombinant protein can then be identified by immunofluorescence or can be purified with antibodies that recognize the epitope.

NEW BIOLOGICAL TARGETS FOR DRUG DEVELOPMENT

One of the outcomes of the progress that has been made in the identification and cloning of genes is that many proteins encoded by these genes represent entirely new targets for drug development. In some cases, the genes themselves may represent the ultimate target for the treatment of a disease in the form of gene therapy. The cloning of the CF gene is an example of both a new drug target and a gene that could potentially be used to treat the disease. The protein encoded by this gene, CFTR, is a previously unknown integral membrane protein that functions as a channel for chloride ions. Mutations in *CFTR* underlie the pathophysiology of CF, and in principle, replacement or coexpression of the defective gene with the healthy, nonmutated gene would cure the disease. It is also possible, however, that by understanding the structure and function of the healthy CFTR, drugs could be designed to interact with the mutated CFTR and improve its function.

An important outgrowth of the study of new drug targets is the recognition that many traditional targets, such as enzymes and receptors, are considerably more heterogeneous than previously thought. Thus, instead of one enzyme or receptor, there may be several closely related subtypes, or isoforms, each with the potential of representing a separate drug target. This can be illustrated with the enzyme cyclooxygenase (COX), which is pivotal to the formation of prostaglandins and which is the target of aspirin and the nonsteroidal anti-inflammatory drugs (NSAIDs). Until recently, COX was considered to be a single enzyme, but pharmacological and gene cloning studies have revealed that there are at least three enzyme forms, named COX-1, COX-2, and COX-3. Interestingly, they are differentially regulated. COX-1 is expressed constitutively in many tissues, whereas the expression of COX-2 is induced by inflammatory processes. Thus, the development of COX-2 selective agents can yield NSAIDs with the same efficacy as existing (nonselective) agents but with fewer side effects, such as those on the gastric mucosa.

The elucidation of the family of adrenergic receptors is another example in which molecular cloning studies have revealed previously unknown heterogeneity, with the consequence of providing new targets for drug development. The adrenergic receptors mediate the physiological effects of the catecholamines epinephrine and norepinephrine. They are also the targets for many drugs used in the treatment of such conditions as congestive heart failure, asthma, hypertension,

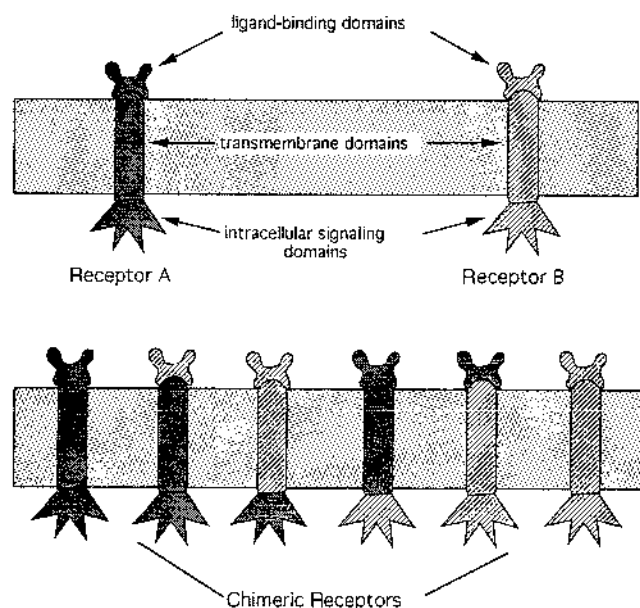

Figure 4.8 • Chimeric receptors.

TABLE 4.4 Selected Examples of Receptor Subtype Heterogeneity

Receptor Superfamily	Original Subtypes	Present Subtypes
G-protein-coupled		
Adrenergic	$\beta_1, \beta_2, \alpha_1, \alpha_2$	$\beta_1, \beta_2, \beta_3, \alpha_{1A}, \alpha_{1B}, \alpha_{1D}, \alpha_2A, \alpha_2B, \alpha_2C$
Dopamine	D ₁ , D ₂	D ₁ , D ₂ ^a , D ₃ , D ₄ , D ₅
Prostaglandin E ₂	EP ₁ , EP ₂ , EP ₃	EP ₁ , EP ₂ , EP ₃ ^a , EP ₄
Receptor tyrosine kinase neurotrophins	Nerve growth factor receptor	TrkA ^a , TrkB, TrkC ^a
DNA binding		
Estrogen	Estrogen receptor	ERR1, ERR2
Thyroid hormone	Thyroid hormone receptor	TR α , TR β
Retinoic acid	Retinoic acid receptor	RAR α , RAR β
Ligand-activated channels		
Glycine	Glycine and/or strychnine receptor	$\alpha_1, \alpha_2, \alpha_3$ (multisubunit) ^b
GABA _A	GABA and/or benzodiazepine receptor	$\alpha_1, \alpha_2, \alpha_3, \alpha_4, \alpha_5, \alpha_6$ (multisubunit) ^b

^aAlternative mRNA splicing creates additional receptor heterogeneity.

^bOnly the heterogeneity of the ligand-binding subunit is listed; a multisubunit structure combined with the heterogeneity of the other subunits creates a very large number of potential subtypes.

glaucoma, and benign prostatic hypertrophy. Prior to the molecular cloning and purification of adrenergic receptors, the pharmacological classification of this family of receptors consisted of four subtypes: α_1 , α_2 , β_1 , and β_2 . The initial cloning of the α -adrenergic receptor in 1986 and subsequent gene cloning studies revealed at least nine subtypes: $\beta_1, \beta_2, \beta_3, \alpha_{1A}, \alpha_{1B}, \alpha_{1D}, \alpha_2A, \alpha_2B,$ and α_2C (Chapter 16).

The evidence that there are nine subtypes of adrenergic receptors is very important in terms of understanding the physiology of the adrenergic receptors and of developing drugs that can selectively interact with these subtypes. For example, in the case of the α_2 -agonist *p*-aminoclonidine, an agent used to lower intraocular pressure (IOP) in the treatment of glaucoma, it may now be possible to explain some of the drug's pharmacological side effects (e.g., bradycardia and sedation) by invoking interactions with the additional α_2 -adrenergic receptor subtypes. Of considerable interest is the possibility that these pharmacological effects (i.e., lowering of IOP, bradycardia, and sedation) are each mediated by one of the three different α_2 -receptor subtypes. If this is true, it might be possible to develop a subtype-selective α_2 -agonist that lowers IOP but does not cause bradycardia or sedation. Likewise, it might even be possible to take advantage of the pharmacology and develop α_2 -adrenergic agents that selectively lower heart rate or produce sedation.

The discovery of subtypes of receptors and enzymes by molecular cloning studies seems to be the rule rather than the exception and is offering a plethora of potential new drug targets (Table 4.4). To note just a few: 5 dopamine receptor subtypes have been cloned, replacing 2 defined pharmacologically (Chapter 13); 7 serotonin receptor subtypes have been cloned, replacing 3; 4 genes encoding receptors for prostaglandin E₂ have been isolated, including 12 additional alternative mRNA splice variants; and 3 receptors for nerve growth factor have been cloned, replacing 1.

NOVEL DRUG-SCREENING STRATEGIES

The combination of the heterologous expression of cloned DNA, the molecular cloning of new biological targets, and the ability to manipulate gene sequences has created powerful new tools that can be applied to the process of drug discovery and development. In its most straightforward application, the

ability to simply express newly identified receptor protein targets offers a novel means of obtaining information that may be difficult, or even impossible, to obtain from more complex native biological systems. There is a reason for this. A newly identified protein can be expressed in isolation. Even for closely related enzyme or receptor subtypes, heterologous expression of the individual subtype can potentially provide data that are specific for the subtype being expressed, whereas the data from native biological systems will reflect the summation of the individual subtypes that may be present.

The potential advantage of heterologous expression is illustrated in Figure 4.9 for the interaction of a drug with multiple binding sites. In *panel A*, which can represent the data

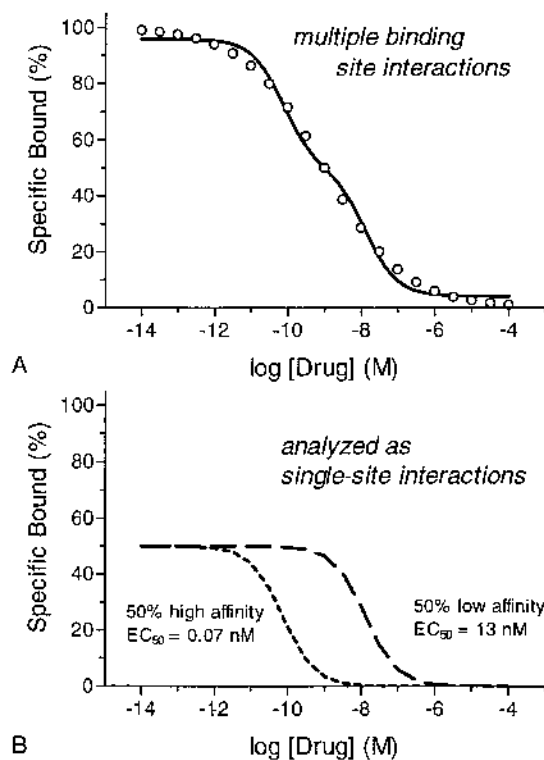

Figure 4.9 • Convoluted data from binding to multiple receptor subtypes versus class mass action.

obtained from a native biological system, the data are complex, and the curve reflects interactions of the drug with two populations of receptors: one with high affinity, representing 50% of the total receptor population, and one with low affinity, representing the remaining 50%. The individual contributions of these two populations of receptors are indicated in *panel B*, which could also reflect the data obtained if rDNA encoding these two receptors were expressed individually in a heterologous expression system. Although in some cases, the data, as in *panel A*, can be analyzed with success, frequently they cannot, especially if more than two subtypes are present or if any one subtype makes up less than 10% of the total receptor population or if the affinities of the drug for the two receptor populations differ by less than 10-fold.

Another important reason for integrating heterologous expression into drug-screening strategies is that data can usually be obtained for the human target protein rather than an animal substitute. This does not mean that organ preparations or animal models will be totally replaced. For the purposes of the identification of lead compounds and the optimization of selectivity, affinity, etc., however, the use of recombinant expression systems provides some obvious advantages.

By combining heterologous expression with novel functional assays, it is possible to increase both specificity and throughput (the number of compounds that can be screened per unit time). For example, reporter genes have been developed that respond to various intracellular second messengers, such as the activation of guanine nucleotide-binding proteins (G proteins), and levels of cyclic adenosine monophosphate (cAMP), or calcium. One approach to the development of novel functional assays involves the use of promoter regions in DNA that control the transcription of genes. This approach is exemplified by the cAMP response element (CRE). This is a specifically defined sequence of DNA that is a binding site for the cAMP response element-binding (CREB) protein. In the unstimulated condition, the binding of CREB to the CRE prevents the transcription and expression of genes that follow it (Fig. 4.10). When CREB

is phosphorylated by cAMP-dependent protein kinase A (PKA), however, its conformation changes, permitting the transcription and expression of the downstream gene. Thus, increases in intracellular cAMP, such as those caused by receptors that activate adenylyl cyclase (e.g., β -adrenergic, vasopressin, etc.), will stimulate the activity of PKA, which, in turn, results in the phosphorylation of CREB and the activation of gene transcription.

In nature, there are a limited number of genes whose activity is regulated by a CRE. Biologically, however, the expression of almost any gene can be regulated in a cAMP-dependent fashion if it is placed downstream of a CRE, using rDNA techniques. If the products of the expression of the downstream gene can be easily detected, they can serve as reporters for any receptor or enzyme that can modulate the formation of cAMP in the cell. The genes encoding chloramphenicol acetyl transferase (CAT), luciferase, and β -galactosidase are three examples of potential "reporter genes," whose products can be easily detected. Sensitive enzymatic assays have been developed for all of these enzymes; thus, any changes in their transcription will be quickly reflected by changes in enzyme activity. By coexpressing the reporter gene along with the genes encoding receptors and enzymes that modulate cAMP formation, it is possible to obtain very sensitive functional measures of the activation of the coexpressed enzyme or receptor.

Another example of the use of a reporter gene for high-throughput drug screening is the receptor selection and amplification technology (r-SAT) assay. This assay takes advantage of the fact that the activation of several different classes of receptors can cause cellular proliferation. If genes for such receptors are linked with a reporter gene, such as β -galactosidase, the activity of the reporter will be increased as the number of cells increase as a consequence of receptor activation. Initially, a limitation of this assay was that it only worked with receptors that normally coupled to cellular proliferation; by making a mutation in one of the second-messenger proteins involved with the proliferative response, however, it was possible to get additional

Figure 4.10 • Activation of transcription by a cAMP response element (CRE). CREB is phosphorylated by cAMP-dependent protein kinase.

receptors to work in this assay. This second-messenger protein, G_q , was cloned, and a recombinant chimera was made that included part of another second messenger known as G_i . In native cells, receptors that activate G_i are not known for their stimulation of cell proliferation, but when such receptors are coexpressed in the r-SAT assay with the chimeric G_q , their activity can be measured.

A similar strategy involving chimeric proteins has been used for receptors whose second-messenger signaling pathways are not clearly understood. For example, the development of potential therapeutic agents acting on the hGH receptor has been difficult because of a lack of a good signaling assay. The functional activity of other receptors that are structurally and functionally related to the growth hormone receptor can be measured, however, in a cell proliferation assay. One such receptor that has been cloned is the murine receptor for granulocyte colony-stimulating factor (G-CSF). By making a recombinant chimeric receptor containing the ligand-binding domain of the hGH receptor with the second-messenger-coupling domain of the murine G-CSF receptor, it was possible to stimulate cellular proliferation with hGH.

In addition to providing a useful pharmacological screen for hGH analogs, the construction of this chimeric receptor provides considerable insight into the mechanism of agonist-induced growth hormone receptor activation. The growth hormone-binding domain is clearly localized to the extracellular amino terminus of the receptor, whereas the transmembrane and intracellular domains are implicated in the signal transduction process. It was also determined that successful signal transduction required receptor dimerization by the agonist (i.e., simultaneous interaction of two receptor molecules with one molecule of growth hormone). Based on this information, a mechanism-based strategy was used for the design of potential antagonists. Thus, hGH analogs were prepared, were incapable of producing receptor dimerization, and were found to be potent antagonists.

PROCESSING OF THE RECOMBINANT PROTEIN

Processing the fermentation contents to isolate a recombinant protein is often a difficult operation, requiring as much art as science. In the fermentation broth are whole bacterial cells, lysed cells, cellular fragments, nucleotides, normal bacterial proteins, the recombinant protein, and particulate medium components. If a Gram-negative bacterium such as *E. coli* has been used, lipopolysaccharide endotoxins (pyrogens) may be present. When animal cell cultures are used, it is commonly assumed that virus particles may be present. Viruses can also be introduced by the culture nutrients, generated by an infected cell line, or introduced by animal serum. Purification of an rDNA protein while maintaining the factors that keep it in its active three-dimensional conformation from this mixture may be difficult, because each step must be designed to ensure that the protein remains intact and pharmacologically active. Assays must be designed that allow the activity of the protein to be assessed at each purification step. Consequently, the structure and activity of the recombinant protein must be considered at all stages of purification, and assays must be conducted to measure the amount of purified, intact protein.

A general scheme for purification of an rDNA protein is as follows⁹⁵:

- *Particulate removal.* Particulates may be removed by centrifugation, filtration, ultrafiltration, and tangential flow filtration. Virus particles may be inactivated by heating if the rDNA peptide can tolerate the procedure.
- *Concentration.* The volume of the mixture is reduced, which increases the concentration of the contents. Often, concentration is achievable by the filtration step, especially if ultrafiltration is used.
- *Initial purification.* The initial purification of the mixture is sometimes accomplished by precipitation of the proteins, using a slow, stepwise increase of the ionic strength of the solution (salting out). Ammonium sulfate is a typical salt that can be used in cold, aqueous solutions. Water-miscible organic solvents such as trichloroacetic acid and polyethylene glycol (PEG) change the dielectric constant of the solution and also effect precipitation of proteins.
- *Intermediate purification.* In this stage, the proteins may be dialyzed against water to remove salts that were used in the precipitation step. Ion exchange chromatography is used to effect a somewhat crude separation of the proteins based on their behavior in a pH or salt gradient on the resin. Another step that may be taken is size exclusion (gel filtration) chromatography. Gels of appropriate molecular weight cutoffs can yield a somewhat low-resolution separation of proteins of a desired molecular weight. If a native bacterial protein that has been carried this far is nearly the same molecular weight as the rDNA protein, no separation will occur.
- *Final purification.* Final purification usually involves the use of high-resolution chromatography, typically high-performance liquid chromatography. An abundance of commercial stationary phases allows various types of adsorption chromatography (normal and reversed phase), ion exchange chromatography, immunoaffinity chromatography, hydrophobic interaction chromatography, and size exclusion chromatography. The protein fractions are simply collected when they elute from the column and are concentrated and assayed for activity.
- *Sterilization and formulation.* This step can be accomplished by ultrafiltration to remove pyrogens or by heating if the protein can withstand this. Formulation might involve reconstitution into stable solutions for administration or determining the optimum conditions for stability when submitting for clinical trials.

Complicating factors include (a) proteins unfolding into an inactive conformation during processing (it may not be possible to refold the protein correctly) and (b) proteases that are commonly produced by bacterial, yeast, and mammalian cells, which may partially degrade the protein.

PHARMACEUTICS OF RECOMBINANT DNA-PRODUCED AGENTS

rDNA methods have facilitated the production of very pure, therapeutically useful proteins. The physicochemical and pharmaceutical properties of these agents are those of proteins, which means that pharmacists must understand the chemistry (and the chemistry of instability) of proteins to store, handle, dispense, reconstitute, and administer these

protein drugs. Instabilities among proteins may be physical or chemical. In the former case, the protein might stick to glass vessels or flocculate, altering the dose that the patient will receive. In the latter case, chemical reactions taking place on the protein may alter the type or stereochemistry of the amino acids, change the position of disulfide bonds, cleave the peptide chains themselves, and alter the charge distribution of the protein. Any of these can cause unfolding (denaturation) of the protein and loss of activity, rendering the molecule useless as a drug. Chemical instability can be a problem during the purification stages of a protein, when the molecule might be subjected to acids or bases, but instability could occur at the point of administration when, for example, a lyophilized protein is reconstituted. The pharmacist must understand a few concepts of the chemical and physical instability of proteins to predict and handle potential problems.

Chemical Instability of Proteins⁶⁷

See Figure 4.11.

- **Hydrolysis.** Hydrolytic reactions of the peptide bonds can break the polymer chain. Aspartate residues hydrolyze 100 times faster in dilute acids than do other amino acids under the same conditions. As a general rule of peptide hydrolysis, Asp-Pro > Asp-X or X-Asp bonds. This property of Asp is probably a result of an autocatalytic function of the Asp side chain carboxyl group. Asn, Asp, Gln, and Glu hydrolyze exceptionally easily if they occur next to Gly, Ser, Ala, and Pro. Within these groupings, Asn and Gln accelerate hydrolysis more at low pH, whereas Asp and Glu hydrolyze most readily at high pH, when the side chain carboxyl groups are ionized.
- **Deamidation.** Gln and Asn undergo hydrolytic reactions that deaminate their side chains. These reactions convert neutral amino acid residues into charged ones. Gln is converted to Glu and Asn to Asp. The amino acid type is changed, but the chain is not cleaved. This process is, effectively, primary sequence isomerization, and it may influence biological activity. The deamidation reaction of Asn residues is accelerated under neutral or alkaline pH conditions. A five-membered cyclic imide intermediate formed by intramolecular attack of the nitrogen atom on the carbonyl carbon of the Asn side chain is the accelerant. The cyclic imide spontaneously hydrolyzes to give a mixture of residues—the aspartyl peptide and an isoform.
- **Racemization.** Base-catalyzed racemization reactions can occur in any of the amino acids except glycine, which is achiral. Racemizations yield proteins with mixtures of L- and D-amino acid configurations. The reaction occurs following the abstraction of the α -hydrogen from the amino acid to form a carbanion. As should be expected, the stability of the carbanion controls the rate of the reaction. Asp, which undergoes racemization via a cyclic imide intermediate, racemizes 105 times faster than free Asn. By comparison, other amino acids in a protein racemize about 2 to 4 times faster than their free counterparts.
- **β -Elimination.** Proteins containing Cys, Ser, Thr, Phe, and Lys undergo facile β -elimination in alkaline conditions that facilitate formation of an α -carbanion.
- **Oxidation.** Oxidation can occur at the sulfur-containing amino acids Met and Cys and at the aromatic amino acids His, Trp, and Tyr. These reactions can occur during protein

processing as well as in storage. Methionine ($\text{CH}_3\text{—S—R}$) is oxidizable at low pH by hydrogen peroxide or molecular oxygen to yield a sulfoxide (R—SO—CH_3) and a sulfone ($\text{R—SO}_2\text{—CH}_3$). The thiol group of Cys (R—SH) can undergo successive oxidation to the corresponding sulfenic acid (R—SOH), disulfide (R—S—S—R), sulfinic acid ($\text{R—SO}_2\text{H}$), and sulfonic acid ($\text{R—SO}_3\text{H}$). Several factors, including pH, influence these reactions. Free —SH groups can be converted into disulfide bonds (—S—S—) and vice versa. In the phenomenon of disulfide exchange, disulfide bonds break and reform in different positions, causing incorrect folding of the protein. Major changes in the three-dimensional structure of the peptide can abolish activity. Oxidation of the aromatic rings of His, Trp, and Tyr residues is believed to occur with various oxidizing enzymes.

Physical Instability of Proteins⁹⁶

Chemical alterations are not the only source of protein instability. A protein is a large, globular polymer that exists in some specific forms of secondary, tertiary, and quaternary structure. A protein is not a fixed, rigid structure. The molecule is in dynamic motion, and the structure samples an array of three-dimensional space. During this motion, non-covalent intramolecular bonds can break, reform, and break again, but the overall shape remains centered around an energy minimum that represents the most likely (and pharmacologically active) conformer of the molecule. Any major change in the conformation can abolish the activity of the protein. Small drug molecules do not demonstrate this problem. A globular protein normally folds so that the hydrophobic groups are directed to the inside and the hydrophilic groups are directed to the outside. This arrangement facilitates the water solubility of the protein. If the normal protein unfolds, it can refold to yield changes in hydrogen bonding, charge, and hydrophobic effects. The protein loses its globular structure, and the hydrophobic groups can be repositioned to the outside. The unfolded protein can subsequently undergo further physical interactions. The loss of the globular structure of a protein is referred to as *denaturation*.

Denaturation is, by far, the most widely studied aspect of protein instability. In the process, the three-dimensional folding of the native molecule is disrupted at the tertiary and, possibly, the secondary structure level. When a protein denatures, physical structure rather than chemical composition changes. The normally globular protein unfolds, exposing hydrophobic residues and abolishing the native three-dimensional structure. Factors that affect the denaturation of proteins are temperature, pH, ionic strength of the medium, inclusion of organic solutes (urea, guanidine salts, acetamide, and formamide), and the presence of organic solvents such as alcohols or acetone. Denaturation can be reversible or irreversible. If the denatured protein can regain its native form when the denaturant is removed by dialysis, reversible denaturation will occur. Denatured proteins are generally insoluble in water, lack biological activity, and become susceptible to enzymatic hydrolysis. The air–water interface presents a hydrophobic surface that can facilitate protein denaturation. Interfaces like these are commonly encountered in drug delivery devices and intravenous (IV) bags.

Surface adsorption of proteins is characterized by adhesion of the protein to surfaces, such as the walls of the containers

Hydrolysis-Deamidation

Base-Catalyzed β -Elimination

Figure 4.11 • A. Protein decomposition reactions. B. β -Elimination. B

of the dosage form and drug delivery devices, ampuls, and IV tubing. Proteins can adhere to glass, plastics, rubber, polyethylene, and polyvinylchloride. This phenomenon is referred to as *flocculation*. The internal surfaces of IV delivery pumps and IV delivery bags pose particular problems of this kind. Flocculated proteins cannot be dosed properly.

Aggregation results when protein molecules, in aqueous solution, self-associate to form dimers, trimers, tetramers, hexamers, and large macromolecular aggregates. Self-association depends on the pH of the medium as well as solvent composition, ionic strength, and dielectric properties. Moderate amounts of denaturants (below the concentration that would cause denaturation) may also cause protein aggregation. Partially unfolded intermediates have a tendency to aggregate. Concentrated protein solutions, such as an immunoglobulin for injection, may aggregate with storage time on the shelf. The presence of particulates in the preparation is the pharmacist's clue that the antibody solution is defective.

Precipitation usually occurs along with denaturation. Detailed investigations have been conducted with insulin, which forms a finely divided precipitate on the walls of an infusion device or its dosage form container. It is believed that insulin undergoes denaturation at the air–water interface, facilitating the precipitation process. The concentration of zinc ion, pH, and the presence of adjuvants such as protamine also affect the precipitation reaction of insulin.

Immunogenicity of Biotechnologically Produced Drugs^{97,98}

Proteins, by their very nature, are antigens. A human protein, innocuous at its typical physiological concentration, may exhibit completely different immunogenic properties when administered in the higher concentration that would be used as a drug. Unless a biotechnology-derived protein is engineered to be 100% complementary to the human form, it will differ among several major epitopes. The protein may have modifications of its amino acid sequence (substitutions of one amino acid for another). There may be additions or deletions of amino acids, N-terminal methionyl groups, incorrect or abnormal folding patterns, or oxidation of a sulfur-containing side chain of a methionine or a cysteine. Additionally, when a protein has been produced by using a bacterial vector, a finite amount of immunoreactive material may pass into the final product. All of these listed items contribute to the antigenicity of a biotechnologically produced protein. When it is administered to a human patient, the host's immune system will react to the protein just as it would to a microbial attack and neutralize it. This is why research has been undertaken to create 100% human protein drugs, such as insulin, which patients will need to take for a long time. In addition, some of the most promising biotechnology products, the MABs, are produced in mice by use of *humanized* genes to avoid human reaction to the mouse antibody.

DELIVERY AND PHARMACOKINETICS OF BIOTECHNOLOGY PRODUCTS⁹⁹

As with any drug class, the medicinal chemist and pharmacist must be concerned with the absorption, distribution, metabolism, and excretion (ADME) parameters of protein drugs. Biotechnology-produced drugs add complexities that

are not encountered with “traditional” low-molecular-weight drug molecules. ADME parameters are necessary to compute pharmacokinetic and pharmacodynamic parameters for a given protein. As for any drug, these parameters are essential in calculating the optimum dose for a given response, determining how often to administer the drug to obtain a steady state, and adjusting the dose to obtain the best possible residence time at the receptor (pharmacodynamic parameters).

Delivery of drugs with the molecular weights and properties of proteins into the human body is a complex task. The oral route cannot be used with a protein because the acidity of the stomach will catalyze its hydrolysis unless the drug is enteric coated. Peptide bonds are chemically labile, and proteolytic enzymes that are present throughout the body can attack and destroy protein drugs. Hydrolysis and peptidase decomposition also occur during membrane transport through the vascular endothelium, at the site of administration, and at sites of reaction in the liver, blood, kidneys, and most tissues and fluids of the body. It is possible to circumvent these enzymes by saturating them with high concentrations of drug or by coadministering peptidase inhibitors. Oxidative metabolism of aromatic rings and sulfur oxidation can also occur. Proteins typically decompose into small fragments that are readily hydrolyzed, and the individual amino acids are assimilated into new peptides. A potentially serious hindrance to a pharmacokinetic profile is the tendency of proteins administered as drugs to bind to plasma proteins, such as serum albumin. If this happens, they enter a new biodistribution compartment from which they may slowly exit. Presently, the routes of administration that are available for protein drugs are largely subcutaneous (SC) and intramuscular (IM). Much ongoing research is targeted at making peptide drugs more bioavailable. An example of this is conjugation of interleukin-2 (IL-2) with PEG. These so-called pegylated proteins tend to have a slower elimination clearance and a longer $t_{1/2}$ than IL-2 alone. Another strategy being used is the installation of a prosthetic sugar moiety onto the peptide. The sugar moiety will adjust the partition coefficient of the drug, probably making it more water soluble.

RECOMBINANT DRUG PRODUCTS

Hormones

HUMAN INSULIN, RECOMBINANT^{100–102}

Human insulin was the first pharmacologically active biological macromolecule to be produced through genetic engineering. The FDA approved the drug in 1982 for the treatment of type 1 (insulin-dependent) diabetes (see Chapter 27). The insulin protein is a two-chain polypeptide containing 51 amino acid residues. Chain A is composed of 21 amino acids, and chain B contains 30. The human insulin molecule has three disulfide linkages, CysA₇ to CysB₇, CysA₂₀ to CysB₁₉, and an intrachain linkage, CysA₆ to CysA₁₁. Insulin is secreted by the β -cells of the pancreatic islets of Langerhans, initially as a single peptide chain called *proinsulin*. Enzymatic cleavage of the propeptide releases the insulin.

Historically, insulin was isolated from bovine or porcine sources. Using these agents was not without difficulty. Both porcine and bovine insulin differ in amino acid sequence,

with Ala replacing Thr at the C-terminus of the human B chain (B₃₀). Bovine insulin also differs in sequence from human insulin, with Ala substituting for Thr at A₈ and Val substituting for isoleucine at A₁₀. These differences, small though they may seem, result in immunological reactions in some patients. Adjustments to the formulation of bovine and porcine insulin led to products that differed in time of onset, time to peak reduction in glucose, and duration of action. These parameters were varied by addition of protamine and zinc (which yielded a particulate insulin with a longer duration of action), and adjustment of the pH to neutrality, which stabilized the preparation. Insulins were characterized as regular (short-duration Iletin, 4–12 hours), semilente (ultra-short duration), lente (intermediate [1–3 hours to peak, 24 hours duration]), and ultralente (extended duration). An additional form of insulin was NPH (neutral protamine Hagedorn), which had an intermediate time of onset and time to peak (1–3 hours) and a long duration of action (16–24 hours).

Producing a recombinant insulin that is chemically and physically indistinguishable from the human pancreatic hormone was a major accomplishment. The problem with immunoreactivity has been eliminated, the pyrogen content of the rDNA product is nil, the insulin is not contaminated with other peptides, and the hormone can be biosynthesized in larger quantities. Human insulin (rDNA) is available as Humulin, Novolin, and several analogs that differ in their pharmacokinetic profiles. Humulin is produced by using recombinant *E. coli*; Novolin is prepared by using recombinant *S. cerevisiae*, a yeast. There have been modifications in the production procedure since the initial successful biosynthesis. Prior to 1986, Humulin was produced by creating two different vectors, one for the A chain and one for the B chain, and inserting them into *E. coli*. The A chain and the B chain would be secreted into the medium, and the two were joined chemically to form rDNA insulin. Today, the entire proinsulin gene is used to create a recombinant organism, and the connecting peptide in proinsulin is cleaved by two enzymes (an endopeptidase and a carboxypeptidase B), yielding insulin (for details see Chapter 27).

Insulin rDNA is available in several¹⁰³ forms. Insulin lispro (Humalog) has a more rapid (15–30 minutes) onset and a shorter duration (3–6.5 hours) of action than regular human insulin (onset 30–60 minutes, duration 6–10 hours). It is effective when administered 15 minutes before a meal, unlike regular insulin, which must be injected 30 minutes before a meal. In lispro, the B-chain amino acids B₂₈Pro and B₂₉Lys are exchanged. Insulin aspart (NovoLog), onset 15 to 30 minutes, duration 3 to 6.5 hours, with a single amino acid substitution of Asp for Pro at B₂₈, is effective when administered 5 to 10 minutes before a meal. The ultra-long-acting agent insulin glargine has the Asp at A₂₁ replaced by Gly and has two Arg residues added at the C-terminus of the B chain. Insulin glargine, administered subcutaneously, has a duration of action of 24 to 48 hours. The alteration in basicity of this agent causes it to precipitate at neutral pH, creating a depot effect.

Insulin rDNA has been very successful. The only problem has arisen in patients who have been using porcine or bovine insulin for a long time. Some patients who are switched to rDNA human insulin report difficulty in “feeling their glucose level,” and these patients require extra counseling in the use of the recombinant hormone.

GLUCAGON¹⁰⁴

The hormone glucagon (GlucaGen) is biosynthesized in the pancreas as a high-molecular-weight protein from which the active macromolecule is released by proteolytic cleavage. Glucagon is a single chain of 29 amino acids and generally opposes the actions of insulin. Bovine and porcine glucagons, which possess structures identical with human glucagon, have been in use for years. The rDNA form has been approved by the FDA for use in severe hypoglycemia and as a radiological diagnostic aid. Glucagon relaxes smooth muscles in the gastrointestinal (GI) tract, decreasing GI motility and improving the quality of radiological examinations. In the treatment of severe hypoglycemia in insulin-dependent diabetics, GlucaGen causes the liver to convert glycogen to glucose. Left untreated, severe hypoglycemia (low-blood-sugar reactions) can cause prolonged loss of consciousness and may be fatal. The rDNA drug has the benefit that there is no chance of acquiring bovine spongiform encephalopathy from glucagon therapy. This condition, also known as *mad cow disease*, is caused by a prion that was suspected to infect animal pancreas tissue.

HUMAN GROWTH HORMONE, RECOMBINANT^{105,106}

hGH is a protein that is essential for normal growth and development in humans. hGH affects many aspects of human development and metabolism including longitudinal growth, regulation (increase) of protein synthesis and lipolysis, and regulation (decrease) of glucose metabolism. hGH has been used as a drug since the 1950s, and it has been extremely successful in the treatment of classic growth hormone deficiency, chronic renal insufficiency, Turner syndrome, failure to lactate in women, and Prader-Willi syndrome. In its long history, the hormone has been remarkably successful and free of side effects.

The primary form of hGH in the circulation is a 22-kDa, nonglycosylated protein produced in the anterior pituitary and composed of 191 amino acid residues linked by disulfide bridges in two peptide loops. The structure of hGH is globular, with four antiparallel α -helical regions. Endogenous hGH is composed of about 85% of the 22-kDa monomer, 5% to 10% of a 20-kDa monomer, and 5% of a mixture of disulfide-linked dimers, oligomers, and other modified forms. From the late 1950s, hGH was isolated from pituitary extracts of cadavers. A prion associated with the preparation was suspected to cause Creutzfeldt-Jakob disease, a fatal degenerative neurological disorder.

The first use of rhGH was reported in 1982. rhGH preparations were first produced in *E. coli*. These preparations contained a terminal methionine and 192 amino acids. Natural sequence rhGH has since been produced in mammalian (mouse) cell culture.

Somatrem, the first recombinant preparation, introduced in 1985, contains the natural 191-amino acid primary sequence plus one methionyl residue on the N-terminal end. The somatropin products all contain the 191-amino acid sequence and are identical with the hGH produced by the pituitary gland. The three-dimensional crystal structure shows that the protein is oblate, with most of its nonpolar amino acid side chains projecting toward the interior of the molecule. This rhGH is pharmacologically identical with natural hGH.

Most current formulations of rhGH are supplied in lyophilized form and must be reconstituted prior to injection. Typically, 5 to 10 mg of protein are supplied in a powdered glycine and/or mannitol phosphate buffer. The preparation is reconstituted with sterile water for injection, and the stability of the product is quite good. If stored at 2°C to 8°C, rhGH will remain stable for 2 years.

rhGH undergoes rapid, predictable metabolism *in vivo* in the kidney and the liver. Chemically, the metabolites are those expected for any peptide: deamidation of Asn and Gln and oxidation of Met, Trp, His, and Tyr.

FOLLICLE-STIMULATING HORMONE^{107,108}

The gonadotropin follicle-stimulating hormones (FSH), follitropin alfa (Gonal-F) and follitropin beta (Follistim), are produced in the anterior lobe of the pituitary gland. FSH can function in two ways. On the one hand, it causes increased spermatogenesis in men. On the other hand, in concert with estrogen and luteinizing hormone (LH), it stimulates follicular growth and development in women. Consequently, FSH may be useful in the treatment of infertility.

FSH is a member of a superfamily of proteins, all structurally related, which includes LH, chorionic gonadotropin, and thyroid-stimulating hormone (TSH). It is a heterodimer, the α subunit contains 92 amino acids, and the β subunit contains 111 amino acids. The protein is rather heavily glycosylated and has a molecular mass of approximately 35 kDa. The traditional source for isolation of FSH was postmenopausal urine, which provided a preparation that was less than 5% pure and was significantly contaminated by LH. The recombinant human FSH (rhFSH) is produced in a mammalian cell line, the CHO.

Follitropin α and follitropin β are the same protein, but they differ with respect to the way they are formulated. Both preparations are lyophilized. The α form is formulated with sucrose (as a bulk modifying agent and a lyoprotectant) and the components of phosphate buffer. The β form contains sucrose, with sodium citrate as a stabilizer and polysorbate 20 as a lyoprotectant and a dispersant. The products are

reconstituted immediately before administration. The shelf life of both preparations is 2 years when they are stored in the supplied containers at less than 30°C (not frozen) and protected from light.

THYROTROPIN ALPHA^{109,110}

Human TSH, thyrotropin alpha (Thyrogen), is a heterodimeric protein of molecular mass ~28,000 to 30,000 Da. The α subunit is composed of 92 amino acids, and the β subunit, 112. The specificity of the protein is controlled by the β subunit. TSH binds to TSH receptors on normal thyroid epithelial cells or on well-differentiated cancerous thyroid tissue to stimulate iodine uptake into the gland, organification of iodine, and secretion of thyroglobulin, T₃, and T₄. The drug is used as a tool for radioiodine imaging in the diagnosis of thyroid cancer.

Cytokines

HEMATOPOIETIC GROWTH FACTORS

Among all of the events taking place in the immune system, the bone marrow, and the bloodstream, the process of hematopoiesis is probably the most complicated. All of the cells in the blood and the immune system can trace their lineage back to a common, parental hematopoietic stem cell in the bone marrow. This cell is referred to as *pluripotent* because under the proper stimulation, it can differentiate into any other cell. The processes of maturation, proliferation, and differentiation are under the strict control of several cytokines (Table 4.5) that regulate a host of cellular events. Two distinct blood cell lineages exist: the lymphoid lineage that gives rise to B and T lymphocytes, and the myeloid lineage that produces granulocytes (macrophages, neutrophils, eosinophils, basophils, and mast cells), as well as platelets and erythrocytes. As many as 20 of the hematopoiesis-associated cytokines have been cloned and expressed. Some of these are listed in Table 4.5.

The cascade is shown in Figure 4.12. A further feature of the pluripotent stem cell deserves mention. Each stem cell divides into two daughter cells, one an active hematopoietic

TABLE 4.5 Examples of Important Cytokines

Cytokine	Biological Function
Interleukin-1	Maturation and proliferation of B cells; activation of NK cells, inflammation, fever
Interleukin-2	
Interleukin-3	Stimulates growth and differentiation of T-cell response; used to treat cancer or transplant patients
Interleukin-4

Stem cell factor	Inhibits Th1 cytokine production IFN- γ , TNF β , IL-2
	Acute-phase protein production
	Controls the ratio of T _H 1-T _H 2
	Induces production of IFN- γ , increases NK cell activity
	Stimulates red cell production
	Acts with IL-3 to control myeloid branch
	Neutrophil production
	Macrophage production
	Controls activity through myeloid branch

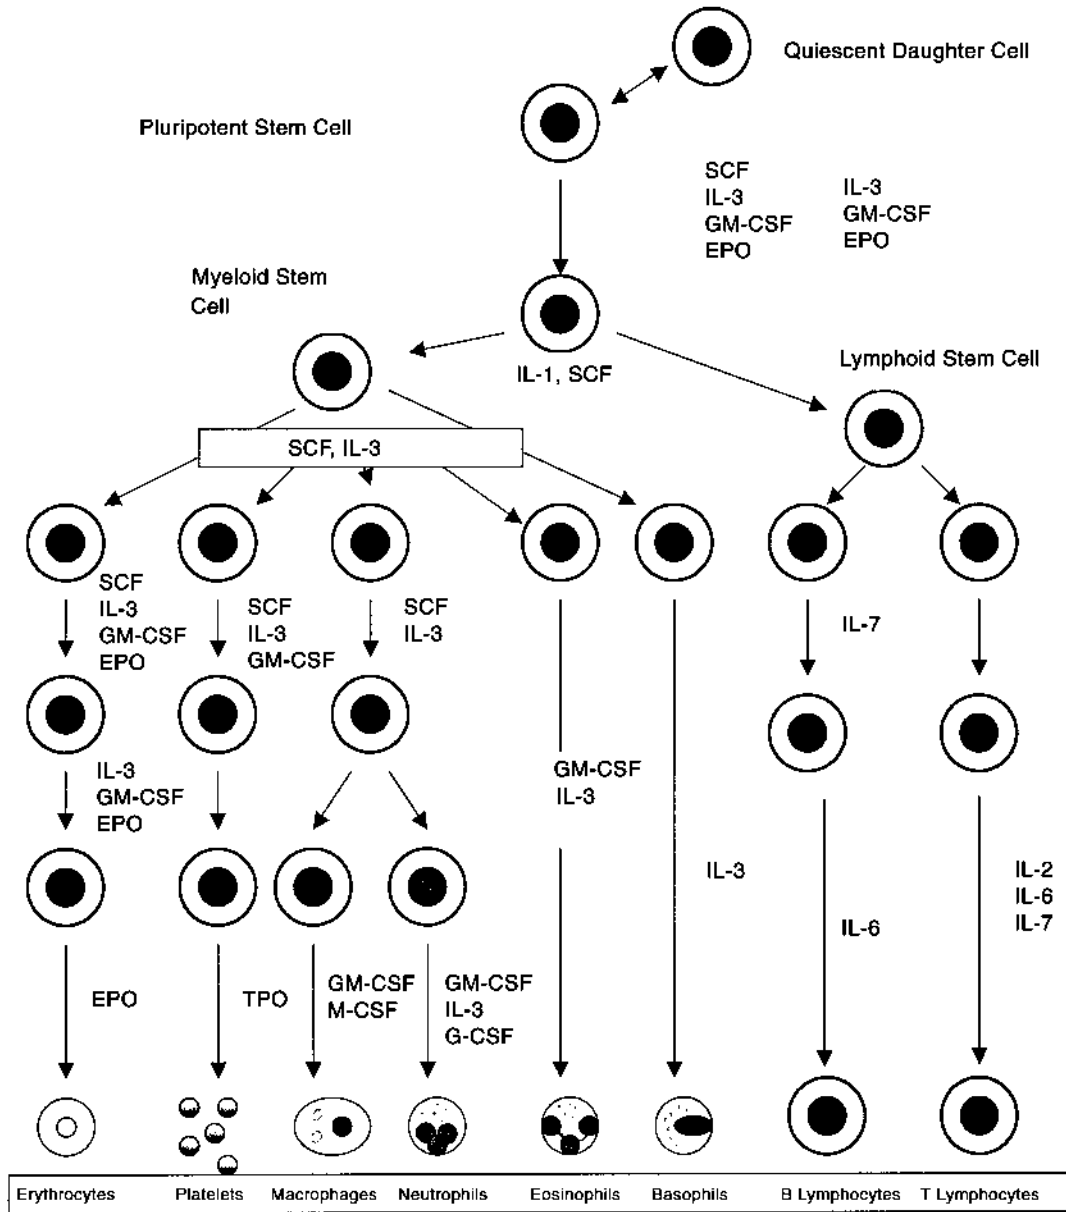

Figure 4.12 • Cytokine-mediated cascade leading to different blood cell types. (EPO, erythropoietin; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte–macrophage colony-stimulating factor; IL-X, interleukins; M-CSF, macrophage colony-stimulating factor; SCF, stem cell factor; TPO, thrombopoietin.)

progenitor and one quiescent. The active precursor matures to give hematopoietic progenitors and then circulating blood cells. The quiescent stem cells rejoin the stem cell pool. Hence, the number of parental cells is always the same. This process is termed *self-renewal*.

PRODUCTS

Erythropoietin Alfa^{111–113}

Erythropoietin alfa, recombinant Epoetin Alfa, Epogen, Procrit, is a glycoprotein that stimulates red blood cell production. It is produced in the kidney, and it activates the proliferation and differentiation of specially committed erythroid progenitors in the bone marrow. Epoetin alfa (Epogen) is a 165-amino acid glycoprotein that is manufactured in mammalian cells by rDNA technology. The protein is heav-

ily glycosylated and has a molecular mass of approximately 30,400 Da. Erythropoietin is composed of four antiparallel α -helices. The rDNA protein has the same amino acid sequence as natural erythropoietin.

Epoetin is indicated to treat anemia of chronic renal failure patients, anemia in zidovudine-treated HIV-infected patients, and in cancer patients taking chemotherapy. The results in these cases have been dramatic; most patients respond with a clinically significant increase in hematocrit.

Filgrastim^{114,115}

Filgrastim, G-CSF, Neupogen, stimulates the proliferation of granulocytes (especially neutrophils) by mobilizing hematopoietic stem cells in the bone marrow. Endogenous G-CSF is a glycoprotein produced by monocytes, fibroblasts, and endothelial cells. G-CSF is a protein of 174 amino

acids, with a molecular mass of approximately 18,800 Da. The native protein is glycosylated.

Filgrastim selectively stimulates proliferation and differentiation of neutrophil precursors in the bone marrow. This leads to the release of mature neutrophils into the circulation from the bone marrow. Filgrastim also affects mature neutrophils by enhancing phagocytic activity, priming the cellular metabolic pathways associated with the respiratory burst, enhancing antibody-dependent killing, and increasing the expression of some functions associated with cell surface antigens.

In patients receiving chemotherapy with drugs such as cyclophosphamide, doxorubicin, and etoposide, the incidence of neutropenia accompanied by fever is rather high. Administration of G-CSF reduces the time of neutrophil recovery and duration of fever in adults with acute myelogenous leukemia. The number of infections, days that antibiotics are required, and duration of hospitalization are also reduced.

Filgrastim¹¹⁶ is identical with G-CSF in its amino acid sequence, except that it contains an N-terminal methionine that is necessary for expression of the vector in *E. coli*. The protein is not glycosylated. Filgrastim is supplied in a 0.01 M sodium acetate buffer containing 5% sorbitol and 0.004% polysorbate 80. It should be stored at 2°C to 8°C without freezing. Under these conditions, the shelf life is 24 months. Avoid shaking when reconstituting; although the foaming will not harm the product, it may alter the amount of drug that is drawn into a syringe.

Sargramostim^{117,118}

Sargramostim, granulocyte–macrophage colony-stimulating factor (GM-CSF), Leukine, is a glycoprotein of 127 amino acids, consisting of three molecular subunits of 19,500, 16,800, and 15,500 Da. The endogenous form of GM-CSF is produced by T lymphocytes, endothelial fibroblasts, and macrophages. Recombinant GM-CSF, produced in *S. cerevisiae*, differs from native human GM-CSF only by substitution of a leucine for an arginine at position 23. This substitution facilitates expression of the gene in the yeast. The site of glycosylation in the recombinant molecule may possibly differ from that of the native protein.

Sargramostim binds to specific receptors on target cells and induces proliferation, activation, and maturation. Administration to patients causes a dose-related increase in the peripheral white blood cell count. Unlike G-CSF, GM-CSF is a multilineage hematopoietic growth factor that induces partially committed progenitor cells to proliferate and differentiate along the granulocyte and the macrophage pathways. It also enhances the function of mature granulocytes and macrophages/monocytes. GM-CSF increases the chemotactic, antifungal, and antiparasitic activities of granulocytes and monocytes. It also increases the cytotoxicity of monocytes toward neoplastic cell lines and activates polymorphonuclear leukocytes to inhibit the growth of tumor cells.

Sargramostim is used to reconstitute the myeloid tissue after autologous bone marrow transplant and following chemotherapy in acute myelogenous leukemia. The preparation decreases the incidence of infection, decreases the number of days that antibiotics are required, and decreases the duration of hospital stays.

Sargramostim is supplied as a solution or powder (for solution). Both forms should be stored at 2°C to 8°C without

freezing. The liquid and powder have expiration dates of 24 months. The reconstituted powder and the aqueous solution should not be shaken.

Becaplermin¹¹⁹

Becaplermin, Regranex Gel, an endogenous polypeptide that is released from cells that are involved in the healing process, is a recombinant human platelet–derived growth factor (rhPDGF-BB). The “BB” signifies that becaplermin is the homodimer of the B chain. Becaplermin is produced by a recombinant strain of *S. cerevisiae* containing the gene for the B chain of PDGF. The protein has a molecular mass of approximately 25 kDa and is a homodimer composed of two identical polypeptide chains that are linked by disulfide bonds. It is a growth factor that activates cell proliferation, differentiation, and function, and it is released from cells involved in the healing process.

Becaplermin is formulated as a gel recommended for topical use in the treatment of ulcerations of the skin secondary to diabetes.

Interferons

The interferons are a family of small proteins or glycoproteins of molecular masses ranging from 15,000 to 25,000 Da and 145 to 166 amino acids long. Eukaryotic cells secrete interferons in response to viral infection. Their mechanism of action is bimodal. The immediate effect is the recruitment of natural killer (NK) cells to kill the host cell harboring the virus (Fig. 4.13). Interferons then induce a state of viral resistance in cells in the immediate vicinity, preventing spread of the virus. Additionally, interferons induce a cascade of antiviral proteins from the target cell, one of which is 2',5'-oligoadenylate synthetase. This enzyme catalyzes the conversion of ATP into 2',5'-oligoadenylate, which activates ribonuclease R, hydrolyzing viral RNA. Interferons can be defined as cytokines that mediate antiviral, antiproliferative, and immunomodulatory activities.

Three classes of interferon (IFN) have been characterized: α (alpha), β (beta), and γ (gamma) (see Table 4.6). α -Interferons are glycoproteins derived from human leukocytes. β -Interferons are glycoproteins derived from fibroblasts and macrophages. They share a receptor with α -interferons. γ -Interferons are glycoproteins derived from human T lymphocytes and NK cells. These interferons are acid labile and used to be called “type 2 interferon.” The receptor for IFN- γ is smaller than that for IFN- α and IFN- β , 90 to 95 kDa versus 95 to 110 kDa, respectively. The three classes are not homogeneous, and each may contain several different molecular species. For example, at least 18 genetically and molecularly distinct human α -interferons have

Figure 4.13 • Antiviral mechanism of action of the interferons.

TABLE 4.6 Interferons Used Therapeutically

Interferon Type	Endogenous Source	Available Drug Products
Alpha	Leukocytes	Interferon alfa-2a Interferon alfa-2b Interferon alfa-2c
Beta	Fibroblasts, macrophages	Beta-1a Beta-1b
Gamma	T Lymphocytes, natural killer cells	Gamma-1b

been identified, each differing in the amino acid substitution at positions 23 and 34. Interferons alfa-2a, alfa-2b, and alfa-2c have been purified and are either in clinical use or in development. A listing of commercially available α -interferons is given in Table 4.7.

As a class, the interferons possess some common side effects. These are flulike symptoms, headache, fever, muscle aches, back pain, chills, nausea and vomiting, and diarrhea. At the injection site, pain, edema, hemorrhage, and inflammation are common. Dizziness is also commonly reported.

For the pharmacist, when predicting drug interactions with the interferons, cytochrome P450 metabolism should always be a key consideration. Most of the interferons inhibit cytochrome P450, causing drugs that are metabolized by this route to reach higher-than-normal and, possibly, toxic concentrations in the blood and tissues.

PRODUCTS: α -INTERFERONS

*Interferon Alfa-2a (Recombinant)*¹²⁰

Interferon alfa-2a (recombinant), Roferon A, is expressed in an *E. coli* system and purified by using high-affinity mouse MAb chromatography. The protein consists of 165 amino acids with a molecular mass of approximately 19,000 Da and contains lysine at position 23 and histidine at position 34.

Interferon alfa-2a is used in the treatment of hairy cell leukemia and AIDS-related Kaposi sarcoma in selected patients older than 18 years of age. It is also used to treat chronic hepatitis C, and in patients with this disease, interferon alfa-2a can normalize serum alanine aminotransferase (ALT) levels, improve liver histology, and decrease viral load. The drug has a direct antiproliferative activity against tumor cells. Modulation of the host immune response probably plays a role in the antitumor activity of interferon alfa-2a.

The interferon is supplied as a solution or as a powder for solution. The solution contains 0.72% NaCl. The powder contains 0.9% NaCl, 0.17% human serum albumin, and 0.33% phenol. The interferon vials, if properly stored at 2°C to 8°C without freezing, expire in 30 months. Prefilled syringes expire in 24 months. The solutions should not be shaken because the albumin will cause frothing.

*Pegylated Interferon Alfa-2a*¹²¹

Pegylated interferon alfa-2a, Pegasys, is a covalent conjugate of recombinant interferon alfa-2a (approximate molecular mass, 20 kDa) with a singly branched bis-monomethoxy PEG chain (approximate molecular mass, 40 kDa). The PEG moiety is linked at a single site to the interferon alfa moiety by a stable amide bond to lysine. Peginterferon alfa-2a has an approximate molecular mass of 60 kDa. Pegasys provides sustained therapeutic serum levels for up to a full week (168 hours). The drug is approved for the treatment of adults with chronic hepatitis C who have compensated liver disease and who have not been previously treated with interferon alfa. Efficacy has also been demonstrated in patients with compensated cirrhosis.

*Interferon Alfa-2b (Recombinant)*¹²²

Interferon alfa-2b, Intron A, a water-soluble protein of 165 amino acids and an approximate molecular mass of 19,200 Da, is expressed from a recombinant strain of *E. coli*. This interferon molecule possesses an arginine at position 23 and a histidine at position 34.

Interferon alfa-2b is a broad-spectrum agent. It is indicated for hairy cell leukemia, condyloma acuminata (genital or

^aSC, subcutaneously; IM, intramuscularly; IV, intravenously.

venereal warts), AIDS-related Kaposi sarcoma, and chronic hepatitis B and C infections.

Intron A can be administered by the SC, IM, or IV routes, by infusion or by intralesional routes. The dose is 1 to 35 million IU/day, depending on the application. The drug is supplied as a solution or as a powder for solution, and both forms contain albumin, glycine, and sodium phosphate buffer. Hence, they should not be shaken. Vials of solution should be stored at 2°C to 8°C without freezing. The powder is stable for 18 months at room temperature or 7 days at 45°C.

Interferon Alfa-n1¹²³

Interferon alfa-n1, Wellferon, is a mixture of α -interferons isolated from a human lymphoblastoid cell line after induction with mouse parainfluenza virus type 1 (Sendai strain). Each of the subtypes of IFN- α in this product consists of 165 or 166 amino acids with an average molecular mass of 26,000 Da. The product is a mixture of each of the nine predominant subtypes of IFN- α .

Interferon alfa-n1 is indicated to treat chronic hepatitis C in patients 18 years of age or older who have no decompensated liver disease. The exact mechanism of action for interferon alfa-n1 in the treatment of this disease has not been elucidated.

This drug may be administered SC or IM, with a usual dose of 3 million IU 3 times per week. Interferon alfa-n1 is supplied as a solution containing tromethamine and buffered saline with human albumin as a stabilizer. Hence, the solution should not be shaken. The solution should be stored at 2°C to 8°C without freezing, and should be discarded if freezing occurs. Properly stored solution expires in 24 months.

Interferon Alfa-n3¹²⁴

Interferon alfa-n3, Alferon N, is an α -interferon expressed from human leukocytes that are antigen-stimulated with avian Sendai virus. The Sendai virus is propagated in chicken eggs. The protein consists of at least 14 molecular subtypes. The average chain length is 166 amino acids, and the molecular mass range is 16,000 to 27,000 Da. The polydisperse interferon alfa-n3 is extremely pure, because it is processed by affinity chromatography over a bed of mouse MAbs specifically raised for the protein.

Interferon alfa-n3 is indicated for intralesional treatment of refractory or recurrent condyloma acuminata (genital warts) in patients 18 years of age or older. These warts are associated with human papillomavirus (HPV). Interferon alfa-n3 is especially useful in patients who have not responded well to other modalities (podophyllin resin, surgery, laser, or cryotherapy). Interferon alfa-n3 is also being investigated for the treatment of non-Hodgkin lymphoma, herpes simplex virus, rhinovirus, vaccinia, and varicella zoster. A usual dose in condyloma acuminata is 250,000 IU/wart, injected with a 30-gauge needle around the base of the lesion.

Interferon alfa-n3 is contraindicated in persons sensitive to mouse immunoglobulin G (IgG), egg protein, and neomycin.

Interferon alfa-n3 is supplied as a solution with the protein in phosphate-buffered saline with phenol as a preservative. The solution should be stored at 2°C to 8°C without freezing. Properly stored solution expires at 18 months.

Interferon Alfacon-1 (Recombinant)

Interferon alfacon-1 (recombinant), Infergen,¹²⁵ is a "consensus" interferon that shares structural elements of IFN- α and several subtypes. The range of activity is about

the same as the other alpha species, but the specific activity is greater.

The 166-amino acid sequence of alfacon-1 is synthetic. It was developed by comparing several natural IFN- α subtypes and assigning the *most common* amino acid to each variable position. Additionally, four amino acid changes were made to facilitate synthesis. The DNA sequence is also constructed by chemical synthesis. Interferon alfacon-1 differs from interferon alfa-n2 at 20/166 amino acids, yielding 88% homology. The protein has a molecular mass of approximately 19,400 Da.

Interferon alfacon-1 is used in the treatment of chronic hepatitis C virus (HCV) infection in patients 18 years of age or older with compensated liver disease and who have anti-HCV serum antibodies or HCV RNA.

The drug is administered by the SC route in a dose of 9 μ g 3 times per week. Interferon alfacon-1 is supplied as a solution in phosphate-buffered saline. It should be stored at 2°C to 8°C without freezing. Avoid shaking the solution.

PRODUCTS: β -INTERFERONS

A listing of two commercially available IFN- β s is given in Table 4.8.

Interferon Beta-1a (Recombinant)¹²⁶

Interferon beta-1a (recombinant), Avonex, is a glycoprotein with 166 amino acids. It has a molecular mass of approximately 22,000 Da. The site of glycosylation is at the asparagine residue at position 80. Interferon beta-1a possesses a cysteine residue at position 17, as does the native molecule. Natural IFN- β and interferon beta-1a are glycosylated, with each containing a single carbohydrate moiety. The overall complex has 89% protein and 11% carbohydrate by weight. Recombinant interferon beta-1a is expressed in CHO cells containing the recombinant gene for human IFN- β and is equivalent to the human form secreted by fibroblasts.

Interferon beta-1a is indicated for the treatment of relapsing forms of MS. Patients treated with interferon beta-1a demonstrate a slower progression to disability and a less noticeable breakdown of the blood-brain barrier as observed in gadolinium-enhanced magnetic resonance imaging (MRI).

TABLE 4.8 β -Interferons

	Interferon Beta-1a (Avonex)	Interferon Beta-1b (Betaseron)
Recombinant system	CHO cells	<i>Escherichia coli</i>
Type	Asn ₈₀ complex carbohydrate	Not glycosylated
Concentration	30 μ g or 6 million IU/mL	250 μ g or 8 million IU/mL
Supplied form	Powder for reconstitution	Powder for reconstitution
Diluent	Sterile water—no preservatives	NaCl 0.54% without preservatives
Storage	2°C–8°C; do not freeze	2°C–8°C; do not freeze
Dosage	30 μ g once a week	250 μ g every other day
Route	Intramuscular	Subcutaneous
Notable side effects	Injection site reactions, 3%; no necrosis	Injection site reactions, 85%; necrosis, 5%

Although the exact mechanism of action of interferon beta-1a in MS has not been elucidated, it is known that the drug exerts its biological effects by binding to specific receptors on the surface of human cells. This binding initiates a cascade of intracellular events that lead to the expression of interferon-induced gene products. These include 2',5'-oligoadenylate synthetase and β_2 microglobulin. These products have been measured in the serum and in cellular fractions of blood collected from patients treated with interferon beta-1a. The functionally specific interferon-induced proteins have not been defined for MS.

Adverse effects include flulike syndrome at the start of therapy that decreases in severity as treatment progresses. Interferon beta-1a is a potential abortifacient and an inhibitor of cytochrome P450.

The dosage form is a powder for solution that is reconstituted in sterile water. Excipients are human albumin, sodium chloride, and phosphate buffer. The solution can be stored at 2°C to 8°C and should be discarded if it freezes. The lyophilized powder expires in 15 months. After reconstitution, the solution should be used within 6 hours. The solution should not be shaken because of the albumin content.

Interferon Beta-1b (Recombinant)¹²⁷

Interferon beta-1b, Betaseron, is a protein that is expressed in a recombinant *E. coli*. It is equivalent in type to the interferon that is expressed by human fibroblasts. Interferon beta-1b possesses 165 amino acids and has an approximate molecular mass of 18.5 kDa. The native form has 166 amino acids and weighs 23 kDa. Interferon beta-1b contains a serine residue at position 17 rather than the cysteine in native IFN- β and does not contain the complex carbohydrate side chains found in the natural molecule. In addition to its antiviral activity, interferon beta-1b possesses immunomodulating activity.

Interferon beta-1b is administered SC to decrease the frequency of clinical exacerbation in ambulatory patients with relapsing–remitting multiple sclerosis (RRMS). RRMS is characterized by unpredictable attacks resulting in neurological deficits, separated by variable periods of remission.

Although it is not possible to delineate the mechanisms by which interferon beta-1b exerts its activity in MS, it is known that the interferon binds to specific receptors on cell surfaces and induces the expression of several interferon-induced gene products, such as 2',5'-oligoadenylate synthetase and protein kinase. Additionally, interferon beta-1b blocks the synthesis of INF- γ , which is believed to be involved in MS attacks.

Interferon beta-1b is supplied as powder for solution with albumin and/or dextrose as excipients. It should be stored at 2°C to 8°C without freezing. After reconstitution, the solution can be stored in the refrigerator for 3 hours. The solution should not be shaken.

A major difference between interferon beta-1a and beta-1b is that beta-1b causes more hemorrhage and necrosis at the injection site than does interferon beta-1a.

PRODUCTS: γ -INTERFERON

Interferon Gamma-1b (Recombinant)¹²⁸

Interferon gamma-1b, Actimmune, is a recombinant protein expressed in *E. coli*. IFN- γ is the cytokine that is secreted by human T lymphocytes and NK cells. It is a single-chain glycoprotein composed of 140 amino acids. The crystal structure

of the protein reveals several helical segments arranged to approximate a toric shape.

Interferon gamma-1b is indicated for reducing the frequency and severity of serious infections associated with chronic granulomatous disease, an inherited disorder characterized by deficient phagocyte oxidase activity. In this disease, macrophages try to respond to invading organisms but lack the key oxidative enzymes to dispose of them. To compensate, additional macrophages are recruited into the infected region and form a granulomatous structure around the site. IFN- γ can stimulate the oxidative burst in macrophages and may reverse the situation.

Interferon gamma-1b is supplied as a solution in sterile water for injection. The solution must be stored at 2°C to 8°C, without freezing. The product cannot tolerate more than 12 hours at room temperature.

THE INTERLEUKINS

Aldesleukin¹²⁹

Aldesleukin, T-cell growth factor, thymocyte-stimulating factor, Proleukin, is recombinant IL-2 expressed in an engineered strain of *E. coli* containing an analog of the human IL-2 gene. The recombinant product is a highly purified protein of 133 amino acids with an approximate molecular mass of 15,300 Da. Unlike native IL-2, aldesleukin is not glycosylated, has no N-terminal alanine, and has serine substituted for Cys at site 125. Aldesleukin exists in solution as biologically active, noncovalently bound microaggregates with an average size of 27 IL-2 molecules. This contrasts with traditional solution aggregates of proteins, which often form irreversibly bound structures that are biologically inactive.

Aldesleukin enhances lymphocyte mitogenesis and stimulates long-term growth of human IL-2-dependent cell lines. IL-2 also enhances the cytotoxicity of lymphocytes. Induction of NK cell and lymphocyte-activated killer (LAK) cell activity occurs, as does induction of production. In mouse and human tumor cell lines, aldesleukin activates cellular immunity in patients with profound lymphocytosis, eosinophilia, and thrombocytopenia. Aldesleukin also activates the production of cytokines, including tumor necrosis factor (TNF), IL-1, and IFN- γ . In vivo experiments in mouse tumor models have shown inhibition of tumor growth. The mechanism of the antitumor effect of aldesleukin is unknown.

Aldesleukin is indicated for the treatment of metastatic renal cell carcinoma in adults. It is also indicated for the treatment of metastatic melanoma in adults. Research is under way on the use of aldesleukin for the treatment of various cancers (including head and neck cancers), treatment of acute myelogenous leukemia, and adjunct therapy in the treatment of Kaposi sarcoma. Renal and hepatic function is typically impaired during therapy with aldesleukin, so interaction with other drugs that undergo elimination by these organs is possible.

Aldesleukin is supplied as a powder for solution. After reconstitution, the solution should not be shaken. The preparation is solubilized with sodium dodecyl sulfate (SDS) in a phosphate buffer. Aldesleukin should be stored as nonreconstituted powder at 2°C to 8°C and never frozen. Reconstituted vials can be frozen and thawed once in 7 days without loss of activity. It expires over a period of 18 months.

Denileukin Diftitox (Recombinant)¹³⁰

Denileukin diftitox, recombinant, Ontak, is an example of a drug that acts like a Trojan horse. One part of the molecule is involved in recognition and binds selectively with the diseased cell, and a highly toxic second part of the molecule effects a kill. Denileukin diftitox is a fusion protein expressed by a recombinant strain of *E. coli*. It is an rDNA-derived cytotoxic protein composed of the amino acid sequences for diphtheria toxin fragments A and B (Met₁-Thr₃₈₇)-His, followed by the sequences for IL-2 (Ala₁-Thr₁₃₃). The fusion protein has a molecular mass of 58,000 Da. We can think of this large protein as a molecule of diphtheria toxin in which the receptor-binding domain has been replaced by IL-2 sequences, thereby changing its binding specificity. Cells that express the high-affinity (α , β , γ) IL-2 receptor bind the protein tightly. The IL-2 component is used as a director to bring the cytotoxic species in contact with tumor cells. The diphtheria toxin inhibits cellular protein synthesis and the cells die. Malignant cells in certain leukemias and lymphomas, including cutaneous T-cell lymphoma, express the high-affinity IL-2 receptor on their cell surfaces. It is these cells that denileukin diftitox targets.

Denileukin diftitox is indicated for the treatment of persistent or recurrent cutaneous T-cell lymphoma whose malignant cells express the CD25 component of the IL-2 receptor.

Denileukin diftitox is supplied as a frozen solution in water for injection. It should be stored at -10°C or colder. It is suggested that the vials be thawed in a refrigerator at 2°C to 8°C for less than 24 hours or at room temperature for 1 to 2 hours. Prepared solutions should be used within 6 hours. The drug is administered by IV infusion from a bag or through a syringe pump.

Oprelvekin (Recombinant)^{131,132}

Oprelvekin, Neumega, is recombinant human IL-11 that is expressed in a recombinant strain of *E. coli* as a thioredoxin and/or rhIL-11 fusion protein. The fusion protein is cleaved and purified to obtain the rhIL-11 protein. The protein is 177 amino acids in length and has a mass of approximately 19,000 Da. Oprelvekin differs from the natural 178-amino acid IL-11 by lacking an N-terminal proline. This alteration has not resulted in differences in bioactivity either in vitro or in vivo.

IL-11 is a thrombopoietic growth factor. It directly stimulates the proliferation of hematopoietic stem cells as well as megakaryocyte progenitor cells. This process induces megakaryocyte maturation and increased production of platelets. The primary hematopoietic activity of oprelvekin is stimulation of megakaryocytopoiesis and thrombopoiesis. Primary osteoblasts and mature osteoclasts express mRNAs for both IL-11 and its receptor, IL-11R alpha. Hence, both bone-forming and bone-resorbing cells are possible targets for IL-11.

Oprelvekin is indicated for the prevention of severe thrombocytopenia. It reduces the need for platelet transfusions after myelosuppressive chemotherapy in patients with nonmyeloid malignancies who are at high risk for severe thrombocytopenia. Efficacy has been demonstrated in persons who have experienced severe thrombocytopenia following a previous chemotherapy cycle.

Oprelvekin causes many adverse reactions. Among these are edema, neutropenic fever, headache, nausea and/or

vomiting, dyspnea, and tachycardia. Patients must be monitored closely.

Oprelvekin is supplied as a lyophilized powder for reconstitution. Excipients include glycine and phosphate buffer components. The powder has a shelf life of 24 months. It should be stored at 2°C to 8°C . If it is frozen, thaw it before reconstitution.

Tumor Necrosis Factor (Recombinant)¹³³⁻¹³⁵

The TNFs (Etanercept, Enbrel) are members of a family of cytokines that are produced primarily in the innate immune system by activated mononuclear phagocytes. Along with IL-1, TNF is typically the first cytokine to be produced upon infection, and its reactions can be both positive and negative. On the one hand, TNF can cause cytotoxicity and inflammation, and on the other hand, it serves as a signal to the adaptive immune response. The TNFs are all endogenous pyrogens, and they cause chills, fever, and flulike symptoms. There are two forms of TNF: TNF α (cachectin) and TNF β (lymphotoxin). Both bind to the same receptor and cause similar effects.

Etanercept is a dimeric fusion protein consisting of the extracellular ligand-binding portion of the human 75-kDa (p75) TNF receptor (TNFR) linked to the Fc portion of human isotype IgG₁. The Fc component of etanercept contains the CH₂ domain, the CH₃ domain, and the hinge region, but not the CH₁ domain of IgG₁. These regions are responsible for the biological effects of immunoglobulins. Etanercept is produced in recombinant CHO cultures. It consists of a peptide chain of 934 amino acids and has a molecular mass of approximately 150 kDa. It binds specifically to TNF and blocks its interaction with cell surface TNFRs. Each etanercept molecule binds specifically to two TNF molecules in the synovial fluid of rheumatoid arthritis patients. It is equally efficacious at blocking TNF α and TNF β . The drug is indicated for reducing signs and symptoms and inhibiting the progression of structural damage in patients with moderately to severely active rheumatoid arthritis. Etanercept is also indicated for reducing signs and symptoms of moderately to severely active polyarticular-course juvenile rheumatoid arthritis in patients 4 years of age and older who have had an inadequate response to one or more disease-modifying antirheumatic drugs (DMARDs). Etanercept is also indicated for reducing signs and symptoms of active arthritis in patients with psoriatic arthritis.

ENZYMES**Blood-Clotting Factors**

The blood clotting system of the human body is typically in a carefully balanced homeostatic state. If damage occurs to a blood vessel wall, a clot will form to wall off the damage so that the process of regeneration can begin. Normally this process is highly localized to the damaged region, so that the hemostatic response does not cause thrombi to migrate to distant sites or persist longer than it is needed. Lysis of blood clots occurs through the conversion of plasminogen to plasmin, which causes fibrinolysis, converting insoluble fibrin to soluble fibrinopeptides. The plasminogen-plasmin conversion is catalyzed by several blood and tissue activators,

among them urokinase, kallikrein, plasminogen activators, and some undefined inhibitors. More specifically, the conversion of plasminogen to plasmin is catalyzed by two extremely specific serine proteases: a urokinase plasminogen activator (uPA) and a tissue plasminogen activator (tPA). This section focuses on tPA.

Human tPA is a serine protease that is synthesized in the vascular endothelial cells. It is a single-chain peptide composed of 527 amino acids and has a molecular mass of approximately 64,000 Da. About 7% of the mass of the molecule consists of carbohydrate. The molecule contains 35 Cys residues. These are fully paired, giving the tPA molecule 17 disulfide bonds. There are four N-linked glycosylation sites recognized by consensus sequences Asn-X-Ser/Thr at residues 117, 184, 218, and 448. It is suspected that Thr₆₁ bears an *O*-fucose residue. There are two forms of tPA that differ by the presence or absence of a carbohydrate group at Asp₁₈₄. Type I tPA is glycosylated at Asn₁₁₇, Asn₁₈₄, and Asn₄₄₈, whereas type II tPA lacks a glycosyl group at Asn₁₈₄. Asn₂₁₈ is typically unsubstituted in both forms. Asn₁₁₇ contains a high-mannose oligosaccharide, whereas Asn substituents 184 and 448 are complex carbohydrate substituted. During the process of fibrinolysis the single-chain protein is cleaved between Arg₂₇₅ and Ile₂₇₆ by plasmin to yield two-chain tPA. Two-chain tPA consists of a heavy chain (the A chain, derived from the N-terminus) and a light chain (B chain), linked by a single disulfide bond between Cys₂₆₄ and Cys₃₉₅. The A chain bears some unique structural features: the finger region (residues 6–36), the growth factor region (approximate residues 44–80), and two kringle domains. These domains are disulfide-closed loops, mostly β sheet in structure. The finger and kringle 2 are responsible for tPA binding to fibrin and for the activation of plasminogen. The function of kringle 1 is not known. The B chain contains the serine protease domain that contains the His-Asp-Ser unit that cleaves plasminogen.

TISSUE PLASMINOGEN ACTIVATOR, RECOMBINANT^{136,137}

Recombinant tPA (rtPA), alteplase (Activase), is identical with endogenous tPA. rtPA lacks a glycosyl residue at Asn₁₈₄. At one time, rtPA was produced in two-chain form in CHO cultures. Now, large-scale cultures of recombinant human melanoma cells in fermenters are used to produce a product that is about 80% single-chain rtPA.

Alteplase is used to improve ventricular function following an acute myocardial infarction, including reducing the incidence of congestive heart failure and decreasing mortality. The drug is also used to treat acute ischemic stroke after computed tomography (CT) or other diagnostic imaging has ruled out intracranial hemorrhage. rtPA is also used in cases of acute pulmonary thromboembolism and is being investigated for unstable angina pectoris.

Alteplase is supplied as powder for injection, and in reconstituted form (normal saline or 5% dextrose in water) is intended for IV infusion only. The solution expires in 8 hours at room temperature and must be prepared just before use.

RETEPLASE

Reteplase (Retavase) is a deletion mutant variant of tPA that is produced in recombinant *E. coli*. The deletions are in domains responsible for half-life, fibrin affinity, and thrombolytic potency. It consists of the kringle-2 domain

TABLE 4.9 Comparison of the Pharmacokinetic Parameters of Alteplase and Reteplase

Pharmacokinetic Parameter	Alteplase	Reteplase
Effective $t_{1/2}$ (minutes)	5	13–16
Volume of distribution (L)	8.1	6
Plasma clearance (mL/min)	360–620	250–450

and protease domain of tPA but lacks the kringle-1 domain and the growth factor domain. It is considered a third-generation thrombolytic agent and has a mechanism of action similar to that of alteplase. Reteplase acts directly by catalyzing the cleavage of plasminogen and initiating thrombolysis. It has high thrombolytic potency. A comparison of alteplase and reteplase is given in Table 4.9.

TENECTEPLASE¹³⁷

Tenecteplase is a tPA produced by recombinant CHO cells. The molecule is a 527-amino acid glycoprotein developed by introducing the following modifications to the cDNA construct: Thr₁₀₃ to Asp, Asp₁₁₇ to Gln, both within the kringle-1 domain, and a tetra-alanine substitution at amino acids 296 to 299 in the protease domain. The drug is a sterile, lyophilized powder recommended for single IV bolus administration after reconstitution with sterile water. Tenecteplase should be administered immediately after reconstitution.

FACTOR VIII¹³⁸

Antihemophilic factor VIII (recombinant), Recombinate, Kogenate, Bioclote, Helixate, is a plasma protein that functions in the normal blood-clotting cascade by increasing the V_{max} for the activation of clotting factor X by factor IXa in the presence of calcium ions and negatively charged phospholipids. Factor VIII is used in the treatment of hemophilia A. Hemophilia A is a congenital disorder characterized by bleeding. The introduction of factor VIII as a drug has improved the quality of life and the life expectancy of individuals with this disorder. Unfortunately, it has been necessary to rely on an unsure source (human plasma) for the factor. Exposure of patients to alloantigens and viruses has been a concern. Factor VIII derived from a recombinant source will potentially eliminate many of these problems and provide an essentially unlimited supply of the drug.

Factor VIII is biosynthesized as a single-chain polypeptide of 2,332 amino acids. The protein is very heavily glycosylated. Shortly after biosynthesis, peptide cleavage occurs and plasma factor VIII circulates as an 80-kDa light chain associated with a series of heavy chains of approximately 210 kDa in a metal ion-stabilized complex. Factor VIII possesses 25 potential N-linked glycosylation sites and 22 Cys residues. The 210-kDa heavy chain is further cleaved by proteases to yield a series of proteins of molecular mass 90 to 188 kDa. The 90- to 188-kDa protein molecules form a metal ion-stabilized complex with the light chain.

Recombinant factor VIII is produced in two recombinant systems: in batch culture of transfected CHO cells or in continuous culture of BHK cells. There are four types of recombinant factor VIII available. All four are produced by inserting a cDNA construct encoding the entire peptide sequence into the

CHO cell or BHK cell line. The CHO cell product contains a Gal α [1 \rightarrow 3]Gal unit, whereas the BHK enzyme does not. Recombinant factor VIII is polydisperse, containing multiple peptide homologues including an 80-kDa protein and various modifications of an approximately 90-kDa subunit protein. The product contains no blood products and is free of microbes and pyrogens.

Recombinant factor VIII is indicated for the treatment of classical hemophilia (hemophilia A) and for the prevention and treatment of hemorrhagic episodes and perioperative management of patients with hemophilia A. The drug is also indicated for the treatment of hemophilia A in persons who possess inhibitors to factor VIII.

Recombinant factor VIII is supplied in sterile, single-dose vials. The product is stabilized with human albumin and lyophilized. The product must be stored at 2°C to 8°C, without freezing. In some instances, the powder may be stored at room temperature for up to 3 months without loss of biological activity. Shaking of the reconstituted product should be avoided because of the presence of the albumin. The drug must be administered by IV bolus or drip infusion within 3 hours of reconstitution.

Because trace amounts of mouse or hamster protein may copurify with recombinant factor VIII, one should be cautious when administering the drug to individuals with known hypersensitivity to plasma-derived antihemophilic factor or with hypersensitivity to biological preparations with trace amounts of mouse or hamster proteins.

CLOTTING FACTOR IX (RECOMBINANT)^{139,140}

When a person is deficient in clotting factor IX (Christmas factor), hemophilia B results. Hemophilia B affects primarily males and accounts for about 15% of all cases of hemophilia. Treatment involves replacement of factor IX so that the blood will clot. Recombinant coagulation factor IX (BeneFIX) is a highly purified protein produced in recombinant CHO cells, free of blood products. The product is a glycoprotein of molecular mass approximately 55,000 Da. It consists of 415 amino acids in a single chain. The primary amino acid sequence of BeneFIX is identical with the Ala₁₄₈ allelic form of plasma-derived factor IX, and it has structural and functional characteristics similar to those of the endogenous protein. The recombinant protein is purified by chromatography, followed by membrane filtration. SDS-polyacrylamide gel electrophoresis shows that the product exists primarily as a single component.

Clotting factor IX, recombinant, is indicated for the control and prevention of hemorrhagic episodes in persons with hemophilia B (Christmas disease), including the control and prevention of bleeding in surgical procedures.

BeneFIX is supplied as a sterile lyophilized powder. It should be stored at 2°C to 8°C. The product will tolerate storage at room temperature not above 25°C for 6 months. The drug becomes unstable, following reconstitution, and must be used within 3 hours.

DROTRECIGIN ALFA¹⁴¹

About 750,000 people are diagnosed with sepsis in the United States each year, and of these, an estimated 30% will die from it, despite treatment with IV antibiotics and supportive care. Patients with severe sepsis often experience failures of various systems in the body, including the circulatory system, the

kidneys, and clotting. Drotrecogin alfa (activated), drotrecogin alfa (activated; Xigris), is a recombinant form of human activated protein C. Activated protein C exerts an antithrombotic effect by inhibiting factors Va and VIIIa. In vitro data indicate that activated protein C has indirect profibrinolytic activity through its ability to inhibit plasminogen activator inhibitor-1 (PAI-1) and to limit generation of activated thrombin-activatable fibrinolysis inhibitor. Additionally, in vitro data indicate that activated protein C may exert an anti-inflammatory effect by inhibiting TNF production by monocytes, by blocking leukocyte adhesion to selectins, and by limiting the thrombin-induced inflammatory responses within the microvascular epithelium.

Vials of drotrecogin alfa should be stored at 2°C to 8°C without freezing. The reconstituted solution is stable for 14 hours at 25°C.

Anticoagulant

LEPIRUDIN, RECOMBINANT¹⁴²

Leeches (*Hirudo medicinalis*) have been used medicinally for centuries to treat injuries in which blood engorges the tissues. The logic behind this is solid: leeches produce an agent known as *hirudin* that is a potent, specific thrombin inhibitor. Leeches have been used to prevent thrombosis in the microvasculature of reattached digits. Lepirudin (Refludan) is an rDNA-derived protein produced in yeast. It has a molecular mass of approximately 7,000 Da. Lepirudin differs from the natural polypeptide, in that it has an N-terminal leucine instead of isoleucine and is missing a sulfate function at Tyr₆₃.

Other Enzymes

RECOMBINANT HUMAN DEOXYRIBONUCLEASE I (DNASE)¹⁴³

DNase is a human endonuclease, normally present in saliva, urine, pancreatic secretions, and blood. The enzyme catalyzes the hydrolysis of extracellular DNA into oligonucleotides. Aerosolized recombinant human deoxyribonuclease I (rhDNase), dornase alfa, Pulmozyme, has been formulated into an inhalation agent for the treatment of pulmonary disease in patients with CF.

Among the clinical manifestations of CF are obstruction of the airways by viscous, dehydrated mucus. Pulmonary function is diminished, and microbes can become entrapped in the viscid matrix. A cycle of pulmonary obstruction and infection leads to progressive lung destruction and eventual death before the age of 30 for most CF patients. The immune system responds by sending in neutrophils, and these accumulate and eventually degenerate, releasing large amounts of DNA. The high levels of extracellular DNA released and the mucous glycoproteins are responsible for the degenerating lung function. The DNA-rich secretions also bind to aminoglycoside antibiotics typically used to treat the infections. In vitro studies showed that the viscosity of the secretions could be reduced by application of DNase I.

Before DNase was purified and sequenced from human sources, a partial DNA sequence from bovine DNase (263 amino acids) was used to create a library that could be used to screen a human pancreatic DNA library. This facilitated the development of the human recombinant protein. The endogenous human and recombinant protein sequences are identical.

rhDNase was cloned, sequenced, and expressed to examine the potential of DNase I as a drug for use in CF. It has been shown that cleavage of high-molecular-weight DNA into smaller fragments by treatment with aerosolized rhDNase improves the clearance of mucus from the lungs and reduces the exacerbations of respiratory symptoms requiring parenteral antibiotics.

rhDNase I is a monomeric glycoprotein consisting of 260 amino acids produced in CHO cell culture. The molecule possesses four Cys residues and two sites that probably contain N-linked glycosides. The molecular mass of the molecule is about 29 kDa. DNase I is an endonuclease that cleaves double-stranded DNA (and to some extent, single-stranded DNA) into 5'-phosphate-terminated polynucleotides. Activity depends on the presence of calcium and magnesium ions.

Pulmozyme is approved for use in the treatment of CF patients, in conjunction with standard therapies, to reduce the frequency of respiratory infections requiring parenteral antibiotics and to improve pulmonary function. The dose is delivered at a level of 2.5 mg daily with a nebulizer. Pulmozyme is not a replacement for antibiotics, bronchodilators, and daily physical therapy.

CEREZYME

Type 1 Gaucher disease is a hereditary condition occurring in about 1:40,000 individuals. It is characterized by a functional deficiency in β -glucocerebrosidase enzyme activity and the resulting accumulation of lipid glucocerebroside in tissue macrophages, which become engorged and are termed *Gaucher cells*. Gaucher cells typically accumulate in the liver, spleen, and bone marrow and, occasionally, in lung, kidney, and intestine. Secondary hematological sequelae include severe anemia and thrombocytopenia in addition to characteristic progressive hepatosplenomegaly. Skeletal complications are common and are frequently the most debilitating and disabling feature of Gaucher disease. Possible skeletal complications are osteonecrosis, osteopenia with secondary pathological fractures, remodeling failure, osteosclerosis, and bone crises.

Cerezyme (Imiglucerase)¹⁴⁴ is a recombinant, macrophage-targeted variant of human β -glucocerebrosidase, purified from CHO cells. It catalyzes the hydrolysis of the glycolipid glucocerebroside to glucose and ceramide following the normal degradation pathway for membrane lipids.

Cerezyme is supplied as a lyophilized powder for reconstitution. The powder should be stored at 2°C to 8°C until used. The reconstituted product for IV infusion is stable for 12 hours at room temperature.

VACCINES

Vaccines and immunizing biologicals are covered thoroughly in Chapter 5 of this text, so no lengthy discussion is given here. Vaccine production is a natural application of rDNA technology, aimed at achieving highly pure and efficacious products. Currently, there are four rDNA vaccines approved for human use. A number of others are in clinical trials for some rather exotic uses. It would appear that biotechnological approaches to vaccines will bring about some very useful drugs.

Products

RECOMBIVAX AND ENGERIX-B¹⁴⁵

Recombivax and Engerix-B are interchangeable for immunization against hepatitis B virus (HBV, serum hepatitis). Both contain a 226-amino acid polypeptide composing 22-nm diameter particles that possess the antigenic epitopes of the HBV surface coat (S) protein. The products from two manufacturers are expressed from recombinant *S. cerevisiae*. It is recommended that patients receive 3 doses, with the second dose 1 month after the first and the third dose 6 months after the first. The route and site of injection are IM in deltoid muscle or, for infants and young children, in the anterolateral thigh. The vaccines achieve 94% to 98% immunogenicity among adults 20 to 39 years of age, 1 to 2 months after the third dose. Adults older than 40 years of age reach 89% immunogenicity. Infants, young children, and adolescents achieve 96% to 99% immunogenicity.

The vaccine is supplied as a suspension adsorbed to aluminum hydroxide. The shelf life is 36 months. The vaccine should be stored at 2°C to 8°C and should be discarded if frozen. Freezing destroys potency.

LYMERIX¹⁴⁶

Lyme disease is caused by the spirochete *Borrelia burgdorferi*. The microorganism is transmitted primarily by ticks and is endemic in heavily wooded areas and forests. The disease produces arthritis-like symptoms. A vaccine against Lyme disease was created by developing a recombinant *E. coli* that contains the gene for the bacterial outer surface protein. This protein (OspA) is a single polypeptide chain of 257 amino acids with covalently bound lipids at the N-terminus. The vaccine is formulated as a suspension with aluminum hydroxide as an adsorption adjuvant. In testing, subjects between 15 and 70 years immunized with 3 doses of LYMERIX at 0, 1, and 12 months demonstrated a 78% decrease in the likelihood of infection.

LYMERIX has a shelf life of 24 months. It should be stored at 2°C to 8°C and must be discarded if frozen. If necessary, the vaccine can tolerate 4 days at room temperature.

COMVAX

Comvax is a combination of *Haemophilus influenzae* type b conjugate and hepatitis B (recombinant). It was recently approved by the Advisory Committee on Immunization Practices (ACIP). Each 0.5-mL dose contains 7.5 μ g of *H. influenzae* type b polyribosylribitol phosphate (PRP), 125 μ g of *Neisseria meningitidis* outer membrane protein complex (OMPC), and 5 μ g of hepatitis B surface antigen (HBsAg) on an aluminum hydroxide adjuvant. The Committee on Infectious Diseases, the American Academy of Pediatrics, and the Advisory Academy of Family Physicians recommend that all infants receive the vaccine. Three doses should be administered at ages 2, 4, and 12 to 15 months. The vaccine should not be administered to infants younger than 6 weeks because of potential suppression of the immune response to PRP-OMPC with subsequent doses of Comvax TM. The series should be completed by 12 to 15 months.

TABLE 4.10 Vaccines Developed Using Biotechnology

Vaccine	Type	Use
MAGE-12: 170–178	Vaccine	Breast, colorectal, lung cancers; melanoma; sarcoma
MART-1 melanoma vaccine	Vaccine	Metastatic melanoma
Mylovenge	Vaccine	Multiple myeloma
Myeloma-derived idiotypic Ag vaccine	Vaccine	Multiple myeloma
Melacine melanoma therapeutic vaccine	Therapeutic vaccine	Stage IV malignant melanoma
NBI-6024	Peptide therapeutic vaccine	Type 1 diabetes
Antigastrin therapeutic vaccine	Vaccine	Gastroesophageal reflux disease
Helivax <i>Helicobacter pylori</i> vaccine	Cellular vaccine	<i>H. pylori</i> infection
Hepatitis E vaccine	Recombinant subunit vaccine	Hepatitis E prophylaxis
StreptAvax	Vaccine	Group A streptococci, including necrotizing fasciitis, strep throat, and rheumatic fever
Hepatitis B vaccine	Recombinant vaccine	Hepatitis B prophylaxis

Vaccines in Development

Quite a number of biotechnology-generated vaccines are in development (Table 4.10).

Some of them are in the category of “therapeutic vaccines.” These vaccines are designed to bind to cellular receptors, endogenous molecules, and so on, producing specific pharmacological effects. For example, if a cell has a particular receptor that binds a ligand to activate the cell, binding an antibody raised by a specific vaccine to the receptor will prevent activation. If a tumor has a requirement for such a receptor–ligand binding, using a vaccine to develop antibody to the receptor or the ligand should prevent or slow cellular proliferation.

PREPARATION OF ANTIBODIES^{147–149}

Hybridoma (Monoclonal Antibody) Techniques

In a humoral immune response, B-lymphocyte–derived plasma cells produce antibodies with variations in chemical structure. Biologically, these variations extend the utility of the secreted antibody. These variations are caused by affinity maturation, the tendency for the affinity of antibody for antigen to increase with each challenge, and mutation at the time of somatic recombination. These phenomena produce antibodies with slightly different specificities. Because the clones of antibody-producing cells provide more than one structural type of antibody, they are called *polyclonal antibodies*. Another type of antibody consists of highly homogeneous populations of hybrid proteins produced by one clone of specially prepared B lymphocytes. These antibodies, lacking structural variations, are highly “focused” on their antigenic counterparts’ determinants or epitopes, and are called *monoclonal*.

A problem with creating MABs is that one cannot simply prepare an antibody-producing B lymphocyte and propagate it. Such cells live only briefly in the laboratory environment. Instead, antibody-producing cells are fused with an immortal (tumor) cell line to create *hybridomas*—long-lived, antibody-secreting cells. The trick is to select the monoclonal cells that produce the desired antibody. The hybridoma technique has opened the door to new therapeutic antibodies, imaging agents, radiological diagnostic test kits, targeted radionuclide delivery agents, and home test kits.

In the hybridoma method (Fig. 4.14), a mouse or other small animal is sensitized with an antigen. When a high enough titer of antibody against the selected antigen has been attained, the animal is sacrificed and its spleen cells are collected. The spleen cells contain a large number of B lymphocytes, and it is certain that some will be able to produce antigen-specific antibodies. Because the spleen cells are normal B lymphocytes, they have a very short lifetime in cell cultures. Therefore, a method must be used to extend their lifetime.

To produce MABs, B cells are fused with immortal myeloma cells in the presence of fusogens such as PEG. This procedure produces genetically half-normal and half-myeloma cells. Because the myeloma cells are immortal, the longevity problem is solved. The selection process depends on two different myeloma cell lines: one lacking the enzyme hypoxanthine-guanine phosphoribosyl transferase (HGPRT), a key enzyme in the nucleotide salvage pathways, and the other lacking the *Tk* gene, a key gene in the pyrimidine biosynthetic pathways. The spleen B cells are HGPRT and *Tk* (+), whereas the myeloma cells are HGPRT and *Tk* (–). This myeloma cell line cannot survive in a medium containing aminopterin, a thymidylate synthetase inhibitor, because it cannot synthesize pyrimidines. The HGPRT (–) cell line cannot use the purine salvage pathways to make nucleotides, forcing it to use thymidylate synthetase. With thymidylate synthetase inhibited, the cell dies. After fusion, cells are maintained on a medium containing hypoxanthine, aminopterin, and thymidine (HAT). Only cells that are “correctly” fused between one spleen cell (HGPRT [+]) and one myeloma cell (immortal), that is, a hybridoma, can survive in HAT medium. Fused myeloma cells (myeloma–myeloma) lack the correct genes and cannot survive. Fused spleen cells (spleen–spleen) cannot grow in culture. Thus, only the fused hybridoma (myeloma–spleen) survives. Hypoxanthine and thymidine furnish precursors for the growth of HGPRT (+) cells. Aminopterin suppresses cells that failed to fuse. Hybridomas can be isolated in a 96-well plate and transferred into larger cultures for proliferation. The culture medium will eventually contain a high concentration of MAB against the original antigen. This antibody can be purified to homogeneity.

MABs, being proteins, tend to be highly immunogenic in humans. This is especially true of the MABs produced in mouse culture. Humans begin to develop antibodies to

Figure 4.14 • General method for the preparation of monoclonal antibodies, using hybridomas and HAT medium. (Ab, antibody; Ag, antigen.)

mouse MAbs after a single dose. This is natural. The human host is mounting an antibody response to a foreign antigen. The human antimouse antibody (known as *HAMA*) response has tended to limit the use of monoclonals in human therapy.

In developing a method for making MAbs useful in humans, it is necessary to remove the mouse immunogenic characteristics from the MAb. The antigen-recognition region (Fab) of the MAb must retain its ability to bind to the antigen, however. If this feature is altered, the antibody will likely be useless. Within the light and heavy chains of the Fab portions of antibody molecules are regions that are called *complementarity-determining regions* or CDRs. Each chain possesses three of these. One of the CDRs, CDR3, is located at the juncture of the variable and common domains. CDR3 is also referred to as the *hypervariable region* because most of the variability of the antibody molecule is concentrated there. These must be intact for specific antigen–antibody binding. Immune responses against murine MAb are directed against not only the variable regions, but also the constant regions. Hence, to decrease the

immunogenicity of an MAb one must create antibodies that have been “humanized.” In MAb production, usually the V_H and V_L domains of a human antibody are replaced by the corresponding regions from the mouse antibody, leaving the specificity intact, but using human constant regions that should not be immunogenic. Antibodies like these are called *chimeric*, and they are less immunogenic and have a longer half-life in human patients. Examples of chimeric MAbs are abciximab, rituximab, infliximab, and basiliximab.

Methods are available for the development of MAbs with 95% to 100% human sequence. By using transgenic mice, all of the essential human antibody genes can be expressed.

Monoclonal Antibody Drugs

RITUXIMAB^{150,151}

Rituximab (Rituxan, Chimeric) is an MAb directed against the CD20 antigen expressed on the surfaces of normal and malignant B lymphocytes. The MAb is produced in mammalian (CHO) suspension culture and is a chimeric (murine/human) MAb of the $IgG_1 \kappa$ type. The protein is

composed of murine light and heavy chain variable regions and human constant regions. Rituximab is indicated for the treatment of patients with relapsed or refractory, low-grade or follicular, CD20(+) B-cell non-Hodgkin lymphoma. Rituximab binds specifically to antigen CD20 (human B-lymphocyte-restricted differentiation antigen, a hydrophobic transmembrane protein expressed on pre-B and mature B lymphocytes). CD20 is a protein of 35 to 37 kDa, and it may play a role in B cell activation and regulation and may be a calcium ion channel. The antigen is also expressed on more than 90% of non-Hodgkin lymphoma B cells but is not found on hematopoietic stem cells, pro-B cells, normal plasma cells, or other normal tissues. CD20 regulates the early steps in the activation process for cell cycle initiation and differentiation.

GEMTUZUMAB OZOGAMICIN^{152,153}

Gemtuzumab ozogamicin (Mylotarg, fusion molecule) is an MAb derived from the CD33 antigen, a sialic acid-dependent adhesion protein expressed on the surface of leukemia blasts and immature normal cells of myelomonocytic origin but not on normal hematopoietic stem cells. CD33 binds sialic acid and appears to regulate signaling in myeloid cells. The antibody is recombinant, humanized IgG₄ κ , linked with the cytotoxic antitumor antibiotic ozogamicin (from the calicheamicin family). More than 98.3% of the amino acids of gemtuzumab are of human origin. The constant region of the MAb contains human sequences, whereas the CDRs derive from a murine antibody that binds CD33. The antibody is linked to *N*-acetyl- γ -calicheamicin via a bifunctional linker.

Gemtuzumab ozogamicin is indicated for the treatment of patients with CD33-positive acute myeloid leukemia in first relapse among adults 60 years of age or older who are not considered candidates for cytotoxic chemotherapy.

Gemtuzumab ozogamicin binds to the CD33 antigen expressed by hematopoietic cells. This antigen is expressed on the surface of leukemic blasts in more than 80% of patients with acute myeloid leukemia. CD33 is also expressed on normal and leukemic myeloid colony-forming cells, including leukemic clonogenic precursors, but it is not expressed on pluripotent hematopoietic stem cells or nonhematopoietic cells. Binding of the anti-CD33 antibody results in a complex that is internalized. On internalization the calicheamicin derivative is released inside the lysosomes of the myeloid cells. The released calicheamicin derivative binds to the minor groove of DNA and causes double-strand breaks and cell death.

ALEMTUZUMAB^{154,155}

Alemtuzumab (Campath) is humanized MAb (Campath-1H) that is directed against the 21- to 28-kDa cell surface glycoprotein CD52. CD52 is expressed on the surface of normal and malignant B and T lymphocytes, NK cells, monocytes, macrophages, and tissues of the male reproductive system. The Campath-1H antibody is an IgG₁ κ form with humanized variable and constant regions and CDRs from a rat MAb, Campath-1G.

Alemtuzumab is indicated for the treatment of B-cell chronic lymphocytic leukemia in patients who have been treated with alkylating agents and who have failed on this therapy. Alemtuzumab binds to CD52, a nonmodulating

antigen that is present on the surface of essentially all B and T lymphocytes; most monocytes, macrophages, and NK cells, and a subpopulation of granulocytes. The proposed mechanism of action is antibody-dependent lysis of leukemic cells following cell surface binding.

BASILIXIMAB¹⁵⁶⁻¹⁵⁸

Basiliximab (Simulect, Chimeric) is an MAb produced by a mouse monoclonal cell line that has been engineered to produce the basiliximab IgG₁ κ antibody glycoprotein. The product is chimeric (murine/human). Basiliximab is indicated for prophylaxis of acute organ rejection in patients receiving renal transplantation when used as part of a regimen of immunosuppressants and corticosteroids. Basiliximab is also indicated in pediatric renal transplantation.

Basiliximab specifically binds to the IL-2 receptor α -chain (the CD25 antigen, part of the three-component IL-2 receptor site). These sites are expressed on the surfaces of activated T lymphocytes. Once bound, it blocks the IL-2 α receptor with extremely high affinity. This specific, high-affinity binding to IL-2 α competitively inhibits IL-2-mediated activation of lymphocytes, a critical event in the cellular immune response in allograft rejection.

DACLIZUMAB^{159,160}

Molecularly, daclizumab (Zenapax, Chimeric) is an IgG₁ MAb that binds specifically to the α subunit of the IL-2 receptor (the complete, high-affinity activated IL-2 receptor consists of interacting α , β , and γ subunits). IL-2 receptors are expressed on the surfaces of activated lymphocytes, where they mediate lymphocyte clonal expansion and differentiation. Daclizumab is a chimeric protein (90% human and 10% mouse) IgG₁. The MAb targets only recently activated T cells that have interacted with antigen and have developed from their naive form into their activated form. It is at this time that the IL-2 receptors are expressed. The human amino acid sequences of daclizumab derive from constant domains of human IgG, and the variable domains are derived from the fused Eu myeloma antibody. The murine sequences derive from CDRs of a mouse anti-IL2 α antibody.

The indications for daclizumab are prophylaxis of acute organ rejection in patients receiving renal transplants, as part of an immunosuppressant regimen including cyclosporine and corticosteroids. The mechanism of action is the same as that of basiliximab.

MUROMONAB-CD3¹⁶¹⁻¹⁶³

Muromonab-CD3 (murine, Orthoclone-OKT3) is an unmodified mouse immunoglobulin, an IgG_{2a}, monoclonal. It binds a glycoprotein on the surface of mature T lymphocytes. Mature T cells have, as part of the signal transduction machinery of the T-cell receptor complex, a set of three glycoproteins that are collectively called CD3. Together with the protein zeta, the CD3 molecules become phosphorylated when the T-cell receptor is bound to a peptide fragment and the major histocompatibility complex. The phosphorylated CD3 and zeta molecules transmit information into the cell, ultimately producing transcription factors that enter the nucleus and direct the T-cell activity. By binding to CD3, muromonab-CD3 prevents signal transduction into T cells.

Muromonab-CD3 blocks the function of T cells that are involved in acute renal rejection. Hence, it is indicated for the treatment of acute allograft rejection in heart and liver transplant recipients resistant to standard steroid therapies.

ABCIXIMAB^{164,165}

Abciximab (ReoPro, chimeric) is an MAb engineered from the glycoprotein IIb/IIIa receptor of human platelets. The preparation is fragmented, containing only the Fab portion of the antibody molecule. This MAb is a chimeric human–mouse immunoglobulin. The Fab fragments may contain mouse variable heavy- and light-chain regions and human constant heavy- and light-chain regions.

Abciximab is indicated as an adjunct to percutaneous transluminal coronary angioplasty or atherectomy for the prevention of acute cardiac ischemic complications in patients at high risk for abrupt closure of a treated coronary vessel. Abciximab appears to decrease the incidence of myocardial infarction.

Abciximab binds to the intact GPIIb/GPIIIa receptor, which is a member of the integrin family of adhesion receptors and the major platelet-specific receptors involved in aggregation. The antibody prevents platelet aggregation by preventing the binding of fibrinogen, the von Willebrand factor, and other adhesion molecules on activated platelets. The inhibition of binding to the surface receptors may be a result of steric hindrance or conformational effects preventing large molecules from approaching the receptor.

TRASTUZUMAB^{166,167}

Trastuzumab (Herceptin, humanized) is an MAb engineered from the human epidermal growth factor receptor type 2 (HER2) protein. This MAb is a human–murine immunoglobulin. It contains human structural domains (framework) and the CDR of a murine antibody (4D5) that binds specifically to HER2. IgG₁ κ is the type structure, and the antibody is monoclonal. The protein inhibits the proliferation of human tumor cells that overexpress HER2.

Trastuzumab is indicated for use as a single agent for the treatment of patients with metastatic breast cancer whose tumors overexpress the HER2 protein and who have not received chemotherapy for their metastatic disease.

The HER2 proto-oncogene encodes a transmembrane receptor protein of 185 kDa that is structurally related to the epidermal growth factor receptor HER2. Overexpression of this protein is observed in 25% to 30% of primary breast cancers. Trastuzumab binds with high affinity to the extracellular domain of HER2. It inhibits the proliferation of human tumor cells that overexpress HER2. Trastuzumab also mediates the process of antibody-mediated cellular cytotoxicity (ADCC). This process, leading to cell death, is preferentially exerted on HER2-overexpressing cancer cells over those that do not overexpress HER2.

INFLIXIMAB^{168,169}

The MAb infliximab (Remicade, chimeric) is produced from cells that have been sensitized with human TNF α . The MAb is a chimeric human–mouse immunoglobulin. The constant regions are of human peptide sequence and the variable regions are murine. The MAb is of type IgG₁ κ .

Infliximab is indicated for the treatment of moderately to severely active Crohn disease to decrease signs and symptoms in patients who had an inadequate response to conventional treatments. Infliximab binds specifically to TNF α . It neutralizes the biological activity of TNF α by binding with high affinity to soluble and transmembrane forms of the TNF. Infliximab destroys TNF α -producing cells. An additional mechanism by which infliximab could work is as follows: by inhibiting TNF α , pathways leading to IL-1 and IL-6 are inhibited. These interleukins are inflammatory cytokines. Inhibiting their production blocks some of the inflammation common to Crohn disease.

Monoclonal Antibody Radionuclide Test Kits

ARCITUMOMAB¹⁷⁰

Arcitumomab (CEA-Scan) is a murine monoclonal Fab' fragment of IMMU-4, an MAb generated in murine ascites fluid. Both IMMU-4 and arcitumomab react with carcinoembryonic antigen (CEA), a tumor-associated antigen whose expression is increased in various carcinomas, especially those of the GI tract. The preparation is a protein, murine Ig Fab fragment from IgG₁, for chemical labeling with Tc-99m.

Arcitumomab/Tc-99m is for use with standard diagnostic evaluations for detecting the presence, location, and extent of recurrent or metastatic colorectal carcinoma involving the liver, extrahepatic abdomen, and pelvis, with a histologically confirmed diagnosis. IMMU-4 (and the Fab' fragments of arcitumomab) bind to carcinoembryonic antigen (CEA), whose expression is increased in carcinoma. Arcitumomab/Tc-99m is injected, and the radionuclide scan is read 2 to 5 hours later.

NOFETUMOMAB MERPENTAN¹⁷¹

Nofetumomab merpentan (Verluma Kit) is the Fab fragment derived from the murine MAb NR-LU-10. The product is a protein, IgG_{2b}, monoclonal that has been fragmented from NR-LU-10. Nofetumomab possesses only the Fab portion. NR-LU-10 and nofetumomab are directed against a 40-kDa protein antigen that is expressed in various cancers and some normal tissues.

Nofetumomab is indicated for the detection and evaluation of extensive-stage disease in patients with biopsy-confirmed, previously untreated small cell lung cancer by bone scan, CT scan (head, chest, abdomen), or chest x-ray.

Nofetumomab merpentan possesses a linker and a chelator that binds the technetium to the peptide. This is a phenthioate ligand, 2,3,5,6-tetrafluorophenyl-4,5-bis-S-[1-ethoxyethyl]-thioacetamidopentanoate, hence the name *merpentan*.

SATUMOMAB PENDETIDE¹⁷²

Satumomab pentetide (OncoScint, murine) is a kit for In-111. Satumomab is prepared from a murine antibody raised to a membrane-enriched extract of human breast carcinoma hepatic metastasis. It is a protein, IgG₁ κ antibody, and monoclonal. The MAb recognizes tumor-associated glycoprotein (TAG) 72, a mucinlike molecule with a mass greater than 100,000 Da.

Satumomab is indicated as a diagnostic aid in determining the extent and location of extrahepatic malignant disease

in patients with known colorectal and ovarian cancer. This agent is used after standard diagnostic tests are completed and when additional information is needed. The cancer must be recurrent or previously diagnosed by other methods.

Satumomab localizes to TAG 72. The antibody is chemically modified so that it links to radioactive indium-111, which is mixed with the antibody just prior to injection. Imaging techniques will reveal the localization of the satumomab as "hot spots." To link the indium-111 to the satumomab protein, a linker-chelator is used. This is glycytyrosyl-(*N*, ϵ -diethylenetriaminepentaacetic acid)-lysine hydrochloride.

IMCIROMAB PENTETATE¹⁷³

Imciromab pentetate (murine; Myoscint Kit for the preparation of indium-111 imciromab pentetate) is a murine immunoglobulin fragment raised to the heavy chain of human myosin. The drug is a protein of the IgG₂ κ class. It is monoclonal, consisting of the Fab-binding fragments only, and it is bound to the linker-chelator diethylenetriamine pentaacetic acid for labeling with indium-111. Imciromab binds to the heavy chain of human myosin, the intracellular protein found in cardiac and skeletal muscle cells.

Imciromab pentetate is indicated for detecting the presence and location of myocardial injury in patients after a suspected myocardial infarction. In normal myocardium, intracellular proteins such as myosin are isolated from the extravascular space by the cell membrane and are inaccessible to antibody binding. After myocyte injury, the cell membrane loses integrity and becomes permeable to macromolecules, which allows Imciromab-In-111 to enter the cells, where it binds to intracellular myosin. The drug localizes in infarcted tissues, where radionuclide scanning can visualize it.

CAPROMAB PENDETIDE¹⁷⁴

Capromab (ProstaScint Kit for the preparation of In-111 capromab pendetide, murine) is an MAb (murine IgG₁ κ) that derives from an initial sensitization with a glycoprotein expressed by prostate epithelium known as *prostate surface membrane antigen* (PSMA). The MAb recognizes PSMA specifically and thus is specific for prostate adenocarcinomas. The drug is used in newly diagnosed patients with proven prostate cancer who are at high risk for pelvic lymph metastasis. PSMA has been found in many primary and metastatic prostate cancer lesions. The cytoplasmic domain marker 7E11-C5.3 reacts with more than 95% of adenocarcinomas evaluated.

To join the indium-111 to the antibody, a linker-chelator is used. This moiety is glycytyrosyl-(*N*-ethylenetriaminepentaacetic acid)-lysine HCl.

A Therapeutic Radionuclide Monoclonal Antibody¹⁷⁵

IBRITUMOMAB TIUXETAN

Ibritumomab (Zevalin kits to prepare In-111 Zevalin and Y-90 Zevalin, murine) is an MAb derived from an initial sensitization with CD20 antigen, expressed on the surface of normal and malignant B cells. The antibody is a murine IgG₁ κ subtype, directed against CD20 antigen. It is produced in a CHO cell line. Ibritumomab is indicated for use as a multistage regimen to treat patients with relapsed or

refractory low-grade, follicular, or transformed B-cell non-Hodgkin lymphoma, including patients with rituximab-refractory follicular non-Hodgkin lymphoma.

Ibritumomab tiuxetan binds specifically to CD20 antigen (human B-lymphocyte-restricted differentiation antigen). CD20 is expressed on pre-B and mature B lymphocytes and on more than 90% of B-cell non-Hodgkin lymphoma. When the CDR of ibritumomab tiutuxan binds to the CD20 antigen, apoptosis is initiated. The tiutuxan chelate binds indium-111 and yttrium-90 tightly. Beta emission induces cellular damage by forming free radicals in the target cells and neighboring cells. Tiutuxan is [*N*-[2-bis(carboxymethyl)amino]-3-(*p*-isothiocyanatophenyl)propyl]-[*N*-[2-bis(carboxymethyl)amino]2-(methyl)-ethyl]glycine.

In-Home Test Kits¹⁷⁶

There are various MAb-based in-home test kits that are designed to detect pregnancy and ovulation. For example, a pregnancy test kit targets the antigen human chorionic gonadotropin and displays a certain sign if the test is positive. The other type of test kit predicts ovulation by targeting LH in the urine. Just before ovulation, LH surges. The test kit is designed to detect and signal the time of ovulation. These test kits, based on the complex techniques of MAbs, are designed to be as simple and error-free as possible for patients.

GENOMICS

*Genomics*¹⁷⁷ is a term that means "a study of genes and their functions." Currently, genomics is probably the central driving force for new drug discovery and for novel treatments for disease. Gene therapy is a concept that is often discussed. The human genome project, which was largely completed in the year 2000, provided over 4 billion bp of data that have been deposited in public databases. Sequencing the genome itself was an enormous task, but the correlation of genomic data with disease states, sites of microbial attachment, and drug receptor sites is still in its infancy. Once these problems are solved, genomic data will be used to diagnose and treat disease and to develop new drugs specifically for disease states (and possibly specific for a patient). Studying the genetics of biochemical pathways will provide an entry into enzyme-based therapies. There will undoubtedly be a host of new targets for drug therapy. Because deciphering the information that the genomic sequence provides is a complex undertaking, these benefits are probably going to occur years in the future.

Unraveling the Genomic Code to Determine Structure–Function Relationships: Bioinformatics

When considering the topic of bioinformatics, one must recognize that this is a broad term, covering many different research areas. The roots of bioinformatics lie in the decades-old field of computational biology. Advances in computer technology that yielded faster computations fueled the expansion of this field into many different scientific areas, as did the development of new mathematical algorithms that allowed highly sophisticated problems to be solved quickly. For instance, with the computer technology available in 2003, it is relatively straightforward to determine a three-dimensional

structure of a protein by x-ray crystallography, by nuclear magnetic resonance–distance geometry–molecular dynamics approaches, or to compare a large set of genes structurally. Out of bioinformatics have grown some new scientific disciplines: functional genomics, structural genomics, and evolutionary genomics. The term *bioinformatics* is routinely applied to experiments in genomics that rely on sophisticated computations.

One reason why computational methods are so critical is that biological macromolecules must be simulated in a three-dimensional environment for realistic comparisons and visualizations to be made. A typical molecule is represented in a computer by a set of three Cartesian coordinates per atom that specify the position of each atom in space. There are sets of three-atom and dihedral angles to specify interatomic connectivity, and designations for the start and end points of chains, where needed. Fortunately, it is a relatively simple matter to build or download molecules from databases. Although the Cartesian coordinate system provides the relative positions of the atoms in space, the computer offers the opportunity to let the molecule evolve in the fourth dimension, time. This is where energy minimization routines and molecular dynamics simulations are used.

Functional Genomics

Functional genomics seeks to make an *inference* about the function of a gene (Fig. 4.15). Given a novel gene sequence to be tested, the functional genomics method starts by comparing the new gene with genetic sequences in a database. In some cases, the name of the gene, a function, or a close analogy to previously identified genes can be made. The test gene is then used as a template to construct, in a computer, a three-dimensional model of the protein. The three-dimensional model is refined by searching databases for possible folded structures of the protein product. Lastly, the likely folded structure of the protein from the new gene is *inferred* by comparison with folding patterns of proteins of known structure and function.

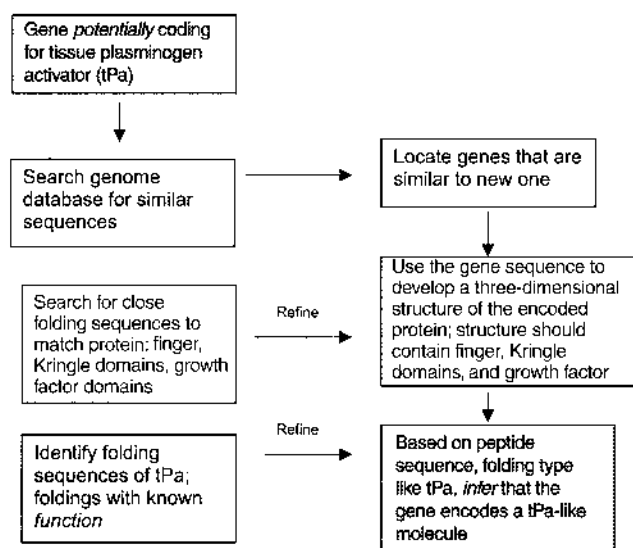

Figure 4.15 • Steps in the practice of functional genomics.

The aforementioned method is not without difficulty. There is a lot of genetic overlap between organisms of different types. Usually, as a first step, the genomic sequences of prokaryotes and *Archaeobacteria* are subtracted out, but there can still be overlap with organisms such as yeasts. In addition, the human genome possesses introns and exons, and the genetic components that encode one protein may lie on parts of one chromosome that are separated by a large number of nucleotides, or the gene may even be distributed over more than one chromosome.

DNA Microarrays^{178,179}

Each cell in the human body contains a full set of chromosomes and an identical complement of genes. At any given time in a given cell, only a fraction of these genes may be expressed. It is the expressed genes that give each cell its uniqueness. We use the term *gene expression* to describe the transcription of the information contained in the DNA code into mRNA molecules that are translated into the proteins that perform the major functions of the cell. The amount and type of mRNA that is produced by a cell provides information on which genes are being expressed and how the cell responds dynamically to changing conditions (e.g., disease). Gene expression can act as an “on/off” switch to control which genes are expressed, and a level regulator, somewhat like a volume control, that increases or decreases the level of expression as necessary. Thus, genes can be on or off, and low or high.

Historically, scientists wishing to study gene expression could analyze mRNA from cell lines, but the complexity of the task meant that only a few genes could be studied at once. The advent of DNA microarray technology allows scientists to analyze expression of thousands of genes in a single experiment, quickly and efficiently. DNA microarray technology facilitates the identification and classification of DNA sequence information and takes steps toward assigning functions to the new genes. The fundamental precept of microarray technology is that any mRNA molecule can hybridize to the DNA template from which it originated.

In a typical microarray experiment, an array is constructed of many DNA samples. Automation that was developed for the silicon chip industry helps in this procedure, spotting thousands of different DNA samples on glass plates, silicon chips, or nylon wafers. mRNA isolated from probe cells is treated with a mixture of fluorescent-tagged (usually red, green, and yellow) nucleotides in the presence of reverse transcriptase. This process generates fluorescent-tagged cDNA. The fluor will emit light when excited with a laser. The labeled nucleic acids are considered *mobile probes* that, when incubated with the stationary DNA, hybridize or bind to the complementary molecules (sequences that can base pair with each other). After hybridization, bound cDNA is detected by use of a laser scanner. Data on the presence or absence of fluorescence, the color, and the intensity at the various points in the array are acquired in a computer for analysis.

As an example, we can consider two cells: cell type 1, a healthy cell, and cell type 2, a diseased cell. Both cell types contain an identical set of four genes: A, B, C, and D. mRNA is isolated from each cell type and used to create fluorescent-tagged cDNA. In this case, red and green are used. Labeled samples are mixed and incubated with a microarray that contains the immobilized genes A, B, C, and D.

The tagged molecules bind to the sites on the array corresponding to the genes being expressed in each cell. A robotic scanner, also a product of silicon chip technology, excites the fluorescent labels, and images are stored in a computer. The computer can compute the red-to-green fluorescence ratio, subtract out background noise, and so on. The computer creates a table of the intensity of red-to-green fluorescence for every point in the matrix. Perhaps both cells express the same levels of gene A, cell 1 expresses more of gene B, cell 2 (the diseased cell) expresses more of gene C, and neither cell expresses gene D. This is a simplistic explanation; experiments have been reported in which as many as 30,000 spots have been placed in the microarray.

DNA microarrays can detect changes in gene expression levels, expression patterns (e.g., the cell cycle), genomic gains and losses (e.g., lost or broken parts of chromosomes in cancer cells), and mutations in DNA (single-nucleotide polymorphism [SNPs]). SNPs are also of interest because they may provide clues about how different people respond to a single drug in different ways.

Proteomics^{180,181}

The word *proteome* describes *protein* expressed by a *genome*. Proteomics is a scientific endeavor that attempts to study the sum total of all of the proteins in a cell from the point of view of their individual functions and how the interaction of specific proteins with other cellular components affects the function of these proteins. Not surprisingly, this is a very complex task. There are many more proteins than there are genes, and in biochemical pathways, a protein rarely acts by itself. At present, we know that the expression of multiple genes is involved for any given disease process. "Simply" knowing the gene sequence rarely unmasks the function of the encoded protein or its relevance to a disease. Consequently, the science of proteomics is not developed to the point at which drug discovery can be driven by gene sequence information. There have been, however, some significant technology-driven approaches to the field. High-throughput high-resolution mass spectroscopy allows the amino acid sequences of proteins to be determined very quickly. The technique of two-dimensional gel electrophoresis has likewise advanced the science of proteomics. Proteomics will, undoubtedly, eventually provide targets for drug discovery and the detection of disease states.

Pharmacogenomics¹⁸²

When pharmaceutical companies develop new drugs for any given disease state, they are limited by a lack of knowledge about how individual patients will respond to the agent. No simple algorithms exist that facilitate prediction of whether a patient will respond negatively (an adverse drug reaction), positively (the desired outcome), or not at all. Consequently, drugs are developed for an "average" patient. The manufacturer relies on clinical studies to expose potential adverse reactions and publishes them in statistical format to guide the physician. Nevertheless, when a physician prescribes a drug to a patient he or she has no way of knowing the outcome. Statistics show clearly that a single drug does not provide a positive outcome in all patients. This "one-drug-does-not-fit-all" concept has its basis in the genetics of a patient, and the science of studying these phenomena is called *pharmacogenomics*.

A patient's response to a drug, positive or negative, is a highly complex trait that may be influenced by the activities of many different genes. ADME, as well as the receptor-binding relationship, are all under the control of proteins, lipids, and carbohydrates, which are in turn under the control of the patient's genes. When the fact that a person's genes display small variations in their DNA base content was recognized, genetic prediction of response to drugs or infectious microbes became possible. Pharmacogenomics is the science that looks at the inherited variations in genes that dictate drug response and tries to define the ways in which these variations can be used to predict if a patient will have a positive response to a drug, an adverse one, or none at all.

Cataloging the genetic variations is an important phase of present research activity. Scientists look for SNPs in a person's gene sequences. SNPs are viewed as markers for slight genomic variation. Unfortunately, traditional gene sequencing is slow and expensive, preventing for now the general use of SNPs as diagnostic tools. DNA microarrays may make it possible to identify SNPs quickly in a patient's cells. SNP screening may help to determine a response to a drug before it is prescribed. Obviously, this would be a tremendous tool for the physician.

ANTISENSE TECHNOLOGY

During the process of transcription, double-stranded DNA is separated into two strands by polymerases. These strands are named the *sense* (coding or [+]) strand and the *antisense* (template or [-]) strand. The antisense DNA strand serves as the template for mRNA synthesis in the cell. Hence, the code for ribosomal protein synthesis is normally transmitted through the antisense strand. Sometimes, the sense DNA strand will code for a molecule of RNA. In this case, the resulting RNA molecule is called *antisense RNA*. Antisense RNA sequences were first reported to be naturally occurring molecules in which endogenous strands formed complementarily to cellular mRNA, resulting in the repression of gene expression. Hence, they may be natural control molecules. Rationally designed antisense oligonucleotide interactions occur when the base pairs of a synthetic, specifically designed antisense molecule align precisely with a series of bases in a target mRNA molecule.

Antisense oligonucleotides may inhibit gene expression transiently by masking the ribosome-binding site on mRNA, blocking translation and thus preventing protein synthesis, or permanently by cross-linkage between the oligonucleotide and the mRNA. Most importantly, ribonuclease H (RNase H) can recognize the DNA-RNA duplex (antisense DNA binding to mRNA), or an RNA-RNA duplex (antisense RNA interacting with mRNA), disrupting the base pairing interactions and digesting the RNA portion of the double helix. Inhibition of gene expression occurs because the digested mRNA is no longer competent for translation and resulting protein synthesis.

Antisense technology is beginning to be used to develop drugs that might be able to control disease by blocking the genetic code, interfering with damaged or malfunctioning genes. Among the possible therapeutic antisense agents under investigation are agents for chronic myelogenous leukemia, HIV infection and AIDS, cytomegalovirus retinitis in AIDS patients, and some inflammatory diseases.

 GENE THERAPY

Gene therapy arguably represents the ultimate application of rDNA technology to the treatment of disease. There are two ways to envision gene therapy: (a) the replacement of a defective gene with a normal gene or (b) the addition of a gene whose product can help fight a disease such as a viral infection or cancer. In the former case, replacement of a defective gene, an actual cure can be effected instead of just treating the symptoms. For example, in CF, a defective gene has been clearly identified as the cause of the disease. It is possible that replacement of the defective gene with a corrected one could produce a cure. Similar possibilities exist for other inherited genetic disorders such as insulin-dependent diabetes, growth hormone deficiency, hemophilia, and sickle cell anemia.

The ability to transfer genes into other organisms has other important applications, including the heterologous production of recombinant proteins (discussed previously) and the development of animal models for the study of human diseases. Another area of exploration is the introduction of recombinant genes as biological response modifiers, for example, in preventing rejection following organ transplantation. If genes encoding host major histocompatibility complexes could be introduced into transplanted cells, the transplanted tissue might be recognized as “self.” It might also be possible to introduce genes for substances such as transforming growth factor- β that would decrease local cell-mediated immune

responses. An opposite strategy might be considered for the treatment of cancer, whereby transplanted cells could be used to target cancer cells, increasing local cell-mediated immune responses.

The transfer of genes from one organism to another is termed *transgenics*, and an animal that has received such a transgene is referred to as a *transgenic animal*. If the transgene is incorporated into the *germ cells* (eggs and sperm), it will be inherited and passed on to successive generations. If the transgene is incorporated into other cells of the body (*somatic cells*), it will be expressed only as long as the newly created transgenic cells are alive. Hence, if a terminally differentiated, postmitotic cell receives a transgene it will not undergo further cell division, whereas if a transgene is created in an undifferentiated stem cell, the product will continuously be expressed in new cells.

 AFTERWORD

Clearly, biotechnology has become an integral part of pharmaceutical care. Pharmacists need to become comfortable with biotechnology and its language to deliver this kind of care to their patients. This chapter has tried to present an overview of the major biotechnological arenas present in the year 2009. The field is advancing rapidly, and every pharmacist must stay current with the literature on biotechnology.

 R E V I E W Q U E S T I O N S 

- Describe the pharmaceuticals-related problems with biotechnologically produced drugs.
- Why cannot biotechnologically produced drugs be administered orally?
- What is GenBank? Why is it important scientifically?
- Describe pharmacogenomics. Describe proteomics. How do these two differ?
- What are chimeric receptors?

CHAPTER 5

Immunobiologicals

JOHN M. BEALE, JR.

CHAPTER OVERVIEW

The immune system constitutes the body's defense against infectious agents. It protects the host by identifying and eliminating or neutralizing agents that are recognized as nonself. The entire range of immunological responses affects essentially every organ, tissue, and cell of the body. Immune responses include, in part, antibody (Ab) production, allergy, inflammation, phagocytosis, cytotoxicity, transplant and tumor rejection, and the many signals that regulate these responses.¹ At its most basic, the human immune system can be described in terms of the cells that compose it. Every aspect of the immune system, whether innate and nonspecific or adaptive and specific, is controlled by a set of specialized cells. Thus, this discussion of some of the fundamentals of immunology begins with the cells of the immune system.

CELLS OF THE IMMUNE SYSTEM

All immune cells derive from *pluripotent* stem cells in the bone marrow. These are cells that can differentiate into any other cell type, given the right kind of stimulus (Scheme 5.1). Various modes of differentiation beyond the stem cell give rise to unique cellular types, each with a specific function in the immune system. The first stage of differentiation gives rise to two intermediate types of stem cells and creates a branch point.² These cells are the myeloid cells (myeloid lineage) and the lymphoid cells (lymphoid lineage). Carrying the lineage further leads to additional branching. The myeloid cells differentiate into erythrocytes and platelets and also monocytes and granulocytes. The lymphoid cell differentiates into B cells and T cells, the cells that are at the center of adaptive immunity. The switching system for each pathway and cell type is governed by several colony-stimulating factors, stem cell factors, and interleukins. These control proliferation, differentiation, and maturation of the cells.

Major Histocompatibility Antigens: Self versus Nonself

The development of most immune responses depends on the recognition of what is *self* and what is *not self*. This determination must be clear and must be done in a very general way. This recognition is achieved by the expression of specialized surface markers on human cells. The major group of markers involved in this recognition consists of surface proteins. These are referred to as the *major histocompatibility complex*³ (MHC) or *major histocompatibility antigens*. Proteins ex-

pressed on the cell surfaces are class I MHCs and class II MHCs. Both classes are highly polymorphic and so are highly specific to each individual. Class I MHCs can be found on virtually all nucleated cells in the human body, whereas class II MHC molecules are associated only with B lymphocytes and macrophages. Class I MHCs are markers that are recognized by natural killer cells and cytotoxic T lymphocytes. When a class I MHC is coexpressed with viral antigens on virus-infected cells, cytotoxic target cells are signaled. Class II MHC molecules are markers indicating that a cooperative immune state exists between immunocompetent cells, such as between an antigen-presenting cell (APC) and a T-helper cell during the induction of Ab formation.

Granulocytes⁴

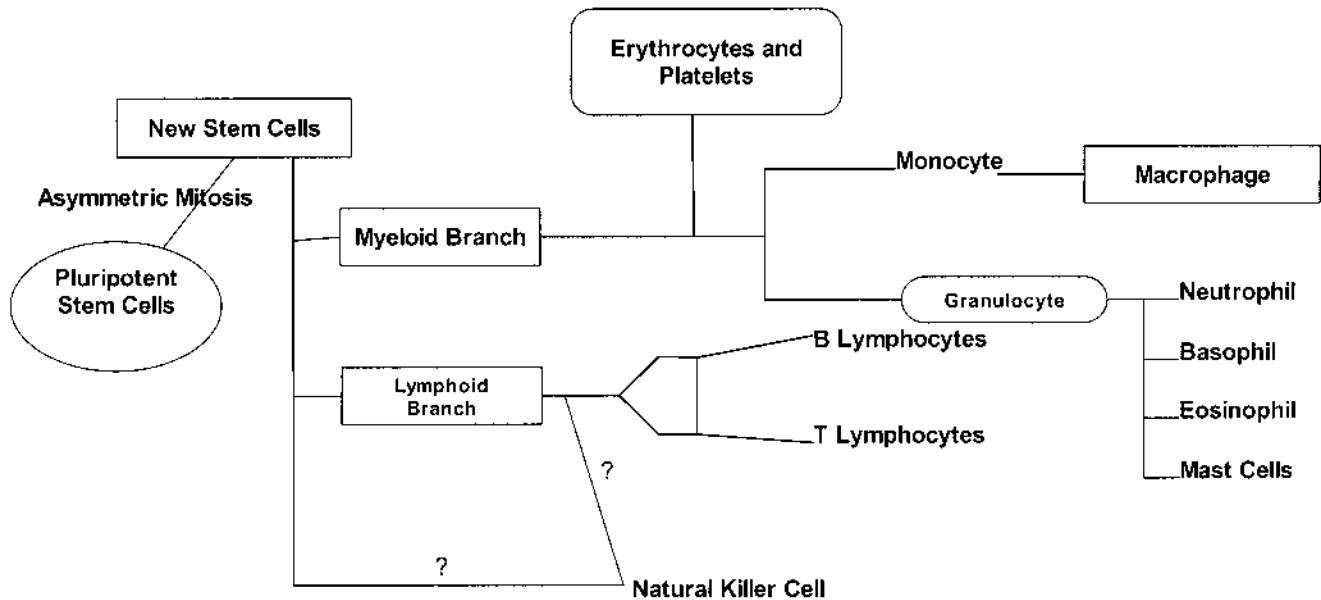

If one views a granulocyte under a microscope, one can observe dense intracytoplasmic granules. The granules contain inflammatory mediators and digestive enzymes that destroy invading pathogens, control the rate and pathway of migration of chemotactic cells, and cause dilation of blood vessels at the infected site. The increased blood flow ensures that an ample supply of granulocytes and inflammatory mediators reaches the site of infection. There is a family of granulocytic cells, each member with its own specialized function. Under microscopic examination, some granulocytes are seen to be multinuclear and some mononuclear. The configuration of the nuclear region and the staining behavior provide ways of classifying granulocytes.

Neutrophils⁴

Neutrophils are the primary innate defense against pathogenic bacteria. They make up most (50%–75%) of the leukocyte fraction in the blood. Microscopically, neutrophils have multilobed nuclei. They respond to chemical motility factors, such as complement mediators released from infected or inflamed tissues, and migrate to a site of infection by the process of chemotaxis. There, they recognize, adhere to, and phagocytose invading microbes.

Phagocytes

The phagocytic process is initiated by contact and adhesion of an invading cell with a phagocyte cell membrane. Adhesion triggers a process whereby the phagocytic cell extrudes pseudopodia that surround the adhering microbe. As this process progresses, the microbe is actually surrounded by the phagocyte cell membrane. Then, invagination of the membrane fully engulfs the particle, and the membrane is

Scheme 5.1 • Lineages of blood cells. All blood cells derive from a pluripotent stem cell. Various cytokines direct the cells into their specific populations.

resealed with the particle encased inside an intracellular vacuolar body called a *phagosome*. Lysosomes in the cytoplasm then fuse with the phagosome to form *phagolysosomes*. The antimicrobial compounds in the phagosomes and lysosomes kill the engulfed pathogen and enzymatically cleave its remains into smaller pieces.

Eosinophils⁵

Eosinophils are granulocytes that can function as phagocytes, but much less efficiently than neutrophils can. They are present as 2% to 4% of blood leukocytes. Their name derives from the intense staining reaction of their intracellular granules with the dye eosin. Eosinophil granules contain inflammatory mediators such as histamine and leukotrienes, so it makes sense that these cells are associated with the allergic response. Clues to the functions of eosinophils come from their behavior in certain disease states. Eosinophil counts are elevated above normal in the tissues in many different diseases, but they are recognized primarily for their diagnostic role in parasitic infections and in allergies. Eosinophils have a unique mode of action that lends to their extreme importance. Unlike neutrophils, eosinophils need not phagocytose a parasite to kill it. Indeed, some parasites are too large to allow phagocytosis. Eosinophils can physically surround a large parasite, forming a cell coat around the invader. Eosinophil granules release oxidative substances capable of destroying even large, multicellular parasites. Hence, even when phagocytosis fails, a mechanism exists to destroy large parasites.

Mast Cells and Basophils

Mast cells and basophils also release the inflammatory mediators commonly associated with allergy. Mast cells are especially prevalent in the skin, lungs, and nasal mucosa; their granules contain histamine. Basophils, present at only 0.2% of the leukocyte fraction in the blood, also contain histamine granules, but basophils are found circulating in the blood

and not isolated in connective tissue. Both mast cells and basophils have high-affinity immunoglobulin E (IgE) receptors. Complexes of antigen molecules with IgE receptors on the cell surface lead to cross-linking of IgE and distortion of the cell membrane. The distortion causes the mast cell to degranulate, releasing mediators of the allergic response. Because of its association with hypersensitivity, IgE has been called “reagin” in the allergy literature. Diagnostically, IgE levels are elevated in allergy, systemic lupus erythematosus, and rheumatoid arthritis. Cromolyn sodium is a drug that prevents mast cell degranulation and thus blocks the allergic response. Cromolyn is used in asthma.

Macrophages and Monocytes^{4,5}

Macrophages and monocytes are mononuclear cells that are capable of phagocytosis. In addition to their phagocytic capabilities, they biosynthesize and release soluble factors (complement, monokines) that govern the acquired immune response. The half-life of monocytes in the bloodstream is about 10 hours, during which time they migrate into tissues and differentiate into macrophages. A macrophage is a terminally differentiated monocyte. Macrophages possess a true anatomical distribution because they develop in the tissues to have specialized functions. Special macrophages are found in tissues such as the liver, lungs, spleen, gastrointestinal (GI) tract, lymph nodes, and brain. These specific macrophages are called either *histiocytes* (generic term) or by certain specialized names (*Kupffer cells* in liver, *Langerhans cells* in skin, *alveolar macrophages* in lung) (Table 5.1). The entire macrophage network is called the *reticuloendothelial system*. Other macrophages exist free in the tissues, where they carry out more nonspecific functions. Macrophages kill more slowly than neutrophils but have a much broader spectrum. It has been estimated that more than 100 soluble inflammatory substances are produced by macrophages. These substances account for macrophages’ prolific abilities to direct, modulate, stimulate, and retard the immune response.

TABLE 5.1 The Reticuloendothelial System

Tissue	Cell
Liver	Kupffer cells
Lung	Alveolar macrophages (dust cells)
Peritoneum	Peritoneal macrophages
Spleen	Dendritic cells
Skin	Langerhans cells
Brain	Microglial cells

Macrophages possess a very specialized function; they act as APCs (Fig. 5.1). APCs are responsible for the preprocessing of antigens, amplifying the numbers of antigenic determinant units, and presenting these determinant structures to the programming cells of the immune system. APCs in-

ternalize an organism or particle and digest it into small fragments still recognizable as antigen. The fragments are conjugated with molecules of the major histocompatibility complex 2 (MHC-II). These complexes are responsible for self or nonself cell recognition and ascertain that cells being processed are not self. MHCs also direct the binding of the antigenic determinant with immunoreactive cells. Once the antigen-MHC-II complex forms, it undergoes transcytosis to the macrophage's cell surface, where B lymphocytes and T-helper cells recognize the antigen via the B surface Ab and T-cell receptors. It is this step that transfers specificity and memory information from the determinant into the immune system through the modulation of B-cell differentiation. Under the regulatory influence of the T-helper cells, B cells are stimulated to differentiate into plasma cells that produce Ab. The T-helper cells accelerate and retard the

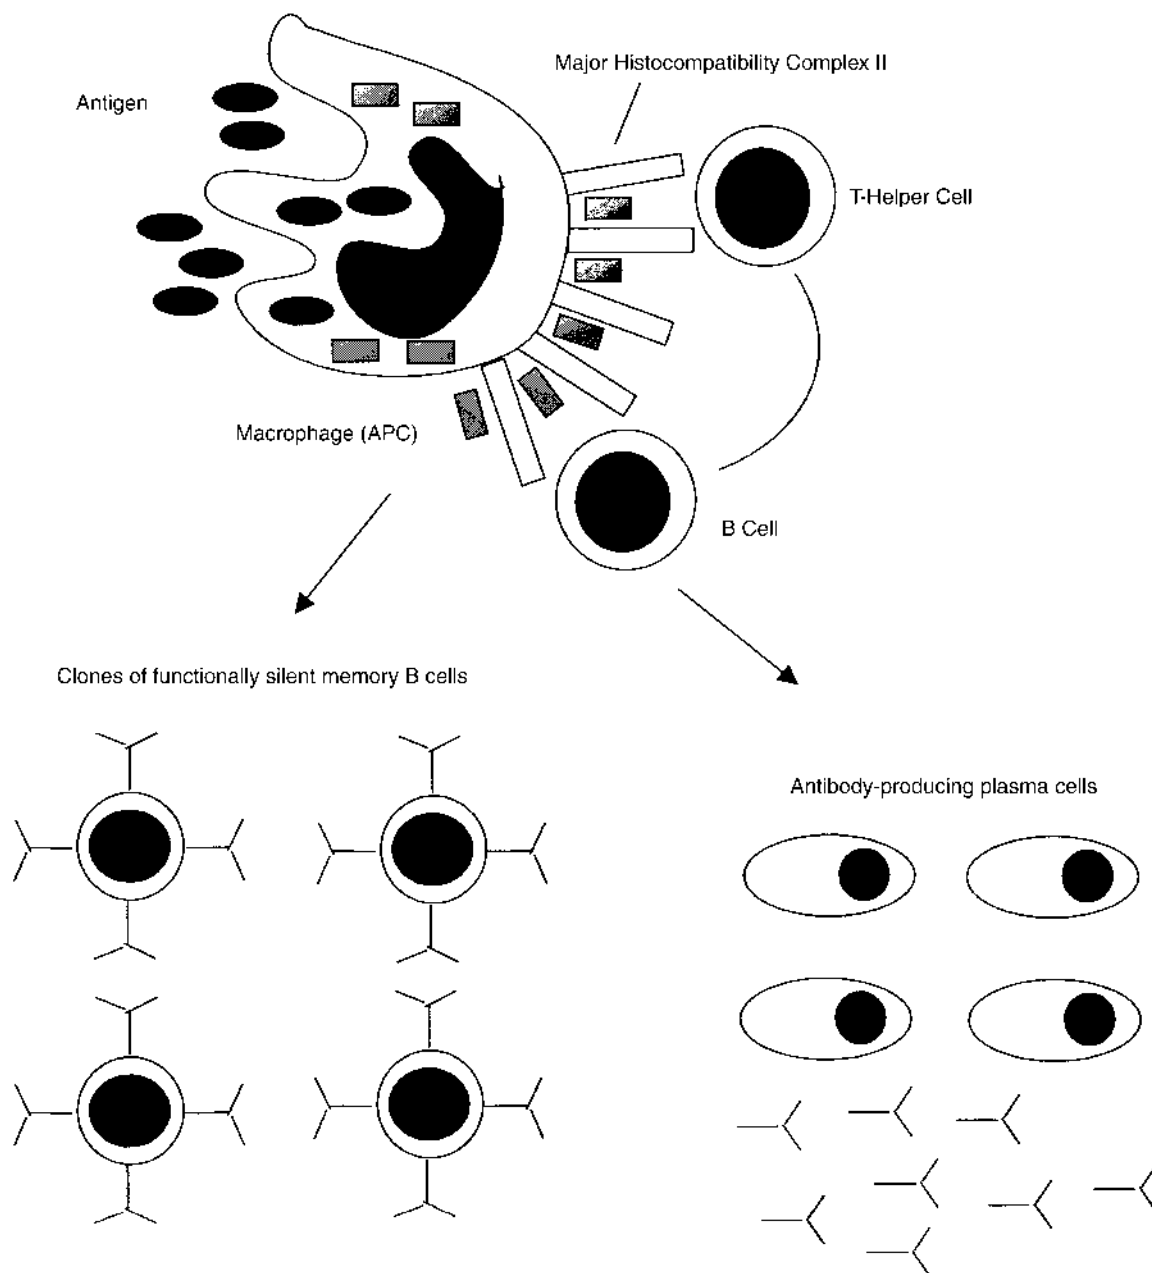

Figure 5.1 • Antigen capture and presentation by a macrophage lead to clones of Ab-producing plasma cells and memory B cells.

process as necessary. Thus, unlike the granulocytes, which have only destructive functions, monocytes and macrophages regulate and program the immune response.

The Lymphoid Cell Line: B and T Cells²

The lymphoid cell line differentiates into two types of lymphocytes, the B lymphocytes and the T lymphocytes. These cells constitute only about 20% to 45% of blood leukocytes. They are small cells, only slightly larger than an erythrocyte, but B and T cells can be identified microscopically by large nuclei that occupy most of the cytoplasmic volume. The nuclei are large to contain enough DNA to enable the T and B cells to biosynthesize massive amounts of protein needed to carry out their immune functions. T lymphocytes are involved in cell-mediated immunity (CMI); B lymphocytes differentiate into Ab-producing plasma cells. B lymphocytes express antibodies on their surfaces that bind antigens. T lymphocytes express specialized T-cell receptors on their surfaces that bind major histocompatibility complex 1 (MHC-I) and 2 (MHC-II) complexed with antigenic peptide fragments.

IMMUNITY

Immunity in humans can be conceptualized in several different ways. If just the type and specificity of the immune response are considered, the ideas of *innate* and *acquired* immunity are used. If only the components that are involved in the immune response are considered, the processes can be divided into *humoral* and *cellular* immunity. If the location of the immune response is considered, we find that the immune system consists of *serosal* (in the serum) immunity and *mucosal* (on mucosal epithelium surfaces) immunity.

Innate Immunity

Innate immunity is the most basic form of immunity and includes immune systems that are present in a human from birth. A clear distinction must be made between innate immunity and acquired (adaptive) immunity, which develops after birth, and then only after an antigenic challenge (Table 5.2). Innate immunity is the first line of defense against invasion by microbes and can be characterized as fast in response, nonspecific, and lacking in memory of the challenge. Acquired immunity develops through a complex system of reactions that are triggered by invasion with an infectious agent. It is slow in response to an infection, is *highly specific*, and has memory of previous infections. The memory, or anamnestic response, is responsible for the extremely rapid development of the immune response with subsequent challenges and is a hallmark of acquired immunity.

TABLE 5.2 Characteristics of Innate versus Acquired Immunity

Innate Immunity	Acquired Immunity
Present from birth	Develops later
Rapid	Slow
Nonspecific	Specific
No memory	Memory

There are three separate components of innate immunity that work in concert to provide the whole response. There are physical barriers, cellular barriers, and soluble factors. The physical barriers include the largest, most exposed organ of the body (the skin), the mucosa, and its associated mucus. The keratinized layer of protein and lipid in the stratum corneum of the skin protects physically against various environmental, biological, and chemical assaults. The protection afforded by mucosal surfaces, such as those that are found in the throat, mouth, nose, and GI tract, is due to a surface epithelium. The epithelium consists of single or multiple layers of epithelial cells with tight gap junctions between them. This type of structure provides an impermeable physical barrier to microorganisms. Most of the time, epithelium is further protected by the secretion of mucus, such as from goblet cells in the GI mucosa. Mucus is a viscous layer consisting of glycopeptide and an acidic glycoprotein called *mucin*. Mucus can prevent penetration of microbial cells into the epithelium, significantly decreasing the possibility of infection by the mucosal route. Other components of the physical barriers in innate immunity are the tears (containing lysozyme), the acidic pH of the stomach, the low pH and flow of the urine, and the cilia in the lungs that constantly beat upward to remove inspired particulates and microbes.

Two components of the cellular innate immune response have already been discussed, granulocytes in the blood and tissue macrophages. When an infection occurs in the tissues, chemotactic factors liberated at the site migrate down a concentration gradient to the surrounding area. These agents make the capillary beds porous. Neutrophils follow the concentration gradient across the endothelium to the site of infection. There are three types of chemotactic factors: (a) formylmethionyl (f-Met) peptides released from the invading bacteria, (b) leukotrienes secreted by phagocytes, and (c) peptide fragments released from activated complement proteins such as C_{3a} and C_{5a}. Neutrophils and macrophages engulf and destroy microorganisms by phagocytosis. Nonphagocytic cells are also involved in the innate immune response, providing soluble chemical factors that enhance the innate response.

Soluble factors of innate immunity include (a) bactericidal factors, (b) complement, and (c) interferon. A bactericidal factor (Table 5.3) is an agent that kills bacteria. Perhaps the most fundamental bactericidal factor is the acid in the stomach. Secreted by goblet cells in the mucosal epithelial lining, stomach acid is responsible for disposing of most of the microbes that are consumed orally. Phagocytes or hepatocytes produce the other bactericidal factors. Most of these are directed toward the phagosome, where the predigested, phagocytically encapsulated

TABLE 5.3 Bactericidal Factors

Factor	Formation	Site of Action
Oxygen ions and radicals	Induced	Phagosomes
Acid hydrolases	Preformed	Lysosomes
Cationic proteins	Preformed	Phagosomes
Defensins	Preformed	Phagosomes or extracellular
Lactoferrin	Preformed	Phagosomes

TABLE 5.4 Acute Phase Factors

Acute Phase Factor	Function/Activity
C-reactive protein	Chemotaxis and enhancement of phagocytosis
α_1 -Antitrypsin	Inhibition of proteases
Complement factors	Control of the complement cascade
Fibrinogen	Blood coagulation

bacterial cell is enclosed. The antimicrobial factors kill the immobilized microbes.

There are two types of antimicrobial factors, those that are preformed inside the phagocyte and one that is *induced* in response to the phagocytic process. The most important of the antimicrobial mechanisms is the respiratory burst, which generates oxygen radicals—superoxide, hydroxyl radicals, and hydrogen peroxide. The respiratory burst is the only induced mechanism. All of the active oxygen species are highly destructive to bacterial as well as host cells, so they are not produced until they are needed. The defensins are arginine- or cysteine-rich bactericidal peptides that exhibit an extremely broad spectrum of antimicrobial activity. The defensins will kill bacteria (Gram-positive and Gram-negative), fungi, and even some viruses. The mechanism of action of the defensins is unknown, but because the peptides are highly charged in an opposite sense to bacterial cell membranes, an electrostatic, membrane-disruptive interaction might be involved. Bacteria have an absolute requirement for iron, and to compete with the host for this element, they secrete high-affinity siderophore factors that scavenge iron from the host's stores. Lactoferrin is a substance produced by the host that binds iron more tightly than the bacterial chelator, preventing the invading organism's access to a critical nutrient. Lysozyme is an important component of the antimicrobial system. This enzyme hydrolyzes [1–4]-glycosidic bonds, as in the peptidoglycan of bacterial cell walls. Lysozyme is present in almost all body fluids, including tears and saliva.

Hepatocytes produce an array of *acute phase proteins* (Table 5.4) that are released into the serum during inflammation or infection. These proteins do not act directly on bacteria, but they augment the bactericidal activity of other antimicrobial factors.

COMPLEMENT

Complement is a system of at least 20 separate proteins and cofactors that continuously circulate in the bloodstream. Complement acts to kill bacterial cells that are missed by the neutrophils and the macrophages. There are actually two separate complement pathways. One, the *classical pathway*, operates in the adaptive or acquired immune response. The classical pathway has an absolute requirement for an Ab–antigen complex as a trigger. The other, the *alternative pathway*, requires no Ab or antigen to initiate and is operative in innate immunity. Both pathways operate in a tightly regulated cascade fashion. The proteins normally circulate as inactive proenzymes. When the pathways are activated, the product of each step activates the subsequent step.

THE ALTERNATIVE COMPLEMENT PATHWAY

In the alternative pathway, C3 is the initiating peptide (Fig. 5.2). In the serum, C3 is somewhat unstable (it is sensitive to proteases) and spontaneously decomposes into a large, active C3b fragment and a smaller, catalytically inactive

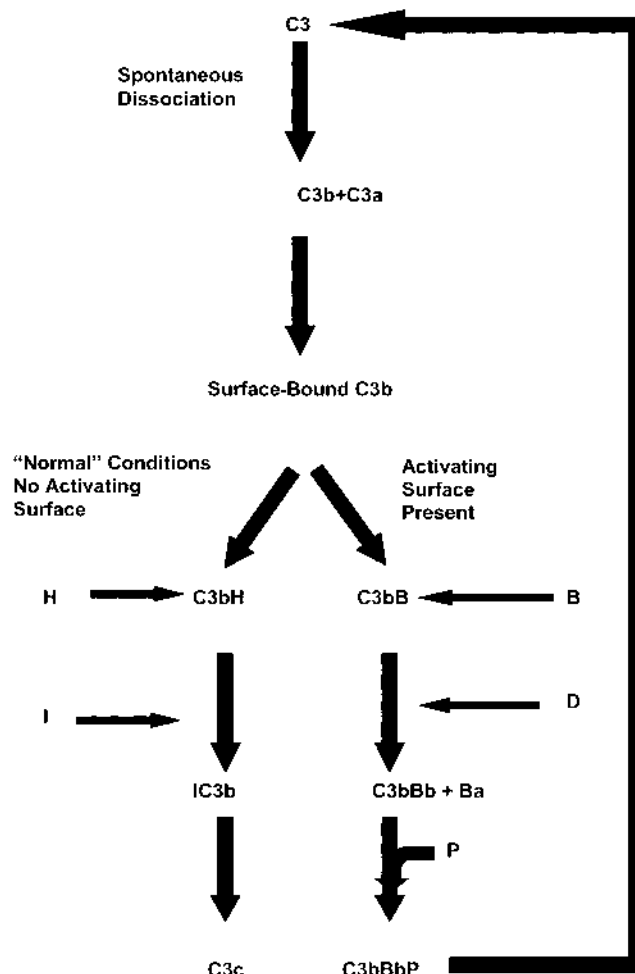

Figure 5.2 • Control of the alternative complement pathway by activating surfaces. When complement component C3b binds to a surface, there exist two possible outcomes. Under normal conditions, when no activating surface is present (e.g., if C3b has contacted normal tissue), sequential addition of blood cofactors H and I converts C3b into C3c, inactivating the complement protein. If an activating surface such as a microbe or damaged tissue is encountered, sequential addition of factors B and D drives the alternative pathway to the normal properdin (P) intermediate, and the complement cascade is triggered. The properdin-containing component (C3bBbP) feeds back to the beginning of the pathway, generating more C3.

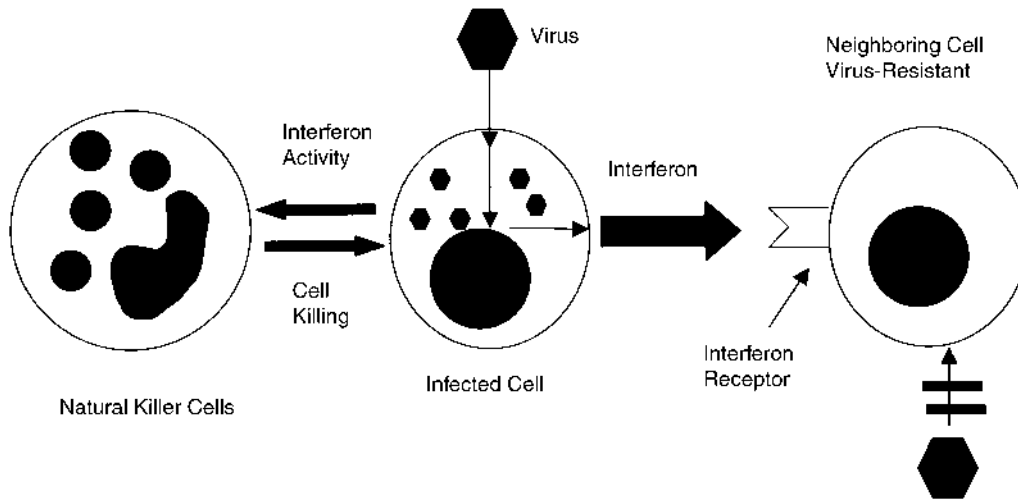

Figure 5.3 • The function of interferon. When a virus infects a host cell, the cell expresses interferon. Interferon activates natural killer cells, causing killing of the infected host cells and elimination of the reservoir of infection. At the same time, interferon induces an antiviral state in neighboring cells, effectively breaking the cycle of infection.

C3a fragment. C3b now becomes bound to a surface, and it has two fates. We can define two types of surfaces. One, the nonactivating surface, is a surface that contains sialic acid or other acidic polysaccharides. The other, an activating surface, contains none of the acidic polysaccharides or sialic acid. This type conforms to a bacterial cell surface. Under normal circumstances, C3b will bind to a nonactivating surface. On binding, the C3b fragment becomes associated with factor H, a β -globulin that associates with an α chain on C3b. Sialic acid increases the affinity for factor H 100-fold. Factor H alters the shape of C3b in such a way that it becomes susceptible to attack by factor I, a serine esterase that cleaves the α chain of C3b, producing inactive iC3b. Attack by another protease produces a fragment designated C3c. In this pathway, factor H accelerates the decay of C3b. When factors H and I work together, they destroy C3b as fast as it is produced and shut down the pathway.

If C3b binds to an activating surface, the ability to bind to factor H is reduced, and C3b binds to a protein called factor B, forming C3bB. Bound factor B is cleaved by factor D into a fragment called Bb. The complex C3bBb has high C3-convertase activity and stimulates the pathway further. Factor P (properdin) binds to the complex, extending the half-life of C3bBbP. This fragment binds to the terminal complement components (C5–C9), creating a membrane attack complex and thus lysing the cell.

THE CLASSICAL COMPLEMENT PATHWAY

The classical complement pathway differs from the alternative pathway in that it requires a trigger in the form of an antigen–Ab complex. Only two antibodies can fix

complement—IgG and IgM. The classical pathway is shown in Figure 5.3. The small fragments that are cleaved from the proenzymes have activities such as chemotactic stimulation and anaphylaxis. The *bar* over the names of some components of the pathway denotes an active complex. Note that the classical pathway does not operate with C1 to C9 in sequence. Rather, the sequence is C1, C4, C2, C3, C5, C6, C7, C8, and C9.

INTERFERONS

An important antiviral system is provided by the interferons (Table 5.5 and Fig. 5.4). The interferons are peptides that, when viral infection occurs, carry out three distinct functions. First, they send a signal to a natural killer cell that essentially leads to the self-destruction of the infected cell. Second, they induce an antiviral state in neighboring cells, limiting the viral infection. Third, when interferon receptors are bound on a target cell, the induction of the formation of antiviral proteins occurs. One such protein is the enzyme 2',5'-oligoadenylate synthetase. This enzyme catalyzes the reaction that converts ATP into 2',5'-oligoadenylate. This compound activates ribonuclease R, which possesses the specificity to hydrolyze viral RNA and thus can stop propagation of the virus inside the cell.

Acquired (Adaptive) Immunity

When the host is exposed to an antigen or organism that has been contacted previously, the *adaptive immune response* ensues. The adaptive immune response works through the B and T lymphocytes, which possess surface

TABLE 5.5 Interferons

Interferon	Producing Cells	Producing Mechanism	Isotypes	Molecular Mass	Receptor
Type 1					
IFN- α	Leukocytes		17	16–27 kDa	95–110 kDa
IFN- β	Fibroblasts	Viral infection	1	20 kDa	95–110 kDa
Type 2					
IFN- γ	T lymphocytes	Mitogen stimulation	1	20–24 kDa	90–95 kDa

Figure 5.4 • Classical complement pathway.

receptors specific for each invading organism. To account for all possible permutations of antigenic structure, natural and synthetic, that the host might encounter, the adaptive immune system uses genetic recombination of DNA and RNA splicing as a way of encoding its antibodies. Lymphocytes can recognize an estimated 10^7 different types of antigens through this genetic recombination mechanism, far more than a person is likely to encounter during a lifetime. Adaptive immunity is Ab-mediated immunity, based on circulating pools of antibodies that react with, and

inactivate, antigens. These antibodies are found in the globulin fraction of the serum. Consequently, antibodies are also referred to as *immunoglobulins* (Ig). The adaptive immune response has the property of *memory*. The sensitivity, specificity, and memory for a particular antigen are retained, and subsequent exposures stimulate an enhanced response. Hence, the adaptive immune response differs from the innate in two respects: *specificity* and *memory*.

The adaptive immune response, like the innate, can be divided into two branches: humoral immunity and CMI. Humoral immunity is circulating immunity and is mediated by B lymphocytes and differentiated B lymphocytes known as plasma cells. CMI is controlled by the T lymphocytes. The immune function of T lymphocytes cannot be transferred by serum alone; the T cells must be present, whereas the immunity of the humoral system can be isolated from the serum and transferred. T cells are specially tailored to deal with intracellular infections (such as virus-infected cells), whereas B cells secrete soluble antibodies that can neutralize pathogens before their entry into host cells. Both B and T cells possess specific receptors on their surfaces to recognize unique stimulatory antigens. When B cells are stimulated, they express specific Ig or surface antibodies that are capable of binding to the antigen. A fraction of the B-cell population does not differentiate into Ab-producing cells but forms a pool of cells that retain the immunological memory. T cells express a specific antigen receptor, the T-cell receptor, similar in structure to the surface Ig receptor of B cells. This receptor is activated by a piece of processed antigen (presented with MHC-II). Activated T cells release soluble factors such as interleukins, cytokines, interferons, lymphokines, and colony-stimulating factors, all of which regulate the immune response. Interactions with some of these help to regulate the B-cell activity, directing the innate immune response.

IMMUNOGLOBULIN STRUCTURE AND FUNCTION

An Ab or Ig is composed of peptide chains with carbohydrate pendant groups. A schematic of the Ab IgG is shown in Figure 5.5. The peptide chains form the quaternary structure of the Ig, while the carbohydrate moieties serve

Figure 5.5 • Structure of immunoglobulin G (IgG), showing antigen-binding regions and key elements of the molecule.

as antigen-recognition groups and probably as conformation-stabilizing units. The general structure of the Ig looks something like a Y, with the antigen-binding regions at the bifurcated end. In this area are peptide sequences that are “programmable” by the immune system to allow the Ig to recognize a large number of antigens.

Treatment with either of two enzymes, papain or pepsin, digests an Ab into fragments that are useful in understanding its molecular structure. Papain clips the Ab into two fragments that contain the antigen-binding regions. These fragments have been termed the *Fab*, or *antigen-binding fragment*. The remaining part of the Ab after papain digestion contains two peptide chains linked by a disulfide bond. Treatment of the same Ab with pepsin yields the two Fab units joined by the disulfide bond, plus two of the distal peptide chains. These distal units have been crystallized and, hence, are termed the *Fc fragment* (for “crystallizable”). The disulfide bond, therefore, provides a demarcation between the two molecular regions. The nomenclature of an Ab includes a high-molecular weight, or heavy, chain on the inside and a low-molecular weight, or light, chain on the outside.

IMPORTANT FEATURES OF ANTIBODY MOLECULAR STRUCTURE^{4,6}

As stated previously, the tip end of the Fab region binds antigen. There are two of these regions, so we say that the Ab is *bivalent* and can bind two antigen molecules. The overall amino acid sequence of the Ab dictates its conformation. The peptide sequence for most antibodies is similar, except for the hypervariable regions. The amino acid sequence at the end of the heavy chain (Fc) determines the class of the Ig (i.e., IgG, IgM, etc.). All antibodies resemble each other in basic shape, but each has a unique amino acid sequence that is complementary to the antigen in a “lock-and-key” interaction (antigen–Ab specificity). Some, such as IgM, are pentamers of IgG (Fig. 5.6). In reality, the lock-and-key model is too simplistic, and an induced fit model is preferred.

ANTIBODY PRODUCTION AND PROGRAMMING OF THE IMMUNE SYSTEM

The main element of the programming portion of the immune system is the macrophage. A common property of macrophages is *phagocytosis*, the capacity to engulf a particle or cell through invagination and sealing off of the cell membrane. The macrophages involved in the immune response set in motion a unique amplification process, so that a large response is obtained relative to the amount of antigen processed. The macrophages engulf antigenic particles and incorporate them into their cytoplasm, where the antigens are fragmented. The fragments are then combined with MHC-II, displayed on the cell membrane of the macrophage, and presented to the immune system. The presented antigens interact with B cells, causing differentiation to plasma cells and Ab secretion. T-helper cells also interact with the presented antigen and are stimulated to cause the B cells to proliferate and mature. Plasma cells are monoclonal (genetically identical) and produce monoclonal Ab. The process, from the pluripotent stem cell, to the B and T cells, to the plasma cells, is shown in Figure 5.1.

Figure 5.6 • Pentameric structure of immunoglobulin M (IgM).

ANTIBODY FORMATION⁵

Figure 5.1 also indicates the actual Ab-producing steps. Plasma cells are clones of Ab-producing cells, which amplify the Ab response by their sheer numbers. The plasma cells can easily be regenerated if called on to do so by the memory functions. A population of plasma cells is shown at the bottom of the diagram. These are identical and amplify and produce large quantities of Ab, proportionally much greater than the amount of antigen that was initially processed.

THE ANAMNESTIC RESPONSE⁵

Because the programmed immune system has the property of memory, subsequent exposures to the same antigen are immediately countered. The actual memory response is referred to as the *anamnestic response*, a secondary response of high Ab titer to a particular antigen. This is due to “memory cell” formation as a result of the initial antigen stimulus (sensitization or immunization). The anamnestic response is demonstrated in Figure 5.7.

ANTIGEN–ANTIBODY REACTIONS⁴

An Ab is bivalent, and an antigen is multivalent, so lattice formation can occur (Fig. 5.8). The complex may be fibrous, particulate, matrixlike, soluble, or insoluble. These characteristics dictate the means of its disposal. Four fundamental reactions describe these processes: neutralization, precipitation, agglutination, and bacteriolysis.

Neutralization

Neutralization is an immunological disposal reaction for bacteria and for toxins (which are small and soluble). Once they bind the Ab, they are no longer toxic because their active site structures are covered and they cannot bind their

Figure 5.7 • Diagram of the time course of the anamnestic (memory) response. After the first immunization (week 1), the titer of Ab increases slowly to a low level and wanes. A challenge with the same antigen (shown in the diagram at week 4) elicits rapid development of a high titer of Ab in the blood.

targets. Examples of toxins are tetanospasmin (tetanus toxin; *Clostridium tetani*) and diphtheria toxin. Both react with specific receptors in the inhibitory interneurons of the nervous system, causing spastic paralysis or flaccid paralysis, respectively. When an Ab blocks the toxin's receptor-binding region, it can no longer bind to the neural receptors and is rendered harmless. The toxin–Ab complex is soluble and requires no further processing. The complex can then

Figure 5.8 • Combining ratios of Ab and antigen. Because the Ab is bivalent, there exist a set of conditions under which optimal proportions yield a stable lattice structure, neutralizing the antigen. If antigen or Ab is in excess, the lattice will not form.

be eliminated by the kidneys. Bacteria are immobilized by neutralization.

Precipitation

When a soluble antigen reacts with an Ab, it may form an insoluble particulate precipitate. Such a complex cannot remain in the bloodstream in its insoluble state. These species must be removed by the spleen or through the reticuloendothelial system by phagocytosis.

Agglutination

Bacterial cells may be aggregated by binding to antibodies that mask negative ionic surface charges and cross-link cellular structures (Fig. 5.8). The bacteria are thus immediately immobilized. This limits their ability to maintain an infection, but it forms a particulate matrix. This type of complex must also undergo elimination through the reticuloendothelial system.

Bacteriolysis

Bacteriolysis is a complement-mediated reaction. The last five proteins in the cascade self-assemble to produce a membrane attack complex that disrupts the cell membranes of bacteria, acting like bacitracin or amphotericin B. The cell membranes lose integrity, cell contents leak out, membrane transport systems fail, and the cell dies. This type of reaction yields products that require no special treatment.

ANTIBODY TYPES AND REACTIONS

Ab types and reactions are classified on the basis of variations in a common section of the Fc fragment that governs biological activity in a general way.

IgG

IgG (Fc = γ) (Fig. 5.5) participates in precipitation reactions, toxin neutralizations, and complement fixation. IgG is the major (70%) human Ig. The Fab tip fixes antigen, and the Fc fragment can fix complement to yield agglutination or lysis. IgG is the only immunoglobulin that crosses the transplacental barrier and the neonatal stomach, so it provides maternal protection. IgG constitutes about 75% of the total Ab in the circulation. It is present at a concentration of about 15 mg/mL and has a half-life of 3 weeks, the longest of any of the Ab types. The light chains of IgG can possess either κ or λ variants. These slight differences in structure are called *isotypes*, and the phenomenon is termed *isotypic variation*.

IgM

IgM (Fc = μ) (Fig. 5.6) is present at a concentration of about 1.5 mg/mL and has a half-life of less than 1 week. This Ab participates in opsonization, agglutination reactions, and complement fixation. Opsonization, as stated previously, is a “protein coating” or tagging of a bacterium that renders it more susceptible to phagocytosis. A complex of the Fc portion of IgM plus C3b of complement is that protein. IgM is the first immunoglobulin formed during immunization, but it wanes and gives way to IgG. IgM is a pentamer, and its agglutination potency is about 1,000 times that of IgG. IgM is also responsible for the A, B, and O blood groups. The fundamental monomeric IgM structure is much like that of IgG. The pentamer is held together by disulfide bonds and a single J (joining) peptide. The affinity of an IgM monomer for antigen is less than that of IgG, but the multimeric structure raises the *avidity* of the molecule for an antigen.

Figure 5.9 • Structure of immunoglobulin A (IgA), the mucosal Ab that protects the GI tract and the respiratory mucosa.

IgA

IgA ($Fc = \alpha$) (Fig. 5.9) is found in exocrine gland secretions (milk, saliva, tears), where it protects mucous membranes (e.g., in the respiratory tract). It is present in the serum as a monomer at a concentration of 1 to 2 mg/mL, but humans secrete about 1 g of the dimer per day in the mucosal fluids. Secretory IgA consists of two IgG-like units linked together at the Fc regions by a peptide known as the secretory fragment and a J fragment. The secretory fragment is actually part of the membrane receptor for IgA. The IgA molecule on the mucosal side of the membrane binds antigen, then binds to the receptor. By a process of transcytosis, the IgA–antigen complex is moved from the mucosa to the bloodstream, where IgG and IgM can react. Because it is distributed on the mucosa, IgA has an anatomically specific distribution, unlike the other antibodies. IgA is the mediator of oral polio vaccination (the mucosal reaction gives way to systemic protection).

IgD

IgD ($Fc = \delta$) is present on the surface of B cells and, along with monomeric surface IgM, is an antigen receptor that activates Ig production. There is less than 0.1 mg/mL in the bloodstream, and the half-life is only 3 days.

IgE

IgE ($Fc = \epsilon$) is the Ab responsible for hypersensitivity reactions. IgE complexes have a high affinity for host cell surfaces and can damage the host. High levels of IgE are found in persons with allergies of various types, as well as in autoimmune diseases. The Fc fragment is responsible for the Ig–cell reactivity. An Ab–plus–antigen reaction yields the typical Ab–antigen complex. The Fc portion of the Ab is actually part of the mast cell. When antigen binds to the Fab portion of the Ab, the IgE molecules become cross-linked. This probably distorts the membrane of the mast cells and stimulates them to release histamine, which causes bronchial constriction, itching, redness, and anaphylaxis.

ACQUISITION OF IMMUNITY

Several types of immunity must be considered when describing vaccines and other immunobiologicals. Some are artificial and some are natural. *Natural immunity* is endowed by phagocytic white blood cells, lysozyme in tears, the skin, and so on. *Acquired immunity* is acquired after birth (or by passage from mother to fetus). Thus, immunity may be classified as follows:

- **Active acquired immunity:** The host produces his or her own Ab.

- **Naturally acquired active immunity:** Occurs on recovery from a disease (or from antigen exposure).
- **Artificially acquired active immunity:** Occurs as a response to sensitization by a vaccine or toxoid.
- **Passive acquired immunity:** The subject receives Ab from an outside source, such as a γ -globulin injection, or by transplacental transfer.
- **Naturally acquired passive immunity:** Temporary neonatal protection from maternal IgG passes to the fetus in utero; this type of immunity is not long-lasting.
- **Artificially acquired passive immunity:** An Ab is given by injection (e.g., by an antitoxin or a γ -globulin injection).

Definitions of Immunobiologicals

Immunobiologicals include antigenic substances, such as vaccines and toxoids, or Ab-containing preparations, such as globulins and antitoxins, from human or animal donors. These products are used for active or passive immunization or therapy. All of the following are examples of immunobiologicals:

- **Vaccine:** A suspension of live (usually attenuated) or inactivated microorganisms (e.g., bacteria, viruses, or rickettsiae) or fractions thereof, administered to induce immunity and prevent infectious disease or its sequelae. Some vaccines contain highly defined antigens (e.g., the polysaccharide of *Haemophilus influenzae* type b [Hib] or the surface antigen of hepatitis B), others have antigens that are complex or incompletely defined (e.g., killed *Bordetella pertussis* or live attenuated viruses).
- **Toxoid:** A modified bacterial toxin that has been made nontoxic but retains the ability to stimulate the formation of antitoxin.
- **Immune globulin (IG):** A sterile solution containing antibodies from human blood. It is obtained by cold ethanol fractionation of large pools of blood plasma and contains 15% to 18% protein. Intended for intramuscular administration, IG is primarily intended for routine maintenance of immunity in certain immunodeficient persons and for passive immunization against measles and hepatitis A. IG does not transmit hepatitis B virus (HBV), human immunodeficiency virus (HIV), or other infectious diseases.
- **Intravenous immune globulin (IGIV):** A product derived from blood plasma from a donor pool similar to the IG pool but prepared so it is suitable for intravenous use. IGIV does not transmit infectious diseases. It is primarily used for replacement therapy in primary Ab deficiency disorders and for the treatment of Kawasaki disease, immune thrombocytopenia purpura, hypogammaglobulinemia in chronic lymphocytic leukemia, and some cases of HIV infection.
- **Specific immune globulin:** Special preparations obtained from blood plasma from donor pools preselected for a high Ab content against a specific antigen (e.g., hepatitis B immune globulin, varicella-zoster immune globulin [VZIG], rabies immune globulin, tetanus immune globulin, vaccinia immune globulin, and cytomegalovirus immune globulin). Like IG and IGIV, these preparations do not transmit infectious disease.
- **Antitoxin:** A solution of antibodies (e.g., diphtheria antitoxin and botulinum antitoxin) derived from the serum of animals immunized with specific antigens. Antitoxins are used to confer passive immunity and for treatment.

Vaccination denotes the physical act of administering a vaccine or toxoid. *Immunization* is a more inclusive term denoting the process of inducing or providing immunity artificially by administering an immunobiological. Immunization may be active or passive.

Immunobiologicals (Vaccines and Toxoids)⁶⁻¹⁰

A *vaccine* may be defined as a solution or suspension of killed or live/attenuated virus, killed rickettsia, killed or live/attenuated bacteria, or antigens derived from these sources, which are used to confer active, artificially acquired immunity against that organism or related organisms. When administered, the vaccine represents the initial exposure, resulting in the acquisition of immunity. A subsequent exposure or challenge (a disease) results in the anamnestic, or memory, response.

METHODS OF VACCINE PRODUCTION

Vaccine production methods have varied greatly over the years and are best discussed according to a parallel chronological and sophistication approach.

Killed (Inactivated) Pathogen

In this method, the normal pathogen is treated with a strong, denaturing disinfectant like formaldehyde or phenol. The process denatures the proteins and carbohydrates that are essential for the organism to live and infect a host, but if treated properly, the surface antigens are left intact. The process must be done carefully to control the unwinding of proteins or carbohydrates by denaturation, because the preparation must be recognized as the original antigen. The main problems with killed pathogen vaccines are the following: (a) if the vaccine is not inactivated totally, disease can result; (b) if the preparation is overtreated, vaccine failure usually results because of denaturation; (c) the production laboratory must grow the pathogen in large quantities to be commercially useful, putting laboratory technicians at risk; and (d) the patient may experience abnormal and harmful responses, such as fever, convulsions, and death. These vaccines typically are viewed as “dirty” vaccines, and some, like the pertussis vaccine, have been associated with problems serious enough to warrant their temporary removal from the market.

Live/Attenuated Pathogens

The word *attenuated* for our purposes simply means “low virulence.” The true pathogen is altered phenotypically so that it cannot invade the human host and cannot get ahead of the host’s immune system. Low-pathogenicity strains such as these were originally obtained by passage of the microbes through many generations of host animals. The idea was that the animal and the pathogen, if both were to survive, needed to adapt to live with each other without either partner being killed. Poliovirus is attenuated in this fashion in monkey kidney tissue. In a live/attenuated vaccine, antigenicity is still required, as is infectivity (polio vaccine yields an infection), but the host’s immune system must be able to stay ahead of the infection. The key problems are the following: (a) the vaccine cannot be used if the patient is immunocompromised, has fever or malignancy, or is taking immunosuppressive drugs; (b) these vaccines should not be used during pregnancy; and (c) the attenuated organ-

ism commonly reverts to the virulent strain, which was the reason for the failure of some early polio vaccines. Today, biological quality control is very stringent, and these problems have been eliminated.

Live/Attenuated Related Strain

The live/attenuated related strain is antigenically related so that it can provide cross-immunity to the pathogen. For example, cowpox virus can be used in place of smallpox virus. The strains are antigenically similar enough so that the host’s immune system reacts to the related strain to provide protection against the normal pathogen. The main advantage is that a true pathogen is not being used so that the chance of contracting the actual disease is zero. The problem with such vaccines is that they cause an infection. Cowpox is known to spread to the central nervous system in 1 in 10⁵ cases, causing a potentially fatal form of meningitis.

Cellular Antigen from a Pathogen

The surface antigen (i.e., what is recognized as foreign) is harvested from the pathogen, purified, and reconstituted into a vaccine preparation. These antigens can take several forms, including the carbohydrate capsule, as in *Neisseria meningitidis*; pili, as in *N. gonorrhoeae*; flagella from motile bacteria (the basis for an experimental cholera vaccine); or the viral protein coat, as in the vaccine for hepatitis B. Advantages of the method are that there is virtually no chance of disease, contamination, or reversion and there are no storage problems. This method is currently as close to a “perfect approach” as we have. A problem is that the pathogen must be grown under careful control or an unsure source must be relied on. For example, hepatitis B vaccine was originally prepared from the serum of a controlled population of human carriers. Imagine the impact if one of the carriers developed another blood-borne disease. Additionally, these are strain-specific antigens (e.g., *N. gonorrhoeae* may require 1,500 different pili antigens). Acellular vaccines may exhibit lower antigenicity in the very young and may require several injections for full immunological competence. To be safe and consistent, the antigenic component must be identified. Given the complex nature of biological materials, this is not always easy or even possible.

Genetically Engineered Pathogens⁵

The techniques of genetic engineering have allowed the pharmaceutical industry to prepare absolutely pure surface antigens while totally eliminating the pathogenic organism from the equation. As shown in Figure 5.10, the virus contains surface antigens (designated by *filled circles*). Inside the viral capsule is a circular piece of deoxyribonucleic acid (DNA) containing genes for the various biological molecules of the virus. The diagram shows, at about 3 o’clock, a small piece of DNA that codes for the surface antigen. The strategy is to isolate this piece of DNA and insert it into a rapidly growing expression vector for production of the surface protein. In this case, *Escherichia coli* serves as an excellent vector. It contains a plasmid that can be removed, clipped open, and used as a cassette to carry the viral DNA. Additionally, *E. coli* can be grown in batch to produce the viral surface antigen. To begin, the DNA is removed from the virus and the plasmid is removed from the vector. Viral and bacterial nucleic acid is treated with a restriction

Figure 5.10 • Preparation of a genetically engineered Ab.

endonuclease, which cleaves the DNA and plasmid at designated restriction sites. The viral DNA is cleaved into several fragments, each of which is ligated into the *E. coli* plasmid with a ligase enzyme. Plasmids are inserted into *E. coli*, and the organism is grown in batch fermentation. The organisms containing the gene for the viral surface protein can be separated by screening and purified to serve as the ultimate antigen producer—free of contamination or pathogenic viral particles. The pure antigen may then be constituted into a vaccine and used in human hosts.

USE OF VACCINES IN COMBINATION: DOSING^{5,11}

Types of Vaccines

There are three basic types of vaccine preparations that are used clinically:

1. A *simple vaccine* contains one strain of a disease-causing organism (e.g., plague vaccine, *Pasteurella pestis*, and smallpox vaccine).
2. A *multivalent vaccine* is prepared from two or more strains of an organism that cause the same disease (e.g., polio is trivalent). Administration of the multiple strains is required for full protection because their antigens are not cross-immunizing. The immune system must mount a separate immune response to each strain.
3. A *polyvalent vaccine* is prepared from two or more organisms that cause different diseases. Polyvalent vaccines are given for convenience, primarily so that a child can be given one shot rather than several. The measles–mumps–rubella (MMR) vaccine is of the polyvalent type.

Types of Dosing

Vaccines can be administered according to various dosing regimens, depending on the vaccine type and the purpose of the injection:

1. A *single-dose vaccine* is usually assumed to confer, with one shot, “lifetime immunity.” The smallpox vaccine was a single-dose vaccine.
2. In a *multiple-dosing regimen*, several doses are given, spaced weeks or months apart, to get maximum immunogenicity. Multiple dosing is usually done with inactivated vaccines, which are less antigenic. Multiple dosing is not the same as a booster dose.
3. A *booster dose* is administered years after the initial immunization schedule (regardless of single or multiple first dose). As a patient ages, Ab levels may wane. A booster is used to bolster immunity. Also, boosters are used if a patient is known or suspected to have been exposed to a pathogen (e.g., tetanus).
4. A *coadministered vaccine* is possible only if one vaccine does not interfere with another.
5. There are two physical forms of vaccines: A *fluid vaccine* is a solution or a suspension of the vaccine in saline of an aqueous buffer; the solution or suspension in an *adsorbed vaccine* is adsorbed on a matrix of aluminum or calcium phosphate. Like a sustained-release dosage form, in theory, there is longer exposure via a depot injection. The higher surface area of the matrix will be exposed to the immune system. Generally, adsorbed vaccines are preferred.

Pharmaceutical Principles of Vaccines

As expected for a live biological preparation, heat destroys live viral and bacterial vaccines. If the agent is not killed, the antigen may be altered. Like many biologicals, lyophilized vaccines are unstable after reconstitution. Ice crystals formed inside the protein structure during freeze-drying expand during thawing and disrupt the structure of the vaccine. Live vaccines can be inactivated by minute amounts of detergent. Detergent residue adhering to glassware is concentrated enough to act as a disinfectant. It is safe to use only plastic implements specified for the vaccine. The suspending medium may be sterile water, saline, or more complex systems containing protein or other constituents derived from the medium in which the vaccine is produced (e.g., serum proteins, egg antigens, and cell culture–derived antigens). Concentrated Ab suspensions (γ -globulins) are typical amphiphilic proteins and aggregate on storage. If injected, the particulates may cause anaphylaxis. Preservatives may be components of vaccines, antitoxins, and globulins. These components are present to inhibit or prevent bacterial growth in viral cultures or the final product or to stabilize the antigens or antibodies. Allergic reactions can occur if the recipient is sensitive to one of these additives (e.g., mercurial compounds [thimerosal], phenols, albumin, glycine, or neomycin).

Storage and Handling of Immunobiologicals

Failure to follow the exact recommendations for storage and handling of immunobiologicals can lead to an impotent preparation. During reconstituting, storing, and handling of immunobiologicals, the most important recommendation is to follow the package insert exactly. Vaccines should always be stored at their recommended temperature. Certain vaccines, such as polio vaccine, are sensitive to increased

temperature. Other vaccines, such as oral polio vaccine, diphtheria and tetanus toxoids, and acellular pertussis vaccine, hepatitis B vaccine, influenza vaccine, and Hib conjugate vaccine (Hib-CV; among others), are sensitive to freezing.

Viral Vaccines¹²

SMALLPOX VACCINE (DRYVAX)

Smallpox vaccine is live *vaccinia* (cowpox) virus grown on the skin of a bovine calf. Smallpox is a highly lethal and disfiguring disease that was common throughout history. Smallpox vaccine was used routinely in the United States but today is no longer recommended. (There have been no reported cases of smallpox since the 1940s.) In 1982, smallpox was declared eradicated worldwide. With smallpox, the risks of the vaccine outweigh the benefits; the vaccine penetrates the central nervous system and potentially fatal encephalitis occurs in 1 of 10⁵ patients. After exposure to smallpox, the vaccine can be injected to lessen the severity of the disease.

INFLUENZA VACCINE^{13–17}

Influenza vaccine is a multivalent inactivated influenza virus or viral subunits (split vaccine). The virus is grown on chick embryo and inactivated by exposure to ultraviolet (UV) light or formaldehyde. The antigen type is protein. The vaccine in the United States contains thimerosal, a mercurial, as a preservative. *Influenza* is a respiratory tract infection with a 2-day incubation period. The disease may be devastating and can lead to pneumonia. Without the vaccine, influenza is common in epidemics and pandemics. To clarify, the *flu* is a GI infection with diarrhea and vomiting. Influenza requires weeks of incubation. Influenza is caused by two main genetic strains each year (A and B): type A is most common in humans; type B is less common. The virus mutates very rapidly, and vaccines must be tailored yearly. The World Health Organization (WHO) and the Centers for Disease Control and Prevention (CDC) monitor the migration of the disease from Southeast Asia, type the strains causing the occurrences, and order a vaccine to counter the organisms most likely to enter the United States. Influenza A viruses are categorized according to two cell surface protein antigens: hemagglutinin (H) and neuraminidase (N). Each of these is divided further into subtypes (H1, H2; N1, N2). Individual strains within a subtype are named for the location, isolation sequence number, and year of isolation (e.g., A/Beijing/2/90 [H1N1]). For example, the WHO-recommended formula for 2001 to 2002 included the following antigens: A/New Caledonia/20/99 (H1N1), A/Moscow/10/99 (H3N2), B/Sichuan/379/99, 15 μ g each per 0.5 mL. A typical vaccine will be a mixture of three strains. Strains are selected each year in the spring on the basis of the disease trends observed and are released in the autumn. In general, those patients who are at high risk for complications from influenza are the following:

- Persons 65 years of age or older
- Residents of nursing homes and other chronic-care facilities that house persons of any age who have chronic medical conditions
- Adults and children who have chronic disorders of the pulmonary or cardiovascular systems, including asthma
- Adults and children who have required medical follow-up or hospitalization during the preceding year because

of chronic metabolic diseases (including diabetes mellitus), renal dysfunction, hemoglobinopathies, or immunosuppression (including immunosuppression caused by medications or HIV infection)

- Children and teenagers (aged 6 months–18 years) who are receiving long-term aspirin therapy and, therefore, might be at risk for developing Reye syndrome after influenza infection
- Women who will be in the second or third trimester of pregnancy during the influenza season
- Healthcare workers and those in close contact with persons at high risk, including household members
- Household members (including children) of persons in groups at high risk, including persons with pulmonary disorders, such as asthma, and healthcare workers who are at higher risk because of close contact

It is impossible to contract influenza from the vaccine. The only side effects may be local pain and tenderness at the injection site, with low-grade fever in 3% to 5% of patients. Aspirin and acetaminophen are effective in combating these symptoms. Allergic reactions are rare but may be seen in persons allergic to eggs. Immunity to influenza vaccine takes 2 weeks to develop. Some people fear the vaccine because of reports of a strange paralysis and lack of nerve sensation associated with the 1976 swine flu vaccine. This problem, Guillain-Barré syndrome, was associated only with this 1976 vaccine and has not been associated with vaccines since.¹⁷

POLIO VACCINES^{18–20}

Polio is a dangerous viral infection that affects both muscle mass and the spinal cord. Some children and adults who contract polio become paralyzed, and some may die because of respiratory paralysis. Polio was the cause of the “infantile paralysis” epidemic of 1950 to 1953, which led to many paralyzed children and the specter of patients spending their lives in an iron lung. Serious cases of polio cause muscle pain and may make movement of the legs and/or arms difficult or impossible and, as stated previously, may make breathing difficult. Milder cases last a few days and may cause fever, sore throat, headache, and nausea. Interest in polio has increased because of recent local outbreaks; large numbers of people are unimmunized. There are no drugs or special therapies to cure polio; treatment is only supportive. The symptoms of polio may reappear 40 to 50 years after a severe infection. This phenomenon is known as postpolio muscle atrophy (PPMA). PPMA is not a reinfection or reactivation of the virus but is probably a form of rapid aging in polio survivors. There are two types of polio vaccines.

Inactivated Polio Vaccine (IPV)

There are several synonyms for the IPV vaccine: IPV, e-IPV, ep-IPV, and the Salk vaccine (1954 [IPOL, Aventis-Pasteur]). e-IPV is an enhanced potency poliovirus, more potent and immunogenic than any of the previous IPV formulations. e-IPV is recommended for all four infant doses because of the incidence of rare cases of oral polio vaccine (OPV)–associated paralytic poliomyelitis. e-IPV is also preferred for adults for the same reason. IPV is a trivalent (strains 1, 2, 3) vaccine grown in monkey kidney culture and subjected to elaborate precautions to ensure inactivation (typically, formaldehyde is used). The antigen form is whole

virus. The antigen type is protein. The vaccine is injected to cause induction of active systemic immunity from polio but does not stop polio carriers, who shed the virus from the oral and nasal cavities.

Trivalent Oral Polio Vaccine (TOPV)

TOPV (Sabin vaccine, 1960) is a live attenuated whole virus vaccine (antigen type, protein) containing polio strains 1, 2, and 3. The virus culture is grown on monkey kidney tissue with the use of an elaborate attenuation protocol. Oral administration of the vaccine yields a local GI infection, and the initial immune response is via IgA (mucosal, local to the GI tract). The IgA–antigen complex undergoes transcytosis across the mucosal membrane, and systemic immunity is induced as IgM and IgG form. A major caution with TOPV is that it is a live vaccine and must never be injected. Indications are the following:

- Mass vaccination campaigns to control outbreaks of paralytic polio.
- Unvaccinated children who will travel in less than 4 weeks to areas where polio is endemic.
- Children of parents who do not accept the recommended number of vaccine injections. These children may receive OPV only for the third or fourth dose or both. In such cases, the healthcare provider should administer OPV only after discussing the risk of OPV-associated paralytic poliomyelitis with parents or caregivers.
- e-IPV is recommended for routine use in all four immunizing doses in infants and children.
- The WHO has advocated giving children e-IPV instead of TOPV to prevent exposure of others to virus shed through the nose and mouth.^{21,22}

RUBELLA VACCINE²³

German measles is a disease that was once called the “3-day measles” and was considered a normal childhood illness. It is a mild disease with few consequences, except in the first trimester of pregnancy. In these mothers, rubella causes birth defects in 50% of cases. Defects may include heart disease, deafness, blindness, learning disorders, and spontaneous abortion of the fetus. Symptoms of rubella are a low-grade fever, swollen neck glands, and a rash that lasts for about 3 days. About 1 of every 10 women of childbearing age in the United States is not protected against rubella. Also, 20% of all adults escaped this normal childhood disease or are not vaccinated.

Rubella vaccine (German measles vaccine, live, Meruvax II, Merck) is a live, attenuated rubella virus produced in human diploid cell culture. The antigen form of the vaccine is whole virus. The antigen type is protein. The vaccine is administered as part of the normal immunization schedule at 15 months. Side effects are minimal, but there may be some soreness and pain at the site of injection and stiffness of the joints.

A problem with the vaccine is that administration of a live virus is contraindicated in pregnancy. Indications are the following:

- Persons aged 12 months to puberty should be immunized routinely.
- Previously unimmunized children of susceptible pregnant women should receive the MMR vaccine. The trivalent vaccine is preferred for persons likely to be susceptible to mumps and rubella.

- Immunization of susceptible nonpregnant adolescent or adult women of childbearing potential is called for if precautions to avoid pregnancy are observed.
- Almost all children and some adults require more than one dose of MMR vaccine.
- On the first routine visit to the obstetrician/gynecologist, the immune status should be checked. If the woman is not immunized against rubella, the physician should administer the vaccine and stress avoiding pregnancy for 3 months.
- If the patient is already pregnant, the physician should not administer the vaccine.
- If exposure is suspected, the cord blood should be monitored for the presence of rubella antibodies.
- All unimmunized women should be vaccinated immediately after delivery of the baby.

MEASLES VACCINE (ATTENUVAX, MERCK)²³

Measles is a very serious, highly contagious disease. It causes a high fever, rash, and a cough lasting 1 to 2 weeks. Some patients experience extreme sensitivity to light. The rash may occur inside the eyelids, producing a very painful condition. In the United States, between 3,000 and 28,000 cases occur each year, depending on factors such as weather and localized outbreaks. Outbreaks are very common in neighborhoods and schools. One of ten children contracting measles will develop an ear infection or pneumonia. Measles may infect the brain (encephalitis) and lead to convulsions, hearing loss, and mental disability. In the United States, 1 of every 500 to 10,000 children contracting measles dies from it. Severe sickness and death are more common in babies and adults than in elementary schoolchildren or teenagers. Measles has been linked to multiple sclerosis. In 1977, a severe epidemic occurred in the United States, and 50,000 cases were reported. Only 60% of the population was vaccinated.

Measles vaccine is composed of live/attenuated measles virus that is grown on chick embryo culture with an attenuation protocol. Indications are the following:

- Selective induction of active immunity against measles virus.
- Trivalent MMR vaccine is the preferred immunizing form for most children and many adults.
- Almost all children and many adults require more than one dose of MMR.
- Prior to international travel, persons susceptible to any of the three viruses should receive the single-antigen vaccine or the trivalent vaccine, as appropriate.
- Most persons born before 1956 are likely to have contracted the disease naturally and are not considered susceptible.
- Persons born after 1956 or those who lack adequate documentation of having had the disease should be vaccinated.

The vaccine is required by law at 15 months and again at 11 to 12 years of age. The vaccine can be administered after exposure to measles to lessen the disease severity. This is because Ab to the vaccine develops in 7 days, while the incubation period for the disease is 11 days. The vaccine should not be administered in pregnancy and should always be administered with great care to women of childbearing age. Because measles vaccine is cultivated in egg medium, care must be used in patients who are allergic to eggs and egg products. For this reason, a test dose regimen is used. The administration protocol is shown in Figure 5.11.

MUMPS VACCINE^{24,25}

Mumps virus causes fever, headache, and a painful swelling of the parotid glands under the jaw. Mumps can be serious and is highly contagious. Prior to the vaccine, the disease was passed from child to child with ease. The disease runs its course over several days. Between 4,500 and 13,000 cases of mumps occur as outbreaks in the United States every year. In severe cases, mumps may cause inflammation of the coverings of the brain and spinal cord (meningitis); this occurs in about 10% of infected persons. Swelling of the brain itself occurs in 1 of 200 patients. Men may experience a painful swelling of the testicles (orchitis), which may presage sterility. Women may experience a corresponding infection of the ovaries. Male teens are often sicker than other groups of either sex. Mumps early in childhood has been linked to the development of juvenile diabetes.

The mumps vaccine (Mumpsvox, Merck) is a live, attenuated virus grown on chick embryo culture with attenuation protocols. The antigen form is whole virus. The antigen type is protein. Indications are the following:

- Induction of artificially acquired active immunity against mumps.
- Before international travel, immunize any susceptible individuals with the single-antigen vaccine or the trivalent MMR vaccine, as appropriate.
- Most children and some adults need more than one dose of MMR vaccine.
- Persons born prior to 1956 are generally considered immune.

Caution. Mumps vaccine is supplied with a diluent. Use only this diluent for reconstitution. Addition of a diluent with an antimicrobial preservative can render the vaccine inactive. The vaccine is normally administered to children at 15 months of age and again at 11 to 12 years. Because mumps vaccine is cultivated in egg medium, care used to be advised in patients allergic to eggs and egg products. Recent data show that persons who are allergic to egg and egg products fail to react to the mumps vaccine.

COMBINATION PRODUCTS (POLYVALENT VIRAL VACCINES)

If two or more vaccines are free of interference with each other, they can be administered as a mixture (polyvalent) for convenience. Examples of polyvalent viral vaccines are measles–rubella (MR), rubella–mumps (RM), and MMR. MMR is indicated for routine immunization at 15 months (not given at <1 year unless the child has been exposed or lacks immunocompetence). This is because maternal Abs interfere with development of vaccine immunity in small children. If the MMR is given at less than 1 year, revaccination is needed at 15 months of age.

CHICKENPOX VACCINE^{21,26–30}

Chickenpox is caused by varicella-zoster virus. Every year, about 3.5 million people in the United States, mostly children, contract chickenpox. The incidence peaks between 3 and 9 years of age. Chickenpox causes a generalized rash, with 300 to 500 blisterlike lesions occurring on the scalp, face, and trunk. Symptoms include loss of appetite, malaise, and headache. The disease is usually benign

but can lead to bacterial superinfection, pneumonia, encephalitis, and Reye syndrome. About 50 to 100 previously healthy children die of the disease. About 2% of all cases occur in adults, who have more serious symptoms than children have.

Varicella vaccine (Varivax, Merck) is derived from live virus from a child with natural varicella. The virus has been attenuated by passage through a series of guinea pig and human cell cultures. The final preparation is a lyophilized live, attenuated virus. The antigen form is whole virus. The antigen type is protein. The vaccine is well tolerated, with pain and redness at the injection site as the only side effects. The vaccine has shown tremendous success in reducing infections. Indications are the following:

- The vaccine is recommended for children 12 months to 12 years old as a single dose.
- Adults who are exposed to chickenpox should continue to receive VZIG.
- In elderly persons, varicella vaccine can boost immunity to varicella-zoster virus and may prevent or attenuate herpes zoster (shingles) attacks.

HEPATITIS VACCINES^{30–40}

Hepatitis is a complex of diseases that causes fever, nausea, abdominal pain, jaundice, liver failure, and death. There are five clinically recognized types (A, B, C, D, and E).

Hepatitis A Vaccine

Hepatitis A virus (HAV; infectious hepatitis) causes an acute disease with an abrupt onset. About 15 to 50 days of incubation are required before the disease becomes clinically noticeable. The primary sign is jaundice. The disease lasts several weeks and is followed by complete recovery. Hepatitis A is transmitted when the virus is taken in by mouth. The fecal–oral route and close contact, unwashed food, and contaminated water account for most of the routes of transmission. The sexual anal–oral route is also a route of spread. Children under the age of 3 frequently have no symptoms but can transmit the disease to adults in child care centers. An injection of hepatitis A immune globulin is one way of preventing the disease but is only effective for about 30 days.

The hepatitis A vaccine (Havrix) is an inactivated preparation that is produced by propagation of the virus in cultured human diploid cells and then is inactivated with formalin. The antigen form is lysed whole viruses. The antigen type is protein. The course of immunization involves two injections over a 4-week period and a booster 12 months after the first injection. Indications are the following:

- Persons traveling outside the United States, except to Australia, Canada, Japan, New Zealand, and Western Europe
- Persons with chronic liver disease
- Persons living in an outbreak zone
- Persons who inject medications
- Persons engaging in high-risk sexual activity
- Child care workers caring for children younger than 2 years of age
- Developing countries with poor sanitation

Side effects are minor and usually limited to soreness at the injection site and fever.

Hepatitis B Vaccine

HBV, the cause of serum hepatitis, is a much more insidious, chronic disease, transmitted by needles, mucosal contact, blood, or high-risk sexual activity. The highest risk for contraction of hepatitis B is among intravenous drug abusers. The disease is linked to cirrhosis and liver cancer. There are about 200,000 new cases reported per year in the United States; of these, 10% become carriers, one fifth die from cirrhosis, and 1,000 die from liver cancer. The hepatitis B vaccine was first introduced in 1981. Initially, it was prepared as an inactivated vaccine from the plasma of carefully screened human, high-titer carriers/donors. In 1986, the recombinant DNA (rDNA) vaccine (Engerix B, Recombivax) was introduced to the market. The rDNA vaccine contains only viral subunits and may be used with hepatitis B immune globulin in a postexposure setting to boost the ability of the host to resist the infection. In adults, three doses should be given, at 0, 1, and 6 months. In children, the vaccine is given at birth, 1 month, and 9 months. Administration may be delayed in premature infants whose immune systems are not fully developed. If not immunized at birth, a child should receive three doses by 18 months. If the mother tests positive for hepatitis B, the vaccine plus the immune globulin must be given at or shortly after birth. The vaccine is 95% effective and is typically without side effects. Several high-risk groups have been identified: healthcare workers, student healthcare workers, people living in high-risk environments, and dentists. They should receive a three-dose course of the vaccine. In most other cases, a physician can judge whether a patient is at high risk or not. Side effects of the vaccine are minor.

Hepatitis C Vaccine

Hepatitis C virus (HCV) was once called hepatitis non-A, non-B but has been recognized as a separate entity. HCV infection is spread primarily by the parenteral route (transfusions), and unlike HBV, maternal–fetal and sexual transmission are uncommon. Acute infection may show few symptoms; fewer than 25% of patients develop full-blown hepatitis. Administration of interferon alpha (IFN- α) during the early acute phase can cure most patients. Unfortunately, 50% to 60% of those with HCV infection develop chronic hepatitis. This is often manifested by periodic increases in hepatic enzyme levels. Cirrhosis develops in 20% of chronic infectees; this usually requires 15 to 20 years to develop. Patients with HCV are at risk for hepatocellular carcinoma. Estimates are that 150,000 to 170,000 new cases occur in the United States per year. Intravenous drug users, transfusion patients, and healthcare workers are at highest risk.

Development of an HCV vaccine proved difficult but was accomplished in 1998. There are 15 genotypes, and the virus can modulate its antigens within the host's body. A new approach using genetic material from the virus, analogous to the approach to the influenza vaccine, is said to be promising.⁴¹

Hepatitis E

Hepatitis E virus (HEV) causes disease clinically indistinguishable from hepatitis A. Symptoms include malaise, anorexia, abdominal pain, arthritis-like symptoms, and fever. Distinguishing HEV from HAV must be done genetically. The incubation period is 2 to 9 weeks. The disease is usually mild and resolves in 2 weeks, with no sequelae. The fatality rate is 0.1% to 1%, except in pregnant women where the rate soars to 20%. No outbreaks have been reported in

the United States as of 1996. There is currently no vaccine against HEV.

ROTAVIRUS VACCINE

There is a rotavirus vaccine included in the Recommended Childhood Immunization Schedule. This vaccine is used to provide immunity against rotavirus, the most common cause of severe diarrhea in children in the United States. All children have at least one rotavirus infection in the first 5 years of life, and there are about 20 deaths per year in this country. Children between the ages of 3 and 24 months of age have the highest rates of severe disease and hospitalization. The rotavirus vaccine is an oral vaccine, given as a series of three doses. It is recommended that the vaccine be administered at 2, 4, and 6 months of age. The most common side effect seems to be fever.

HUMAN PAPILLOMAVIRUS VACCINE

Human papillomavirus (HPV) is a sexually transmitted virus. It is passed through genital contact (such as vaginal and anal sex). The virus is also able to be transmitted by skin-to-skin contact. At least 50% of people who have had sex will have HPV at some time in their lives. Most contractees do not display any signs, and HPV may resolve on its own without causing any health problems.

Anyone who has ever had genital contact with another person may have HPV. Both men and women may contract and pass the virus often without knowing it. Because there may not be any signs, a person may have HPV even if years have passed since he or she had sex. A person is more likely to contract HPV if he or she has sex at an early age, has multiple sex partners, or has sex with a person who has had many partners.

There are many varieties of HPV. Not all of them cause health problems. Some strains of HPV cause genital warts or cervical cancer. HPV types 16 and 18 cause approximately 70% of cervical cancers. HPV types 6 and 11 cause approximately 90% of genital warts. There is no cure for the virus itself. There are treatments for genital warts, cervical changes, and cervical cancers. In a patient with genital warts, even if treated, the virus may still be present and may be passed onto sex partners. Even if not treated, warts may resolve, stay the same, increase in size, or increase in number. Warts such as these will not become cancerous. All women should get regular Pap tests. The Pap test looks for cell changes caused by HPV. The test finds cell changes early—so the cervix can be treated before the cells become cancerous. The test can also find cancer in its early stages, so it can be treated before it becomes too serious. Only rarely will a patient die from cervical cancer if the disease is caught early. There is a diagnostic test for HPV. This test is approved by the U.S. Food and Drug Administration (FDA) for HPV testing in women 30 years old or older. This test may be able to locate HPV even before there are changes to the cervix. One can lower one's chances of getting HPV by abstinence, limiting the number of partners and using condoms.

There is a vaccine for HPV. This vaccine, marketed as Gardasil, prevents infection with HPV by virus subtypes 6, 11, 16, and 18. The vaccine is highly safe, and the only side effect in a patient might be a slight fever. Redness and irritation at the site of injection is also possible. The vaccine contains no live HPV virus, so it is impossible to get the disease from the vaccine. Gardasil is between 95% and 100%

efficacious against HPV types 6, 11, 16, and 18. The vaccine is approved by the FDA for girls and women with the age of 9 to 26 years. It is best to get the vaccine before becoming sexually active. The vaccine is given in a three-shot regimen after the first injection. The second injection is given 2 months later, and followed by a third injection 6 months after the first injection. The vaccine will not treat or cure HPV. It may help people who have one type of HPV from being infected with other types. For example, if the patient has type 6 HPV, it may protect that patient from contracting type 16.

Bacterial Vaccines⁴¹⁻⁴⁴

PERTUSSIS VACCINE

Pertussis, also known as whooping cough, is a highly communicable infection caused by *B. pertussis*. *B. pertussis* produces an endotoxin that causes a spectrum of symptoms in a host. Pertussis occurs mainly in children, and there is no effective treatment once the disease becomes manifest. *Bordetella* endotoxin attacks the tracheal mucosa and causes extreme irritation. The inflammatory responses produce the characteristic "whooping inspiration" associated with pertussis. The swollen and irritated tissues may lead to choking in children. The cough may last for months and is often called the "hundred-day cough." About 4,200 cases of pertussis occur yearly in the United States. Pertussis is most dangerous to babies (younger than 1 year old). Even with the best supportive medical care, complications occur. At least 50% of pertussis patients must be hospitalized, 16% get pneumonia, 2% develop convulsions, and 1 in 200 babies dies or has lifelong complications.

Pertussis vaccine has been highly controversial in recent years. The original vaccine consisted of killed pertussis bacilli (*B. pertussis*) and was considered somewhat "dirty." Side effects such as fever and convulsions were common, and health authorities in the United States, Japan, and the United Kingdom decided that the risk of the vaccine outweighed the risk of contracting the disease. In all three of these countries, pertussis vaccine was removed from the routine immunization schedules. Almost immediately, pertussis, which had been held in check, began to occur in epidemics. In 1992, a new vaccine was developed that consists of bacterial fractions, combined with tetanus and diphtheria toxoids. This vaccine, called Acell-Immune, or diphtheria–tetanus–acellular pertussis (DTaP), is safe and highly effective and has been added to the routine immunization schedule. The vaccine is adsorbed and is used for routine immunization as the polyvalent preparation diphtheria–tetanus–pertussis (DTP) (at 2, 4, 6, and 15 months and at 4–6 years). Pertussis vaccination is recommended for most children. There is also a diphtheria–tetanus whole-cell pertussis (DTwP) vaccine on the market, but it is considered to be higher in side effects than DTaP. Lastly, a DTaP/Hib vaccine preparation is on the market and is recommended for use only as the fourth dose of the series. At present, the only indication is induction of active immunity against diphtheria and tetanus toxins and pertussis from age 6 weeks up to the seventh birthday.

HAEMOPHILUS INFLUENZA TYPE B CONJUGATE VACCINE

Hib causes the most common type of bacterial meningitis and is a major cause of systemic disease in children younger

than 6 years old. The chances of contracting the disease are about 1 in 200. Of these contractees, 60% of all patients develop meningitis, while 40% display systemic signs. Hib is a tremendous problem in daycare centers, where the risk of contracting the disease is 400 times greater than in the general population. Hib has approximately a 10% mortality rate, and one third of all survivors have some sort of permanent damage, such as hearing loss, blindness, or impaired vision. Hib can also cause a throat inflammation that results in fatal choking or ear, joint, and skin infections.

Hib-CV is a sterile, lyophilized capsular polysaccharide from Hib vaccine, conjugated to various protein fragments. The antigen type is polysaccharide (phosphoribosyl ribitol phosphate) conjugated to protein. The conjugation produces a stronger, longer-lasting response through the adjuvant effect. Hib-CV is safe and almost completely effective and is a mandatory part of the childhood immunization schedule. The various forms of Hib-CV on the market are not generically equivalent. Indications are the following:

- Induction of artificially acquired active immunity against invasive disease caused by encapsulated Hib
- Routine immunization of all infants beginning at 2 months of age, recommended in the United States
- Immunization of risk groups, including children attending daycare centers, persons of low socioeconomic status, and household contacts of Hib cases

TUBERCULOSIS VACCINE

Tuberculosis (TB) is a serious disease caused by *Mycobacterium tuberculosis*. The organism becomes established in the lungs and forms walled-off abscesses that shield the bacterium from the immune system. The disease is diagnosed by a chest radiograph. Until the 1940s, persons with TB were sent to sanatoria, special hospitals to isolate TB patients. The vaccine is referred to as the bacillus Calmette-Guérin (BCG) vaccine and is a live/attenuated strain of *Mycobacterium bovis*. The antigenic form is the whole bacterium, and the antigen type is protein. The vaccine is of questionable efficacy and has been judged only 50% to 77% effective. The duration of protection is highly questionable. The incidence of TB in the United States is so low that the vaccine is not indicated in most cases. Indications are:

- Induction of artificially acquired active immunity against *M. tuberculosis* var. *hominis* to lower the risk of serious complications from TB
- Recommended for purified protein derivative of tuberculin (PPD) skin test—negative infants and children at high risk of intimate and prolonged exposure to persistently treated or ineffectively treated patients with infectious pulmonary TB
- Persons who are continuously exposed to TB patients who have mycobacteria resistant to isoniazid and rifampin and who cannot be removed from the source of exposure
- Healthcare workers in an environment where a high proportion of *M. tuberculosis* isolates are resistant to both isoniazid (INH) and rifampin, where there is a strong possibility of transmission of infection, and where infection control procedures have failed

An adverse effect of the BCG vaccine includes a positive TB skin test. A red blister forms within 7 to 10 days, then ulcerates and scars within 6 months. BCG is a live vaccine,

so it cannot be administered to immunosuppressed patients, burn patients, or pregnant women unless exposed (and even then not in the first trimester).

CHOLERA VACCINE

Cholera is a disease caused by *Vibrio cholerae* that presents as severe, watery diarrhea caused by an enterotoxin secreted by the 01-serotype of *V. cholerae*. The disease occurs in pandemics in India, Bangladesh, Peru, and Latin America. The organisms never invade the enteric epithelium; instead, they remain in the lumen and secrete their enterotoxin. There are about 17 known virulence-associated genes necessary for colonization and toxin secretion. Secretory diarrhea is caused by release of an enterotoxin called *cholera toxin*, which is nearly identical with *E. coli* enterotoxin. It is composed of five binding peptides B and a catalytic peptide A. The peptides B bind to ganglioside GM₁ on the surface of the epithelial cells, setting in motion a series of events that causes diarrhea. The vaccine consists of whole cells of *V. cholerae* 01 that have been inactivated. The antigen form of the vaccine is whole bacterium, and the antigen type is protein toxin and lipopolysaccharide. Indications are the following:

- Induction of active immunity against cholera, such as in individuals traveling to or residing in epidemic or endemic areas
- Individuals residing in areas where cholera is endemic

MENINGOCOCCAL POLYSACCHARIDE VACCINE⁴⁵

Meningococcal vaccine is an inactivated vaccine composed of capsular polysaccharide fragments of *Neisseria meningitidis*. There are four polysaccharide serotypes represented in the vaccine: A, C, Y, and W-135. The type A polysaccharide consists of a polymer of *N*-acetyl-*O*-mannosamine phosphate; the group C polysaccharide is mostly *N*-acetyl-*O*-acetylneuraminic acid. The antigens are conjugated to diphtheria toxoid carrier. Indications are the following:

- Induction of active immunity against selected strains of *N. meningitidis*
- Military recruits during basic training
- College freshmen and those living in dormitories
- Travelers to countries with epidemic meningococcal disease
- Household or institutional contacts of those with meningococcal disease
- Immunosuppressed persons (HIV, *Streptococcus pneumoniae*)
- To stop certain meningococcal group C outbreaks
- Persons aged 2 through 55 years of age at risk for invasive meningococcal disease

PNEUMOCOCCAL VACCINE

Pneumococcus is also known as *S. pneumoniae* or diplococcus. The microorganism protects itself from the immune system by producing a capsular polysaccharide that is highly antigenic. This polysaccharide is used to prepare the vaccine. The antigen form of pneumococcal vaccine is capsular polysaccharide fragments, and the antigen type is a polysaccharide mixture. The antigen is 23-valent. The following are indications:

- Induction of active immunity against pneumococcal disease caused by the pneumococcal antigen types included

in the vaccine (the vaccine protects against pneumococcal pneumonia, pneumococcal bacteremia, and other pneumococcal infections)

- All adults at least 65 years old
- All immunocompetent individuals who are at increased risk of the disease because of pathological conditions
- Children at least 2 years old with chronic illness associated with increased risk of pneumococcal disease or its complications

Toxoids

Toxoids are detoxified toxins used to initiate active immunity (i.e., create an antitoxin). They are typically produced by formaldehyde treatment of the toxin. They are safe and unquestionably efficacious.

DISEASE STATES

All of these diseases are produced not by a bacterium but by an exotoxin produced by that organism. For example, powerful exotoxins are produced by *Corynebacterium diphtheriae* and *C. tetani*. The exotoxins are the most serious part of the disease. In both of the previously described disease states, survival does not confer immunity to subsequent infections, so lifelong vaccine boosters are needed.

In diphtheria, the exotoxin causes production of a pseudomembrane in the throat; the membrane then adheres to the tonsils. The organism releases a potent exotoxin that causes headache, weakness, fever, and adenitis. Severe diphtheria carries a 10% fatality rate. Only a few cases per year are reported in the United States.

Tetanus is caused by a skin wound with anaerobic conditions at the wound site. A potent exotoxin (tetanospasmin) is produced that attacks the nervous system. The first sign of disease is jaw stiffness; eventually, the jaw becomes fixed (lockjaw). The disease is essentially a persistent tonic spasm of the voluntary muscles. Fatality from tetanus is usually through asphyxia. Even with supportive treatment, tetanus is about 30% fatal in the United States. Recovery requires prolonged hospitalization. There have been 50 to 90 reported cases per year in the United States since 1975. There is no natural immunity to the exotoxin. The general rule of thumb is to follow the childhood immunization schedule carefully and immunize all persons of questionable immunization status. Adults require a booster every 10 years; patients who cannot remember their last one are due for another.

CLINICALLY USED TOXOIDS

Adsorbed Tetanus Toxoid

Tetanus is a disease that is also known as lockjaw. The causative organism is the anaerobic spore-forming bacterium *C. tetani*. The organism in the toxoid, adsorbed tetanus toxoid (T, adsorbed), is designated inactivated. The antigen form is toxoid, and the antigen type is protein. This toxoid lasts approximately 10 years. A booster is recommended if injured or every 5 years. Reactions other than pain at the site of injection are rare. Fluid tetanus toxoid is recommended only for the rare individual who is hypersensitive to the aluminum adjuvant.

Adsorbed Diphtheria and Tetanus Toxoid

This is recommended for children younger than 7 years old who should not get pertussis vaccine (designated DT).

Recommended Immunization Schedule for Persons Aged 0 Through 6 Years—United States • 2009

For those who fall behind or start late, see the catch-up schedule

Vaccine ▼	Age ►	Birth	1 month	2 months	4 months	6 months	12 months	15 months	18 months	19–23 months	2–3 years	4–6 years

Adsorbed Tetanus and Diphtheria Toxoid for Adults

Adsorbed tetanus and diphtheria toxoid for adults (designated Td) is for children older than 7 years and for adults. It has a lower level of diphtheria toxoid (1/15) because older children are much more sensitive to “D.” It is used for immunization of schoolchildren.

DTP

DTP is D and T toxoids with pertussis vaccine.

DTP Adsorbed

DTP adsorbed is used for early vaccination of infants in repeated doses, starting at 2 to 3 months.

The Routine Childhood Immunization Schedule

Figures 5.11, 5.12, and 5.13 show the Routine Childhood Immunization Schedule formulated by the Advisory Committee on Immunization Practices (2009). This schedule

should be followed for all children and young adults regardless of economic circumstances. The three charts show the schedule for children aged birth to 6 years (Fig. 5.11), 7 to 18 years (Fig. 5.12), and the catch-up schedule when doses of vaccine are missed (Fig. 5.13).

NEW VACCINE TECHNOLOGIES: ADJUVANT TECHNOLOGY

In spite of the long history of vaccines, only a few adjuvants and vaccine delivery systems have been licensed for human use. There are several reasons for this. Vaccines based on live-attenuated organisms are invasive and are efficiently delivered to APCs. Pattern-recognized components of the cellular pathogens are recognized by the innate immune system and trigger an innate response. With the trend of using subunit vaccines and isolated antigens, immune potentiators and delivery systems have become major issues in vaccine technology.

Recommended Immunization Schedule for Persons Aged 7 Through 18 Years—United States • 2009

Measles, Mumps, Rubella ⁷	12 mos	4 weeks			
Varicella ⁸	12 mos	3 months if the person is younger than age 13 years 4 weeks if the person is aged 13 years or older			

Figure 5.13 • Catch-up immunization schedule for persons aged 4 months through 18 years who start late or who are more than 1 month behind. (Available at: <http://www.cdc.gov/vaccines/recs/schedules/child-schedule.htm#printable>. Accessed January 23, 2009.)

There are a series of significant hurdles to the development of modern vaccines. Poor optimized vaccines must be improved. New vaccines for immunizing against diseases for which no vaccines exist are imperative. It is necessary to be able to respond quickly with vaccines to newly developing pathogenic organisms. The primary elements of useful vaccines are the antigen (against which the adaptive immune response is elicited), immunostimulants that activate the innate immune system, and delivery systems that target the vaccines to the appropriate site in a timely fashion.

Antigens

- Whole inactivated or attenuated organisms or a mixture of various strains
- Isolated and purified proteins, glycoproteins, and carbohydrates
- Recombinant proteins and glycoproteins

Immune Potentiators

- Bacterial products
- Toxins and lipids
- Nucleic acids
- Peptidoglycans
- Carbohydrates, peptides
- Cytokines and hormones
- Small molecules

Delivery Systems

- Mineral salts
- Surfactants
- Synthetic microparticles
- Oil-in-water emulsions
- Liposome

In designing a vaccine, first, an antigen is required. The antigen is the species against which an anamnestic immune response is targeted. In many cases, antigen selection is confounded by a multiplicity providing many potential antigens to choose from. Bacterial pathogens, often display this multiplicity. The manner in which the antigen is presented is also important. It may be necessary to maintain a specific three-dimensional tertiary structure for the antigen to be recognized.

It hasn't always been appreciated that the innate immune system, must be stimulated to modulate the adaptive immune response. Adjuvants, which stimulate early innate immune responses, aid in stimulating a strong and extended adaptive immune response. The nature of the vaccine delivery systems that target the vaccines to the appropriate immune cells is important to gain the necessary stimulation of the immune system.

The functional immune system is composed of two primary components. The innate immune system has evolved

to respond within minutes, primarily to molecular patterns found in microbial pathogens. The adaptive immune response develops slowly, over days or weeks and generates highly specific responses based on antibodies targeted against a pathogen's antigens. The innate response is the first line of defense. Adaptive immunity uses selection and clonal expansion of immune cells containing specific, somatically rearranged receptor genes (T- and B-cell receptors) that recognize antigen from the pathogen. This response is specific and long-lasting (immunological memory). The innate immune responses lead to a fast burst of inflammatory cytokines and activation of APCs such as macrophages and dendritic cells (DCs). These responses are not clonal and lead to a conditioning of the immune system for later development of specific adaptive immune responses.

The innate immune response must be able to distinguish pathogenic microbes from self-components. To do this, the innate immune system depends on some fairly constant receptors that detect specific signatures from pathogens. These signatures have been highly conserved throughout evolution. The signatures are referred to as pathogen-associated molecular patterns (PAMPs). It has been shown that when one includes PAMP substances in experimental vaccines, a strong and long-lasting adaptive immune response develops. PAMPs are recognized by specific pattern recognition receptors. A number of such receptors have been identified. They are expressed on neutrophils, macrophages, DCs, and natural killer cells, as well as B cells in nonimmunological cells such as epithelial and endothelial cells. When PAMPs bind to pattern recognition receptors cells bearing the pattern recognition receptors are activated and begin to secrete chemokines and cytokines, and induce maturation and chemotaxis of other immune cells. Taken together, an inflammatory environment is created. This inflammation supports development of the adaptive immune responses.

What are pattern recognition receptors? Basically, they are receptors that do not induce phagocytosis such as Toll-like receptors (TLRs) and nucleotide oligomerization domain (NOD) proteins. They can also be receptors that induce phagocytosis such as mannose receptors, scavenger receptors, and β -glucan receptors. These receptors directly recognized ligands on the surface of pathogenic microbes and cause them to be engulfed by phagocytosis capable cells such as macrophages. The nonphagocytic receptors that recognized PAMPs can be extracellular (TLRs) or intracellular (NOD proteins). Activation of these receptors leads to a signal transduction cascade that activates transcription factors that result in expression of inflammatory cytokines and other cellular activation processes. These processes have been reviewed previously. It is now known that signaling of the innate immune system involves a highly complex effect of transmembrane and intracellular proteins. It is these that provide an extensive set of possible targets for vaccine adjuvants.

How does innate immunity lead to the conditioning of the adaptive immune response? Pattern recognition receptors signaling causes the activation of transcription factors such as NF- κ B and IRF3 (interferon regulatory factor 3). Activation of these pattern recognition receptors produces the necessary inflammatory environment that supports fast development of host defenses. NF- κ B controls the expression of proinflammatory cytokines such as IL- 1β and TNF- α , while IRF3 causes production of antiviral type 1 interferon (IFN- α and

IFN- β). It has been shown that portions of the innate immune response are absolutely essential for development of antigen-specific immunity. Therefore, elements of the innate immune response are potential targets for vaccine antigens.

A suitable adjuvant can enhance the effectiveness of a vaccine by accelerating the generation of a formidable immune response. Additionally, the adjuvant can cause veined responses for longer duration and can induce local mucosal immune responses all of which generate antibodies with increased avidity and neutralization capacity. An adjuvant also can elicit cytotoxic T lymphocytes, enhancing immune responses in people with weakened immune systems, such as children, elderly, or immunocompromised adults. Adjuvants can be important in commercial production of vaccines by reducing the amount of antigen that is required to generate a robust immune response, thus reducing the cost of the vaccine. A good functional definition of an adjuvant is a component added to a vaccine and enhances the immunogenicity of the antigens *in vivo*. It is very common to categorize adjuvants in terms of two types of systems. Immune potentiators tend to activate innate immunity directly. A good immune potentiator might facilitate the development of cytokines or react through pattern recognition receptors (which can be bacterial cell wall components). A delivery system such as an emulsion or microparticle can target vaccine antigens selectively to APCs and may put the antigens and immune potentiators in the same location where they can do the most good. It has been shown that the choice of a good immune potentiators and delivery system can enhance antigen-specific immune responses *in vivo*. This can be very important in the development of subunit vaccines, which typically generate a low-level immunity. A mixture of the immune potentiators, the delivery system, and the antigen, can optimize the immune response.

Current adjuvants that are licensed for use in humans are the mineral salts such as aluminum and calcium. Several bacterial and viral antigens have been adsorbed onto aluminum and calcium salts. Other types of adjuvants include emulsion and surfactant adjuvants, particulate delivery vehicles, microbial derivatives such as lipid A, and DCs and cytokines. These latter agents have not been licensed for use in humans at the present time, but many of these are being used in clinical trials at the present time. Indeed, vaccine development has historically focused on enhancing Ab responses and not the innate immune system. So most of the commonly used antigens elevate serum Ab titers, but do little to elicit the innate immune response. The requirement for vaccines against chronic illnesses such as HIV, HCV, TB, and herpes simplex virus as well as cancer, has caused researchers to focus their efforts on generation of cellular immune responses. Adjuvants that elicit this effect are being developed and clinically tested at the present time. A new recognition of the immunobiology of TLRs and pattern recognition receptors in general, immunoregulatory cells, and cells of innate and active immunity and their roles in responding and clearing specific diseases provides the background for their development.

Most of the research in vaccine development to the present time has been aimed at finding new antigens that can be used for protection against disease and ways that they can be presented to the immune system. Because of this, only a few delivery systems such as aluminum salts and oil and water

emulsions have been investigated. At the present time, no immune potentiators have been approved for human use in prophylactic vaccines. There are several reasons for this situation, but the main one seems to be concern over the toxicity of these agents. Research over the last few years has centered on developing strategies for immune potentiator discovery. Indeed, the methods of high throughput screening that are used in the development of new drugs are being applied to immune potentiators and in the development of vaccine adjuvants.

While it is true that most natural PAMPs are based on polysaccharides, nucleic acids, or lipids, it has been shown that peptides can activate various pattern recognition receptors. Therefore, immune modulators can be based on simple peptides. This recognition opens the possibility of screening peptide libraries produced by combinatorial peptide synthesis for generation of new peptide ligands of pattern recognition receptors. Of course, using peptides is not without difficulty. Peptides display poor pharmacokinetic profiles, low bioavailability, and degradation *in vivo*. As with other biological peptides that are being tested as drugs, widespread use might be restricted.

Another possibility for development of an adjuvant centers on using DCs, which are known to provide potency lymphocyte responses. DCs are being investigated in vaccines against various cancers. The difficulty and cost involved in preparing cell-based vaccine adjuvants probably will restrict their use in prophylactic vaccines. They will, however, likely be used in therapeutic vaccinations. Several TLR ligands such as lipopolysaccharide, have been tested for their ability to activate DCs to produce stimulatory molecules and chemotaxis. DCs have been shown to increase T-cell responses and can block inhibitory effects of regulatory cells. DCs also produce migration and recruitment of natural killer cells to the lymph nodes to provide stimulation of interferon γ necessary for T-helper cell polarization.

There are many barriers to be overcome in the development of adjuvants for vaccination. Because of the need for qualitatively specific immune responses, no single adjuvant will be broadly useful. Indeed, it will be necessary to use antigens on a tailor-made basis for different conditions. Dosing of the adjuvants according to one of the currently available routes of administration may not work for small molecules, and it may be required that specialized formulations be developed for delivery of the adjuvant into the cells and for retention at the site of injection. The highly potent activation of the innate immune response may cause toxic side effects, and hence may require methods to prevent diffusion from the injection site. Because some of the targets for the innate immune system are intracellular potentiators may be required to be membrane permeable and metabolically stable. Lastly, regulatory guidelines for licensing of new adjuvants are still being developed. It is not known what the scope of three clinical testing and toxicity testing will be required for adjuvant approval.

Although there is a growing acceptance by regulatory agencies and commercial vaccine producers that improved vaccine adjuvants are needed to meet the infectious disease challenges in future, new technologies carry the uncertainty of unknown risks and present the safety and regulatory hurdles that will be encountered with the additional novel

immune potentiators and delivery systems the final vaccine formulations may be significant and are still largely ill-defined. The key focus should be on separating the potential increases in immune toxicity from improved immunogenicity provided by vaccine adjuvants.

NEW VACCINE TECHNOLOGIES: NUCLEIC ACID VACCINES

Naked nucleic acids (divested of any component of protein, carbohydrate, or lipid) are immunostimulatory and in principle can be used as vaccines. Short molecules of DNA and RNA are relatively simple to synthesize and can be tailored to immunize against bacterial and viral infections and cancers. Following administration (from a “gene gun” or by injection into the skin or muscle in solution or suspension like conventional vaccines) the genetic vaccines are taken up and translated into protein by the host cells. The protein, generated *in situ*, acts as an antigen and triggers the immune system. Because the naked nucleic acids lack coat protein such as would be present in viruses, they are not susceptible to neutralizing Ab reactions that could decrease their efficacy.

Entry into host cells presents a problem. On one hand, DNA can be spontaneously taken up by the cells, then transcribed and translated to produce protein. The uptake process may be inefficient. Cationic lipids have been tested to facilitate movement of DNA (as a complex) across the cell and nuclear membranes. These have been found to work fairly well in some cases. Other avenues of administration focus on mucosal surfaces of the lungs, digestive tract, and reproductive systems. Because mucosal surfaces are important barriers to infection and transmission of infectious diseases, they offer important possibilities for genetic vaccine administration.

A typical description of how a genetic vaccine works involves the specialized, bone marrow–derived DCs. DCs are the immune system’s most powerful APCs. Antigen can be acquired by DCs in three principal ways. They can be directly transfected by nucleic acid vaccines. DCs are also known to acquire soluble antigen from the interstitial spaces that has been secreted or released by transfected cells. DCs can also engulf entire cells that have been injured or killed as a result of the vaccine or its function. Once the antigen has been taken up by the DCs, it is presented on their cell surfaces. DCs then express and elaborate surface adhesion molecules and chemokine receptors that cause them to migrate to the lymphatic organs. It is in these organs that the DCs are most effective at activating immune responses. It has been proposed that cell death induced by transfection of host cells by vaccines is the signal for activation of DCs by providing “danger signals” to those cells. The effect of these danger signals more strongly modulates the immune response.

New research has suggested that α -virus replicon-based naked DNA provides a stronger, more significant activation of the immune system than does naked DNA or RNA itself.

Despite a host of attractive possibilities presented by nucleic acid vaccines, no naked nucleic acid vectors have been approved for use in humans. Human data is lacking, and nucleic acid vaccines have not been unequivocally demonstrated to have significant efficacy in prevention or treatment

(as therapeutic vaccines) of infectious diseases or cancers. Immunization with naked nucleic acids is relatively inefficient, and virus vectors generally induce a much greater immune response than do nucleic acid vaccines. The viral coat protein dramatically increases the virus's replication

efficiency. Naked nucleic acids do not possess this feature. Despite being unproven in humans at the present time, genetic vaccines represent a fertile area for vaccine research. Presumably, as research proceeds the problems with using nucleic acid vaccines will be surmounted.

CHAPTER 6

Anti-infective Agents

JOHN M. BEALE, JR.

CHAPTER OVERVIEW

The history of work on the prevention of bacterial infection can be traced back to the 19th century when Joseph Lister (in 1867) introduced antiseptic principles for use in surgery and posttraumatic injury.¹ He used phenol (carbolic acid) as a wash for the hands, as a spray on an incision site, and on bandages applied to wounds. Lister's principles caused a dramatic decrease in the incidence of postsurgical infections.

Around 1881 and continuing to 1900, microbiologist Paul Ehrlich, a disciple of Robert Koch, began work with a set of antibacterial dyes and antiparasitic organic arsenicals. His goal was to develop compounds that retained antimicrobial activity at the expense of toxicity to the human host; he called the agents that he sought "magic bullets." At the time that Ehrlich began his experiments, there were only a few compounds that could be used in treating infectious diseases, and none was very useful in the treatment of severe Gram-positive and Gram-negative infections. Ehrlich discovered that the dyes and arsenicals could stain target cells *selectively* and that the antimicrobial properties of the dyes paralleled the staining activity. This discovery was the first demonstration of *selective toxicity*, the property of certain chemicals to kill one type of organism while not harming another. Selective toxicity is the main tenet of modern antimicrobial chemotherapy, and Ehrlich's seminal discovery paved the way for the development of the sulfonamides and penicillins and the elucidation of the mechanisms of their selective toxicity. Prior to Ehrlich's studies, the *local* antimicrobial properties of phenol and iodine were well known, but the only useful *systemic* agents were the herbal remedies cinchona for malaria and ipecac for amebic dysentery. Ehrlich's discovery of compound 606, the effective antisyphilitic drug Salvarsan,^{2,3} was a breakthrough in the treatment of a serious, previously untreatable disease.

Gentian Violet

Until the 1920s, most successful anti-infective agents were based on the group-IIB element mercury and the group-VA elements arsenic and antimony. Atoxyl (sodium arsanilate and arsphenamine) was used for sleeping sickness.⁴ Certain dyes, such as gentian violet and methylene blue, were also found to be somewhat effective, as were a few chemical congeners of the quinine molecule. Some of these agents represented significant achievements in anti-infective therapy, but they also possessed some important limitations. Heavy metal toxicity after treatment with mercury, arsenic, and antimony severely limited the usefulness of agents containing these elements.

Just prior to 1950, great strides were made in anti-infective therapy. The sulfonamides and sulfones (this chapter), more effective phenolic compounds such as hexachlorophene,

Methylene Blue

synthetic antimalarial compounds (Chapter 7), and several antibiotics (Chapter 8) were introduced to the therapeutic armamentarium.

Anti-infective agents may be classified according to various schemes. The chemical type of the compound, the biological property, and the therapeutic indication may be used singly or in combination to describe the agents. In this textbook, a combination of these classification schemes is used to organize the anti-infective agents. When several chemically divergent compounds are indicated for a specific disease or group of diseases, the therapeutic classification is used, and the drugs are subclassified according to chemical type. When the information is best unified and presented in a chemical or biological classification system, as for the sulfonamides or antibacterial antibiotics, then one of these classification systems is used.

This chapter addresses an extremely broad base of anti-infective agents, including the local compounds (alcohols, phenols, oxidizing agents, halogen-containing compounds, cationic surfactants, dyes, and mercurials), preservatives, antifungal agents, synthetic antibacterial drugs, antitubercular and antiprotozoal agents, and anthelmintics. Other chapters in this text are devoted to antibacterial antibiotics (Chapter 8), antiviral agents (Chapter 9), and antineoplastic antibiotics (Chapter 10).

Anti-infective agents that are used locally are called *germicides*, and within this classification, there are two primary subtypes (see Table 6.1) and several other definitions of sanitization. Antiseptics are compounds that kill (*-cidal*) or prevent the growth of (*-static*) microorganisms when applied to *living tissue*. This caveat of use on living tissue points to the properties that the useful antiseptic must have. The ideal antiseptic must have low-enough toxicity that it can be used directly on skin or wounds; it will exert a rapid and sustained lethal action against microorganisms (the spectrum may be narrow or broad depending on the use). The agent should have a low surface tension so that it will spread into the wound; it should retain activity in the presence of body fluids (including pus), be nonirritating to tis-

sues, be nonallergenic, lack systemic toxicity when applied to skin or mucous membranes, and not interfere with healing. No antiseptic available today meets all of these criteria. A few antibiotics, such as bacitracin, polymyxin, silver sulfadiazine, and neomycin, are poorly absorbed through the skin and mucous membranes and are used topically for the treatment of local infections; they have been found very effective against infections such as these. In general, however, the topical use of antibiotics has been restricted by concern about the development of resistant microbial strains and possible allergic reactions. These problems can reduce the usefulness of these antibiotics for more serious infections.

A *disinfectant* is an agent that prevents transmission of infection by the destruction of pathogenic microorganisms when applied to *inanimate objects*. The ideal disinfectant exerts a rapidly lethal action against all potentially pathogenic microorganisms and spores, has good penetrating properties into organic matter, shares compatibility with organic compounds (particularly soaps), is not inactivated by living tissue, is noncorrosive, and is aesthetically pleasing (nonstaining and odorless). Locally acting anti-infective drugs are widely used by the lay public and are prescribed by members of the medical profession (even though the effectiveness of many of the agents has not been established completely). The germicide may be harmful in certain cases (i.e., it may retard healing). Standardized methods for evaluating and comparing the efficacy of germicides have only recently been developed.

Numerous classes of chemically divergent compounds possess local anti-infective properties. Some of these are outlined in Table 6.2.

The most important means of preventing transmission of infectious agents from person to person or from regions of high microbial load, such as the mouth, nose, or gut, to potential sites of infection is simply *washing the hands*. In fact, one of the breakthroughs in surgical technique in the 1800s was the finding that the incidence of postsurgical infection decreased dramatically if surgeons washed their hands before operating. Regular hand washing is properly done without disinfection to minimize drying, irritation, and sensitization of the skin. Simple soap and warm water remove bacteria efficiently. Skin disinfectants along with soap and water are usually used as preoperative surgical scrubs and sterilants for surgical incisions.

TABLE 6.1 Definitions and Standards for Removing Microorganisms

Antisepsis	Application of an agent to living tissue for the purpose of preventing infection
Decontamination	Destruction or marked reduction in the number or activity of microorganisms
Disinfection	Chemical or physical treatment that destroys most vegetative microbes or viruses, but not spores, in or on inanimate surfaces
Sanitization	Reduction of microbial load on an inanimate surface to a level considered acceptable for public health purposes
Sterilization	A process intended to kill or remove all types of microorganisms, including spores, and usually including viruses with an acceptably low probability of survival
Pasteurization	A process that kills nonsporulating microorganisms by hot water or steam at 65°C–100°C

EVALUATION OF THE EFFECTIVENESS OF A STERILANT

Evaluation of the effectiveness of antiseptics, disinfectants, and other sterilants (Table 6.1), although seemingly simple in principle, is an extremely complex task. One must consider the intrinsic resistance of the microbe, the microbial load, the mixture of the population of microorganisms present, the amount and nature of organic material present (e.g., blood, feces, tissue), the concentration and stability of the disinfectant or sterilant, the time and temperature of exposure, the pH, and the hydration and binding of the agent to surfaces. In summary, a host of parameters must be considered for each sterilant, and experimental assays may be difficult. Specific, standardized assays of activity are defined for each use. Toxicity for human subjects must also be evaluated. The Environmental Protection Agency (EPA)

TABLE 6.2 Common Sterilants and Their Range of Use

regulates disinfectants and sterilants and the Food and Drug Administration (FDA) regulates antiseptics.

There are some problems with improper use of these agents. Antiseptics and disinfectants may become contaminated by resistant microorganisms (e.g., spores), *Pseudomonas aeruginosa*, or *Serratia marcescens* and may actually transmit infection. Most topical antiseptics interfere with wound healing to some degree, so they should be used according to the proper directions and for a limited length of time.

ALCOHOLS AND RELATED COMPOUNDS

Alcohols and aldehydes have been used as antiseptics and disinfectants for many years.⁵ Two of the most commonly used antiseptics and disinfectants are ethyl and isopropyl alcohol.

The antibacterial potencies of the primary alcohols (against test cultures of *Staphylococcus aureus*) increase with molecular weight until the 8-carbon atom octanol is reached. In general, one oxygen atom is capable of solubilizing seven or eight carbon atoms in water. As the primary alcohol chain length increases, van der Waals interactions increase, and the ability to penetrate microbial membranes increases. As water solubility decreases, the apparent antimicrobial potency diminishes with molecular weight. Branching of the alcohol chain decreases antibacterial potency; weaker van der Waals forces brought about by branching do not penetrate bacterial cell membranes as efficiently. The isomeric alcohols' potencies decrease in the order primary > secondary > tertiary. Despite this fact, 2-propanol (isopropyl alcohol) is used commercially instead of *n*-propyl alcohol, because it is less expensive. Isopropyl alcohol is slightly more active than ethyl alcohol against vegetative bacterial growth, but both alcohols are largely ineffective against spores. The activity of alcohols against microorganisms is the result of their ability to denature important proteins and carbohydrates.

Alcohol

Ethanol (ethyl alcohol, wine spirit) is a clear, colorless, volatile liquid with a burning taste and a characteristic pleasant odor. It is flammable, miscible with water in all proportions, and soluble in most organic solvents. Commercial ethanol contains approximately 95% ethanol by volume. This concentration forms an azeotrope with water that distills at 78.2°C. Alcohol has been known for centuries as a product of fermentation from grain and many other carbohydrates. Ethanol can also be prepared synthetically by the sulfuric-acid-catalyzed hydration of ethylene.

The commerce in, and use of, alcohol in the United States is strictly controlled by the Treasury Department, which has provided the following definition for “alcohol”: “The term *alcohol* means that substance known as ethyl alcohol, hydrated oxide of ethyl, or spirit of wine, from whatever source or whatever process produced, having a proof of 160 or more and not including the substances commonly known as whiskey, brandy, rum, or gin.”

Denatured alcohol is ethanol that has been rendered unfit for use in intoxicating beverages by the addition of other substances. *Completely denatured alcohol* contains added wood alcohol (methanol) and benzene and is unsuitable for either internal or external use. *Specially denatured alcohol* is ethanol treated with one or more substances so that its use may be permitted for a specialized purpose. Examples are iodine in alcohol for tincture of iodine, methanol, and other substances in mouthwashes and aftershave lotions, and methanol in alcohol for preparing plant extracts.

The primary medicinal use of alcohol is external, as an antiseptic, preservative, mild counterirritant, or solvent. Rubbing alcohol is used as an astringent, rubefacient, and a mild local anesthetic. The anesthetic effect is results from the evaporative refrigerant action of alcohol when applied to the skin. Ethanol has even been injected near nerves and ganglia to alleviate pain. It has a low narcotic potency and has been used internally in diluted form as a mild sedative, a weak vasodilator, and a carminative.

Alcohol is metabolized in the human body by a series of oxidations:

Acetaldehyde causes nausea, vomiting, and vasodilatory flushing. This fact has been used in aversion therapy with the drug disulfiram, which blocks aldehyde dehydrogenase, allowing acetaldehyde to accumulate.

Alcohol is used in the practice of pharmacy for the preparation of spirits, tinctures, and fluidextracts. *Spirits* are preparations containing ethanol as the sole solvent, whereas *tinctures* are hydroalcoholic mixtures. Many fluidextracts contain alcohol as a cosolvent.

The accepted bactericidal concentration of 70% alcohol is not supported by a study that discovered that the kill rates of microorganisms suspended in alcohol concentrations between 60% and 95% were not significantly different.⁶ Concentrations below 60% are also effective, but longer contact times are necessary. Concentrations above 70% can be used safely for preoperative sterilization of the skin.⁷ Alcohols are flammable and must be stored in cool, well-ventilated areas.

Dehydrated Ethanol

Dehydrated ethanol, or *absolute ethanol*, contains not less than 99% w/w of $\text{C}_2\text{H}_5\text{OH}$. It is prepared commercially by azeotropic distillation of an ethanol–benzene mixture, with provisions made for efficient removal of water. Absolute ethanol has a very high affinity for water and must be stored in tightly sealed containers. This form of ethanol is used primarily as a chemical reagent or solvent but has been injected for the local relief of pain in carcinomas and neuralgias. Absolute alcohol cannot be ingested because there is always some benzene remaining from the azeotropic distillation that cannot be removed.

Isopropyl Alcohol

Isopropanol (2-propanol) is a colorless, volatile liquid with a characteristic odor and a slightly bitter taste. It is considered a suitable substitute for ethanol in most cases but must not be ingested. Isopropyl alcohol is prepared commercially by the sulfuric-acid-catalyzed hydration of propylene:

The alcohol forms a constant-boiling mixture with water that contains 91% v/v of 2-propanol. Isopropyl alcohol is used primarily as a disinfectant for the skin and for surgical instruments. The alcohol is rapidly *bactericidal* in the concentration

range of 50% to 95%. A 40% concentration is considered equal in antiseptic efficacy to a 60% ethanol in water solution. *Azeotropic isopropyl alcohol*, *United States Pharmacopeia (USP)*, is used on gauze pads for sterilization of the skin prior to hypodermic injections. Isopropyl alcohol is also used in pharmaceuticals and toiletries as a solvent and preservative.

Ethylene Oxide

Ethylene oxide, $\text{C}_2\text{H}_4\text{O}$, is a colorless, flammable gas that liquefies at 12°C . It has been used to sterilize temperature-sensitive medical equipment and certain pharmaceuticals that cannot be heat sterilized in an autoclave. Ethylene oxide diffuses readily through porous materials and very effectively destroys all forms of microorganisms at ambient temperatures.⁸

Ethylene oxide forms explosive mixtures in air at concentrations ranging from 3% to 80% by volume. The explosion hazard is eliminated when the gas is mixed with sufficient concentrations of carbon dioxide. *Carboxide* is a commercial sterilant containing 10% ethylene oxide and 90% carbon dioxide by volume that can be handled and released in air without danger of explosion. Sterilization is accomplished in a sealed, autoclave-like chamber or in gas-impermeable bags.

The mechanism of the germicidal action of ethylene oxide probably involves the alkylation of functional groups in nucleic acids and proteins by nucleophilic opening of the oxide ring. Ethylene oxide is a nonselective alkylating agent, and for that reason is extremely toxic and potentially carcinogenic. Exposure to skin and mucous membranes should be avoided, and inhalation of the gas should be prevented by use of an appropriate respiratory mask during handling and sterilization procedures.

Aldehydes

Formaldehyde Solution

Formalin is a colorless aqueous solution that officially contains not less than 37% w/v of formaldehyde (HCHO), with methanol added to retard polymerization. Formalin is miscible with water and alcohol and has a characteristic pungent aroma. Formaldehyde readily undergoes oxidation and polymerization, leading to formic acid and paraformaldehyde.

hyde, respectively, so the preparation should be stored in tightly closed, light-resistant containers. Formalin must be stored at temperatures above 15°C to prevent cloudiness, which develops at lower temperatures.

The germicidal action of formaldehyde is slow but powerful. The mechanism of action is believed to involve direct, nonspecific alkylation of nucleophilic functional groups (amino, hydroxyl, and sulfhydryl) in proteins and nucleic acids to form carbinol derivatives. The action of formaldehyde is not confined to microorganisms. The compound is irritating to mucous membranes and causes hardening of the skin. Oral ingestion of the solution leads to severe gastrointestinal distress. Contact dermatitis is common with formalin, and pure formaldehyde is suspected to be a carcinogen.

Glutaraldehyde Disinfectant Solution

Glutaraldehyde (Cidex, a 5-carbon dialdehyde) is used as a dilute solution for sterilization of equipment and instruments that cannot be autoclaved. Commercial glutaraldehyde is stabilized in alkaline solution. The preparation actually consists of two components, glutaraldehyde and buffer, which are mixed together immediately before use. The activated solution contains 2% glutaraldehyde buffered at pH 7.5 to 8.0. Stabilized glutaraldehyde solutions retain more than 80% of their original activity 30 days after preparation,⁹ whereas the nonstabilized alkaline solutions lose about 44% of their activity after 15 days. At higher pH (>8.5), glutaraldehyde rapidly polymerizes. Nonbuffered solutions of glutaraldehyde are acidic, possibly because of an acidic proton on the cyclic hemiacetal form. The acidic solutions are stable but lack sporicidal activity.

PHENOLS AND THEIR DERIVATIVES

Phenol, *USP*, remains the standard to which the activity of most germicidal substances is compared. The *phenol coefficient*

is defined as the ratio of a dilution of a given test disinfectant to the dilution of phenol that is required to kill (to the same extent) a strain of *Salmonella typhi* under carefully controlled time and temperature conditions. As an example, if the dilution of a test disinfectant is 10-fold greater than the dilution of phenol, the phenol coefficient is 10. Obviously, the phenol coefficient of phenol itself is 1. The phenol coefficient test has many drawbacks. Phenols and other germicides do not kill microorganisms uniformly, so variations in the phenol coefficient will occur. Moreover, the conditions used to conduct the test are difficult to reproduce exactly, so high variability between different measurements and laboratories is expected. Hence, the phenol coefficient may be unreliable.

Several phenols are actually more bactericidal than phenol itself. Substitution with alkyl, aryl, and halogen (especially in the *para* position) groups increases bactericidal activity. Straight-chain alkyl groups enhance bactericidal activity more than branched groups. Alkylated phenols and resorcinols are less toxic than the parent compounds while retaining bactericidal properties. Phenols denature bacterial proteins at low concentrations, whereas lysis of bacterial cell membranes occurs at higher concentrations.

Phenol

Phenol (carbolic acid) is a colorless to pale-pink crystalline material with a characteristic “medicinal odor.” It is soluble to the extent of 1 part to 15 parts water, very soluble in alcohol, and soluble in methanol and salol (phenyl salicylate).

Phenol exhibits germicidal activity (general protoplasmic poison), is caustic to skin, exerts local anesthetic effects, and must be diluted to avoid tissue destruction and dermatitis.

Sir Joseph Lister introduced phenol as a surgical antiseptic in 1867, and it is still used occasionally as an antipruritic in phenolated calamine lotion (0.1%–1% concentrations). A 4% solution of phenol in glycerin has been used to cauterize small wounds. Phenol is almost obsolete as an antiseptic and disinfectant.

Liquified Phenol

Liquified phenol is simply phenol containing 10% water. The liquid form is convenient for adding phenol to various pharmaceutical preparations because it can be measured and transferred easily. The water content, however, precludes its use in fixed oils or liquid petrolatum, because the solution is not miscible with lipophilic ointment bases.

p-Chlorophenol

p-Chlorophenol is used in combination with camphor in liquid petrolatum as an external antiseptic and anti-irritant. The compound has a phenol coefficient of about 4.

p-Chloro-m-xyleneol

p-Chloro-*m*-xyleneol (PC-MX; Metasep) is a nonirritating antiseptic agent with broad-spectrum antibacterial and antifungal properties. It is marketed in a 2% concentration as a shampoo. It has also been used topically for the treatment of tinea (ringworm) infections such as athlete's foot (tinea pedis) and jock itch (tinea cruris).

**Hexachlorophene**

Hexachlorophene, 2,2'-methylenebis (3,4,6-trichlorophenol); 2,2'-dihydroxy-3,5,6,3',5', 6'-hexachlorodiphenylmethane (Gamophen, Surgicon, pHisoHex) is a white to light-tan crystalline powder that is insoluble in water but is soluble in alcohol and most other organic solvents. A biphenol such as hexachlorophene will, in general, possess greater potency than a monophenol. In addition, as expected, the increased degree of chlorination of hexachlorophene increases its antiseptic potency further.

Hexachlorophene is easily adsorbed onto the skin and enters the sebaceous glands. Because of this, topical application elicits a prolonged antiseptic effect, even in low concentrations. Hexachlorophene is used in concentrations of 2% to 3% in soaps, detergent creams, lotions, and shampoos for various antiseptic uses. It is, in general, effective against Gram-positive bacteria, but many Gram-negative bacteria are resistant.

The systemic toxicity of hexachlorophene in animals after oral and parenteral administration had been known for some time, but in the late 1960s and early 1970s, reports of neurotoxicity in infants bathed in hexachlorophene and in burn patients cleansed with the agent prompted the FDA to ban its use in over-the-counter (OTC) antiseptic and cosmetic preparations.¹⁰ Hexachlorophene is still available by prescription.

Cresol

Cresol is actually a mixture of three isomeric methylphenols:

The mixture occurs as a yellow to brownish yellow liquid that has a characteristic odor of creosote. Cresol is obtained from coal tar or petroleum by alkaline extraction into aqueous medium, acidification, and fractional distillation. The mixture is an inexpensive antiseptic and disinfectant. It possesses a phenol coefficient of 2.5. Cresol is sparingly soluble in water, although alcohols and other organic solvents will solubilize it. The drawback to its use as an antiseptic is its unpleasant odor.

Chlorocresol

4-Chloro-3-methylphenol occurs as colorless crystals. Chlorocresol is only slightly soluble in water. At the low concentration that can be achieved in aqueous media, the compound is only useful as a preservative.

**Thymol**

Isopropyl *m*-cresol is extracted from oil of *Thymus vulgaris* (thyme, of the mint family) by partitioning into alkaline aqueous medium followed by acidification. The crystals obtained from the mother liquor are large and colorless, with a thymelike odor. Thymol is only slightly soluble in water, but it is extremely soluble in alcohols and other organic solvents. Thymol has mild fungicidal properties and is used in alcohol solutions and in dusting powders for the treatment of tinea (ringworm) infections.

**Eugenol**

4-Allyl-2-methoxyphenol is obtained primarily from clove oil. It is a pale-yellow liquid with a strong aroma of cloves and a pungent taste. Eugenol is only slightly soluble in water but is miscible with alcohol and other organic solvents. Eugenol possesses both local anesthetic and antiseptic activity and can be directly applied on a piece of cotton to relieve toothaches. Eugenol is also used in mouthwashes because of its antiseptic property and pleasant taste. The phenol coefficient of eugenol is 14.4.

Resorcinol

m-Dihydroxybenzene (resorcin), or resorcinol, is prepared synthetically. It crystallizes as white needles or as an amorphous powder that is soluble in water and alcohol. Resorcinol is light sensitive and oxidizes readily, so it must be stored in tight, light-resistant containers. It is much less stable in solution, especially at alkaline pH. Resorcinol is only a weak antiseptic (phenol coefficient 0.4). Nevertheless, it is used in 1% to 3% solutions and in ointments and pastes in concentrations of 10% to 20% for the treatment of skin conditions such as ringworm, eczema, psoriasis, and seborrheic dermatitis. In addition to its antiseptic action, resorcinol is a *keratolytic* agent. This property causes the stratum corneum of the skin to slough, opening the barrier to penetration for antifungal agents.

Hexylresorcinol

4-Hexylresorcinol, or “hexylresorcinol,” is a white crystalline substance with a faint phenolic odor. When applied to the tongue it produces a sensation of numbness. It is freely soluble in alcohol but only slightly soluble in water (1–20,000 parts). Hexylresorcinol is an effective antiseptic, possessing both bactericidal and fungicidal properties. The phenol coefficient of hexylresorcinol against *S. aureus* is 98. As is typical for alkylated phenols, hexylresorcinol possesses surfactant properties. The compound also has local anesthetic activity. Hexylresorcinol is formulated into throat lozenges because of its local anesthetic and antiseptic properties. These preparations are probably of little value. Hexylresorcinol (in the concentration in the lozenge) is probably not antiseptic, and the local anesthetic property can anesthetize the larynx, causing temporary laryngitis.

OXIDIZING AGENTS

In general, oxidizing agents that are of any value as germicidal agents depend on their ability to liberate oxygen in the tissues. Many of these agents are inorganic compounds, including hydrogen peroxide, several metal peroxides, and sodium perborate. All of these react in the tissues to generate oxygen and oxygen radicals. Other oxidizing agents, such as KMnO_4 , denature proteins in microorganisms through a direct oxidation reaction. Oxidizing agents are especially effective against anaerobic bacteria and can be used in cleansing contaminated wounds. The bubbles that form during the liberation of oxygen help to dislodge debris. The effectiveness of the oxidizing agents is somewhat limited by their generally poor penetrability into infected tissues and organic matter. Additionally, the action of the oxidizers is typically transient.

Carbamide Peroxide Topical Solution

Carbamide peroxide (Gly-Oxide) is a stable complex of urea and hydrogen peroxide. It has the molecular formula $\text{H}_2\text{NCONH}_2 \cdot \text{H}_2\text{O}_2$. The commercial preparation is a solution of 12.6% carbamide peroxide in anhydrous glycerin. When mixed with water, hydrogen peroxide is liberated. Carbamide peroxide is used as both an antiseptic and disinfectant. The preparation is especially effective in the treatment of oral ulcerations or in dental care. The oxygen bubbles that are liberated remove debris.

Hydrous Benzoyl Peroxide

Hydrous benzoyl peroxide (Oxy-5, Oxy-10, Vanoxide) is a white granular powder. In its pure powder form, it is explosive. The compound is formulated with 30% water to make it safer to handle.

Compounded at 5% and 10% concentrations, benzoyl peroxide is both keratolytic and keratogenic. It is used in the treatment of acne. Benzoyl peroxide induces proliferation of epithelial cells, leading to sloughing and repair.¹¹

HALOGEN-CONTAINING COMPOUNDS

IODOPHORS

Elemental iodine (I_2) is probably the oldest germicide still in use today. It was listed in 1830 in *USP-II* as a tincture and a liniment. Iodine tincture (2% iodine in 50% alcohol with sodium iodide), strong iodine solution (Lugol's solution, 5% iodine in water with potassium iodide), and iodine solution (2% iodine in water with sodium iodide) are currently official preparations in the *USP*. The iodide salt is admixed to increase the solubility of the iodine and to reduce its volatility. Iodine is one of the most effective and useful of the germicides. It probably acts to inactivate proteins by iodination of aromatic residues (phenylalanyl and tyrosyl) and oxidation (sulfhydryl groups). Mixing with several nonionic and cationic surfactants can solubilize iodine. Complexes form that retain the germicidal properties of the iodine while reducing its volatility and removing its irritant properties.¹² In some of the more active, nonionic surfactant complexes, it is estimated that approximately 80% of the dissolved iodine remains available in bacteriologically active form. These active complexes, called *iodophors*, are both bactericidal and fungicidal.

Povidone–Iodine

Povidone–iodine (Betadine, Isodine, polymer polyvinylpyrrolidone [PVP]–iodine) is a charge-transfer complex of iodine with the nonionic surfactant PVP. The complex is extremely water soluble and releases iodine very slowly. Hence, the preparation provides a nontoxic, nonvolatile, and nonstaining form of iodine that is not irritating to the skin or to wounds. Approximately 10% of the iodine in the complex is bioavailable. Povidone–iodine is used as an aqueous solution for presurgical disinfection of the incision site. It can also be used

to treat infected wounds and damage to the skin, and it is effective for local bacterial and fungal infections. Several other forms of PVP-iodine are available, including aerosols, foams, ointments, surgical scrubs, antiseptic gauze pads, sponges, mouthwashes, and a preparation that disinfects whirlpool baths and hot tubs.

CHLORINE-CONTAINING COMPOUNDS

Chlorine and chlorine-releasing compounds have been used in the disinfection of water supplies for more than a century. The discovery that hypochlorous acid (HOCl) is the active germicidal species that is formed when chlorine is dissolved in water led to the development and use of the first inorganic hypochlorite salts such as NaOCl and Ca(OCl)₂. Later, organic *N*-chloro compounds were developed as disinfectants. These compounds release hypochlorous acid when dissolved in water, especially in the presence of acid. Two equally plausible mechanisms have been proposed for the germicidal action of hypochlorous acid: the chlorination of amide nitrogen atoms and the oxidation of sulfhydryl groups in proteins. Organic compounds that form stable *N*-chloro derivatives include amides, imides, and amidines. *N*-Chloro compounds slowly release HOCl in water. The antiseptic effect of these agents is optimal at around pH 7.

Halazone

p-Dichlorosulfamoylbenzoic acid is a white, crystalline, photosensitive compound with a faint chlorine odor. Halazone is only slightly soluble in water at pH 7 but becomes very soluble in alkaline solutions. The sodium salt of halazone is used to disinfect drinking water.

Chloroazodin

N,N-Dichlorodicarbonamidine (Azochloramid) is a bright yellow crystalline solid with a faint odor of chlorine. It is mostly insoluble in water and organic solvents and is unstable to light or heat. Chloroazodin will explode if heated above 155°C. The compound is soluble enough in water to be used in very dilute solution to disinfect wounds, as packing for dental caries, and for lavage and irrigation. A glyceryltriacetate solution is used as a wound dressing. The antiseptic action of chloroazodin is long lasting because of its extremely slow reaction with water.

Oxychlorosene Sodium

Oxychlorosene (Clorpactin) is a complex of the sodium salt of dodecylbenzenesulfonic acid and hypochlorous acid. The complex slowly releases hypochlorous acid in solution.

Oxychlorosene occurs as an amorphous white powder that has a faint odor of chlorine. It combines the germicidal properties of HOCl with the emulsifying, wetting, and keratolytic actions of an anionic detergent. The agent has a marked and rapid-*cidal* action against most microorganisms, including both Gram-positive and Gram-negative bacteria, molds, yeasts, viruses, and spores. Oxychlorosene is used to treat localized infections (especially when resistant organisms are present), to remove necrotic tissue from massive infections or radiation necrosis, to counteract odorous discharges, to act as an irritant, and to disinfect cysts and fistulas. Oxychlorosene is marketed as a powder for reconstitution into a solution. A typical application uses a 0.1% to 0.5% concentration in water. Dilutions of 0.1% to 0.2% are used in urology and ophthalmology.

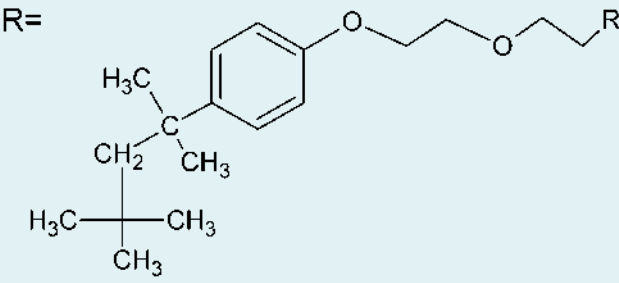

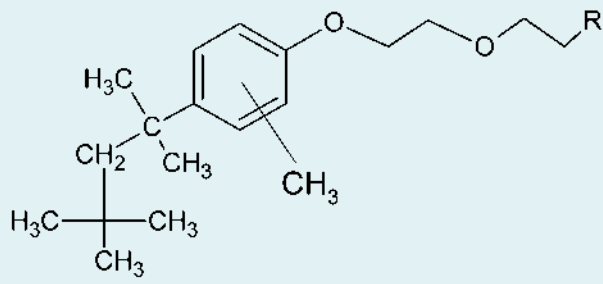

CATIONIC SURFACTANTS

All of the cationic surfactants are quaternary ammonium compounds (Table 6.3). For that reason, they are always ionized in water and exhibit surface-active properties. The compounds, with a polar head group and nonpolar hydrocarbon chain, form micelles by concentrating at the interface of immiscible solvents. The surface activity of these compounds, exemplified by lauryl triethylammonium sulfate, results from two structural moieties: (a) a cationic head group, which has a high affinity for water and (b) a long hydrocarbon tail, which has an affinity for lipids and nonpolar solvents.

At the right concentration (the critical micelle concentration), the molecules concentrate at the interface between immiscible solvents, such as water and lipid, and water-in-oil or oil-in-water emulsions may be formed with the ammonium head group in the water layer and the nonpolar hydrocarbon chain associated with the oil phase. The synthesis and antimicrobial actions of the members of this class of com-

TABLE 6.3 Analogs of Dimethylbenzylammonium Chloride

Compound	R
Benzalkonium Chloride	$R = nC_8H_{17}$ to $C_{16}H_{33}$
Benzethonium Chloride	
Methylbenzethonium Chloride	

pounds were first reported in 1908, but it was not until the pioneering work of Gerhard Domagk in 1935¹³ that attention was directed to their usefulness as antiseptics, disinfectants, and preservatives.

The cationic surfactants exert a bactericidal action against a broad spectrum of Gram-positive and Gram-negative bacteria. They are also active against several pathogenic species of fungi and protozoa. All spores resist these agents. The mechanism of action probably involves dissolution of the surfactant into the microbial cell membrane, destabilization, and subsequent lysis. The surfactants may also interfere with enzymes associated with the cell membrane.

The cationic surfactants possess several other properties. In addition to their broad-spectrum antimicrobial activity, they are useful as germicides. They are highly water soluble, relatively nontoxic, stable in solution, nonstaining, and noncorrosive. The surface activity causes a keratolytic action in the stratum corneum and, hence, provides good tissue penetration. In spite of these advantages, the cationic

surfactants present several difficulties. Soaps and other anionic detergents inactivate them. All traces of soap must be removed from skin and other surfaces before they are applied. Tissue debris, blood, serum, and pus reduce the effectiveness of the surfactants. Cationic surfactants are also adsorbed on glass, talc, and kaolin to reduce or prevent their action. The bactericidal action of cationic surfactants is slower than that of iodine. Solutions of cationic surfactants intended for disinfecting surgical instruments, gloves, etc. should never be reused because they can harbor infectious microorganisms, especially *Pseudomonas* and *Enterobacter* spp.

Benzalkonium Chloride

Alkylbenzyltrimethylammonium chloride (Zephiran) is a mixture of alkylbenzyltrimethylammonium chlorides of the general formula $[C_6H_5CH_2N(CH_3)_3R]^+Cl^-$, where R represents a mixture of alkyl chains beginning with C_8H_{17} and extending to higher homologues with $C_{12}H_{25}$, $C_{14}H_{29}$, and $C_{16}H_{33}$. The

higher-molecular-weight homologues compose the major fractions. Although variations in the physical and antimicrobial properties exist between individual members of the mixture, they are of little importance in the chemistry of the overall product. Benzalkonium chloride occurs as a white gel that is soluble in water, alcohol, and organic solvents. Aqueous solutions are colorless, slightly alkaline, and very foamy.

Benzalkonium chloride is a detergent, an emulsifier, and a wetting agent. It is used as an antiseptic for skin and mucous membranes in concentrations of 1:750 to 1:20,000. For irrigation, 1:20,000 to 1:40,000 concentrations are used. For storage of surgical instruments, 1:750 to 1:5,000 concentrations are used, with 0.5% NaNO₃ added as a preservative.

Methylbenzethonium Chloride

Benzyl dimethyl[2-[2-[4-(1,1,3,3-tetramethylbutyl) tolyl]oxy]ethoxy]ethyl]ammonium chloride (Diaparene) is a mixture of methylated derivatives of methylbenzethonium chloride. It is used specifically for the treatment of diaper rash in infants, caused by the yeast *Candida albicans*, which produces ammonia. The agent is also used as a general antiseptic. Its properties are virtually identical to those of benzethonium chloride.

Benzethonium Chloride

Benzyl dimethyl[2-[2-[p-(1,1,3,3-tetramethylbutyl)phenoxy]ethoxy]ethyl]ammonium chloride (Phemerol chloride) is a colorless crystalline powder that is soluble in water, alcohol, and most organic solvents. The actions and uses of this agent are similar to those of benzalkonium chloride. It is used at a 1:750 concentration for skin antiseptics. For the irrigation of mucous membranes, a 1:5,000 solution is used. A 1:500 tincture is also available.

Cetylpyridinium Chloride

1-Hexadecylpyridinium chloride is a white powder that is very soluble in water and alcohol. In this compound, the quaternary nitrogen atom is a member of an aromatic pyridine ring.

Chlorhexidine Gluconate

The cetyl derivative is the most active of a series of alkylpyridinium compounds. It is used as a general antiseptic in concentrations of 1:100 to 1:1,000 for intact skin, 1:1,000 for minor lacerations, and 1:2,000 to 1:10,000 for the irrigation of mucous membranes. Cetylpyridinium chloride is also available in the form of throat lozenges and a mouthwash at a 1:20,000 dilution.

Chlorhexidine Gluconate

1,6-Di(4'-chlorophenyldiguanido)hexane gluconate (Hibiclens) is the most effective of a series of antibacterial biguanides originally developed in Great Britain.¹⁴

The antimicrobial properties of the biguanides were discovered as a result of earlier testing of these compounds as possible antimalarial agents (Chapter 7). Although the biguanides are technically not bisquaternary ammonium compounds and, therefore, should probably be classified separately, they share many physical, chemical, and antimicrobial properties with the cationic surfactants. The biguanides are strongly basic, and they exist as dications at physiological pH. In chlorhexidine, the positive charges are counterbalanced by gluconate anions (not shown). Like cationic surfactants, these undergo inactivation when mixed with anionic detergents and complex anions such as phosphate, carbonate, and silicate.

Chlorhexidine has broad-spectrum antibacterial activity but is not active against acid-fast bacteria, spores, or viruses. It has been used for such topical uses as preoperative skin disinfection, wound irrigation, mouthwashes, and general sanitization. Chlorhexidine is not absorbed through skin or mucous membranes and does not cause systemic toxicity.

DYES

Organic dyes were used very extensively as anti-infective agents before the discovery of the sulfonamides and the antibiotics. A few cationic dyes still find limited use as anti-infectives. These include the triphenylmethane dyes gentian violet and basic fuchsin and the thiazine dye methylene blue. The dyes form colorless *leucobase* forms under alkaline conditions. Cationic dyes are active against Gram-positive bacteria and many fungi; Gram-negative bacteria are generally resistant. The difference in susceptibility is probably related to the cellular characteristics that underlie the Gram stain.

Gentian Violet

Gentian violet is variously known as hexamethyl-*p*-rosaniline chloride, crystal violet, methyl violet, and methylrosaniline chloride. It occurs as a green powder or green flakes with a metallic sheen. The compound is soluble in water (1:35) and alcohol (1:10) but insoluble in nonpolar organic solvents. Gentian violet is available in vaginal suppositories for the treatment of yeast infections. It is also used as a 1% to 3% solution for the treatment of ringworm and yeast infections. Gentian violet has also been used orally as an anthelmintic for strongyloidiasis (threadworm) and oxyuriasis.

Basic Fuchsin

Basic fuchsin is a mixture of the chlorides of rosaniline and *p*-rosaniline. It exists as a green crystalline powder with a metallic appearance. The compound is soluble in water and in alcohol but insoluble in ether. Basic fuchsin is a component of carbol-fuchsin solution (Castellani's paint), which is used topically in the treatment of fungal infections, notably ringworm and athlete's foot.

Methylene Blue

Methylene blue is 3,7-bis(dimethylamino)-phenazathionium chloride (Urised). The compound occurs as a dark green crystalline powder with a metallic appearance that is soluble in water (1:25) and alcohol (1:65).

Methylene blue has weak antiseptic properties that make it useful for the treatment of cystitis and urethritis. The action of methylene blue is considered to be bacteriostatic. The compound colors the urine and stool blue green.

Hexamethyl *p*-Rosaniline
Chloride

Leucobase

MERCURY COMPOUNDS (MERCURIALS)

Mercury and its derivatives have been used in medicine for centuries. Elemental mercury incorporated into ointment bases was used topically for the treatment of localized infections and syphilis. Several inorganic salts of mercury, such as mercuric chloride (HgCl_2) and mercurous chloride (calomel, Hg_2Cl_2) were at one time widely used as antiseptics. Ammoniated mercury [$\text{Hg}(\text{NH}_2)\text{Cl}$] is still occasionally used for skin infections such as impetigo, psoriasis, and ringworm. Mercuric oxide is sometimes used to treat inflammation resulting from infection of the eye. Although the potential interaction of mercuric ion with the tissues is greatly reduced by the low water solubility of these agents, they can be irritating and can cause hypersensitivity reactions; therefore, their use is not recommended.

The comparatively few organomercurials still in use are employed as antiseptics, preservatives, or diuretics. Organomercurials can be grouped into two general classes: (a) compounds with at least one carbon-mercury bond that does not ionize readily and (b) compounds with mercury bonded to heteroatoms (e.g., oxygen, nitrogen, sulfur) that ionize partially or completely. In addition to its effect on ionization, the organic moiety may increase the lipid solubility of an organomercurial compound, thereby facilitating its penetration into microorganisms and host tissues.

The antibacterial action of mercury compounds is believed to result from their reaction with sulfhydryl (-SH) groups in enzymes and other proteins to form covalent compounds of the type $\text{R-S-Hg-R}'$. This action is reversible by treatment with thiol-containing compounds such as cysteine and dimercaprol (BAL); hence, organomercurials, reacting reversibly, are largely bacteriostatic. The antibacterial activity of organomercurial antiseptics is greatly reduced in serum because of the presence of proteins that inactivate mercury compounds. Organomercurial antiseptics are not very effective against spores.

The disadvantages of mercurials for antiseptic and disinfectant uses far outweigh any possible advantages that they might have. Hence, other more effective and less potentially toxic agents are preferable.

Nitromersol

3-(Hydroxymercuri)-4-nitro-*o*-cresol inner salt (Metaphen) occurs as a yellow powder that is practically insoluble in

water and is sparingly soluble in alcohol and most organic solvents. The sodium salt probably has the "inner salt" structure in which the inner shell electrons of mercury are occupied.¹⁵ The bonding to mercury in this salt should be collinear, thus the following structure is somewhat improbable. Nevertheless, this structure is shown in the *USP* and the *Merck Index*.

Nitromersol is nonirritating to mucous membranes and is nonstaining. Therefore, at one time, it was a very popular antiseptic for skin and ocular infections. Nitromersol has largely been replaced by superior agents.

Thimerosal

[(*o*-Carboxyphenyl)-thio]ethylmercury sodium salt (Merthiolate) is a cream-colored, water-soluble powder. It is nonstaining and nonirritating to tissues. Thimerosal is a weakly bacteriostatic antiseptic that is applied topically in ointments or aqueous solutions.

PRESERVATIVES

Preservatives are added to various dosage forms and cosmetic preparations to prevent microbial contamination. In parenteral and ophthalmic preparations, preservatives are used to maintain sterility in the event of accidental contamination during use. An ideal preservative would be effective at low concentrations against all possible microorganisms, be nontoxic and compatible with other constituents of the preparation, and be stable for the shelf life of the preparation. The ideal preservative does not exist, but there is quite a bit of experience with some of them. In some cases, combinations of preservative agents are used to approximate a mixture of ideal features.

p-Hydroxybenzoic Acid Derivatives

Esters of *p*-hydroxybenzoic acid (parabens) have distinct antifungal properties. Their toxicity to the human host is typically low because they undergo rapid hydrolysis *in vivo* to *p*-hydroxybenzoic acid, which is quickly conjugated and excreted. This property makes the parabens useful as preservatives for liquid dosage forms. The preservative activity generally increases with molecular weight, but the methyl ester is most effective against molds, whereas the propyl ester is most effective against yeasts. The more lipid-soluble propyl ester is the preferred preservative for drugs in oil or lipophilic bases.

Methylparaben

Methyl *p*-hydroxybenzoate, or methylparaben, is a white crystalline powder. It is soluble in water and alcohol but only slightly soluble in nonpolar organic solvents. Methylparaben is used as a safeguard against mold growth.

Propylparaben

Propyl *p*-hydroxybenzoate, or propylparaben, occurs as a white crystalline powder that is slightly soluble in water but soluble in most organic solvents. It is used as a preservative, primarily to retard yeast growth. Propylparaben sodium is a water-soluble sodium salt of the 4-phenol group. The pH of solutions of propylparaben sodium is basic (pH ~10).

Butylparaben

n-Butyl *p*-hydroxybenzoate (butylparaben) occurs as a white crystalline powder that is sparingly soluble in water but very soluble in alcohols and in nonpolar organic solvents.

Ethylparaben

Ethyl *p*-hydroxybenzoate (ethylparaben) is a white crystalline powder that is slightly soluble in water but soluble in alcohol and most organic solvents.

Other Preservatives

Chlorobutanol

1,1,1-Trichloro-2-methyl-2-propanol is a white crystalline solid with a camphorlike aroma. It occurs in an anhydrous form and a hemihydrate form, both of which sublime at room temperature and pressure. Chlorobutanol is slightly soluble in water and soluble in alcohol and in organic solvents.

Chlorobutanol is used as a bacteriostatic agent in pharmaceuticals for injection, ophthalmic use, and intranasal administration. It is unstable when heated in aqueous solution,

especially at pH greater than 7. Under these conditions, chlorobutanol undergoes elimination. Solutions with a pH of approximately 5 are reasonably stable at 25°C. Chlorobutanol is stable in oils and organic solvents.

Benzyl Alcohol

Benzyl alcohol (phenylcarbinol, phenylmethanol) occurs naturally as the unesterified form in oil of jasmine and in esters of acetic, cinnamic, and benzoic acids in gum benzoin, storax resin, Peru balsam, tolu balsam, and some volatile oils. It is soluble in water and alcohol and is a clear liquid with an aromatic odor.

Benzyl alcohol is commonly used as a preservative in vials of injectable drugs in concentrations of 1% to 4% in water or saline solution. Benzyl alcohol has the added advantage of having a local anesthetic action. It is commonly used in ointments and lotions as an antiseptic in the treatment of various pruritic skin conditions.

Phenylethyl Alcohol

Phenylethyl alcohol (2-phenylethanol, orange oil, rose oil, $C_6H_5CH_2CH_2OH$) is a clear liquid that is sparingly soluble in water (~2%). It occurs naturally in rose oil and pine-needle oil. It is used primarily in perfumery.

Benzoic Acid

Benzoic acid and its esters occur naturally in gum benzoin and in Peru and tolu balsams. It is found as a white crystalline solid that slowly sublimates at room temperature and is steam distillable. It is slightly soluble in water (0.3%) but more soluble in alcohol and in other polar organic solvents. It has a pK_a of 4.2. Benzoic acid is used externally as an antiseptic in lotions, ointments, and mouthwashes. It is more effective as a preservative in foods and pharmaceutical products at low pH (less than the pK_a). When used as a preservative in emulsions, its effectiveness depends on both pH and distribution into the two phases.¹⁶

Sodium Benzoate

Sodium benzoate is a white crystalline solid that is soluble in water and alcohol. It is used as a preservative in acidic liquid preparations in which benzoic acid is released.

Sodium Propionate

Sodium propionate occurs as transparent colorless crystals that are soluble in water and alcohol. It is an effective antifungal agent that is used as a preservative. Sodium propionate is most effective at low pH.

Sorbic Acid

2,4-Hexadienoic acid is an effective antifungal preservative. It is sparingly soluble in water and has a pK_a of 4.8. Sorbic acid is used to preserve syrups, elixirs, ointments, and lotions containing components such as sugars that support mold growth.

Potassium Sorbate

Potassium sorbate occurs as a white crystalline material that is soluble in water and alcohol. It is used in the same way as sorbic acid when greater water solubility is required.

Phenylmercuric Nitrate

Phenylmercuric nitrate is a mixture of phenylmercuric nitrate and phenylmercuric hydroxide. It occurs as a white crystalline material that is sparingly soluble in water and slightly soluble in alcohol. It is used in concentrations of 1:10,000 to 1:50,000 to preserve injectable drugs against bacterial contamination. A disadvantage to organomercurials is that their bacteriostatic efficacy is reduced in the presence of serum.

Phenylmercuric Acetate

Acetoxyphenylmercury occurs as white prisms that are soluble in alcohol but only slightly soluble in water. It is used as a preservative.

ANTIFUNGAL AGENTS

General Introduction to Fungi: Medical Mycology

The discovery that some infectious diseases could be attributed to fungi actually preceded the pioneering work of Pasteur and Koch with pathogenic bacteria by several years. Two microbiologists, Schönlein and Gruby, studied the fungus *Trichophyton schoenleinii* in 1839. In that same year, Langenbeck reported the yeastlike microorganism responsible for thrush (*C. albicans*). Gruby isolated the fungus responsible for favus on potato slices, rubbed it on the head of a child, and produced the disease. Hence, he fulfilled Koch's postulates 40 years before they were formulated.¹⁷ In spite of its earlier beginnings, medical mycology was quickly overshadowed by bacteriology, and it has only recently begun to receive the serious attention that it deserves. This is perhaps attributable to the relatively benign nature of the common mycoses, the rarity of the most serious ones, and the need for a morphological basis for differential identification of these structurally complex forms.

Cursory examination shows that fungal infections fall into two well-defined groups: the superficial and the deep-

seated mycoses.¹⁸ The superficial mycoses are, by far, the most common and are caused, for the most part, by a relatively homogeneous group of fungi, the dermatophytes. These include the various forms of tinea, or ringworm, which are infections of the hair or hair follicles, the superficial infections of the intertriginous or flat areas of hairless skin, and infections of the nails. As a rule, these lesions are mild, superficial, and restricted. The causative microbes are specialized saprophytes with the unusual ability to digest keratin. They have their ultimate reservoir in the soil. Unlike the deep-seated mycoses, however, they are frequently transmitted from one host to another (e.g., athlete's foot). A species of yeast, *Candida*, also produces a dermatophyte-like disease.

Systemic Mycoses

The deep-seated, systemic mycoses have a sporadic distribution,¹⁹ being common in some parts of the world and unknown in other geographical areas. These diseases have a heterogeneous etiology. Diseases caused by the systemic organisms include histoplasmosis, sporotrichosis, blastomycosis, coccidioidomycosis, cryptococcosis, and paracoccidioidomycosis. The causative agents for these diseases are soil-inhabiting saprophytes with the ability to adapt to the internal environment of their host. These organisms share a common route of infection. Fungal spores are inhaled into the lung, and a mild, coldlike condition may result. This may be the only symptom. In most cases, disease is inapparent. In asymptomatic disease, diagnosis is often made serendipitously. Sensitization, which reflects present or previous experience with the organism, may be detected by a skin test or other immunological procedure. The immune system deals with these infections by walling them off or by producing the giant cells that are common in type IV hypersensitivities. X-ray examination or autopsy frequently reveals these lesions. As stated previously, the causative organisms of the systemic infections are not typically transmitted from one host to another, but infection by the organism in an endemic area may be very common. Few infections develop into the severe, deep, spreading, and often-fatal disease seen in some persons. If the infection is symptomatic, the clinical signs may be those of a mild, self-limiting disease; or the infection may become progressive, with severe symptoms, tissue and organ damage, and, frequently, death. Recovery from a deep-seated infection of this type is accompanied by an uncertain anamnestic immune response.

Opportunistic Fungal Infections^{20,21}

In recent years, because of overzealous use of antibacterial antibiotics, the use of immunosuppressive agents, cytotoxins, irradiation, and steroids, a new category of systemic mycoses has become prominent. These are the opportunistic fungal infections. There has been a precipitous rise in the incidence of these diseases. The patient, as a result of drug therapy, underlying disease, or medical manipulation, is deprived of the normal defenses conferred by microbial flora. This allows organisms of normally *low inherent virulence* to exploit the host. Such infections include systemic candidiasis, aspergillosis, and mucormycosis. Bacterial infections such as Gram-negative septicemia, nocardiosis, and *Pseudomonas* infection, fungal infections such as with *Pneumocystis carinii*, and viral opportunists such as

cytomegalovirus also attack such patients. Multiple infections with various microorganisms are common. *C. albicans* is a particularly common opportunist. This yeast is a member of the normal microbial flora of human hosts, especially in the vagina. Use of contraceptives often predisposes a patient to infection by *Candida* spp. Fungal flora that inhabit the bowel may develop into a superinfection with the use of antibiotics to sterilize the bowel before surgery. Oral candidiasis is common in poorly nourished persons, in patients on immunosuppressive drugs, and in persons with acquired immunodeficiency syndrome (AIDS). Opportunists can grow in nearly every circumstance in which a patient's immune system is compromised.

Cutaneous Infections (Dermatophytoses)²²⁻²⁴

By far, the most common types of human fungal disease are among the dermatophytoses. These are superficial infections of the keratinized epidermis and keratinized epidermal appendages (i.e., the hair and nails). The severity of an infection depends largely on the location of the lesion and the species of the fungus involved. Though certain other fungi, notably *Candida* spp., produce clinically similar diseases, a somewhat homogeneous group of fungi, termed the *dermatophytes*, is responsible for most cases. The ability of these organisms to invade and parasitize the cornified tissues of hair, skin, and nails is closely associated with, and dependent on, their common physiological characteristic—metabolic use of the highly insoluble scleroprotein keratin. The biochemical use of keratin is rare and is shared by the dermatophyte species of the family Gymnoascaceae, with only a few species of the family Onygenaceae, and certain tineae. In humans, the genera *Trichophyton* (notably *T. rubrum* [nails, beard, smooth skin], *T. tonsurans* [scalp, beard, nails], *T. violaceum* [scalp, skin nails], *T. mentagrophytes* [commonest cause of athlete's foot], *T. verrucosum* [scalp, beard], and *T. rubrum* [psoriasis-like lesions of smooth skin, infections of nails]), *Microsporum* (*M. gypseum* [scalp], *M. fulvum* [scalp, hairless skin], and *M. canis* [scalp, hairless skin]), and *Epidermophyton* (eczema) contain the most common dermatophytes. These organisms cause the conditions known as tinea (ringworm). Some of the common tinea infections are listed in Table 6.4. The fungus *Pityrosporum orbiculare* causes an additional type, tinea versicolor. This organism, called *Malassezia furfur* in older literature, causes yellow to brown patches or continuous scaling over the trunk and occasionally the legs, face, and neck. The affected areas may be identified by the inability to tan in the sun.

Regardless of the type of fungus that is causing an infection (Table 6.5), treatment is extremely difficult because fungi, like mammals, are eukaryotes. Many biochemical structures, especially the cell membranes, are nearly identi-

TABLE 6.4 Locations of the Common Types of Tinea (Ringworm)

Type	Location
Tinea manuum	Hand

Cutaneous infections	Ringworm of scalp, hairless skin, nails	Dermatophytes, <i>Microsporum</i> , <i>Trichophyton</i> , <i>Epidermophyton</i>
Subcutaneous infections	Candidosis of skin, mucous membranes, nails; sometimes generalized	<i>Candida albicans</i> and related forms
	Chromomycosis Mycotic mycetoma Entomophthoromycosis	<i>Fonsecaea</i> and related forms <i>Allescheria boydii</i> , <i>Madurella mycetoma</i> , etc. <i>Basidiobolus haptosporus</i> , <i>Conidiobolus coronatus</i>
Systemic infections	Histoplasmosis Blastomycosis Paracoccidioidomycosis Coccidioidomycosis Cryptococcosis Sporotrichosis Aspergillosis Mucormycosis Histoplasmosis duboisii	<i>Histoplasma capsulatum</i> <i>Blastomyces dermatiditis</i> <i>Paracoccidioides brasiliensis</i> <i>Coccidioides immitis</i> <i>Cryptococcus neoformans</i> <i>Sporothrix schenckii</i> <i>Aspergillus fumigates</i> <i>Mucor</i> spp., <i>Absidia</i> spp., <i>Rhizopus</i> spp. <i>Histoplasma capsulatum</i> var. <i>duboisii</i>

cal, as are many biochemical reactions. Consequently, drugs that will kill a fungus will have a toxic effect on human cells at normal doses.

A slight difference exists in the cell membranes. Lipid bilayers by themselves are unstable and would be unable to hold their shape and support their functions. Sterols are embedded in the bilayers to act as stiffening agents. The 3-hydroxyl group represents the polar “head” group, and the non-polar sterol skeleton and side chain align perfectly with the nonpolar chains of the bilayer. In human cells, the sterol in the membrane is cholesterol (Fig. 6.1). In fungi, the sterol is ergosterol (Fig. 6.2). This difference amounts to the only source of selectivity that we have in treating fungal infections. New antifungal drug development has focused on this difference as a way to achieve selectivity, creating highly potent antifungal drugs that are much less toxic to the human host.

Subcutaneous Fungal Infections²²

Subcutaneous mycosis refers to a group of fungal diseases in which both the skin and subcutaneous tissue are involved but typically no dissemination to the internal organs occurs.

The causative agents are classified among several unrelated genera. They have the following characteristics in common: (a) they are primarily soil saprophytes of very low-grade virulence and invasive ability; and (b) in most human and animal infections, they gain access as a result of a trauma to the tissue. Many, if not all, organisms have the potential to establish local infections under certain circumstances, depending on their adaptability and the response of the host. The tissue reaction in most cases varies with the agent in question but usually remains a localized lesion similar to that elicited by a foreign body. The major disease types are chromomycosis, sporotrichosis, mycetoma, lobomycosis, and entomophthoromycosis. A type of dimorphism accompanies infection by agents of some of these groups. The organisms undergo a morphogenesis from their saprophytic form into a tissue or parasitic stage.

Tissue Reactions of Fungal Disease²³

The tissue response of the host to the infecting fungus varies widely and depends somewhat on various invasive organisms. In dermatophyte infections, erythema is gener-

Figure 6.1 ● Cholesterol embedded in a lipid bilayer.

Figure 6.2 • Ergosterol embedded in a lipid bilayer.

ally produced and is a result of the irritation of the tissues by the organism. Sometimes, severe inflammation, followed by scar tissue and keloid formation, occurs. This results from an exaggerated inflammatory response and an allergic reaction to the organism and its products.

With organisms that invade living tissue, such as those responsible for subcutaneous and systemic disease, there is generally a uniform acute pyogenic reaction that gives way to various chronic disease outcomes. Granuloma with caseation and fibrocaceous pulmonary granuloma are potential outcomes of infection with *Histoplasma capsulatum*, and thrombotic arteritis, a thrombosis characterized by a purulent coagulative necrosis and invasion of blood vessels, may be caused during aspergillosis and mucormycosis. The large numbers of fungal species of many morphotypes, their disease etiology, and the diversity of outcomes make medical mycology a complex field.

Topical Agents for Dermatophytoses

Collectively, the dermatophytoses are called *tinea*, or *ring-worm*. Since these infections tend to be topical, their treatment has been directed to surface areas of the skin. The skin is a formidable barrier to drug penetration, and many of the topical agents work best if an adjuvant is added that opens the barrier function of the skin. Keratolytic agents such as salicylic acid or other α -hydroxy compounds perform this function reasonably well.

FATTY ACIDS

Adults have an acidic, fatty substance in and on the skin called *sebum*. Sebum functions as a natural antifungal agent, part of the innate immune system. Fatty acids have been used for years with the idea that if a substance similar to sebum could be applied to the infected area, the effect of the sebum would be augmented and fungi could be eradicated. The application of fatty acids or their salts does in fact have an antifungal effect, albeit a feeble one.

The higher-molecular-weight fatty acids have the advantage of having lower volatility. Salts of fatty acids are also fungicidal and provide nonvolatile forms for topical application.

Propionic Acid

Propionic acid is an antifungal agent that is nonirritating and nontoxic. After application, it is present in perspiration

in low concentration ($\sim 0.01\%$). Salt forms with sodium, potassium, calcium, and ammonium are also fungicidal. Propionic acid is a clear, corrosive liquid with a characteristic odor. It is soluble in water and alcohol. The salts are usually used because they are nonvolatile and odorless.

Zinc Propionate

Zinc propionate occurs as an anhydrous form and as a monohydrate. It is very soluble in water but only sparingly soluble in alcohol. The salt is unstable to moisture, forming zinc hydroxide and propionic acid. Zinc propionate is used as a fungicide, particularly on adhesive tape.

Sodium Caprylate

Sodium caprylate is prepared from caprylic acid, which is a component of coconut and palm oils. The salt precipitates as cream-colored granules that are soluble in water and sparingly soluble in alcohol.

Sodium caprylate is used topically to treat superficial dermatomycoses caused by *C. albicans* and *Trichophyton*, *Microsporum*, and *Epidermophyton* spp. The sodium salt can be purchased in solution, powder, and ointment forms.

Zinc Caprylate

Zinc caprylate is a fine white powder that is insoluble in water or alcohol. The compound is used as a topical fungicide. The salt is highly unstable to moisture.

Undecylenic Acid

10-Undecenoic acid (Desenex, Cruex) obtained from the destructive distillation of castor oil. Undecylenic acid is a viscous yellow liquid. It is almost completely insoluble in water but is soluble in alcohol and most organic solvents.

Undecylenic acid is one of the better fatty acids for use as a fungicide, although cure rates are low. It can be used in concentrations up to 10% in solutions, ointments, powders,

and emulsions for topical administration. The preparation should never be applied to mucous membranes because it is a severe irritant. Undecylenic acid has been one of the agents traditionally used for athlete's foot (*tinea pedis*). Cure rates are low, however.

Triacetin

Glyceryl triacetate (Enzactin, Fungacetin) is a colorless, oily liquid with a slight odor and a bitter taste. The compound is soluble in water and miscible with alcohol and most organic solvents.

The activity of triacetin is a result of the acetic acid released by hydrolysis of the compound by esterases present in the skin. Acid release is a self-limiting process because the esterases are inhibited below pH 4.

Salicylic Acid and Resorcinol

Salicylic acid is a strong aromatic acid (pK_a 2.5) with both antiseptic and keratolytic properties. It occurs as white, needle-like crystals or a fluffy crystalline powder, depending on how the compound was brought out of solution. Salicylic acid is only slightly soluble in water but is soluble in most organic solvents. The greater acidity of salicylic acid and its lower solubility in water compared with *p*-hydroxybenzoic acid are the consequence of intramolecular hydrogen bonding.

Salicylic acid is used externally in ointments and solutions for its antifungal and keratolytic properties. By itself, salicylic acid is a poor antifungal agent.

m-Hydroxyphenol (resorcinol) possesses antiseptic and keratolytic activity. It occurs as white, needlelike crystals and has a slightly sweet taste. Resorcinol is soluble in water, alcohols, and organic solvents.

Benzoic Acid

Benzoic acid possesses appreciable antifungal effects, but it cannot penetrate the outer layer of the skin in infected areas. Therefore, benzoic acid when used as an antifungal agent must be admixed with a keratolytic agent. Suitable mixtures are benzoic acid and salicylic acid and benzoic acid and resorcinol. An old preparation that is still in use is Whitfield's Ointment, *USP*. This ointment contains benzoic acid, 6%, and salicylic acid, 6%, in a petrolatum base. The cure rates from preparations like these are low.

PHENOLS AND THEIR DERIVATIVES

Several phenols and their derivatives possess topical antifungal properties. Some of these, such as hexylresorcinols and parachlorometaxyleneol have been used for the treatment of tinea infections. Two phenolic compounds, clioquinol and haloprogin, are still official in the *USP*. A third agent, ciclopirox olamine, is not a phenol but has properties like those of phenols. All of these agents appear to interfere with cell membrane integrity and function in susceptible fungi.

Haloprogin

3-Iodo-2-propynyl-2,4,5-trichlorophenyl ether (Halotex) crystallizes as white to pale yellow forms that are sparingly soluble in water and very soluble in ethanol. It is an ethereal derivative of a phenol. Haloprogin is used as a 1% cream for the treatment of superficial tinea infections.

Formulations of haloprogin should be protected from light because the compound is photosensitive. Haloprogin is available as a solution and a cream, both in a 1% concentration. Haloprogin is probably not the first topical agent that should be recommended. Although the cure rates for topical fungal infections are relatively high, they come at a high price. The lesion typically worsens before it improves. Inflammation and painful irritation are common.

Clioquinol

5-Chloro-7-iodo-8-quinolinol, 5-chloro-8-hydroxy-7-iodoquinoline, or iodochlorhydroxyquin (Vioform) occurs as a spongy, light-sensitive, yellowish white powder that is insoluble in water. Vioform was initially used as a substitute for iodoform in the belief that it released iodine in the tissues. It has been used as a powder for many skin conditions, such as atopic dermatitis, eczema, psoriasis, and impetigo. A 3% ointment or cream has been used vaginally as a treatment for *Trichomonas vaginalis* vaginitis. The best use for Vioform is in the topical treatment of fungal infections such as athlete's foot and jock itch. A combination with hydrocortisone (Vioform HC) is also available.

Figure 6.3 • Mechanism of action of 5-fluorocytosine.

Ciclopirox Olamine²⁵

6-Cyclohexyl-1-hydroxyl-4-methyl-2(1*H*)-pyridinone ethanolamine salt (Loprox) is a broad-spectrum antifungal agent intended only for topical use. It is active against dermatophytes as well as pathogenic yeasts (*C. albicans*) that are causative agents for superficial fungal infections.

Ciclopirox is considered an agent of choice in the treatment of cutaneous candidiasis, tinea corporis, tinea cruris, tinea pedis, and tinea versicolor. It is a second-line agent for the treatment of onychomycosis (ringworm of the nails). Loprox is formulated as a cream and a lotion, each containing 1% of the water-soluble ethanolamine salt. Ciclopirox is believed to act on cell membranes of susceptible fungi at low concentrations to block the transport of amino acids into the cells. At higher concentrations, membrane integrity is lost, and cellular constituents leak out.

Nucleoside Antifungals

Flucytosine²⁶

5-Fluorocytosine, 5-FC, 4-amino-5-fluoro-2(1*H*)-pyrimidinone, 2-hydroxy-4-amino-5-fluoropyrimidine (Ancobon). 5-Fluorocytosine is an orally active antifungal agent with a very narrow spectrum of activity. It is indicated only for the treatment of serious systemic infections caused by susceptible strains of *Candida* and *Cryptococcus* spp.

The mechanism of action of 5-fluorocytosine (5-FC) has been studied in detail and is presented in Figure 6.3. The drug enters the fungal cell by active transport on ATPases that normally transport pyrimidines. Once inside the cell, 5-fluorocytosine is deaminated in a reaction catalyzed by cytosine deaminase to yield 5-fluorouracil (5-FU). 5-Fluorouracil is the active metabolite of the drug. 5-Fluorouracil enters into pathways of both ribonucleotide and deoxyribonucleotide synthesis. The fluororibonucleotide triphosphates are incorporated into RNA, causing faulty RNA synthesis. This pathway causes cell death. In the deoxyribonucleotide series, 5-fluorodeoxyuridine monophosphate (F-dUMP) binds to 5,10-methylenetetrahydrofolic acid, interrupting the one-carbon pool substrate that feeds thymidylate synthesis. Hence, DNA synthesis is blocked.

Resistance to 5-FC is very common, and it occurs at several levels. A main one is at the step in which the drug is transported into the fungal cell. The transport system simply becomes impermeable to 5-FC. The cytosine deaminase step is another point at which resistance occurs, and the UMP pyrophosphorylase reaction is a third point at which fungal cells can become resistant. Regardless of which of these mechanisms operates, fungal resistance develops rapidly and completely when 5-FC is administered. After a few dosing intervals, the drug is essentially useless. One strategy used to decrease resistance and to prolong the effect of 5-FC is to administer it with the polyene antibiotic amphotericin B. The antibiotic creates holes in the fungal cell membrane, bypassing the transport step and allowing 5-FC to enter. Additionally, a lower dose of 5-FC can be used, preventing resistance by other mechanisms for a longer period.

Antifungal Antibiotics^{27,28}

The antifungal antibiotics make up an important group of antifungal agents. All of the antibiotics are marked by their complexity. There are two classes: the polyenes, which contain a large number of agents with only a few being useful, and griseofulvin (one member of the class).

POLYENES

Several structurally complex antifungal antibiotics have been isolated from soil bacteria of the genus *Streptomyces*. The compounds are similar, in that they contain a system of conjugated double bonds in macrocyclic lactone rings. They differ from the erythromycin-type structures (macrolides; see Chapter 8), in that they are larger and contain the conjugated *-ene* system of double bonds. Hence, they are called the *polyene antibiotics*. The clinically useful polyenes fall into two groupings on the basis of the size of the macrolide ring. The 26-membered-ring polyenes, such as natamycin (pimaricin), form one group, whereas the 38-membered macrocycles, such as amphotericin B and nystatin, form the other group. Also common to the polyenes are (a) a series of hydroxyl groups on the acid-derived portion of the ring and (b) a glycosidically linked deoxyaminohexose called *mycosamine*. The number of double bonds in the macrocyclic ring differs also. Natamycin, the smallest macrocycle, is a pentaene; nystatin is a hexaene; and amphotericin B is a heptaene.

The polyenes have no activity against bacteria, rickettsia, or viruses, but they are highly potent, broad-spectrum antifungal agents. They do have activity against certain protozoa, such as *Leishmania* spp. They are effective against pathogenic yeasts, molds, and dermatophytes. Low concentrations of the polyenes in vitro will inhibit *Candida* spp., *Coccidioides immitis*, *Cryptococcus neoformans*, *H. capsulatum*, *Blastomyces dermatitidis*, *Mucor mucedo*, *Aspergillus fumigatus*, *Cephalosporium* spp., and *Fusarium* spp.

The use of the polyenes for the treatment of systemic infections is limited by the toxicities of the drugs, their low water solubilities, and their poor chemical stabilities. Amphotericin B, the only polyene useful for the treatment of serious systemic infections, must be solubilized with a detergent. The other polyenes are indicated only as topical agents for superficial fungal infections.

The mechanism of action of the polyenes has been studied in some detail. Because of their three-dimensional shape, a barrel-like nonpolar structure capped by a polar group (the sugar), they penetrate the fungal cell membrane, acting as “false membrane components,” and bind closely with ergosterol, causing membrane disruption, cessation of membrane enzyme activity, and loss of cellular constituents, especially potassium ions. In fact, the first observable in vitro reaction upon treating a fungal culture with amphotericin B is the loss of potassium ions. The drug is fungistatic at low concentrations and fungicidal at high concentrations. This suggests that at low concentrations, the polyenes bind to a membrane-bound enzyme component, such as an ATPase.

Amphotericin B

The isolation of amphotericin B (Fungizone) was reported in 1956 by Gold et al.²⁹ The compound was purified from the fermentation beer of a soil culture of the actinomycete *Streptomyces nodosus*, which was isolated in Venezuela. The first isolate from the streptomycete was a separable mixture of two compounds, designated amphotericins A and B. In test cultures, compound B proved to be more active, and this is the one used clinically.³⁰ The structure and absolute stereochemistry are as shown.

Amphotericin B is believed to interact with membrane sterols (ergosterol in fungi) to produce an aggregate that forms a transmembrane channel. Intermolecular hydrogen bonding interactions among hydroxyl, carboxyl, and amino groups stabilize the channel in its open form, destroying symport activity and allowing the cytoplasmic contents to leak out. The effect is similar with cholesterol. This explains the toxicity in human patients. As the name implies, amphotericin B is an amphoteric substance, with a primary amino group attached to the mycosamine ring and a carboxyl group on the macrocycle. The compound forms deep yellow crystals that are sparingly soluble in organic solvents but insoluble in water. Although amphotericin B forms salts with both acids and bases, the salts are only slightly soluble in water (~0.1 mg/mL) and, hence, cannot be used systemically. To create a parenteral dosage form, amphotericin B is stabilized as a buffered colloidal dispersion in micelles with sodium deoxycholate.³¹ The barrel-like structure of the antibiotic develops interactive forces with the micellar components, creating a soluble dispersion. The preparation is light, heat, salt, and detergent sensitive.

Parenteral amphotericin B is indicated for the treatment of severe, potentially life-threatening fungal infections, including disseminated forms of coccidioidomycosis and histoplasmosis, sporotrichosis, North American blastomycosis, cryptococcosis, mucormycosis, and aspergillosis.

The usefulness of amphotericin B is limited by a high prevalence of adverse reactions. Nearly 80% of patients treated with amphotericin B develop nephrotoxicity. Fever, headache, anorexia, gastrointestinal distress, malaise, and muscle and joint pain are common. Pain at the site of injection and thrombophlebitis are frequent complications of intravenous administration. The drug must never be administered intramuscularly. The hemolytic activity of amphotericin B may be a consequence of its ability to leach cholesterol from erythrocyte cell membranes.

For fungal infections of the central nervous system (CNS) (e.g., cryptococcosis), amphotericin B is mixed with cerebrospinal fluid (CSF) that is obtained from a spinal tap.

The solution of amphotericin B is then reinjected through the tap. For severe infections, this procedure may need to be repeated many times.

Amphotericin B for injection is supplied as a sterile lyophilized cake or powder containing 50 mg of antibiotic with 41 mg of sodium deoxycholate to be dispersed in 10 mL of water. The infusion, providing 0.1 mg/mL, is prepared by further dilution (1:50) with 5% dextrose for injection. Normal saline cannot be used because it will break the micelles. The suspension should be freshly prepared and used within 24 hours. Even the powder should be refrigerated and protected from light.

Several sterile dosage forms³² with amphotericin B admixed with a lipid carrier have been developed with the goal of counteracting the dose-limiting toxicity of the drug following parenteral administration. These include amphotericin B colloidal dispersion (Amphocil, Amphocyte), which contains nearly equal parts of the drug and cholesterol sulfate in a suspension of disklike particles; Abelcet, a 1:1 combination of amphotericin B with *L*- α -dimyristoylphosphatidylcholine (7 parts) and *L*- α -dimyristoylphosphatidylglycerol (3 parts) to create a suspension of ribbonlike sheets; and liposomal amphotericin B (AmBisome), a small lamellar vesicular preparation consisting of an approximately 1:10 molar ratio of amphotericin B and lipid (hydrogenated soy phosphatidyl choline, cholesterol, and distearoylphosphatidylcholine in a 10:5:4 ratio) for an aqueous suspension.

The rationale behind these lipid preparations is simple: amphotericin B should have a greater avidity for the lipid vehicle than for cholesterol in cell membranes. Hence, toxicity should be reduced. Lipid-associated amphotericin B should be drawn into the reticuloendothelial system, concentrating in the lymphatic tissues, spleen, liver, and lungs, where infectious fungi tend to locate. Lipases elaborated by the fungi and the host should release the drug from the lipid carrier, making it available to bind ergosterol in fungal cell membranes to exert its fungistatic and fungicidal activities.

Clinical use of each of the approved lipid preparations has shown reduced renal toxicity. Liposomal amphotericin B has been approved specifically for the treatment of pulmonary aspergillosis because of its demonstrated superiority to the sodium deoxycholate-stabilized suspension.

Amphotericin B is also used topically to treat cutaneous and mucocutaneous mycoses caused by *C. albicans*. The drug is supplied in various topical forms, including a 3% cream, a 3% lotion, a 3% ointment, and a 100-mg/mL oral

suspension. The oral suspension is intended for the treatment of oral and pharyngeal candidiasis. The patient should swish the suspension in his or her mouth and swallow it. The suspension has a very bad taste, so compliance may be a problem. A slowly developing resistance to amphotericin B has been described. This is believed to relate to alterations in the fungal cell membrane.

Nystatin

Nystatin (Mycostatin) is a polyene antibiotic that was first isolated in 1951 from a strain of the actinomycete *Streptomyces noursei* by Hazen and Brown.³³ It occurs as a yellow to light tan powder. Nystatin is very slightly soluble in water and sparingly soluble in organic solvents. The compound is unstable to moisture, heat, and light.

The aglycone portion of nystatin is called *nystatinolide*. It consists of a 38-membered macrolide lactone ring containing single tetraene and diene moieties separated by two methylene groups.³⁴ The aglycone also contains eight hydroxyl groups, one carboxyl group, and the lactone ester functionality. The entire compound is constructed by linking the aglycone to mycosamine. The complete structure of nystatin has been determined by chemical degradation and x-ray crystallography.³⁵

Nystatin is not absorbed systemically when administered by the oral route. It is nearly insoluble under all conditions. It is also too toxic to be administered parenterally. Hence, it is used only as a topical agent. Nystatin is a valuable agent for the treatment of local and gastrointestinal monilial infections caused by *C. albicans* and other *Candida* species. For the treatment of cutaneous and mucocutaneous candidiasis, it is supplied as a cream, an ointment, and a powder. Vaginal tablets are available for the control of vaginal candidiasis. Oral tablets and troches are used in the treatment of gastrointestinal and oral candidiasis. Combinations of nystatin with tetracycline can be used to prevent monilial overgrowth caused by the destruction of bacterial microflora of the intestine during tetracycline therapy.

Although nystatin is a pure compound of known structure, its dosage is still expressed in terms of units. One milligram of nystatin contains not less than 2,000 USP units.

Natamycin^{36,37}

Natamycin (pimaricin; Natacyn) is a polyene antibiotic obtained from cultures of *Streptomyces natalensis*.

The natamycin structure consists of a 26-membered lactone ring containing a tetraene chromophore, an α,β -unsaturated lactone carbonyl group, three hydroxyl groups, a carboxyl

Nystatin

group, a *trans* epoxide, and a glycosidically joined mycosamine. Like the other polyene antibiotics, natamycin is amphoteric.

The mechanism action of the smaller polyenes differs from that of amphotericin B and nystatin. The 26-membered-ring polyenes cause both potassium ion leakage and cell lysis at the same concentration, whereas the 38-membered-ring polyenes cause potassium leakage at low, fungistatic concentrations and cell lysis at high, fungicidal concentrations. The smaller polyenes are fungistatic and fungicidal within the same concentration range.

Natamycin possesses *in vitro* activity against several yeasts and filamentous fungi, including *Candida*, *Aspergillus*, *Cephalosporium*, *Penicillium*, and *Fusarium* spp. The drug is supplied as a 5% ophthalmic suspension intended for the treatment of fungal conjunctivitis, blepharitis, and keratitis.

Other Antifungal Antibiotics

Griseofulvin

Griseofulvin (Grisactin, Gris-PEG, Grifulvin) was first reported in 1939 by Oxford et al.³⁸ as an antibiotic obtained from the fungus *Penicillium griseofulvum*. It was isolated originally as a “curling factor” in plants. Application of extracts containing the antibiotic to fungus-infected leaf parts caused the leaf to curl up. The drug has been used for many years for its antifungal action in plants and animals. In 1959, griseofulvin was introduced into human medicine for the treatment of tinea infections by the systemic route.

Griseofulvin is an example of a rare structure in nature, a spiro compound. The structure of griseofulvin was determined by Grove et al.³⁹ to be 7-chloro-2',4,6-trimethoxy-6', β -methylspiro[benzofuran-2(3*H*)-1'-[2]cyclohexene]-3,4'-dione. The compound is a white, bitter, heat-stable powder or crystalline solid that is sparingly soluble in water but soluble in alcohol and other nonpolar solvents. It is very stable when dry.

Griseofulvin has been used for a long time for the systemically delivered treatment of refractory ringworm infections of the body, hair, nails, and feet caused by species of dermatophytic fungi including *Trichophyton*, *Microsporum*,

and *Epidermophyton*. After systemic absorption, griseofulvin is carried by the systemic circulation and capillary beds to the skin, nails, and hair follicles, where it concentrates in keratin precursor cells, which are gradually exfoliated and replaced by healthy tissue. Griseofulvin is a fungistatic agent, and as the new, healthy tissue develops, the drug prevents reinfection. Treatment must be continued until all of the infected tissue has been exfoliated, because old tissues will still support and harbor fungal growth. Therapy in slow-growing tissues, such as the nails, must be continued for several months. Compliance with the drug regimen is mandatory. In some cases, such as with the nails, it is possible to observe new, healthy tissue growing in to replace the infected tissue. Griseofulvin neither possesses antibacterial activity nor is effective against *P. obiculare*, the organism that causes tinea versicolor.

Few adverse effects have been reported for griseofulvin. The most common ones are allergic reactions such as rash and urticaria, gastrointestinal upset, headache, dizziness, and insomnia.

The oral bioavailability of griseofulvin is very poor. The compound is highly lipophilic with low water solubility. The most successful attempts at improving absorption have centered on creating micronized (ultramicrosized, microsized) griseofulvin. Reducing the particle size, in theory, should improve dissolution in the stomach and absorption. The efficiency of gastric absorption of griseofulvin ultramicrosized versus the microsized form is about 1.5, allowing a dosage reduction of one third. Several structural derivatives have been synthesized, but they have failed to improve absorption. Perhaps the best advice that the pharmacist can give a patient who is about to use griseofulvin is to take the drug with a fatty meal, as with salad dressing.

Griseofulvin is a mitotic spindle poison.^{39,40} *In vitro*, it rapidly arrests cell division in metaphase. It causes a rapid, reversible dissolution of the mitotic spindle apparatus, probably by binding with the tubulin dimer that is required for microtubule assembly. The selective toxicity to fungi is probably because of the propensity of the drug to concentrate in tissues rich in keratin, where dermatophytes typically establish infections.

Allylamines and Related Compounds

The allylamine class of antifungal agents was discovered as a result of random screening of a chemical inventory for compounds with antifungal activity. Structure–activity studies in the series subsequently led to the discovery of compounds with enhanced potency and potential oral activity, such as terbinafine.^{41,42} Investigation of the mechanism of action of the allylamines demonstrated that the compounds interfere with an early step in ergosterol biosynthesis, namely, the epoxidation of squalene catalyzed by squalene epoxidase. Squalene epoxidase⁴³ forms an epoxide at the C2–C3 position of squalene (Fig. 6.4). Opening of the epoxide under acid catalysis yields a carbocation that initiates the “squalene zipper” reaction that forms the steroid nucleus. Inhibition of squalene epoxidase shuts down the biosynthesis of ergosterol and causes an accumulation of squalene, which destabilizes the fungal cell membrane. The allylamines exert a fungicidal action against dermatophytes and other filamentous fungi, but their action against pathogenic yeasts, such as *Candida* spp., is largely fungistatic.

Figure 6.4 • Squalene epoxidase reaction.

Although mammalian squalene epoxidase is weakly inhibited by the allylamines, cholesterol biosynthesis does not appear to be altered.

Two allylamines, naftifine and terbinafine, have been approved as topical agents for the treatment of tinea pedis, tinea cruris, and tinea corporis caused by *Trichophyton rubrum*, *Trichophyton mentagrophytes*, or *Epidermophyton floccosum*, respectively. The topical agent tolnaftate, although not an allylamine, inhibits squalene epoxidase and has a spectrum of activity similar to that of the allylamines. Hence, tolnaftate is classified with the allylamines. The allylamines are weak bases that form hydrochloride salts that are slightly soluble in water.

Naftifine Hydrochloride

N-Methyl-*N*-(3-phenyl-2-propenyl)-1-naphthalenemethanamine hydrochloride (Naftin) is a white crystalline powder that is soluble in polar solvents such as ethanol and methylene chloride. It is supplied in a 1% concentration in a cream and in a gel for the topical treatment of ringworm, athlete's foot, and jock itch. Although unapproved for these uses, naftifine has shown efficacy for treatment of ringworm of the beard, ringworm of the scalp, and tinea versicolor.

Terbinafine Hydrochloride

(*E*)-*N*-(6,6-dimethyl-2-hepten-4-ynyl)-*N*-methyl-1-naphthalenemethanamine hydrochloride (Lamisil) is an off-white crystalline material that is soluble in polar organic solvents such as methanol, ethanol, and methylene chloride but is only slightly soluble in water. The highly lipophilic free base is insoluble in water. Terbinafine hydrochloride is available in a 1% cream for topical administration for the treatment of tinea pedis, tinea corporis, and tinea cruris. Terbinafine is more potent than naftifine and has also demonstrated oral activity against onychomycosis (ringworm of the nails). It has not been approved in the United States for oral administration.

Tolnaftate

O,2-Naphthyl *m,N*-dimethylthiocarbamate (Tinactin, Aftate, NP-27) is a white crystalline solid that is insoluble in water, sparingly soluble in alcohol, and soluble in most organic solvents. The compound, a thioester of β -naphthol, is fungicidal against dermatophytes, such as *Trichophyton*, *Microsporum*, and *Epidermophyton* spp., that cause superficial tinea infections. Tolnaftate is available in a concentration of 1% in creams, powders, aerosols, gels, and solutions for the treatment of ringworm, jock itch, and athlete's foot. Tolnaftate has been shown to act as an inhibitor of squalene epoxidase⁴⁴ in susceptible fungi, so it is classified with the allylamine antimycotics. Tolnaftate is formulated into preparations intended to be used with artificial fingernails to counteract the increased chance of ringworm of the nail beds.

Azole Antifungal Agents

The azoles represent a class of synthetic antifungal agents that possess a unique mechanism of action. With these drugs, one can achieve selectivity for the infecting fungus over the host. Depending on the azole drug used, one can treat infections ranging from simple dermatophytoses to life-threatening, deep systemic fungal infections. Research currently under way in the United States is aimed at developing more potent azoles and compounds that penetrate the blood-brain barrier more effectively. The first members of the class were highly substituted imidazoles, such as clotrimazole and miconazole. Structure-activity studies revealed that the imidazole ring could be replaced with a bioisosteric 1,2,4-triazole ring without adversely affecting the antifungal properties of the molecule. Hence, the more generic term *azoles* refers to this class of antifungal agents.

ANTIFUNGAL SPECTRUM

The azoles tend to be effective against most fungi that cause superficial infections of the skin and mucous membranes, including the dermatophytes such as *Trichophyton*, *Epidermophyton*, and *Microsporum* spp. and yeasts such as *C. albicans*. On the other hand, they also exhibit activity against yeasts that cause systemic infections, including *C. immitis*, *C. neoformans*, *Paracoccidioides brasiliensis*, *Petrellidium boydii*, *B. dermatitidis*, and *H. capsulatum*.

MECHANISM OF ACTION

The effects of the azoles on fungal biochemistry have been studied extensively, but there is still much to be learned.⁴⁵ At

high in vitro concentrations (micromolar), the azoles are fungicidal; at low in vitro concentrations (nanomolar), they are fungistatic. The fungicidal effect is clearly associated with damage to the cell membrane, with the loss of essential cellular components such as potassium ions and amino acids. The fungistatic effect of the azoles at low concentration has been associated with inhibition of membrane-bound enzymes. A cytochrome P450-class enzyme, lanosterol 14 α -demethylase, is the likely target for the azoles.⁴⁶ P450 possesses a heme moiety as part of its structure (Fig. 6.5), and the basic electron pairs of the azole rings can occupy a binding site on P450, preventing the enzyme from turning over. The function of lanosterol 14 α -demethylase is to oxidatively remove a methyl group from lanosterol during ergosterol biosynthesis.

Figure 6.5 • The inhibitory action of azole antifungal agents on the lanosterol 14 α -demethylase reaction.

When demethylation is inhibited, the 14α -sterol accumulates in the membrane, causing destabilization. As this happens, repair mechanisms, such as chitin synthesis, are initiated to patch the damage. This degrades membrane function further. Lanosterol 14α -demethylase is also required for mammalian biosynthesis of cholesterol, and the azoles are known to inhibit cholesterol biosynthesis.⁴⁷ In general, higher concentrations of the azoles are needed to inhibit the mammalian enzyme. This provides selectivity for antifungal action. The 1,2,4-triazoles appear to cause a lower incidence of endocrine effects and hepatotoxicity than the corresponding imidazoles, possibly because of a lower affinity for the mammalian cytochrome P450 enzymes involved.⁴⁸ The primary mode of resistance to the triazoles and imidazoles in *C. albicans* is the development of mutations in *ERG 11*, the gene coding for C14- α -sterol demethylase. These mutations appear to protect heme in the enzyme pocket from binding to azole but allow access of the natural substrate of the enzyme, lanosterol. Cross-resistance is conferred to all azoles. Increased azole efflux by the ATP-binding cassette (ABC-1, which normally transports cholesterol) and major facilitator superfamily transporters can add to fluconazole resistance in *C. albicans* and *C. glabrata*. Increased production of C14- α -sterol demethylase could be another cause of resistance.

STRUCTURE-ACTIVITY RELATIONSHIPS

The basic structural requirement for members of the azole class is a weakly basic imidazole or 1,2,4-triazole ring (pK_a of 6.5–6.8) bonded by a nitrogen-carbon linkage to the rest of the structure. At the molecular level, the amidine nitrogen atom (N-3 in the imidazoles, N-4 in the triazoles) is believed to bind to the heme iron of enzyme-bound cytochrome P450 to inhibit activation of molecular oxygen and prevent oxidation of steroidal substrates by the enzyme. The most potent antifungal azoles possess two or three aromatic rings, at least one of which is halogen substituted (e.g., 2,4-dichlorophenyl, 4-chlorophenyl, 2,4-difluorophenyl), and other nonpolar functional groups. Only 2, and/or 2,4 substitution yields effective azole compounds. The halogen atom that yields the most potent compounds is fluorine, although functional groups such as sulfonic acids have been shown to do the same. Substitution at other positions of the ring yields inactive compounds. Presumably, the large nonpolar portion of these molecules mimics the nonpolar steroidal part of the substrate for lanosterol 14α -demethylase, lanosterol, in shape and size.

The nonpolar functionality confers high lipophilicity to the antifungal azoles. The free bases are typically insoluble in water but are soluble in most organic solvents, such as ethanol. Fluconazole, which possesses two polar triazole moieties, is an exception, in that it is sufficiently water soluble to be injected intravenously as a solution of the free base.

PRODUCTS

Clotrimazole

1-(*o*-Chloro- α,α -diphenylbenzyl)imidazole (Lotrimin, Gyne-Lotrimin, Mycelex) is a broad-spectrum antifungal drug that is used topically for the treatment of tinea infections and candidiasis. It occurs as a white crystalline solid that is sparingly soluble in water but soluble in alcohol and most organic solvents. It is a weak base that can be solubilized by dilute mineral acids.

Clotrimazole is available as a solution in polyethylene glycol 400, a lotion, and a cream in a concentration of 1%. These are all indicated for the treatment of tinea pedis, tinea cruris, tinea capitis, tinea versicolor, or cutaneous candidiasis. A 1% vaginal cream and tablets of 100 mg and 500 mg are available for vulvovaginal candidiasis. Clotrimazole is extremely stable, with a shelf life of more than 5 years.

Although clotrimazole is effective against various pathogenic yeasts and is reasonably well absorbed orally, it causes severe gastrointestinal disturbances. It is also extensively protein bound and, hence, is not considered optimally bioavailable. Clotrimazole is not considered suitable for the treatment of systemic infections.

Econazole Nitrate

1-[2-[(4-Chlorophenyl)methoxy]-2-(2,4-dichlorophenyl)ethyl]-1*H*-imidazole (Spectazole) is a white crystalline nitric acid salt of econazole. It is only slightly soluble in water and most organic solvents.

Econazole is used as a 1% cream for the topical treatment of local tinea infections and cutaneous candidiasis.

Butoconazole Nitrate

1-[4-(4-Chlorophenyl)-2-[(2,6-dichlorophenyl)thio]butyl]-1*H*-imidazole (Femstat) is an extremely broad-spectrum antifungal drug that is specifically effective against *C. albicans*. It is supplied as a vaginal cream containing 2% of the salt. It is intended for the treatment of vaginal candidiasis.

Sulconazole Nitrate

1-[2,4-Dichloro- β -[*p*-chlorobenzyl]thio]phenethyl]imidazole mononitrate (Exelderm) is the white crystalline nitric acid salt of sulconazole. It is sparingly soluble in water but soluble in ethanol. The salt is used in a solution and a cream

in 1% concentration for the treatment of local tinea infections, such as jock itch, athlete's foot, and ringworm.

Oxiconazole Nitrate

(*Z*)-1-(2,4-dichlorophenyl)-2-(1*H*-imidazol-1-yl)ethanone-*O*-[2,4-dichlorophenyl)methyl]oxime mononitrate (Oxistat) is a white crystalline nitric acid salt. It is used in cream and lotion dosage forms in 1% concentration for the treatment of tinea pedis, tinea corporis, and tinea capitis.

Tioconazole

1-[2-[(2-chloro-3-thienyl)methoxy]2-(2,4-dichlorophenyl)ethyl]-1*H*-imidazole (Vagistat) is used for the treatment of vulvovaginal candidiasis. A vaginal ointment containing 6.5% of the free base is available. Tioconazole is more effective against *Torulopsis glabrata* than are other azoles.

Miconazole Nitrate

1-[2-(2,4-Dichlorophenyl)-2-[2,4-dichlorophenyl]-methoxy]ethyl]-1*H*-imidazole mononitrate (Monistat, Micatin) is a weak base with a pK_a of 6.65. The nitric acid salt occurs as white crystals that are sparingly soluble in water and most organic solvents.

The free base is available in an injectable form, solubilized with polyethylene glycol and castor oil, and intended for the treatment of serious systemic fungal infections, such as candidiasis, coccidioidomycosis, cryptococcosis, petriellidiosis, and paracoccidioidomycosis. It may also be used for the treatment of chronic mucocutaneous candidiasis. Although serious toxic effects from the systemic administration of miconazole are comparatively rare, thrombophlebitis, pruritus, fever, and gastrointestinal upset are relatively common.

Miconazole nitrate is supplied in various dosage forms (cream, lotion, powder, and spray) for the treatment of tinea infections and cutaneous candidiasis. Vaginal creams and suppositories are also available for the treatment of vaginal candidiasis. A concentration of 2% of the salt is used in most topical preparations.

Ketoconazole

1-Acetyl-4-[4-[[2-(2,4-dichlorophenyl)-2(1*H*-imidazole-1-yl)methyl]-1,3-dioxolan-4-yl]methoxy]phenyl]piperazine (Nizoral) is a broad-spectrum imidazole antifungal agent that is administered orally for the treatment of systemic fungal infections. It is a weakly basic compound that occurs as a white crystalline solid that is very slightly soluble in water.

The oral bioavailability of ketoconazole depends on an acidic pH for dissolution and absorption. Antacids and drugs such as H_2 -histamine antagonists and anticholinergics that inhibit gastric secretion interfere with its oral absorption. Ketoconazole is extensively metabolized to inactive metabolites, and the primary route of excretion is enterohepatic. It is estimated to be 95% to 99% bound to protein in the plasma.

Hepatotoxicity, primarily of the hepatocellular type, is the most serious adverse effect of ketoconazole. Ketoconazole is known to inhibit cholesterol biosynthesis,⁴⁷ suggesting that lanosterol 14 α -demethylase is inhibited in mammals as well as in fungi. High doses have also been reported to lower testosterone and corticosterone levels, reflecting the inhibition of cytochrome P450-requiring enzymes involved in human steroid hormone biosynthesis.⁴⁸ Cytochrome P450 oxidases responsible for the metabolism of various drugs may also be inhibited by ketoconazole to cause enhanced effects. Thus, ketoconazole causes clinically significant increases in plasma concentrations of cyclosporine, phenytoin, and terfenadine. It may also enhance responses to sulfonylurea hypoglycemic and coumarin anti-coagulant drugs.

Ketoconazole is a racemic compound, consisting of the *cis*-2*S*,4*R* and *cis*-2*R*,4*S* isomers. An investigation of the relative potencies of the four possible diastereomers of ketoconazole against rat lanosterol 14 α -demethylase⁴⁹ indicated that the 2*S*,4*R* isomer was 2.5 times more active than its 2*R*,4*S* enantiomer. The *trans*-isomers, 2*S*,4*S* and 2*R*,4*R*, are much less active.⁴⁹

Ketoconazole is recommended for the treatment of the following systemic fungal infections: candidiasis (including oral thrush and the chronic mucocutaneous form), coccidioidomycosis, blastomycosis, histoplasmosis, chromomycosis, and paracoccidioidomycosis. It is also used orally to treat severe refractory cutaneous dermatophytic infections not responsive to topical therapy or oral griseofulvin. The antifungal actions of ketoconazole and the polyene antibiotic amphotericin B are reported to antagonize each other.

Ketoconazole is also used topically in a 2% concentration in a cream and in a shampoo for the management of cutaneous candidiasis and tinea infections.

Terconazole

cis-1-[4-[[2-(2,4-Dichlorophenyl)-2-(1*H*-1,2,4-triazol-1-ylmethyl)-1,3-dioxolan-4-yl]methoxy]phenyl]-4-(1-methylethyl)piperazine (Terazol), or terconazole, is a triazole derivative that is used exclusively for the control of vulvovaginal moniliasis caused by *C. albicans* and other *Candida* species. It is available in creams containing 0.4% and 0.8% of the free base intended for 7-day and 3-day treatment periods, respectively. Suppositories containing 80 mg of the free base are also available.

Itraconazole

4-[4-[4-[4-[[2-(2,4-Dichlorophenyl)-2-(1*H*-1,2,4-triazol-1-ylmethyl)-1,3-dioxolan-4-yl]methoxy]phenyl]-1-piperazinyl]phenyl]-2,4-dihydro-2-(1-methylpropyl)-3*H*-1,2,4-triazol-3-one (Sporanox) is a unique member of the azole class that contains two triazole moieties in its structure, a weakly basic 1,2,4-triazole and a nonbasic 1,2,4-triazol-3-one.

Itraconazole is an orally active, broad-spectrum antifungal agent that has become an important alternative to ketoconazole. An acidic environment is required for optimum solubilization and oral absorption of itraconazole. Drugs such as H_2 -histamine antagonists and antacids, which

reduce stomach acidity, reduce its gastrointestinal absorption. Food greatly enhances the absorption of itraconazole, nearly doubling its oral bioavailability. The drug is avidly bound to plasma proteins (nearly 99% at clinically effective concentrations) and extensively metabolized in the liver. Only one of the numerous metabolites, namely 1-hydroxyitraconazole, has significant antifungal activity. Virtually none of the unchanged drug is excreted in the urine. Thus, the dosage need not be adjusted in patients with renal impairment. The terminal elimination half-life of itraconazole ranges from 24 to 40 hours.

The primary indications for itraconazole are for the treatment of systemic fungal infections including blastomycosis, histoplasmosis (including patients infected with human immunodeficiency virus [HIV]), nonmeningeal coccidioidomycosis, paracoccidioidomycosis, and sporotrichosis. It may also be effective in the treatment of pergellosis, disseminated and deep organ candidiasis, coccidioidal meningitis, and cryptococcosis.

In general, itraconazole is more effective and better tolerated than is ketoconazole. Unlike ketoconazole, it is not hepatotoxic and does not cause adrenal or testicular suppression in recommended therapeutic doses.¹⁴ Nonetheless, itraconazole can inhibit cytochrome P450 oxidases involved in drug and xenobiotic metabolism and is known to increase plasma levels of the antihistaminic drugs terfenadine and astemizole.

Fluconazole

α -(2,4-Difluorophenyl)- α -(1*H*-1,2,4-triazol-1-ylmethyl)-1*H*-1,2,4-triazole-1-ethanol or 2,4-difluoro- α , α -bis(1*H*-1,2,4-triazol-1-ylmethyl)benzyl alcohol (Diflucan) is a water-soluble bis-triazole with broad-spectrum antifungal properties that is suitable for both oral and intravenous administration as the free base. Intravenous solutions of fluconazole contain 2 mg of the free base in 1 mL of isotonic sodium chloride or 5% dextrose vehicle.

The oral bioavailability of fluconazole, following administration of either tablet or oral suspension dosage forms, is excellent. Apparently, the presence of two weakly basic triazole rings in the molecule confers sufficient aqueous solubility to balance the lipophilicity of the 2,4-difluorophenyl group. The oral absorption of fluconazole, in contrast to the oral absorption of ketoconazole or itraconazole, is not affected by alteration in gastrointestinal acidity or the presence of food.

Fluconazole has a relatively long elimination half-life, ranging from 27 to 34 hours. It penetrates well into all body cavities, including the CSF. Plasma protein binding of fluconazole is less than 10%; the drug is efficiently removed from the blood by hemodialysis. Fluconazole experiences little or no hepatic metabolism and is excreted substantially unchanged in the urine. A small amount of unchanged fluconazole (~10%) is excreted in the feces. Side effects of fluconazole are largely confined to minor gastrointestinal symptoms. Inhibition of cytochrome P450 oxidases by fluconazole can give rise to clinically significant interactions involving increased plasma levels of cyclosporine, phenytoin, and the oral hypoglycemic drugs (tolbutamide, glipizide, and glyburide). Fluconazole does not appear to interfere with corticosteroid or androgen biosynthesis in dosages used to treat systemic fungal infections.

Fluconazole is recommended for the treatment and prophylaxis of disseminated and deep organ candidiasis. It is also used to control esophageal and oropharyngeal candidiasis. Because of its efficient penetration into CSF, fluconazole is an agent of choice for the treatment of cryptococcal meningitis and for prophylaxis against cryptococcosis in AIDS patients. Although fluconazole is generally less effective than either ketoconazole or itraconazole against nonmeningeal coccidioidomycosis, it is preferred therapy for coccidioid meningitis. Fluconazole lends itself to one-dose therapies for vaginal candidiasis.

NEWER ANTIFUNGAL STRATEGIES

A newer azole is voriconazole.⁵⁰

Unlike fluconazole, voriconazole has potent activity against a broad variety of fungi, including the clinically important pathogens. Several publications have substantiated the use of voriconazole against some of the newer and rarer fungal pathogens. Voriconazole is more potent than itraconazole against *Aspergillus* spp. and is comparable to posaconazole,⁵⁰ another azole that is in clinical trials, in its activity against *C. albicans*. In general, *Candida* spp. that are less susceptible to fluconazole possess higher MICs to voriconazole. The in vitro activity of posaconazole appears to be similar to that of voriconazole. Posaconazole is now in phase III clinical trials, and evidence of the efficacy of posaconazole against various fungal models, especially the rarer ones, continues to accumulate. Posaconazole exhibits high oral bioavailability, but its low water solubility makes its formulation into an intravenous solution impossible.

A search for potential prodrug forms of posaconazole has yielded a possible candidate, SCH 59884. The compound is inactive in vitro but is dephosphorylated in vivo to yield the active 4-hydroxybutyrate ester. This compound is hydrolyzed to the parent compound in the serum. Posaconazole undergoes extensive enterohepatic recycling, and most of the dose is eliminated in the bile and feces.

Syn2869 is a novel broad-spectrum compound that contains the piperazine-phenyl-triazolone side chain common to itraconazole and posaconazole, and it displays potency and an antifungal spectrum similar to those of the latter. Syn2869 demonstrates better activity than itraconazole in animal models of *C. albicans*, *C. glabrata*, and *C. neoformans*. The oral bioavailability (F) is 60%, and higher

tissue-to-serum ratios than those found for itraconazole were claimed to contribute to the greater efficacy of the compound in a model of invasive pulmonary aspergillosis. Syn2869 also demonstrates considerable activity against the common mold pathogens.

ECHINOCANADINS AND PNEUMOCANADINS

Echinocanadins⁵¹ and the closely related pneumocanadins⁵² are natural products that were discovered in the 1970s. They act as noncompetitive inhibitors of (1,3)- β -*D*-glucan synthase,⁵³ an enzyme complex that forms stabilizing glucan polymers in the fungal cell wall. Three water-soluble derivatives of the echinocanadins and pneumocanadins are in end-stage clinical development but have not yet been marketed.

LY 303366 is a pentyloxyterphenyl side chain derivative of echinocandin B that was discovered at Eli Lilly. It was licensed for parenteral use in 2000. Studies have shown that the MICs of LY 303366 against *Candida* spp. range from 0.08 to 5.12 μ g/mL, and similar activity was obtained against *Aspergillus* spp. Studies show highly potent activity of the compound in animal models of disseminated candidiasis, pulmonary aspergillosis, and esophageal candidiasis.

AUREOBASIDINS⁵⁴

Aureobasidin A is a cyclic depsipeptide that is produced by fermentation in cultures of *Aureobasidium pullulan*. Aureobasidin A acts as a tight-binding noncompetitive inhibitor of the enzyme inositol phosphorylceramide synthase (IPC synthase⁵⁵), which is an essential enzyme for fungal sphingolipid biosynthesis. A unique structural feature of the aureobasidins is the *N*-methylation of four of seven amide nitrogen atoms. The lack of tautomerism dictated by *N*-methylation may contribute to forming a stable solution conformer that is shaped somewhat like an arrowhead, the presumed biologically active conformation of aureobasidin-A.

The pradimycins and benanomycins are naphthacenequinones that bind mannan in the presence of Ca^{2+} to disrupt the cell membrane in pathogenic fungi. Both

demonstrate good in vitro and in vivo activity against *Candida* spp. and *C. neoformans* clinical isolates.

SYNTHETIC ANTIBACTERIAL AGENTS

Several organic compounds obtained by chemical synthesis on the basis of model compounds have useful antibacterial activity for the treatment of local, systemic, and/or urinary tract infections. Some chemical classes of synthetic antibacterial agents include the sulfonamides, certain nitroheterocyclic compounds (e.g., nitrofurans, metronidazole), and the quinolones. Some antibacterial agents that fail to achieve adequate concentrations in the plasma or tissues for the treatment of systemic infections following oral or parenteral administration are concentrated in the urine, where they can be effective for eradicating urinary tract infections. Nitrofurantoin (a nitrofuran), nalidixic acid (a quinolone), and methenamine are examples of such urinary tract anti-infectives.

Quinolones

The quinolones comprise a series of synthetic antibacterial agents patterned after nalidixic acid, a naphthyridine derivative introduced for the treatment of urinary tract infections in 1963. Isosteric heterocyclic groupings in this class include the quinolones (e.g., norfloxacin, ciprofloxacin, lomefloxacin), the naphthyridines (e.g., nalidixic acid, enoxacin), and the cinnolines (e.g., cinoxacin). Up to the present time, the clinical usefulness of the quinolones has been largely confined to the treatment of urinary tract infections. For urinary tract infections, good oral absorption, activity against common Gram-negative urinary pathogens, and comparatively higher urinary (compared with plasma and tissue) concentrations are the key useful properties. As a result of extensive structure-activity investigations leading to compounds with enhanced potency, extended spectrum of activity, and improved absorption and distribution properties, the class has evolved to the point that certain newer members

Aureobasidin A

Pradimycin A

Benanomycin A

are useful for the treatment of various serious systemic infections. In fact, these more potent analogs are sometimes classified separately (from the urinary tract-specific agents) as the fluoroquinolones, because all members of the group have a 6-fluoro substituent in common.

Structure–activity studies have shown that the 1,4-dihydro-4-oxo-3-pyridinecarboxylic acid moiety is essential for antibacterial activity. The pyridone system must be annulated with an aromatic ring. Isosteric replacements of nitrogen for carbon atoms at positions 2 (cinnolines), 5 (1,5-naphthyridines), 6 (1,6-naphthyridines), and 8 (1,8-naphthyridines) are consistent with retention of antibacterial activity. Although the introduction of substituents at position 2 greatly reduces or abolishes activity, positions 5, 6, 7 (especially), and 8 of the annulated ring may be substituted with good effects. For example, piperazinyl and 3-aminopyrrolidinyl substitutions at position 7 have been shown to convey enhanced activity on members of the quinolone class against *P. aeruginosa*. Fluorine atom substitution at position 6 is also associated with significantly enhanced antibacterial activity. Alkyl substitution at the 1-position is essential for activity, with lower alkyl (methyl, ethyl, cyclopropyl) compounds generally having progressively greater potency. Aryl substitution at the 1-position is also consistent with antibacterial activity, with a 2,4-difluorophenyl group providing optimal potency. Ring condensations at the 1,8-, 5,6-, 6,7-, and 7,8-positions also lead to active compounds.

The effective antibacterial spectrum of nalidixic acid and the earliest members of the quinolone class (e.g., oxolinic acid, cinoxacin) are largely confined to Gram-negative bacteria, including common urinary pathogens such as *Escherichia coli*, *Klebsiella*, *Enterobacter*, *Citrobacter*, and *Proteus* spp. *Shigella*, *Salmonella*, and *Providencia* are also susceptible. Strains of *P. aeruginosa*, *Neisseria gonorrhoeae*, and *Haemophilus influenzae* are resistant, as are the Gram-positive cocci and anaerobes. Newer members of the class possessing 6-fluoro and 7-piperazinyl substituents exhibit an extended spectrum of activity that includes effectiveness against additional Gram-negative pathogens (e.g., *P. aeruginosa*, *H. influenzae*, *N. gonorrhoeae*), Gram-positive cocci (e.g., *S. aureus*), and some streptococci. The quinolones generally exhibit poor activity against most anaerobic bacteria, including most *Bacteroides* and *Clostridium* species. In many cases, bacterial strains that have developed resistance to the antibacterial antibiotics, such as penicillin-resistant gonococci, methicillin-resistant *S. aureus*, and aminoglycoside-resistant *P. aeruginosa* are susceptible to the quinolones.

The bactericidal action of nalidixic acid and its congeners is known to result from the inhibition of DNA synthesis. This effect is believed to be caused by the inhibition of bacterial DNA gyrase (topoisomerase II), an enzyme responsible for introducing negative supercoils into circular duplex DNA.⁵⁶ Negative supercoiling relieves the torsional stress of helical DNA, facilitates unwinding, and, thereby, allows transcription and replication to occur. Although nalidixic acid inhibits gyrase activity, it binds only to single-stranded DNA and not to either the enzyme or double-helical DNA.⁵⁶ Bacterial DNA gyrase is a tetrameric enzyme consisting of two A and two B subunits, encoded by the *gyrA* and *gyrB* genes. Bacterial strains resistant to the quinolones have been identified, with decreased binding affinity to the enzyme because of amino acid substitution in either A or B subunits resulting from mutations in either *gyrA*⁵⁷ or *gyrB*⁵⁸ genes.

The highly polar quinolones are believed to enter bacterial cells through densely charged porin channels in the outer bacterial membrane. Mutations leading to altered porin proteins can lead to decreased uptake of quinolones and cause resistance.⁵⁹ Also, there is evidence for energy-dependent efflux of quinolones by some bacterial species. A quantitative structure–activity relationship (QSAR) study of bacterial cellular uptake of a series of quinolones⁶⁰ revealed an inverse relationship of uptake versus log *P* (a measure of lipophilicity) for Gram-negative bacteria, on the one hand, but a positive correlation of quinolone uptake to log *P* in Gram-positive bacteria, on the other. This result probably reflects the observed differences in outer envelope structures of Gram-negative and Gram-positive bacteria.⁶¹

The incidence (relatively low, <1%) of CNS effects associated with the quinolones (e.g., irritability, tremor, sleep disorders, vertigo, anxiety, agitation, convulsions) has been attributed to antagonism of γ -aminobutyric acid (GABA) receptors in the brain by the quinolones. Only fluoroquinolones having a 1-piperidino, a 3-amino-1-pyrrolidino, or similar basic moiety at the 7-position appear to have this property.⁶¹ The low incidence of CNS effects for most quinolones is apparently because of their inability to penetrate the blood-brain barrier.

Another property of the quinolone class is phototoxicity, extreme sensitivity to sunlight. Quinolones possessing a halogen atom at the 8-position (e.g., lomefloxacin) have the highest incidence of phototoxicity, whereas those having an amino (e.g., sparfloxacin) or methoxy group at either the 5- or 8-position have the lowest incidence.⁶¹

The antibacterial quinolones can be divided into two classes on the basis of their dissociation properties in physiologically relevant conditions. The first class, represented by nalidixic acid, oxolinic acid (no longer marketed in the United States), and cinoxacin, possesses only the 3-carboxylic acid group as an ionizable functionality. The p*K*_a values for the 3-carboxyl group in nalidixic acid and other quinolone antibacterial drugs fall in the range of 5.6 to 6.4 (Table 6.6).⁶² These comparatively high p*K*_a values relative to the p*K*_a of 4.2 for benzoic acid are attributed to the acid-weakening effect of hydrogen bonding of the 3-carboxyl group to the adjacent 4-carbonyl group.⁶²

The second class of antibacterial quinolones embraces the broad-spectrum fluoroquinolones (namely, norfloxacin, enoxacin, ciprofloxacin, ofloxacin, lomefloxacin, and sparfloxacin), all of which possess, in addition to the 3-carboxylic acid group, a basic piperazino functionality at the 7-position and a 6-fluoro substituent. The p*K*_a values for the

TABLE 6.6 Dissociation and Isoelectric Constants for Antibacterial Quinolones

Ciprofloxacin	6.08	8.73	7.42	444
Ofloxacin	5.88	8.06	6.97	146
Lomefloxacin	5.65	9.04	7.35	3,018

Data are taken from Ross, D. L., and Riley, C. M.: *J. Pharm. Biomed. Anal.* 12: 1325, 1994.

^aEach value represents an average of literature values.

more basic nitrogen atom of the piperazino group fall in the range of 8.1 to 9.3 (Table 6.6).⁶² At most physiologically relevant pH values, significant dissociation of both the 3-carboxylic acid and the basic 7-(1-piperazino) groups occurs, leading to significant fractions of zwitterionic species. As an example, the dissociation equilibria for norfloxacin are illustrated in Figure 6.6.^{62,63}

The tendency for certain fluoroquinolones (e.g., norfloxacin, ciprofloxacin) in high doses to cause crystalluria in alkaline urine is, in part, caused by the predominance of the comparatively less soluble zwitterionic form. Solubility data presented for ofloxacin in the 15th edition of the *USP* dramatically illustrate the effect of pH on water solubility of compounds of the fluoroquinolone class. Thus, the solubility of ofloxacin in water is 60 mg/mL at pH values ranging from 2 to 5, falls to 4 mg/mL at pH 7 (near the isoelectric point, pI), and rises to 303 mg/mL at pH 9.8.

The excellent chelating properties of the quinolones provide the basis for their incompatibility with antacids,

hematinics, and mineral supplements containing divalent or trivalent metals. The quinolones may form 1:1, 2:1, or 3:1 chelates with metal ions such as Ca^{+2} , Mg^{+2} , Zn^{+2} , Fe^{+2} , Fe^{+3} , and Bi^{+3} . The stoichiometry of the chelate formed depends on various factors, such as the relative concentrations of chelating agent (quinolone) and metal ion present, the valence (or charge) on the metal ion, and the pH. Since such chelates are often insoluble in water, coincidental oral administration of a quinolone with an antacid, a hematinic, or a mineral supplement can significantly reduce the oral bioavailability of the quinolone. As an example, the insoluble 2:1 chelate formed between ciprofloxacin and magnesium ion is shown in Figure 6.7. The presence of divalent ions (such as Mg^{+2}) in the urine may also contribute to the comparatively lower solubility of certain fluoroquinolones in urine than in plasma.

Nalidixic Acid

1-Ethyl-1,4-dihydro-7-methyl-4-oxo-1,8-naphthyridine-3-carboxylic acid (NegGram) occurs as a pale buff crystalline

Figure 6.6 • Ionization equilibria in the quinolone antibacterial drugs.

Figure 6.7 • A 2:1 chelate of a Mg^{2+} ion by ciprofloxacin.

powder that is sparingly soluble in water and ether but soluble in most polar organic solvents.

Nalidixic acid is useful in the treatment of urinary tract infections in which Gram-negative bacteria predominate. The activity against indole-positive *Proteus* spp. is particularly noteworthy, and nalidixic acid and its congeners represent important alternatives for the treatment of urinary tract infections caused by strains of these bacteria resistant to other agents. Nalidixic acid is rapidly absorbed, extensively metabolized, and rapidly excreted after oral administration. The 7-hydroxymethyl metabolite is significantly more active than the parent compound. Further metabolism of the active metabolite to inactive glucuronide and 7-carboxylic acid metabolites also occurs. Nalidixic acid possesses a $t_{1/2elim}$ of 6 to 7 hours. It is eliminated, in part, unchanged in the urine and 80% as metabolites.

Cinoxacin

1-Ethyl-1,4-dihydro-4-oxo[1,3]dioxolo[4,5g]cinnoline-3-carboxylic acid (Cinobac) is a close congener (isostere) of oxolinic acid (no longer marketed in the United States) and has antibacterial properties similar to those of nalidixic and oxolinic acids.

It is recommended for the treatment of urinary tract infections caused by strains of Gram-negative bacteria susceptible to these agents. Early clinical studies indicate that the drug possesses pharmacokinetic properties superior to those of either of its predecessors. Thus, following oral administration, higher urinary concentrations of cinoxacin than of nalidixic acid or oxolinic acid are achieved. Cinoxacin appears to be more completely absorbed and less protein bound than nalidixic acid.

Norfloxacin

1-Ethyl-6-fluoro-1,4-dihydro-4-oxo-7-(1-piperazinyl)-3-quinolinecarboxylic acid (Noroxin) is a pale yellow crystalline powder that is sparingly soluble in water. This quinoline has broad-spectrum activity against Gram-negative and Gram-positive aerobic bacteria. The fluorine atom provides increased potency against Gram-positive organisms, whereas the piperazine moiety improves antipseudomonal activity. Norfloxacin is indicated for the treatment of urinary tract infections caused by *E. coli*, *K. pneumoniae*, *Enterobacter cloacae*, *Proteus mirabilis*, indole-positive *Proteus* spp., including *P. vulgaris*, *Providencia rettgeri*, *Morganella morganii*, *P. aeruginosa*, *S. aureus*, and *S. epidermidis*, and group-D streptococci. It is generally not effective against obligate anaerobic bacteria. Norfloxacin in a single 800-mg oral dose has also been approved for the treatment of uncomplicated gonorrhea. The oral absorption of norfloxacin is about 40%. The drug is 15% protein bound and is metabolized in the liver. The $t_{1/2elim}$ is 4 to 8 hours. Approximately 30% of a dose is eliminated in the urine and feces.

The oral absorption of norfloxacin is rapid and reasonably efficient. Approximately 30% of an oral dose is excreted in the urine in 24 hours, along with 5% to 8% consisting of less active metabolites. There is significant biliary excretion, with about 30% of the original drug appearing in the feces.

Enoxacin

1-Ethyl-6-fluoro-1,4-dihydro-4-oxo-7-(1-piperazinyl)-1,8-naphthyridine-3-carboxylic acid (Penetrex) is a quinolone with broad-spectrum antibacterial activity that is used primarily for the treatment of urinary tract infections and sexually transmitted diseases. Enoxacin has been approved for the treatment of uncomplicated gonococcal urethritis and has also been shown to be effective in chancroid caused by *Haemophilus ducreyi*. A single 400-mg dose is used for these indications. Enoxacin is also approved for the treatment of acute (uncomplicated) and chronic (complicated) urinary tract infections.

Enoxacin is well absorbed following oral administration. Oral bioavailability approaches 98%. Concentrations of the drug in the kidneys, prostate, cervix, fallopian tubes, and myometrium typically exceed those in the plasma. More than 50% of the unchanged drug is excreted in the urine. Metabolism, largely catalyzed by cytochrome P450 enzymes in the liver, accounts for 15% to 20% of the orally administered dose of enoxacin. The relatively short elimination half-life of enoxacin dictates twice-a-day dosing for the treatment of urinary tract infections.

Some cytochrome P450 isozymes, such as CYP 1A2, are inhibited by enoxacin, resulting in potentially important interactions with other drugs. For example, enoxacin has been reported to decrease theophylline clearance, causing increased plasma levels and increased toxicity. Enoxacin forms insoluble chelates with divalent metal ions present in antacids and hematinics, which reduce its oral bioavailability.

Ciprofloxacin

1-Cyclopropyl-6-fluoro-1,4-dihydro-4-oxo-7-(1-piperazinyl)-3-quinolinecarboxylic acid (Cipro, Cipro IV) is supplied in both oral and parenteral dosage forms. The hydrochloride salt is available in 250-, 500-, and 750-mg tablets for oral administration. Intravenous solutions containing 200 mg and 400 mg are provided in concentrations of 0.2% in normal saline and 1% in 5% dextrose solutions.

The bioavailability of ciprofloxacin following oral administration is good, with 70% to 80% of an oral dose being absorbed. Food delays, but does not prevent, absorption. Significant amounts (20%–35%) of orally administered ciprofloxacin are excreted in the feces, in part because of biliary excretion. Biotransformation to less active metabolites accounts for about 15% of the administered drug. Approximately 40% to 50% of unchanged ciprofloxacin is excreted in the urine following oral administration. This value increases to 50% to 70% when the drug is injected intravenously. Somewhat paradoxically, the elimination half-life of ciprofloxacin is shorter following oral administration ($t_{1/2}$, 4 hours) than it is following intravenous administration ($t_{1/2}$, 5–6 hours). Ciprofloxacin inhibits the P450 species CYP 1A2.

The oral dose of this quinolone is typically 25% higher than the parenteral dose for a given indication. Probenecid significantly reduces the renal clearance of ciprofloxacin, presumably by inhibiting its active tubular secretion. Ciprofloxacin is widely distributed to virtually all parts of the body, including the CSF, and is generally considered to provide the best distribution of the currently marketed quinolones. This property, together with the potency and broad antibacterial spectrum of ciprofloxacin, accounts for the numerous therapeutic indications for the drug. Ciprofloxacin also exhibits higher potency against most Gram-negative bacterial species, including *P. aeruginosa*, than other quinolones.

Ciprofloxacin is an agent of choice for the treatment of bacterial gastroenteritis caused by Gram-negative bacilli such as enteropathogenic *E. coli*, *Salmonella* spp. (including *S. typhi*), *Shigella* spp., *Vibrio* spp., and *Aeromonas hydrophilia*. It is widely used for the treatment of respiratory tract infections and is particularly effective for controlling bronchitis and pneumonia caused by Gram-negative bacteria. Ciprofloxacin is also used for combating infections of the skin, soft tissues, bones, and joints. Both uncomplicated and complicated urinary tract infections caused by Gram-negative bacteria can be treated effectively with ciprofloxacin. It is particularly useful for the control of chronic infections characterized by renal tissue involvement. The drug also has important applications in controlling venereal diseases. A combination of ciprofloxacin with the cephalosporin antibiotic ceftriaxone is recommended as the treatment of choice for disseminated gonorrhea, whereas a single-dose treatment with ciprofloxacin plus doxycycline, a tetracycline antibiotic (Chapter 8), can usually eradicate gonococcal urethritis. Ciprofloxacin has also been used for chancroid. The drug has been approved for postexposure treatment of inhalational anthrax.

Injectable forms of ciprofloxacin are incompatible with drug solutions that are alkaline because of the reduced solubility of the drug at pH 7. Thus, intravenous solutions should not be mixed with solutions of ticarcillin sodium, mezlocillin sodium, or aminophylline. Ciprofloxacin may also induce crystalluria under the unusual circumstance that urinary pH rises above 7 (e.g., with the use of systemic alkalinizers or a carbonic anhydrase inhibitor or through the action of urease elaborated by certain species of Gram-negative bacilli).

Ofloxacin

9-Fluoro-2,3-dihydro-3-methyl-10(4-methyl-1-piperazin-yl)-7-oxo-7H-pyrido[1,2,3-de]-1,4-benzoxazine-6-carboxylic acid (Floxin, Floxin IV) is a member of the quinolone class of

antibacterial drugs wherein the 1- and 8-positions are joined in the form of a 1,4-oxazine ring.

Ofloxacin resembles ciprofloxacin in its antibacterial spectrum and potency. Like ciprofloxacin, this quinolone is also widely distributed into most body fluids and tissues. In fact, higher concentrations of ofloxacin are achieved in CSF than can be obtained with ciprofloxacin. The oral bioavailability of ofloxacin is superior (95%–100%) to that of ciprofloxacin, and metabolism is negligible (~3%). The amount of an administered dose of ofloxacin excreted in the urine in a 24- to 48-hour period ranges from 70% to 90%. There is relatively little biliary excretion of this quinolone. Although food can slow the oral absorption of ofloxacin, blood levels following oral or intravenous administration are comparable. The elimination half-life of ofloxacin ranges from 4.5 to 7 hours.

Ofloxacin has been approved for the treatment of infections of the lower respiratory tract, including chronic bronchitis and pneumonia, caused by Gram-negative bacilli. It is also used for the treatment of pelvic inflammatory disease and is highly active against both gonococci and chlamydia. In common with other fluoroquinolones, ofloxacin is not effective in the treatment of syphilis. A single 400-mg oral dose of ofloxacin in combination with the tetracycline antibiotic doxycycline is recommended by the Centers for Disease Control and Prevention (CDC) for the outpatient treatment of acute gonococcal urethritis. Ofloxacin is also used for the treatment of urinary tract infections caused by Gram-negative bacilli and for prostatitis caused by *E. coli*. Infections of the skin and soft tissues caused by staphylococci, streptococci, and Gram-negative bacilli may also be treated with ofloxacin.

Because ofloxacin has an asymmetric carbon atom in its structure, it is obtained and supplied commercially as a racemate. The racemic mixture has been resolved, and the enantiomers independently synthesized and evaluated for antibacterial activity.⁶⁴ The 3*S*(–) isomer is substantially more active (8–125 times, depending on the bacterial species) than the 3*R*(+) isomer and has recently been marketed as levofloxacin (Levaquin) for the same indications as the racemate.

Lomefloxacin

1-Ethyl-6,8-difluoro-1,4-dihydro-7-(3-methyl-1-piperazinyl)-4-oxo-3-quinolinecarboxylic acid (Maxaquin) is a difluorinated quinolone with a longer elimination half-life (7–8 hours) than other members of its class. It is the only quinolone for which once-daily oral dosing suffices. The oral bioavailability of lomefloxacin is estimated to be 95% to 98%. Food slows, but does not prevent, its oral absorption. The extent of biotransformation of lomefloxacin is only about 5%, and high concentrations of unchanged drug, ranging from 60% to 80%, are excreted in the urine. The comparatively long half-life of lomefloxacin is apparently because of its excellent tissue distribution and renal reabsorption and not

because of plasma protein binding (only ~10%) or enterohepatic recycling (biliary excretion is estimated to be ~10%).

Lomefloxacin has been approved for two primary indications. First, it is indicated for acute bacterial exacerbations of chronic bronchitis caused by *H. influenzae* or *Moraxella (Branhamella) catarrhalis*, but not if *Streptococcus pneumoniae* is the causative organism. Second, it is used for prophylaxis of infection following transurethral surgery. Lomefloxacin also finds application in the treatment of acute cystitis and chronic urinary tract infections caused by Gram-negative bacilli.

Lomefloxacin reportedly causes the highest incidence of phototoxicity (photosensitivity) of the currently available quinolones. The presence of a halogen atom (fluorine, in this case) at the 8-position has been correlated with an increased chance of phototoxicity in the quinolones.⁴⁰

Sparfloxacin

Sparfloxacin, (*cis*)-5-amino-1-cyclopropyl-7-(3,5-dimethyl-1-piperazinyl)-6,8-difluoro-1,4-dihydro-4-oxo-3-quinolinecarboxylic acid, is a newer fluoroquinolone.

This compound exhibits higher potency against Gram-positive bacteria, especially staphylococci and streptococci, than the fluoroquinolones currently marketed. It is also more active against chlamydia and the anaerobe *Bacteroides fragilis*. The activity of sparfloxacin against Gram-negative bacteria is also very impressive, and it compares favorably with ciprofloxacin and ofloxacin in potency against *Mycoplasma* spp., *Legionella* spp., *Mycobacteria* spp., and *Listeria monocytogenes*. Sparfloxacin has a long elimination half-life of 18 hours, which permits once-a-day dosing for most indications. The drug is widely distributed into most fluids and tissues. Effective concentrations of sparfloxacin are achieved for the treatment of skin and soft tissue infections, lower respiratory infections (including bronchitis and bacterial pneumonias), and pelvic inflammatory disease caused by gonorrhea and chlamydia. Sparfloxacin has also been recommended for the treatment of bacterial gastroenteritis and cholecystitis. The oral bioavailability of sparfloxacin is claimed to be good, and sufficient unchanged drug is excreted to be effective for the treatment of urinary tract infections. Nearly 20% of an orally administered dose is excreted as an inactive glucuronide.

The incidence of phototoxicity of sparfloxacin is the lowest of the fluoroquinolones, because of the presence of the 5-amino group, which counteracts the effect of the 8-fluoro substituent.

Levofloxacin

Nitrofurans

The first nitroheterocyclic compounds to be introduced into chemotherapy were the nitrofurans. Three of these compounds—nitrofurazone, furazolidone, and nitrofurantoin—have been used for the treatment of bacterial infections of various kinds for nearly 50 years. A fourth nitrofuran, nifurtimox, is used as an antiprotozoal agent to treat trypanosomiasis and leishmaniasis. Another nitroheterocyclic of considerable importance is metronidazole, which is an amebicide (a trichomonicide) and is used for the treatment of systemic infections caused by anaerobic bacteria. This important drug is discussed later in this chapter.

The nitrofurans are derivatives of 5-nitro-2-furaldehyde, formed on reaction with the appropriate hydrazine or amine derivative. Antimicrobial activity is present only when the nitro group is in the 5-position.

Nitrofurazone R=

Furazolidone R=

Nitrofurantoin R=

The mechanism of antimicrobial action of the nitrofurans has been extensively studied, but it still is not fully understood. In addition to their antimicrobial actions, the nitrofurans are known to be mutagenic and carcinogenic under certain conditions. It is thought that DNA damage caused by metabolic reaction products may be involved in these cellular effects.

Nitrofurazone

5-Nitro-2-furaldehyde semicarbazone (Furacin) occurs as a lemon-yellow crystalline solid that is sparingly soluble in water and practically insoluble in organic solvents. Nitrofurazone is chemically stable, but moderately light sensitive.

It is used topically in the treatment of burns, especially when bacterial resistance to other agents may be a concern. It may also be used to prevent bacterial infection associated with skin grafts. Nitrofurazone has a broad spectrum of activity against Gram-positive and Gram-negative bacteria, but it is not active against fungi. It is bactericidal against most bacteria commonly causing surface infections, including *S. aureus*, *Streptococcus* spp., *E. coli*, *Clostridium perfringens*, *Enterobacter (Aerobacter) aerogenes*, and *Proteus* spp.; however, *P. aeruginosa* strains are resistant.

Nitrofurazone is marketed in solutions, ointments, and suppositories in a usual concentration of 0.2%.

Furazolidone

3-[(5-Nitrofurylidene)amino]-2-oxazolidinone (Furoxone) occurs as a yellow crystalline powder with a bitter after-taste. It is insoluble in water or alcohol. Furazolidone has bactericidal activity against a relatively broad range of intestinal pathogens, including *S. aureus*, *E. coli*, *Salmonella*, *Shigella*, *Proteus* spp., *Enterobacter*, and *Vibrio cholerae*. It is also active against the protozoan *Giardia lamblia*. It is recommended for the oral treatment of bacterial or protozoal diarrhea caused by susceptible organisms. The usual adult dosage is 100 mg 4 times daily.

Only a small fraction of an orally administered dose of furazolidone is absorbed. Approximately 5% of the oral dose is detectable in the urine in the form of several metabolites. Some gastrointestinal distress has been reported with its use. Alcohol should be avoided when furazolidone is being used because the drug can inhibit aldehyde dehydrogenase.

Nitrofurantoin

Nitrofurantoin, 1-(5-nitro-2-furfurylidene)-1-aminohydantoin (Furadantin, Macrofantin), is a nitrofuran derivative that is suitable for oral use. It is recommended for the treatment of urinary tract infections caused by susceptible strains of *E. coli*, enterococci, *S. aureus*, *Klebsiella*, *Enterobacter*, and *Proteus* spp. The most common side effects are gastrointestinal (anorexia, nausea, and vomiting); however, hypersensitivity reactions (pneumonitis, rashes, hepatitis, and hemolytic anemia) have occasionally been observed. A macrocrystalline form (Macrofantin) is claimed to improve

gastrointestinal tolerance without interfering with oral absorption.

Methenamine and Its Salts

Methenamine

The activity of hexamethylenetetramine (Urotropin, Uritone) depends on the liberation of formaldehyde. The compound is prepared by evaporating a solution of formaldehyde and strong ammonia water to dryness.

The free base exists as an odorless, white crystalline powder that sublimes at about 260°C. It dissolves in water to form an alkaline solution and liberates formaldehyde when warmed with mineral acids. Methenamine is a weak base with a pK_a of 4.9.

Methenamine is used internally as a urinary antiseptic for the treatment of chronic urinary tract infections. The free base has practically no bacteriostatic power; formaldehyde release at the lower pH of the kidney is required. To optimize the antibacterial effect, an acidifying agent such as sodium biphosphate or ammonium chloride generally accompanies the administration of methenamine.

Certain bacterial strains are resistant to the action of methenamine because they elaborate urease, an enzyme that hydrolyzes urea to form ammonia. The resultant high urinary pH prevents the activation of methenamine, rendering it ineffective. This problem can be overcome by the coadministration of the urease inhibitor acetohydroxamic acid (Lithostat).

Methenamine Mandelate

Hexamethylenetetramine mandelate (Mandelamine) is a white crystalline powder with a sour taste and practically no odor. It is very soluble in water and has the advantage of providing its own acidity, although in its use, the custom is to carry out a preliminary acidification of the urine for 24 to 36 hours before administration.

Methenamine Hippurate

Methenamine hippurate (Hiprex) is the hippuric acid salt of methenamine. It is readily absorbed after oral administration and is concentrated in the urinary bladder, where it exerts its antibacterial activity. Its activity is increased in acid urine.

Urinary Analgesics

Pain and discomfort frequently accompany bacterial infections of the urinary tract. For this reason, certain analgesic agents, such as the salicylates or phenazopyridine, which concentrate in the urine because of their solubility properties, are combined with a urinary anti-infective agent.

Phenazopyridine Hydrochloride

Cl^-

Phenazopyridine hydrochloride, 2,6-diamino-3-(phenylazopyridine hydrochloride (Pyridium), is a brick-red, fine crystalline powder. It is slightly soluble in alcohol, in chloroform, and in water.

Phenazopyridine hydrochloride was formerly used as a urinary antiseptic. Although it is active in vitro against staphylococci, streptococci, gonococci, and *E. coli*, it has no useful antibacterial activity in the urine. Thus, its present utility lies in its local analgesic effect on the mucosa of the urinary tract.

Usually, phenazopyridine is given in combination with urinary antiseptics. For example, it is available as Azogantisin, a fixed-dose combination with the sulfonamide antibacterial sulfisoxazole, and as Urobiotic, a combination with the antibiotic oxytetracycline and the sulfonamide sulfamethizole (Chapter 8). The drug is rapidly excreted in the urine, to which it gives an orange-red color. Stains in fabrics may be removed by soaking in a 0.25% solution of sodium dithionite.

Antitubercular Agents

Ever since Koch identified the tubercle bacillus, *Mycobacterium tuberculosis*, there has been keen interest in the development of antitubercular drugs. The first breakthrough in antitubercular chemotherapy occurred in 1938 with the

observation that sulfanilamide had weak bacteriostatic properties. Later, the sulfone derivative dapsone (4,4'-diaminodiphenylsulfone) was investigated clinically. Unfortunately, this drug, which is still considered one of the most effective drugs for the treatment of leprosy and also has useful antimalarial properties, was considered too toxic because of the high dosages used. The discovery of the antitubercular activity of the aminoglycoside antibiotic streptomycin by Waksman et al. in 1944 ushered in the modern era of tuberculosis treatment. This development was quickly followed by discoveries of the antitubercular properties of *p*-aminosalicylic acid (PAS) first and then, in 1952, of isoniazid. Later, the usefulness of the synthetic drug ethambutol and, eventually, of the semisynthetic antibiotic rifampin was discovered.

Combination therapy, with the use of two or more antitubercular drugs, has been well documented to reduce the emergence of strains of *M. tuberculosis* resistant to individual agents and has become standard medical practice. The choice of antitubercular combination depends on various factors, including the location of the disease (pulmonary, urogenital, gastrointestinal, or neural), the results of susceptibility tests and the pattern of resistance in the locality, the physical condition and age of the patient, and the toxicities of the individual agents. For some time, a combination of isoniazid and ethambutol, with or without streptomycin, was the preferred choice of treatment among clinicians in this country. However, the discovery of the tuberculocidal properties of rifampin resulted in its replacement of the more toxic antibiotic streptomycin in most regimens. The synthetic drug pyrazinamide, because of its sterilizing ability, is also considered a first-line agent and is frequently used in place of ethambutol in combination therapy. Second-line agents for tuberculosis include the antibiotics cycloserine, kanamycin, and capreomycin and the synthetic compounds ethionamide and PAS.

A major advance in the treatment of tuberculosis was signaled by the introduction of the antibiotic rifampin into therapy. Clinical studies indicated that when rifampin is included in the regimen, particularly in combination with isoniazid and ethambutol (or pyrazinamide), the period required for successful therapy is shortened significantly. Previous treatment schedules without rifampin required maintenance therapy for at least 2 years, whereas those based on the isoniazid–rifampin combination achieved equal or better results in 6 to 9 months.

Once considered to be on the verge of worldwide eradication, as a result of aggressive public health measures and effective chemotherapy, tuberculosis has made a comeback of alarming proportions in recent years.⁶⁵ A combination of factors has contributed to the observed increase in tuberculosis cases, including the worldwide AIDS epidemic, the general relaxation of public health policies in many countries, the increased overcrowding and homelessness in major cities, and the increased emergence of multidrug-resistant strains of *M. tuberculosis*.

The development of drugs useful for the treatment of leprosy has long been hampered, in part, by the failure of the causative organism, *Mycobacterium leprae*, to grow in cell culture. However, the recent availability of animal models, such as the infected mouse footpad, now permits *in vivo* drug evaluations. The increasing emergence of strains of *M. leprae* resistant to dapsone, long considered the mainstay for leprosy treatment, has caused public health officials to advocate combination therapy.

Mycobacteria other than *M. tuberculosis* and *M. leprae*, commonly known as “atypical” mycobacteria, were first established as etiological agents of diseases in the 1950s. Atypical mycobacteria are primarily saprophytic species that are widely distributed in soil and water. Such organisms are not normally considered particularly virulent or infectious. Diseases attributed to atypical mycobacteria are on the increase, however, in large part because of the increased numbers of immunocompromised individuals in the population resulting from the AIDS epidemic and the widespread use of immunosuppressive agents with organ transplantation.

The most common disease-causing species are *Mycobacterium avium* and *Mycobacterium intracellulare*, which have similar geographical distributions, are difficult to distinguish microbiologically and diagnostically, and are thus considered a single complex (MAC). The initial disease attributed to MAC resembles tuberculosis, but skin and musculoskeletal tissues may also become involved. The association of MAC and HIV infection is dramatic. An overwhelming disseminated form of the disease occurs in severely immunocompromised patients, leading to high morbidity and mortality. Another relatively common atypical mycobacterium, *Mycobacterium kansasii*, also causes pulmonary disease and can become disseminated in immunocompromised patients. Patients infected with *M. kansasii* can usually be treated effectively with combinations of antitubercular drugs. MAC infections, in contrast, are resistant to currently available chemotherapeutic agents.

Isoniazid

Isonicotinic acid hydrazide, isonicotinyl hydrazide, or INH (Nydradid) occurs as a nearly colorless crystalline solid that is very soluble in water. It is prepared by reacting the methyl ester of isonicotinic acid with hydrazine.

Isoniazid is a remarkably effective agent and continues to be one of the primary drugs (along with rifampin, pyrazinamide, and ethambutol) for the treatment of tuberculosis. It is not, however, uniformly effective against all forms of the disease. The frequent emergence of strains of the tubercle bacillus resistant to isoniazid during therapy was seen as the major shortcoming of the drug. This problem has been largely, but not entirely, overcome with the use of combinations.

The activity of isoniazid is manifested on the growing tubercle bacilli and not on resting forms. Its action, which is considered bactericidal, is to cause the bacilli to lose lipid content by a mechanism that has not been fully elucidated. The most generally accepted theory suggests that the principal effect of isoniazid is to inhibit the synthesis of mycolic acids,^{66,67} high-molecular-weight, branched β -hydroxy fatty acids that constitute important components of the cell walls of mycobacteria.

A mycobacterial catalase–peroxidase enzyme complex is required for the bioactivation of isoniazid.⁶⁸ A reactive

species, generated through the action of these enzymes on the drug, is believed to attack a critical enzyme required for mycolic acid synthesis in mycobacteria.⁶⁹ Resistance to INH, estimated to range from 25% to 50% of clinical isolates of INH-resistant strains, is associated with loss of catalase and peroxidase activities, both of which are encoded by a single gene, *katG*.⁷⁰ The target for the action of INH has recently been identified as an enzyme that catalyzes the NADH-specific reduction of 2-*trans*-enoylacyl carrier protein, an essential step in fatty acid elongation.⁷¹ This enzyme is encoded by a specific gene, *inhA*, in *M. tuberculosis*.⁷² Approximately 20% to 25% of INH-resistant clinical isolates display mutations in the *inhA* gene, leading to altered proteins with apparently reduced affinity for the active form of the drug. Interestingly, such INH-resistant strains also display resistance to ethionamide, a structurally similar antitubercular drug.⁷² On the other hand, mycobacterial strains deficient in catalase–peroxidase activity are frequently susceptible to ethionamide.

Although treatment regimens generally require long-term administration of isoniazid, the incidence of toxic effects is remarkably low. The principal toxic reactions are peripheral neuritis, gastrointestinal disturbances (e.g., constipation, loss of appetite), and hepatotoxicity. Coadministration of pyridoxine is reported to prevent the symptoms of peripheral neuritis, suggesting that this adverse effect may result from antagonism of a coenzyme action of pyridoxal phosphate. Pyridoxine does not appear to interfere with the antitubercular effect of isoniazid. Severe hepatotoxicity rarely occurs with isoniazid alone; the incidence is much higher, however, when it is used in combination with rifampin.

Isoniazid is rapidly and almost completely absorbed following oral administration. It is widely distributed to all tissues and fluids within the body, including the CSF. Approximately 60% of an oral dose is excreted in the urine within 24 hours in the form of numerous metabolites as well as the unchanged drug. Although the metabolism of isoniazid is very complex, the principal path of inactivation involves acetylation of the primary hydrazine nitrogen. In addition to acetylisoniazid, the isonicotinyl hydrazones of pyruvic and α -ketoglutaric acids, isonicotinic acid, and isonicotinuric acid have been isolated as metabolites in humans.⁷³ The capacity to inactivate isoniazid by acetylation is an inherited characteristic in humans. Approximately half of persons in the population are fast acetylators (plasma half-life, 45–80 minutes), and the remainder slow acetylators (plasma half-life, 140–200 minutes).

Ethionamide

2-Ethylthioisonicotinamide (Trecator SC) occurs as a yellow crystalline material that is sparingly soluble in water. This nicotinamide has weak bacteriostatic activity *in vitro* but, because of its lipid solubility, is effective *in vivo*. In contrast to the isoniazid series, 2-substitution enhances activity in the thioisonicotinamide series.

Ethionamide is rapidly and completely absorbed following oral administration. It is widely distributed throughout the body and extensively metabolized to predominantly inactive forms that are excreted in the urine. Less than 1% of the parent drug appears in the urine.

Ethionamide is considered a secondary drug for the treatment of tuberculosis. It is used in the treatment of isoniazid-resistant tuberculosis or when the patient is intolerant to isoniazid and other drugs. Because of its low potency, the highest tolerated dose of ethionamide is usually recommended. Gastrointestinal intolerance is the most common side effect associated with its use. Visual disturbances and hepatotoxicity have also been reported.

Pyrazinamide

Pyrazinocarboxamide (PZA) occurs as a white crystalline powder that is sparingly soluble in water and slightly soluble in polar organic solvents. Its antitubercular properties were discovered as a result of an investigation of heterocyclic analogs of nicotinic acid, with which it is isosteric. Pyrazinamide has recently been elevated to first-line status in short-term tuberculosis treatment regimens because of its tuberculocidal activity and comparatively low short-term toxicity. Since pyrazinamide is not active against metabolically inactive tubercle bacilli, it is not considered suitable for long-term therapy. Potential hepatotoxicity also obviates long-term use of the drug. Pyrazinamide is maximally effective in the low pH environment that exists in macrophages (monocytes). Evidence suggests bioactivation of pyrazinamide to pyrazinoic acid by an amidase present in mycobacteria.⁷⁴

Because bacterial resistance to pyrazinamide develops rapidly, it should always be used in combination with other drugs. Cross-resistance between pyrazinamide and either isoniazid or ethionamide is relatively rare. The mechanism of action of pyrazinamide is not known. Despite its structural similarities to isoniazid and ethionamide, pyrazinamide apparently does not inhibit mycolic acid biosynthesis in mycobacteria.

Pyrazinamide is well absorbed orally and widely distributed throughout the body. The drug penetrates inflamed meninges and, therefore, is recommended for the treatment of tuberculous meningitis. Unchanged pyrazinamide, the corresponding carboxylic acid (pyrazinoic acid), and the 5-hydroxy metabolite are excreted in the urine. The elimination half-life ranges from 12 to 24 hours, which allows the drug to be administered on either once-daily or even twice-weekly dosing schedules. Pyrazinamide and its metabolites are reported to interfere with uric acid excretion. Therefore, the drug should be used with great caution in patients with hyperuricemia or gout.

Ethambutol

Ethambutol, (+)-2,2'-(ethylenediimino)-di-1-butanol dihydrochloride, or EMB (Myambutol), is a white crystalline powder freely soluble in water and slightly soluble in alcohol.

Ethambutol is active only against dividing mycobacteria. It has no effect on encapsulated or other nonproliferating forms. The *in vitro* effect may be bacteriostatic or bactericidal, depending on the conditions. Its selective toxicity toward mycobacteria appears to be related to the inhibition of the incorporation of mycolic acids into the cell walls of these organisms.

This compound is remarkably stereospecific. Tests have shown that, although the toxicities of the *dextro*, *levo*, and *meso* isomers are about equal, their activities vary considerably. The *dextro* isomer is 16 times as active as the *meso* isomer. In addition, the length of the alkylene chain, the nature of the branching of the alkyl substituents on the nitrogens, and the extent of *N*-alkylation all have a pronounced effect on the activity.

Ethambutol is rapidly absorbed after oral administration, and peak serum levels occur in about 2 hours. It is rapidly excreted, mainly in the urine. Up to 80% is excreted unchanged, with the balance being metabolized and excreted as 2,2'-(ethylenediimino)dibutyric acid and the corresponding dialdehyde.

Ethambutol is not recommended for use alone, but in combinations with other antitubercular drugs in the chemotherapy of pulmonary tuberculosis.

Aminosalicylic Acid

4-Aminosalicylic acid occurs as a white to yellowish white crystalline solid that darkens on exposure to light or air. It is slightly soluble in water but more soluble in alcohol. Alkali metal salts and the nitric acid salt are soluble in water, but the salts of hydrochloric acid and sulfuric acid are not. The acid undergoes decarboxylation when heated. An aqueous solution has a pH of approximately 3.2.

PAS is administered orally in the form of the sodium salt, usually in tablet or capsule form. Symptoms of gastrointestinal irritation are common with both the acid and the sodium salt. Various enteric-coated dosage forms have been used in an attempt to overcome this disadvantage. Other forms that are claimed to improve gastrointestinal tolerance include the calcium salt, the phenyl ester, and a combination with an anion exchange resin (Rezi-PAS). An antacid such as aluminum hydroxide is frequently prescribed.

The oral absorption of PAS is rapid and nearly complete, and it is widely distributed into most of the body fluids and tissues, with the exception of the CSF, in which levels are significantly lower. It is excreted primarily in the urine as both unchanged drug and metabolites. The *N*-acetyl derivative is the principal metabolite, with significant amounts of

the glycine conjugate also being formed. When administered with isoniazid (which also undergoes *N*-acetylation), PAS increases the level of free isoniazid. The biological half-life of PAS is about 2 hours.

The mechanism of antibacterial action of PAS is similar to that of the sulfonamides. Thus, it is believed to prevent the incorporation of *p*-aminobenzoic acid (PABA) into the dihydrofolic acid molecule catalyzed by the enzyme dihydrofolate synthetase. Structure-activity studies have shown that the amino and carboxyl groups must be *para* to each other and free; thus, esters and amides must readily undergo hydrolysis *in vivo* to be effective. The hydroxyl group may be *ortho* or *meta* to the carboxyl group, but optimal activity is seen in the former.

For many years, PAS was considered a first-line drug for the chemotherapy of tuberculosis and was generally included in combination regimens with isoniazid and streptomycin. However, the introduction of the more effective and generally better tolerated agents, ethambutol and rifampin, has relegated it to alternative drug status.

Aminosalicylate Sodium

Sodium 4-aminosalicylate (sodium PAS), a salt, occurs in the dihydrate form as a yellow-white powder or crystalline solid. It is very soluble in water in the pH range of 7.0 to 7.5, at which it is the most stable. Aqueous solutions decompose readily and darken. Two pH-dependent types of reactions occur: decarboxylation (more rapid at low pH) and oxidation (more rapid at high pH). Therefore, solutions should be prepared within 24 hours of administration.

Clofazimine

Clofazimine (Lamprene) is a basic red dye that exerts a slow bactericidal effect on *M. leprae*, the bacterium that causes leprosy. It occurs as a dark red crystalline solid that is insoluble in water.

Clofazimine is used in the treatment of lepromatous leprosy, including dapsone-resistant forms of the disease. In addition to its antibacterial action, the drug appears to possess anti-inflammatory and immune-modulating effects that are of value in controlling neuritic complications and in suppressing erythema nodosum leprosum reactions associated with lepromatous leprosy. It is frequently used in combination with other drugs, such as dapsone or rifampin.

The mechanisms of antibacterial and anti-inflammatory actions of clofazimine are not known. The drug is known to bind to nucleic acids and concentrate in reticuloendothelial tissue. It can also act as an electron acceptor and may interfere with electron transport processes.

The oral absorption of clofazimine is estimated to be about 50%. It is a highly lipid-soluble drug that is distributed into lipoidal tissue and the reticuloendothelial system. Urinary excretion of unchanged drug and metabolites is negligible. Its half-life after repeated dosage is estimated to be about 70 days. Severe gastrointestinal intolerance to clofazimine is relatively common. Skin pigmentation, ichthyosis and dryness, rash, and pruritus also occur frequently.

Clofazimine has also been used to treat skin lesions caused by *Mycobacterium ulcerans*.

Antitubercular Antibiotics

RIFAMYCINS

The rifamycins are a group of chemically related antibiotics obtained by fermentation from cultures of *Streptomyces mediterranei*. They belong to a class of antibiotics called the *ansamycins* that contain a macrocyclic ring bridged across two nonadjacent positions of an aromatic nucleus. The term *ansa* means "handle," describing well the topography of the structure. The rifamycins and many of their semisynthetic derivatives have a broad spectrum of antimicrobial activity. They are most notably active against Gram-positive bacteria and *M. tuberculosis*. However, they are also active against some Gram-negative bacteria and many viruses. Rifampin, a semisynthetic derivative of rifamycin B, was released as an antitubercular agent in the United States in 1971. A second semisynthetic derivative, rifabutin, was approved in 1992 for the treatment of atypical mycobacterial infections.

The chemistry of rifamycins and other ansamycins has been reviewed.⁷⁵ All of the rifamycins (A, B, C, D, and E) are biologically active. Some of the semisynthetic derivatives of rifamycin B are the most potent known inhibitors of DNA-directed RNA polymerase in bacteria,⁷⁶ and their action is bactericidal. They have no activity against the mammalian enzyme. The mechanism of action of rifamycins as inhibitors of viral replication appears to differ from that for their bactericidal action. Their net effect is to inhibit the formation of the virus particle, apparently by preventing a specific polypeptide conversion.⁷⁷ Rifamycins bind to the β subunit of bacterial DNA-dependent RNA polymerases to prevent chain initiation.⁷⁸ Bacterial resistance to rifampin has been associated with mutations leading to amino acid substitution in the β subunit.⁷⁸ A high level of cross-resistance between various rifamycins has been observed.

Rifampin

Rifampin (Rifadin, Rimactane, Rifampicin) is the most active agent in clinical use for the treatment of tuberculosis. A dosage of as little as 5 $\mu\text{g}/\text{mL}$ is effective against sensitive strains of *M. tuberculosis*. Rifampin is also highly active against staphylococci and *Neisseria*, *Haemophilus*, *Legionella*, and *Chlamydia* spp. Gram-negative bacilli are much less sensitive to rifampin. However, resistance to rifampin develops rapidly in most species of bacteria, including the tubercle bacillus. Consequently, rifampin is used only in combination with other antitubercular drugs, and it is ordinarily not recommended for the treatment of other

bacterial infections when alternative antibacterial agents are available.

Toxic effects associated with rifampin are relatively infrequent. It may, however, interfere with liver function in some patients and should neither be combined with other potentially hepatotoxic drugs nor used in patients with impaired hepatic function (e.g., chronic alcoholics). The incidence of hepatotoxicity was significantly higher when rifampin was combined with isoniazid than when either agent was combined with ethambutol. Allergic and sensitivity reactions to rifampin have been reported, but they are infrequent and usually not serious. Rifampin is a powerful inducer of hepatic cytochrome P450 oxygenases. It can markedly potentiate the actions of drugs that are inactivated by these enzymes. Examples include oral anticoagulants, barbiturates, benzodiazepines, oral hypoglycemic agents, phenytoin, and theophylline.

Rifampin is also used to eradicate the carrier state in asymptomatic carriers of *Neisseria meningitidis* to prevent outbreaks of meningitis in high-risk areas such as military facilities. Serotyping and sensitivity tests should be performed before its use because resistance develops rapidly. However, a daily dose of 600 mg of rifampin for 4 days suffices to eradicate sensitive strains of *N. meningitidis*. Rifampin has also been very effective against *M. leprae* in experimental animals and in humans. When it is used in the treatment of leprosy, rifampin should be combined with dapsone or some other leprostatic agent to minimize the emergence of resistant strains of *M. leprae*.

Other, nonlabeled uses of rifampin include the treatment of serious infections such as endocarditis and osteomyelitis caused by methicillin-resistant *S. aureus* or *S. epidermidis*, Legionnaires disease when resistant to erythromycin, and prophylaxis of *H. influenzae*-induced meningitis.

Rifampin occurs as an orange to reddish brown crystalline powder that is soluble in alcohol but only sparingly soluble in water. It is unstable to moisture, and a desiccant (silica gel) should be included with rifampin capsule containers. The expiration date for capsules stored in this way is 2 years. Rifampin is well absorbed after oral administration to provide effective blood levels for about 8 hours. Food, however, markedly reduces its oral absorption, and rifampin should be administered on an empty stomach. The drug is distributed in effective concentrations to all body fluids and tissues except the brain, despite the fact that it is 70% to 80% protein bound in the plasma. The principal excretory route is through the bile and feces, and high concentrations of rifampin and its primary metabolite, deacetyl-rifampin,

are found in the liver and biliary system. Deacetyl rifampin is also biologically active. Equally high concentrations of rifampin are found in the kidneys, and although substantial amounts of the drug are passively reabsorbed in the renal tubules, its urinary excretion is significant. Patients should be made aware that rifampin causes a reddish orange discoloration of the urine, stool, saliva, tears, and skin. It can also permanently discolor soft contact lenses.

Rifampin is also available in a parenteral dosage form consisting of a lyophilized sterile powder that, when reconstituted in 5% dextrose or normal saline, provides 600 mg of active drug in 10 mL for slow intravenous infusion. The parenteral form may be used for initial treatment of serious cases and for retreatment of patients who cannot take the drug by the oral route. Parenteral solutions of rifampin are stable for 24 hours at room temperature. Although rifampin is stable in the solid state, in solution it undergoes various chemical changes whose rates and nature are pH and temperature dependent.⁷⁹ At alkaline pH, it oxidizes to a quinone in the presence of oxygen; in acidic solutions, it hydrolyzes to 3-formyl rifamycin SV. Slow hydrolysis of the ester functions also occurs, even at neutral pH.

Rifabutin

Rifabutin, the spiroimidazopiperidyl derivative of rifamycin B was approved in the United States for the prophylaxis of disseminated MAC in AIDS patients on the strength of clinical trials establishing its effectiveness. The activity of rifabutin against MAC organisms greatly exceeds that of rifamycin. This rifamycin derivative is not effective, however, as monotherapy for existing disseminated MAC disease.

Rifabutin is a very lipophilic compound with a high affinity for tissues. Its elimination is distribution limited, with a half-life averaging 45 hours (range, 16–69 hours). Approximately 50% of an orally administered dose of rifabutin is absorbed, but the absolute oral bioavailability is only about 20%. Extensive first-pass metabolism and significant biliary excretion of the drug occur, with about 35% and 53% of the orally administered dose excreted, largely as metabolites, in the feces and urine, respectively. The 25-*O*-desacetyl and 31-hydroxy metabolites of rifabutin have been identified. The parent drug is 85% bound to plasma proteins in a concentration-independent manner. Despite its greater potency against *M. tuberculosis* in vitro, rifabutin is considered inferior to rifampin for the short-term therapy of tuberculosis because of its significantly lower plasma concentrations.

Although rifabutin is believed to cause less hepatotoxicity and induction of cytochrome P450 enzymes than rifampin, these properties should be borne in mind when the drug is used prophylactically. Rifabutin and its metabolites are highly colored compounds that can discolor skin, urine, tears, feces, etc.

Cycloserine

D-(+)-4-Amino-3-isoxazolidinone (Seromycin) is an antibiotic that has been isolated from the fermentation beer of three different *Streptomyces* species: *S. orchidaceus*, *S. garyphalus*, and *S. lavendulus*. It occurs as a white to pale yellow crystalline material that is very soluble in water. It is stable in alkaline, but unstable in acidic, solutions. The compound slowly dimerizes to 2,5-bis(aminoxymethyl)-3,6-diketopiperazine in solution or standing.

The structure of cycloserine was reported simultaneously by Kuehl et al.⁸⁰ and Hidy et al.⁸¹ to be D-(+)-4-amino-3-isoxazolidinone. It has been synthesized by Stammer et al.⁸² and by Smart et al.⁸³ Cycloserine is stereochemically related to D-serine. However, the L-form has similar antibiotic activity.

Cycloserine is presumed to exert its antibacterial action by preventing the synthesis of cross-linking peptide in the formation of bacterial cell walls.⁸⁴ Rando⁸⁵ has recently suggested that it is an antimetabolite for alanine, which acts as a suicide substrate for the pyridoxal phosphate-requiring enzyme alanine racemase. Irreversible inactivation of the enzyme thereby deprives the cell of the D-alanine required for the synthesis of the cross-linking peptide.

Although cycloserine exhibits antibiotic activity in vitro against a wide spectrum of both Gram-negative and Gram-positive organisms, its relatively weak potency and frequent toxic reactions limit its use to the treatment of tuberculosis. It is recommended for patients who fail to respond to other tuberculostatic drugs or who are known to be infected with organisms resistant to other agents. It is usually administered orally in combination with other drugs, commonly isoniazid.

Sterile Capreomycin Sulfate

Capastat sulfate, or capreomycin, is a strongly basic cyclic peptide isolated from *Streptomyces capreolus* in 1960 by Herr et al.⁸⁶ It was released in the United States in 1971 exclusively as a tuberculostatic drug. Capreomycin, which resembles viomycin (no longer marketed in the United States) chemically and pharmacologically, is a second-line agent used in combination with other antitubercular drugs. In particular, it may be used in place of streptomycin when either the patient is sensitive to, or the strain of *M. tuberculosis* is resistant to, streptomycin. Similar to viomycin, capreomycin is a potentially toxic drug. Damage to the eighth cranial nerve and renal damage, as with viomycin, are the more serious toxic effects associated with capreomycin therapy. There are, as yet, insufficient clinical data for a reliable comparison of the relative toxic potentials of capreomycin and streptomycin. Cross-resistance among strains of tubercle bacilli is rare between capreomycin and streptomycin.

Four capreomycins, designated IA, IB, IIA, and IIB, have been isolated from cultures of *S. capreolus*. The clinical agent contains primarily IA and IB. The close chemical relationship between capreomycins IA and IB and viomycin was established,⁸⁷ and the total synthesis and proof of structure of the capreomycins were later accomplished.⁸⁸ The structures of capreomycins IIA and IIB correspond to those of IA and IB but lack the β -lysyl residue. The sulfate salts are freely soluble in water.

ANTIPROTOZOAL AGENTS

In the United States and other countries of the temperate zone, protozoal diseases are of minor importance, whereas bacterial and viral diseases are widespread and are the cause of considerable concern. On the other hand, protozoal diseases are highly prevalent in tropical Third World countries, where they infect both human and animal populations, causing suffering, death, and enormous economic hardship. Protozoal diseases that are found in the United States are malaria, amebiasis, giardiasis, trichomoniasis, toxoplasmosis, and, as a direct consequence of the AIDS epidemic, *P. carinii* pneumonia (PCP).

Although amebiasis is generally thought of as a tropical disease, it actually has a worldwide distribution. In some areas with temperate climates in which sanitation is poor, the prevalence of amebiasis has been estimated to be as high as 20% of the population. The causative organism, *Entamoeba histolytica*, can invade the wall of the colon or other parts of the body (e.g., liver, lungs, skin). An ideal chemotherapeutic agent would be effective against both the intestinal and extraintestinal forms of the parasite.

Amebicides that are effective against both intestinal and extraintestinal forms of the disease are limited to the somewhat toxic alkaloids emetine and dehydroemetine, the nitroimidazole derivative metronidazole, and the antimalarial agent chloroquine (Chapter 7). A second group of amebicides that are effective only against intestinal forms of the disease includes the aminoglycoside antibiotic paromomycin, the 8-hydroxyquinoline derivative iodoquinol, the arsenical compound carbarsone, and diloxanide.

Other protozoal species that colonize the intestinal tract and cause enteritis and diarrhea are *Balantidium coli* and the flagellates, *G. lamblia* and *Cryptosporidium* spp. Balantidiasis responds best to tetracycline. Metronidazole and iodoquinol may also be effective. Giardiasis may be treated effectively with furazolidone, metronidazole, or the antimalarial drug quinacrine (Chapter 7). Cryptosporidiosis is normally self-limiting in immunocompetent patients and is not normally treated. The illness can be a serious problem in AIDS patients because no effective therapy is currently available.

Trichomoniasis, a venereal disease caused by the flagellated protozoan *T. vaginalis*, is common in the United States and throughout the world. Although it is not generally considered serious, this affliction can cause serious physical discomfort. Oral metronidazole provides effective treatment against all forms of the disease. It is also used to eradicate the organism from asymptomatic male carriers.

P. carinii is an opportunistic pathogen that may colonize the lungs of humans and other animals and, under the right conditions, can cause pneumonia. The organism has long been classified as a protozoan, but recent RNA evidence suggests that it may be more closely related to fungi. At one time, occasional cases of PCP were known to occur in premature, undernourished infants and in patients receiving immunosuppressant therapy. The situation changed with the onset of the AIDS epidemic. It is estimated that at least 60% and possibly as high as 85% of patients infected with HIV develop PCP during their lifetimes.

The combination of the antifolate trimethoprim and the sulfonamide sulfamethoxazole constitutes the treatment of choice for PCP. Other effective drugs include pentamidine, atovaquone, and a new antifolate, trimetrexate.

Toxoplasma gondii is an obligate intracellular protozoan that is best known for causing blindness in neonates. Toxoplasmosis, the disseminated form of the disease in which the lymphatic system, skeletal muscles, heart, brain, eye, and placenta may be affected, has become increasingly prevalent in association with HIV infection. A combination of the antifolate pyrimethamine and the sulfa drug sulfadiazine constitutes the most effective therapy for toxoplasmosis.

Various forms of trypanosomiasis, chronic tropical diseases caused by pathogenic members of the family Trypanosomidae, occur both in humans and in livestock. The principal disease in humans, sleeping sickness, can be broadly classified into two main geographic and etiological groups: African sleeping sickness caused by *Trypanosoma gambiense* (West African), *Trypanosoma rhodesiense* (East African), or *Trypanosoma congolense*; and South American sleeping sickness (Chagas disease) caused by *Trypanosoma cruzi*. Of the various forms of trypanosomiasis, Chagas disease is the most serious and generally the most resistant to chemotherapy. Leishmaniasis is a chronic tropical disease caused by various flagellate protozoa of the genus *Leishmania*. The more common visceral form caused by *Leishmania donovani*, called *kala-azar*, is similar to Chagas disease. Although these diseases are widespread in tropical areas of Africa and South and Central America, they are of minor importance in the United States, Europe, and Asia.

Chemotherapy of trypanosomiasis and leishmaniasis remains somewhat primitive and is often less than effective. In fact, it is doubtful that these diseases can be controlled by chemotherapeutic measures alone, without successful control of the intermediate hosts and vectors that transmit them. Heavy metal compounds, such as the arsenicals and antimonials, are sometimes effective but frequently toxic. The old standby suramin appears to be of some value in long- and short-term prophylaxis. The nitrofurans derivative nifurtimox may be a major asset in the control of these diseases, but its potential toxicity remains to be fully determined.

Metronidazole

2-Methyl-5-nitroimidazole-1-ethanol (Flagyl, Protostat, Metro IV) is the most useful of a group of antiprotozoal nitroimidazole derivatives that have been synthesized in various laboratories throughout the world. Metronidazole was first marketed for the topical treatment of *T. vaginalis* vaginitis. It has since been shown to be effective orally against both the acute and carrier states of the disease. The drug also possesses useful amebicidal activity and is, in fact, effective against both intestinal and hepatic amebiasis. It has also been found of use in the treatment of such other protozoal diseases as giardiasis and balantidiasis.

More recently, metronidazole has been found to possess efficacy against obligate anaerobic bacteria, but it is ineffective against facultative anaerobes or obligate aerobes. It is particularly active against Gram-negative anaerobes, such as *Bacteroides* and *Fusobacterium* spp. It is also effective against Gram-positive anaerobic bacilli (e.g., *Clostridium* spp.) and cocci (e.g., *Peptococcus*, *Peptidostreptococcus* spp.). Because of its bactericidal action, metronidazole has become an important agent for the treatment of serious infections (e.g., septicemia, pneumonia, peritonitis, pelvic infections, abscesses, meningitis) caused by anaerobic bacteria.

The common characteristic of microorganisms (bacteria and protozoa) sensitive to metronidazole is that they are anaerobic. It has been speculated that a reactive intermediate

formed in the microbial reduction of the 5-nitro group of metronidazole covalently binds to the DNA of the microorganism, triggering the lethal effect.⁸⁹ Potential reactive intermediates include the nitroxide, nitroso, hydroxylamine, and amine. The ability of metronidazole to act as a radiosensitizing agent is also related to its reduction potential.

Metronidazole is a pale yellow crystalline substance that is sparingly soluble in water. It is stable in air but is light sensitive. Despite its low water solubility, metronidazole is well absorbed following oral administration. It has a large apparent volume of distribution and achieves effective concentrations in all body fluids and tissues. Approximately 20% of an oral dose is metabolized to oxidized or conjugated forms. The 2-hydroxy metabolite is active; other metabolites are inactive.

Metronidazole is a weak base that possesses a pK_a of 2.5. Although it is administered parenterally only as the free base by slow intravenous infusion, metronidazole for injection is supplied in two forms: a ready-to-inject 100-mL solution containing 5 mg of base per mL; and a hydrochloride salt as 500 mg of a sterile lyophilized powder. Metronidazole hydrochloride for injection must first be reconstituted with sterile water to yield 5 mL of a solution having a concentration of 100 mg/mL and a pH ranging from 0.5 to 2.0. The resulting solution must then be diluted with either 100 mL of normal saline or 5% dextrose and neutralized with 5 mEq of sodium bicarbonate to provide a final solution of metronidazole base with an approximate concentration of 5 mg/mL and a pH of 6 to 7. Solutions of metronidazole hydrochloride are unsuitable for intravenous administration because of their extreme acidity. Reconstituted metronidazole hydrochloride solutions are stable for 96 hours at 30°C, whereas ready-to-use solutions of metronidazole base are stable for 24 hours at 30°C. Both solutions should be protected from light.

Diloxanide

Furamide, or eutamide, is the 2-furoate ester of 2,2-dichloro-4'-hydroxy-*N*-methylacetanilide. It was developed as a result of the discovery that various α,α -dichloroacetamides possessed amebicidal activity in vitro. Diloxanide itself and many of its esters are also active, and drug metabolism studies indicate that hydrolysis of the amide is required for the amebicidal effect. Nonpolar esters of diloxanide are more potent than polar ones. Diloxanide furoate has been used in the treatment of asymptomatic carriers of *E. histolytica*. Its effectiveness against acute intestinal amebiasis or hepatic abscesses, however, has not been established. Diloxanide furoate is a white crystalline powder. It is administered orally only as 500-mg tablets and may be obtained in the United States from the CDC in Atlanta, Georgia.

8-Hydroxyquinoline

Oxine, quinophenol, or oxyquinoline is the parent compound from which the antiprotozoal oxyquinolines have been derived. The antibacterial and antifungal properties of

oxine and its derivatives, which are believed to result from the ability to chelate metal ions, are well known. Aqueous solutions of acid salts of oxine, particularly the sulfate (Chinosol, Quinosol), in concentrations of 1:3,000 to 1:1,000, have been used as topical antiseptics. The substitution of an iodine atom at the 7-position of 8-hydroxyquinolines yields compounds with broad-spectrum amebicidal properties.

Iodoquinol

5,7-Diiodo-8-quinolinol, 5,7-diiodo-8-hydroxyquinoline, or diiodohydroxyquin (Yodoxin, Diodoquin, Diquinol) is a yellowish to tan microcrystalline, light-sensitive substance that is insoluble in water. It is recommended for acute and chronic intestinal amebiasis but is not effective in extraintestinal disease. Because a relatively high incidence of toxic neuropathy has occurred with its use, iodoquinol should not be used routinely for traveler's diarrhea.

Emetine and Dehydroemetine

The alkaloids emetine and dehydroemetine are obtained by separation from extracts of ipecac. They occur as levorotatory, light-sensitive white powders that are insoluble in water. The alkaloids readily form water-soluble salts. Solutions of the hydrochloride salts intended for intramuscular injection should be adjusted to pH 3.5 and stored in light-resistant containers.

Emetine and dehydroemetine exert a direct amebicidal action on various forms of *E. histolytica*. They are protoplasmic poisons that inhibit protein synthesis in protozoal and mammalian cells by preventing protein elongation. Because their effect in intestinal amebiasis is solely symptomatic and the cure rate is only 10% to 15%, they should be used only in combination with other agents. The high concentrations of the alkaloids achieved in the liver and other tissues after intramuscular injection provide the basis for their high effectiveness against hepatic abscesses and

other extraintestinal forms of the disease. Toxic effects limit the usefulness of emetine. It causes a high frequency of gastrointestinal distress (especially nausea and diarrhea), cardiovascular effects (hypotension and arrhythmias), and neuromuscular effects (pain and weakness). A lower incidence of cardiotoxicity has been associated with the use of dehydroemetine (Mebadin), which is available from the CDC and is also amebicidal.

Emetine and dehydroemetine have also been used to treat balantidial dysentery and fluke infestations, such as fascioliasis and paragonimiasis.

Pentamidine Isethionate

4,4'-(Pentamethylenedioxy)dibenzamidine diisethionate (NebuPent, Pentam 300) is a water-soluble crystalline salt that is stable to light and air. The principal use of pentamidine is for the treatment of pneumonia caused by the opportunistic pathogenic protozoan *P. carinii*, a frequent secondary invader associated with AIDS. The drug may be administered by slow intravenous infusion or by deep intramuscular injection for PCP. An aerosol form of pentamidine is used by inhalation for the prevention of PCP in high-risk patients infected with HIV who have a previous history of PCP infection or a low peripheral CD4⁺ lymphocyte count.

Both the inhalant (aerosol) and parenteral dosage forms of pentamidine isethionate are sterile lyophilized powders that must be made up as sterile aqueous solutions prior to use. Sterile water for injection must be used to reconstitute the aerosol, to avoid precipitation of the pentamidine salt. Adverse reactions to the drug are common. These include cough and bronchospasm (inhalation) and hypertension and hypoglycemia (injection).

Pentamidine has been used for the prophylaxis and treatment of African trypanosomiasis. It also has some value for treating visceral leishmaniasis. Pentamidine rapidly disappears from the plasma after intravenous injection and is distributed to the tissues, where it is stored for a long period. This property probably contributes to the usefulness of the drug as a prophylactic agent.

Atovaquone

3-[4-(4-Chlorophenyl)-cyclohexyl]-2-hydroxy-1,4-naphthoquinone (Mepron) is a highly lipophilic, water-insoluble analog of ubiquinone 6, an essential component of the mitochondrial electron transport chain in microorganisms. The structural similarity between atovaquone and ubiquinone suggests that the former may act as an antimetabolite for the latter and thereby interfere with the function of electron transport enzymes.

Atovaquone was originally developed as an antimalarial drug, but *Plasmodium falciparum* was found to develop a rapid tolerance to its action. More recently, the effectiveness of atovaquone against *P. carinii* was discovered. It is a currently recommended alternative to trimethoprim-sulfamethoxazole (TMP-SMX) for the treatment and prophylaxis of PCP in patients intolerant to this combination. Atovaquone was also shown to be effective in eradicating *T. gondii* in preclinical animal studies.

The oral absorption of atovaquone is slow and incomplete, in part because of the low water solubility of the drug. Aqueous suspensions provide significantly better absorption than do tablets. Food, especially if it has a high fat content, increases atovaquone absorption. Significant enterohepatic recycling of atovaquone occurs, and most (nearly 95%) of the drug is excreted unchanged in the feces. In vivo, atovaquone is largely confined to the plasma, where it is extensively protein bound (>99.9%). The half-life of the drug ranges from 62 to 80 hours. The primary side effect is gastrointestinal intolerance.

Eflornithine

Eflornithine is used for the treatment of West African sleeping sickness, caused by *Trypanosoma brucei gambiense*. It is specifically indicated for the meningoencephalitic stage of the disease. Eflornithine is a myelosuppressive drug that causes high incidences of anemia, leukopenia, and thrombocytopenia. Complete blood cell counts must be monitored during the course of therapy.

The irreversible inactivation of ornithine decarboxylase by eflornithine is accompanied by decarboxylation and release of fluoride ion from the inhibitor,⁹⁰ suggesting enzyme-catalyzed activation of the inhibitor. Only the (–) isomer, stereochemically related to L-ornithine, is active.

Eflornithine is supplied as the hydrochloride salt. It may be administered either intravenously or orally. Approximately 80% of the unchanged drug is excreted in the urine. Penetration of eflornithine into the CSF is facilitated by inflammation of the meninges.

Nifurtimox

Nifurtimox is 4-[(5-nitrofurfurylidene) amino]-3-methylthiomorpholine-1,1-dioxide, or Bayer 2502 (Lampit). The observation that various derivatives of 5-nitrofurfuraldehyde possessed, in addition to their antibacterial and antifungal

properties, significant and potentially useful antiprotozoal activity eventually led to discovery of particular nitrofurans with antitrypanosomal activity.

The most important of such compounds is nifurtimox because of its demonstrated effectiveness against *T. cruzi*, the parasite responsible for South American trypanosomiasis. In fact, use of this drug represents the only clinically proven treatment for both acute and chronic forms of the disease. Nifurtimox is available in the United States from the CDC.

Nifurtimox is administered orally. Oral bioavailability is high, but considerable first-pass metabolism occurs. The half-life of nifurtimox is 2 to 4 hours. The drug is poorly tolerated, with a high incidence of nausea, vomiting, abdominal pain, and anorexia reported. Symptoms of central and peripheral nervous system toxicity also frequently occur with nifurtimox.

Benznidazole

N-Benzyl-2-nitroimidazole-1-acetamide (Radanil, Rochagan) is a nitroimidazole derivative that is used for the treatment of Chagas disease. It is not available in the United States but is used extensively in South America. The effectiveness of benznidazole is similar to that of nifurtimox. Therapy for American trypanosomiasis with oral benznidazole requires several weeks and is frequently accompanied by adverse effects such as peripheral neuropathy, bone marrow depression, and allergic-type reactions.

Melarsoprol

2-*p*-(4,6-Diamino-*s*-triazin-2-yl-amino)phenyl-4-hydroxymethyl-1,3,2-dithiarsoline (Mel B, Arsobal) is prepared by reduction of a corresponding pentavalent arsanilate to the trivalent arsenoxide followed by reaction of the latter with 2,3-dimercapto-1-propanol (British anti-Lewisite [BAL]). It has become the drug of choice for the treatment of the later stages of both forms of African trypanosomiasis. Melarsoprol has the advantage of excellent penetration into the CNS and, therefore, is effective against meningoencephalitic forms of *T. gambiense* and *T. rhodesiense*. Trivalent arsenicals tend to be more toxic to the host (as well as the parasites) than the corresponding pentavalent compounds. The bonding of arsenic with sulfur atoms tends to reduce host toxicity, increase chemical stability (to oxidation), and improve distribution of the compound to the arsenoxide. Melarsoprol shares the toxic properties of other

arsenicals, however, so its use must be monitored for signs of arsenic toxicity.

Sodium Stibogluconate

Sodium antimony gluconate (Pentostam) is a pentavalent antimonial compound intended primarily for the treatment of various forms of leishmaniasis. It is available from the CDC as the disodium salt, which is chemically stable and freely soluble in water. The 10% aqueous solution used for either intramuscular or intravenous injection has a pH of approximately 5.5. Like all antimonial drugs, this drug has a low therapeutic index, and patients undergoing therapy with it should be monitored carefully for signs of heavy metal poisoning. Other organic antimonial compounds are used primarily for the treatment of schistosomiasis and other flukes.

The antileishmanial action of sodium stibogluconate requires its reduction to the trivalent form, which is believed to inhibit phosphofructokinase in the parasite.

Dimercaprol

2,3-Dimercapto-1-propanol, BAL, or dithioglycerol is a foul-smelling, colorless liquid. It is soluble in water (1:20) and alcohol. It was developed by the British during World War II as an antidote for "Lewisite," hence the name British anti-Lewisite or BAL. Dimercaprol is effective topically and systemically as an antidote for poisoning caused by arsenic, antimony, mercury, gold, and lead. It can, therefore, also be used to treat arsenic and antimony toxicity associated with overdose or accidental ingestion of organoarsenicals or organoantimonials.

The antidotal properties of BAL are associated with the property of heavy metals to react with sulfhydryl (SH) groups in proteins (e.g., the enzyme pyruvate oxidase) and interfere with their normal function. 1,2-Dithiol compounds such as BAL compete effectively with such proteins for the metal by reversibly forming metal ring compounds of the following type:

These are relatively nontoxic, metabolically conjugated (as glucuronides), and rapidly excreted.

BAL may be applied topically as an ointment or injected intramuscularly as a 5% or 10% solution in peanut oil.

Suramin Sodium

Suramin sodium is a high-molecular-weight bisurea derivative containing six sulfonic acid groups as their sodium salts. It was developed in Germany shortly after World War I as a byproduct of research efforts directed toward the development of potential antiparasitic agents from dyestuffs.

The drug has been used for more than half a century for the treatment of early cases of trypanosomiasis. Not until several decades later, however, was suramin discovered to be a long-term prophylactic agent whose effectiveness after a single intravenous injection is maintained for up to 3 months. The drug is tightly bound to plasma proteins, causing its excretion in the urine to be almost negligible.

Tissue penetration of the drug does not occur, apparently because of its high molecular weight and highly ionic character. Thus, an injected dose remains in the plasma for a very long period. Newer, more effective drugs are now available for short-term treatment and prophylaxis of African sleeping sickness. Suramin is also used for prophylaxis of onchocerciasis. It is available from the CDC.

ANTHELMINTICS

Anthelmintics are drugs that have the capability of ridding the body of parasitic worms or helminths. The prevalence of human helminthic infestations is widespread throughout the globe and represents a major world health problem, particularly in Third World countries. Helminths parasitic to humans and other animals are derived from two phyla, Platyhelminthes and Nematelminthes. Cestodes (tapeworms) and trematodes (flukes) belong to the former, and nematodes or true roundworms belong to the latter. The helminth infestations of major concern on the North American continent are caused by roundworms (i.e., hookworm, pinworm, and *Ascaris* spp.). Human

tapeworm and fluke infestations are rarely seen in the United States.

Several classes of chemicals are used as anthelmintics and include phenols and derivatives, piperazine and related compounds, antimalarial compounds (Chapter 7), various heterocyclic compounds, and natural products.

Piperazine

Hexahydropyrazine or diethylenediamine (Arthriticine, Dispermin) occurs as colorless, volatile crystals of the hexahydrate that are freely soluble in water. After the discovery of the anthelmintic properties of a derivative diethylcarbamazine, the activity of piperazine itself was established. Piperazine is still used as an anthelmintic for the treatment of pinworm (*Enterobius* [*Oxyuris*] *vermicularis*) and roundworm (*Ascaris lumbricoides*) infestations. It is available in various salt forms, including the citrate (official in the *USP*) in syrup and tablet forms.

Piperazine blocks the response of the ascaris muscle to acetylcholine, causing flaccid paralysis in the worm, which is dislodged from the intestinal wall and expelled in the feces.

Diethylcarbamazepine Citrate

N,N-Diethyl-4-methyl-1-piperazinecarboxamide citrate or 1-diethylcarbamy-4-methylpiperazine dihydrogen citrate (Hetrazan) is a highly water-soluble crystalline compound that has selective anthelmintic activity. It is effective against various forms of filariasis, including Bancroft, onchocerciasis, and laviasis. It is also active against ascariasis. Relatively few adverse reactions have been associated with diethylcarbamazine.

Pyrantel Pamoate

Trans-1,4,5,6,-Tetrahydro-1-methyl-2-[2-(2'-thienyl)ethenyl]pyrimidine pamoate (Antiminth) is a depolarizing neuromuscular blocking agent that causes spastic paralysis in susceptible helminths. It is used in the treatment of infestations caused by pinworms and roundworms (ascariasis). Because its action opposes that of piperazine, the two anthelmintics should not be used together. More than half of the oral dose is excreted in the feces unchanged. Adverse effects associated with its use are primarily gastrointestinal.

Thiabendazole

2-(4-Thiazolyl)benzimidazole (Mintezol) occurs as a white crystalline substance that is only slightly soluble in water but is soluble in strong mineral acids. Thiabendazole is a basic compound with a pK_a of 4.7 that forms complexes with metal ions.

Thiabendazole inhibits the helminth-specific enzyme fumarate reductase.⁹¹ It is not known whether metal ions are involved or if the inhibition of the enzyme is related to thiabendazole's anthelmintic effect. Benzimidazole anthelmintic drugs such as thiabendazole and mebendazole also arrest nematode cell division in metaphase by interfering with microtubule assembly.⁹² They exhibit a high affinity for tubulin, the precursor protein for microtubule synthesis.

Thiabendazole has broad-spectrum anthelmintic activity. It is used to treat enterobiasis, strongyloidiasis (threadworm infection), ascariasis, uncinariasis (hookworm infection), and trichuriasis (whipworm infection). It has also been used to relieve symptoms associated with cutaneous larva migrans (creeping eruption) and the invasive phase of trichinosis. In addition to its use in human medicine, thiabendazole is widely used in veterinary practice to control intestinal helminths in livestock.

Mebendazole

Methyl 5-benzoyl-2-benzimidazolecarbamate (Vermox) is a broad-spectrum anthelmintic that is effective against various nematode infestations, including whipworm, pinworm, roundworm, and hookworm. Mebendazole irreversibly blocks glucose uptake in susceptible helminths, thereby depleting glycogen stored in the parasite. It apparently does not affect glucose metabolism in the host. It also inhibits cell division in nematodes.⁷¹

Mebendazole is poorly absorbed by the oral route. Adverse reactions are uncommon and usually consist of abdominal discomfort. It is teratogenic in laboratory animals and, therefore, should not be given during pregnancy.

Albendazole

Methyl 5-(propylthio)-2-benzimidazolecarbamate (Eskazole, Zentel) is a broad-spectrum anthelmintic that is not currently marketed in North America. It is available from the manufacturer on a compassionate use basis. Albendazole is widely used throughout the world for the treatment of intestinal nematode infection. It is effective as a single-dose treatment for ascariasis, New and Old World hookworm infections, and trichuriasis. Multiple-dose therapy with albendazole can eradicate pinworm, threadworm, capillariasis, clonorchiasis, and hydatid disease. The effectiveness of albendazole against tapeworms (cestodes) is generally more variable and less impressive.

Albendazole occurs as a white crystalline powder that is virtually insoluble in water. The oral absorption of albendazole is enhanced by a fatty meal. The drug undergoes rapid and extensive first-pass metabolism to the sulfoxide, which is the active form in plasma. The elimination half-life of the sulfoxide ranges from 10 to 15 hours. Considerable biliary excretion and enterohepatic recycling of albendazole sulfoxide occurs. Albendazole is generally well tolerated in single-dose therapy for intestinal nematodes. The high-dose, prolonged therapy required for clonorchiasis or echinococcal disease therapy can result in adverse effects such as bone marrow depression, elevation of hepatic enzymes, and alopecia.

Niclosamide

5-Chloro-*N*-(2-chloro-4-nitrophenyl)-2-hydroxybenzamide or 2,5'-dichloro-4'-nitrosalicylanilide (Cestocide, Mansonil, Yomesan) occurs as a yellowish white, water-insoluble powder. It is a potent taeniocide that causes rapid disintegration of worm segments and the scolex. Penetration of the drug into various cestodes appears to be facilitated by the digestive juices of the host, in that very little of the drug is absorbed by the worms *in vitro*. Niclosamide is well tolerated following oral administration, and little or no systemic absorption of it occurs. A saline purge 1 to 2 hours after

ingestion of the taeniocide is recommended to remove the damaged scolex and worm segments. This procedure is mandatory in the treatment of pork tapeworm infestation to prevent possible cysticercosis resulting from release of live ova from worm segments damaged by the drug.

Bithionol

2,2'-Thiobis(4,6-dichlorophenol), or bis(2-hydroxy-3,5-dichlorophenyl)sulfide (Lorothidol, Bithin), a chlorinated bisphenol, was formerly used in soaps and cosmetics for its antimicrobial properties but was removed from the market for topical use because of reports of contact photodermatitis. Bithionol has useful anthelmintic properties and has been used as a fasciolicide and taeniocide. It is still considered the agent of choice for the treatment of infestations caused by the liver fluke *Fasciola hepatica* and the lung fluke *Paragonimus westermani*. Niclosamide is believed to be superior to it for the treatment of tapeworm infestations.

Oxamniquine

1,2,3,4-Tetrahydro-2-[(isopropylamino)methyl]-7-nitro-6-quinolinemethanol (Vansil) is an antischistosomal agent that is indicated for the treatment of *Schistosoma mansoni* (intestinal schistosomiasis) infection. It has been shown to inhibit DNA, RNA, and protein synthesis in schistosomes.⁹³ The 6-hydroxymethyl group is critical for activity; metabolic activation of precursor 6-methyl derivatives is critical. The oral bioavailability of oxamniquine is good; effective plasma levels are achieved in 1 to 1.5 hours. The plasma half-life is 1 to 2.5 hours. The drug is extensively metabolized to inactive metabolites, of which the principal one is the 6-carboxy derivative.

The free base occurs as a yellow crystalline solid that is slightly soluble in water but soluble in dilute aqueous mineral acids and soluble in most organic solvents. It is available in capsules containing 250 mg of the drug. Oxamniquine is generally well tolerated. Dizziness and drowsiness are common, but transitory, side effects. Serious reactions, such as epileptiform convulsions, are rare.

Praziquantel

2-(Cyclohexylcarbonyl)-1,2,3,6,7,11b-hexahydro-4*H*-pyrazino[2,1-*a*]isoquinolin-4-one (Biltricide) is a broad-spectrum agent that is effective against various trematodes

(flukes). It has become the agent of choice for the treatment of infections caused by schistosomes (blood flukes).

The drug also provides effective treatment for fasciolopiasis (intestinal fluke), clonorchiasis (Chinese liver fluke), fascioliasis (sheep liver fluke), opisthorchosis (liver fluke), and paragonimiasis (lung fluke). Praziquantel increases cell membrane permeability of susceptible worms, resulting in the loss of extracellular calcium. Massive contractions and ultimate paralysis of the fluke musculature occurs, followed by phagocytosis of the parasite.

Following oral administration, about 80% of the dose is absorbed. Maximal plasma concentrations are achieved in 1 to 3 hours. The drug is rapidly metabolized in the liver in the first-pass. It is likely that some of the metabolites are also active. Praziquantel occurs as a white crystalline solid that is insoluble in water. It is available as 600-mg film-coated tablets. The drug is generally well tolerated.

Ivermectin

Ivermectin (Cardomec, Eqvalan, Ivomec) is a mixture of 22,23-dihydro derivatives of avermectins B_{1a} and B_{1b} prepared by catalytic hydrogenation. Avermectins are members of a family of structurally complex antibiotics produced by fermentation with a strain of *Streptomyces avermitilis*. Their discovery resulted from an intensive screening of cultures for anthelmintic agents from natural sources.⁹⁴ Ivermectin is active in low dosage against a wide variety of nematodes and arthropods that parasitize animals.⁹⁵

The structures of the avermectins were established by a combination of spectroscopic⁹⁶ and x-ray crystallographic⁹⁷ techniques to contain pentacyclic 16-membered-ring aglycones glycosidically linked at the 3-position to a disaccharide

that comprises two oleandrose sugar residues. The side chain at the 25-position of the aglycone is *sec*-butyl in avermectin B_{1a}, whereas in avermectin B_{1b}, it is isopropyl. Ivermectin contains at least 80% of 22,23-dihydroavermectin B_{1a} and no more than 20% 22,23-dihydroavermectin B_{1b}.

Ivermectin has achieved widespread use in veterinary practice in the United States and many countries throughout the world for the control of endoparasites and ectoparasites in domestic animals.⁹⁵ It has been found effective for the treatment of onchocerciasis (“river blindness”) in humans,⁹⁸ an important disease caused by the roundworm *Oncocerca volvulus*, prevalent in West and Central Africa, the Middle East, and South and Central America. Ivermectin destroys the microfilariae, immature forms of the nematode, which create the skin and tissue nodules that are characteristic of the infestation and can lead to blindness. It also inhibits the release of microfilariae by the adult worms living in the host. Studies on the mechanism of action of ivermectin indicate that it blocks interneuron–motor neuron transmission in nematodes by stimulating the release of the inhibitory neurotransmitter GABA.⁹⁵ The drug has been made available by the manufacturer on a humanitarian basis to qualified treatment programs through the World Health Organization.

ANTISCABIOUS AND ANTIPEDICULAR AGENTS

Scabicides (antiscabious agents) are compounds used to control the mite *Sarcoptes scabiei*, an organism that thrives under conditions of poor personal hygiene. The incidence of scabies is believed to be increasing in the United States and worldwide and has, in fact, reached pandemic proportions.⁹⁹ Pediculicides (antipedicular agents) are used to eliminate head, body, and crab lice. Ideal scabicides and pediculicides must kill the adult parasites and destroy their eggs.

Benzyl Benzoate

Benzyl benzoate is a naturally occurring ester obtained from Peru balsam and other resins. It is also prepared synthetically from benzyl alcohol and benzoyl chloride. The ester is a clear colorless liquid with a faint aromatic odor. It is insoluble in water but soluble in organic solvents.

Benzyl benzoate is an effective scabicide when applied topically. Immediate relief from itching probably results from a local anesthetic effect; however, a complete cure is frequently achieved with a single application of a 25% emulsion of benzyl benzoate in oleic acid, stabilized with triethanolamine. This preparation has the additional advantage of being essentially odorless, nonstaining, and nonirritating to the skin. It is applied topically as a lotion over the entire dampened body, except the face.

Lindane

Lindane is 1,2,3,4,5,6-hexachlorocyclohexane, γ -benzene hexachloride, or benzene hexachloride (Kwell, Scabene, Kwildane, G-Well). This halogenated hydrocarbon is prepared by the chlorination of benzene. A mixture of isomers is obtained in this process, five of which have been isolated: α , β , γ , δ , and ϵ . The γ -isomer, present to 10% to 13% in the mixture, is responsible for the insecticidal activity. The γ -isomer may be separated by various extraction and chromatographic techniques.

Lindane occurs as a light buff to tan powder with a persistent musty odor, and it is bitter. It is insoluble in water but soluble in most organic solvents. It is stable under acidic or neutral conditions but undergoes elimination reactions under alkaline conditions.

The action of lindane against insects is threefold: it is a direct contact poison, it has a fumigant effect, and it acts as a stomach poison. The effect of lindane on insects is similar to that of DDT. Its toxicity in humans is somewhat lower than that of DDT. Because of its lipid solubility properties, however, lindane when ingested tends to accumulate in the body.

Lindane is used locally as a cream, lotion, or shampoo for the treatment of scabies and pediculosis.

CROTAMITON

N-Ethyl-*N*-(2-methylphenyl)-2-butenamide, or *N*-ethyl-*o*-crotonotoluidide (Eurax), is a colorless, odorless oily liquid. It is virtually insoluble in water but soluble in most organic solvents.

Crotamiton is available in 10% concentration in a lotion and a cream intended for the topical treatment of scabies.

Its antipruritic effect is probably because of a local anesthetic action.

Permethrin

Permethrin is 3-(2,2-Dichloroethenyl)-2,2-dimethylcyclopropanecarboxylic acid (3-phenoxyphenyl)methyl ester or 3-(phenoxyphenyl)methyl (\pm)-*cis*, *trans*-3-(2,2-dichloroethenyl)-2,2-dimethylcyclopropanecarboxylate (Nix). This synthetic pyrethrinoid compound is more stable chemically than most natural pyrethrins and is at least as active as an insecticide. Of the four isomers present, the 1(*R*),*trans* and 1(*R*),*cis*-isomers are primarily responsible for the insecticidal activity. The commercial product is a mixture consisting of 60% *trans* and 40% *cis* racemic isomers. It occurs as colorless to pale yellow low-melting crystals or as a pale yellow liquid and is insoluble in water but soluble in most organic solvents.

Permethrin exerts a lethal action against lice, ticks, mites, and fleas. It acts on the nerve cell membranes of the parasites to disrupt sodium channel conductance. It is used as a pediculicide for the treatment of head lice. A single application of a 1% solution effects cures in more than 99% of cases. The most frequent side effect is pruritus, which occurred in about 6% of the patients tested.

ANTIBACTERIAL SULFONAMIDES

The sulfonamide antimicrobial drugs were the first effective chemotherapeutic agents that could be used systemically for the cure of bacterial infections in humans. Their introduction led to a sharp decline in the morbidity and mortality of infectious diseases. The rapid development of widespread resistance to the sulfonamides soon after their introduction and the increasing use of the broader-spectrum penicillins in the treatment of infectious disease diminished the usefulness of sulfonamides. Today, they occupy a rather small place in the list of therapeutic agents that can be used for infectious disease. They are not completely outmoded, however. In the mid-1970s, the development of a combination of trimethoprim and sulfamethoxazole and the demonstration of its usefulness in the treatment and prophylaxis of certain opportunistic microbial infections led to resurgence in the use of some sulfonamides.

Fritz Mietzsch and Joseph Klarer of the I. G. Farbenindustrie laboratories systematically synthesized a series of azo dyes, each containing the sulfonamide functional group, as potential antimicrobial agents. Sulfonamide azo dyes were included in the test series because they were readily synthesized and possessed superior staining properties. The Bayer pathologist-bacteriologist who evaluated the new Mietzsch-Klarer dyes was a physician named Gerhard Domagk.¹⁰⁰⁻¹⁰² In 1932, Domagk began to study a brilliant red dye, later named Prontosil. Prontosil was found to protect against, and cure, streptococcal infections in mice.¹⁰⁰ Interestingly, Prontosil was

inactive on bacterial cultures. Domagk and others continued to study Prontosil, and in 1933, the first of many cures of severe bacterial infections in humans was reported by Foerster,¹⁰³ who treated a 10-month-old infant suffering from staphylococcal septicemia and obtained a dramatic cure. The credit for most of the discoveries relating to Prontosil belongs to Domagk, and for his pioneering work in chemotherapy he was awarded the Nobel Prize in medicine and physiology in 1938. The Gestapo prevented him from actually accepting the award, but after the war, he received it in Stockholm in 1947.

Prontosil is totally inactive *in vitro* but possesses excellent activity *in vivo*. This property of the drug attracted much attention and stimulated a large body of research activity into the sulfonamides. In 1935, Trefouel and coinvestigators¹⁰⁴ performed a structure–activity study on the sulfonamide azo dyes and concluded that the azo linkage was reductively cleaved to release the active antibacterial product, sulfanilamide. This finding was confirmed in 1937 when Fuller¹⁰⁵ isolated free sulfanilamide from the blood and urine of patients being treated with Prontosil. Favorable clinical results were reported with Prontosil and the active metabolite itself, sulfanilamide, in purpural sepsis and meningococcal

infections. All of these findings ushered in the modern era of chemotherapy and the concept of the *prodrug*.

Following the dramatic success of Prontosil, a host of sulfanilamide derivatives was synthesized and tested. By 1948, more than 4,500 compounds¹⁰⁶ had been evaluated. Of these, only about two dozen have been used in clinical practice. In the late 1940s, broader experience with sulfonamides had begun to demonstrate toxicity in some patients, and resistance problems brought about by indiscriminate use of sulfonamides limited their use throughout the world. The penicillins were excellent alternatives to the sulfonamides, and they largely replaced the latter in antimicrobial chemotherapy.

Today, there are a few sulfonamides (Table 6.7) and especially sulfonamide-trimethoprim combinations that are used extensively for opportunistic infections in patients with AIDS.¹⁰⁷ A primary infection that is treated with the combination is PCP. The sulfonamide-trimethoprim combination can be used for treatment and prophylaxis. Additionally, cerebral toxoplasmosis can be treated in active infection or prophylactically. Urinary tract infections and burn therapy^{107–111} round out the list of therapeutic applications. The sulfonamides are drugs of choice for a few other types of infections, but their use is quite limited in modern antimicrobial chemotherapy.^{107–111}

The sulfonamides can be grouped into three classes on the basis of their use: oral absorbable agents, designed to give systemic distribution; *oral nonabsorbable agents* such as sulfasalazine; and topical agents such as sodium sulfacetamide ophthalmic drops.

TABLE 6.7 Therapy with Sulfonamide Antibacterials

Disease/Infection	Sulfonamides Commonly Used
Relatively Common Use	
Treatment and prophylaxis of <i>Pneumocystis carinii</i> pneumonia Treatment and prophylaxis of cerebral toxoplasmosis First attack of urinary tract infection Burn therapy: prevention and treatment of bacterial infection Conjunctivitis and related superficial ocular infections Chloroquine-resistant malaria (Chapter 9)	Trimethoprim-sulfamethoxazole Pyrimethamine-sulfadiazine Trimethoprim-sulfamethoxazole Silver sulfadiazine and mafenide Sodium sulfacetamide Combinations with quinine, others Sulfadoxine Sulfalene
Less Common Infections/Diseases	
Nocardiosis Severe traveler's diarrhea Meningococcal infections	Trimethoprim-sulfamethoxazole Trimethoprim-sulfamethoxazole Sulfonamides, only if proved to be sulfonamide sensitive; otherwise, penicillin G, ampicillin, or (for penicillin-allergic patients) chloramphenicol should be used
Generally Not Useful	
Streptococcal infections Prophylaxis of recurrent rheumatic fever Other bacterial infections	Most are resistant to sulfonamides Most are resistant to sulfonamides The low cost of penicillin and the widespread resistance to sulfonamides limit their use; sulfonamides are still used in a few countries
Vaginal infections Reduction of bowel flora Ulcerative colitis	The FDA and USP-DI find no evidence of efficacy Effectiveness not established Corticosteroid therapy often preferred Relapses common with sulfonamides Salicylazosulfapyridine Side effects of the sulfanilamides sometimes mimic ulcerative colitis

Nomenclature of the Sulfonamides

Sulfonamide is a generic term that denotes three different cases:

1. Antibacterials that are *aniline-substituted sulfonamides* (the “sulfanilamides”).

2. *Prodrugs* that react to generate active sulfanilamides (i.e., sulfasalazine).
3. *Nonaniline* sulfonamides (i.e., mafenide acetate).

There are also other commonly used drugs that are sulfonamides or sulfanilamides. Among these are the oral hypoglycemic drug tolbutamide, the diuretic furosemide, and the diuretic chlorthalidone.

In pharmaceutical chemistry, pK_b values are not used to compare compounds that are Lewis bases. Instead, if a pK_a of an amine is given, it refers to its salt acting as the conjugate acid. For example, aniline with a pK_a of 4.6 refers to

It does not refer to

A negative charge on a nitrogen atom is typically not stable unless it can be delocalized by resonance. This is what

happens with the sulfanilamides. Therefore, the single pK_a usually given for sulfanilamides refers to the loss of an amide proton (Fig. 6.8)

Mechanism of Action of the Sulfonamides

Folinic acid (N^5 -formyltetrahydrofolic acid), N^5,N^{10} -methylene tetrahydrofolic acid, and N^{10} -formyltetrahydrofolic acid are intermediates of several biosynthetic pathways that compose the one-carbon pool in animals, bacteria, and plants. A key reaction involving folate coenzymes is catalyzed by the enzyme thymidylate synthase, which transfers a methyl group from N^5,N^{10} -tetrahydrofolic acid to deoxyuridine monophosphate to form deoxythymidine monophosphate, an important precursor to DNA (Fig. 6.9).

Another key reaction is the generation of formyl groups for the biosynthesis of formylmethionyl tRNA units, the primary building blocks in protein synthesis. The sulfonamides are structural analogs of PABA that competitively inhibit the action of dihydropteroate synthase, preventing the addition of PABA to pteridine diphosphate and blocking the net biosynthesis of folate coenzymes. This action arrests bacterial growth and cell division. The competitive nature of the sulfonamides' action means that the drugs do no permanent damage to a microorganism; hence, they are bacteriostatic. The sulfonamides must be maintained at a minimum effective concentration to arrest the growth of bacteria long enough for the host's immune system to eradicate them.

Folate coenzymes are biosynthesized from dietary folic acid in humans and other animals. Bacteria and protozoa must biosynthesize them from PABA and pteridine diphosphate. Microbes cannot assimilate folic acid from the growth medium or from the host. The reasons for this are poorly understood,¹⁰² but one possibility is that bacterial cell walls may be impermeable to folic acid.

Trimethoprim is an inhibitor of dihydrofolate reductase, which is necessary to convert dihydrofolic acid (FAH₂) into tetrahydrofolic acid (FAH₄) in bacteria (Fig. 6.10). Anand has reviewed this biochemistry.¹⁰² Trimethoprim does not have a

Figure 6.8 • General nomenclature of the sulfonamides.

Other examples of folate-requiring one-carbon pool reactions:

Coenzyme	Reaction
N ¹⁰ -Formyl-FAH ₄	Met-tRNA \longrightarrow Formyl-Met-tRNA
N ⁵ N ¹⁰ =Methylene-FAH ₄	Glycine \longrightarrow Serine
N ⁵ -Formyl-FAH ₂	Homocysteine \longrightarrow Methionine

Figure 6.9 • The thymidylate synthetase reaction and other reactions representing the one-carbon pool.

Figure 6.10 • Folate pathways in humans and bacteria and the sites of inhibition by sulfonamides and trimethoprim. (continues on next page)

high affinity for the malaria protozoan's folate reductase, but it does have a high affinity for bacterial folate reductase.

The reverse situation exists for the antimalarial drug pyrimethamine.¹¹² Trimethoprim does have some affinity for human folate reductase, and this is the cause of some of the toxic effects of the drug.

Spectrum of Action of the Sulfonamides

Sulfonamides inhibit Gram-positive and Gram-negative bacteria, nocardia, *Chlamydia trachomatis*, and some protozoa. Some enteric bacteria, such as *E. coli* and *Klebsiella*, *Salmonella*, *Shigella*, and *Enterobacter* spp. are inhibited. Sulfonamides are infrequently used as single agents. Once drugs of choice for infections such as PCP, toxoplasmosis, nocardiosis, and other bacterial infections, they have been largely replaced by the fixed drug combination TMP-SMX and many

other antimicrobials. Many strains of once-susceptible species, including meningococci, pneumococci, streptococci, staphylococci, and gonococci are now resistant. Sulfonamides are, however, useful in some urinary tract infections because of their high excretion fraction through the kidneys.

Ionization of Sulfonamides

The sulfonamide group, SO_2NH_2 , tends to gain stability if it loses a proton, because the resulting negative charge is resonance stabilized.

Since the proton-donating form of the functional group is not charged, we can characterize it as an HA acid, along with carboxyl groups, phenols, and thiols. The loss of a proton can be associated with a pK_a for all of the compounds in the series. For example, the pK_a of sulfisoxazole (pK_a 5.0) indicates that the sulfonamide is a slightly weaker acid than acetic acid (pK_a 4.8).

Figure 6.10 • (Continued)

Crystalluria and the pK_a

Despite the tremendous ability of sulfanilamide to effect cures of pathogenic bacteria, its benefits were often offset by the propensity of the drug to cause severe renal damage by crystallizing in the kidneys. Sulfanilamides and their metabolites (usually acetylated at N^4) are excreted almost entirely in the urine. The pK_a of the sulfonamido group of sulfanilamide is 10.4, so the pH at which the drug is 50% ionized is 10.4. Obviously, unless the pH is above the pK_a , little of the water-soluble salt is present. Because the urine is usually about pH 6 (and potentially lower during bacterial infections), essentially all of the sulfanilamide is in the relatively insoluble, nonionized form in the kidneys. The sulfanilamide coming out of solution in the urine and kidneys causes crystalluria.

Early approaches to adjusting the solubility of sulfanilamide in the urine were the following:

1. Greatly increasing the urine flow. During the early years of sulfonamide use, patients taking the drugs were cautioned to "force fluids." The idea was that if the glomerular filtration rate could be increased, there would be less opportunity for seed crystals to form in the renal tubules.
2. Increasing the pH of the urine. The closer the pH of the urine is to 10.4 (for sulfanilamide itself), the more of the highly water-soluble salt form will be present. Oral sodium bicarbonate sometimes was, and occasionally still is, given to raise urine pH. The bicarbonate was administered before the initial dose of sulfanilamide and then prior to each successive dose.
3. Preparing derivatives of sulfanilamide that have lower pK_a values, closer to the pH of the urine. This approach has been taken with virtually all sulfonamides in clinical use today. Examples of the pK_a values of some ionizable sulfonamides are shown in Table 6.8.

4. Mixing different sulfonamides to achieve an appropriate total dose. The solubilities of the sulfonamides are independent of each other, and more of a mixture of sulfanilamides can stay in water solution at a given pH than can a single sulfonamide. Hence, trisulfapyrimidines, *USP* (triple sulfa), contain a mixture of sulfadiazine, sulfamerazine, and sulfamethazine. Such mixtures are seldom used today, however, because the individual agents have sufficiently low pK_a values to be partially ionized and adequately soluble in the urine, *providing that at least the normal urine flow is maintained*. Patients must be cautioned to maintain a normal fluid intake; forcing fluids, however, is no longer necessary.

The newer, semisynthetic sulfonamides possess lower pK_a values because electron-withdrawing, heterocyclic rings are attached to N^1 , providing additional stability for the salt form. Hence, the drugs donate a proton more easily, and the pK_a values are lowered. Simpler electron withdrawing groups were extensively investigated but were found to be too toxic, poorly active, or both.

Metabolism, Protein Binding, and Distribution

Except for the poorly absorbed sulfonamides used for ulcerative colitis and reduction of bowel flora and the topical burn preparations (e.g., mafenide), sulfonamides and trimethoprim tend to be absorbed quickly and distributed well. As Mandell and Petri noted, sulfonamides can be found in the urine "within 30 minutes after an oral dose."¹⁰⁸

The sulfonamides vary widely in plasma protein binding; for example, sulfisoxazole, 76%; sulfamethoxazole, 60%; sulfamethoxypyridazine, 77%; and sulfadiazine, 38%. (Anand¹⁰² has published an excellent table comparing the percentage of protein binding, lipid solubility, plasma half-life, and N^4 metabolites.) The fraction that is protein bound is not active as an antibacterial, but because the binding is reversible, free, and therefore active, sulfonamide eventually becomes available. Generally, the more lipid soluble a sulfonamide is, at physiological pH, the more of it will be protein bound. Fujita and Hansch¹¹³ have found that among sulfonamides with similar pK_a values, the lipophilicity of the

TABLE 6.8 pK_a Values for Clinically Useful Sulfonamides

Sulfonamide	pK _a
Sulfadiazine	6.5
Sulfamerazine	7.1
Sulfamethazine	7.4
Sulfisoxazole	5.0
Sulfamethoxazole	6.1

N¹ group has the largest effect on protein binding. N⁴-acetate metabolites of the sulfonamides are more lipid soluble and, therefore, more protein bound than the starting drugs themselves (which have a free 4-amino group that decreases lipid solubility). Surprisingly, the N⁴-acetylated metabolites, although more strongly protein bound, are excreted more rapidly than the parent compounds.

Currently, the relationship between plasma protein binding and biological half-life is unclear. Many competing factors are involved, as reflected in sulfadiazine, with a serum half-life of 17 hours, which is much less protein bound than sulfamethoxazole, with a serum half-life of 11 hours.¹⁰²

Sulfonamides are excreted primarily as mixtures of the parent drug, N⁴-acetates, and glucuronides.¹¹⁴ The N⁴-acetates and glucuronides are inactive. For example, sulfisoxazole is excreted about 80% unchanged, and sulfamethoxazole is excreted 20% unchanged. Sulfadimethoxine is about 80% excreted as the glucuronide. The correlation between structure and route of metabolism has not yet been delineated, though progress has been made by Fujita.¹¹³ Vree et al.,¹¹⁴ however, have described the excretion kinetics and pK_a values of N¹- and N⁴-acetylsulfamethoxazole and other sulfonamides.

About 45% of trimethoprim and about 66% of sulfamethoxazole are partially plasma protein bound. Whereas about 80% of excreted trimethoprim and its metabolites are active as antibacterials, only 20% of sulfamethoxazole and its metabolites are active, with most of the activity coming from largely unmetabolized sulfamethoxazole. Six metabolites of trimethoprim are known.¹¹⁵ It is likely, therefore, that sulfonamide-trimethoprim combinations using a sulfonamide with a higher active urine concentration will be developed in the future for urinary tract infections. Sulfamethoxazole and trimethoprim have similar half-lives, about 10 to 12 hours, but the half-life of the active fraction of sulfamethoxazole is shorter, about 9 hours.¹¹⁵ (Ranges of half-lives have been summarized by Gleckman et al.,¹¹⁶ and a detailed summary of pharmacokinetics has been made by Hansen.¹¹⁵) In patients with impaired renal function, concentrations of sulfamethoxazole and its metabolites may greatly increase in the plasma. A fixed combination of sulfamethoxazole and trimethoprim should not be used for patients with low creatinine clearances.

Mechanisms of Microbial Resistance to Sulfonamides

As noted previously, indiscriminate use of sulfonamides has led to the emergence of many drug-resistant strains of bacteria. Resistance is most likely a result of a compensatory increase in the biosynthesis of PABA by resistant bacteria,¹¹⁷ although other mechanisms such as alterations in the binding strength of sulfonamides to the pathway enzymes, decreased

permeability of the cell membrane, and active efflux of the sulfonamide may play a role.^{102,116} As a rule, if a microbe is resistant to one sulfonamide, it is resistant to all. Of note is the finding that sulfonamide resistance can be quickly transferred from a resistant bacterial strain to a previously sensitive one in one or two generations. This resistance propagation is most likely a result of R-factor conjugation, as is the case for tetracycline resistance.

Several explanations have been reported to account for bacterial resistance to the dihydrofolate reductase inhibitor trimethoprim, including intrinsic resistance at the enzymatic level, the development of the ability by the bacteria to use the host's 5-deoxythymidine monophosphate (dTMP), and R-factor conjugation.

Synergistic Activities of Sulfonamides and Folate Reductase Inhibitors

If biosynthesis of bacterial (or protozoal) folate coenzymes is blocked at more than one point in the pathway, the result will be a synergistic antimicrobial effect. This is beneficial because the microbe will not develop resistance as readily as it would with a singly blocked pathway. The synergistic approach is used widely in antibacterial therapy with the combination of sulfamethoxazole and trimethoprim^{102,118–120} (Septra, Bactrim, Co-Trimoxazole) and in antimalarial therapy with pyrimethamine plus a sulfonamide or quinine. Additional combinations with trimethoprim have been investigated (e.g., with rifampin).^{121,122}

Toxicity and Side Effects

Various serious toxicity and hypersensitivity problems have been reported with sulfonamide and sulfonamide–trimethoprim combinations. Mandell and Petri¹⁰⁸ note that these problems occur in about 5% of all patients. Hypersensitivity reactions include fever, rash, Stevens-Johnson syndrome, skin eruptions, allergic myocarditis, photosensitization, and related conditions. Hematological side effects also sometimes occur, especially hemolytic anemia in individuals with a deficiency of glucose-6-phosphate dehydrogenase. Other reported hematological side effects include agranulocytosis and aplastic anemia. Crystalluria may occur, even with the modern sulfonamides, when the patient does not maintain normal fluid intake. Nausea and related gastrointestinal side effects are sometimes noted. Detailed summaries of incidences of side effects with trimethoprim-sulfamethoxazole have been published by Wormser and Deutsch¹¹⁸ and by Gleckman et al.¹¹⁶

Structure–Activity Relationships

As noted previously in this chapter, several thousand sulfonamides have been investigated as antibacterials (and many as antimalarials). From these efforts, several structure–activity relationships have been proposed, as summarized by Anand.¹⁰² The aniline (N⁴) amino group is very important for activity because any modification of it other than to make prodrugs results in a loss of activity. For example, all of the N⁴-acetylated metabolites of sulfonamide are inactive.

Various studies have shown that the active form of sulfonamide is the N¹-ionized salt. Thus, although many modern sulfonamides are much more active than unsubstituted sulfanilamide, they are only 2 to 6 times more active if equal amounts of N¹-ionized forms are compared.¹²³ Maximal

TABLE 6.9 Characteristics of Absorbable Short- and Intermediate-Acting Sulfonamides

Sulfonamide	Half-Life	Oral Absorption
Sulfisoxazole	Short (6 hours)	Prompt (peak levels in 1–4 hours)
Sulfamethizole	Short (9 hours)	Prompt
Sulfadiazine	Intermediate (10–17 hours)	Slow (peak levels in 4–8 hours)
Sulfamethoxazole	Intermediate (10–12 hours)	Slow
Sulfadoxine	Long (7–9 days)	Intermediate
Pyrimidine		
Trimethoprim	Intermediate (11 hours)	Prompt

activity seems to be exhibited by sulfonamides between pK_a 6.6 and 7.4.^{123–126} This reflects, in part, the need for enough nonionized (i.e., more lipid soluble) drug to be present at physiological pH to be able to pass through bacterial cell walls.¹²⁷ Fujita and Hansch¹¹³ also related pK_a , partition coefficients, and electronic (Hammett) parameters with sulfonamide activity (Table 6.9).

Sulfamethizole

4-Amino-*N*-(5-methyl-1,3,4-thiadiazol-2-yl)benzenesulfonamide; *N*¹-(5-methyl-1,3,4-thiadiazol-2-yl)sulfanilamide; 5-methyl-2-sulfanilamido-1,3,4-thiadiazole. Sulfamethizole's plasma half-life is 2.5 hours. This compound is a white crystalline powder soluble 1:2,000 in water.

Sulfisoxazole

4-Amino-*N*-(3,4-dimethyl-5-isoxazolyl)benzenesulfonamide; *N*¹-(3,4-dimethyl-5-isoxazolyl)sulfanilamide; 5-sulfanilamido-3,4-dimethylisoxazole. Sulfisoxazole's plasma half-life is 6 hours. This compound is a white, odorless, slightly bitter, crystalline powder. Its pK_a is 5.0. At pH 6, this sulfonamide has a water solubility of 350 mg in 100 mL, and its acetyl derivative has a solubility of 110 mg in 100 mL of water.

Sulfisoxazole possesses the action and the uses of other sulfonamides and is used for infections involving sulfonamide-sensitive bacteria. It is claimed to be effective in the treatment of Gram-negative urinary infections.

Sulfisoxazole Acetyl

N-[(4-Aminophenyl)sulfonyl]-*N*-(3,4-dimethyl-5-isoxazolyl)acetamide; *N*-(3,4-dimethyl-5-isoxazolyl)-*N*-sulfanilyl-

acetamide; *N*¹-acetyl-*N*¹-(3,4-dimethyl-5-isoxazolyl)sulfanilamide. Sulfisoxazole acetyl shares the actions and uses of the parent compound, sulfisoxazole. The acetyl derivative is tasteless and, therefore, suitable for oral administration, especially in liquid preparations. The acetyl compound is split in the intestinal tract and absorbed as sulfisoxazole; that is, it is a *prodrug* for sulfisoxazole.

Sulfisoxazole Diolamine

4-Amino-*N*-(3,5-dimethyl-5-isoxazolyl)benzenesulfonamide compound with 2,2'-iminobis[ethanol](1:1); 2,2'-iminodiethanol salt of *N*¹-(3,4-dimethyl-5-isoxazolyl)sulfanilamide. This salt is prepared by adding enough diethanolamine to a solution of sulfisoxazole to bring the pH to about 7.5. It is used as a salt to make the drug more soluble in the physiological pH range of 6.0 to 7.5 and is used in solution for systemic administration of the drug by slow intravenous, intramuscular, or subcutaneous injection when high enough blood levels cannot be maintained by oral administration alone. It also is used for instillation of drops or ointment in the eye for the local treatment of susceptible infections.

Sulfamethazine

4-Amino-*N*-(4,6-dimethyl-2-pyrimidinyl)benzenesulfonamide; *N*¹-(4,6-dimethyl-2-pyrimidinyl)sulfanilamide; 2-sulfanilamido-4,6-dimethylpyrimidine. Sulfamethazine's plasma half-life is 7 hours. This compound is similar in chemical properties to sulfamerazine and sulfadiazine but does have greater water solubility than either. Its pK_a is 7.2. Because it is more soluble in acid urine than sulfamerazine is, the possibility of kidney damage from use of the drug is decreased. The human body appears to handle the drug unpredictably; hence, there is some disfavor to its use in this country except in combination sulfa therapy (in trisulfapyrimidines, *USP*) and in veterinary medicine.

Sulfacetamide

N-[(4-Aminophenyl)sulfonyl]-acetamide; *N*-sulfanilylacetamide; *N*¹-acetylsulfanilamide. Sulfacetamide's plasma half-life is 7 hours. This compound is a white crystalline powder, soluble in water (1:62.5 at 37°C) and in alcohol. It

is very soluble in hot water, and its water solution is acidic. It has a pK_a of 5.4.

Sulfachloropyridazine

N^1 -(6-Chloro-3-pyridazinyl) sulfanilamide. Sulfachloropyridazine's plasma half-life is 8 hours.

Sulfapyridine

4-Amino- N -2-pyridinylbenzenesulfonamide; N^1 -2-pyridyl-sulfanilamide. Sulfapyridine's plasma half-life is 9 hours. This compound is a white, crystalline, odorless, and tasteless substance. It is stable in air but slowly darkens on exposure to light. It is soluble in water (1:3,500), in alcohol (1:440), and in acetone (1:65) at 25°C. It is freely soluble in dilute mineral acids and aqueous solutions of sodium and potassium hydroxide. The pK_a is 8.4. Its outstanding effect in curing pneumonia was first recognized by Whitby; however, because of its relatively high toxicity, it has been supplanted largely by sulfadiazine and sulfamerazine. Several cases of kidney damage have resulted from acetylsulfapyridine crystals deposited in the kidneys. It also causes severe nausea in most patients. Because of its toxicity, it is used only for dermatitis herpetiformis.

Sulfapyridine was the first drug to have an outstanding curative action on pneumonia. It gave impetus to the study of the whole class of N^1 heterocyclically substituted derivatives of sulfanilamide.

Sulfamethoxazole

4-Amino- N -(5-methyl-3-isoxazolyl)benzenesulfonamide; N^1 -(5-methyl-3-isoxazolyl) sulfanilamide (Gantanol). Sulfamethoxazole's plasma half-life is 11 hours.

Sulfamethoxazole is a sulfonamide drug closely related to sulfisoxazole in chemical structure and antimicrobial activity. It occurs as a tasteless, odorless, almost white crystalline powder. The solubility of sulfamethoxazole in the pH range of 5.5 to 7.4 is slightly lower than that of sulfisoxazole

but higher than that of sulfadiazine, sulfamerazine, or sulfamethazine.

Following oral administration, sulfamethoxazole is not absorbed as completely or as rapidly as sulfisoxazole, and its peak blood level is only about 50% as high.

Sulfadiazine

4-Amino- N -2-pyrimidinylbenzenesulfonamide; N^1 -2-pyrimidinylsulfanilamide; 2-sulfanilamidopyrimidine. Sulfadiazine's plasma half-life is 17 hours. It is a white, odorless crystalline powder soluble in water to the extent of 1:8,100 at 37°C and 1:13,000 at 25°C, in human serum to the extent of 1:620 at 37°C, and sparingly soluble in alcohol and acetone. It is readily soluble in dilute mineral acids and bases. Its pK_a is 6.3.

Sulfadiazine Sodium

Soluble sulfadiazine is an anhydrous, white, colorless, crystalline powder soluble in water (1:2) and slightly soluble in alcohol. Its water solutions are alkaline (pH 9–10) and absorb carbon dioxide from the air, with precipitation of sulfadiazine. It is administered as a 5% solution in sterile water intravenously for patients requiring an immediately high blood level of the sulfonamide.

Mixed Sulfonamides

The danger of crystal formation in the kidneys from administration of sulfonamides has been greatly reduced through the use of the more soluble sulfonamides, such as sulfisoxazole. This danger may be diminished still further by administering mixtures of sulfonamides. When several sulfonamides are administered together, the antibacterial action of the mixture is the summation of the activity of the total sulfonamide concentration present, but the solubilities are independent of the presence of similar compounds. Thus, by giving a mixture of sulfadiazine, sulfamerazine, and sulfacetamide, the same therapeutic level can be maintained with much less danger of crystalluria, because only one third of the amount of any one compound is present. Descriptions of some of the mixtures used follow.

Trisulfapyrimidines, Oral Suspension

The oral suspension of trisulfapyrimidines contains equal weights of sulfadiazine, *USP*; sulfamerazine, *USP*; and sulfamethazine, *USP*, either with or without an agent to raise the pH of the urine.

Trisulfapyrimidines, Tablets

Trisulfapyrimidine tablets contain essentially equal quantities of sulfadiazine, sulfamerazine, and sulfamethazine.

Sulfadoxine and Pyrimethamine

The mixture of sulfadoxine and pyrimethamine (Fansidar) is used for the treatment of *P. falciparum* malaria in patients in whom chloroquine resistance is suspected. It is also used for malaria prophylaxis for travelers to areas where chloroquine-resistant malaria is endemic.

This compound is particularly effective against *Clostridium welchii* in topical application and was used during World War II by the German army for prophylaxis of wounds. It is not effective orally. It is currently used alone or with antibiotics in the treatment of slow-healing, infected wounds.

Topical Sulfonamides

Sulfacetamide Sodium

N-Sulfanilylacetamide monosodium salt (Sodium Sulamyd) is obtained as the monohydrate and is a white, odorless, bitter, crystalline powder that is very soluble (1:2.5) in water. Because the sodium salt is highly soluble at the physiological pH of 7.4, it is especially suited, as a solution, for repeated topical applications in the local management of ophthalmic infections susceptible to sulfonamide therapy.

Some patients treated for burns with large quantities of this drug have developed metabolic acidosis. To overcome this adverse effect, a series of new organic salts was prepared.¹⁶ The acetate in an ointment base proved to be the most efficacious.

Sulfisoxazole Diolamine

Sulfisoxazole diolamine is described with the short- and intermediate-acting sulfonamides and also used in intravenous and intramuscular preparations.

Silver Sulfadiazine (Silvadene)

The silver salt of sulfadiazine applied in a water-miscible cream base has proved to be an effective topical antimicrobial agent, especially against *Pseudomonas* spp. This is particularly significant in burn therapy because pseudomonads are often responsible for failures in therapy. The salt is only slightly soluble and does not penetrate the cell wall but acts on the external cell structure. Studies using radioactive silver have shown essentially no absorption into body fluids. Sulfadiazine levels in the serum were about 0.5 to 2 mg/100 mL.

Triple Sulfa

Triple sulfa (sulfabenzamide, sulfacetamide, and sulfathiazole; Femguard) is used as a vaginal cream in the treatment of *Haemophilus vaginalis* vaginitis.

This preparation is reported to be easier to use than other standard burn treatments, such as application of freshly prepared dilute silver nitrate solutions or mafenide ointment.

Nonabsorbable Sulfonamides

TOPICAL SULFONAMIDES FOR BURN THERAPY

Mafenide Acetate

4-(Aminomethyl)benzenesulfonamide acetate (Sulfamylon) is a homologue of the sulfanilamide molecule. It is not a true sulfanilamide-type compound, as it is not inhibited by PABA. Its antibacterial action involves a mechanism that differs from that of true sulfanilamide-type compounds.

Sulfonamides for Intestinal Infections, Ulcerative Colitis, or Reduction of Bowel Flora

Each of the sulfonamides in this group is a prodrug, which is designed to be poorly absorbable, though usually, in practice, a little is absorbed. Therefore, usual precautions with sulfonamide therapy should be observed. In the large intestine, the *N*⁴-protecting groups are cleaved, releasing the free

sulfonamide antibacterial agent. Today, only one example is used clinically, sulfasalazine.

Sulfasalazine

Sulfasalazine (2-hydroxy-5[[4-[(2-pyridinylamino)sulfonyl]phenyl]azo]benzoic acid or 5-[*p*-(2-pyridylsulfamoyl)phenylazo]salicylic acid) is a brownish yellow, odorless powder, slightly soluble in alcohol but practically insoluble in water, ether, and benzene.

Sulfasalazine is broken down in the body to *m*-aminosalicylic acid and sulfapyridine. The drug is excreted through the kidneys and is detectable colorimetrically in the urine, producing an orange-yellow color when the urine is alkaline and no color when the urine is acid.

DIHYDROFOLATE REDUCTASE INHIBITORS

Trimethoprim

Trimethoprim (5-[(3,4,5-trimethoxyphenyl)methyl]-2,4-pyrimidinediamine or 2,4-diamino-5-(3,4,5-trimethoxybenzyl)pyrimidine) is closely related to several antimalarials but does not have good antimalarial activity by itself; it is, however, a potent antibacterial. Originally introduced in combination with sulfamethoxazole, it is now available as a single agent.

Approved by the FDA in 1980, trimethoprim as a single agent is used only for the treatment of uncomplicated urinary tract infections. The argument for trimethoprim as a single agent was summarized in 1979 by Wormser and Deutsch.¹¹⁸ They point out that several studies comparing trimethoprim with TMP-SMX for the treatment of chronic urinary tract infections found no statistically relevant difference between the two courses of therapy. Furthermore, some patients cannot take sulfonamide products for the reasons discussed previously in this chapter. The concern is that when used as a single agent, bacteria now susceptible to trimethoprim will rapidly develop resistance. In combination with a sulfonamide, however, the bacteria will be less likely to do so. That is, they will not survive long enough to easily develop resistance to both drugs.

Sulfamethoxazole and Trimethoprim

The synergistic action of the combination of these two drugs is discussed previously in this chapter.

SULFONES

The sulfones are primarily of interest as antibacterial agents, though there are some reports of their use in the treatment of malarial and rickettsial infections. They are less effective than the sulfonamides. PABA partially antagonizes the action of many of the sulfones, suggesting that the mechanism of action is similar to that of the sulfonamides. Further, infections that arise in patients being treated with sulfones are cross-resistant to sulfonamides. Several sulfones have proved useful in the treatment of leprosy, but among them only dapsone is clinically used today.

It has been estimated that there are about 11 million cases of leprosy in the world, of which about 60% are in Asia (with 3.5 million in India alone). The first reports of dapsone resistance prompted the use of multidrug therapy with dapsone, rifampin, and clofazimine combinations in some geographic areas.¹²⁸

The search for antileprotic drugs has been hampered by the inability to cultivate *M. leprae* in artificial media and by the lack of experimental animals susceptible to human leprosy. A method of isolating and growing *M. leprae* in the footpads of mice and in armadillos has been reported and has permitted a much wider range of research. Sulfones were introduced into the treatment of leprosy after it was found that sodium glucosulfone was effective in experimental tuberculosis in guinea pigs.

The parent sulfone, dapsone (4,4'-sulfonyldianiline), is the prototype for various analogs that have been widely studied. Four variations on this structure have given active compounds:

1. Substitution on both the 4- and 4'-amino functions
2. Monosubstitution on only one of the amino functions
3. Nuclear substitution on one of the benzenoid rings
4. Replacement of one of the phenyl rings with a heterocyclic ring

The antibacterial activity and the toxicity of the disubstituted sulfones are thought to be chiefly caused by the formation in vivo of dapsone. Hydrolysis of disubstituted derivatives to the parent sulfone apparently occurs readily in the acid medium of the stomach but only to a very limited extent following parenteral administration. Monosubstituted and nuclear-substituted derivatives are believed to act as entire molecules.

Dapsone

Dapsone (4,4'-sulfonylbisbenzeneamine; 4,4'-sulfonyldianiline; *p,p'*-diaminodiphenylsulfone; or DDS [Avlosulfon]) occurs as an odorless, white crystalline powder that is very slightly soluble in water and sparingly soluble in alcohol. The pure compound is light stable, but traces of impurities, including water, make it photosensitive and thus susceptible to discoloration in light. Although no chemical change is detectable following discoloration, the drug should be protected from light.

Dapsone is used in the treatment of both lepromatous and tuberculoid types of leprosy. Dapsone is used widely for all forms of leprosy, often in combination with clofazimine and rifampin. Initial treatment often includes rifampin with dapsone, followed by dapsone alone. It is also used to prevent

the occurrence of multibacillary leprosy when given prophylactically.

Dapsone is also the drug of choice for dermatitis herpetiformis and is sometimes used with pyrimethamine for treatment of malaria and with trimethoprim for PCP.

Serious side effects can include hemolytic anemia, methemoglobinemia, and toxic hepatic effects. Hemolytic effects can be pronounced in patients with glucose-6-phosphate dehydrogenase deficiency. During therapy, all patients require frequent blood counts.

REVIEW QUESTIONS

1. What is the definition of an antiseptic?
2. What happens to the antimicrobial activity of alcohols as the carbon chain becomes more branched?
3. What kind of bond associates iodine with polyvinylpyrrolidone in PVP-iodine?
4. What is the most active agent for the clinical treatment of tuberculosis?
5. What is the function of dihydrofolate reductase in bacteria?

Antimalarials

JOHN H. BLOCK

CHAPTER OVERVIEW

Malaria, one of the most widespread diseases, is caused by a *Plasmodium* parasite and is transmitted to humans by the *Anopheles* mosquito. It infects several hundred million people each year, results in several million deaths annually, and is a complex disease to treat. The causative agent is a group of parasitical protozoa of the *Plasmodium* genus transmitted by the female *Anopheles* mosquito. Its original treatment was quinine that became the prototypical molecule for the first generation of synthetic antimalarial drugs. The target for drug treatment and prophylaxis is the parasite, and each advance in the drug treatment of this disease has resulted in the parasite developing resistance. One of the most effective preventions is controlling the mosquito population that is the vector carrying the parasite to humans. The human immune system does respond to the parasite, but the development of an effective vaccine has been a challenge. Sequencing the *Plasmodium* genome is providing information that may lead to other approaches to prevent and treat this debilitating disease.

History

Malaria's name is derived from "mala aria" or bad air, and has been called *ague*, *intermittent fever*, *marsh fever*, and *The Fever*.^{1,2} The name is based on the early knowledge that malaria was associated with swamps and badly drained areas. The use of quinine for treating malaria has been known since the 17th century. Although malaria is an ancient disease, its upsurge seems to coincide with the advent of farming about 20,000 years ago. The clearing of land provided areas for ponds containing still water. The *Anopheles gambiae* mosquito uses still water that sits in ponds and containers to breed. The gathering of humans in farming communities provided the necessary concentration of people to form a reservoir of hosts for the parasite and "food" for the mosquitoes breeding in the ponds.³⁻⁶

Proof that the *Anopheles* mosquito is the carrier of the causative protozoa was obtained by Dr. Ronald Ross who was recognized in 1902 by receipt of the Nobel Prize in Medicine. In a scenario somewhat similar to that where definitive proof that yellow fever was transmitted by the *Aedes aegypti* mosquito was required, Dr. Ross strongly argued that malaria was transmitted by an insect vector and finally demonstrated that the parasite was carried in the stomach and salivary glands of the *Anopheles* mosquito. The latter discovery was important because it helped resolve the dispute whether malaria was spread by the bite of the mosquito or drinking water containing mosquito eggs and larvae.⁷ The impact of malaria on the human species

continues to be devastating. The role of diseases such as smallpox, plague, yellow fever, and polio on human history is fascinating, but, fortunately, is mostly historical. Although smallpox has been eliminated, the latter three diseases do reappear, but the cases are isolated. Plague is treated effectively with antibiotics, and there are vaccines for yellow fever and polio.

There are three potential ways to control malaria: elimination of the vector, drug therapy, and vaccination. Elimination of the vector is the simplest and most cost-effective. Drug therapy has the same challenges as those with development of antibiotics, resistance to the drug. The current antimalarial drugs, although reasonably effective, also have significant adverse reactions, and resistance is increasing. So far, no effective vaccine has been developed that is effective *in vivo*, but that may be changing because of a better understanding how the human immune system interacts with the parasite. The malaria parasite does elicit an immune response as evidenced by the fact that children with an initial exposure are more likely to die than adults who have recurring attacks.

Because malaria has been eliminated from North America, Europe, and parts of Asia, it becomes a potential problem when citizens from a malaria-free area travel into an area where malaria is endemic. It is common for these travelers going into areas where malaria is endemic to receive prescriptions for antimalarial drugs and use them prophylactically.⁸ Many times, citizens of malaria-free countries returning from areas where malaria is endemic plus citizens of the latter countries who are coming to the malaria-free countries will have contracted malaria and will require antimalarial drugs for several months following their return. Also, there will be restriction on their ability to be blood donors. Most prescriptions for antimalarial drugs in North America are indicated for prophylaxis of travelers going to and coming from areas of the world where malaria is endemic.

Malaria

Malaria is caused by four species of the one-cell protozoan of the *Plasmodium* genus. They are:

Plasmodium falciparum: This species is estimated to cause approximately 50% of all malaria. It causes the most severe form of the disease and, because patients feel ill between acute attacks, debilitating form of the disease. One of the reasons it leaves the patient so weak is because it infects up to 65% of the patient's erythrocytes.

Plasmodium vivax: This species is the second most common species causing about 40% of all malarial cases. It can be very chronic in recurrence because it can reinfect liver cells.

Plasmodium malariae: Although causing only 10% of all malarial cases, relapses are very common.

Plasmodium ovale: This species is least common.

Figure 7.1 outlines the steps of the parasite as it is injected into the victim and where drug therapy might be effective. The mosquito stores the sporozoite form of the protozoan in its salivary glands. Upon biting the patient, the sporozoites are injected into the patient's blood. Ideally, this would be a good site for intervention before the parasite can infect the liver or erythrocyte. In the case of drug therapy, people living in areas endemic with malaria (and the mosquito vector) would need to take the drug constantly. Although this would be plausible for people living temporarily in these areas, it is not practical for the permanent residents. It is true that anti-malarial drugs could be formulated into implanted depot dosage forms, but these are expensive, and many times require trained medical personnel to implant the drug.

Within minutes after being injected into the patient's blood, the sporozoites begin entering hepatocytes where they become primary schizonts and then merozoites. At this point, there are no symptoms. Depending on the *Plasmodium* species, the merozoites either rupture the infected hepatocytes and enter systemic circulation or infect other liver cells. The latter process is seen with *P. vivax*, *P. malariae*, and *P. ovale*, but not *P. falciparum*, and produces secondary schizonts.

This secondary infection of the liver can be very damaging and is one of the sites for possible drug intervention. Killing the secondary schizonts would accomplish two things, protect the liver from further damage and eliminate a reservoir of schizonts that can change to merozoites and enter systemic circulation. It needs to be noted that, as the

protozoan changes from sporozoite to schizont to merozoites, its immunological character changes. Determination of the *Plasmodium* genome has shown that each form of the parasite produces a different set of proteins. At the same time, once the merozoites have left the hepatocyte and are in systemic circulation, they are susceptible to attack by the patient's immune system provided that it has "learned" to recognize the parasite. Therefore, another site for vaccine development is the merozoite stage. Depending on the *Plasmodium* species, a merozoite vaccine may or may not provide much protection to the liver, but it could reduce subsequent infection of the erythrocytes.

Merozoites in systemic circulation now infect the patient's erythrocytes where they reside for 3 to 4 days before reproducing. The reproduction stage in the erythrocyte can either produce more merozoites or another form called gametocytes. The latter has different immunological properties from the other forms. Either way, the newly formed merozoites or gametocytes burst out of the infected erythrocytes. The new merozoites infect additional erythrocytes and continue the cycle of reproducing, bursting out of the erythrocytes, and infecting more erythrocytes. The debris from the destroyed erythrocytes is one of the causes of severe fever and chills. Also, the patient's immune system will respond with repeated exposure to the parasite, and this will contribute to the patient's discomfort.

The conversion of merozoites results in male and female gametocytes. After entering the mosquito, they "mate," producing zygotes in the mosquito's stomach. The latter reside in the mosquito's stomach endothelium oocysts. Eventually, they migrate as sporozoites to the mosquito's salivary gland where the cycle begins again when the mosquito bites a

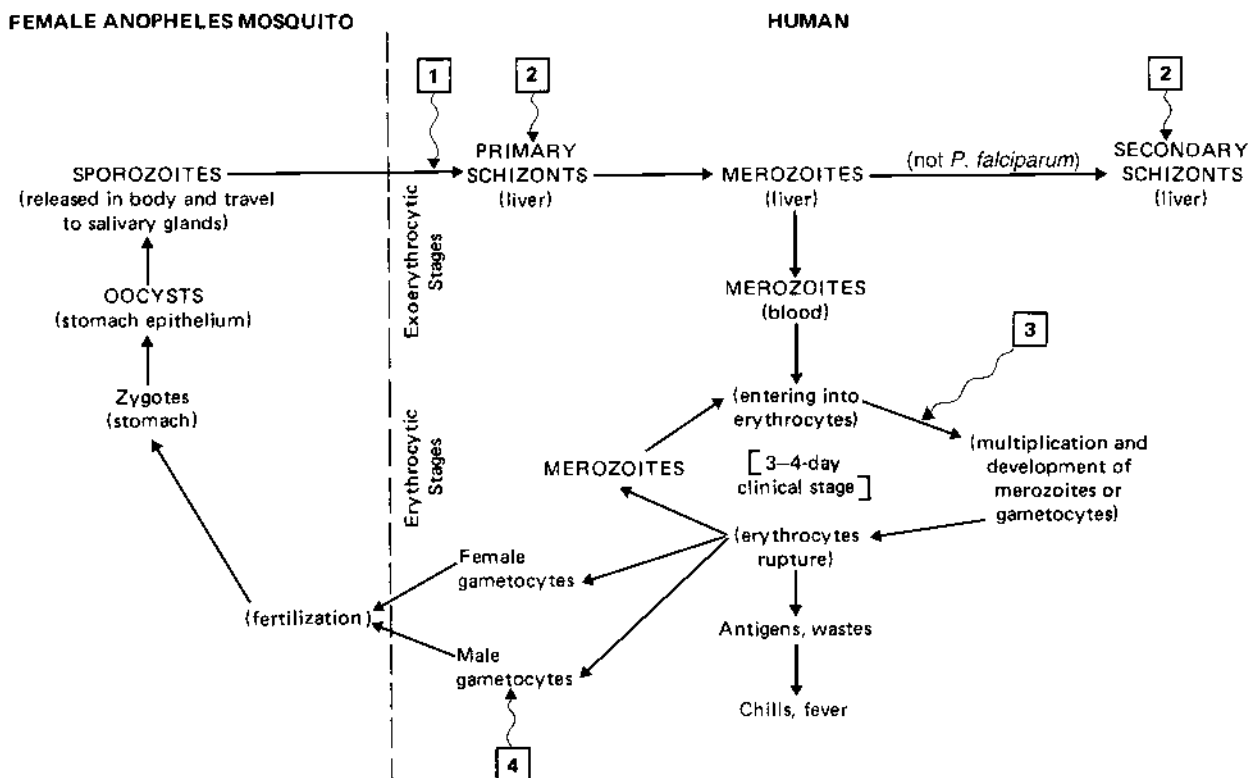

Figure 7.1 • Stages of the parasite that causes malaria after injection into its victim. See discussion in the text. □ indicates site of antimalarial drug action in humans.

human. Note that, in effect, there are two reservoirs or vectors for the parasite: the mosquito that infects humans and humans that infect mosquitoes. Consistent with the latter, there have been some attempts at developing prophylactic agents that would be in the blood ingested by the mosquito. These drugs would stop further development of the parasite in the mosquito, preventing the insect from being a carrier.

PLASMODIUM GENOME

There are at least two benefits to decoding the parasite's genome. One is to find a protein or biochemical reaction that is unique to *Plasmodium* species such that a drug can be designed that is selectively toxic to the protozoan. A second goal is to understand the genetic changes that lead to drug resistance. One of the main reasons for the increase in malaria since the late 1990s is the developing resistance to chloroquine, an antimalarial that has been widely used against *P. falciparum*. This resistance is blamed for the increasing mortality rates in Africa and to the resurgence of malaria.

The *P. falciparum* genome consists of the 30 million base pairs, forming 5,000 to 6,000 genes. It is nearly 80% adenine (A)-thymine (T) rich, making it difficult to tally base pairs on the parasites' 14 chromosomes.^{9,10} (In contrast, the human genome is about 59% A-T.) The high A-T concentration made determination of the *Plasmodium* genome difficult to sequence because (a) it was more difficult to slice the chromosomal deoxyribonucleic acid (DNA) strands into smaller distinct segments that make it easier to sequence the nucleotides and then reassemble them into chromosome; and (b) the computer software would fail and had to be modified.¹¹ Because *P. vivax* is difficult to propagate in the laboratory, obtaining its genome has been a challenge. It turns out that although it resembles *P. falciparum*'s genome, it possesses novel gene families and potential alternative invasion pathways not previously recognized.¹²

Human Mutations that Protect against Malaria

There are at least six mutations in the human species that provide protection against malaria. These predominate in populations that historically lived and continue to live in areas endemic with malaria. The six mutations are sickling disease (formerly sickle cell anemia), glucose-6-phosphate dehydrogenase deficiency, hemoglobin C, various thalassemias, increased production of nitric oxide (NO), and pyruvate kinase deficiency. Sickling disease can be fatal in homozygotes although treatment has greatly improved. Heterozygotes usually are asymptomatic and show a 90% decrease in the chance of dying from *P. falciparum*.¹³ Homozygotes with hemoglobin C usually are asymptomatic.¹⁴ Erythrocyte glucose-6-phosphate dehydrogenase deficiency (actually 10%–15% of normal activity in the erythrocyte) can cause hemolytic anemia and prehepatic jaundice when the patient takes certain drugs or is exposed to some viral infections. Ironically, some of the antimalarial drugs must be used with caution in patients with erythrocyte glucose-6-phosphate dehydrogenase deficiency to minimize the risk of hemolytic anemia. The increased levels of oxidized glutathione in the erythrocyte that are deficient in this enzyme may prevent the parasite from maturing in the

erythrocyte. The significance of thalassemia varies with the type of anemia and whether or not the patient is homozygote or heterozygote. The most recent identified mutation is pyruvate kinase deficiency. Because erythrocytes lack mitochondria, this enzyme is key to the formation of adenosine triphosphate (ATP) from phosphoenolpyruvate.¹⁵ These mutations produce an erythrocyte such that the parasite has difficulty reproducing.

Another mutation is the ability of certain populations to increase their production of NO. The site is in the promoter region of the gene for nitric oxide synthase 2 that generates NO from arginine and involves a mutation where cytosine is replaced by thymine. The result is higher circulating levels of NO. Mechanistically, it is not known how increased NO provides this protection, because there appears to be no significant difference between blood levels of the parasite in individuals with the mutation compared with those with "normal" NO synthase. The protection may be from complications seen with malaria, giving the patient's immune system time to respond to the parasite.¹⁶

Controlling the Vector, the *Anopheles* Mosquito

The *Anopheles* mosquito has adapted very well to human habitats. As already pointed out, it requires still water to lay its eggs, wait for them to hatch, and then let the larvae, who feed on microscopic organisms in the still water, mature. Transient still water is ideal because it likely is not going to contain predators that will feed on the eggs and larvae. In general, mosquitoes need 1 to 2 weeks to develop into mature insects. This usually is enough time before predators begin to populate the still water.

Currently, there are two ways to control the mosquito carrier. One is to prevent contact between humans and the insect. Because the *Anopheles* mosquito is a nocturnal feeder, it is easier to control compared with the *Aedes aegypti* mosquito, which is a day feeder and carries both dengue and yellow fever. Putting screens on windows and using mosquito netting in bedrooms are very effective. The latter, when insecticide impregnated, has proven very effective.¹⁷ As simple as the use of treated nets may seem, they produce a logistical challenge. It has been estimated that in 2007, 130 to 264 million treated nets are required to reach 80% coverage for 133 million children younger than 5 years and pregnant women living in 123 million households in risk areas in Africa.¹⁸

Second, elimination of the *Anopheles* mosquito, usually by application of insecticide and destroying its breeding areas, are the most effective ways to eliminate (as opposed to control) malaria. Areas that have been successful at eliminating infected mosquitoes include North America, Europe, and Russia. To do this, the adult female mosquito must be killed and breeding areas (still water) must be drained. One of the most effective insecticides has been dichlorodiphenyltrichloroethane (DDT). Dr. Paul Muller received the 1948 Nobel Prize in Medicine for discovering that DDT kills the malaria-carrying *Anopheles* mosquito. DDT is very long lasting and, unfortunately, accumulates in the environment. Although being long lasting is beneficial from the standpoint of mosquito control, it also means that these insecticides get into the food chain and can affect both animals, including birds, and humans. Indeed, use of DDT has been banned in

most economically developed countries. Unfortunately, the areas of the world where malaria is endemic are economically poor and cannot (a) afford the newer insecticides that must be reapplied because they degrade, (b) fund and maintain the infrastructure to eliminate breeding areas, and (c) provide medical facilities, staff, and drugs to treat their citizens.

POVERTY AND MALARIA

In general, malaria is endemic in areas of the world where poverty is rampant. There is not the infrastructure to eliminate the mosquito-breeding ponds, provide the insecticides to kill the mosquito and screens to separate the population from the mosquito, and provide the necessary drugs to treat the disease. In addition to pharmacological treatment, proper nutrition is important in surviving a malaria attack. The patient must replace the destroyed erythrocytes and, depending on the species of *Plasmodium*, hepatocytes. This requires calories from a high-quality diet that provides essential nutrients including amino acids, lipids, and trace minerals. The World Health Organization's 2008 Report (see Selected Reading) has scored countries based on the populations' lifestyles and availability of resources. Lack of proper food is one of those resources. In other words, just as the pathology of malaria is complex, so is its control and treatment.

Development of Vaccines

The complex nature of the parasite and its interactions with human red blood cells provide a large number of antigenic sites for the immune system.¹⁹ A T-cell response that includes both CD4+ and CD8+ T cells and production of interferon and nitric oxide synthase induction is additional evidence that the human immune system does detect the parasite and responds accordingly.²⁰ An ideal vaccine should, at a minimum, be effective against both *P. falciparum* and *P. vivax*, the two species responsible for 90% of malarial cases. Currently, the RTS,S/AS01E vaccine is showing promise (see Selected Reading in the References at the end of the chapter). It contains surface proteins from the sporozoite stage, meaning it is designed for the immune system to stop the parasite as it enters the patient's blood from the mosquito and before the parasite can reach the liver where it matures and multiplies.

Development of Antimalarial Drugs

New antimalarial drugs must be developed constantly because the protozoa develop resistance by various mechanisms (see discussion of mechanisms with the different drugs), and there are a wide variety of adverse reactions. The combination of cost of drugs and their adverse reactions can make patient compliance difficult. Because there are four different species of protozoa that cause malaria, no one antimalarial drug is effective against all four species. There is a tremendous need for effective antimalarial agents.

STIMULATION OF ANTIMALARIAL RESEARCH BY WAR

From 1941 to 1946 (World War II), more than 15,000 substances were synthesized and screened as possible antimalarial agents by the United States, Australia, and Great Britain. Activity increased again during the Vietnam War, especially because of the increasing problem of resistance to commonly used antimalarials. During the decade 1968 to 1978, more than 250,000 compounds were investigated as part of a U.S. Army search program.²¹ Department of Defense funding of this research has continued.

Drugs Used to Prevent and Treat Malaria

There are four possible sites (Fig. 7.1) for drug therapy at this stage of the disease.

1. Kill the sporozoites injected by the mosquito and/or prevent the sporozoites from entering the liver.
2. Kill the schizonts residing in hepatocytes and/or prevent them from becoming merozoites.
3. Kill the merozoites in the blood and/or prevent them from developing into gametocytes.
4. Kill the gametocytes before they can enter the mosquito and reproduce into zygotes. Some have argued that the focus at this stage should be on the male gametocytes. This would block the female gametocytes from mating.

Antimalarial drugs (Table 7.1) are good examples of anti-infective agents with poor selective toxicity. Contrast them with the antibiotics (Chapter 8). Tetracyclines, chloramphenicol, and aminoglycosides act against bacterial ribosomes, but not mammalian. Penicillins and cyclosporins inhibit bacterial cell wall cross-linking, and mammals have cell membranes, not cell walls. The fluoroquinolones inhibit bacterial gyrase, but not mammalian topoisomerases. The biochemistry of the *Plasmodium* genus is similar to mammals, making it difficult to design drugs that will not adversely affect the patient. Some have indications beyond that of treating and preventing malaria. Nearly all of the antimalarial drugs currently in use are based on prototypical molecules isolated from plants (see Selected Reading).

CINCHONA ALKALOIDS

The cinchona tree produces four alkaloids that function as prototypical molecules from which, until recently, most antimalarial drugs were based. These alkaloids (Fig. 7.2) are the enantiomeric pair quinine and quinidine and their desmethoxy analogs, cinchonidine (for quinine) and cinchonine (for quinidine). (Unfortunately, the nomenclature for the two series of alkaloids is inconsistent.) Their numbering system is based on rubane. The stereochemistry differs at positions 8 and 9 with quinine and cinchonidine being S,R and quinidine (cinchonine) being R,S. Historically, quinine has been the main treatment for malaria until the advent of World War II when battle in areas where malaria was endemic led to the search for more effective agents.

TABLE 7.1 Summary of Current Drugs Used to Prevent and Treat Malaria

Class	Generic Name	Indications for Malaria	Other Indications	Dosing Ranges for Treatment and Prophylaxis of Malaria
Cinchona alkaloids	Quinine	Chloroquine-resistant <i>P. falciparum</i> ; combination with other antimalarials; not indicated for prophylaxis	Nocturnal leg cramps (see FDA restrictions on over-the-counter sales)	<i>Adults</i> : 260–650 mg t.i.d. for 6–12 days <i>Children</i> : 10 mg/kg every 8 hours for 5–7 days
	Quinidine	Not indicated for malaria in the United States	Cardiac arrhythmias	
4-Aminoquinolines	Chloroquine	Prophylaxis and treatment of <i>P. vivax</i> , <i>P. Malariae</i> , <i>P. ovale</i> malaria, and susceptible strains of <i>P. falciparum</i> malaria	Extraintestinal (liver) amebiasis The following indications are not approved in the United States Forms of hypercalcemia Rheumatoid arthritis Discoid and systemic lupus erythematosus Porphyria cutanea tarda Solar urticaria	Doses are expressed as chloroquine base equivalent <i>Prophylaxis for Children</i> : 5 mg/kg weekly up to a maximum of 300 mg <i>Prophylaxis for Adults</i> : 300 mg weekly See Centers for Disease Control and Prevention for current recommendations for treatment of acute attacks
	Hydroxychloroquine	Prophylaxis and treatment of <i>P. vivax</i> , <i>P. Malariae</i> , <i>P. ovale</i> malaria, and susceptible strains of <i>P. falciparum</i> malaria	Rheumatoid arthritis Discoid and systemic lupus erythematosus The following indications are not approved in the United States Forms of hypercalcemia Porphyria cutanea tarda Solar urticaria	Doses are expressed as hydroxychloroquine base equivalent <i>Prophylaxis for Children</i> : 5 mg/kg weekly up to a maximum adult dose <i>Prophylaxis for Adults</i> : 310 mg weekly on the same day; begin 1–2 weeks prior to exposure and continue for 4 weeks after leaving the endemic area See Centers for Disease Control and Prevention for current recommendations for treatment of acute attacks <i>Prophylaxis (CDC) Children</i> : 62–250 mg weekly based on weight starting 1 week before travel and continuing for 4 weeks after leaving the endemic area <i>Prophylaxis for Adults</i> : 250 mg weekly for 4 weeks then 250 mg every other week starting 1 week before travel and continuing for 4 weeks after leaving the endemic area <i>Treatment for Adults</i> : 1,250 mg as a single dose taken with food and at least 240-mL water
	Mefloquine	Prophylaxis of <i>P. falciparum</i> (including chloroquine-resistant strains) and <i>P. vivax</i> malaria; treatment of <i>P. falciparum</i> and <i>P. vivax</i> malaria	None	
8-Aminoquinolines	Primaquine	Prophylaxis and treatment of <i>P. vivax</i>	None	<i>Children</i> : 0.5 mg/kg/day for 14 days <i>Adults</i> : 26.3 mg daily for 14 days <i>Prophylaxis</i> : begin only 1–2 days before travel and for 4 weeks after leaving the area; total use normally does not exceed 4 months <i>Children</i> : 2 mg/kg/day up to 100 mg/day <i>Adults</i> : 100 mg once daily <i>Adults</i> : 500 mg every 6 hours for 3 doses (1,500 mg) repeated 7 days later <i>Children</i> : 250–375 mg based on body weight; follow the same schedule as adults
Polycyclics	Doxycycline	Prophylaxis against <i>P. falciparum</i> strains resistant to chloroquine and sulfadoxine–pyrimethamine	Bacteria infections	<i>Children</i> : 2 mg/kg/day up to 100 mg/day <i>Adults</i> : 100 mg once daily <i>Adults</i> : 500 mg every 6 hours for 3 doses (1,500 mg) repeated 7 days later <i>Children</i> : 250–375 mg based on body weight; follow the same schedule as adults
	Halfantrine	Treatment of <i>P. falciparum</i> and <i>P. vivax</i>	None	

Class	Generic Name	Indications for Malaria	Other Indications	Dosing Ranges for Treatment and Prophylaxis of Malaria
Artemisinin family (usually used in combination with another antimalarial)	Artemisinin	Appears effective against all <i>Plasmodium</i> species including <i>P. falciparum</i> and <i>P. vivax</i>	None	<i>Adults</i> : 20 mg/kg on day 1 followed by 10 mg/kg for next 6 days
	Artemether	Similar profile as artemisinin	None	<i>Adults</i> : 4 mg/kg for 3 days followed by 1.6 mg/kg for 3 days
	Artesunate	Similar profile as artemisinin	None	<i>Adults</i> : 4 mg/kg for 3 days followed by 2 mg/kg for 2–4 days
	Dihydro-artemisinin	Similar profile as artemisinin	None	<i>Adults</i> : 4 mg/kg on day 1 followed by 2 mg/kg for 6 days
	Artemotil	Similar profile as artemisinin	None	<i>Adults</i> : 150 mg/kg by IM injection
Fixed combinations	Sulfadoxine and pyrimethamine	Prophylaxis and treatment of chloroquine-resistant <i>P. falciparum</i>	None	Each tablet contains 500-mg sulfadoxine and 25-mg pyrimethamine <i>Prophylaxis</i> : Begin 1–2 days prior to departure and continue for 4–6 weeks after return <i>Children</i> : ¼–1½ tablets based on age and whether administered once or twice weekly <i>Adults</i> : 1–2 tablets once or twice weekly <i>Treatment for Children</i> : ½–2 tablets based on age during an attack <i>Treatment for Adults</i> : 2–3 tablets during an attack
	Atovaquone and proguanil	Prophylaxis and treatment of <i>P. falciparum</i> resistant to other antimalarial drugs	None	<i>Adult Tablet</i> : 250-mg atovaquone & 100-mg proguanil <i>Pediatric Tablet</i> : 62.5-mg atovaquone & 25-mg proguanil <i>Prophylaxis</i> : Begin 1–2 days prior to departure and continue for 7 days after return <i>Children</i> : 1–3 pediatric tablets as a single daily dose based on weight <i>Adults</i> : 1 adult tablet daily <i>Treatment</i> : Take as a single dose for 3 consecutive days <i>Children</i> : 1–3 pediatric tablets as a single daily dose based on weight <i>Adults</i> : 4 tablets as a single daily dose for 3 consecutive days
	Artemether and lumefantrine	Treatment of <i>P. falciparum</i> resistant to other antimalarial drugs	None	<i>Adult Tablet</i> : 20-mg artemether & 120-mg lumefantrine; 4-dose regimen over 48 hrs or 6-dose regimen over 3 days <i>Pediatric Tablet</i> : 10-mg artemether & 60-mg lumefantrine; 4-dose regimen over 48 hrs or 6-dose regimen over 3 days

Quinine and Quinidine. Quinine has been used for “fevers” in South America since the 1600s. The pure alkaloids, quinine, and cinchonine were isolated in 1820. The stereoisomer, quinidine, is a more potent antimalarial, but it is also more toxic (less selectively toxic). Quinine is lethal for all *Plasmodium* schizonts (site 2 in Fig. 7.1) and the gametocytes (site 4) from *P. vivax* and *P. malariae*, but not for *P. falciparum*. Today, quinine’s spectrum of activity is considered too narrow for prophylactic use relative to the

synthetic agents. The mechanism of action is discussed in the chloroquine section. The mechanism of resistance to quinine is poorly understood and varies with the susceptibility of the parasite to other aminoquinoline antimalarial drugs. Quinine is still indicated for malaria caused by *P. falciparum* resistant to other agents including chloroquine. Many times it is administered in combination with pyrimethamine and sulfadoxine, doxycycline, or mefloquine depending the specific form of malaria and geographical location.

Figure 7.2 • Cinchona alkaloids.

A toxic syndrome is referred to as cinchonism. Symptoms start with tinnitus, headache, nausea, and disturbed vision. If administration is not stopped, cinchonism can proceed to involvement of the gastrointestinal tract, nervous and cardiovascular system, and the skin.

Quinine has also been used for nocturnal leg cramps, but pharmacists must remember that the Food and Drug Administration (FDA) ordered a stop to marketing quinine over the counter for this use because of a lack of proper studies proving its efficacy and possible adverse reactions.

The stereoisomer, quinidine, is a schizonticide, but its primary indication is cardiac arrhythmias. It is a good example where stereochemistry is important because it provides a significantly different pharmacological spectrum. Quinidine is discussed further in Chapter 19.

4-Aminoquinolines

The 4-aminoquinolines (Fig. 7.3) are the closest of the anti-malarials that are based on the quinine structure. This group is substituted at the same position 4 as quinine and have an asymmetric carbon equivalent to quinine's C-9 position.

Just as with quinine, both isomers are active and the 4-aminoquinoline racemic mixtures are used. For the newest drug in this series, mefloquine, only the *R,S*-isomer is marketed. A significant difference from the commercial cinchona alkaloids is replacing the 6'-methoxy on quinine with a 7-chloro substituent on three of the 4-aminoquinolines. Amodiaquine is no longer used in the United States, and sontoquine has fallen into disuse.

Chloroquine and Chloroquine Phosphate. Chloroquine can be considered the prototypical structure that succeeded quinine and came into use in the mid-1940s. The phosphate salt is used in oral dosage forms (tablets), and the hydrochloride salt is administered parenterally. Until recently, chloroquine has been the main antimalarial drug used for both prophylaxis and treatment. Note that the list of indications for many of the other drugs in this chapter include *Plasmodium* resistant to chloroquine. It is indicated for *P. vivax*, *P. malariae*, *P. ovale*, and susceptible strains of *P. falciparum*. Chloroquine belongs to the 4-aminoquinoline series of which hundreds have been evaluated, but only about three to four are still in use.

Figure 7.3 • 4-Aminoquinolines.

Even though this drug has been used for many years, its mechanism of action is still not known. Its main site of action appears to be the parasite involving the erythrocyte's lysosome. The following actions have been suggested based on experimental evidence. A very complex mechanism is based on ferriprotoporphyrin IX, which is released by *Plasmodium* containing erythrocytes, acting as a chloroquine receptor. The combination of ferriprotoporphyrin IX and chloroquine causes lysis of the parasite's and/or the erythrocyte's membrane. Finally, there is evidence that chloroquine may interfere with *Plasmodium*'s ability to digest the erythrocyte hemoglobin or the parasite's nucleoprotein synthesis. The mechanism is based on the drug entering the erythrocyte's lysosome, which has an acid environment, where it becomes protonated. The protonated (positively charged) chloroquine is now trapped inside the lysosome because the pore that leads out of the lysosome is also positively charged. This leaves chloroquine bound to the patient's hemoglobin preventing the parasite from processing it properly.²⁴

In general, chloroquine and the other 4-aminoquinolines are not effective against exoerythrocytic parasites. Note that each of the mechanisms require that the parasite be inside the erythrocyte. Therefore, chloroquine does not prevent relapses of *P. vivax* or *P. ovale* malaria. The drug is also indicated for the treatment of extraintestinal amebiasis.

Effective such as chloroquine has been, it is a poor example of selective toxicity. Adverse reactions include retinopathy, hemolysis in patients with glucose-6-phosphate dehydrogenase deficiency (same mutation that confers resistance against malaria), muscular weakness, exacerbation of psoriasis and porphyria, and impaired liver function. Further examples of poor selective toxicity include off-label indications that include rheumatoid arthritis, systemic and discoid lupus erythemaosis (possibly as a immunosuppressant), and various dermatological conditions.

The increase in *P. falciparum* resistant to chloroquine is considered to be one of the main reasons for the increase in both the incidence and deaths from malaria. The key *Plasmodium* gene that confers resistance appears to be the

pfcr gene that codes for a transporter protein. The result of the changes in the gene is that the pore through which chloroquine might exit the lysosome is no longer positive charged, allowing protonated chloroquine to exit the lysosome.³⁵ There are at least eight mutations that have been identified in the *pfcr* gene, and it is postulated that resistance occurs because of an accumulation of these mutations. Chloroquine remains effective when there are fewer mutations in the *pfcr* gene. Once the critical number of mutations has occurred, the parasite spreads over a broad geographical area rendering chloroquine ineffective.²²⁻²⁴

Hydroxychloroquine. In most ways, hydroxychloroquine parallels chloroquine. Structurally, it differs solely with a hydroxy moiety on one of the *N*-ethyl groups. Like chloroquine, it remains in the body for over a month, and prophylactic dosing is once weekly. The other indications, both FDA approved and off-label, are very similar.

Amodiaquine. Amodiaquine is no longer marketed in the United States, but it is available in Africa. Mechanistically, it is very similar to chloroquine and does not have any advantages over the other 4-aminoquinoline drugs. When used for prophylaxis of malaria, it had a higher incidence of hepatitis and agranulocytosis than that was chloroquine. There is evidence that the hydroquinone (phenol) amine system readily oxidizes to a quinone imine (Fig. 7.3) either autoxidatively and/or metabolically, and this product may contribute to amodiaquine's toxicity.

Mefloquine HCl. The newest of the 4-aminoquinolines, mefloquine, is marketed as the *R,S*-isomer. It was developed in the 1960s as part of the U.S. Army's Walter Reed Institute for Medical Research antimalarial research program. It differs significantly from the other agents in

this class by having two trifluoromethyl moieties at positions 2' and 8' and no electronegative substituents at either positions 6' (quinine) or 7' (chloroquine). Mefloquine also differs from chloroquine and its analogs by being a schizonticide (site 2 in Fig. 7.1) acting before the parasite can enter the erythrocyte. There is some evidence that it acts by raising the pH in the parasite's vesicles interfering with its ability to process heme. Mefloquine-resistant strains of *P. falciparum* have appeared. Relapse can occur with acute *P. vivax* that has been treated with mefloquine because the drug does not eliminate the hepatic phase of this species, which can reinfect the liver.

Mefloquine is teratogenic in rats, mice, and rabbits. There is an FDA-required warning that this drug can cause exacerbate mental disorders and is contraindicated in patients with active depression, a recent history of depression, generalized anxiety disorder, psychosis, schizophrenia, and other major psychiatric disorders or a history of convulsions.

8-Aminoquinolines

The other major group of antimalarial drugs based on the cinchona alkaloid quinoline moiety is the substituted 8-aminoquinolines (Fig. 7.4). The first compound introduced in this series was pamaquine. During World War II, pentaquine, isopentaquine, and primaquine became available. Only primaquine, after being used during the Korean war, is in use today. All of the 8-aminoquinolines can cause hemolytic anemia in erythrocytic glucose-6-phosphate dehydrogenase-deficient patients. As pointed out in the introduction to this chapter, this is a common genetic trait found in populations living in areas endemic in malaria and provides some resistance to the parasite. Mechanism of action and spectrum of activity will be found in the primaquine section.

Figure 7.4 • 8-Aminoquinolines.

Very little variations are seen in the structure–activity relationships in this series. The four agents in Figure 7.4 all have a 6-methoxy moiety same as quinine, but the substituents are on the quinoline are located at position 8 rather than carbon-4 as found on the cinchona alkaloids. All agents in this series have a four to five carbon alkyl linkage or bridge between the two nitrogens. With the exception of pentaquine, the other three 8-aminoquinolines have one asymmetric carbon. Although some differences may be seen in the metabolism of each stereoisomer and type of adverse response, there is little difference in antimalarial activity based on the compounds stereochemistry.

Primaquine. Primaquine is the only 8-aminoquinoline currently in use for the treatment of malaria. It is not used for prophylaxis. Its spectrum of activity is one of the narrowest of the currently used antimalarial drugs being indicated only for exoerythrocytic *P. vivax* malaria (site 2 in Fig. 7.1). To treat endoerythrocytic *P. vivax*, chloroquine or a drug indicated for chloroquine-resistant *P. vivax* is used with primaquine. In addition to its approved indication, it is also active against the exoerythrocytic stages of *P. ovale* and primary exoerythrocytic stages of *P. falciparum*. Primaquine also inhibits the gametocyte stage (site 4 in Fig. 7.1) that eliminates the form required to infect the mosquito carrier. In vitro and in vivo studies indicate that the stereochemistry at the asymmetric is not important for antimalarial activity. There appears to be less toxicity with the levorotatory isomer, but this is dose dependent and may not be that important at the doses used to treat exoerythrocytic *P. vivax* malaria.

Although structurally related to the cinchona alkaloids, the 8-aminoquinolines act by a different mechanism of action. Primaquine appears to disrupt the parasite's mitochondria. The result is disruption of several processes including maturation into the subsequent forms. An advantage is destroying exoerythrocytic forms before the parasite can infect erythrocytes. It is the latter step in the infectious process that makes malaria so debilitating.

Polycyclic Antimalarial Drugs

There are three antimalarial drugs that have, in common, polycyclic ring systems (Fig.7.5). The first is the common tetracycline antibiotic, doxycycline. The second is halofantrine, and the third is the discontinued agent that was used in the South Pacific, quinacrine.

Doxycycline. Like the other tetracyclines, doxycycline (see Chapter 8) inhibits the pathogen's protein synthesis by reversibly inhibiting the 30S ribosomal subunit. Bacteria and *Plasmodium* ribosomal subunits differ significantly from mammalian ribosomes such that this group of antibiotics do not readily bind to mammalian ribosomes and, therefore, show good selective toxicity. Although doxycycline is a good antibacterial, its use for malaria is limited to prophylaxis against strains of *P. falciparum* resistant to chloroquine and sulfadoxine–pyrimethamine. This use normally should not exceed 4 months. Because the tetracyclines chelate calcium, they can interfere with development of the permanent teeth in children. Therefore, their use in children definitely should be short term. Also,

Figure 7.5 • Polycyclic antimalarial drugs.

Figure 7.6 • Artemisinin and artemisinin-derived compounds.

tetracycline photosensitivity must be kept in mind, particularly because areas where malaria is endemic are also the areas with the greatest sunlight.

Halofantrine. Structurally, halofantrine differs from all other antimalarial drugs. It is a good example of drug design that incorporates bioisosteric principles as evidenced by the trifluoromethyl moiety. Halofantrine is a schizonticide (sites 1 and 2 in Fig. 7.1) and has no effect on the sporozoite, gametocyte, or hepatic stages. Both the parent compound and *N*-desbutyl metabolite are equally active in vitro. Halofantrine's specific mechanism of action against the parasite is not known. There is contradictory evidence that its mechanism ranges from requiring heme to disrupting the mitochondria. There is a prominent warning that halofantrine can affect nerve conduction in cardiac tissue.

Lumefantrine. Lumefantrine was developed in China. Its mechanism of action is poorly understood. There is some evidence that it inhibits the formation of β -hemin by forming a complex with hemin. Lumefantrine is very lipophilic and is

marketed in combination with the lipophilic artemisinin-derived artemether (Fig. 7.6).

Quinacrine HCl. Quinacrine is no longer available in the United States. It can be considered one of the most toxic of the antimalarial drugs even though, at one time, it was commonly used. It acts at many sites within the cell including intercalation of DNA strands, succinic dehydrogenase and mitochondrial electron transport, and cholinesterase. It may be tumorigenic and mutagenic and has been used as a sclerosing agent. Because it is an acridine dye, quinacrine can cause yellow discoloration of the skin and urine.

Artemisinin

The artemisinin series (Fig. 7.6) are the newest of the anti-malarial drugs and are structurally unique when compared with the compounds previously and currently used. The parent compound, artemisinin, is a natural product extracted from the dry leaves of *Artemisia Annu* (sweet wormwood). The plant has to be grown each year from seed because mature plants may lack the active drug. The

Figure 7.7 • Sulfadoxine and pyrimethamine.

growing conditions are critical to maximize artemisinin yield. Thus far, the best yields have been obtained from plants grown in North Vietnam, Chongqing province in China, and Tanzania.²⁵

All of the structures in Figure 7.6 are active against the *Plasmodium* genera that cause malaria. The key structure characteristic appears to be a “trioxane” consisting of the endoperoxide and dioxepin oxygens. This is shown by the somewhat simpler series of 3-aryltrioxanes at the bottom of Figure 7.6, which are active against the parasite. Note that the stereochemistry at position 12 is not critical.²⁶ Although in the victim’s erythrocyte, the malaria parasite consumes the hemoglobin consisting of ferrous (Fe^{+2}) iron converting it to toxic hemozoin containing ferric (Fe^{+3}) and then reduced to heme with its ferrous iron. The heme iron reacts with the trioxane moiety releasing reactive oxygen and carbon radicals and the highly reactive $\text{Fe}^{\text{IV}} = \text{O}$ species. The latter is postulated to be lethal to the parasite.^{27,28}

With the reduction of artemisinin to dihydroartemisinin, an asymmetric carbon forms and it is possible to form oil soluble and water soluble prodrugs. Both stereoisomers are active just as is seen in the simpler aryltrioxanes. The chemistry forming each of the artemisinin prodrugs results in the predominance of one isomer. The β -isomer predominates when producing the nonpolar methyl and ethyl ethers, whereas the α -isomer is the predominate product when forming the water-soluble hemisuccinate ester. The latter can be administered as 10-mg rectal capsules for patients who cannot take medication orally and parenteral treatment is not available.

Fixed Combinations

Because resistance is a frequent problem in the prophylaxis and treatment of malaria, combination therapies that use two distinctly different mechanisms have been developed. One combination inhibits folic acid biosynthesis and dihydrofolate reductase, and another combination acts on the parasite’s mitochondria and its dihydrofolate reductase. Both drugs in the third combination act on hemozoin, but by two different mechanisms.

Sulfadoxine and Pyrimethamine. This combination (Fig. 7.7) uses a drug from the sulfonamide antibacterial group and a pyrimidinediamine similar to trimethoprim (see Chapter 8). The combination is considered a schizonticide (site 2 in Fig. 7.1). The sulfonamide, sulfadoxine, interferes with the parasite’s ability to synthesize folic acid, and the pyrimidinediamine, pyrimethamine, inhibits the reduction of folic acid to its active tetrahydrofolate coenzyme form. Sulfonamides block the incorporation of *p*-aminobenzoic acid (PABA) forming dihydropteroic acid. Note the structures of dihydrofolic acid and tetrahydrofolic acid and how PABA is the central part of the folate structure (see Chapter 28). Normally, sulfonamides exhibit excellent selective toxicity because humans do not synthesize the vitamin folic acid. Nevertheless, there are warnings of severe to fatal occurrences of erythema multiforme, Stevens-Johnson syndrome, toxic epidermal necrolysis, and serum-sickness syndromes attributed to the sulfadoxine.

Pyrimethamine, developed in the 1950s, inhibits the reduction of folic acid and dihydrofolic acid to the active tetrahydrofolate coenzyme form. Although the latter is required for many fundamental reactions involving pyrimidine biosynthesis, the focus in the parasite is regeneration of N^5, N^{10} -methylene tetrahydrofolate from dihydrofolate. The synthesis of thymidine 5′-monophosphate from deoxyuridine 5′-monophosphate is a universal reaction in all cells forming DNA. There are enough differences in this enzyme and dihydrofolate reductase found in mammalian, bacterial, and *Plasmodium* cells that folate reductase inhibitors can be developed that show reasonable selective toxicity. In the case of the malaria parasite, the intimate relationship between thymidylate synthase and

Atovaquone

Proguanil

Figure 7.8 • Atovaquone and proguanil.

dihydrofolate reductase is such that pyrimethamine inhibits both enzymes.

This combination is indicated for prophylaxis and treatment of chloroquine resistance *P. falciparum* and may be used in combination with quinine. Although indicated only for *P. falciparum*, the combination is active against all the asexual erythrocytic forms. It has no activity against the sexual gametocyte form. The fixed combination contains 500-mg sulfadoxine and 25-mg pyrimethamine. There is a wide number of sulfonamides that could be used in combination with pyrimethamine. The usual approach is to use a sulfonamide that has similar pharmacokinetic properties with the dihydrofolate reductase inhibitor. For this combination, the peak plasma sulfadoxine occurs in 2.5 to 6 hours and pyrimethamine 1.5 to 8 hours. Resistance has developed with much of it involving mutations in either or both of the genes coding for dihydrofolate reductase and thymidylate synthase.

Atovaquone and Proguanil HCl. Atovaquone and proguanil HCl (Fig. 7.8) are administered in combination in the ratio of 2.5 atovaquone to 1 proguanil HCl measured in mg (not mmoles). Proguanil, developed in 1945, is an early example of a prodrug. It is metabolized to cycloguanil

(Fig. 7.9), primarily by CYP2C19. The polymorphic nature of this hepatic enzyme explains why certain subpopulations do not respond to proguanil. These groups cannot convert proguanil to the active cycloguanil.

The basis for this combination is two distinct and unrelated mechanisms of action against the parasite. Atovaquone is a selective inhibitor of the *Plasmodium's* mitochondrial electron transport system, and cycloguanil is a dihydrofolate reductase inhibitor. Atovaquone's chemistry is based on its being a naphthoquinone and participating in oxidation–reduction reactions as part of its quinone–hydroquinone system. It is patterned after Coenzyme Q found in the mitochondrial electron transport chains. The drug selectively interferes with mitochondrial electron transport, particularly at the parasite's cytochrome bc_1 site. This deprives the cell of needed ATP and could cause the cell to become anaerobic. Resistance to this drug comes from a mutation in the parasite's cytochrome.

Cycloguanil (Proguanil) interferes with deoxythymidylate synthesis by inhibiting dihydrofolate reductase. Resistance to proguanil/cycloguanil is attributed to amino acid changes near the dihydrofolate reductase binding site. Its elimination half-life (48–72 hour) is much shorter than the other anti-malarial dihydrofolate reductase, pyrimethamine (mean

Figure 7.9 • Conversion of proguanil to cycloguanil by CYP2C19.

Fosmidomycin

FR900098

elimination half-life of 111 hours). The combination is effective against both erythrocytic and exoerythrocytic *Plasmodium*. This drug combination is indicated for malaria resistant to chloroquine, halofantrine, mefloquine, and amodiaquine. Its main site is the sporozoite stage (site 1 in Fig. 7.1).

Artemether and Lumefantrine. These two antimalarials interfere with heme metabolism, thereby stopping development of the parasite in the erythrocyte states. Artemether, with its endoperoxide, acts oxidatively and lumefantrine may form a complex with hemin.

Future Trends

VACCINES

The development of an effective vaccine has been one of the most frustrating aspects in the prevention of malaria. There is no question that the *Plasmodium* parasite invokes an immune response. The problem seems to be identifying the antigenic component or components that cause a strong immune response. As already described, the RTS,S/AS01E vaccine is the only one showing promise.

NEW DRUG COMBINATIONS

Because of the general success of the artemisinin-based antimalarials, there have been several combinations evaluated. As mentioned previously, the artemether and lumefantrine combination has been approved. Undergoing phase III studies is a pyronaridine (Fig. 7.5) and artesunate (Fig. 7.6). Pyronaridine inhibits formation of hematin, possibly by a similar mechanism to that of chloroquine.²⁹

Figure 7.11 • Nonmevalonate pathway.

Figure 7.12 • Possible glutathione reductase inhibitors.

NEW DRUG APPROACHES

Inhibition of the Nonmevalonate Pathway. Fosmidomycin (Fig. 7.10) was isolated from a *Streptomyces* fermentation broth in 1980. Its selective toxicity is based on inhibiting a biochemical pathway not found in humans and mammals in general. This is the nonmevalonate pathway to form isoprenoids. Mammals, including humans, form their isoprenoids solely by mevalonic acid pathway. Many microorganisms have both pathways. Whereas the mevalonate pathway starts with three molecules of acetyl Co forming 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) followed by reduction to mevalonic acid by HMG-CoA reductase (site of the statin drugs), the nonmevalonate pathway is carbohydrate based (Fig. 7.11). Condensation of pyruvate and glyceraldehyde-3-phosphate by DOXP synthase produces the five carbon 1-deoxy-D-xylulose-5-phosphate (DOXP), which undergoes a complex reduction and isomerization forming 2-C-methyl-D-erythritol-4-phosphate. The enzyme for this reaction, DOXP reductoisomerase, is inhibited by fosmidomycin. The basic five-carbon isoprene unit, isopentenyl diphosphate concludes the pathway. The atoms have been numbered to

help follow the isomerization of the deoxy-xylulose intermediate to form the erythritol compound. The malaria parasite only has the nonmevalonate pathway, and initial studies show fosmidomycin to be relatively nontoxic in humans.³⁰ Replacement of fosmidomycin's *N*-aldehyde with an acetate produces a very active antimalarial agent that has been designated as FR900098.³¹

Inhibitors of Glutathione Reductase. The erythrocyte maintains a high oxygen environment and, therefore, has an elaborate reductase system to hold heme iron in the ferrous state. In contrast, the *Plasmodium* parasite lacks the antioxidant system to thrive in the erythrocyte's high oxygen environment and, therefore, has to rely on the erythrocyte's reductase pathways. This has led to development of compounds (Fig. 7.12) that inhibit erythrocytic glutathione reductase using chloroquine has the starting point for transport into the erythrocyte and naphthoquinone moiety to inhibit glutathione reductase.³² These two molecules also are examples of the dual function approach in which the molecule attacks the parasite by two different mechanisms of action.

REVIEW QUESTIONS

1. Why is malaria seen in agricultural areas where humans live close to each other?
2. What nondrug methods are used to prevent humans from contracting malaria?
3. Why should it be possible to develop a vaccine against malaria?
4. Which two *Plasmodium* species are the preferable targets for antimalarial drug therapy because they account for nearly 90% of the cases?
5. Name the cells where the parasite resides.
6. Why is combination therapy becoming more common?

CHAPTER 8

Antibacterial Antibiotics

JOHN M. BEALE, JR.

CHAPTER OVERVIEW

Since Alexander Fleming accidentally discovered penicillin in 1929, the numbers of antibiotics that have been added to our therapeutic armamentarium has grown tremendously. Along with immunizing biologicals, antibiotics have turned the tide in terms of the treatment of infectious disease. They are truly medical miracles. Yet, because of the overuse of many of these agents and the biochemical fickleness of many bacteria, resistance to antibiotics has become a serious problem in the 21st century. Indeed, there are now organisms that cannot be arrested or killed by any of the common antibiotics. Clearly, new approaches are needed. This chapter will present each of the antibiotics as chemical classes, such as tetracyclines, aminoglycosides, macrolides, and β -lactam antibiotics. In each class, it is important to note the different ranges of bacteria that each will treat. Notably, it is difficult to define an absolute range for any antibiotic. Populations of bacteria differ in their characteristics among regions and hospitals in those region. So, sometimes, an antibiotic is listed as effective against a particular bacterial strain, but the concentration needed to kill the organism is too high. The bottom line is that when describing efficacy of an antibiotic against a particular organism, it is necessary to look at clinical results. This chapter will describe ranges of activity in a general sense. The history of the antibiotics is an interesting one and is well worth considering. Hence, the chapter will begin with a brief historical overview.

HISTORICAL BACKGROUND

Sir Alexander Fleming's accidental discovery of the antibacterial properties of penicillin in 1929¹ is largely credited with initiating the modern antibiotic era. Not until 1938, however, when Florey and Chain introduced penicillin into therapy, did practical medical exploitation of this important discovery begin to be realized. Centuries earlier, humans had learned to use crude preparations empirically for the topical treatment of infections, which we now assume to be effective because of the antibiotic substances present. As early as 500 to 600 BC, molded curd of soybean was used in Chinese folk medicine to treat boils and carbuncles. Moldy cheese had also been used for centuries by Chinese and Ukrainian peasants to treat infected wounds. The discovery by Pasteur and Joubert in 1877 that anthrax bacilli were killed when grown in culture in

the presence of certain bacteria, along with similar observations by other microbiologists, led Vuillemin² to define *antibiosis* (literally “against life”) as the biological concept of survival of the fittest, in which one organism destroys another to preserve itself. The word *antibiotic* was derived from this root. The use of the term by the lay public, as well as the medical and scientific communities, has become so widespread that its original meaning has become obscured.

In 1942, Waksman³ proposed the widely cited definition that “an antibiotic or antibiotic substance is a substance produced by microorganisms, which has the capacity of inhibiting the growth and even of destroying other microorganisms.” Later proposals^{4–6} have sought both to expand and to restrict the definition to include any substance produced by a living organism that is capable of inhibiting the growth or survival of one or more species of microorganisms in low concentrations. The advances made by medicinal chemists to modify naturally occurring antibiotics and to prepare synthetic analogs necessitated the inclusion of semisynthetic and synthetic derivatives in the definition. Therefore, a substance is classified as an antibiotic if the following conditions are met:

1. It is a product of metabolism (although it may be duplicated or even have been anticipated by chemical synthesis).
2. It is a synthetic product produced as a structural analog of a naturally occurring antibiotic.
3. It antagonizes the growth or survival of one or more species of microorganisms.
4. It is effective in low concentrations.

The isolation of the antibacterial antibiotic tyrocidin from the soil bacterium *Bacillus brevis* by Dubois suggested the probable existence of many antibiotic substances in nature and provided the impetus for the search for them. An organized search of the order Actinomycetales led Waksman and associates to isolate streptomycin from *Streptomyces griseus*. The discovery that this antibiotic possessed *in vivo* activity against *Mycobacterium tuberculosis* in addition to numerous species of Gram-negative bacilli was electrifying. It was now evident that soil microorganisms would provide a rich source of antibiotics. Broad screening programs were instituted to find antibiotics that might be effective in the treatment of infections hitherto resistant to existing chemotherapeutic agents, as well as to provide safer and more effective chemotherapy. The discoveries of broad-spectrum antibacterial antibiotics such as chloramphenicol and the tetracyclines, antifungal antibiotics

such as nystatin and griseofulvin (see Chapter 6), and the ever-increasing number of antibiotics that may be used to treat infectious agents that have developed resistance to some of the older antibiotics, attest to the spectacular success of this approach as it has been applied in research programs throughout the world.

◆ CURRENT STATUS

Commercial and scientific interest in the antibiotic field has led to the isolation and identification of antibiotic substances that may be numbered in the thousands. Numerous semisynthetic and synthetic derivatives have been added to the total. Very few such compounds have found application in general medical practice, however, because in addition to the ability to combat infections or neoplastic disease, an antibiotic must possess other attributes. First, it must exhibit sufficient selective toxicity to be decisively effective against pathogenic microorganisms or neoplastic tissue, on the one hand, without causing significant toxic effects, on the other. Second, an antibiotic should be chemically stable enough to be isolated, processed, and stored for a reasonable length of time without deterioration of potency. The amenability of an antibiotic for oral or parenteral administration to be converted into suitable dosage forms to provide active drug *in vivo* is also important. Third, the rates of biotransformation and elimination of the antibiotic should be slow enough to allow a convenient dosing schedule, yet rapid and complete enough to facilitate removal of the drug and its metabolites from the body soon after administration has been discontinued. Some groups of antibiotics, because of certain unique properties, have been designated for specialized uses, such as the treatment of tuberculosis (TB) or fungal infections. Others are used for cancer chemotherapy. These antibiotics are described along with other drugs of the same therapeutic class: antifungal and antitubercular antibiotics are discussed in Chapter 6, and antineoplastic antibiotics are discussed in Chapter 10.

The spectacular success of antibiotics in the treatment of human diseases has prompted the expansion of their use into several related fields. Extensive use of their antimicrobial power is made in veterinary medicine. The discovery that low-level administration of antibiotics to meat-producing animals resulted in faster growth, lower mortality, and better quality has led to the use of these products as feed supplements. Several antibiotics are used to control bacterial and fungal diseases of plants. Their use in food preservation is being studied carefully. Indeed, such uses of antibiotics have necessitated careful studies of their long-term effects on humans and their effects on various commercial processes. For example, foods that contain low-level amounts of antibiotics may be able to produce allergic reactions in hypersensitive persons, or the presence of antibiotics in milk may interfere with the manufacture of cheese.

The success of antibiotics in therapy and related fields has made them one of the most important products of the drug industry today. The quantity of antibiotics produced in the United States each year may now be measured in several millions of pounds and valued at billions of dollars. With research activity stimulated to find new substances to treat viral infections that now are combated with only limited success and with the promising discovery that some

antibiotics are active against cancers that may be viral in origin, the future development of more antibiotics and the increase in the amounts produced seem to be assured.

◆ COMMERCIAL PRODUCTION

The commercial production of antibiotics for medicinal use follows a general pattern, differing in detail for each antibiotic. The general scheme may be divided into six steps: (a) preparation of a pure culture of the desired organism for use in inoculation of the fermentation medium; (b) fermentation, during which the antibiotic is formed; (c) isolation of the antibiotic from the culture medium; (d) purification; (e) assays for potency, sterility, absence of pyrogens, and other necessary data; and (f) formulation into acceptable and stable dosage forms.

◆ SPECTRUM OF ACTIVITY

The ability of some antibiotics, such as chloramphenicol and the tetracyclines, to antagonize the growth of numerous pathogens has resulted in their designation as *broad-spectrum* antibiotics. Designations of spectrum of activity are of somewhat limited use to the physician, unless they are based on clinical effectiveness of the antibiotic against specific microorganisms. Many of the broad-spectrum antibiotics are active only in relatively high concentrations against some of the species of microorganisms often included in the “spectrum.”

◆ MECHANISMS OF ACTION

The manner in which antibiotics exert their actions against susceptible organisms varies. The mechanisms of action of some of the more common antibiotics are summarized in Table 8.1. In many instances, the mechanism of action is not fully known; for a few (e.g., penicillins), the site of action is known, but precise details of the mechanism are still under investigation. The biochemical processes of microorganisms are a lively subject for research, for an understanding of those mechanisms that are peculiar to the metabolic systems of infectious organisms is the basis for the future development of modern chemotherapeutic agents. Antibiotics that interfere with the metabolic systems found in microorganisms and not in mammalian cells are the most successful anti-infective agents. For example, antibiotics that interfere with the synthesis of bacterial cell walls have a high potential for selective toxicity. Some antibiotics structurally resemble some essential metabolites of microorganisms, which suggests that competitive antagonism may be the mechanism by which they exert their effects. Thus, cycloserine is believed to be an antimetabolite for D-alanine, a constituent of bacterial cell walls. Many antibiotics selectively interfere with microbial protein synthesis (e.g., the aminoglycosides, tetracyclines, macrolides, chloramphenicol, and lincomycin) or nucleic acid synthesis (e.g., rifampin). Others, such as the polymyxins and the polyenes, are believed to interfere with the integrity and function of microbial cell membranes. The mechanism of action of an antibiotic determines, in general, whether the agent exerts a bactericidal or a bacteriostatic

TABLE 8.1 Mechanisms of Antibiotic Action

Site of Action	Antibiotic	Process Interrupted	Type of Activity
Cell wall	Bacitracin	Mucopeptide synthesis	Bactericidal
	Cephalosporin	Cell wall cross-linking	Bactericidal
	Cycloserine	Synthesis of cell wall peptides	Bactericidal
	Penicillins	Cell wall cross-linking	Bactericidal
	Vancomycin	Mucopeptide synthesis	Bactericidal
Cell membrane	Amphotericin B	Membrane function	Fungicidal
	Nystatin	Membrane function	Fungicidal
	Polymyxins	Membrane integrity	Bactericidal
Ribosomes	Chloramphenicol	Protein synthesis	Bacteriostatic
50S subunit	Erythromycin	Protein synthesis	Bacteriostatic
	Lincomycins	Protein synthesis	Bacteriostatic
30S subunit	Aminoglycosides	Protein synthesis and fidelity	Bactericidal
	Tetracyclines	Protein synthesis	Bacteriostatic
Nucleic acids	Actinomycin	DNA and mRNA synthesis	Pancidal
	Griseofulvin	Cell division, microtubule assembly	Fungistatic
DNA and/or RNA	Mitomycin C	DNA synthesis	Pancidal
	Rifampin	mRNA synthesis	Bactericidal

action. The distinction may be important for the treatment of serious, life-threatening infections, particularly if the natural defense mechanisms of the host are either deficient or overwhelmed by the infection. In such situations, a bactericidal agent is obviously indicated. Much work remains to be done in this area, and as mechanisms of action are revealed, the development of improved structural analogs of effective antibiotics probably will continue to increase.

CHEMICAL CLASSIFICATION

The chemistry of antibiotics is so varied that a chemical classification is of limited value. Some similarities can be found, however, indicating that some antibiotics may be the products of similar mechanisms in different organisms and that these structurally similar products may exert their activities in a similar manner. For example, several important antibiotics have in common a macrolide structure (i.e., a large lactone ring). This group includes erythromycin and oleandomycin. The tetracycline family comprises a group of compounds very closely related chemically. Several compounds contain closely related amino sugar moieties, such as those found in streptomycins, kanamycins, neomycins, paromomycins, and gentamicins. The antifungal antibiotics nystatin and the amphotericins (see Chapter 6) are examples of a group of conjugated polyene compounds. The bacitracins, tyrothricin, and polymyxin are among a large group of polypeptides that exhibit antibiotic action. The penicillins and cephalosporins are β -lactam ring-containing antibiotics derived from amino acids.

MICROBIAL RESISTANCE

The normal biological processes of microbial pathogens are varied and complex. Thus, it seems reasonable to assume that there are many ways in which they may be inhibited and that different microorganisms that elaborate antibiotics antagonistic to a common "foe" produce compounds that are chemically dissimilar and that act on different processes. In fact, nature has produced many chemically different antibiotics

that can attack the same microorganism by different pathways. The diversity of antibiotic structure has proved to be of real clinical value. As the pathogenic cell develops drug resistance, another antibiotic, attacking another metabolic process of the resisting cell, remains effective. The development of new and different antibiotics has been very important in providing the means for treating resistant strains of organisms that previously had been susceptible to an older antibiotic. More recently, the elucidation of biochemical mechanisms of microbial resistance to antibiotics, such as the inactivation of penicillins and cephalosporins by β -lactamase-producing bacteria, has stimulated research in the development of semisynthetic analogs that resist microbial biotransformation. The evolution of *nosocomial* (hospital-acquired) strains of staphylococci resistant to penicillin and of Gram-negative bacilli (e.g., *Pseudomonas* and *Klebsiella* spp., *Escherichia coli*, and others) often resistant to several antibiotics has become a serious medical problem. No doubt, the promiscuous and improper use of antibiotics has contributed to the emergence of resistant bacterial strains. The successful control of diseases caused by resistant strains of bacteria will require not only the development of new and improved antibiotics but also the rational use of available agents.

β -LACTAM ANTIBIOTICS

Antibiotics that possess the β -lactam (a four-membered cyclic amide) ring structure are the dominant class of agents currently used for the chemotherapy of bacterial infections. The first antibiotic to be used in therapy, penicillin (penicillin G or benzylpenicillin), and a close biosynthetic relative, phenoxymethyl penicillin (penicillin V), remain the agents of choice for the treatment of infections caused by most species of Gram-positive bacteria. The discovery of a second major group of β -lactam antibiotics, the cephalosporins, and chemical modifications of naturally occurring penicillins and cephalosporins have provided semisynthetic derivatives that are variously effective against bacterial species known to be resistant to penicillin, in particular, penicillinase-producing staphylococci and Gram-negative bacilli. Thus, apart from a

few strains that have either inherent or acquired resistance, almost all bacterial species are sensitive to one or more of the available β -lactam antibiotics.

Mechanism of Action

In addition to a broad spectrum of antibacterial action, two properties contribute to the unequalled importance of β -lactam antibiotics in chemotherapy: a potent and rapid bactericidal action against bacteria in the growth phase and a very low frequency of toxic and other adverse reactions in the host. The uniquely lethal antibacterial action of these agents has been attributed to a selective inhibition of bacterial cell wall synthesis.⁷ Specifically, the basic mechanism involved is inhibition of the biosynthesis of the dipeptidoglycan that provides strength and rigidity to the cell wall. Penicillins and cephalosporins acylate a specific bacterial D-transpeptidase,⁸ thereby rendering it inactive for its role in forming peptide cross-links of two linear peptidoglycan strands by transpeptidation and loss of D-alanine. Bacterial D-alanine carboxypeptidases are also inhibited by β -lactam antibiotics.

Binding studies with tritiated benzylpenicillin have shown that the mechanisms of action of various β -lactam antibiotics are much more complex than previously assumed. Studies in *E. coli* have revealed as many as seven different functional proteins, each with an important role in cell wall biosynthesis.⁹ These penicillin-binding proteins (PBPs) have the following functional properties:

- PBPs 1_a and 1_b are transpeptidases involved in peptidoglycan synthesis associated with cell elongation. Inhibition results in spheroplast formation and rapid cell lysis,^{9,10} caused by *autolysins* (bacterial enzymes that create nicks in the cell wall for attachment of new peptidoglycan units or for separation of daughter cells during cell division¹⁰).
- PBP 2 is a transpeptidase involved in maintaining the rod shape of bacilli.¹¹ Inhibition results in ovoid or round forms that undergo delayed lysis.
- PBP 3 is a transpeptidase required for septum formation during cell division.¹² Inhibition results in the formation of filamentous forms containing rod-shaped units that cannot separate. It is not yet clear whether inhibition of PBP 3 is lethal to the bacterium.
- PBPs 4 through 6 are carboxypeptidases responsible for the hydrolysis of D-alanine–D-alanine terminal peptide bonds of the cross-linking peptides. Inhibition of these enzymes is apparently not lethal to the bacterium,¹³ even though cleavage of the terminal D-alanine bond is required before peptide cross-linkage.

The various β -lactam antibiotics differ in their affinities for PBPs. Penicillin G binds preferentially to PBP 3, whereas the first-generation cephalosporins bind with higher affinity to PBP 1_a. In contrast to other penicillins and to cephalosporins, which can bind to PBPs 1, 2, and 3, amdinocillin binds only to PBP 2.

THE PENICILLINS

Commercial Production and Unitage

Until 1944, it was assumed that the active principle in penicillin was a single substance and that variation in activity of different products was because of the amount of inert

materials in the samples. Now we know that during the biological elaboration of the antibiotic, several closely related compounds may be produced. These compounds differ chemically in the acid moiety of the amide side chain. Variations in this moiety produce differences in antibiotic effect and in physicochemical properties, including stability. Thus, one can speak of penicillins as a group of compounds and identify each penicillin specifically. As each of the different penicillins was first isolated, letter designations were used in the United States; the British used Roman numerals.

Over 30 penicillins have been isolated from fermentation mixtures. Some of these occur naturally; others have been biosynthesized by altering the culture medium to provide certain precursors that may be incorporated as acyl groups. Commercial production of biosynthetic penicillins today depends chiefly on various strains of *Penicillium notatum* and *Penicillium chrysogenum*. In recent years, many more penicillins have been prepared semisynthetically and, undoubtedly, many more will be added to the list in attempts to find superior products.

Because the penicillin first used in chemotherapy was not a pure compound and exhibited varying activity among samples, it was necessary to evaluate it by microbiological assay. The procedure for assay was developed at Oxford, England, and the value became known as the *Oxford unit*: 1 Oxford unit is defined as the smallest amount of penicillin that will inhibit, in vitro, the growth of a strain of *Staphylococcus* in 50 mL of culture medium under specified conditions. Now that pure crystalline penicillin is available, the *United States Pharmacopoeia (USP)* defines *unit* as the antibiotic activity of 0.6 μ g of penicillin G sodium reference standard. The weight–unit relationship of the penicillins varies with the acyl substituent and with the salt formed of the free acid: 1 mg of penicillin G sodium is equivalent to 1,667 units, 1 mg of penicillin G procaine is equivalent to 1,009 units, and 1 mg of penicillin G potassium is equivalent to 1,530 units.

The commercial production of penicillin has increased markedly since its introduction. As production increased, the cost dropped correspondingly. When penicillin was first available, 100,000 units sold for \$20. Currently, the same quantity costs less than a penny. Fluctuations in the production of penicillins through the years have reflected changes in the relative popularity of broad-spectrum antibiotics and penicillins, the development of penicillin-resistant strains of several pathogens, the more recent introduction of semisynthetic penicillins, the use of penicillins in animal feeds and for veterinary purposes, and the increase in marketing problems in a highly competitive sales area.

Table 8.2 shows the general structure of the penicillins and relates the structure of the more familiar ones to their various designations.

Nomenclature

The nomenclature of penicillins is somewhat complex and very cumbersome. Two numbering systems for the fused bicyclic heterocyclic system exist. The *Chemical Abstracts* system initiates the numbering with the sulfur atom and assigns the ring nitrogen the 4-position. Thus, penicillins are named as 4-thia-1-azabicyclo[3.2.0]heptanes, according to this system. The numbering system adopted by the *USP* is the reverse of the *Chemical Abstracts* procedure, assigning

TABLE 8.2 Structure of Penicillins

Generic Name	Chemical Name	R Group	Generic Name	Chemical Name	R Group
Penicillin G	Benzylpenicillin		Amoxicillin	D- α -Amino- <i>p</i> -hydroxybenzylpenicillin	
Penicillin V	Phenoxymethylpenicillin		Cyclacillin	1-Aminocyclohexylpenicillin	
Methicillin	2,6-Dimethoxyphenylpenicillin		Carbenicillin	α -Carboxybenzylpenicillin	
Nafcillin	2-Ethoxy-1-naphthylpenicillin		Ticarcillin	α -Carboxy-3-thienylpenicillin	
Oxacillin	5-Methyl-3-phenyl-4-isoxazolylpenicillin		Piperacillin	α -(4-Ethyl-2,3-dioxo-1-piperazinylcarbonylamino)benzylpenicillin	
Cloxacillin	5-Methyl-3-(2-chlorophenyl)-4-isoxazolylpenicillin		Mezlocillin	α -(1-Methanesulfonyl-2-oxoimidazolidino-carbonylamino)benzylpenicillin	
Dicloxacillin	5-Methyl-3-(2,6-dichlorophenyl)-4-isoxazolylpenicillin				
Ampicillin	D- α -Aminobenzylpenicillin				

number 1 to the nitrogen atom and number 4 to the sulfur atom. Three simplified forms of penicillin nomenclature have been adopted for general use. The first uses the name “penam” for the unsubstituted bicyclic system, including the amide carbonyl group, with one of the foregoing numbering systems as just described. Thus, penicillins generally are designated according to the *Chemical Abstracts* system as 5-acylamino-2,2-dimethylpenam-3-carboxylic acids. The second, seen more frequently in the medical literature, uses the name “penicillanic acid” to describe the ring system with substituents that are generally present (i.e., 2,2-dimethyl and 3-carboxyl). A third form, followed in this chapter, uses trivial nomenclature to name the entire 6-carboxylaminopenicillanic acid portion of the molecule penicillin and then

distinguishes compounds on the basis of the R group of the acyl portion of the molecule. Thus, penicillin G is named benzylpenicillin, penicillin V is phenoxymethylpenicillin, methicillin is 2,6-dimethoxyphenylpenicillin, and so on. For the most part, the latter two systems serve well for naming and comparing closely similar penicillin structures, but they are too restrictive to be applied to compounds with unusual substituents or to ring-modified derivatives.

Stereochemistry

The penicillin molecule contains three chiral carbon atoms (C-3, C-5, and C-6). All naturally occurring and microbiologically active synthetic and semisynthetic penicillins have the

same absolute configuration about these three centers. The carbon atom bearing the acylamino group (C-6) has the L configuration, whereas the carbon to which the carboxyl group is attached has the D configuration. Thus, the acylamino and carboxyl groups are *trans* to each other, with the former in the α and the latter in the β orientation relative to the penam ring system. The atoms composing the 6-aminopenicillanic acid (6-APA) portion of the structure are derived biosynthetically from two amino acids, L-cysteine (S-1, C-5, C-6, C-7, and 6-amino) and L-valine (2,2-dimethyl, C-2, C-3, N-4, and 3-carboxyl). The absolute stereochemistry of the penicillins is designated 3S:5R:6R, as shown below.

Synthesis

Examination of the structure of the penicillin molecule shows that it contains a fused ring system of unusual design, the β -lactam thiazolidine structure. The nature of the β -lactam ring delayed elucidation of the structure of penicillin, but its determination resulted from a collaborative research program involving groups in Great Britain and the United States during the years 1943 to 1945.¹⁴ Attempts to synthesize these compounds resulted, at best, in only trace amounts until Sheehan and Henery-Logan¹⁵ adapted techniques developed in peptide synthesis to the synthesis of penicillin V. This procedure is not likely to replace the established fermentation processes because the last step in the

reaction series develops only 10% to 12% penicillin. It is of advantage in research because it provides a means of obtaining many new amide chains hitherto not possible to achieve by biosynthetic procedures.

Two other developments have provided additional means for making new penicillins. A group of British scientists, Batchelor et al.¹⁶ reported the isolation of 6-APA from a culture of *P. chrysogenum*. This compound can be converted to penicillins by acylation of the 6-amino group. Sheehan and Ferris¹⁷ provided another route to synthetic penicillins by converting a natural penicillin, such as penicillin G potassium, to an intermediate (Fig. 8.1), from which the acyl side chain has been cleaved and which then can be treated to form biologically active penicillins with various new side chains. By these procedures, new penicillins, superior in activity and stability to those formerly in wide use, were found, and no doubt others will be produced. The first commercial products of these research activities were phenoxyethylpenicillin (phenethicillin) (Fig. 8.2) and dimethoxyphenylpenicillin (methicillin).

Chemical Degradation

The early commercial penicillin was a yellow-to-brown amorphous powder that was so unstable that refrigeration was required to maintain a reasonable level of activity for a short time. Improved purification procedures provided the white

crystalline material in use today. Crystalline penicillin must be protected from moisture, but when kept dry, the salts will remain stable for years without refrigeration. Many penicillins have an unpleasant taste, which must be overcome in the formation of pediatric dosage forms. All of the natural penicillins are strongly dextrorotatory. The solubility and other physicochemical properties of the penicillins are affected by the nature of the acyl side chain and by the cations used to make salts of the acid. Most penicillins are acids with pK_a values in the range of 2.5 to 3.0, but some are amphoteric. The free acids are not suitable for oral or parenteral administration. The sodium and potassium salts of most penicillins, however, are soluble in water and readily absorbed orally or parenterally. Salts of penicillins with organic bases, such as benzathine, procaine, and hydrabamine, have limited water solubility and are, therefore, useful as depot forms to provide effective blood levels over a long period in the treatment of chronic infections. Some of the crystalline salts of the penicillins are hygroscopic and must be stored in sealed containers.

The main cause of deterioration of penicillin is the reactivity of the strained lactam ring, particularly to hydrolysis. The course of the hydrolysis and the nature of the degradation products are influenced by the pH of the solution.^{18,19} Thus, the β -lactam carbonyl group of penicillin readily undergoes nucleophilic attack by water or (especially) hydroxide ion to form the inactive penicilloic acid, which is reasonably stable in neutral to alkaline solutions but readily undergoes decarboxylation and further hydrolytic reactions in acidic solutions. Other nucleophiles, such as hydroxylamines, alkylamines, and alcohols, open the β -lactam ring to form the corresponding hydroxamic acids, amides, and esters. It has been speculated²⁰ that one of the causes of penicillin allergy may be the formation of antigenic penicilloyl proteins in vivo by the reaction of nucleophilic groups (e.g., ϵ -amino) on specific body proteins with the β -lactam carbonyl group. In strongly acidic solutions (pH < 3), penicillin undergoes a complex series of reactions leading to various inactive degradation products (Fig. 8.3).¹⁹ The first step appears to involve rearrangement to the penicillanic acid. This process is initiated by protonation of the β -lactam nitrogen, followed by nucleophilic attack of the acyl oxygen atom on the β -lactam carbonyl carbon. The subsequent opening of the β -lactam ring destabilizes the thiazolidine ring, which then also suffers acid-catalyzed ring opening to form the penicillanic acid. The latter is very unstable and experiences two major degradation pathways. The most easily understood path involves hydrolysis of the oxazolone ring to form the unstable penamaldic acid. Because it is an enamine, penamaldic acid easily hydrolyzes to penicillamine (a major degradation product) and penaldic acid. The second path involves a complex rearrangement of penicillanic acid to a penillic acid through a series of intramolecular processes that remain to be elucidated completely. Penillic acid (an imidazoline-2-carboxylic acid) readily decarboxylates and suffers hydrolytic ring opening under acidic conditions to form a second major end product of acid-catalyzed penicillin degradation—penilloic acid. Penilloic acid, the major product formed under weakly acidic to alkaline (as well as enzymatic) hydrolytic conditions, cannot be detected as an intermediate under strongly acidic conditions. It exists in equilibrium with penamaldic acid, however, and undergoes decarboxylation in acid to form penilloic acid. The third major product of the degradation is penicilloaldehyde,

formed by decarboxylation of penaldic acid (a derivative of malonaldehyde).

By controlling the pH of aqueous solutions within a range of 6.0 to 6.8 and refrigerating the solutions, aqueous preparations of the soluble penicillins may be stored for up to several weeks. The relationship of these properties to the pharmacetics of penicillins has been reviewed by Schwartz and Buckwalter.²¹ Some buffer systems, particularly phosphates and citrates, exert a favorable effect on penicillin stability, independent of the pH effect. Finholt et al.²² showed that these buffers may catalyze penicillin degradation, however, if the pH is adjusted to obtain the requisite ions. Hydroalcoholic solutions of penicillin G potassium are about as unstable as aqueous solutions.²³ Because penicillins are inactivated by metal ions such as zinc and copper, it has been suggested that the phosphates and the citrates combine with these metals to prevent their existence as free ions in solution.

Oxidizing agents also inactivate penicillins, but reducing agents have little effect on them. Temperature affects the rate of deterioration; although the dry salts are stable at room temperature and do not require refrigeration, prolonged heating inactivates the penicillins.

Acid-catalyzed degradation in the stomach contributes strongly to the poor oral absorption of penicillin. Thus, efforts to obtain penicillins with improved pharmacokinetic and microbiological properties have focused on acyl functionalities that would minimize sensitivity of the β -lactam ring to acid hydrolysis while maintaining antibacterial activity.

Substitution of an electron-withdrawing group in the α position of benzylpenicillin markedly stabilizes the penicillin to acid-catalyzed hydrolysis. Thus, phenoxymethylpenicillin, α -aminobenzylpenicillin, and α -halobenzylpenicillin are significantly more stable than benzylpenicillin in acid solutions. The increased stability imparted by such electron-withdrawing groups has been attributed to decreased reactivity (nucleophilicity) of the side chain amide carbonyl oxygen atom toward participation in β -lactam ring opening to form penicillenic acid. Obviously, α -aminobenzylpenicillin (ampicillin) exists as the protonated form in acidic (as well as neutral) solutions, and the ammonium group is known to be powerfully electron-withdrawing.

Bacterial Resistance

Some bacteria, in particular most species of Gram-negative bacilli, are naturally resistant to the action of penicillins. Other normally sensitive species can develop penicillin resistance (either through natural selection of resistant individuals or through mutation). The best understood and, probably, the most important biochemical mechanism of penicillin resistance is the bacterial elaboration of enzymes that inactivate penicillins. Such enzymes, which have been given the non-specific name *penicillinases*, are of two general types: β -lactamases and acylases. By far, the more important of these are the β -lactamases, enzymes that catalyze the hydrolytic opening of the β -lactam ring of penicillins to produce inactive penicilloic acids. Synthesis of bacterial β -lactamases may be under chromosomal or plasmid R factor control and may be either constitutive or inducible (stimulated by the presence of the substrate), depending on the bacterial species. The well-known resistance among strains of *Staphylococcus aureus* is apparently entirely because of the production of an inducible β -lactamase. Resistance among Gram-negative

Figure 8.3 • Degradation of penicillins.

bacilli, however, may result from other poorly characterized "resistance factors" or constitutive β -lactamase elaboration. β -Lactamases produced by Gram-negative bacilli appear to be cytoplasmic enzymes that remain in the bacterial cell, whereas those elaborated by *S. aureus* are synthesized in the cell wall and released extracellularly. β -Lactamases from different bacterial species may be classified²⁴⁻²⁶ by their structure, their substrate and inhibitor specificities, their physical properties (e.g., pH optimum, isoelectric point, molecular weight), and their immunological properties.

Specific acylases (enzymes that can hydrolyze the acylamino side chain of penicillins) have been obtained from several species of Gram-negative bacteria, but their possi-

ble role in bacterial resistance has not been well defined. These enzymes find some commercial use in the preparation of 6-APA for the preparation of semisynthetic penicillins. 6-APA is less active and hydrolyzed more rapidly (enzymatically and nonenzymatically) than penicillin.

Another important resistance mechanism, especially in Gram-negative bacteria, is decreased permeability to penicillins. The cell envelope in most Gram-negative bacteria is more complex than in Gram-positive bacteria. It contains an outer membrane (linked by lipoprotein bridges to the peptidoglycan cell wall) not present in Gram-positive bacteria, which creates a physical barrier to the penetration of antibiotics, especially those that are hydrophobic.²⁷ Small

hydrophilic molecules, however, can traverse the outer membrane through pores formed by proteins called *porins*.²⁸ Alteration of the number or nature of porins in the cell envelope²⁸ also could be an important mechanism of antibiotic resistance. Bacterial resistance can result from changes in the affinity of PBPs for penicillins.²⁹ Altered PBP binding has been demonstrated in non- β -lactamase-producing strains of penicillin-resistant *Neisseria gonorrhoeae*³⁰ and methicillin-resistant *S. aureus* (MRSA).³¹

Certain strains of bacteria are resistant to the lytic properties of penicillins but remain susceptible to their growth-inhibiting effects. Thus, the action of the antibiotic has been converted from bactericidal to bacteriostatic. This mechanism of resistance is termed *tolerance* and apparently results from impaired autolysin activity in the bacterium.

Penicillinase-Resistant Penicillins

The availability of 6-APA on a commercial scale made possible the synthesis of numerous semisynthetic penicillins modified at the acylamino side chain. Much of the early work done in the 1960s was directed toward the preparation of derivatives that would resist destruction by β -lactamases, particularly those produced by penicillin-resistant strains of *S. aureus*, which constituted a very serious health problem at that time. In general, increasing the steric hindrance at the α -carbon of the acyl group increased resistance to staphylococcal β -lactamase, with maximal resistance being observed with quaternary substitution.³² More fruitful from the standpoint of antibacterial potency, however, was the observation that the α -acyl carbon could be part of an aromatic (e.g., phenyl or naphthyl) or heteroaromatic (e.g., 4-isoxazolyl) system.³³ Substitutions at the *ortho* positions of a phenyl ring (e.g., 2,6-dimethoxy [methicillin]) or the 2-position of a 1-naphthyl system (e.g., 2-ethoxyl [nafcillin]) increase the steric hindrance of the acyl group and confer more β -lactamase resistance than shown by the unsubstituted compounds or those substituted at positions more distant from the α -carbon. Bulkier substituents are required to confer effective β -lactamase resistance among five-membered-ring heterocyclic derivatives.³⁴ Thus, members of the 4-isoxazolyl penicillin family (e.g., oxacillin, cloxacillin, and dicloxacillin) require both the 3-aryl and 5-methyl (3-methyl and 5-aryl) substituents for effectiveness against β -lactamase-producing *S. aureus*.

Increasing the bulkiness of the acyl group is not without its price, however, because all of the clinically available penicillinase-resistant penicillins are significantly less active than either penicillin G or penicillin V against most non- β -lactamase-producing bacteria normally sensitive to the penicillins. The β -lactamase-resistant penicillins tend to be comparatively lipophilic molecules that do not penetrate well into Gram-negative bacteria. The isoxazolyl penicillins, particularly those with an electronegative substituent in the 3-phenyl group (cloxacillin, dicloxacillin, and floxacillin), are also resistant to acid-catalyzed hydrolysis of the β -lactam, for the reasons described previously. Steric factors that confer β -lactamase resistance, however, do not necessarily also confer stability to acid. Accordingly, methicillin, which has electron-donating groups (by resonance) *ortho* to the carbonyl carbon, is even more labile to acid-catalyzed hydrolysis than is penicillin G because of the more rapid formation of the penicillenic acid derivative.

Extended-Spectrum Penicillins

Another highly significant advance arising from the preparation of semisynthetic penicillins was the discovery that the introduction of an ionized or polar group into the α -position of the side chain benzyl carbon atom of penicillin G confers activity against Gram-negative bacilli. Hence, derivatives with an ionized α -amino group, such as ampicillin and amoxicillin, are generally effective against such Gram-negative genera as *Escherichia*, *Klebsiella*, *Haemophilus*, *Salmonella*, *Shigella*, and non-indole-producing *Proteus*. Furthermore, activity against penicillin G-sensitive, Gram-positive species is largely retained. The introduction of an α -amino group in ampicillin (or amoxicillin) creates an additional chiral center. Extension of the antibacterial spectrum brought about by the substituent applies only to the D-isomer, which is 2 to 8 times more active than either the L-isomer or benzylpenicillin (which are equiactive) against various species of the aforementioned genera of Gram-negative bacilli.

The basis for the expanded spectrum of activity associated with the ampicillin group is not related to β -lactamase inhibition, as ampicillin and amoxicillin are even more labile than penicillin G to the action of β -lactamases elaborated by both *S. aureus* and various species of Gram-negative bacilli, including strains among the ampicillin-sensitive group. Hydrophilic penicillins, such as ampicillin, penetrate Gram-negative bacteria more readily than penicillin G, penicillin V, or methicillin. This selective penetration is believed to take place through the porin channels of the cell membrane.³⁵

α -Hydroxy substitution also yields "expanded-spectrum" penicillins with activity and stereoselectivity similar to that of the ampicillin group. The α -hydroxybenzylpenicillins are, however, about 2 to 5 times less active than their corresponding α -aminobenzyl counterparts and, unlike the latter, not very stable under acidic conditions.

Incorporation of an acidic substituent at the α -benzyl carbon atom of penicillin G also imparts clinical effectiveness against Gram-negative bacilli and, furthermore, extends the spectrum of activity to include organisms resistant to ampicillin. Thus, α -carboxybenzylpenicillin (carbenicillin) is active against ampicillin-sensitive, Gram-negative species and additional Gram-negative bacilli of the genera *Pseudomonas*, *Klebsiella*, *Enterobacter*, indole-producing *Proteus*, *Serratia*, and *Providencia*. The potency of carbenicillin against most species of penicillin G-sensitive, Gram-positive bacteria is several orders of magnitude lower than that of either penicillin G or ampicillin, presumably because of poorer penetration of a more highly ionized molecule into these bacteria. (Note that α -aminobenzylpenicillins exist as zwitterions over a broad pH range and, as such, are considerably less polar than carbenicillin.) This increased polarity is apparently an advantage for the penetration of carbenicillin through the cell envelope of Gram-negative bacteria via porin channels.³⁵

Carbenicillin is active against both β -lactamase-producing and non- β -lactamase-producing strains of Gram-negative bacteria. It is somewhat resistant to a few of the β -lactamases produced by Gram-negative bacteria, especially members of the Enterobacteriaceae family.³⁶ Resistance to β -lactamases elaborated by Gram-negative bacteria, therefore, may be an important component of carbenicillin's activity against some ampicillin-resistant organisms. β -Lactamases produced by *Pseudomonas* spp., however, readily hydrolyze carbenicillin. Although carbenicillin is also somewhat

resistant to staphylococcal β -lactamase, it is considerably less so than methicillin or the isoxazolyl penicillins, and its inherent antistaphylococcal activity is less impressive than that of the penicillinase-resistant penicillins. The penicillinase-resistant penicillins, despite their resistance to most β -lactamases, however, share the lack of activity of penicillin G against Gram-negative bacilli, primarily because of an inability to penetrate the bacterial cell envelope.

Compared with the aminoglycoside antibiotics, the potency of carbenicillin against such Gram-negative bacilli as *Pseudomonas aeruginosa*, *Proteus vulgaris*, and *Klebsiella pneumoniae* is much less impressive. Large parenteral doses are required to achieve bactericidal concentrations in plasma and tissues. The low toxicity of carbenicillin (and the penicillins in general), however, usually permits (in the absence of allergy) the use of such high doses without untoward effects. Furthermore, carbenicillin (and other penicillins), when combined with aminoglycosides, exerts a synergistic bactericidal action against bacterial species sensitive to both agents, frequently allowing the use of a lower dose of the more toxic aminoglycoside than is normally required for treatment of a life-threatening infection. The chemical incompatibility of penicillins and aminoglycosides requires that the two antibiotics be administered separately; otherwise, both are inactivated. Iyengar et al.³⁷ showed that acylation of amino groups in the aminoglycoside by the β -lactam of the penicillin occurs.

Unlike the situation with ampicillin, the introduction of asymmetry at the α -benzyl carbon in carbenicillin imparts little or no stereoselectivity of antibacterial action; the individual enantiomers are nearly equally active and readily epimerized to the racemate in aqueous solution. Because it is a derivative of phenylmalonic acid, carbenicillin readily decarboxylates to benzylpenicillin in the presence of acid; therefore, it is not active (as carbenicillin) orally and must be administered parenterally. Esterification of the α -carboxyl group (e.g., as the 5-indanyl ester) partially protects the compound from acid-catalyzed destruction and provides an orally active derivative that is hydrolyzed to carbenicillin in the plasma. The plasma levels of free carbenicillin achieved with oral administration of such esters, however, may not suffice for effective treatment of serious infections caused by some species of Gram-negative bacilli, such as *P. aeruginosa*.

A series of α -acylureido-substituted penicillins, exemplified by azlocillin, mezlocillin, and piperacillin, exhibit greater activity against certain Gram-negative bacilli than carbenicillin. Although the acylureidopenicillins are acylated derivatives of ampicillin, the antibacterial spectrum of activity of the group is more like that of carbenicillin. The acylureidopenicillins are, however, superior to carbenicillin against *Klebsiella* spp., *Enterobacter* spp., and *P. aeruginosa*. This enhanced activity is apparently not because of β -lactamase resistance, in that both inducible and plasmid-mediated β -lactamases hydrolyze these penicillins. More facile penetration through the cell envelope of these particular bacterial species is the most likely explanation for the greater potency. The acylureidopenicillins, unlike ampicillin, are unstable under acidic conditions; therefore, they are not available for oral administration.

Protein Binding

The nature of the acylamino side chain also determines the extent to which penicillins are plasma protein bound.

Quantitative structure–activity relationship (QSAR) studies of the binding of penicillins to human serum^{38,39} indicate that hydrophobic groups (positive π dependence) in the side chain appear to be largely responsible for increased binding to serum proteins. Penicillins with polar or ionized substituents in the side chain exhibit low-to-intermediate fractions of protein binding. Accordingly, ampicillin, amoxicillin, and cyclacillin experience 25% to 30% protein binding, and carbenicillin and ticarcillin show 45% to 55% protein binding. Those with nonpolar, lipophilic substituents (nafcillin and isoxazolyl penicillins) are more than 90% protein bound. The penicillins with less complex acyl groups (benzylpenicillin, phenoxymethylpenicillin, and methicillin) fall in the range of 35% to 80%. Protein binding is thought to restrict the tissue availability of drugs if the fraction bound is sufficiently high; thus, the tissue distribution of the penicillins in the highly bound group may be inferior to that of other penicillins. The similarity of biological half-lives for various penicillins, however, indicates that plasma protein binding has little effect on duration of action. All of the commercially available penicillins are secreted actively by the renal active transport system for anions. The reversible nature of protein binding does not compete effectively with the active tubular secretion process.

Allergy to Penicillins

Allergic reactions to various penicillins, ranging in severity from a variety of skin and mucous membrane rashes to drug fever and anaphylaxis, constitute the major problem associated with the use of this class of antibiotics. Estimates place the prevalence of hypersensitivity to penicillin G throughout the world between 1% and 10% of the population. In the United States and other industrialized countries, it is nearer the higher figure, ranking penicillin the most common cause of drug-induced allergy. The penicillins that are most frequently implicated in allergic reactions are penicillin G and ampicillin. Virtually all commercially available penicillins, however, have been reported to cause such reactions; in fact, cross-sensitivity among most chemical classes of 6-acylamino penicillanic acid derivatives has been demonstrated.⁴⁰

The chemical mechanisms by which penicillin preparations become antigenic have been studied extensively.²⁰ Evidence suggests that penicillins or their rearrangement products formed in vivo (e.g., penicillic acids)⁴¹ react with lysine ϵ -amino groups of proteins to form penicilloyl proteins, which are major antigenic determinants.^{42,43} Early clinical observations with the biosynthetic penicillins G and V indicated a higher incidence of allergic reactions with unpurified, amorphous preparations than with highly purified, crystalline forms, suggesting that small amounts of highly antigenic penicilloyl proteins present in unpurified samples were a cause. Polymeric impurities in ampicillin dosage forms have been implicated as possible antigenic determinants and a possible explanation for the high frequency of allergic reactions with this particular semisynthetic penicillin. Ampicillin is known to undergo pH-dependent polymerization reactions (especially in concentrated solutions) that involve nucleophilic attack of the side chain amino group of one molecule on the β -lactam carbonyl carbon atom of a second molecule, and so on.⁴⁴ The high frequency of antigenicity shown by ampicillin polymers, together with

TABLE 8.3 Classification and Properties of Penicillins

Penicillin	Source	Acid Resistance	Oral Absorption (%)	Plasma Protein Binding (%)	β -Lactamase Resistance (<i>S. aureus</i>)	Spectrum of Activity	Clinical Use
Benzylpenicillin	Biosynthetic	Poor	Poor (20)	50–60	No	Intermediate	Multipurpose
Penicillin V	Biosynthetic	Good	Good (60)	55–80	No	Intermediate	Multipurpose
Methicillin	Semisynthetic	Poor	None	30–40	Yes	Narrow	Limited use
Nafcillin	Semisynthetic	Fair	Variable	90	Yes	Narrow	Limited use
Oxacillin	Semisynthetic	Good	Fair (30)	85–94	Yes	Narrow	Limited use
Cloxacillin	Semisynthetic	Good	Good (50)	88–96	Yes	Narrow	Limited use
Dicloxacillin	Semisynthetic	Good	Good (50)	95–98	Yes	Narrow	Limited use
Ampicillin	Semisynthetic	Good	Fair (40)	20–25	No	Broad	Multipurpose
Amoxicillin	Semisynthetic	Good	Good (75)	20–25	No	Broad	Multipurpose
Carbenicillin	Semisynthetic	Poor	None	50–60	No	Extended	Limited use
Ticarcillin	Semisynthetic	Poor	None	45	No	Extended	Limited use
Mezlocillin	Semisynthetic	Poor	Nil	50	No	Extended	Limited use
Piperacillin	Semisynthetic	Poor	Nil	50	No	Extended	Limited use

their isolation and characterization in some ampicillin preparations, supports the theory that they can contribute to ampicillin-induced allergy.⁴⁵

Classification

Various designations have been used to classify penicillins, based on their sources, chemistry, pharmacokinetic properties, resistance to enzymatic spectrum of activity, and clinical uses (Table 8.3). Thus, penicillins may be biosynthetic, semisynthetic, or (potentially) synthetic; acid-resistant or not; orally or (only) parenterally active; and resistant to β -lactamases (penicillinases) or not. They may have a narrow, intermediate, broad, or extended spectrum of antibacterial activity and may be intended for multipurpose or limited clinical use. Designations of the activity spectrum as narrow, intermediate, broad, or extended are relative and do not necessarily imply the breadth of therapeutic application. Indeed, the classification of penicillin G as a “narrow-spectrum” antibiotic has meaning only relative to other penicillins. Although the β -lactamase-resistant penicillins have a spectrum of activity similar to that of penicillin G, they generally are reserved for the treatment of infections caused by penicillin G-resistant, β -lactamase-producing *S. aureus* because their activity against most penicillin G-sensitive bacteria is significantly inferior. Similarly, carbenicillin and ticarcillin usually are reserved for the treatment of infections caused by ampicillin-resistant, Gram-negative bacilli because they offer no advantage (and have some disadvantages) over ampicillin or penicillin G in infections sensitive to them.

Products

Penicillin G

For years, the most popular penicillin has been penicillin G, or benzylpenicillin. In fact, with the exception of patients allergic to it, penicillin G remains the agent of choice for the treatment of more different kinds of bacterial infection than any other antibiotic. It was first made available as the water-soluble salts of potassium, sodium, and calcium. These salts of penicillin are inactivated by the gastric juice and are not effective when administered orally unless antacids, such as calcium carbonate, aluminum hydroxide, and magnesium trisilicate; or a strong buffer, such as sodium citrate, is added. Also, because penicillin is absorbed poorly from the

intestinal tract, oral doses must be very large, about five times the amount necessary with parenteral administration. Only after the production of penicillin had increased enough to make low-priced penicillin available did the oral dosage forms become popular. The water-soluble potassium and sodium salts are used orally and parenterally to achieve high plasma concentrations of penicillin G rapidly. The more water-soluble potassium salt usually is preferred when large doses are required. Situations in which hyperkalemia is a danger, however, as in renal failure, require use of the sodium salt; the potassium salt is preferred for patients on salt-free diets or with congestive heart conditions.

The rapid elimination of penicillin from the bloodstream through the kidneys by active tubular secretion and the need to maintain an effective concentration in blood have led to the development of “repository” forms of this drug. Suspensions of penicillin in peanut oil or sesame oil with white beeswax added were first used to prolong the duration of injected forms of penicillin. This dosage form was replaced by a suspension in vegetable oil, to which aluminum monostearate or aluminum distearate was added. Today, most repository forms are suspensions of high-molecular weight amine salts of penicillin in a similar base.

Penicillin G Procaine

The first widely used amine salt of penicillin G was made with procaine. Penicillin G procaine (Crysticillin, Duracillin, Wycillin) can be made readily from penicillin G sodium by treatment with procaine hydrochloride. This salt is considerably less soluble in water than the alkali metal salts, requiring about 250 mL to dissolve 1 g. Free penicillin is released only as the compound dissolves and dissociates. It has an activity of 1,009 units/mg. A large number of preparations for injection of penicillin G procaine are commercially available. Most of these are either suspensions in water to which a suitable dispersing or suspending agent, a

buffer, and a preservative have been added or suspensions in peanut oil or sesame oil that have been gelled by the addition of 2% aluminum monostearate. Some commercial products are mixtures of penicillin G potassium or sodium with penicillin G procaine; the water-soluble salt provides rapid development of a high plasma concentration of penicillin, and the insoluble salt prolongs the duration of effect.

Penicillin G Benzathine

Since penicillin G benzathine, *N,N'*-dibenzylethylenediamine dipenicillin G (Bicillin, Permapen), is the salt of a diamine, 2 moles of penicillin are available from each molecule. It is very insoluble in water, requiring about 3,000 mL to dissolve 1 g. This property gives the compound great stability and prolonged duration of effect. At the pH of gastric juice, it is quite stable, and food intake does not interfere with its absorption. It is available in tablet form and in several parenteral preparations. The activity of penicillin G benzathine is equivalent to 1,211 units/mg.

Several other amines have been used to make penicillin salts, and research is continuing on this subject. Other amines that have been used include 2-chloroprocaine; *L-N*-methyl-1,2-diphenyl-2-hydroxyethylamine (*L*-ephedamine); dibenzylamine; tripelennamine (Pyribenzamine); and *N,N'*-bis-(dehydroabietyl)ethylenediamine (hydrabamine).

Penicillin V

In 1948, Behrens et al.⁴⁶ reported penicillin V, phenoxymethylpenicillin (Pen Vee, V-Cillin) as a biosynthetic product. It was not until 1953, however, that its clinical value was recognized by some European scientists. Since then, it has enjoyed wide use because of its resistance to hydrolysis by gastric juice and its ability to produce uniform concentrations in blood (when administered orally). The free acid requires about 1,200 mL of water to dissolve 1 g,

and it has an activity of 1,695 units/mg. For parenteral solutions, the potassium salt is usually used. This salt is very soluble in water. Solutions of it are made from the dry salt at the time of administration. Oral dosage forms of the potassium salt are also available, providing rapid, effective plasma concentrations of this penicillin. The salt of phenoxymethylpenicillin with *N,N'*-bis(dehydroabietyl)ethylenediamine (hydrabamine, Compicillin-V) provides a very long-acting form of this compound. Its high water insolubility makes it a desirable compound for aqueous suspensions used as liquid oral dosage forms.

Methicillin Sodium

During 1960, methicillin sodium, 2,6-dimethoxyphenylpenicillin sodium (Staphcillin), the second penicillin produced as a result of the research that developed synthetic analogs, was introduced for medicinal use.

Reacting 2,6-dimethoxybenzoyl chloride with 6-APA forms 6-(2,6-dimethoxybenzamido)penicillanic acid. The sodium salt is a white, crystalline solid that is extremely soluble in water, forming clear, neutral solutions. As with other penicillins, it is very sensitive to moisture, losing about half of its activity in 5 days at room temperature. Refrigeration at 5°C reduces the loss in activity to about 20% in the same period. Solutions prepared for parenteral use may be kept as long as 24 hours if refrigerated. It is extremely sensitive to acid (a pH of 2 causes 50% loss of activity in 20 minutes); thus, it cannot be used orally.

Methicillin sodium is particularly resistant to inactivation by the penicillinase found in staphylococci and somewhat more resistant than penicillin G to penicillinase from *Bacillus cereus*. Methicillin and many other penicillinase-resistant penicillins induce penicillinase formation, an observation that has implications concerning use of these agents in the treatment of penicillin G-sensitive infections. Clearly, the use of a penicillinase-resistant penicillin should not be followed by penicillin G.

The absence of the benzyl methylene group of penicillin G and the steric protection afforded by the 2- and 6-methoxy groups make this compound particularly resistant to enzymatic hydrolysis.

Methicillin sodium has been introduced for use in the treatment of staphylococcal infections caused by strains resistant to other penicillins. It is recommended that it not be used in general therapy, to avoid the possible widespread development of organisms resistant to it.

The incidence of interstitial nephritis, a probable hypersensitivity reaction, is reportedly higher with methicillin than with other penicillins.

Oxacillin Sodium

Oxacillin sodium, (5-methyl-3-phenyl-4-isoxazolyl)penicillin sodium monohydrate (Prostaphlin), is the salt of a semisynthetic penicillin that is highly resistant to inactivation by penicillinase. Apparently, the steric effects of the 3-phenyl and 5-methyl groups of the isoxazolyl ring prevent the binding of this penicillin to the β -lactamase active site and, thereby, protect the lactam ring from degradation in much the same way as has been suggested for methicillin. It is also relatively resistant to acid hydrolysis and, therefore, may be administered orally with good effect.

Oxacillin sodium, which is available in capsule form, is reasonably well absorbed from the gastrointestinal (GI) tract, particularly in fasting patients. Effective plasma levels of oxacillin are obtained in about 1 hour, but despite extensive plasma protein binding, it is excreted rapidly through the kidneys. Oxacillin experiences some first-pass metabolism in the liver to the 5-hydroxymethyl derivative. This metabolite has antibacterial activity comparable to that of oxacillin but is less avidly protein bound and more rapidly excreted. The halogenated analogs cloxacillin, dicloxacillin, and floxacillin experience less 5-methyl hydroxylation.

The use of oxacillin and other isoxazolylpenicillins should be restricted to the treatment of infections caused by staphylococci resistant to penicillin G. Although their spectrum of activity is similar to that of penicillin G, the isoxazolylpenicillins are, in general, inferior to it and the phenoxymethylpenicillins for the treatment of infections caused by penicillin G-sensitive bacteria. Because isoxazolylpenicillins cause allergic reactions similar to those produced by other penicillins, they should be used with great caution in patients who are penicillin sensitive.

Cloxacillin Sodium

The chlorine atom *ortho* to the position of attachment of the phenyl ring to the isoxazole ring enhances the activity of cloxacillin sodium, [3-(*o*-chlorophenyl)-5-methyl-4-isoxazolyl]penicillin sodium monohydrate (Tegopen), over that of oxacillin, not by increasing its intrinsic antibacterial activity but by enhancing its oral absorption, leading to higher plasma levels. In almost all other respects, it resembles oxacillin.

Dicloxacillin Sodium

The substitution of chlorine atoms on both carbons *ortho* to the position of attachment of the phenyl ring to the isoxazole ring is presumed to enhance further the stability of the oxacillin congener dicloxacillin sodium, [3-(2,6-dichlorophenyl)-5-methyl-4-isoxazolyl]penicillin sodium monohydrate (Dynapen, Pathocil, Veracillin) and to produce high plasma concentrations of it. Its medicinal properties and use are similar to those of cloxacillin sodium. Progressive halogen substitution, however, also increases the fraction bound to protein in the plasma, potentially reducing the concentration of free antibiotic in plasma and tissues. Its medicinal properties and use are the same as those of cloxacillin sodium.

Nafcillin Sodium

Nafcillin sodium, 6-(2-ethoxy-1-naphthyl)penicillin sodium (Unipen), is another semisynthetic penicillin that resulted from the search for penicillinase-resistant compounds. Like methicillin, nafcillin has substituents in positions *ortho* to the point of attachment of the aromatic ring to the carboxamide group of penicillin. No doubt, the ethoxy group and the second ring of the naphthalene group play steric roles in stabilizing nafcillin against penicillinase. Very similar structures have been reported to produce similar results in some substituted 2-biphenylpenicillins.³³

Unlike methicillin, nafcillin is stable enough in acid to permit its use by oral administration. When it is given orally, its absorption is somewhat slow and incomplete, but satisfactory plasma levels may be achieved in about 1 hour. Relatively small amounts are excreted through the kidneys; most is excreted in the bile. Even though some cyclic reabsorption from the gut may occur, nafcillin given orally should be readministered every 4 to 6 hours. This salt is readily soluble in water and may be administered intramuscularly or intravenously to obtain high plasma concentrations quickly for the treatment of serious infections.

Nafcillin sodium may be used in infections caused solely by penicillin G-resistant staphylococci or when streptococci are present also. Although it is recommended that it be used exclusively for such resistant infections,

nafcillin is also effective against pneumococci and group A β -hemolytic streptococci. Because, like other penicillins, it may cause allergic side effects, it should be administered with care.

Ampicillin

Ampicillin, 6-[D- α -aminophenylacetamido]penicillanic acid, D- α -aminobenzylpenicillin (Penbritin, Polycillin, Omnipen, Amcill, Principen), meets another goal of the research on semisynthetic penicillins—an antibacterial spectrum broader than that of penicillin G. This product is active against the same Gram-positive organisms that are susceptible to other penicillins, and it is more active against some Gram-negative bacteria and enterococci than are other penicillins. Obviously, the α -amino group plays an important role in the broader activity, but the mechanism for its action is unknown. It has been suggested that the amino group confers an ability to cross cell wall barriers that are impenetrable to other penicillins. D-(-)-Ampicillin, prepared from D-(-)- α -aminophenylacetic acid, is significantly more active than L-(+)-ampicillin.

Ampicillin is not resistant to penicillinase, and it produces the allergic reactions and other untoward effects found in penicillin-sensitive patients. Because such reactions are relatively rare, however, it may be used to treat infections caused by Gram-negative bacilli for which a broad-spectrum antibiotic, such as a tetracycline or chloramphenicol, may be indicated but not preferred because of undesirable reactions or lack of bactericidal effect. Ampicillin is not so widely active, however, that it should be used as a broad-spectrum antibiotic in the same manner as the tetracyclines. It is particularly useful for the treatment of acute urinary tract infections caused by *E. coli* or *Proteus mirabilis* and is the agent of choice against *Haemophilus influenzae* infections. Ampicillin, together with probenecid, to inhibit its active tubular excretion, has become a treatment of choice for gonorrhea in recent years. β -Lactamase-producing strains of Gram-negative bacteria that are highly resistant to ampicillin, however, appear to be increasing in the world population. The threat from such resistant strains is particularly great with *H. influenzae* and *N. gonorrhoeae*, because there are few alternative therapies for infections caused by these organisms. Incomplete absorption and excretion of effective concentrations in the bile may contribute to the effectiveness of ampicillin in the treatment of salmonellosis and shigellosis.

Ampicillin is water soluble and stable in acid. The protonated α -amino group of ampicillin has a pK_a of 7.3,⁴⁶ and thus it is protonated extensively in acidic media, which explains ampicillin's stability to acid hydrolysis and instability to alkaline hydrolysis. It is administered orally and is absorbed from the intestinal tract to produce peak plasma concentrations in about 2 hours. Oral doses must be repeated about every 6 hours because it is excreted rapidly and unchanged through the kidneys. It is available as a white,

crystalline, anhydrous powder that is sparingly soluble in water or as the colorless or slightly buff-colored crystalline trihydrate that is soluble in water. Either form may be used for oral administration, in capsules or as a suspension. Earlier claims of higher plasma levels for the anhydrous form than for the trihydrate following oral administration have been disputed.^{47,48} The white, crystalline sodium salt is very soluble in water, and solutions for injections should be administered within 1 hour after being made.

Bacampicillin Hydrochloride

Bacampicillin hydrochloride (Spectrobid) is the hydrochloride salt of the 1-ethoxycarbonyloxyethyl ester of ampicillin. It is a prodrug of ampicillin with no antibacterial activity. After oral absorption, bacampicillin is hydrolyzed rapidly by esterases in the plasma to form ampicillin.

Oral absorption of bacampicillin is more rapid and complete than that of ampicillin and less affected by food. Plasma levels of ampicillin from oral bacampicillin exceed those of oral ampicillin or amoxicillin for the first 2.5 hours but thereafter are the same as for ampicillin and amoxicillin.⁴⁹ Effective plasma levels are sustained for 12 hours, allowing twice-a-day dosing.

Amoxicillin

Amoxicillin, 6-[D-(-)- α -amino-*p*-hydroxyphenylacetamido]penicillanic acid (Amoxil, Larotid, Polymox), a semisynthetic penicillin introduced in 1974, is simply the *p*-hydroxy analog of ampicillin, prepared by acylation of 6-APA with *p*-hydroxyphenylglycine.

Its antibacterial spectrum is nearly identical with that of ampicillin, and like ampicillin, it is resistant to acid, susceptible to alkaline and β -lactamase hydrolysis, and weakly protein bound. Early clinical reports indicated that orally administered amoxicillin possesses significant advantages over ampicillin, including more complete GI absorption to give higher plasma and urine levels, less diarrhea, and little or no effect of food on absorption.⁵⁰ Thus, amoxicillin has largely replaced ampicillin for the treatment of certain systemic and urinary tract infections for which oral administration is desirable. Amoxicillin is reportedly less effective than ampicillin in the treatment of bacillary dysentery, presumably because of its greater GI absorption. Considerable evidence suggests that oral absorption of α -aminobenzyl-substituted penicillins (e.g.,

ampicillin and amoxicillin) and cephalosporins is, at least in part, carrier mediated,⁵¹ thus explaining their generally superior oral activity.

Amoxicillin is a fine, white to off-white, crystalline powder that is sparingly soluble in water. It is available in various oral dosage forms. Aqueous suspensions are stable for 1 week at room temperature.

Carbenicillin Disodium, Sterile

Carbenicillin disodium, disodium α -carboxybenzylpenicillin (Geopen, Pyopen), is a semisynthetic penicillin released in the United States in 1970, which was introduced in England and first reported by Ancred et al.⁵² in 1967. Examination of its structure shows that it differs from ampicillin in having an ionizable carboxyl group rather than an amino group substituted on the α -carbon atom of the benzyl side chain. Carbenicillin has a broad range of antimicrobial activity, broader than any other known penicillin, a property attributed to the unique carboxyl group. It has been proposed that the carboxyl group improves penetration of the molecule through cell wall barriers of Gram-negative bacilli, compared with other penicillins.

Carbenicillin is not stable in acids and is inactivated by penicillinase. It is a malonic acid derivative and, as such, decarboxylates readily to penicillin G, which is acid labile. Solutions of the disodium salt should be freshly prepared but, when refrigerated, may be kept for 2 weeks. It must be administered by injection and is usually given intravenously.

Carbenicillin has been effective in the treatment of systemic and urinary tract infections caused by *P. aeruginosa*, indole-producing *Proteus* spp., and *Providencia* spp., all of which are resistant to ampicillin. The low toxicity of carbenicillin, with the exception of allergic sensitivity, permits the use of large dosages in serious infections. Most clinicians prefer to use a combination of carbenicillin and gentamicin for serious pseudomonal and mixed coliform infections. The two antibiotics are chemically incompatible, however, and should never be combined in an intravenous solution.

Carbenicillin Indanyl Sodium

Efforts to obtain orally active forms of carbenicillin led to the eventual release of the 5-indanyl ester carbenicillin indanyl, 6-[2-phenyl-2-(5-indanyloxycarbonyl)acetamido]penicillanic acid (Geocillin), in 1972. Approximately 40% of the usual oral dose of indanyl carbenicillin is absorbed. After absorption, the ester is hydrolyzed rapidly by plasma and tissue esterases to yield carbenicillin. Thus, although the highly lipophilic and highly protein-bound ester has in vitro activity comparable with that of carbenicillin, its activity in vivo is due to carbenicillin. Indanyl carbenicillin thus provides an orally active alternative for the treatment of carbenicillin-sensitive systemic and urinary tract infections caused by *Pseudomonas* spp., indole-positive *Proteus* spp., and selected species of Gram-negative bacilli.

Clinical trials with indanyl carbenicillin revealed a relatively high frequency of GI symptoms (nausea, occasional vomiting, and diarrhea). It seems doubtful that the high doses required for the treatment of serious systemic infections could be tolerated by most patients. Indanyl carbenicillin occurs as the sodium salt, an off-white, bitter powder that is freely soluble in water. It is stable in acid. It should be protected from moisture to prevent hydrolysis of the ester.

Ticarcillin Disodium, Sterile

Ticarcillin disodium, α -carboxy-3-thienylpenicillin (Ticar), is an isostere of carbenicillin in which the phenyl group is replaced by a thienyl group. This semisynthetic penicillin derivative, like carbenicillin, is unstable in acid and, therefore, must be administered parenterally. It is similar to carbenicillin in antibacterial spectrum and pharmacokinetic properties. Two advantages for ticarcillin are claimed: (a) slightly better pharmacokinetic properties, including higher serum levels and a longer duration of action; and (b) greater in vitro potency against several species of Gram-negative bacilli, most notably *P. aeruginosa* and *Bacteroides fragilis*. These advantages can be crucial in the treatment of serious infections requiring high-dose therapy.

Mezlocillin Sodium, Sterile

Mezlocillin (Mezlin) is an acylureidopenicillin with an antibacterial spectrum similar to that of carbenicillin and ticarcillin; however, there are some major differences. It is much more active against most *Klebsiella* spp., *P. aeruginosa*, anaerobic bacteria (e.g., *Streptococcus faecalis* and *B. fragilis*), and *H. influenzae*. It is recommended for the treatment of serious infections caused by these organisms.

Mezlocillin is not generally effective against β -lactamase-producing bacteria, nor is it active orally. It is available as a white, crystalline, water-soluble sodium salt for injection. Solutions should be prepared freshly and, if not used within 24 hours, refrigerated. Mezlocillin and other acylureidopenicillins, unlike carbenicillin, exhibit nonlinear pharmacokinetics. Peak plasma levels, half-life, and area under the time curve increase with increased dosage. Mezlocillin has less effect on bleeding time than carbenicillin, and it is less likely to cause hypokalemia.

Piperacillin Sodium, Sterile

Piperacillin (Pipracil) is the most generally useful of the extended-spectrum acylureidopenicillins. It is more active than mezlocillin against susceptible strains of Gram-negative aerobic bacilli, such as *Serratia marcescens*, *Proteus*, *Enterobacter*, *Citrobacter* spp., and *P. aeruginosa*. Mezlocillin, however, appears to be more active against *Providencia* spp. and *K. pneumoniae*. Piperacillin is also active against anaerobic bacteria, especially *B. fragilis* and *S. faecalis* (enterococcus). β -Lactamase-producing strains of these organisms are, however, resistant to piperacillin, which is hydrolyzed by *S. aureus* β -lactamase. The β -lactamase susceptibility of piperacillin is not absolute because β -lactamase-producing, ampicillin-resistant strains of *N. gonorrhoeae* and *H. influenzae* are susceptible to piperacillin.

Piperacillin is destroyed rapidly by stomach acid; therefore, it is active only by intramuscular or intravenous administration. The injectable form is provided as the white, crystalline, water-soluble sodium salt. Its pharmacokinetic properties are very similar to those of the other acylureidopenicillins.

β -LACTAMASE INHIBITORS

The strategy of using a β -lactamase inhibitor in combination with a β -lactamase-sensitive penicillin in the therapy for infections caused by β -lactamase-producing bacterial strains has, until relatively recently, failed to live up to its obvious promise. Early attempts to obtain synergy against such resistant strains, by using combinations consisting of a β -lactamase-resistant penicillin (e.g., methicillin or oxacillin) as a competitive inhibitor and a β -lactamase-sensitive penicillin (e.g., ampicillin or carbenicillin) to kill the organisms, met with limited success. Factors that may contribute to the failure of such combinations to achieve synergy include (a) the failure of most lipophilic penicillinase-resistant penicillins to penetrate the cell envelope of Gram-negative bacilli in effective concentrations, (b) the reversible binding of

penicillinase-resistant penicillins to β -lactamase, requiring high concentrations to prevent substrate binding and hydrolysis, and (c) the induction of β -lactamases by some penicillinase-resistant penicillins.

The discovery of the naturally occurring, mechanism-based inhibitor clavulanic acid, which causes potent and progressive inactivation of β -lactamases (Fig. 8.4), has created renewed interest in β -lactam combination therapy. This interest has led to the design and synthesis of additional mechanism-based β -lactamase inhibitors, such as sulbactam and tazobactam, and the isolation of naturally occurring β -lactams, such as the thienamycins, which both inhibit β -lactamases and interact with PBPs.

The chemical events leading to the inactivation of β -lactamases by mechanism-based inhibitors are very complex. In a review of the chemistry of β -lactamase inhibition, Knowles⁵³ has described two classes of β -lactamase inhibitors: class I inhibitors that have a heteroatom leaving group at position 1 (e.g., clavulanic acid and sulbactam) and class II inhibitors that do not (e.g., the carbapenems). Unlike competitive inhibitors, which bind reversibly to the enzyme they inhibit, mechanism-based inhibitors react with the enzyme in much the same way that the substrate does. With the β -lactamases, an acyl-enzyme intermediate is formed by reaction of the β -lactam with an active-site serine hydroxyl group of the enzyme. For normal substrates, the acyl-enzyme intermediate readily undergoes hydrolysis, destroying the substrate and freeing the enzyme to attack more substrate. The acyl-enzyme intermediate formed when a mechanism-based inhibitor is attacked by the enzyme is diverted by tautomerism to a more stable imine form that hydrolyzes more slowly to eventually free the enzyme (transient inhibition), or for a class I inhibitor, a second group on the enzyme may be attacked to inactivate it. Because these inhibitors are also substrates for the enzymes that they inactivate, they are sometimes referred to as "suicide substrates."

Because class I inhibitors cause prolonged inactivation of certain β -lactamases, they are particularly useful in combination with extended-spectrum, β -lactamase-sensitive penicillins to treat infections caused by β -lactamase-producing bacteria. Three such inhibitors, clavulanic acid, sulbactam, and tazobactam, are currently marketed in the United States for this purpose. A class II inhibitor, the carbapenem derivative imipenem, has potent antibacterial activity in addition to its ability to cause transient inhibition of some β -lactamases. Certain antibacterial cephalosporins with a leaving group at the C-3 position can cause transient inhibition of β -lactamases by forming stabilized acyl-enzyme intermediates. These are discussed more fully later in this chapter.

The relative susceptibilities of various β -lactamases to inactivation by class I inhibitors appear to be related to the molecular properties of the enzymes.^{25,54,55} β -Lactamases belonging to group A, a large and somewhat heterogeneous group of serine enzymes, some with narrow (e.g., penicillinases or cephalosporinases) and some with broad (i.e., general β -lactamases) specificities, are generally inactivated by class I inhibitors. A large group of chromosomally encoded serine β -lactamases belonging to group C with specificity for cephalosporins are, however, resistant to inactivation by class I inhibitors. A small group of Zn^{2+} -requiring metallo- β -lactamases (group B) with broad substrate specificities⁵⁶ are also not inactivated by class I inhibitors.

Figure 8.4 • Mechanism-based inhibition of β -lactamases.

Products

Clavulanate Potassium

Clavulanic acid is an antibiotic isolated from *Streptomyces clavuligeris*. Structurally, it is a 1-oxopenam lacking the 6-acylamino side chain of penicillins but possessing a 2-hydroxyethylidene moiety at C-2. Clavulanic acid exhibits very weak antibacterial activity, comparable with that of 6-APA and, therefore, is not useful as an antibiotic. It is, however, a potent inhibitor of *S. aureus* β -lactamase and plasmid-mediated β -lactamases elaborated by Gram-negative bacilli.

Combinations of amoxicillin and the potassium salt of clavulanic acid are available (Augmentin) in various fixed-dose oral dosage forms intended for the treatment of skin, respiratory, ear, and urinary tract infections caused by β -lactamase-producing bacterial strains. These combinations are effective against β -lactamase-producing strains of *S. aureus*, *E. coli*, *K. pneumoniae*, *Enterobacter*, *H. influenzae*, *Moraxella catarrhalis*, and *Haemophilus ducreyi*, which are resistant to amoxicillin alone. The oral

bioavailability of amoxicillin and potassium clavulanate is similar. Clavulanic acid is acid-stable. It cannot undergo penicillanic acid formation because it lacks an amide side chain.

Potassium clavulanate and the extended-spectrum penicillin ticarcillin have been combined in a fixed-dose, injectable form for the control of serious infections caused by β -lactamase-producing bacterial strains. This combination has been recommended for septicemia, lower respiratory tract infections, and urinary tract infections caused by β -lactamase-producing *Klebsiella* spp., *E. coli*, *P. aeruginosa*, and other *Pseudomonas* spp., *Citrobacter* spp., *Enterobacter* spp., *S. marcescens*, and *S. aureus*. It also is used in bone and joint infections caused by these organisms. The combination contains 3 g of ticarcillin disodium and 100 mg of potassium clavulanate in a sterile powder for injection (Timentin).

Sulbactam

Sulbactam is penicillanic acid sulfone or 1,1-dioxopenicillanic acid. This synthetic penicillin derivative is a potent inhibitor of *S. aureus* β -lactamase as well as many β -lactamases elaborated by Gram-negative bacilli. Sulbactam has weak intrinsic antibacterial activity but potentiates the activity of ampicillin and carbenicillin against β -lactamase-producing *S. aureus* and members of the Enterobacteriaceae family. It does not, however, synergize with either carbenicillin or ticarcillin against *P. aeruginosa* strains resistant to these agents. Failure of sulbactam to penetrate the cell envelope is a possible explanation for the lack of synergy.

Fixed-dose combinations of ampicillin sodium and sulbactam sodium, marketed under the trade name *Unasyn* as sterile powders for injection, have been approved for use in the United States. These combinations are recommended for the treatment of skin, tissue, intra-abdominal, and gynecological infections caused by β -lactamase-producing strains of *S. aureus*, *E. coli*, *Klebsiella* spp., *P. mirabilis*, *B. fragilis*, and *Enterobacter* and *Acinetobacter* spp.

Tazobactam

Tazobactam is a penicillanic acid sulfone that is similar in structure to sulbactam. It is a more potent β -lactamase inhibitor than sulbactam⁵⁷ and has a slightly broader spectrum of activity than clavulanic acid. It has very weak antibacterial activity. Tazobactam is available in fixed-dose, injectable combinations with piperacillin, a broad-spectrum penicillin consisting of an 8:1 ratio of piperacillin sodium to tazobactam sodium by weight and marketed under the trade name *Zosyn*. The pharmacokinetics of the two drugs are very similar. Both have short half-lives ($t_{1/2} \sim 1$ hour), are minimally protein bound, experience very little metabolism, and are excreted in active forms in the urine in high concentrations.

Approved indications for the piperacillin-tazobactam combination include the treatment of appendicitis, postpartum endometritis, and pelvic inflammatory disease caused by β -lactamase-producing *E. coli* and *Bacteroides* spp., skin and skin structure infections caused by β -lactamase-producing *S. aureus*, and pneumonia caused by β -lactamase-producing strains of *H. influenzae*.

CARBAPENEMS

Thienamycin

Thienamycin is a novel β -lactam antibiotic first isolated and identified by researchers at Merck⁵⁸ from fermentation of cultures of *Streptomyces cattleya*. Its structure and absolute configuration were established both spectroscopically and by total synthesis.^{59,60} Two structural features of thienamycin are shared with the penicillins and cephalosporins: a fused bicyclic ring system containing a β -lactam and an equivalently attached 3-carboxyl group. In other respects, the thienamycins represent a significant departure from the established β -lactam antibiotics. The bicyclic system consists of a carbapenem containing a double bond between C-2 and C-3 (i.e., it is a 2-carbapenem, or Δ^2 -carbapenem, system). The double bond in the bicyclic structure creates considerable ring strain and increases the reactivity of the β -lactam to ring-opening reactions. The side chain is unique in two respects:

it is a simple 1-hydroxyethyl group instead of the familiar acylamino side chain, and it is oriented to the bicyclic ring system rather than having the usual β orientation of the penicillins and cephalosporins. The remaining feature is a 2-aminoethylthioether function at C-2. The absolute stereochemistry of thienamycin has been determined to be 5*R*:6*S*:8*S*. Several additional structurally related antibiotics have been isolated from various *Streptomyces* spp., including the four epithienamycins, which are isomeric to thienamycin at C-5, C-6, or C-8, and derivatives in which the 2-aminoethylthio side chain is modified.

Thienamycin displays outstanding broad-spectrum antibacterial properties *in vitro*.⁶¹ It is highly active against most aerobic and anaerobic Gram-positive and Gram-negative bacteria, including *S. aureus*, *P. aeruginosa*, and *B. fragilis*. Furthermore, it is resistant to inactivation by most β -lactamases elaborated by Gram-negative and Gram-positive bacteria and, therefore, is effective against many strains resistant to penicillins and cephalosporins. Resistance to lactamases appears to be a function of the α -1-hydroxyethyl side chain because this property is lost in the 6-nor derivative and epithienamycins with *S* stereochemistry show variable resistance to the different β -lactamases.

An unfortunate property of thienamycin is its chemical instability in solution. It is more susceptible to hydrolysis in both acidic and alkaline solutions than most β -lactam antibiotics, because of the strained nature of its fused ring system containing an endocyclic double bond. Furthermore, at its optimally stable pH between 6 and 7, thienamycin undergoes concentration-dependent inactivation. This inactivation is believed to result from intermolecular aminolysis of the β -lactam by the cysteamine side chain of a second molecule. Another shortcoming is its susceptibility to hydrolytic inactivation by renal dehydropeptidase-I (DHP-I),⁶² which causes it to have an unacceptably short half-life *in vivo*.

Imipenem-Cilastatin

Imipenem is *N*-formimidoylthienamycin, the most successful of a series of chemically stable derivatives of thienamycin in which the primary amino group is converted to a nonnucleophilic basic function.⁶³ Cilastatin is an inhibitor of DHP-I. The combination (Primaxin) provides a chemically and enzymatically stable form of thienamycin that has clinically useful pharmacokinetic properties. The half-life of the drug is nonetheless short ($t_{1/2} \sim 1$ hour) because of renal tubular secretion of imipenem. Imipenem retains the extraordinary broad-spectrum antibacterial properties of thienamycin. Its bactericidal activity results from the inhibition of cell wall synthesis associated with bonding to PBPs 1_b and 2. Imipenem is very stable to most β -lactamases. It is an inhibitor of β -lactamases from certain Gram-negative bacteria resistant to other β -lactam antibiotics (e.g., *P. aeruginosa*, *S. marcescens*, and *Enterobacter* spp.).

Imipenem is indicated for the treatment of a wide variety of bacterial infections of the skin and tissues, lower respiratory tract, bones and joints, and genitourinary tract, as well as of septicemia and endocarditis caused by β -lactamase-producing strains of susceptible bacteria. These include aerobic Gram-positive organisms such as *S. aureus*, *Staphylococcus epidermidis*, enterococci, and viridans streptococci; aerobic Gram-negative bacteria such as *E. coli*, *Klebsiella*, *Serratia*, *Providencia*, *Haemophilus*, *Citrobacter*, and indole-positive *Proteus* spp., *Morganella morganii*, *Acinetobacter* and *Enterobacter* spp., and *P. aeruginosa* and anaerobes such as *B. fragilis* and *Clostridium*, *Peptococcus*, *Peptidostreptococcus*, *Eubacterium*, and *Fusobacterium* spp. Some *Pseudomonas* spp. are resistant, such as *P. maltophilia* and *P. cepacia*, as are some methicillin-resistant staphylococci. Imipenem is effective against non- β -lactamase-producing strains of these and additional bacterial species, but other less expensive and equally effective antibiotics are preferred for the treatment of infections caused by these organisms.

The imipenem–cilastatin combination is marketed as a sterile powder intended for the preparation of solutions for intravenous infusion. Such solutions are stable for 4 hours at 25°C and up to 24 hours when refrigerated. The concomitant administration of imipenem and an aminoglycoside antibiotic results in synergistic antibacterial activity in vivo. The two types of antibiotics are, however, chemically incompatible and should never be combined in the same intravenous bottle.

NEWER CARBAPENEMS

The extended spectrum of antibacterial activity associated with the carbapenems together with their resistance to inactivation by most β -lactamases make this class of β -lactams an attractive target for drug development. In the design of new carbapenems, structural variations are being investigated with the objective of developing analogs with advantages over imipenem. Improvements that are particularly desired include stability to hydrolysis catalyzed by DHP-I,⁶² stability to bacterial metallo- β -lactamases (“carbapenemases”)⁵⁶ that hydrolyze imipenem, activity against MRSA,³¹ and increased potency against *P. aeruginosa*, especially imipenem-resistant strains. Enhanced pharmacokinetic properties, such as oral bioavailability and a longer duration of action, have heretofore received little emphasis in carbapenem analog design.

Early structure–activity studies established the critical importance of the Δ^2 position of the double bond, the 3-carboxyl group, and the 6- α -hydroxyethyl side chain for both broad-spectrum antibacterial activity and β -lactamase stability in carbapenems. Modifications, therefore, have concentrated on variations at positions 1 and 2 of the carbapenem nucleus. The incorporation of a β -methyl group at the 1-position gives the carbapenem stability to hydrolysis by renal DHP-I.^{64,65} Substituents at the 2-position, however, appear to affect

primarily the spectrum of antibacterial activity of the carbapenem by influencing penetration into bacteria. The capability of carbapenems to exist as zwitterionic structures (as exemplified by imipenem and biapenem), resulting from the combined features of a basic amine function attached to the 2-position and the 3-carboxyl group, may enable these molecules to enter bacteria via their charged porin channels.

Meropenem

Meropenem is a second-generation carbapenem that, to date, has undergone the most extensive clinical evaluation.⁶⁶ It has recently been approved as Merrem for the treatment of infections caused by multiply-resistant bacteria and for empirical therapy for serious infections, such as bacterial meningitis, septicemia, pneumonia, and peritonitis. Meropenem exhibits greater potency against Gram-negative and anaerobic bacteria than does imipenem, but it is slightly less active against most Gram-positive species. It is not effective against MRSA. Meropenem is not hydrolyzed by DHP-I and is resistant to most β -lactamases, including a few carbapenemases that hydrolyze carbapenem.

Meropenem

Meropenem metabolite

Like imipenem, meropenem is not active orally. It is provided as a sterile lyophilized powder to be made up in normal saline or 5% dextrose solution for parenteral administration. Approximately 70% to 80% of unchanged meropenem is excreted in the urine following intravenous or intramuscular administration. The remainder is the inactive metabolite formed by hydrolytic cleavage of the β -lactam ring. The lower incidence of nephrotoxicity of meropenem (compared with imipenem) has been correlated with its greater stability to DHP-I and the absence of the DHP-I inhibitor cilastatin in the preparation. Meropenem appears

to be less epileptogenic than imipenem when the two agents are used in the treatment of bacterial meningitis.

Biapenem

Biapenem is a newer second-generation carbapenem with chemical and microbiological properties similar to those of meropenem.⁶⁷ Thus, it has broad-spectrum antibacterial activity that includes most aerobic Gram-negative and Gram-positive bacteria and anaerobes. Biapenem is stable to DHP-I⁶⁷ and resistant to most β -lactamases.⁶⁸ It is claimed to be less susceptible to metallo- β -lactamases than either imipenem or meropenem. It is not active orally.

CEPHALOSPORINS

Historical Background

The cephalosporins are β -lactam antibiotics isolated from *Cephalosporium* spp. or prepared semisynthetically. Most of the antibiotics introduced since 1965 have been semisynthetic cephalosporins. Interest in *Cephalosporium* fungi began in 1945 with Giuseppe Brotzu's discovery that cultures of *C. acremonium* inhibited the growth of a wide variety of Gram-positive and Gram-negative bacteria. Abraham and Newton^{68a} in Oxford, having been supplied cultures of the fungus in 1948, isolated three principal antibiotic components: cephalosporin P1, a steroid with minimal antibacterial activity; cephalosporin N, later discovered to be identical with synnematin N (a penicillin derivative now called penicillin N that had earlier been isolated from *C. salmosynnematum*); and cephalosporin C.

The structure of penicillin N was discovered to be D-(4-amino-4-carboxybutyl)penicillanic acid. The amino acid side chain confers more activity against Gram-negative bacteria, particularly *Salmonella* spp., but less activity against Gram-positive organisms than penicillin G. It has been used successfully in clinical trials for the treatment of typhoid fever but was never released as an approved drug.

Cephalosporin C turned out to be a close congener of penicillin N, containing a dihydrothiazine ring instead of the thiazolidine ring of the penicillins. Despite the observation that cephalosporin C was resistant to *S. aureus* β -lactamase,

early interest in it was not great because its antibacterial potency was inferior to that of penicillin N and other penicillins. The discovery that the α -aminoacyl side chain could be removed to efficiently produce 7-aminocephalosporanic acid (7-ACA),^{69,70} however, prompted investigations that led to semisynthetic cephalosporins of medicinal value. The relationship of 7-ACA and its acyl derivatives to 6-APA and the semisynthetic penicillins is obvious. Woodward et al.⁷¹ have prepared both cephalosporin C and the clinically useful cephalothin by an elegant synthetic procedure, but the commercially available drugs are obtained from 7-ACA as semisynthetic products.

Nomenclature

The chemical nomenclature of the cephalosporins is slightly more complex than even that of the penicillins because of the presence of a double bond in the dihydrothiazine ring. The fused ring system is designated by *Chemical Abstracts* as 5-thia-1-azabicyclo[4.2.0]oct-2-ene. In this system, cephalothin is 3-(acetoxymethyl)-7-[2-(thienylacetyl)amino]-8-oxo-5-thia-1-azabicyclo[4.2.0]oct-2-ene-2-carboxylic acid. A simplification that retains some of the systematic nature of the *Chemical Abstracts* procedure names the saturated bicyclic ring system with the lactam carbonyl oxygen *cepham* (cf., *penam* for penicillins). According to this system, all commercially available cephalosporins and cephamycins are named 3-*cephems* (or Δ^3 -cephems) to designate the position of the double bond. (Interestingly, all known 2-*cephems* are inactive, presumably because the β -lactam lacks the necessary ring strain to react sufficiently.) The trivialized forms of nomenclature of the type that have been applied to the penicillins are not consistently applicable to the naming of cephalosporins because of variations in the substituent at the 3-position. Thus, although some cephalosporins are named as derivatives of cephalosporanic acids, this practice applies only to the derivatives that have a 3-acetoxymethyl group.

Semisynthetic Derivatives

To date, the more useful semisynthetic modifications of the basic 7-ACA nucleus have resulted from acylations of the 7-amino group with different acids or nucleophilic substitution or reduction of the acetoxyl group. Structure-activity relationships (SARs) among the cephalosporins appear to parallel those among the penicillins insofar as the acyl group is concerned. The presence of an allylic acetoxyl function in the 3-position, however, provides a reactive site at which various 7-acylaminocephalosporanic acid structures can easily be varied by nucleophilic displacement reactions. Reduction of the 3-acetoxymethyl to a 3-methyl substituent to prepare 7-aminodesacetylcephalosporanic acid (7-ADCA)

Penicillin N

Cephalosporin C

Cephalosporin

Cephams

Cephalosporanic Acid

derivatives can be accomplished by catalytic hydrogenation, but the process currently used for the commercial synthesis of 7-ADCA derivatives involves the rearrangement of the corresponding penicillin sulfoxide.⁷² Perhaps the most noteworthy development thus far is the discovery that 7-phenylglycyl derivatives of 7-ACA and especially 7-ADCA are active orally.

In the preparation of semisynthetic cephalosporins, the following improvements are sought: (a) increased acid stability, (b) improved pharmacokinetic properties, particularly better oral absorption, (c) broadened antimicrobial spectrum, (d) increased activity against resistant microorganisms (as a result of resistance to enzymatic destruction, improved penetration, increased receptor affinity, etc.), (e) decreased allergenicity, and (f) increased tolerance after parenteral administration.

Structures of cephalosporins currently marketed in the United States are shown in Table 8.4.

Chemical Degradation

Cephalosporins experience various hydrolytic degradation reactions whose specific nature depends on the individual structure (Table 8.4).⁷³ Among 7-acylaminocephalosporanic acid derivatives, the 3-acetoxymethyl group is the most reactive site. In addition to its reactivity to nucleophilic displacement reactions, the acetoxyl function of this group readily undergoes solvolysis in strongly acidic solutions to form the desacetylcephalosporin derivatives. The latter lactonize to form the desacetylcephalosporin lactones, which are virtually inactive. The 7-acylamino group of some cephalosporins can also be hydrolyzed under enzymatic (acylases) and, possibly, nonenzymatic conditions to give 7-ACA (or 7-ADCA) derivatives. Following hydrolysis or solvolysis of the 3-acetoxymethyl group, 7-ACA also lactonizes under acidic conditions (Fig. 8.5).

The reactive functionality common to all cephalosporins is the β -lactam. Hydrolysis of the β -lactam of cephalosporins is believed to give initially cephalosporoic acids (in which the

R' group is stable, [e.g., $R' = H$ or S heterocycle]) or possibly anhydrosacetylcephalosporoic acids (7-ADCA, for the 7-acylaminocephalosporanic acids). It has not been possible to isolate either of these initial hydrolysis products in aqueous systems. Apparently, both types of cephalosporanic acid undergo fragmentation reactions that have not been characterized fully. Studies of the *in vivo* metabolism⁷⁴ of orally administered cephalosporins, however, have demonstrated arylacetylglucines and arylacetamidoethanols, which are believed to be formed from the corresponding arylacetyl-aminoacetaldehydes by metabolic oxidation and reduction, respectively. The aldehydes, no doubt, arise from nonenzymatic hydrolysis of the corresponding cephalosporoic acids. No evidence for the intramolecular opening of the β -lactam ring by the 7-acylamino oxygen to form oxazolones of the penicillanic acid type has been found in the cephalosporins. At neutral to alkaline pH, however, intramolecular aminolysis of the β -lactam ring by the α -amino group in the 7-ADCA derivatives cephaloglycin, cephadrine, and cefadroxil occurs, forming diketopiperazine derivatives.^{75,76} The formation of dimers and, possibly, polymers from 7-ADCA derivatives containing an α -amino group in the acylamino side chain may also occur, especially in concentrated solutions and at alkaline pH values.

Oral Cephalosporins

The oral activity conferred by the phenylglycyl substituent is attributed to increased acid stability of the lactam ring, resulting from the presence of a protonated amino group on the 7-acylamino portion of the molecule. Carrier-mediated transport of these dipeptide-like, zwitterionic cephalosporins⁵¹ is also an important factor in their excellent oral activity. The situation, then, is analogous to that of the α -aminobenzylpenicillins (e.g., ampicillin). Also important for high acid stability (and, therefore, good oral activity) of the cephalosporins is the absence of the leaving group at the 3-position. Thus, despite the presence of the phenylglycyl side chain in its structure, the

cephalosporanic acid derivative cephaloglycin is poorly absorbed orally, presumably because of solvolysis of the 3-acetoxy group in the low pH of the stomach. The resulting 3-hydroxyl derivative undergoes lactonization under acidic conditions. The 3-hydroxyl derivatives and, especially, the corresponding lactones are considerably less active in vitro than the parent cephalosporins. Generally, acyl derivatives of 7-ADCA show lower in vitro antibacterial potencies than the corresponding 7-ACA analogs.

Oral activity can also be conferred in certain cephalosporins by esterification of the 3-carboxylic acid group to form acid-stable, lipophilic esters that undergo hydrolysis in the plasma. Cefuroxime axetil and cefpodoxime proxetil are two β -lactamase-resistant alkoximino-cephalosporins that are orally active ester prodrug derivatives of cefuroxime and cefpodoxime, respectively, based on this concept.

Parenteral Cephalosporins

Hydrolysis of the ester function, catalyzed by hepatic and renal esterases, is responsible for some in vivo inactivation of parenteral cephalosporins containing a 3-acetoxymethyl substituent (e.g., cephalothin, cephapirin, and cefotaxime). The extent of such inactivation (20%–35%) is not large enough to seriously compromise the in vivo effectiveness of acetoxyl cephalosporins. Parenteral cephalosporins lacking a hydrolyzable group at the 3-position are not subject to hydrolysis by esterases. Cephadrine is the only cephalosporin that is used both orally and parenterally.

Spectrum of Activity

The cephalosporins are considered broad-spectrum antibiotics with patterns of antibacterial effectiveness comparable

to that of ampicillin. Several significant differences exist, however. Cephalosporins are much more resistant to inactivation by β -lactamases, particularly those produced by Gram-positive bacteria, than is ampicillin. Ampicillin, however, is generally more active against non- β -lactamase-producing strains of Gram-positive and Gram-negative bacteria sensitive to both it and the cephalosporins. Cephalosporins, among β -lactam antibiotics, exhibit uniquely potent activity against most species of *Klebsiella*. Differential potencies of cephalosporins, compared with penicillins, against different species of bacteria have been attributed to several variable characteristics of individual bacterial species and strains, the most important of which probably are (a) resistance to inactivation by β -lactamases, (b) permeability of bacterial cells, and (c) intrinsic activity against bacterial enzymes involved in cell wall synthesis and cross-linking.

β -Lactamase Resistance

The susceptibility of cephalosporins to various lactamases varies considerably with the source and properties of these enzymes. Cephalosporins are significantly less sensitive than all but the β -lactamase-resistant penicillins to hydrolysis by the enzymes from *S. aureus* and *Bacillus subtilis*. The "penicillinase" resistance of cephalosporins appears to be a property of the bicyclic cephem ring system rather than of the acyl group. Despite natural resistance to staphylococcal β -lactamase, the different cephalosporins exhibit considerable variation in rates of hydrolysis by the enzyme.⁷⁷ Thus, of several cephalosporins tested in vitro, cephalothin and cefoxitin are the most resistant, and cephaloridine and cefazolin are the least resistant. The same acyl functionalities that impart β -lactamase resistance in the penicillins unfortunately render cephalosporins virtually inactive against *S. aureus* and other Gram-positive bacteria.

Figure 8.5 • Degradation of cephalosporins.

β -Lactamases elaborated by Gram-negative bacteria present an exceedingly complex picture. Well over 100 different enzymes from various species of Gram-negative bacilli have been identified and characterized,²⁵ differing widely in specificity for various β -lactam antibiotics. Most of these enzymes hydrolyze penicillin G and ampicillin faster than the cephalosporins. Some inducible β -lactamases belonging to group C, however, are “cephalosporinases,” which hydrolyze cephalosporins more rapidly. Inactivation by β -lactamases is an important factor in determining resistance to cephalosporins in many strains of Gram-negative bacilli.

The introduction of polar substituents in the aminoacyl moiety of cephalosporins appears to confer stability to some β -lactamases.⁷⁸ Thus, cefamandole and cefonicid, which contain an α -hydroxyphenylacetyl (or mandoyl) group, and

ceforanide, which has an *o*-aminophenyl acetyl group, are resistant to a few β -lactamases. Steric factors also may be important because cefoperazone, an acylureidocephalosporin that contains the same 4-ethyl-2,3-dioxo-1-piperazinylcarbonyl group present in piperacillin, is resistant to many β -lactamases. Oddly enough, piperacillin is hydrolyzed by most of these enzymes.

Two structural features confer broadly based resistance to β -lactamases among the cephalosporins: (a) an alkoximino function in the aminoacyl group and (b) a methoxyl substituent at the 7-position of the cephem nucleus having α stereochemistry. The structures of several β -lactamase-resistant cephalosporins, including cefuroxime, cefotaxime, ceftizoxime, and ceftriaxone, feature a methoximino acyl group. β -Lactamase resistance is enhanced modestly if the

oximino substituent also features a polar function, as in cefazidime, which has a 2-methylpropionic acid substituent on the oximino group. Both steric and electronic properties of the alkoximino group may contribute to the β -lactamase resistance conferred by this functionality since *syn*-isomers are more potent than *anti*-isomers.⁷⁸ β -Lactamase-resistant 7 α -methoxycephalosporins, also called cephamycins because they are derived from cephamycin C (an antibiotic isolated from *Streptomyces*), are represented by ceftiofex, cefotetan, cefmetazole, and the 1-oxocephalosporin moxalactam, which is prepared by total synthesis.

Base- or β -lactamase-catalyzed hydrolysis of cephalosporins containing a good leaving group at the 3-position is accompanied by elimination of the leaving group. The enzymatic process occurs in a stepwise fashion, beginning with the formation of a tetrahedral transition state, which quickly collapses into an acyl-enzyme intermediate (Fig. 8.6). This intermediate can then either undergo hydrolysis to free the enzyme (path 1) or suffer elimination of the leaving group to form a relatively stable acyl-enzyme with a conjugated imine structure (path 2). Because of the stability of the acyl-enzyme intermediate, path 2 leads to transient inhibition of the enzyme. Faraci

and Pratt^{79,79a} have shown that cephalothin and cefoxitin inhibit certain β -lactamases by this mechanism, whereas analogs lacking a 3' leaving group do not.

Antipseudomonal Cephalosporins

Species of *Pseudomonas*, especially *P. aeruginosa*, represent a special public health problem because of their ubiquity in the environment and their propensity to develop resistance to antibiotics, including the β -lactams. The primary mechanisms of β -lactam resistance appear to involve destruction of the antibiotics by β -lactamases and/or interference with their penetration through the cell envelope. Apparently, not all β -lactamase-resistant cephalosporins penetrate the cell envelope of *P. aeruginosa*, as only cefoperazone, moxalactam, cefotaxime, ceftizoxime, ceftriaxone, and ceftazidime have useful antipseudomonal activity. Two cephalosporins, moxalactam and cefoperazone, contain the same polar functionalities (e.g., carboxy and *N*-acylureido) that facilitate penetration into *Pseudomonas* spp. by the penicillins (see carbenicillin, ticarcillin, and piperacillin). Unfortunately, strains of *P. aeruginosa* resistant to cefoperazone and cefotaxime have been found in clinical isolates.

Figure 8.6 • Inhibition of β -lactamases by cephalosporins.

Adverse Reactions and Drug Interactions

Like their close relatives, the penicillins, the cephalosporin antibiotics are comparatively nontoxic compounds that, because of their selective actions on cell wall cross-linking enzymes, exhibit highly selective toxicity toward bacteria. The most common adverse reactions to the cephalosporins are allergic and hypersensitivity reactions. These vary from mild rashes to life-threatening anaphylactic reactions. Allergic reactions are believed to occur less frequently with cephalosporins than with penicillins. The issue of cross-sensitivity between the two classes of β -lactams is very complex, but the incidence is considered to be very low (estimated between 3% and 7%). The physician faced with the decision of whether or not to administer a cephalosporin to a patient with a history of penicillin allergy must weigh several factors, including the severity of the illness being treated, the effectiveness and safety of alternative therapies, and the severity of previous allergic responses to penicillins.

Cephalosporins containing an *N*-methyl-5-thiotetrazole (MTT) moiety at the 3-position (e.g., cefamandole, cefotetan, cefmetazole, moxalactam, and cefoperazone) have been implicated in a higher incidence of hypoprothrombinemia than cephalosporins lacking the MTT group. This effect, which is enhanced and can lead to severe bleeding in patients with poor nutritional status, debilitation, recent GI surgery, hepatic disease, or renal failure, is apparently because of inhibition of vitamin K–requiring enzymes involved in the carboxylation of glutamic acid residues in clotting factors II, VII, IX, and X to the MTT

group.⁸⁰ Treatment with vitamin K restores prothrombin time to normal in patients treated with MTT-containing cephalosporins. Weekly vitamin K prophylaxis has been recommended for high-risk patients undergoing therapy with such agents. Cephalosporins containing the MTT group should not be administered to patients receiving oral anticoagulant or heparin therapy because of possible synergism with these drugs.

The MTT group has also been implicated in the intolerance to alcohol associated with certain injectable cephalosporins: cefamandole, cefotetan, cefmetazole, and cefoperazone. Thus, disulfiram-like reactions, attributed to the accumulation of acetaldehyde and resulting from the inhibition of aldehyde dehydrogenase–catalyzed oxidation of ethanol by MTT-containing cephalosporins,⁸¹ may occur in patients who have consumed alcohol before, during, or shortly after the course of therapy.

Classification

Cephalosporins are divided into first-, second-, third-, and fourth-generation agents, based roughly on their time of discovery and their antimicrobial properties (Table 8.5). In general, progression from first to fourth generation is associated with a broadening of the Gram-negative antibacterial spectrum, some reduction in activity against Gram-positive organisms, and enhanced resistance to β -lactamases. Individual cephalosporins differ in their pharmacokinetic properties, especially plasma protein binding and half-life, but the structural bases for these differences are not obvious.

TABLE 8.5 Classification and Properties of Cephalosporins

Cephalosporin	Generation	Route of Admin.	Acid Resistant	Plasma Protein Binding (%)	β -Lactamase Resistance	Spectrum of Activity	Antipseudomonal Activity
Cephalexin	First	Oral	Yes	5–15	Poor	Broad	No
Cephadrine	First	Oral, parenteral	Yes	8–17	Poor	Broad	No

Products

Cephalexin

Cephalexin, 7 α -(D-amino- α -phenylacetamido)-3-methylcephemcarboxylic acid (Keflex, Keforal), was designed purposely as an orally active, semisynthetic cephalosporin. The oral inactivation of cephalosporins has been attributed to two causes: instability of the β -lactam ring to acid hydrolysis (cephalothin and cephaloridine) and solvolysis or microbial transformation of the 3-methylacetoxymethyl group (cephalothin, cephaloglycin). The α -amino group of cephalexin renders it acid stable, and reduction of the 3-acetoxymethyl to a methyl group circumvents reaction at that site.

Cephalexin occurs as a white crystalline monohydrate. It is freely soluble in water, resistant to acid, and absorbed well orally. Food does not interfere with its absorption. Because of minimal protein binding and nearly exclusive renal excretion, cephalexin is recommended particularly for the treatment of urinary tract infections. It is also sometimes used for upper respiratory tract infections. Its spectrum of activity is very similar to those of cephalothin and cephaloridine. Cephalexin is somewhat less potent than these two agents after parenteral administration and, therefore, is inferior to them for the treatment of serious systemic infections.

Cephadrine

Cephadrine (Anspor, Velosef) is the only cephalosporin derivative available in both oral and parenteral dosage forms. It closely resembles cephalexin chemically (it may be regarded as a partially hydrogenated derivative of cephalexin) and has very similar antibacterial and pharmacokinetic properties.

It occurs as a crystalline hydrate that is readily soluble in water. Cephadrine is stable to acid and absorbed almost completely after oral administration. It is minimally protein bound and excreted almost exclusively through the kidneys. It is recommended for the treatment of uncomplicated urinary tract and upper respiratory tract infections caused by susceptible organisms. Cephadrine is available in both oral and parenteral dosage forms.

Cefadroxil

Cefadroxil (Duricef) is an orally active semisynthetic derivative of 7-ADCA, in which the 7-acyl group is the D-

hydroxyphenylglycyl moiety. This compound is absorbed well after oral administration to give plasma levels that reach 75% to 80% of those of an equal dose of its close structural analog cephalexin. The main advantage claimed for cefadroxil is its somewhat prolonged duration of action, which permits once-a-day dosing. The prolonged duration of action of this compound is related to relatively slow urinary excretion of the drug compared with other cephalosporins, but the basis for this remains to be explained completely. The antibacterial spectrum of action and therapeutic indications of cefadroxil are very similar to those of cephalexin and cephradine. The D-*p*-hydroxyphenylglycyl isomer is much more active than the L-isomer.

Cefaclor

Cefaclor (Ceclor) is an orally active semisynthetic cephalosporin that was introduced in the American market in 1979. It differs structurally from cephalexin in that the 3-methyl group has been replaced by a chlorine atom. It is synthesized from the corresponding 3-methylenecepham sulfoxide ester by ozonolysis, followed by halogenation of the resulting β -ketoester.⁸² The 3-methylenecepham sulfoxide esters are prepared by rearrangement of the corresponding 6-acylamino penicillanic acid derivative. Cefaclor is moderately stable in acid and achieves enough oral absorption to provide effective plasma levels (equal to about two-thirds of those obtained with cephalexin). The compound is apparently unstable in solution, since about 50% of its antimicrobial activity is lost in 2 hours in serum at 37°C.⁸³ The antibacterial spectrum of activity is similar to that of cephalexin, but it is claimed to be more potent against some species sensitive to both agents. Currently, the drug is recommended for the treatment of non-life-threatening infections caused by *H. influenzae*, particularly strains resistant to ampicillin.

Cefprozil

Cefprozil (Cefzil) is an orally active second-generation cephalosporin that is similar in structure and antibacterial spectrum to cefadroxil. Oral absorption is excellent (oral bioavailability is about 95%) and is not affected by antacids or histamine H₂-antagonists. Cefprozil exhibits greater in vitro activity against streptococci, *Neisseria* spp., and *S. aureus* than does cefadroxil. It is also more active than the first-generation cephalosporins against members of the Enterobacteriaceae family, such as *E. coli*, *Klebsiella* spp.,

P. mirabilis, and *Citrobacter* spp. The plasma half-life of 1.2 to 1.4 hours permits twice-a-day dosing for the treatment of most community-acquired respiratory and urinary tract infections caused by susceptible organisms.

Loracarbef

Loracarbef (Lorabid) is the first of a series of carbacephems prepared by total synthesis to be introduced.⁸⁴ Carbacephems are isosteres of the cephalosporin (or Δ^3 -cephem) antibiotics in which the 1-sulfur atom has been replaced by a methylene (CH_2) group. Loracarbef is isosteric with cefaclor and has similar pharmacokinetic and microbiological properties. Thus, the antibacterial spectrum of activity resembles that of cefaclor, but it has somewhat greater potency against *H. influenzae* and *M. catarrhalis*, including β -lactamase-producing strains. Unlike cefaclor, which undergoes degradation in human serum, loracarbef is chemically stable in plasma. It is absorbed well orally. Oral absorption is delayed by food. The half-life in plasma is about 1 hour.

Cephalothin Sodium

Cephalothin sodium (Keflin) occurs as a white to off-white, crystalline powder that is practically odorless. It is freely soluble in water and insoluble in most organic solvents. Although it has been described as a broad-spectrum antibacterial compound, it is not in the same class as the tetracyclines. Its spectrum of activity is broader than that of penicillin G and more similar to that of ampicillin. Unlike ampicillin, cephalothin is resistant to penicillinase produced by *S. aureus* and provides an alternative to the use of penicillinase-resistant penicillins for the treatment of infections caused by such strains.

Cephalothin is absorbed poorly from the GI tract and must be administered parenterally for systemic infections. It

is relatively nontoxic and acid stable. It is excreted rapidly through the kidneys; about 60% is lost within 6 hours of administration. Pain at the site of intramuscular injection and thrombophlebitis following intravenous injection have been reported. Hypersensitivity reactions have been observed, and there is some evidence of cross-sensitivity in patients noted previously to be penicillin sensitive.

Cefazolin Sodium, Sterile

Cefazolin (Ancef, Kefzol) is one of a series of semisynthetic cephalosporins in which the C-3 acetoxy function has been replaced by a thiol-containing heterocycle—here, 5-methyl-2-thio-1,3,4-thiadiazole. It also contains the somewhat unusual tetrazolylacetyl acylating group. Cefazolin was released in 1973 as a water-soluble sodium salt. It is active only by parenteral administration.

Cefazolin provides higher serum levels, slower renal clearance, and a longer half-life than other first-generation cephalosporins. It is approximately 75% protein bound in plasma, a higher value than for most other cephalosporins. Early in vitro and clinical studies suggest that cefazolin is more active against Gram-negative bacilli but less active against Gram-positive cocci than either cephalothin or cephaloridine. Occurrence rates of thrombophlebitis following intravenous injection and pain at the site of intramuscular injection appear to be the lowest of the parenteral cephalosporins.

Cephapirin Sodium, Sterile

Cephapirin (Cefadyl) is a semisynthetic 7-ACA derivative released in the United States in 1974. It closely resembles cephalothin in chemical and pharmacokinetic properties. Like cephalothin, cephapirin is unstable in acid and must be administered parenterally in the form of an aqueous solution of the sodium salt. It is moderately protein bound (45%–50%) in plasma and cleared rapidly by the kidneys. Cephapirin and cephalothin are very similar in antimicrobial spectrum and potency. Conflicting reports concerning the relative occurrence of pain at the site of injection and thrombophlebitis after intravenous injection of cephapirin and cephalothin are difficult to assess on the basis of available clinical data.

Cefamandole Nafate

Cefamandole (Mandol) nafate is the formate ester of cefamandole, a semisynthetic cephalosporin that incorporates

D-mandelic acids as the acyl portion and a thiol-containing heterocycle (5-thio-1,2,3,4-tetrazole) in place of the acetoxyl function on the C-3 methylene carbon atom. Esterification of the α -hydroxyl group of the D-mandeloyl function overcomes the instability of cefamandole in solid-state dosage forms⁸⁵ and provides satisfactory concentrations of the parent antibiotic in vivo through spontaneous hydrolysis of the ester at neutral to alkaline pH. Cefamandole is the first second-generation cephalosporin to be marketed in the United States.

The D-mandeloyl moiety of cefamandole appears to confer resistance to a few β -lactamases, since some β -lactamase-producing, Gram-negative bacteria (particularly Enterobacteriaceae) that show resistance to cefazolin and other first-generation cephalosporins are sensitive to cefamandole. Additionally, it is active against some ampicillin-resistant strains of *Neisseria* and *Haemophilus* spp. Although resistance to β -lactamases may be a factor in determining the sensitivity of individual bacterial strains to cefamandole, an early study⁸⁶ indicated that other factors, such as permeability and intrinsic activity, are frequently more important. The L-mandeloyl isomer is significantly less active than the D-isomer.

Cefamandole nafate is very unstable in solution and hydrolyzes rapidly to release cefamandole and formate. There is no loss of potency, however, when such solutions are stored for 24 hours at room temperature or up to 96 hours when refrigerated. Air oxidation of the released formate to carbon dioxide can cause pressure to build up in the injection vial.

Cefonicid Sodium, Sterile

Cefonicid Sodium (Monocid) is a second-generation cephalosporin that is structurally similar to cefamandole, except that it contains a methane sulfonic acid group attached to the N-1 position of the tetrazole ring. The antimicrobial spectrum and limited β -lactamase stability of cefonicid are essentially identical with those of cefamandole.

Cefonicid is unique among the second-generation cephalosporins in that it has an unusually long serum half-life of approximately 4.5 hours. High plasma protein binding coupled with slow renal tubular secretion are apparently responsible for the long duration of action. Despite the high

fraction of drug bound in plasma, cefonicid is distributed throughout body fluids and tissues, with the exception of the cerebrospinal fluid.

Cefonicid is supplied as a highly water-soluble disodium salt, in the form of a sterile powder to be reconstituted for injection. Solutions are stable for 24 hours at 25°C and for 72 hours when refrigerated.

Ceforanide, Sterile

Ceforanide (Precef) was approved for clinical use in the United States in 1984. It is classified as a second-generation cephalosporin because its antimicrobial properties are similar to those of cefamandole. It exhibits excellent potency against most members of the Enterobacteriaceae family, especially *K. pneumoniae*, *E. coli*, *P. mirabilis*, and *Enterobacter cloacae*. It is less active than cefamandole against *H. influenzae*, however.

The duration of action of ceforanide lies between those of cefamandole and cefonicid. It has a serum half-life of about 3 hours, permitting twice-a-day dosing for most indications. Ceforanide is supplied as the sterile, crystalline disodium salt. Parenteral solutions are stable for 4 hours at 25°C and for up to 5 days when refrigerated.

Cefoperazone Sodium, Sterile

Cefoperazone (Cefobid) is a third-generation, anti-pseudomonal cephalosporin that resembles piperacillin chemically and microbiologically. It is active against many strains of *P. aeruginosa*, indole-positive *Proteus* spp., *Enterobacter* spp., and *S. marcescens* that are resistant to cefamandole. It is less active than cephalothin against Gram-positive bacteria and less active than cefamandole against most of the Enterobacteriaceae. Like piperacillin, cefoperazone is hydrolyzed by many of the β -lactamases that hydrolyze penicillins. Unlike piperacillin, however, it is resistant to some (but not all) of the β -lactamases that hydrolyze cephalosporins.

Cefoperazone is excreted primarily in the bile. Hepatic dysfunction can affect its clearance from the body. Although only 25% of the free antibiotic is recovered in the urine,

urinary concentrations are high enough to be effective in the management of urinary tract infections caused by susceptible organisms. The relatively long half-life (2 hours) allows dosing twice a day. Solutions prepared from the crystalline sodium salt are stable for up to 4 hours at room temperature. If refrigerated, they will last 5 days without appreciable loss of potency.

Cefoxitin Sodium, Sterile

Cefoxitin (Mefoxin) is a semisynthetic derivative obtained by modification of cephamycin C, a 7 α -methoxy-substituted cephalosporin isolated independently from various *Streptomyces* by research groups in Japan⁸⁷ and the United States. Although it is less potent than cephalothin against Gram-positive bacteria and cefamandole against most of the Enterobacteriaceae, cefoxitin is effective against certain strains of Gram-negative bacilli (e.g., *E. coli*, *K. pneumoniae*, *Providencia* spp., *S. marcescens*, indole-positive *Proteus* spp., and *Bacteroides* spp.) that are resistant to these cephalosporins. It is also effective against penicillin-resistant *S. aureus* and *N. gonorrhoeae*.

The activity of cefoxitin and cephamycins, in general, against resistant bacterial strains is because of their resistance to hydrolysis by β -lactamases conferred by the 7 α -methoxyl substituent.⁸⁸ Cefoxitin is a potent competitive inhibitor of many β -lactamases. It is also a potent inducer of chromosomally mediated β -lactamases. The temptation to exploit the β -lactamase-inhibiting properties of cefoxitin by combining it with β -lactamase-labile β -lactam antibiotics should be tempered by the possibility of antagonism. In fact, cefoxitin antagonizes the action of cefamandole against *E. cloacae* and that of carbenicillin against *P. aeruginosa*.⁸⁹ Cefoxitin alone is essentially ineffective against these organisms.

The pharmacokinetic properties of cefoxitin resemble those of cefamandole. Because its half-life is relatively short, cefoxitin must be administered 3 or 4 times daily. Solutions of the sodium salt intended for parenteral administration are stable for 24 hours at room temperature and 1 week if refrigerated. 7 α -Methoxyl substitution stabilizes, to some extent, the β -lactam to alkaline hydrolysis.

The principal role of cefoxitin in therapy seems to be for the treatment of certain anaerobic and mixed aerobic-anaerobic infections. It is also used to treat gonorrhea caused by β -lactamase-producing strains. It is classified as a second-generation agent because of its spectrum of activity.

Cefotetan Disodium

Cefotetan (Cefotan) is a third-generation cephalosporin that is structurally similar to cefoxitin. Like cefoxitin, cefotetan is resistant to destruction by β -lactamases. It is also a competitive inhibitor of many β -lactamases and causes transient

inactivation of some of these enzymes. Cefotetan is reported to synergize with β -lactamase-sensitive β -lactams but, unlike cefoxitin, does not appear to cause antagonism.⁹⁰

The antibacterial spectrum of cefotetan closely resembles that of cefoxitin. It is, however, generally more active against *S. aureus*, and members of the Enterobacteriaceae family sensitive to both agents. It also exhibits excellent potency against *H. influenzae* and *N. gonorrhoeae*, including β -lactamase-producing strains. Cefotetan is slightly less active than cefoxitin against *B. fragilis* and other anaerobes. *Enterobacter* spp. are generally resistant to cefotetan, and the drug is without effect against *Pseudomonas* spp.

Cefotetan has a relatively long half-life of about 3.5 hours. It is administered on a twice-daily dosing schedule. It is excreted largely unchanged in the urine. Aqueous solutions for parenteral administration maintain potency for 24 hours at 25°C. Refrigerated solutions are stable for 4 days.

Cefotetan contains the MTT group that has been associated with hypoprothrombinemia and alcohol intolerance. Another cephalosporin that lacks these properties should be selected for patients at risk for severe bleeding or alcoholism.

Cefmetazole Sodium

Cefmetazole (Zefazone) is a semisynthetic, third-generation, parenteral cephalosporin of the cephamycin group. Like other cephamycins, the presence of the 7 α -methoxyl group confers resistance to many β -lactamases. Cefmetazole exhibits significantly higher potency against members of the Enterobacteriaceae family but lower activity against *Bacteroides* spp. than cefoxitin. It is highly active against *N. gonorrhoeae*, including β -lactamase-producing strains. In common with other cephamycins, cefmetazole is ineffective against indole-positive *Proteus*, *Enterobacter*, *Providencia*, *Serratia*, and *Pseudomonas* spp. Cefmetazole has the MTT moiety associated with increased bleeding in certain high-risk patients. It has a plasma half-life of 1.1 hours.

Cefuroxime Sodium

Cefuroxime (Zinacef) is the first of a series of α -methoximinoacyl-substituted cephalosporins that constitute most of the third-generation agents available for clinical use. A *syn* alkoximino substituent is associated with β -lactamase stability in

these cephalosporins.⁷⁸ Cefuroxime is classified as a second-generation cephalosporin because its spectrum of antibacterial activity more closely resembles that of cefamandole. It is, however, active against β -lactamase-producing strains that are resistant to cefamandole, such as *E. coli*, *K. pneumoniae*, *N. gonorrhoeae*, and *H. influenzae*. Other important Gram-negative pathogens, such as *Serratia*, indole-positive *Proteus* spp., *P. aeruginosa*, and *B. fragilis*, are resistant.

Cefuroxime is distributed throughout the body. It penetrates inflamed meninges in high enough concentrations to be effective in meningitis caused by susceptible organisms. Three-times-daily dosing is required to maintain effective plasma levels for most sensitive organisms, such as *Neisseria meningitidis*, *Streptococcus pneumoniae*, and *H. influenzae*. It has a plasma half-life of 1.4 hours.

Cefuroxime Axetil

Cefuroxime axetil (Ceftin) is the 1-acetoxyethyl ester of cefuroxime. During absorption, this acid-stable, lipophilic, oral prodrug derivative of cefuroxime is hydrolyzed to cefuroxime by intestinal and/or plasma enzymes. The axetil ester provides an oral bioavailability of 35% to 50% of cefuroxime, depending on conditions. Oral absorption of the ester is increased by food but decreased by antacids and histamine H₂-antagonists. The latter effect may be because of spontaneous hydrolysis of the ester in the intestine because of the higher pH created by these drugs. Axetil is used for the oral treatment of non-life-threatening infections caused by bacteria that are susceptible to cefuroxime. The prodrug form permits twice-a-day dosing for such infections.

Cefpodoxime Proxetil

Cefpodoxime proxetil (Vantin) is the isopropylloxycarbonyl ethyl ester of the third-generation cephalosporin cefpodoxime. This orally active prodrug derivative is hydrolyzed by esterases in the intestinal wall and in the plasma to provide cefpodoxime. Tablets and a powder for the preparation of an aqueous suspension for oral pediatric administration are available. The oral bioavailability of cefpodoxime from the proxetil is estimated to be about 50%. Administration of the prodrug with food enhances its absorption. The plasma half-life is 2.2 hours, which permits administration on a twice-daily schedule.

Cefpodoxime is a broad-spectrum cephalosporin with useful activity against a relatively wide range of Gram-positive and Gram-negative bacteria. It is also resistant to many β -lactamases. Its spectrum of activity includes *S. pneumoniae*, *Streptococcus pyogenes*, *S. aureus*, *H. influenzae*, *M. catarrhalis*, and *Neisseria* spp. Cefpodoxime is also active against members of the Enterobacteriaceae family, including *E. coli*, *K. pneumoniae*, and *P. mirabilis*. It thus finds use in the treatment of upper and lower respiratory infections, such as pharyngitis, bronchitis, otitis media, and community-acquired pneumonia. It is also useful for the treatment of uncomplicated gonorrhea.

Cefixime

Cefixime (Suprax) is the first orally active, third-generation cephalosporin that is not an ester prodrug to be approved for therapy in the United States. Oral bioavailability is surprisingly high, ranging from 40% to 50%. Facilitated transport of cefixime across intestinal brush border membranes involving the carrier system for dipeptides may explain its surprisingly good oral absorption.⁹¹ This result was not expected because cefixime lacks the ionizable α -amino group present in dipeptides and β -lactams previously known to be transported by the carrier system.^{51,91}

Cefixime is a broad-spectrum cephalosporin that is resistant to many β -lactamases. It is particularly effective against Gram-negative bacilli, including *E. coli*, *Klebsiella* spp., *P. mirabilis*, indole-positive *Proteus*, *Providencia*, and some *Citrobacter* spp. Most *Pseudomonas*, *Enterobacter*, and *Bacteroides* spp. are resistant. It also has useful activity against streptococci, gonococci, *H. influenzae*, and *M. catarrhalis*. It is much less active against *S. aureus*. Cefixime is used for the treatment of various respiratory tract infections (e.g., acute bronchitis, pharyngitis, and tonsillitis) and otitis media. It is also used to treat uncomplicated urinary tract infections and gonorrhea caused by β -lactamase-producing bacterial strains.

The comparatively long half-life of cefixime ($t_{1/2}$ is 3–4 hours) allows it to be administered on a twice-a-day schedule. Renal tubular reabsorption and a relatively high

fraction of plasma protein binding (~65%) contribute to the long half-life. It is provided in two-oral dosage forms: 200- or 400-mg tablets and a powder for the preparation of an aqueous suspension.

Cefotaxime Sodium, Sterile

Cefotaxime (Claforan) was the first third-generation cephalosporin to be introduced. It possesses excellent broad-spectrum activity against Gram-positive and Gram-negative aerobic and anaerobic bacteria. It is more active than moxalactam against Gram-positive organisms. Many β -lactamase-producing bacterial strains are sensitive to cefotaxime, including *N. gonorrhoeae*, *Klebsiella* spp., *H. influenzae*, *S. aureus*, and *E. cloacae*. Some, but not all, *Pseudomonas* strains are sensitive. Enterococci and *Listeria monocytogenes* are resistant.

The *syn*-isomer of cefotaxime is significantly more active than the *anti*-isomer against β -lactamase-producing bacteria. This potency difference is, in part, because of greater resistance of the *syn*-isomer to the action of β -lactamases.⁷⁸ The higher affinity of the *syn*-isomer for PBPs, however, may also be a factor.⁹²

Cefotaxime is metabolized in part to the less active desacetyl metabolite. Approximately 20% of the metabolite and 25% of the parent drug are excreted in the urine. The parent drug reaches the cerebrospinal fluid in sufficient concentration to be effective in the treatment of meningitis. Solutions of cefotaxime sodium should be used within 24 hours. If stored, they should be refrigerated. Refrigerated solutions maintain potency up to 10 days.

Ceftizoxime Sodium, Sterile

Ceftizoxime (Cefizox) is a third-generation cephalosporin that was introduced in 1984. This β -lactamase-resistant agent exhibits excellent activity against the Enterobacteriaceae, especially *E. coli*, *K. pneumoniae*, *E. cloacae*, *Enterobacter aerogenes*, indole-positive and indole-negative *Proteus* spp., and *S. marcescens*. Ceftizoxime is claimed to be more active than cefoxitin against *B. fragilis*. It is also very active against Gram-positive bacteria. Its activity against *P. aeruginosa* is somewhat variable and lower than that of either cefotaxime or cefoperazone.

Ceftizoxime is not metabolized in vivo. It is excreted largely unchanged in the urine. Adequate levels of the drug are achieved in the cerebrospinal fluid for the treatment of Gram-negative or Gram-positive bacterial meningitis. It must be administered on a thrice-daily dosing schedule because of its relatively short half-life. Ceftizoxime sodium is very stable in the dry state. Solutions maintain potency for up to 24 hours at room temperature and 10 days when refrigerated.

Ceftriaxone Disodium, Sterile

Ceftriaxone (Rocephin) is a β -lactamase-resistant cephalosporin with an extremely long serum half-life. Once-daily dosing suffices for most indications. Two factors contribute to the prolonged duration of action of ceftriaxone: high protein binding in the plasma and slow urinary excretion. Ceftriaxone is excreted in both the bile and the urine. Its urinary excretion is not affected by probenecid. Despite its comparatively low volume of distribution, it reaches the cerebrospinal fluid in concentrations that are effective in meningitis. Nonlinear pharmacokinetics are observed.

Ceftriaxone contains a highly acidic heterocyclic system on the 3-thiomethyl group. This unusual dioxotriazine ring system is believed to confer the unique pharmacokinetic properties of this agent. Ceftriaxone has been associated with sonographically detected “sludge,” or pseudolithiasis, in the gallbladder and common bile duct.⁹³ Symptoms of cholecystitis may occur in susceptible patients, especially those on prolonged or high-dose ceftriaxone therapy. The culprit has been identified as the calcium chelate.

Ceftriaxone exhibits excellent broad-spectrum antibacterial activity against both Gram-positive and Gram-negative organisms. It is highly resistant to most chromosomally and plasmid-mediated β -lactamases. The activity of ceftriaxone against *Enterobacter*, *Citrobacter*, *Serratia*, indole-positive *Proteus*, and *Pseudomonas* spp. is particularly impressive. It is also effective in the treatment of ampicillin-resistant gonorrhea and *H. influenzae* infections but generally less active than cefotaxime against Gram-positive bacteria and *B. fragilis*.

Solutions of ceftriaxone sodium should be used within 24 hours. They may be stored up to 10 days if refrigerated.

Ceftazidime Sodium, Sterile

Ceftazidime (Fortaz, Tazidime) is a β -lactamase-resistant third-generation cephalosporin that is noted for its antipseudomonal activity. It is active against some strains of *P. aeruginosa* that are resistant to cefoperazone and ceftriaxone. Ceftazidime is also highly effective against β -lactamase-producing strains of the Enterobacteriaceae family. It is generally less active than cefotaxime against Gram-positive bacteria and *B. fragilis*.

The structure of ceftazidime contains two noteworthy features: (a) a 2-methylpropionoximinoacyl group that confers β -lactamase resistance and, possibly, increased permeability through the porin channels of the cell envelope and (b) a pyridinium group at the 3-position that confers zwitterionic properties on the molecule.

Ceftazidime is administered parenterally 2 or 3 times daily, depending on the severity of the infection. Its serum half-life is about 1.8 hours. It has been used effectively for the treatment of meningitis caused by *H. influenzae* and *N. meningitidis*.

NEWER CEPHALOSPORINS

Cephalosporins currently undergoing clinical trials or recently being marketed in the United States fall into two categories: (a) orally active β -lactamase-resistant cephalosporins and (b) parenteral β -lactamase-resistant antipseudomonal cephalosporins. The status of some of these compounds awaits more extensive clinical evaluation. Nonetheless, it appears that any advances they represent will be relatively modest.

Ceftibuten

Ceftibuten (Cedax) is a recently introduced, chemically novel analog of the oximino cephalosporins in which an olefinic methylene group ($C=CHCH_2-$) with *Z* stereochemistry has replaced the *syn* oximino ($C=NO-$) group. This isosteric replacement yields a compound that retains resistance to hydrolysis catalyzed by many β -lactamases, has enhanced chemical stability, and is orally active. Oral absorption is rapid and nearly complete. It has the highest oral bioavailability of the third-generation cephalosporins.⁹⁴ Ceftibuten is excreted largely unchanged in the urine and has a half-life of about 2.5 hours. Plasma protein binding of this cephalosporin is estimated to be 63%.

Ceftibuten possesses excellent potency against most members of the Enterobacteriaceae family, *H. influenzae*, *Neisseria* spp., and *M. catarrhalis*. It is not active against *S. aureus* or *P. aeruginosa* and exhibits modest antistrepococ-

cal activity. Ceftibuten is recommended in the management of community-acquired respiratory tract, urinary tract, and gynecological infections.

Cefpirome

Cefpirome (Cefrom) is a newer parenteral, β -lactamase-resistant cephalosporin with a quaternary ammonium group at the 3-position of the cephem nucleus. Because its potency against Gram-positive and Gram-negative bacteria rivals that of the first-generation and third-generation cephalosporins, respectively, cefpirome is being touted as the first fourth-generation cephalosporin.⁹⁵ Its broad spectrum includes methicillin-sensitive staphylococci, penicillin-resistant pneumococci, and β -lactamase-producing strains of *E. coli*, *Enterobacter*, *Citrobacter*, and *Serratia* spp. Its efficacy against *P. aeruginosa* is comparable with that of ceftazidime. Cefpirome is excreted largely unchanged in the urine with a half-life of 2 hours.

Cefepime

Cefepime (Maxipime, Axepin) is a parenteral, β -lactamase-resistant cephalosporin that is chemically and microbiologically similar to cefpirome. It also has a broad antibacterial spectrum, with significant activity against both Gram-positive and Gram-negative bacteria, including streptococci, staphylococci, *Pseudomonas* spp., and the Enterobacteriaceae. It is active against some bacterial isolates that are resistant to ceftazidime.⁹⁶ The efficacy of cefepime has been demonstrated in the treatment of urinary tract infections, lower respiratory tract infections, skin and soft tissue infections, chronic osteomyelitis, and intra-abdominal and biliary infections. It is excreted in the urine with a half-life of 2.1 hours. It is bound minimally to plasma proteins. Cefepime is also a fourth-generation cephalosporin.

Future Developments in Cephalosporin Design

Recent research efforts in the cephalosporin field have focused primarily on two desired antibiotic properties: (a) increased permeability into Gram-negative bacilli, leading to

TOC-039

enhanced efficacy against permeability-resistant strains of Enterobacteriaceae and *P. aeruginosa*, and (b) increased affinity for altered PBPs, in particular the PBP 2a (or PBP 2') of MRSA.³¹

The observation that certain catechol-substituted cephalosporins exhibit marked broad-spectrum antibacterial activity led to the discovery that such compounds and other analogs capable of chelating iron could mimic natural siderophores (iron-chelating peptides) and thus be actively transported into bacterial cells via the *tonB*-dependent iron-transport system.^{97,98} This provides a means of attacking bacterial strains that resist cellular penetration of cephalosporins.

A catechol-containing cephalosporin that exhibits excellent in vitro antibacterial activity against clinical isolates and promising pharmacokinetic properties is GR-69153. GR-69153 is a parenteral β -lactamase-resistant cephalosporin with a broad spectrum of activity against Gram-positive and Gram-negative bacteria.

The antibacterial spectrum of GR-69153 includes most members of the Enterobacteriaceae family, *P. aeruginosa*, *H. influenzae*, *N. gonorrhoeae*, *M. catarrhalis*, staphylococci, streptococci, and *Acinetobacter* spp. It was not active against enterococci, *B. fragilis*, or MRSA. The half-life of GR-69153 in human volunteers was determined to be 3.5 hours, suggesting that metabolism by catechol-*O*-methyltransferase may not be an important factor. The relatively long half-life would permit once-a-day parenteral dosing for the treatment of many serious bacterial infections.

An experimental cephalosporin that has exhibited considerable promise against MRSA in preclinical evaluations is TOC-039.

TOC-039 is a parenteral, β -lactamase-resistant, hydroxyimino cephalosporin with a vinylthiopyridyl side chain attached to the 3-position of the cephem nucleus. It is a broad-spectrum agent that exhibits good activity against most aerobic Gram-positive and Gram-negative bacteria, including staphylococci, streptococci, enterococci, *H. influenzae*, *M. catarrhalis*, and most of the Enterobacteriaceae family.⁹⁹ A few strains of *P. vulgaris*, *S. marcescens*, and *Citrobacter freundii* are resistant, and TOC-039 is inactive against *P. aeruginosa*. Although the minimum inhibiting concentration (MIC) of TOC-039 against MRSA is slightly less than that of vancomycin, it is more rapidly bacteriocidal. Future clinical evaluations will determine if TOC-039 has the appropriate pharmacokinetic and antibacterial properties in vivo to be approved for the treatment of bacterial infections in humans.

MONOBACTAMS

The development of useful monobactam antibiotics began with the independent isolation of sulfazecin (SQ 26,445) and other monocyclic β -lactam antibiotics from saprophytic soil bacteria in Japan¹⁰⁰ and the United States.¹⁰¹ Sulfazecin was found to be weakly active as an antibacterial agent but highly resistant to β -lactamases.

Extensive SAR studies¹⁰² eventually led to the development of aztreonam, which has useful properties as an antibacterial agent. Early work established that the 3-methoxy group, which was in part responsible for β -lactamase stability in the series, contributed to the low antibacterial potency

and poor chemical stability of these antibiotics. A 4-methyl group, however, increases stability to β -lactamases and activity against Gram-negative bacteria at the same time. Unfortunately, potency against Gram-positive bacteria decreases. 4,4-Gem-dimethyl substitution slightly decreases antibacterial potency after oral administration.

Products

Aztreonam Disodium

Aztreonam (Azactam) is a monobactam prepared by total synthesis. It binds with high affinity to PBP 3 in Gram-negative bacteria only. It is inactive against Gram-positive bacteria and anaerobes. β -Lactamase resistance is like that of ceftazidime, which has the same isobutyric acid oximinoacyl group. Aztreonam does not induce chromosomally mediated β -lactamases.

Aztreonam is particularly active against aerobic Gram-negative bacilli, including *E. coli*, *K. pneumoniae*, *Klebsiella oxytoca*, *P. mirabilis*, *S. marcescens*, *Citrobacter* spp., and *P. aeruginosa*. It is used to treat urinary and lower respiratory tract infections, intra-abdominal infections, and gynecological infections, as well as septicemias caused by these organisms. Aztreonam is also effective against, but is not currently used to treat, infections caused by *Haemophilus*, *Neisseria*, *Salmonella*, indole-positive *Proteus*, and *Yersinia* spp. It is not active against Gram-positive bacteria, anaerobic bacteria, or other species of *Pseudomonas*.

Urinary excretion is about 70% of the administered dose. Some is excreted through the bile. Serum half-life is 1.7 hours, which allows aztreonam to be administered 2 or 3 times daily, depending on the severity of the infection. Less than 1% of an orally administered dose of aztreonam is absorbed, prompting the suggestion that this β -lactam could be used to treat intestinal infections.

The disodium salt of aztreonam is very soluble in water. Solutions for parenteral administration containing 2% or less are stable for 48 hours at room temperature. Refrigerated solutions retain full potency for 1 week.

Tigemonam

Tigemonam is a newer monobactam that is orally active.¹⁰³ It is highly resistant to β -lactamases. The antibacterial spectrum of activity resembles that of aztreonam. It is very active against the Enterobacteriaceae, including *E. coli*, *Klebsiella*, *Proteus*, *Citrobacter*, *Serratia*, and *Enterobacter* spp. It also exhibits good potency against *H. influenzae* and *N. gonorrhoeae*. Tigemonam is not particularly active against Gram-positive or anaerobic bacteria and is inactive against *P. aeruginosa*.

In contrast to the poor oral bioavailability of aztreonam, the oral absorption of tigemonam is excellent. It could become a valuable agent for the oral treatment of urinary tract infections and other non-life-threatening infections caused by β -lactamase-producing Gram-negative bacteria.

AMINOGLYCOSIDES

The discovery of streptomycin, the first aminoglycoside antibiotic to be used in chemotherapy, was the result of a planned and deliberate search begun in 1939 and brought to fruition in 1944 by Schatz and associates.¹⁰⁴ This success stimulated worldwide searches for antibiotics from the actinomycetes and, particularly, from the genus *Streptomyces*. Among the many antibiotics isolated from that genus, several are compounds closely related in structure to streptomycin. Six of them—kanamycin, neomycin, paromomycin, gentamicin, tobramycin, and netilmicin—currently are marketed in the United States. Amikacin, a semisynthetic derivative of kanamycin A, has been added, and it is possible that additional aminoglycosides will be introduced in the future.

All aminoglycoside antibiotics are absorbed very poorly (less than 1% under normal circumstances) following oral administration, and some of them (kanamycin, neomycin, and paromomycin) are administered by that route for the treatment of GI infections. Because of their potent broad-spectrum antimicrobial activity, they are also used for the treatment of systemic infections. Their undesirable side effects, particularly ototoxicity and nephrotoxicity, have restricted their systemic use to serious infections or infections caused by bacterial strains resistant to other agents. When administered for systemic infections, aminoglycosides must be given parenterally, usually by intramuscular injection. An additional antibiotic obtained from *Streptomyces*, spectinomycin, is also an aminoglycoside but differs chemically and microbiologically from other members of the group. It is used exclusively for the treatment of uncomplicated gonorrhea.

Chemistry

Aminoglycosides are so named because their structures consist of amino sugars linked glycosidically. All have at least one aminohexose, and some have a pentose lacking an amino group (e.g., streptomycin, neomycin, and paromomycin). Additionally, each of the clinically useful aminoglycosides contains a highly substituted 1,3-diaminocyclohexane central ring; in kanamycin, neomycin, gentamicin, and tobramycin, it

is deoxystreptamine, and in streptomycin, it is streptidine. The aminoglycosides are thus strongly basic compounds that exist as polycations at physiological pH. Their inorganic acid salts are very soluble in water. All are available as sulfates. Solutions of the aminoglycoside salts are stable to autoclaving. The high water solubility of the aminoglycosides no doubt contributes to their pharmacokinetic properties. They distribute well into most body fluids but not into the central nervous system, bone, or fatty or connective tissues. They tend to concentrate in the kidneys and are excreted by glomerular filtration. Aminoglycosides are apparently not metabolized *in vivo*.

Spectrum of Activity

Although the aminoglycosides are classified as broad-spectrum antibiotics, their greatest usefulness lies in the treatment of serious systemic infections caused by aerobic Gram-negative bacilli. The choice of agent is generally between kanamycin, gentamicin, tobramycin, netilmicin, and amikacin. Aerobic Gram-negative and Gram-positive cocci (with the exception of staphylococci) tend to be less sensitive; thus, the β -lactams and other antibiotics tend to be preferred for the treatment of infections caused by these organisms. Anaerobic bacteria are invariably resistant to the aminoglycosides. Streptomycin is the most effective of the group for the chemotherapy of TB, brucellosis, tularemia, and *Yersinia* infections. Paromomycin is used primarily in the chemotherapy of amebic dysentery. Under certain circumstances, aminoglycoside and β -lactam antibiotics exert a synergistic action *in vivo* against some bacterial strains when the two are administered jointly. For example, carbenicillin and gentamicin are synergistic against gentamicin-sensitive strains of *P. aeruginosa* and several other species of Gram-negative bacilli, and penicillin G and streptomycin (or gentamicin or kanamycin) tend to be more effective than either agent alone in the treatment of enterococcal endocarditis. The two antibiotic types should not be combined in the same solution because they are chemically incompatible. Damage to the cell wall caused by the β -lactam antibiotic is believed to increase penetration of the aminoglycoside into the bacterial cell.

Mechanism of Action

Most studies concerning the mechanism of antibacterial action of the aminoglycosides were carried out with streptomycin. However, the specific actions of other aminoglycosides are thought to be qualitatively similar. The aminoglycosides act directly on the bacterial ribosome to inhibit the initiation of protein synthesis and to interfere with the fidelity of translation of the genetic message. They bind to the 30S ribosomal subunit to form a complex that cannot initiate proper amino acid polymerization.¹⁰⁵ The binding of streptomycin and other aminoglycosides to ribosomes also causes misreading mutations of the genetic code, apparently resulting from failure of specific aminoacyl RNAs to recognize the proper codons on messenger RNA (mRNA) and hence incorporation of improper amino acids into the peptide chain.¹⁰⁶ Evidence suggests that the deoxystreptamine-containing aminoglycosides differ quantitatively from streptomycin in causing misreading at lower concentrations than those required to prevent initiation of protein synthesis, whereas streptomycin is equally effective in inhibiting initiation and causing

misreading.¹⁰⁷ Spectinomycin prevents the initiation of protein synthesis but apparently does not cause misreading. All of the commercially available aminoglycoside antibiotics are bactericidal, except spectinomycin. The mechanism for the bactericidal action of the aminoglycosides is not known.

Microbial Resistance

The development of strains of Enterobacteriaceae resistant to antibiotics is a well-recognized, serious medical problem. Nosocomial (hospital acquired) infections caused by these organisms are often resistant to antibiotic therapy. Research has established clearly that multidrug resistance among Gram-negative bacilli to various antibiotics occurs and can be transmitted to previously nonresistant strains of the same species and, indeed, to different species of bacteria. Resistance is transferred from one bacterium to another by extrachromosomal R factors (DNA) that self-replicate and are transferred by conjugation (direct contact). The aminoglycoside antibiotics, because of their potent bactericidal action against Gram-negative bacilli, are now preferred for the treatment of many serious infections caused by coliform bacteria. A pattern of bacterial resistance to each of the aminoglycoside antibiotics, however, has developed as their clinical use has become more widespread. Consequently, there are bacterial strains resistant to streptomycin, kanamycin, and gentamicin. Strains carrying R factors for resistance to these antibiotics synthesize enzymes that are capable of acetylating, phosphorylating, or adenylylating key amino or hydroxyl groups of the aminoglycosides. Much of the recent effort in aminoglycoside research is directed toward identifying new, or modifying existing, antibiotics that are resistant to inactivation by bacterial enzymes.

Resistance of individual aminoglycosides to specific inactivating enzymes can be understood, in large measure, by using chemical principles. First, one can assume that if the target functional group is absent in a position of the structure normally attacked by an inactivating enzyme, then the antibiotic will be resistant to the enzyme. Second, steric factors may confer resistance to attack at functionalities otherwise susceptible to enzymatic attack. For example, conversion of a primary amino group to a secondary amine inhibits *N*-acetylation by certain aminoglycoside acetyl transferases. At least nine different types of aminoglycoside-inactivating enzymes have been identified and partially characterized.¹⁰⁸ The sites of attack of these enzymes and the biochemistry of the inactivation reactions is described briefly, using the kanamycin B structure (which holds the dubious distinction of being a substrate for all of the enzymes described) for illustrative purposes (Fig. 8.7).

Aminoglycoside-inactivating enzymes include (a) aminoacyltransferases (designated AAC), which acetylate the 6'-NH₂ of ring I, the 3-NH₂ of ring II, or the 2'-NH₂ of ring I; (b) phosphotransferases (designated APH), which phosphorylate the 3'-OH of ring I or the 2''-OH of ring III; and (c) nucleotidyltransferases (ANT), which adenylate the 2''-OH of ring III, the 4'-OH of ring I, or the 4''-OH of ring III.

The gentamicins and tobramycin lack a 3'-hydroxyl group in ring I (see the section on the individual products for structures) and, consequently, are not inactivated by the phosphotransferase enzymes that phosphorylate that group in the kanamycins. Gentamicin C₁ (but not gentamicins C_{1a}

Figure 8.7 • Inactivation of kanamycin B by bacterial enzymes.

or C₂ or tobramycin) is resistant to the acetyltransferase that acetylates the 6'-amino group in ring I of kanamycin B. All gentamicins are resistant to the nucleotidyltransferase enzyme that adenylates the secondary equatorial 4''-hydroxyl group of kanamycin B because the 4''-hydroxyl group in the gentamicins is *tertiary* and is oriented axially. Removal of functional groups susceptible to attacking an aminoglycoside occasionally can lead to derivatives that resist enzymatic inactivation and retain activity. For example, the 3'-deoxy-, 4'-deoxy-, and 3',4'-dideoxykanamycins are more similar to the gentamicins and tobramycin in their patterns of activity against clinical isolates that resist one or more of the aminoglycoside-inactivating enzymes.

The most significant breakthrough yet achieved in the search for aminoglycosides resistant to bacterial enzymes has been the development of amikacin, the 1-*N*-L(-)-amino- α -hydroxybutyric acid (L-AHBA) derivative of kanamycin A. This remarkable compound retains most of the intrinsic potency of kanamycin A and is resistant to virtually all aminoglycoside-inactivating enzymes known, except the aminoacetyltransferase that acetylates the 6'-amino group and the nucleotidyltransferase that adenylates the 4'-hydroxyl group of ring I.^{108,109} The cause of amikacin's resistance to enzymatic inactivation is unknown, but it has been suggested that introduction of the L-AHBA group into kanamycin A markedly decreases its affinity for the inactivating enzymes. The importance of amikacin's resistance to enzymatic inactivation is reflected in the results of an investigation on the comparative effectiveness of amikacin and other aminoglycosides against clinical isolates of bacterial strains known to be resistant to one or more of the aminoglycosides.¹¹⁰ In this study, amikacin was effective against 91% of the isolates (with a range of 87%–100%, depending on the species). Of the strains susceptible to other systemically useful aminoglycosides, 18% were susceptible to kanamycin, 36% to gentamicin, and 41% to tobramycin.

Low-level resistance associated with diminished aminoglycoside uptake has been observed in certain strains of *P. aeruginosa* isolated from nosocomial infections.¹¹¹ Bacterial susceptibility to aminoglycosides requires uptake of the drug by an energy-dependent active process.¹¹² Uptake is initiated by the binding of the cationic aminoglycoside to anionic phospholipids of the cell membrane. Electron transport-linked transfer of the aminoglycoside through the cell membrane then occurs. Divalent cations such as Ca²⁺ and

Mg²⁺ antagonize the transport of aminoglycosides into bacterial cells by interfering with their binding to cell membrane phospholipids. The resistance of anaerobic bacteria to the lethal action of the aminoglycosides is apparently because of the absence of the respiration-driven active-transport process for transporting the antibiotics.

Structure-Activity Relationships

Despite the complexity inherent in various aminoglycoside structures, some conclusions on SARs in this antibiotic class have been made.¹¹³ Such conclusions have been formulated on the basis of comparisons of naturally occurring aminoglycoside structures, the results of selective semisynthetic modifications, and the elucidation of sites of inactivation by bacterial enzymes. It is convenient to discuss sequentially aminoglycoside SARs in terms of substituents in rings I, II, and III.

Ring I is crucially important for characteristic broad-spectrum antibacterial activity, and it is the primary target for bacterial inactivating enzymes. Amino functions at 6' and 2' are particularly important as kanamycin B (6'-amino, 2'-amino) is more active than kanamycin A (6'-amino, 2'-hydroxyl), which in turn is more active than kanamycin C (6'-hydroxyl, 2'-amino). Methylation at either the 6'-carbon or the 6'-amino positions does not lower appreciably antibacterial activity and confers resistance to enzymatic acetylation of the 6'-amino group. Removal of the 3'-hydroxyl or the 4'-hydroxyl group or both in the kanamycins (e.g., 3',4'-dideoxykanamycin B or dibekacin) does not reduce antibacterial potency. The gentamicins also lack oxygen functions at these positions, as do sisomicin and netilmicin, which also have a 4',5'-double bond. None of these derivatives is inactivated by phosphotransferase enzymes that phosphorylate the 3'-hydroxyl group. Evidently, the 3'-phosphorylated derivatives have very low affinity for aminoglycoside-binding sites in bacterial ribosomes.

Few modifications of ring II (deoxystreptamine) functional groups are possible without appreciable loss of activity in most of the aminoglycosides. The 1-amino group of kanamycin A can be acylated (e.g., amikacin), however, with activity largely retained. Netilmicin (1-*N*-ethylsisomicin) retains the antibacterial potency of sisomicin and is resistant to several additional bacteria-inactivating enzymes. 2''-Hydroxysisomicin is claimed to be resistant to bacterial

strains that adenylate the 2''-hydroxyl group of ring III, whereas 3-deaminosisomicin exhibits good activity against bacterial strains that elaborate 3-acetylating enzymes.

Ring III functional groups appear to be somewhat less sensitive to structural changes than those of either ring I or ring II. Although the 2''-deoxygentamicins are significantly less active than their 2''-hydroxyl counterparts, the 2''-amino derivatives (seldomycins) are highly active. The 3''-amino group of gentamicins may be primary or secondary with high antibacterial potency. Furthermore, the 4''-hydroxyl group may be *axial* or *equatorial* with little change in potency.

Despite improvements in antibacterial potency and spectrum among newer naturally occurring and semisynthetic aminoglycoside antibiotics, efforts to find agents with improved margins of safety have been disappointing. The potential for toxicity of these important chemotherapeutic agents continues to restrict their use largely to the hospital environment.

The discovery of agents with higher potency/toxicity ratios remains an important goal of aminoglycoside research. In a now somewhat dated review, however, Price¹¹⁴ expressed doubt that many significant clinical breakthroughs in aminoglycoside research would occur in the future.

Products

Streptomycin Sulfate, Sterile

Streptomycin sulfate is a white, odorless powder that is hygroscopic but stable toward light and air. It is freely soluble in water, forming solutions that are slightly acidic or nearly neutral. It is very slightly soluble in alcohol and is insoluble in most other organic solvents. Acid hydrolysis yields streptidine and streptobiosamine, the compound that is a combination of L-streptose and *N*-methyl-L-glucosamine.

Streptomycin acts as a triacidic base through the effect of its two strongly basic guanidino groups and the more weakly basic methylamino group. Aqueous solutions may be stored at room temperature for 1 week without any loss of potency, but they are most stable if the pH is between 4.5 and 7.0. The solutions decompose if sterilized by heating, so sterile solutions are prepared by adding sterile distilled water to the sterile powder. The early salts of streptomycin contained impurities that were difficult to remove and caused a histamine-like reaction. By forming a complex with calcium chloride, it was possible to free the streptomycin from these impurities and to obtain a product that was generally well tolerated.

The organism that produces streptomycin, *S. griseus*, also produces several other antibiotic compounds: hydroxystreptomycin, mannisidostreptomycin, and cycloheximide (q.v.).

Of these, only cycloheximide has achieved importance as a medically useful substance. The term *streptomycin A* has been used to refer to what is commonly called streptomycin, and mannisidostreptomycin has been called *streptomycin B*. Hydroxystreptomycin differs from streptomycin in having a hydroxyl group in place of one of the hydrogen atoms of the streptose methyl group. Mannisidostreptomycin has a mannose residue attached in glycosidic linkage through the hydroxyl group at C-4 of the *N*-methyl-L-glucosamine moiety. The work of Dyer et al.^{115,116} to establish the stereochemical structure of streptomycin has been completed, and confirmed with the total synthesis of streptomycin and dihydrostreptomycin by Japanese scientists.¹¹⁷

Clinically, a problem that sometimes occurs with the use of streptomycin is the early development of resistant strains of bacteria, necessitating a change in therapy. Other factors that limit the therapeutic use of streptomycin are chronic toxicities. Neurotoxic reactions have been observed after the use of streptomycin. These are characterized by vertigo, disturbance of equilibrium, and diminished auditory perception. Additionally, nephrotoxicity occurs with some frequency. Patients undergoing therapy with streptomycin should have frequent checks of renal monitoring parameters. Chronic toxicity reactions may or may not be reversible. Minor toxic effects include rashes, mild malaise, muscular pains, and drug fever.

As a chemotherapeutic agent, streptomycin is active against numerous Gram-negative and Gram-positive bacteria. One of the greatest virtues of streptomycin is its effectiveness against the tubercle bacillus, *M. tuberculosis*. By itself, the antibiotic is not a cure, but it is a valuable adjunct to other treatment modalities for TB. The greatest drawback to the use of streptomycin is the rather rapid development of resistant strains of microorganisms. In infections that may be because of bacteria sensitive to both streptomycin and penicillin, the combined administration of the two antibiotics has been advocated. The possible development of damage to the otic nerve by the continued use of streptomycin-containing preparations has discouraged the use of such products. There has been an increasing tendency to reserve streptomycin products for the treatment of TB. It remains one of the agents of choice, however, for the treatment of certain "occupational" bacterial infections, such as brucellosis, tularemia, bubonic plague, and glanders. Because streptomycin is not absorbed when given orally or destroyed significantly in the GI tract, at one time it was used rather widely in the treatment of infections of the intestinal tract. For systemic action, streptomycin usually is given by intramuscular injection.

Neomycin Sulfate

In a search for antibiotics less toxic than streptomycin, Waksman and Lechevalier¹¹⁸ isolated neomycin (Mycifradin, Neobiotic) in 1949 from *Streptomyces fradiae*. Since then, the importance of neomycin has increased steadily, and today, it is considered one of the most useful antibiotics for the treatment of GI infections, dermatological infections, and acute bacterial peritonitis. Also, it is used in abdominal surgery to reduce or avoid complications caused by infections from bacterial flora of the bowel. It has broad-spectrum activity against various organisms and shows a low incidence of toxic and hypersensitivity reactions. It is absorbed very slightly from the digestive tract, so its oral use ordinarily does not

produce any systemic effect. The development of neomycin-resistant strains of pathogens is rarely reported in those organisms against which neomycin is effective.

Neomycin as the sulfate salt is a white to slightly yellow, crystalline powder that is very soluble in water. It is hygroscopic and photosensitive (but stable over a wide pH range and to autoclaving). Neomycin sulfate contains the equivalent of 60% of the free base.

Neomycin, as produced by *S. fradiae*, is a mixture of closely related substances. Included in the "neomycin complex" is neamine (originally designated *neomycin A*) and neomycins B and C. *S. fradiae* also elaborates another antibiotic, the fradycin, which has some antifungal properties but no antibacterial activity. This substance is not present in "pure" neomycin.

The structures of neamine and neomycins B and C are known, and the absolute configurational structures of neamine and neomycin were reported by Hichens and Rinehart.¹¹⁹ Neamine may be obtained by methanolysis of neomycins B and C, during which the glycosidic link between deoxystreptamine and D-ribose is broken. Therefore, neamine is a combination of deoxystreptamine and neosamine C, linked glycosidically (α) at the 4-position of deoxystrepta-

mine. According to Hichens and Rinehart, neomycin B differs from neomycin C by the nature of the sugar attached terminally to D-ribose. That sugar, called *neosamine B*, differs from neosamine C in its stereochemistry. Rinehart et al.¹²⁰ have suggested that in neosamine the configuration is 2,6-diamino-2,6-dideoxy-L-idose, in which the orientation of the 6-aminomethyl group is inverted to the 6-amino-6-deoxy-D-glucosamine in neosamine C. In both instances, the glycosidic links were assumed to be α . Huettneraich¹²¹ later suggested, however, that both of the diamino sugars in neomycin C have the D-glucose configuration and that the glycosidic link is β in the one attached to D-ribose. The latter stereochemistry has been confirmed by the total synthesis of neomycin C.¹²²

Paromomycin Sulfate

The isolation of paromomycin (Humatin) was reported in 1956 from a fermentation with a *Streptomyces* sp. (PD 04998), a strain said to resemble *S. rimosus* very closely. The parent organism had been obtained from soil samples collected in Colombia. Paromomycin, however, more closely resembles neomycin and streptomycin in antibiotic activity than it does oxytetracycline, the antibiotic obtained from *S. rimosus*.

Paromomycin I: $R^1=H$; $R^2=CH_2NH_2$

Paromomycin II: $R^1=CH_2NH_2$; $R^2=H$

The general structure of paromomycin was reported by Haskell et al.¹²³ as one compound. Subsequently, chromatographic determinations have shown paromomycin to consist of two fractions, paromomycin I and paromomycin II. The absolute configurational structures for the paromomycins, as shown in the structural formula, were suggested by Hichens and Rinehart¹¹⁹ and confirmed by DeJongh et al.¹²⁴ by mass spectrometric studies. The structure of paromomycin is the same as that of neomycin B, except that paromomycin contains D-glucosamine instead of the 6-amino-6-deoxy-D-glucosamine found in neomycin B. The same structural relationship is found between paromomycin II and neomycin C. The combination of D-glucosamine and deoxystreptamine is obtained by partial hydrolysis of both paromomycins and is called *paromamine* [4-(2-amino-2-deoxy- α -4-glucosyl)deoxystreptamine].

Paromomycin has broad-spectrum antibacterial activity and has been used for the treatment of GI infections caused by *Salmonella* and *Shigella* spp., and enteropathogenic *E. coli*. Currently, however, its use is restricted largely to the treatment of intestinal amebiasis. Paromomycin is soluble in water and stable to heat over a wide pH range.

Kanamycin Sulfate

Kanamycin (Kantrex) was isolated in 1957 by Umezawa and coworkers¹²⁵ from *Streptomyces kanamyceticus*. Its activity against mycobacteria and many intestinal bacteria, as well as several pathogens that show resistance to other antibiotics, brought a great deal of attention to this antibiotic. As a result, kanamycin was tested and released for medical use in a very short time.

Research activity has been focused intensively on determining the structures of the kanamycins. Chromatography showed that *S. kanamyceticus* elaborates three closely related structures: kanamycins A, B, and C. Commercially available kanamycin is almost pure kanamycin A, the least toxic of the three forms. The kanamycins differ only in the sugar moieties attached to the glycosidic oxygen on the 4-position of the central deoxystreptamine. The absolute configuration of the deoxystreptamine in kanamycins reported by Tatsuoka et al.¹²⁶ is shown above. The chemical relationships among the kanamycins, the neomycins, and the paromomycins were reported by Hichens and Rinehart.¹¹⁹ The kanamycins do not have the D-ribose molecule that is present in neomycins and paromomycins. Perhaps this structural difference is related to the lower toxicity observed with kanamycins. The kanosamine fragment linked glycosidically to the 6-position of deoxystreptamine is 3-amino-3-deoxy-D-glucose (3-D-glucosamine) in all three kanamycins. The structures of the kanamycins have been proved by total synthesis.^{127,128} They differ in the substituted D-glucoses attached glycosidically to the 4-position of

the deoxystreptamine ring. Kanamycin A contains 6-amino-6-deoxy-D-glucose; kanamycin B contains 2,6-diamino-2,6-dideoxy-D-glucose; and kanamycin C contains 2-amino-2-deoxy-D-glucose (see preceding diagram).

Kanamycin is basic and forms salts of acids through its amino groups. It is water soluble as the free base, but it is used in therapy as the sulfate salt, which is very soluble. It is stable to both heat and chemicals. Solutions resist both acids and alkali within the pH range of 2.0 to 11.0. Because of possible inactivation of either agent, kanamycin and penicillin salts should not be combined in the same solution.

The use of kanamycin in the United States usually is restricted to infections of the intestinal tract (e.g., bacillary dysentery) and to systemic infections arising from Gram-negative bacilli (e.g., *Klebsiella*, *Proteus*, *Enterobacter*, and *Serratia* spp.) that have developed resistance to other antibiotics. It has also been recommended for preoperative antiseptics of the bowel. It is absorbed poorly from the intestinal tract; consequently, systemic infections must be treated by intramuscular or (for serious infections) intravenous injections. These injections are rather painful, and the concomitant use of a local anesthetic is indicated. The use of kanamycin in the treatment of TB has not been widely advocated since the discovery that mycobacteria develop resistance very rapidly. In fact, both clinical experience and experimental work¹²⁹ indicate that kanamycin develops cross-resistance in the tubercle bacilli with dihydrostreptomycin, viomycin, and other antitubercular drugs. Like streptomycin, kanamycin may cause decreased or complete loss of hearing. On development of such symptoms, its use should be stopped immediately.

Amikacin

Amikacin, 1-*N*-amino- α -hydroxybutyrylkanamycin A (Amikin), is a semisynthetic aminoglycoside first prepared in Japan. The synthesis formally involves simple acylation of the 1-amino group of the deoxystreptamine ring of kanamycin A with L-AHBA. This particular acyl derivative retains about 50% of the original activity of kanamycin A against sensitive strains of Gram-negative bacilli. The L-AHBA derivative is much more active than the D-isomer.¹³⁰ The remarkable feature of amikacin is that it resists attack by most bacteria-inactivating enzymes and, therefore, is effective against strains of bacteria that are resistant to other aminoglycosides,¹¹⁰ including gentamicin and tobramycin. In fact, it is resistant to all known aminoglycoside-inactivating enzymes, except the aminotransferase that acetylates the 6' amino group¹⁰⁹ and the 4'-nucleotidyl transferase that adenylates the 4'-hydroxyl group of aminoglycosides.¹⁰⁸

Preliminary studies indicate that amikacin may be less ototoxic than either kanamycin or gentamicin.¹³¹ Higher dosages of amikacin are generally required, however, for the

treatment of most Gram-negative bacillary infections. For this reason, and to discourage the proliferation of bacterial strains resistant to it, amikacin currently is recommended for the treatment of serious infections caused by bacterial strains resistant to other aminoglycosides.

Gentamicin Sulfate

Gentamicin (Garamycin) was isolated in 1958 and reported in 1963 by Weinstein et al.¹³² to belong to the streptomycinoid (aminocyclitol) group of antibiotics. It is obtained commercially from *Micromonospora purpurea*. Like the other members of its group, it has a broad spectrum of activity against many common pathogens, both Gram-positive and Gram-negative. Of particular interest is its strong activity against *P. aeruginosa* and other Gram-negative enteric bacilli.

Gentamicin is effective in the treatment of various skin infections for which a topical cream or ointment may be used. Because it offers no real advantage over topical neomycin in the treatment of all but pseudomonal infections, however, it is recommended that topical gentamicin be reserved for use in such infections and in the treatment of burns complicated by pseudomonemia. An injectable solution containing 40 mg of gentamicin sulfate per milliliter may be used for serious systemic and genitourinary tract infections caused by Gram-negative bacteria, particularly *Pseudomonas*, *Enterobacter*, and *Serratia* spp. Because of the development of strains of these bacterial species resistant to previously effective broad-spectrum antibiotics, gentamicin has been used for the treatment of hospital-acquired infections caused by such organisms. Resistant bacterial strains that inactivate gentamicin by adenylation and acetylation, however, appear to be emerging with increasing frequency.

Gentamicin sulfate is a mixture of the salts of compounds identified as gentamicins C₁, C₂, and C_{1a}. These gentamicins were reported by Cooper et al.¹³³ to have the structures shown in the diagram. The absolute stereochemistries of the sugar components and the geometries of the glycosidic linkages have also been established.¹³⁴

Coproducts, but not a part of the commercial product, are gentamicins A and B. Their structures were reported by Maehr and Schaffner¹³⁵ and are closely related to those of the gentamicins C. Although gentamicin molecules are similar in many ways to other aminocyclitols such as streptomycins, they are sufficiently different that their medical effectiveness is significantly greater. Gentamicin sulfate is a white to buff substance that is soluble in water and insoluble in alcohol, acetone, and benzene. Its solutions are stable over a wide pH range and may be autoclaved. It is chemically incompatible with carbenicillin, and the two should not be combined in the same intravenous solution.

Tobramycin Sulfate

Introduced in 1976, tobramycin sulfate (Nebcin) is the most active of the chemically related aminoglycosides called *nebramycins* obtained from a strain of *Streptomyces tenebrar-*

ius. Five members of the nebramycin complex have been identified chemically.¹³⁶

Factors 4 and 4' are 6''-*O*-carbamoylkanamycin B and kanamycin B, respectively; factors 5' and 6 are 6''-*O*-carbamoyltobramycin and tobramycin; and factor 2 is apramycin, a tetracyclic aminoglycoside with an unusual bicyclic central ring structure. Kanamycin B and tobramycin probably do not occur in fermentation broths per se but are formed by hydrolysis of the 6-*O*'-carbamoyl derivatives in the isolation procedure.

The most important property of tobramycin is its activity against most strains of *P. aeruginosa*, exceeding that of gentamicin by twofold to fourfold. Some gentamicin-resistant strains of this troublesome organism are sensitive to tobramycin, but others are resistant to both antibiotics.¹³⁷ Other Gram-negative bacilli and staphylococci are generally more sensitive to gentamicin. Tobramycin more closely resembles kanamycin B in structure (it is 3'-deoxykanamycin B).

Netilmicin Sulfate

Netilmicin sulfate, 1-*N*-ethylsisomicin (Netromycin), is a semisynthetic derivative prepared by reductive ethylation¹³⁸ of sisomicin, an aminoglycoside antibiotic obtained from *Micromonospora inyoensis*.¹³⁹ Structurally, sisomicin and netilmicin resemble gentamicin C_{1a}, a component of the gentamicin complex.

Against most strains of Enterobacteriaceae, *P. aeruginosa*, and *S. aureus*, sisomicin and netilmicin are comparable to gentamicin in potency.¹⁴⁰ Netilmicin is active, however, against many gentamicin-resistant strains, in particular among *E. coli*, *Enterobacter*, *Klebsiella*, and *Citrobacter* spp. A few strains of gentamicin-resistant *P. aeruginosa*, *S. marcescens*, and indole-positive *Proteus* spp. are also sensitive to netilmicin. Very few gentamicin-resistant bacterial strains are sensitive to sisomicin, however. The potency of netilmicin against certain gentamicin-resistant bacteria is attributed to its resistance to inactivation by bacterial enzymes that adenylylate or phosphorylate gentamicin and sisomicin. Evidently, the introduction of a 1-ethyl group in sisomicin markedly decreases the affinity of these enzymes for the molecule in a manner similar to that observed in the 1-*N*-ε-amino-α-hydroxybutyryl amide of kanamycin A (amikacin). Netilmicin, however, is inactivated by most of

the bacterial enzymes that acetylate aminoglycosides, whereas amikacin is resistant to most of these enzymes.

The pharmacokinetic and toxicological properties of netilmicin and gentamicin appear to be similar clinically, though animal studies have indicated greater nephrotoxicity for gentamicin.

Sisomicin Sulfate

Although sisomicin has been approved for human use in the United States, it has not been marketed in this country. Its antibacterial potency and effectiveness against aminoglycoside-inactivating enzymes resemble those of gentamicin. Sisomicin also exhibits pharmacokinetics and pharmacological properties similar to those of gentamicin.

Spectinomycin Hydrochloride, Sterile

The aminocyclitol antibiotic spectinomycin hydrochloride (Trobicin), isolated from *Streptomyces spectabilis* and once called actinospectocin, was first described by Lewis and Clapp.¹⁴¹ Its structure and absolute stereochemistry have been confirmed by x-ray crystallography.¹⁴² It occurs as the white, crystalline dihydrochloride pentahydrate, which is stable in the dry form and very soluble in water. Solutions of spectinomycin, a hemiacetal, slowly hydrolyze on standing and should be prepared freshly and used within 24 hours. It is administered by deep intramuscular injection.

Spectinomycin is a broad-spectrum antibiotic with moderate activity against many Gram-positive and Gram-negative bacteria. It differs from streptomycin and the streptomycin-containing aminoglycosides in chemical and antibacterial properties. Like streptomycin, spectinomycin interferes with the binding of transfer RNA (tRNA) to the ribosomes and thus with the initiation of protein synthesis. Unlike streptomycin or the streptomycin-containing antibiotics, however, it does not cause misreading of the messenger. Spectinomycin exerts a bacteriostatic action and is inferior to other aminoglycosides for most systemic infections. Currently, it is recommended as an alternative to penicillin G salts for the treatment of uncomplicated gonorrhea. A cure rate of more than 90% has been observed in clinical studies for this indication. Many physicians prefer to use a tetracycline or erythromycin for prevention or treatment of suspected gonorrhea in penicillin-sensitive patients because, unlike these agents, spectinomycin is ineffective against syphilis. Furthermore, it is considerably more expensive than erythromycin and most of the tetracyclines.

TETRACYCLINES

Chemistry

Among the most important broad-spectrum antibiotics are members of the tetracycline family. Nine such compounds—tetracycline, rolitetracycline, oxytetracycline, chlortetracycline, demeclocycline, meclocycline, methacycline, doxycycline, and minocycline—have been introduced into medical use. Several others possess antibiotic activity. The tetracyclines are obtained by fermentation procedures from *Streptomyces* spp. or by chemical transformations of the natural products. Their chemical identities have been established by degradation studies and confirmed by the synthesis of three members of the group, oxytetracycline,^{143,144} 6-demethyl-6-deoxytetracycline,¹⁴⁵ and anhydrochlortetracycline,¹⁴⁶ in their (α) forms. The important members of the group are derivatives of an octahydronaphthacene, a hydrocarbon system that comprises four annulated six-membered rings. The group name is derived from this tetracyclic system. The antibiotic spectra and chemical properties of these compounds are very similar but not identical.

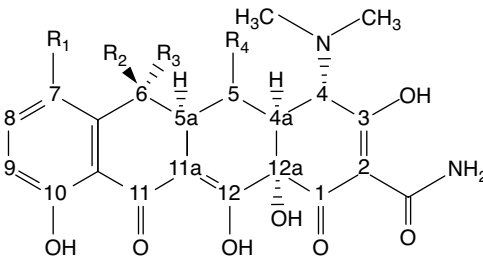

The stereochemistry of the tetracyclines is very complex. Carbon atoms 4, 4a, 5, 5a, 6, and 12a are potentially chiral, depending on substitution. Oxytetracycline and doxycycline, each with a 5 α -hydroxyl substituent, have six asymmetric centers; the others, lacking chirality at C-5, have only five. Determination of the complete, absolute stereochemistry of the tetracyclines was a difficult problem. Detailed x-ray diffraction analysis^{147–149} established the stereochemical formula shown in Table 8.6 as the orientations found in the natural and semisynthetic tetracyclines. These studies also confirmed that conjugated systems exist in the structure from C-10 through C-12 and from C-1 through C-3 and that the formula represents only one of several canonical forms existing in those portions of the molecule.

Structure of the Tetracyclines

The tetracyclines are amphoteric compounds, forming salts with either acids or bases. In neutral solutions, these substances exist mainly as zwitterions. The acid salts, which are formed through protonation of the enol group on C-2, exist as crystalline compounds that are very soluble in water. These amphoteric antibiotics will crystallize out of aqueous solutions of their salts, however, unless stabilized by an excess of acid. The hydrochloride salts are used most commonly for oral administration and usually are encapsulated because they are bitter. Water-soluble salts may be obtained also from bases, such as sodium or potassium hydroxides, but they are not stable in aqueous solutions. Water-insoluble salts are formed with divalent and polyvalent metals.

The unusual structural groupings in the tetracyclines produce three acidity constants in aqueous solutions of the acid salts (Table 8.7). The particular functional groups responsible for each of the thermodynamic pK_a values were determined by Leeson et al.¹⁵⁰ as shown in the diagram that follows. These groupings had been identified previously by Stephens et al.¹⁵¹ as the sites for protonation, but their earlier assignments, which produced the values responsible for

TABLE 8.6 Structures of Tetracyclines

	R ₁	R ₂	R ₃	R ₄
Tetracycline	H	OH	CH ₃	H
Chlortetracycline	Cl	OH	CH ₃	H
Oxytetracycline	H	OH	CH ₃	OH
Demeclocycline	Cl	OH	H	H
Methacycline	H	CH ₂	H	OH
Doxycycline	H	CH ₃	H	OH
Minocycline	N(CH ₃) ₂	H	H	H

pK_{a2} and pK_{a3} , were opposite those of Leeson et al.¹⁵⁰ This latter assignment has been substantiated by Rigler et al.¹⁵²

The approximate pK_a values for each of these groups in the six tetracycline salts in common use are shown (Table 8.7). The values are taken from Stephens et al.,¹⁵¹ Benet and Goyan,¹⁵³ and Barringer et al.¹⁵⁴ The pK_a of the 7-dimethylamino group of minocycline (not listed) is 5.0.

An interesting property of the tetracyclines is their ability to undergo epimerization at C-4 in solutions of intermediate pH range. These isomers are called *epitetracyclines*.

TABLE 8.7 pK_a Values (of Hydrochlorides) in Aqueous Solution at 25°C

	pK_{a1}	pK_{a2}	pK_{a3}
Tetracycline	3.3	7.7	9.5
Chlortetracycline	3.3	7.4	9.3
Demeclocycline	3.3	7.2	9.3
Oxytetracycline	3.3	7.3	9.1
Doxycycline	3.4	7.7	9.7
Minocycline	2.8	7.8	9.3

Under acidic conditions, an equilibrium is established in about 1 day and consists of approximately equal amounts of the isomers. The partial structures below indicate the two forms of the epimeric pair. The 4-epitetracyclines have been isolated and characterized. They exhibit much less activity than the "natural" isomers, thus accounting for the decreased therapeutic value of aged solutions.

Epi

Natural

Strong acids and strong bases attack tetracyclines with a hydroxyl group on C-6, causing a loss in activity through modification of the C ring. Strong acids produce dehydration through a reaction involving the 6-hydroxyl group and the 5a-hydrogen. The double bond thus formed between positions 5a and 6 induces a shift in the position of the double bond between C-11a and C-12 to a position between C-11 and C-11a, forming the more energetically favored resonant system of the naphthalene group found in the inactive anhydrotetracyclines. Bases promote a reaction between the 6-hydroxyl group and the ketone group at the 11-position, causing the bond between the 11 and 11a atoms to cleave, forming the lactone ring found in the inactive isotetracycline. These two unfavorable reactions stimulated research that led to the development of the more stable and longer-acting compounds 6-deoxytetracycline, methacycline, doxycycline, and minocycline.

Stable chelate complexes are formed by the tetracyclines with many metals, including calcium, magnesium, and iron. Such chelates are usually very insoluble in water, accounting for the impaired absorption of most (if not all) tetracyclines in the presence of milk; calcium-, magnesium-, and aluminum-containing antacids; and iron salts. Soluble alkalizers, such as sodium bicarbonate, also decrease the GI absorption of the tetracyclines.¹⁵⁵ Deprotonation of tetracyclines to more ionic species and the observed instability of these products in alkaline solutions may account for this observation. The affinity of tetracyclines for calcium causes them to be incorporated into newly forming bones and teeth as tetracycline–calcium orthophosphate complexes. Deposits of these antibiotics in teeth cause a yellow discoloration that darkens (a photochemical reaction) over time. Tetracyclines are distributed into the milk of lactating mothers and will cross the placental barrier into the fetus. The possible effects of these agents on the bones and teeth of the child should be considered before their use during pregnancy or in children younger than 8 years of age.

Mechanism of Action and Resistance

The strong binding properties of the tetracyclines with metal ions caused Albert¹⁵⁶ to suggest that their antibacterial properties may be because of an ability to remove essential metal ions as chelated compounds. Elucidation of details of the mechanism of action of the tetracyclines,¹⁵⁷ however, has defined more clearly the specific roles of magnesium ions in molecular processes affected by these antibiotics in bacteria. Tetracyclines are specific inhibitors of bacterial protein synthesis. They bind to the 30S ribosomal subunit and, thereby, prevent the binding of aminoacyl tRNA to the mRNA–ribosome complex. Both the binding of aminoacyl tRNA and the binding of tetracyclines at the ribosomal binding site require magnesium ions.¹⁵⁸ Tetracyclines also bind to mammalian ribosomes but with lower affinities, and they apparently do not achieve sufficient intracellular concentrations to interfere with protein synthesis. The selective toxicity of the tetracyclines toward bacteria depends strongly on the self-destructive capacity of bacterial cells to concentrate these

agents in the cell. Tetracyclines enter bacterial cells by two processes: passive diffusion and active transport. The active uptake of tetracyclines by bacterial cells is an energy-dependent process that requires adenosine triphosphate (ATP) and magnesium ions.¹⁵⁹

Three biochemically distinct mechanisms of resistance to tetracyclines have been described in bacteria¹⁶⁰: (a) efflux mediated by transmembrane-spanning, active-transport proteins that reduces the intracellular tetracycline concentration; (b) ribosomal protection, in which the bacterial protein synthesis apparatus is rendered resistant to the action of tetracyclines by an inducible cytoplasmic protein; and (c) enzymatic oxidation. Efflux mediated by plasmid or chromosomal protein determinants *tet-A*, *-E*, *-G*, *-H*, *-K*, and *-L*, and ribosomal protection mediated by the chromosomal protein determinants *tet-M*, *-O*, and *-S* are the most frequently encountered and most clinically significant resistance mechanisms for tetracyclines.

Spectrum of Activity

The tetracyclines have the broadest spectrum of activity of any known antibacterial agents. They are active against a wide range of Gram-positive and Gram-negative bacteria, spirochetes, mycoplasma, rickettsiae, and chlamydiae. Their potential indications are, therefore, numerous. Their bacteriostatic action, however, is a disadvantage in the treatment of life-threatening infections such as septicemia, endocarditis, and meningitis; the aminoglycosides and/or cephalosporins usually are preferred for Gram-negative and the penicillins for Gram-positive infections. Because of incomplete absorption and their effectiveness against the natural bacterial flora of the intestine, tetracyclines may induce superinfections caused by the pathogenic yeast *Candida albicans*. Resistance to tetracyclines among both Gram-positive and Gram-negative bacteria is relatively common. Superinfections caused by resistant *S. aureus* and *P. aeruginosa* have resulted from the use of these agents over time. Parenteral tetracyclines may cause severe liver damage, especially when given in excessive dosage to pregnant women or to patients with impaired renal function.

Structure–Activity Relationships

The large amount of research carried out to prepare semi-synthetic modifications of the tetracyclines and to obtain individual compounds by total synthesis revealed several interesting SARs. Reviews are available that discuss SARs among the tetracyclines in detail,^{161–163} their molecular and clinical properties,¹⁶⁴ and their synthesis and chemical properties.^{162,163,165,166} Only a brief review of the salient structure–activity features is presented here. All derivatives containing fewer than four rings are inactive or nearly inactive. The simplest tetracycline derivative that retains the characteristic broad-spectrum activity associated with this antibiotic class is 6-demethyl-6-deoxytetracycline. Many of the precise structural features present in this molecule must remain unmodified for derivatives to retain activity. The integrity of substituents at carbon atoms 1, 2, 3, 4, 10, 11, 11a, and 12, representing the hydrophilic “southern and eastern” faces of the molecule, cannot be violated drastically without deleterious effects on the antimicrobial properties of the resulting derivatives.

A-ring substituents can be modified only slightly without dramatic loss of antibacterial potency. The enolized tricarbonylmethane system at C-1 to C-3 must be intact for good activity. Replacement of the amide at C-2 with other functions (e.g., aldehyde or nitrile) reduces or abolishes activity. Monoalkylation of the amide nitrogen reduces activity proportionately to the size of the alkyl group. Aminoalkylation of the amide nitrogen, accomplished by the Mannich reaction, yields derivatives that are substantially more water soluble than the parent tetracycline and are hydrolyzed to it in vivo (e.g., rolitetracycline). The dimethylamino group at the 4-position must have the α orientation: 4-epitetracyclines are very much less active than the natural isomers. Removal of the 4-dimethylamino group reduces activity even further. Activity is largely retained in the primary and *N*-methyl secondary amines but rapidly diminishes in the higher alkylamines. A *cis*-A/B-ring fusion with a β -hydroxyl group at C-12a is apparently also essential. Esters of the C-12a hydroxyl group are inactive, with the exception of the formyl ester, which readily hydrolyzes in aqueous solutions. Alkylation at C-11a also leads to inactive compounds, demonstrating the importance of an enolizable β -diketone functionality at C-11 and C-12. The importance of the shape of the tetracyclic ring system is illustrated further by substantial loss in antibacterial potency resulting from epimerization at C-5a. Dehydrogenation to form a double bond between C-5a and C-11a markedly decreases activity, as does aromatization of ring C to form anhydrotetracyclines.

In contrast, substituents at positions 5, 5a, 6, 7, 8, and 9, representing the largely hydrophobic “northern and western” faces of the molecule, can be modified with varying degrees of success, resulting in retention and, sometimes, improvement of antibiotic activity. A 5-hydroxyl group, as in oxytetracycline and doxycycline, may influence pharmacokinetic properties but does not change antimicrobial activity. 5a-Epitetracyclines (prepared by total synthesis), although highly active in vitro, are unfortunately much less impressive in vivo. Acid-stable 6-deoxytetracyclines and 6-demethyl-6-deoxytetracyclines have been used to prepare various monosubstituted and disubstituted derivatives by electrophilic substitution reactions at C-7 and C-9 of the D ring. The more useful results have been achieved with the

introduction of substituents at C-7. Oddly, strongly electron-withdrawing groups (e.g., chloro [lortetracycline] and nitro) and strongly electron-donating groups (e.g., dimethylamino [minocycline]) enhance activity. This unusual circumstance is reflected in QSAR studies of 7- and 9-substituted tetracyclines,^{162,167} which indicated a squared (parabolic) dependence on σ , Hammett's electronic substituent constant, and in vitro inhibition of an *E. coli* strain. The effect of introducing substituents at C-8 has not been studied because this position cannot be substituted directly by classic electrophilic aromatic substitution reactions; thus, 8-substituted derivatives are available only through total synthesis.¹⁶⁸

The most fruitful site for semisynthetic modification of the tetracyclines has been the 6-position. Neither the 6 α -methyl nor the 6 β -hydroxyl group is essential for antibacterial activity. In fact, doxycycline and methacycline are more active in vitro than their parent oxytetracycline against most bacterial strains. The conversion of oxytetracycline to doxycycline, which can be accomplished by reduction of methacycline,¹⁶⁹ gives a 1:1 mixture of doxycycline and epidoxycycline (which has a β -oriented methyl group); if the C-11a α -fluoro derivative of methacycline is used, the β -methyl epimer is formed exclusively.¹⁷⁰ 6-Epidoxycycline is much less active than doxycycline. 6-Demethyl-6-deoxytetracycline, synthesized commercially by catalytic hydrogenolysis of the 7-chloro and 6-hydroxyl groups of 7-chloro-6-demethyltetracycline, obtained by fermentation of a mutant strain of *Streptomyces aureofaciens*,¹⁷¹ is slightly more potent than tetracycline. More successful from a clinical standpoint, however, is 6-demethyl-6-deoxy-7-dimethylaminotetracycline (minocycline)¹⁷² because of its activity against tetracycline-resistant bacterial strains.

6-Deoxytetracyclines also possess important chemical and pharmacokinetic advantages over their 6-oxy counterparts. Unlike the latter, they are incapable of forming anhydrotetracyclines under acidic conditions because they cannot dehydrate at C-5a and C-6. They are also more stable in base because they do not readily undergo β -ketone cleavage, followed by lactonization, to form isotetracyclines. Although it lacks a 6-hydroxyl group, methacycline shares the instability of the 6-oxytetracyclines in strongly acetic conditions. It suffers prototropic rearrangement to the anhydrotetracycline in acid but is stable to β -ketone cleavage followed by lactonization to the isotetracycline in base. Reduction of the 6-hydroxyl group also dramatically changes the solubility properties of tetracyclines. This effect is reflected in significantly higher oil/water partition coefficients of the 6-deoxytetracyclines than of the tetracyclines (Table 8.8).^{173,174} The greater lipid solubility of the 6-deoxy compounds has important pharmacokinetic consequences.^{162,164} Hence, doxycycline and minocycline are absorbed more completely following oral administration, exhibit higher fractions of plasma protein binding, and have higher volumes of distribution and lower renal clearance rates than the corresponding 6-oxytetracyclines.

Polar substituents (i.e., hydroxyl groups) at C-5 and C-6 decrease lipid versus water solubility of the tetracyclines. The 6-position is, however, considerably more sensitive than the 5-position to this effect. Thus, doxycycline (6-deoxy-5-oxytetracycline) has a much higher partition coefficient than either tetracycline or oxytetracycline. Nonpolar substituents (those with positive σ values; see Chapter 2),

TABLE 8.8 Pharmacokinetic Properties^a of Tetracyclines

Tetracycline	K _{pc} Octanol/ Water pH 5.6 ^b	Absorbed Orally (%)	Excreted in Feces (%)	Excreted in Urine (%)	Protein Bound (%)	Volume of Distribution (% body weight)	Renal Clearance (mL/min/ 1.73 m ²)	Half- life (h)

for example, 7-dimethylamino, 7-chloro, and 6-methyl, have the opposite effect. Accordingly, the partition coefficient of chlortetracycline is substantially greater than that of tetracycline and slightly greater than that of demeclocycline. Interestingly, minocycline (5-demethyl-6-deoxy-7-dimethylaminotetracycline) has the highest partition coefficient of the commonly used tetracyclines.

The poorer oral absorption of the more water-soluble compounds tetracycline and oxytetracycline can be attributed to several factors. In addition to their comparative difficulty in penetrating lipid membranes, the polar tetracyclines probably experience more complexation with metal ions in the gut and undergo some acid-catalyzed destruction in the stomach. Poorer oral absorption coupled with biliary excretion of some tetracyclines is also thought to cause a higher incidence of superinfections from resistant microbial strains. The more polar tetracyclines, however, are excreted in higher concentrations in the urine (e.g., 60% for tetracycline and 70% for oxytetracycline) than the more lipid-soluble compounds (e.g., 33% for doxycycline and only 11% for minocycline). Significant passive renal tubular reabsorption coupled with higher fractions of protein binding contributes to the lower renal clearance and longer durations of action of doxycycline and minocycline compared with those of the other tetracyclines, especially tetracycline and oxytetracycline. Minocycline also experiences significant *N*-dealkylation catalyzed by cytochrome P450 oxygenases in the liver, which contributes to its comparatively low renal clearance. Although all tetracyclines are distributed widely into tissues, the more polar ones have larger volumes of distribution than the nonpolar compounds. The more lipid-soluble tetracyclines, however, distribute better to poorly vascularized tissue. It is also claimed that the distribution of doxycycline and minocycline into bone is less than that of other tetracyclines.¹⁷⁵

Products

Tetracycline

Chemical studies on chlortetracycline revealed that controlled catalytic hydrogenolysis selectively removed the 7-chloro atom and so produced tetracycline (Achromycin, Cyclopar, Panmycin, Tetracyn). This process was patented by Conover¹⁷⁶ in 1955. Later, tetracycline was obtained from fermentations of *Streptomyces* spp., but the commercial supply still chiefly depends on hydrogenolysis of chlortetracycline.

Tetracycline is 4-dimethyl amino-1,4,4a,5,5a,6,11,12a-octahydro-3,6,10,12,12a-pentahydroxy-6-methyl-1,11-

dioxo-2-naphthacene-carboxamide. It is a bright yellow, crystalline salt that is stable in air but darkens on exposure to strong sunlight. Tetracycline is stable in acid solutions with a pH above 2. It is somewhat more stable in alkaline solutions than chlortetracycline, but like those of the other tetracyclines, such solutions rapidly lose potency. One gram of the base requires 2,500 mL of water and 50 mL of alcohol to dissolve it. The hydrochloride salt is used most commonly in medicine, though the free base is absorbed from the GI tract about equally well. One gram of the hydrochloride salt dissolves in about 10 mL of water and in 100 mL of alcohol. Tetracycline has become the most popular antibiotic of its group, largely because its plasma concentration appears to be higher and more enduring than that of either oxytetracycline or chlortetracycline. Also, it is found in higher concentration in the spinal fluid than the other two compounds.

Several combinations of tetracycline with agents that increase the rate and the height of plasma concentrations are on the market. One such adjuvant is magnesium chloride hexahydrate (Panmycin). Also, an insoluble tetracycline phosphate complex (Tetrex) is made by mixing a solution of tetracycline, usually as the hydrochloride, with a solution of sodium metaphosphate. There are various claims concerning the efficacy of these adjuvants. The mechanisms of their actions are not clear, but reportedly^{177,178} these agents enhance plasma concentrations over those obtained when tetracycline hydrochloride alone is administered orally. Remmers et al.^{179,180} reported on the effects that selected aluminum–calcium gluconates complexed with some tetracyclines have on plasma concentrations when administered orally, intramuscularly, or intravenously. Such complexes enhanced plasma levels in dogs when injected but not when given orally. They also observed enhanced plasma levels in experimental animals when complexes of tetracyclines with aluminum metaphosphate, aluminum pyrophosphate, or aluminum–calcium phosphinodilactates were administered orally. As noted previously, the tetracyclines can form stable chelate complexes with metal ions such as calcium and magnesium, which retard absorption from the GI tract. The complexity of the systems involved has not permitted

unequivocal substantiation of the idea that these adjuvants compete with the tetracyclines for substances in the alimentary tract that would otherwise be free to complex with these antibiotics and thereby retard their absorption. Certainly, there is no evidence that the metal ions per se act as buffers, an idea alluded to sometimes in the literature.

Tetracycline hydrochloride is also available in ointments for topical and ophthalmic administration. A topical solution is used for the management of acne vulgaris.

Rolitetracline

Rolitetracline, *N*-(pyrrolidinomethyl)tetracycline (Syntetrin), was introduced for use by intramuscular or intravenous injection. This derivative is made by condensing tetracycline with pyrrolidine and formaldehyde in the presence of *tert*-butyl alcohol. It is very soluble in water (1 g dissolves in about 1 mL) and provides a means of injecting the antibiotic in a small volume of solution. It has been recommended for cases when the oral dosage forms are not suitable, but it is no longer widely used.

Chlortetracline Hydrochloride

Chlortetracline (Aureomycin hydrochloride) was isolated by Duggar¹⁸¹ in 1948 from *S. aureofaciens*. This compound, which was produced in an extensive search for new antibiotics, was the first of the group of highly successful tetracyclines. It soon became established as a valuable antibiotic with broad-spectrum activities.

It is used in medicine chiefly as the acid salt of the compound whose systematic chemical designation is 7-chloro-4-(dimethylamino)-1,4,4a,5,5a,6,11,12a-octahydro-3,6,10,12,12a-pentahydroxy-6-methyl-1,11-dioxo-2-naphthacene-carboxamide. The hydrochloride salt is a crystalline powder with a bright yellow color, which suggested its brand name, *Aureomycin*. It is stable in air but slightly photosensitive and should be protected from light. It is odorless and bitter. One gram of the hydrochloride salt will dissolve in about 75 mL of water, producing a pH of about 3. It is only slightly soluble in alcohol and practically insoluble in other organic solvents.

Oral and parenteral forms of chlortetracline are no longer used because of the poor bioavailability and inferior pharmacokinetic properties of the drug. It is still marketed in ointment forms for topical and ophthalmic use.

Oxytetracline Hydrochloride

Early in 1950, Finlay et al.¹⁸² reported the isolation of oxytetracline (Terramycin) from *S. rimosus*. This compound was soon identified as a chemical analog of chlortetra-

cline that showed similar antibiotic properties. The structure of oxytetracline was elucidated by Hochstein et al.¹⁸³ and this work provided the basis for the confirmation of the structure of the other tetracyclines.

Oxytetracline hydrochloride is a pale yellow, bitter, crystalline compound. The amphoteric base is only slightly soluble in water and slightly soluble in alcohol. It is odorless and stable in air but darkens on exposure to strong sunlight. The hydrochloride salt is a stable yellow powder that is more bitter than the free base. It is much more soluble in water, 1 g dissolving in 2 mL, and more soluble in alcohol than the free base. Both compounds are inactivated rapidly by alkali hydroxides and by acid solutions below pH 2. Both forms of oxytetracline are absorbed rapidly and equally well from the digestive tract, so the only real advantage the free base offers over the hydrochloride salt is that it is less bitter. Oxytetracline hydrochloride is also used for parenteral administration (intravenously and intramuscularly).

Methacycline Hydrochloride

The synthesis of methacycline, 6-deoxy-6-demethyl-6-methylene-5-oxytetracline hydrochloride (Randomycin), reported by Blackwood et al.¹⁸⁴ in 1961, was accomplished by chemical modification of oxytetracline. It has an antibiotic spectrum like that of the other tetracyclines but greater potency; about 600 mg of methacycline is equivalent to 1 g of tetracycline. Its particular value lies in its longer serum half-life; doses of 300 mg produce continuous serum antibacterial activity for 12 hours. Its toxic manifestations and contraindications are similar to those of the other tetracyclines.

The greater stability of methacycline, both in vivo and in vitro, results from modification at C-6. Removal of the 6-hydroxy group markedly increases the stability of ring C to both acids and bases, preventing the formation of isotetracyclines by bases. Anhydrotetracyclines still can form, however, by acid-catalyzed isomerization under strongly acidic conditions. Methacycline hydrochloride is a yellow to dark yellow, crystalline powder that is slightly soluble in water and insoluble in nonpolar solvents. It should be stored in tight, light-resistant containers in a cool place.

Demeclocycline

Demeclocycline, 7-chloro-6-demethyltetracycline (Declomycin), was isolated in 1957 by McCormick et al.¹⁷¹ from a mutant strain of *S. aureofaciens*. Chemically, it is 7-chloro-4-(dimethylamino)-1,4,4a,5,5a,6,11,12a-octahydro-3,6,10,12,12a-pentahydroxy-1,11-dioxo-2-naphthacene-carboxamide. Thus, it differs from chlortetracline only in the absence of the methyl group on C-6.

Demeclocycline is a yellow, crystalline powder that is odorless and bitter. It is sparingly soluble in water. A 1% solution has a pH of about 4.8. It has an antibiotic spectrum like that of other tetracyclines, but it is slightly more active than the others against most of the microorganisms for which they are used. This, together with its slower rate of elimination through the kidneys, makes demeclocycline as effective as the other tetracyclines, at about three fifths of the dose. Like the other tetracyclines, it may cause infrequent photosensitivity reactions that produce erythema after exposure to sunlight. Demeclocycline may produce this reaction somewhat more frequently than the other tetracyclines. The incidence of discoloration and mottling of the teeth in youths from demeclocycline appears to be as low as that from other tetracyclines.

Meclocycline Sulfosalicylate

Meclocycline, 7-chloro-6-deoxy-6-demethyl-6-methylene-5-oxytetracycline sulfosalicylate (Meclan), is a semisynthetic derivative prepared from oxytetracycline.¹⁸⁴ Although meclocycline has been used in Europe for many years, it became available only relatively recently in the United States for a single therapeutic indication, the treatment of acne. It is available as the sulfosalicylate salt in a 1% cream.

Meclocycline sulfosalicylate is a bright yellow, crystalline powder that is slightly soluble in water and insoluble in organic solvents. It is light sensitive and should be stored in light-resistant containers.

Doxycycline

A more recent addition to the tetracycline group of antibiotics available for antibacterial therapy is doxycycline, α -6-deoxy-5-oxytetracycline (Vibramycin), first reported by Stephens et al.¹⁸⁵ in 1958. It was obtained first in small yields by a chemical transformation of oxytetracycline, but it is now produced by catalytic hydrogenation of methacycline or by reduction of a benzyl mercaptan derivative of methacycline with Raney nickel. The latter process produces a nearly pure form of the 6 α -methyl epimer. The 6 α -methyl epimer is more than 3 times as active as its β -epimer.¹⁶⁹ Apparently, the difference in orientation of the methyl groups, which slightly affects the shapes of the molecules, causes a substantial difference in biological

effect. Also, absence of the 6-hydroxyl group produces a compound that is very stable in acids and bases and that has a long biological half-life. In addition, it is absorbed very well from the GI tract, thus allowing a smaller dose to be administered. High tissue levels are obtained with it, and unlike other tetracyclines, doxycycline apparently does not accumulate in patients with impaired renal function. Therefore, it is preferred for uremic patients with infections outside the urinary tract. Its low renal clearance may limit its effectiveness, however, in urinary tract infections.

Doxycycline is available as a hydrate salt, a hydrochloride salt solvated as the hemimethanolate hemihydrate, and a monohydrate. The hydrate form is sparingly soluble in water and is used in a capsule; the monohydrate is water insoluble and is used for aqueous suspensions, which are stable for up to 2 weeks when kept in a cool place.

Minocycline Hydrochloride

Minocycline, 7-dimethylamino-6-demethyl-6-deoxytetracycline (Minocin, Vectrin), the most potent tetracycline currently used in therapy, is obtained by reductive methylation of 7-nitro-6-demethyl-6-deoxytetracycline.¹⁷² It was released for use in the United States in 1971. Because minocycline, like doxycycline, lacks the 6-hydroxyl group, it is stable in acids and does not dehydrate or rearrange to anhydro or lactone forms. Minocycline is well absorbed orally to give high plasma and tissue levels. It has a very long serum half-life, resulting from slow urinary excretion and moderate protein binding. Doxycycline and minocycline, along with oxytetracycline, show the least in vitro calcium binding of the clinically available tetracyclines. The improved distribution properties of the 6-deoxytetracyclines have been attributed to greater lipid solubility.

Perhaps the most outstanding property of minocycline is its activity toward Gram-positive bacteria, especially staphylococci and streptococci. In fact, minocycline has been effective against staphylococcal strains that are resistant to methicillin and all other tetracyclines, including doxycycline.¹⁸⁶ Although it is doubtful that minocycline will replace bactericidal agents for the treatment of life-threatening staphylococcal infections, it may become a useful alternative for the treatment of less serious tissue infections. Minocycline has been recommended for the treatment of chronic bronchitis and other upper respiratory tract infections. Despite its relatively low renal clearance, partially compensated for by high serum and tissue levels, it has been recommended for the treatment of

urinary tract infections. It has been effective in the eradication of *N. meningitidis* in asymptomatic carriers.

NEWER TETRACYCLINES

The remarkably broad spectrum of antimicrobial activity of the tetracyclines notwithstanding, the widespread emergence of bacterial genes and plasmids encoding tetracycline resistance has increasingly imposed limitations on the clinical applications of this antibiotic class in recent years.¹⁶⁴ This situation has prompted researchers at Lederle Laboratories to reinvestigate SARs of tetracyclines substituted in the aromatic (D) ring in an effort to discover analogs that might be effective against resistant strains. As a result of these efforts, the glycylicyclines, a class of 9-dimethylglycylamino-(DMG)-substituted tetracyclines exemplified by DMG-minocycline (DMG-MINO), and DMG-6-methyl-6-deoxytetracycline (DMG-DMDOT) were discovered.¹⁸⁷⁻¹⁸⁹

The first of these to be marketed was tigecycline.

X = N(CH₃)₂ 9-(Dimethylglycylamino)minocycline (DMG-MINO)

X = H 9-(Dimethylglycylamino)-6-demethyl-6-deoxytetracycline (DMG-DMDOT)

MACROLIDES

Among the many antibiotics isolated from the actinomycetes is the group of chemically related compounds called the *macrolides*. In 1950, picromycin, the first of this group to be identified as a macrolide compound, was first reported. In 1952, erythromycin and carbomycin were reported as new antibiotics, and they were followed in subsequent years by other macrolides. Currently, more than 40 such compounds are known, and new ones are likely to appear in the future. Of all of these, only two, erythromycin and oleandomycin, have been available consistently for medical use in the United States. In recent years, interest has shifted away from novel macrolides isolated from soil samples (e.g., spiramycin, josamycin, and rosamicin), all of which thus far have proved to be clinically inferior to erythromycin and semisynthetic derivatives of erythromycin (e.g., clarithromycin and azithromycin), which have superior pharmacokinetic properties because of their enhanced acid stability and improved distribution properties.

Chemistry

The macrolide antibiotics have three common chemical characteristics: (a) a large lactone ring (which prompted the name *macrolide*), (b) a ketone group, and (c) a glycosidically linked amino sugar. Usually, the lactone ring has 12, 14, or 16 atoms in it, and it is often unsaturated, with an olefinic group conjugated with the ketone function. (The polyene macrocyclic lactones, such as natamycin and amphotericin B; the ansamycins, such as rifampin; and the polypeptide lactones generally are not included among the macrolide antibiotics.) They may have, in addition to the amino sugar, a neutral sugar that is linked glycosidically to the lactone ring (see discussion that follows under “Erythromycin”). Because of the dimethylamino group on the sugar moiety, the macrolides are bases that form salts with pK_a values between 6.0 and 9.0. This feature has been used to make clinically useful salts. The free bases are only slightly soluble in water but dissolve in somewhat polar organic solvents. They are stable in aqueous solutions at or below room temperature but are inactivated by acids, bases, and heat. The chemistry of macrolide antibiotics has been the subject of several reviews.^{190,191}

Mechanism of Action and Resistance

Some details of the mechanism of antibacterial action of erythromycin are known. It binds selectively to a specific site on the 50S ribosomal subunit to prevent the translocation step of bacterial protein synthesis.¹⁹² It does not bind to mammalian ribosomes. Broadly based, nonspecific resistance to the antibacterial action of erythromycin among many species of Gram-negative bacilli appears to be largely related to the inability of the antibiotic to penetrate the cell walls of these organisms.¹⁹³ In fact, the sensitivities of members of the Enterobacteriaceae family are pH dependent, with MICs decreasing as a function of increasing pH. Furthermore, protoplasts from Gram-negative bacilli, which lack cell walls, are sensitive to erythromycin. A highly specific resistance mechanism to the macrolide antibiotics occurs in erythromycin-resistant strains of *S. aureus*.^{194,195} Such strains produce an enzyme that methylates a specific adenine residue at the erythromycin-binding site of the bacterial 50S ribosomal subunit. The methylated ribosomal RNA remains active in protein synthesis but no longer binds erythromycin. Bacterial resistance to the lincomycins apparently also occurs by this mechanism.

Spectrum of Activity

The spectrum of antibacterial activity of the more potent macrolides, such as erythromycin, resembles that of penicillin. They are frequently active against bacterial strains that are resistant to the penicillins. The macrolides are generally effective against most species of Gram-positive bacteria, both cocci and bacilli, and exhibit useful effectiveness against Gram-negative cocci, especially *Neisseria* spp. Many of the macrolides are also effective against *Treponema pallidum*. In contrast to penicillin, macrolides are also effective against *Mycoplasma*, *Chlamydia*, *Campylobacter*, and *Legionella* spp. Their activity against most species of Gram-negative bacilli is generally low and often unpredictable, though some strains of *H. influenzae* and *Brucella* spp. are sensitive.

Products

Erythromycin

Early in 1952, McGuire et al.¹⁹⁶ reported the isolation of erythromycin (E-Mycin, Erythrocin, Ilotycin) from *Streptomyces erythraeus*. It achieved rapid early acceptance as a well-tolerated antibiotic of value for the treatment of various upper respiratory and soft-tissue infections caused by Gram-positive bacteria. It is also effective against many venereal diseases, including gonorrhea and syphilis, and provides a useful alternative for the treatment of many infections in patients allergic to penicillins. More recently, erythromycin was shown to be effective therapy for Eaton agent pneumonia (*Mycoplasma pneumoniae*), venereal diseases caused by *Chlamydia*, bacterial enteritis caused by *Campylobacter jejuni*, and Legionnaires disease.

The commercial product is erythromycin A, which differs from its biosynthetic precursor, erythromycin B, in having a hydroxyl group at the 12-position of the aglycone. The chemical structure of erythromycin A was reported by Wiley et al.¹⁹⁷ in 1957 and its stereochemistry by Celmer¹⁹⁸ in 1965. An elegant synthesis of erythronolide A, the aglycone present in erythromycin A, was described by Corey et al.¹⁹⁹

The amino sugar attached through a glycosidic link to C-5 is desosamine, a structure found in several other macrolide antibiotics. The tertiary amine of desosamine (3,4,6-trideoxy-3-dimethylamino-D-xylo-hexose) confers a basic character to erythromycin and provides the means by which acid salts may be prepared. The other carbohydrate structure linked as a glycoside to C-3 is called *cladinose* (2,3,6-trideoxy-3-methoxy-3-C-methyl-L-ribo-hexose) and is unique to the erythromycin molecule.

As is common with other macrolide antibiotics, compounds closely related to erythromycin have been obtained from culture filtrates of *S. erythraeus*. Two such analogs have been found, erythromycins B and C. Erythromycin B differs from erythromycin A only at C-12, at which a hydrogen has replaced the hydroxyl group. The B analog is more acid stable but has only about 80% of the activity of erythromycin. The C analog differs from erythromycin by the replacement of the methoxyl group on the cladinose moiety with a hydrogen atom. It appears to be as active as erythromycin but is present in very small amounts in fermentation liquors.

Erythromycin is a very bitter, white or yellow-white, crystalline powder. It is soluble in alcohol and in the other

common organic solvents but only slightly soluble in water. The free base has a pK_a of 8.8. Saturated aqueous solutions develop an alkaline pH in the range of 8.0 to 10.5. It is extremely unstable at a pH of 4 or below. The optimum pH for stability of erythromycin is at or near neutrality.

Erythromycin may be used as the free base in oral dosage forms and for topical administration. To overcome its bitterness and irregular oral absorption (resulting from acid destruction and adsorption onto food), various enteric-coated and delayed-release dose forms of erythromycin base have been developed. These forms have been fully successful in overcoming the bitterness but have solved only marginally problems of oral absorption. Erythromycin has been chemically modified with primarily two different goals in mind: (a) to increase either its water or its lipid solubility for parenteral dosage forms and (b) to increase its acid stability (and possibly its lipid solubility) for improved oral absorption. Modified derivatives of the antibiotic are of two types: acid salts of the dimethylamino group of the desosamine moiety (e.g., the glucoheptonate, the lactobionate, and the stearate) and esters of the 2'-hydroxyl group of the desosamine (e.g., the ethylsuccinate and the propionate, available as the lauryl sulfate salt and known as the estolate).

The stearate salt and the ethylsuccinate and propionate esters are used in oral dose forms intended to improve absorption of the antibiotic. The stearate releases erythromycin base in the intestinal tract, which is then absorbed. The ethylsuccinate and the estolate are absorbed largely intact and are hydrolyzed partially by plasma and tissue esterases to give free erythromycin. The question of bioavailability of the antibiotic from its various oral dosage and chemical forms has caused considerable concern and dispute over the past two decades.²⁰⁰⁻²⁰⁵ It is generally believed that the 2'-esters per se have little or no intrinsic antibacterial activity²⁰⁶ and, therefore, must be hydrolyzed to the parent antibiotic in vivo. Although the ethylsuccinate is hydrolyzed more efficiently than the estolate in vivo and, in fact, provides higher levels of erythromycin following intramuscular administration, an equal dose of the estolate gives higher levels of the free antibiotic following oral administration.^{201,205} Superior oral absorption of the estolate is attributed to its both greater acid stability and higher intrinsic absorption than the ethylsuccinate. Also, oral absorption of the estolate, unlike that of both the stearate and the ethylsuccinate, is not affected by food or fluid volume content of the gut. Superior bioavailability of active antibiotic from oral administration of the estolate over the ethylsuccinate, stearate, or erythromycin base cannot necessarily be assumed, however, because the estolate is more extensively protein bound than erythromycin itself.²⁰⁷ Measured fractions of plasma protein binding for erythromycin-2'-propionate and erythromycin base range from 0.94 to 0.98 for the former and from 0.73 to 0.90 for the latter, indicating a much higher level of free erythromycin in the plasma. Bioavailability studies comparing equivalent doses of the enteric-coated base, the stearate salt, the ethylsuccinate ester, and the estolate ester in human volunteers^{203,204} showed delayed but slightly higher bioavailability for the free base than for the stearate, ethylsuccinate, or estolate.

One study, comparing the clinical effectiveness of recommended doses of the stearate, estolate, ethylsuccinate, and free base in the treatment of respiratory tract infections,

failed to demonstrate substantial differences among them.²⁰⁸ Two other clinical studies, comparing the effectiveness of the ethylsuccinate and the estolate in the treatment of streptococcal pharyngitis, however, found the estolate to be superior.^{209,210}

The water-insoluble ethylsuccinate ester is also available as a suspension for intramuscular injection. The glucoheptonate and lactobionate salts, however, are highly water-soluble derivatives that provide high plasma levels of the active antibiotic immediately after intravenous injection. Aqueous solutions of these salts may also be administered by intramuscular injection, but this is not a common practice.

Erythromycin is distributed throughout the body water. It persists in tissues longer than in the blood. The antibiotic is concentrated by the liver and excreted extensively into the bile. Large amounts are excreted in the feces, partly because of poor oral absorption and partly because of biliary excretion. The serum half-life is 1.4 hours. Some cytochrome P450-catalyzed oxidative demethylation to a less active metabolite may also occur. Erythromycin inhibits cytochrome P450-requiring oxidases, leading to various potential drug interactions. Thus, toxic effects of theophylline, the hydroxycoumarin anticoagulants, the benzodiazepines alprazolam and midazolam, carbamazepine, cyclosporine, and the antihistaminic drugs terfenadine and astemizole may be potentiated by erythromycin.

The toxicity of erythromycin is comparatively low. Primary adverse reactions to the antibiotic are related to its actions on the GI tract and the liver. Erythromycin may stimulate GI motility following either oral or parenteral administration.²¹¹ This dose-related, prokinetic effect can cause abdominal cramps, epigastric distress, and diarrhea, especially in children and young adults. Cholestatic hepatitis occurs occasionally with erythromycin, usually in adults and more frequently with the estolate.

Erythromycin Stearate

Erythromycin stearate (Ethril, Wyamycin S, Erypar) is the stearic acid salt of erythromycin. Like erythromycin base, the stearate is acid labile. It is film coated to protect it from acid degradation in the stomach. In the alkaline pH of the duodenum, the free base is liberated from the stearate and absorbed. Erythromycin stearate is a crystalline powder that is practically insoluble in water but soluble in alcohol and ether.

Erythromycin Ethylsuccinate

Erythromycin ethylsuccinate (EES, Pediamycin, EryPed) is the ethylsuccinate mixed ester of erythromycin in which the 2'-hydroxyl group of the desosamine is esterified. It is absorbed as the ester and hydrolyzed slowly in the body to form erythromycin. It is somewhat acid labile, and its absorption is enhanced by the presence of food. The ester is insoluble in water but soluble in alcohol and ether.

**Erythromycin Estolate**

Erythromycin estolate, erythromycin propionate lauryl sulfate (Ilosone), is the lauryl sulfate salt of the 2'-propionate ester of erythromycin. Erythromycin estolate is acid stable and absorbed as the propionate ester. The ester undergoes slow hydrolysis in vivo. Only the free base binds to bacterial ribosomes. Some evidence, however, suggests that the ester is taken up by bacterial cells more rapidly than the free base and undergoes hydrolysis by bacterial esterases within the cells. The incidence of cholestatic hepatitis is reportedly higher with the estolate than with other erythromycin preparations.

Erythromycin estolate occurs as long needles that are sparingly soluble in water but soluble in organic solvents.

**Erythromycin Gluceptate, Sterile**

Erythromycin gluceptate, erythromycin glucoheptonate (Ilotycin Gluceptate), is the glucoheptonic acid salt of erythromycin. It is a crystalline substance that is freely soluble in water and practically insoluble in organic solvents. Erythromycin gluceptate is intended for intravenous

administration for the treatment of serious infections, such as Legionnaires disease, or when oral administration is not possible. Solutions are stable for 1 week when refrigerated.

**Erythromycin Lactobionate**

Erythromycin lactobionate is a water-soluble salt prepared by reacting erythromycin base with lactobiono- σ -lactone. It occurs as an amorphous powder that is freely soluble in water and alcohol and slightly soluble in ether. It is intended, after reconstitution in sterile water, for intravenous administration to achieve high plasma levels in the treatment of serious infections.

**Clarithromycin**

Clarithromycin (Biaxin) is the 6-methyl ether of erythromycin. The simple methylation of the 6-hydroxyl group of erythromycin creates a semisynthetic derivative that fully retains the antibacterial properties of the parent antibiotic, with markedly increased acid stability and oral bioavailability and reduced GI side effects associated with erythromycin.²¹² Acid-catalyzed dehydration of erythromycin in the stomach initiates as a sequence of reactions, beginning with $\Delta^{6,7}$ -bond migration followed by formation of an 8,9-anhydro-6,9-hemiketal and terminating in a 6,9:9,12-spiroketal. Since neither the hemiketal nor the spiroketal exhibits significant antibacterial activity, unprotected erythromycin is inactivated substantially in the stomach. Furthermore, evidence suggests that the hemiketal may be largely responsible for the GI (prokinetic) adverse effects associated with oral erythromycin.²¹¹

Clarithromycin is well absorbed following oral administration. Its oral bioavailability is estimated to be 50% to 55%. The presence of food does not significantly affect its absorption. Extensive metabolism of clarithromycin by oxidation and hydrolysis occurs in the liver. The major metabolite is the 14-hydroxyl derivative, which retains antibacterial activity. The amount of clarithromycin excreted in the urine ranges from 20% to 30%, depending on the dose, whereas 10% to 15% of the 14-hydroxy metabolite is excreted in the urine. Biliary excretion of clarithromycin is much lower than that of erythromycin. Clarithromycin is widely distributed into the tissues, which retain much higher concentrations than the plasma. Protein-binding fractions in the plasma range from 65% to 70%. The plasma half-life of clarithromycin is 4.3 hours.

Some of the microbiological properties of clarithromycin also appear to be superior to those of erythromycin. It exhibits greater potency against *M. pneumoniae*, *Legionella* spp., *Chlamydia pneumoniae*, *H. influenzae*, and *M. catarrhalis* than does erythromycin. Clarithromycin also has activity against unusual pathogens such as *Borrelia burgdorferi* (the cause of Lyme disease) and the *Mycobacterium avium* complex (MAC). Clarithromycin is significantly more active than erythromycin against group A streptococci, *S. pneumoniae*, and the viridans group of streptococci in vivo because of its superior oral bioavailability. Clarithromycin is, however, more expensive than erythromycin, which must be weighed against its potentially greater effectiveness.

Adverse reactions to clarithromycin are rare. The most common complaints relate to GI symptoms, but these seldom require discontinuance of therapy. Clarithromycin, like erythromycin, inhibits cytochrome P450 oxidases and, thus, can potentiate the actions of drugs metabolized by these enzymes.

Clarithromycin occurs as a white crystalline solid that is practically insoluble in water, sparingly soluble in alcohol, and freely soluble in acetone. It is provided as 250- and 500-mg oral tablets and as granules for the preparation of aqueous oral suspensions containing 25 or 50 mg/mL.

Azithromycin

Azithromycin (Zithromax) is a semisynthetic derivative of erythromycin, prepared by Beckman rearrangement of the corresponding 6-oxime, followed by *N*-methylation and reduction of the resulting ring-expanded lactam. It is a prototype of a series of nitrogen-containing, 15-membered ring macrolides known as *azalides*.²¹³ Removal of the 9-keto group coupled with incorporation of a weakly basic tertiary

amine nitrogen function into the macrolide ring increases the stability of azithromycin to acid-catalyzed degradation. These changes also increase the lipid solubility of the molecule, thereby conferring unique pharmacokinetic and microbiological properties.²¹⁴

The oral bioavailability of azithromycin is good, nearly 40%, provided the antibiotic is administered at least 1 hour before or 2 hours after a meal. Food decreases its absorption by as much as 50%. The pharmacokinetics of azithromycin are characterized by rapid and extensive removal of the drug from the plasma into the tissues followed by a slow release. Tissue levels far exceed plasma concentrations, leading to a highly variable and prolonged elimination half-life of up to 5 days. The fraction of azithromycin bound to plasma proteins is only about 50% and does not exert an important influence on its distribution. Evidence indicates that azithromycin is largely excreted in the feces unchanged, with a small percentage appearing in the urine. Extensive enterohepatic recycling of the drug occurs. Azithromycin apparently is not metabolized to any significant extent. In contrast to the 14-membered ring macrolides, azithromycin does not significantly inhibit cytochrome P450 enzymes to create potential drug interactions.

The spectrum of antimicrobial activity of azithromycin is similar to that observed for erythromycin and clarithromycin but with some interesting differences. In general, it is more active against Gram-negative bacteria and less active against Gram-positive bacteria than its close relatives. The greater activity of azithromycin against *H. influenzae*, *M. catarrhalis*, and *M. pneumoniae* coupled with its extended half-life permits a 5-day dosing schedule for the treatment of respiratory tract infections caused by these pathogens. The clinical efficacy of azithromycin in the treatment of urogenital and other sexually transmitted infections caused by *Chlamydia trachomatis*, *N. gonorrhoeae*, *H. ducreyi*, and *Ureaplasma urealyticum* suggests that single-dose therapy with it for uncomplicated urethritis or cervicitis may have advantages over use of other antibiotics.

Dirithromycin

Dirithromycin (Dynabac) is a more lipid-soluble prodrug derivative of 9*S*-erythromyclamine prepared by condensation of the latter with 2-(2-methoxyethoxy)acetaldehyde.²¹⁵ The 9*N*,11*O*-oxazine ring thus formed is a hemi-aminal that is unstable under both acidic and alkaline aqueous conditions and undergoes spontaneous hydrolysis to form erythromyclamine. Erythromyclamine is a semisynthetic derivative of erythromycin in which the 9-keto group of the erythronolide ring has been converted to an amino group. Erythromyclamine retains the antibacterial properties of

erythromycin in vitro but exhibits poor bioavailability following oral administration. The prodrug, dirithromycin, is provided as enteric-coated tablets to protect it from acid-catalyzed hydrolysis in the stomach.

Orally administered dirithromycin is absorbed rapidly into the plasma, largely from the small intestine. Spontaneous hydrolysis to erythromyclamine occurs in the plasma. Oral bioavailability is estimated to be about 10%, but food does not affect absorption of the prodrug.

The low plasma levels and large volume of distribution of erythromyclamine are believed to result from its rapid distribution into well-perfused tissues, such as lung parenchyma, bronchial mucosa, nasal mucosa, and prostatic tissue. The drug also concentrates in human neutrophils. The elimination half-life is estimated to be 30 to 44 hours. Most of the prodrug and its active metabolite (62%–81% in normal human subjects) are excreted in the feces, largely via the bile, following either oral or parenteral administration. Urinary excretion accounts for less than 3%.

The incidence and severity of GI adverse effects associated with dirithromycin are similar to those seen with oral erythromycin. Preliminary studies indicate that dirithromycin and erythromyclamine do not interact significantly with cytochrome P450 oxygenases. Thus, the likelihood of interference in the oxidative metabolism of drugs such as phenytoin, theophylline, and cyclosporine by these enzymes may be less with dirithromycin than with erythromycin. Dirithromycin is recommended as an alternative to erythromycin for the treatment of bacterial infections of the upper and lower respiratory tracts, such as pharyngitis, tonsillitis, bronchitis, and pneumonia, and for bacterial infections of other soft tissues and the skin. The once-daily dosing schedule for dirithromycin is advantageous in terms of better patient compliance. Its place in therapy remains to be fully assessed.²¹⁶

Troleandomycin

Oleandomycin, as its triacetyl derivative troleandomycin, triacetyloleandomycin (TAO), remains available as an alternative to erythromycin for limited indications permitting use of an oral dosage form. Oleandomycin was isolated by Sobin et al.²¹⁷ The structure of oleandomycin was proposed by Hochstein et al.²¹⁸ and its absolute stereochemistry elucidated by Celmer.²¹⁹ The oleandomycin structure consists of two sugars and a 14-member lactone ring designated an *oleandolide*. One of the sugars is desosamine, also present in erythromycin; the other is L-oleandrose. The sugars are linked glycosidically to the positions 3 and 5, respectively, of oleandolide.

Oleandomycin contains three hydroxyl groups that are subject to acylation, one in each of the sugars and one in the oleandolide. The triacetyl derivative retains the in vivo antibacterial activity of the parent antibiotic but possesses superior pharmacokinetic properties. It is hydrolyzed in vivo to oleandomycin. Troleandomycin achieves more rapid and higher plasma concentrations following oral administration than oleandomycin phosphate, and it has the additional advantage of being practically tasteless. Troleandomycin occurs as a white, crystalline solid that is nearly insoluble in water. It is relatively stable in the solid state but undergoes chemical degradation in either aqueous acidic or alkaline conditions.

Because the antibacterial spectrum of activity of oleandomycin is considered inferior to that of erythromycin, the pharmacokinetics of troleandomycin have not been studied extensively. Oral absorption is apparently good, and detectable blood levels of oleandomycin persist up to 12 hours after a 500-mg dose of troleandomycin. Approximately 20% is recovered in the urine, with most excreted in the feces, primarily as a result of biliary excretion. There is some epigastric distress following oral administration, with an incidence similar to that caused by erythromycin. Troleandomycin is the most potent inhibitor of cytochrome P450 enzymes of the commercially available macrolides. It may potentiate the hepatic toxicity of certain anti-inflammatory steroids and oral contraceptive drugs as well as the toxic effects of theophylline, carbamazepine, and triazolam. Several allergic reactions, including cholestatic hepatitis, have also been reported with the use of troleandomycin.

Approved medical indications for troleandomycin are currently limited to the treatment of upper respiratory infections caused by such organisms as *S. pyogenes* and *S. pneumoniae*. It may be considered an alternative to oral forms of erythromycin. It is available in capsules and as a suspension.

LINCOMYCINS

The lincomycins are sulfur-containing antibiotics isolated from *Streptomyces lincolnensis*. Lincomycin is the most active and medically useful of the compounds obtained from fermentation. Extensive efforts to modify the lincomycin structure to improve its antibacterial and pharmacological properties resulted in the preparation of the 7-chloro-7-deoxy derivative clindamycin. Of the two antibiotics, clindamycin

appears to have the greater antibacterial potency and better pharmacokinetic properties. Lincomycins resemble macrolides in antibacterial spectrum and biochemical mechanisms of action. They are primarily active against Gram-positive bacteria, particularly the cocci, but are also effective against non-spore-forming anaerobic bacteria, actinomycetes, mycoplasma, and some species of *Plasmodium*. Lincomycin binds to the 50S ribosomal subunit to inhibit protein synthesis. Its action may be bacteriostatic or bactericidal depending on various factors, including the concentration of the antibiotic. A pattern of bacterial resistance and cross-resistance to lincomycins similar to that observed with the macrolides has been emerging.¹⁹⁵

Products

Lincomycin Hydrochloride

Lincomycin hydrochloride (Lincocin), which differs chemically from other major antibiotic classes, was isolated by Mason et al.²²⁰ Its chemistry was described by Hoeksema et al.²²¹ who assigned the structure, later confirmed by Slomp and MacKellar,²²² given in the diagram below. Total syntheses of the antibiotic were accomplished independently in 1970 in England and the United States.^{223,224} The structure contains a basic function, the pyrrolidine nitrogen, by which water-soluble salts with an apparent pK_a of 7.6 may be formed. When subjected to hydrazinolysis, lincomycin is cleaved at its amide bond into *trans*-L-4-*n*-propylhygric acid (the pyrrolidine moiety) and methyl α -thiolicosamide (the sugar moiety). Lincomycin-related antibiotics have been reported by Argoudelis²²⁵ to be produced by *S. lincolnensis*. These antibiotics differ in structure at one or more of three positions of the lincomycin structure: (a) the *N*-methyl of the hygric acid moiety is substituted by a hydrogen; (b) the *n*-propyl group of the hygric acid moiety is substituted by an ethyl group; and (c) the thiomethyl ether of the α -thiolicosamide moiety is substituted by a thioethyl ether.

Lincomycin is used for the treatment of infections caused by Gram-positive organisms, notably staphylococci, β -hemolytic streptococci, and pneumococci. It is absorbed moderately well orally and distributed widely in the tissues. Effective concentrations are achieved in bone for the treatment of staphylococcal osteomyelitis but not in the cerebrospinal fluid for the treatment of meningitis. At one time, lincomycin was considered a nontoxic compound, with a low incidence of allergy (rash) and occasional GI complaints (nausea, vomiting, and diarrhea) as the only adverse effects. Recent reports of severe diarrhea and the development of pseudomembranous colitis in patients treated with lincomycin (or clindamycin), however, have necessitated reappraisal of the role of these antibiotics in therapy. In any event, clindamycin is superior to lincomycin for the treatment of most infections for which these antibiotics are indicated.

Lincomycin hydrochloride occurs as the monohydrate, a white, crystalline solid that is stable in the dry state. It is readily soluble in water and alcohol, and its aqueous solutions are stable at room temperature. It is degraded slowly in acid solutions but is absorbed well from the GI tract. Lincomycin diffuses well into peritoneal and pleural fluids and into bone. It is excreted in the urine and the bile. It is available in capsule form for oral administration and in ampules and vials for parenteral administration.

Clindamycin Hydrochloride

In 1967, Magerlein et al.²²⁶ reported that replacement of the 7(*R*)-hydroxy group of lincomycin by chlorine with inversion of configuration resulted in a compound with enhanced antibacterial activity in vitro. Clinical experience with this semisynthetic derivative, clindamycin, 7(*S*)-chloro-7-deoxylincomycin (Cleocin), released in 1970, has established that its superiority over lincomycin is even greater in vivo. Improved absorption and higher tissue levels of clindamycin and its greater penetration into bacteria have been attributed to a higher partition coefficient than that of lincomycin. Structural modifications at C-7 (e.g., 7(*S*)-chloro and 7(*R*)-OCH₃) and of the C-4 alkyl groups of the hygric acid moiety²²⁷ appear to influence activity of congeners more through an effect on the partition coefficient of the molecule than through a stereospecific binding role. Changes in the α -thiolicosamide portion of the molecule seem to decrease activity markedly, however, as evidenced by the marginal activity of 2-deoxylincomycin, its anomer, and 2-*O*-methylincomycin.^{227,228} Exceptions to this are fatty acid and phosphate esters of the 2-hydroxyl group of lincomycin and clindamycin, which are hydrolyzed rapidly in vivo to the parent antibiotics.

Clindamycin is recommended for the treatment of a wide variety of upper respiratory, skin, and tissue infections caused by susceptible bacteria. Its activity against streptococci, staphylococci, and pneumococci is indisputably high, and it is one of the most potent agents available against some non-spore-forming anaerobic bacteria, the *Bacteroides* spp. in particular. An increasing number of reports of clindamycin-associated GI toxicity, which range in severity from diarrhea to an occasionally serious pseudomembranous colitis, have, however, caused some clinical experts to call for a reappraisal of the role of this antibiotic in therapy. Clindamycin- (or lincomycin)-associated colitis may be particularly dangerous in elderly or debilitated patients and has caused deaths in such individuals. The colitis, which is usually reversible when the drug is discontinued, is now believed to result from an overgrowth of a clindamycin-resistant strain of the anaerobic intestinal bacterium *Clostridium difficile*.²²⁹ The intestinal lining is damaged by a glycoprotein endotoxin released by lysis of this organism.

The glycopeptide antibiotic vancomycin has been effective in the treatment of clindamycin-induced pseudomembranous colitis and in the control of the experimentally

induced bacterial condition in animals. Clindamycin should be reserved for staphylococcal tissue infections, such as cellulitis and osteomyelitis, in penicillin-allergic patients and for severe anaerobic infections outside the central nervous system. Ordinarily, it should not be used to treat upper respiratory tract infections caused by bacteria sensitive to other safer antibiotics or in prophylaxis.

Clindamycin is absorbed rapidly from the GI tract, even in the presence of food. It is available as the crystalline, water-soluble hydrochloride hydrate (hyclate) and the 2-palmitate ester hydrochloride salts in oral dosage forms and as the 2-phosphate ester in solutions for intramuscular or intravenous injection. All forms are chemically very stable in solution and in the dry state.

Clindamycin Palmitate Hydrochloride

Clindamycin palmitate hydrochloride (Cleocin Pediatric) is the hydrochloride salt of the palmitic acid ester of cleomycin. The ester bond is to the 2-hydroxyl group of the lincosamine sugar. The ester serves as a tasteless prodrug form of the antibiotic, which hydrolyzes to clindamycin in the plasma. The salt form confers water solubility to the ester, which is available as granules for reconstitution into an oral solution for pediatric use. Although absorption of the palmitate is slower than that of the free base, there is little difference in overall bioavailability of the two preparations. Reconstituted solutions of the palmitate hydrochloride are stable for 2 weeks at room temperature. Such solutions should not be refrigerated because thickening occurs that makes the preparation difficult to pour.

Clindamycin Phosphate

Clindamycin phosphate (Cleocin Phosphate) is the 2-phosphate ester of clindamycin. It exists as a zwitterionic structure that is very soluble in water. It is intended for parenteral (intravenous or intramuscular) administration for the treatment of serious infections and instances when oral administration is not feasible. Solutions of clindamycin phosphate are stable at room temperature for 16 days and for up to 32 days when refrigerated.

been isolated, but unfortunately, their clinical use has been limited by their undesirable side reactions, particularly renal toxicity. Another limitation is the lack of systemic activity of most peptides following oral administration. A chief source of the medicinally important members of this class has been *Bacillus* spp. The antitubercular antibiotics capreomycin and viomycin (see Chapter 6) and the antitumor antibiotics actinomycin and bleomycin are peptides isolated from *Streptomyces* spp. The glycopeptide antibiotic vancomycin, which has become the most important member of this class, is isolated from a closely related actinomycete, *Amycolatopsis orientalis*.

Polypeptide antibiotics variously possess several interesting and often unique characteristics: (a) they frequently consist of several structurally similar but chemically distinct entities isolated from a single source; (b) most of them are cyclic, with a few exceptions (e.g., the gramicidins); (c) they frequently contain D-amino acids and/or “unnatural” amino acids not found in higher plants or animals; and (d) many of them contain non-amino acid moieties, such as heterocycles, fatty acids, sugars, etc. Polypeptide antibiotics may be acidic, basic, zwitterionic, or neutral depending on the number of free carboxyl and amino or guanidino groups in their structures. Initially, it was assumed that neutral compounds, such as the gramicidins, possessed cyclopeptide structures. Later, the gramicidins were determined to be linear, and the neutrality was shown to be because of a combination of the formylation of the terminal amino group and the ethanolamine amidation of the terminal carboxyl group.²³⁰

Antibiotics of the polypeptide class differ widely in their mechanisms of action and antimicrobial properties. Bacitracin and vancomycin interfere with bacterial cell wall synthesis and are effective only against Gram-positive bacteria. Neither antibiotic apparently can penetrate the outer envelope of Gram-negative bacteria. Both the gramicidins and the polymyxins interfere with cell membrane functions in bacteria. However, the gramicidins are effective primarily against Gram-positive bacteria, whereas the polymyxins are effective only against Gram-negative species. Gramicidins are neutral compounds that are largely incapable of penetrating the outer envelope of Gram-negative bacteria. Polymyxins are highly basic compounds that penetrate the outer membrane of Gram-negative bacteria through porin channels to act on the inner cell membrane.²³¹ The much thicker cell wall of Gram-positive bacteria apparently bars penetration by the polymyxins.

Vancomycin Hydrochloride

The isolation of the glycopeptide antibiotic vancomycin (Vancocin, Vancoled) from *Streptomyces orientalis* (renamed *A. orientalis*) was described in 1956 by McCormick et al.²³² The organism originally was obtained from cultures of an Indonesian soil sample and subsequently has been obtained from Indian soil. Vancomycin was introduced in 1958 as an antibiotic active against Gram-positive cocci, particularly streptococci, staphylococci, and pneumococci. It is not active against Gram-negative bacteria, with the exception of *Neisseria* spp. Vancomycin is recommended for use when infections fail to respond to treatment with the more common antibiotics or when the infection is known to be caused by a resistant organism. It is particularly effective for the treatment of endocarditis caused by Gram-positive bacteria.

POLYPEPTIDES

Among the most powerful bactericidal antibiotics are those that possess a polypeptide structure. Many of them have

Vancomycin hydrochloride is a free-flowing, tan to brown powder that is relatively stable in the dry state. It is very soluble in water and insoluble in organic solvents. The salt is quite stable in acidic solutions. The free base is an amphoteric substance, whose structure was determined by a combination of chemical degradation and nuclear magnetic resonance (NMR) studies and x-ray crystallographic analysis of a close analog.²³³ Slight stereochemical and conformational revisions in the originally proposed structure were made later.^{234,235} Vancomycin is a glycopeptide containing two glycosidically linked sugars, glucose and vancosamine, and a complex cyclic peptide aglycone containing aromatic residues linked together in a unique resorcinol ether system.

Vancomycin inhibits cell wall synthesis by preventing the synthesis of cell wall mucopeptide polymer. It does so by binding with the D-alanine-D-alanine terminus of the uridine diphosphate-*N*-acetylmuramyl peptides required for mucopeptide polymerization.²³⁶ Details of the binding were elucidated by the elegant NMR studies of Williamson

et al.²³⁷ The action of vancomycin leads to lysis of the bacterial cell. The antibiotic does not exhibit cross-resistance to β -lactams, bacitracin, or cycloserine, from which it differs in mechanism. Resistance to vancomycin among Gram-positive cocci is rare. High-level resistance in clinical isolates of enterococci has been reported, however. This resistance is in response to the inducible production of a protein, encoded by vancomycin A, that is an altered ligase enzyme that causes the incorporation of a D-alanine-D-lactate depsipeptide instead of the usual D-alanine-D-alanine dipeptide in the peptidoglycan terminus.²³⁸ The resulting peptidoglycan can still undergo cross-linking but no longer binds vancomycin.

Vancomycin hydrochloride is always administered intravenously (never intramuscularly), either by slow injection or by continuous infusion, for the treatment of systemic infections. In short-term therapy, the toxic side reactions are usually slight, but continued use may lead to impaired auditory acuity, renal damage, phlebitis, and rashes. Because it is not absorbed or significantly degraded in the GI tract, vancomycin may be administered orally for the treatment of staphylococcal enterocolitis and for pseudomembranous colitis associated with clindamycin therapy. Some conversion to aglucovancomycin likely occurs in the low pH of the stomach. The latter retains about three fourths of the activity of vancomycin.

Teicoplanin

Teicoplanin (Teichomycin A₂, Targocid) is a mixture of five closely related glycopeptide antibiotics produced by the actinomycete *Actinoplanes teichomyceticus*.^{239,240} The teicoplanin factors differ only in the acyl group in the northernmost of two glucosamines glycosidically linked to the cyclic peptide aglycone. Another sugar, D-mannose, is common to all of the teicoplanins. The structures of the teicoplanin factors were determined independently by a combination of chemical degradation²⁴¹ and spectroscopic^{242,243} methods in three different groups in 1984.

The teicoplanin complex is similar to vancomycin structurally and microbiologically but has unique physical properties that contribute some potentially useful advantages.²⁴⁴ While retaining excellent water solubility, teicoplanin has significantly greater lipid solubility than vancomycin. Thus, teicoplanin is distributed rapidly into tissues and penetrates phagocytes well. The complex has a long elimination half-life, ranging from 40 to 70 hours, resulting from a combination of slow tissue release and a high fraction of protein binding in the plasma (~90%). Unlike vancomycin, teicoplanin is not irritating to tissues and may be administered by intramuscular or intravenous injection. Because of its long half-life, teicoplanin may be administered on a once-a-day dosing schedule. Orally administered teicoplanin is not absorbed significantly and is recovered 40% unchanged in the feces.

Teicoplanin exhibits excellent antibacterial activity against Gram-positive organisms, including staphylococci, streptococci, enterococci, *Clostridium* and *Corynebacterium* spp., *Propionibacterium acnes*, and *L. monocytogenes*. It is not active against Gram-negative organisms, including *Neisseria* and *Mycobacterium* spp. Teicoplanin impairs bacterial cell wall synthesis by complexing with the terminal D-alanine-D-alanine dipeptide of the peptidoglycan, thus preventing cross-linking in a manner entirely analogous to the action of vancomycin.

In general, teicoplanin appears to be less toxic than vancomycin. Unlike vancomycin, it does not cause histamine release following intravenous infusion. Teicoplanin apparently also has less potential for causing nephrotoxicity than vancomycin.

Bacitracin

The organism from which Johnson et al.²⁴⁵ produced bacitracin in 1945 is a strain of *B. subtilis*. The organism had been isolated from debrided tissue from a compound fracture in 7-year-old Margaret Tracy, hence the name “bacitracin.” Bacitracin is now produced from the licheniformis group (*B. subtilis*). Like tyrothricin, the first useful antibiotic obtained from bacterial cultures, bacitracin is a complex

mixture of polypeptides. So far, at least 10 polypeptides have been isolated by countercurrent distribution techniques: A, A¹, B, C, D, E, F₁, F₂, F₃, and G. The commercial product known as bacitracin is a mixture of principally A, with smaller amounts of B, D, E, and F₁₋₃.

The official product is a white to pale buff powder that is odorless or nearly so. In the dry state, bacitracin is stable, but it rapidly deteriorates in aqueous solutions at room temperature. Because it is hygroscopic, it must be stored in tight containers, preferably under refrigeration. The stability of aqueous solutions of bacitracin is affected by pH and temperature. Slightly acidic or neutral solutions are stable for as long as 1 year if kept at a temperature of 0 to 5°C. If the pH rises above 9, inactivation occurs very rapidly. For greatest stability, the

Polymyxin B₁

pH of a bacitracin solution is best adjusted to 4 to 5 by the simple addition of acid. The salts of heavy metals precipitate bacitracin from solution, with resulting inactivation. Ethylenediaminetetraacetic acid (EDTA) also inactivates bacitracin, which led to the discovery that a divalent ion (i.e., Zn^{2+}) is required for activity. In addition to being water soluble, bacitracin is soluble in low-molecular-weight alcohols but insoluble in many other organic solvents, including acetone, chloroform, and ether.

The principal work on the chemistry of the bacitracins has been directed toward bacitracin A, the component in which most of the antibacterial activity of crude bacitracin resides. The structure shown in the diagram was proposed by Stoffel and Craig²⁴⁶ and subsequently confirmed by Ressler and Kashelkar.²⁴⁷

The activity of bacitracin is measured in units per milligram. The potency per milligram is not less than 40 units/mg except for material prepared for parenteral use, which has a potency of not less than 50 units/mg. It is a bactericidal antibiotic that is active against a wide variety of Gram-positive organisms, very few Gram-negative organisms, and some others. It is believed to exert its bactericidal effect through inhibition of mucopeptide cell wall synthesis. Its action is enhanced by zinc. Although bacitracin has found its widest use in topical preparations for local infections, it is quite effective in several systemic and local infections when administered parenterally. It is not absorbed from the GI tract; accordingly, oral administration is without effect, except for the treatment of amebic infections within the alimentary canal.

Polymyxin B Sulfate

Polymyxin (Aerosporin) was discovered in 1947 almost simultaneously in three separate laboratories in the United States and Great Britain.²⁴⁸⁻²⁵⁰ As often happens when similar discoveries are made in widely separated laboratories, differences in nomenclature, referring to both the antibiotic-producing organism and the antibiotic itself, appeared in references to the polymyxins. Because the organisms first designated as *Bacillus polymyxa* and *B. aerosporus* Greer were found to be identical species, the name *B. polymyxa* is used to refer to all of the strains that produce the closely related polypeptides called *polymyxins*. Other organisms (e.g., see "Colistin" later) also produce polymyxins. Identified so far are polymyxins A, B₁,

B₂, C, D₁, D₂, M, colistin A (polymyxin E₁), colistin B (polymyxin E₂), circulins A and B, and polypeptin. The known structures of this group and their properties have been reviewed by Vogler and Studer.²⁵¹ Of these, polymyxin B as the sulfate usually is used in medicine because, when used systemically, it causes less kidney damage than the others.

Polymyxin B sulfate is a nearly odorless, white to buff powder. It is freely soluble in water and slightly soluble in alcohol. Its aqueous solutions are slightly acidic or nearly neutral (pH 5-7.5) and, when refrigerated, stable for at least 6 months. Alkaline solutions are unstable. Polymyxin B was shown to be a mixture by Hausmann and Craig,²⁵² who used countercurrent distribution techniques to obtain two fractions that differ in structure only by one fatty acid component. Polymyxin B₁ contains (+)-6-methyloctan-1-oic acid (isopelargonic acid), a fatty acid isolated from all of the other polymyxins. The B₂ component contains an isooctanoic acid, C₈H₁₆O₂, of undetermined structure. The structural formula for polymyxin B has been proved by the synthesis by Vogler et al.²⁵³

Polymyxin B sulfate is useful against many Gram-negative organisms. Its main use in medicine has been in topical applications for local infections in wounds and burns. For such use, it frequently is combined with bacitracin, which is effective against Gram-positive organisms. Polymyxin B sulfate is absorbed poorly from the GI tract; therefore, oral administration is of value only in the treatment of intestinal infections such as pseudomonas enteritis or infections caused by *Shigella* spp. It may be given parenterally by intramuscular or intrathecal injection for systemic infections. The dosage of polymyxin is measured in units. One milligram contains not less than 6,000 units. Some additional confusion on nomenclature for this antibiotic exists because Koyama et al.²⁵⁴ originally named the product colimycin, and that name is used still. Particularly, it has been the basis for variants used as brand names, such as Coly-Mycin, Colomycin, Colimycin-E, and Colimycin-A.

Colistin Sulfate

In 1950, Koyama et al.²⁵⁴ isolated an antibiotic from *Aerobacillus colistinus* (*B. polymyxa* var. *colistinus*) that was given the name *colistin* (Coly-Mycin S). It was used in Japan and in some European countries for several years before it was made available for medicinal use in the United States. It is recommended especially for the treatment of

Colistin A (Polymyxin E₁)

refractory urinary tract infections caused by Gram-negative organisms such as *Aerobacter*, *Bordetella*, *Escherichia*, *Klebsiella*, *Pseudomonas*, *Salmonella*, and *Shigella* spp.

Chemically, colistin is a polypeptide, reported by Suzuki et al.²⁵⁵ whose major component is colistin A. They proposed the structure shown below for colistin A, which differs from polymyxin B only by the substitution of D-leucine for D-phenylalanine as one of the amino acid fragments in the cyclic portion of the structure. Wilkinson and Lowe²⁵⁶ have corroborated the structure and have shown that colistin A is identical with polymyxin E₁.

Two forms of colistin have been prepared, the sulfate and methanesulfonate, and both forms are available for use in the United States. The sulfate is used to make an oral pediatric suspension; the methanesulfonate is used to make an intramuscular injection. In the dry state, the salts are stable, and their aqueous solutions are relatively stable at acid pH from 2 to 6. Above pH 6, solutions of the salts are much less stable.

Colistimethate Sodium, Sterile

In colistin, five of the terminal amino groups of the α -aminobutyric acid fragment may be readily alkylated. In colistimethate sodium, pentasodium colistinmethanesulfonate, sodium colistimethanesulfonate (Coly-Mycin M), the

methanesulfonate radical is the attached alkyl group, and a sodium salt may be made through each sulfonate. This provides a highly water-soluble compound that is very suitable for injection. In the injectable form, it is given intramuscularly and is surprisingly free from toxic reactions compared with polymyxin B. Colistimethate sodium does not readily induce the development of resistant strains of microorganisms, and there is no evidence of cross-resistance with the common broad-spectrum antibiotics. It is used for the same conditions mentioned for colistin.

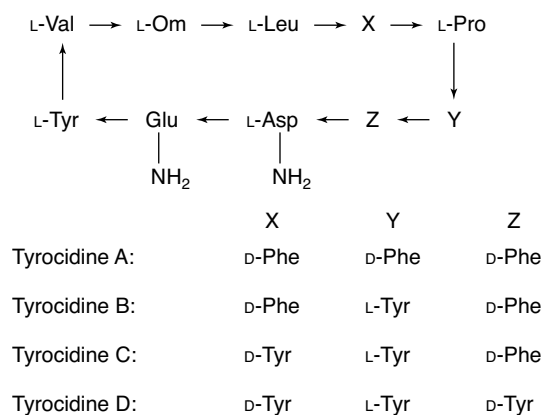

Gramicidin

Gramicidin is obtained from tyrothricin, a mixture of polypeptides usually obtained by extraction of cultures of *B. brevis*. Tyrothricin was isolated in 1939 by Dubos²⁵⁷ in a planned search to find an organism growing in soil that would have antibiotic activity against human pathogens. With only limited use in therapy now, it is of historical interest as the first in the series of modern antibiotics. Tyrothricin is a white to slightly gray or brown-white powder, with little or no odor or taste. It is practically insoluble in water and is soluble in alcohol and dilute acids. Suspensions for clinical use can be prepared by adding an alcoholic solution to calculated amounts of distilled water or isotonic saline solutions.

Tyrothricin is a mixture of two groups of antibiotic compounds, the gramicidins and the tyrocidines. Gramicidins are the more active components of tyrothricin, and this fraction, which is 10% to 20% of the mixture, may be separated and used in topical preparations for the antibiotic effect. Five gramicidins, A₂, A₃, B₁, B₂, and C, have been identified. Their structures have been proposed and confirmed through synthesis by Sarges and Witkop.²³⁰ The gramicidins A differ from the gramicidins B by having a tryptophan moiety substituted by an L-phenylalanine moiety. In gramicidin C, a tyrosine moiety substitutes for a tryptophan moiety. In both of the gramicidin A and B pairs, the only difference is the amino acid located at the end of the chain, which has the neutral formyl group on it. If that amino acid is valine, the compound is either valine-gramicidin A or valine-gramicidin B. If that amino acid is isoleucine, the compound is isoleucine-gramicidin, either A or B.

Tyrocidine is a mixture of tyrocidines A, B, C, and D, whose structures have been determined by Craig et al.^{258,259} The synthesis of tyrocidine A was reported by Ohno et al.²⁶⁰

Gramicidin acts as an ionophore in bacterial cell membranes to cause the loss of potassium ion from the cell.²⁶¹ It is bactericidal.

Tyrothricin and gramicidin are effective primarily against Gram-positive organisms. Their use is restricted to local applications. Tyrothricin can cause lysis of erythrocytes, which makes it unsuitable for the treatment of systemic infections. Its applications should avoid direct contact with the bloodstream through open wounds or abrasions. It is ordinarily safe to use tyrothricin in troches for throat infections, as it is not absorbed from the GI tract. Gramicidin is available in various topical preparations containing other antibiotics, such as bacitracin and neomycin.

UNCLASSIFIED ANTIBIOTICS

Among the many hundreds of antibiotics that have been evaluated for activity, several have gained significant clinical attention but do not fall into any of the previously considered groups. Some of these have quite specific activities against a narrow spectrum of microorganisms. Some have found a useful place in therapy as substitutes for other antibiotics to which resistance has developed.

Chloramphenicol

The first of the widely used broad-spectrum antibiotics, chloramphenicol (Chloromycetin, Amphicol) was isolated

by Ehrlich et al.²⁶² in 1947. They obtained it from *Streptomyces venezuelae*, an organism found in a sample of soil collected in Venezuela. Since then, chloramphenicol has been isolated as a product of several organisms found in soil samples from widely separated places. More importantly, its chemical structure was established quickly, and in 1949, Controulis et al.²⁶³ reported its synthesis. This opened the way for the commercial production of chloramphenicol by a totally synthetic route. It was the first and still is the only therapeutically important antibiotic to be so produced in competition with microbiological processes. Diverse synthetic procedures have been developed for chloramphenicol. The commercial process generally used starts with *p*-nitroacetophenone.²⁶⁴

Chloramphenicol is a white, crystalline compound that is very stable. It is very soluble in alcohol and other polar organic solvents but only slightly soluble in water. It has no odor but has a very bitter taste.

Chloramphenicol possesses two chiral carbon atoms in the acylamidopropanediol chain. Biological activity resides almost exclusively in the *D-threo* isomer; the *L-threo* and the *D-* and *L-erythro* isomers are virtually inactive.

Chloramphenicol is very stable in the bulk state and in solid dosage forms. In solution, however, it slowly undergoes various hydrolytic and light-induced reactions.²⁶⁵ The rates of these reactions depend on pH, heat, and light. Hydrolytic reactions include general acid-base-catalyzed hydrolysis of the amide to give 1-(*p*-nitrophenyl)-2-amino-propan-1,3-diol and dichloroacetic acid and alkaline hydrolysis (above pH 7) of the α -chloro groups to form the corresponding α,α -dihydroxy derivative.

The metabolism of chloramphenicol has been investigated thoroughly.²⁶⁶ The main path involves formation of the 3-*O*-glucuronide. Minor reactions include reduction of the *p*-nitro group to the aromatic amine, hydrolysis of the amide, and hydrolysis of the α -chloroacetamido group, followed by reduction to give the corresponding α -hydroxy-acetyl derivative.

Strains of certain bacterial species are resistant to chloramphenicol by virtue of the ability to produce chloramphenicol acetyltransferase, an enzyme that acetylates the hydroxy groups at the positions 1 and 3. Both the 3-acetoxy and the 1,3-diacetoxy metabolites lack antibacterial activity.

Numerous structural analogs of chloramphenicol have been synthesized to provide a basis for correlation of structure to antibiotic action. It appears that the *p*-nitrophenyl group may be replaced by other aryl structures without appreciable loss in activity. Substitution on the phenyl ring with several different types of groups for the nitro group, a very unusual structure in biological products, does not greatly decrease activity. All such compounds yet tested are less active than chloramphenicol. As part of a QSAR study, Hansch et al.²⁶⁷ reported that the 2-NHCOCF₃ derivative is

1.7 times as active as chloramphenicol against *E. coli*. Modification of the side chain shows that it possesses high specificity in structure for antibiotic action. Conversion of the alcohol group on C-1 of the side chain to a keto group causes appreciable loss in activity. The relationship of the structure of chloramphenicol to its antibiotic activity will not be seen clearly until the mode of action of this compound is known. Brock²⁶⁸ reports on the large amount of research that has been devoted to this problem. Chloramphenicol exerts its bacteriostatic action by a strong inhibition of protein synthesis. The details of such inhibition are as yet undetermined, and the precise point of action is unknown. Some process lying between the attachment of amino acids to sRNA and the final formation of protein appears to be involved.

The broad-spectrum activity of chloramphenicol and its singular effectiveness in the treatment of some infections not amenable to treatment by other drugs made it an extremely popular antibiotic. Unfortunately, instances of serious blood dyscrasias and other toxic reactions have resulted from the promiscuous and widespread use of chloramphenicol in the past. Because of these reactions, it is recommended that it not be used in the treatment of infections for which other antibiotics are as effective and less hazardous. When properly used, with careful observation for untoward reactions, chloramphenicol provides some of the very best therapy for the treatment of serious infections.²⁶⁹

Chloramphenicol is recommended specifically for the treatment of serious infections caused by strains of Gram-positive and Gram-negative bacteria that have developed resistance to penicillin G and ampicillin, such as *H. influenzae*, *Salmonella typhi*, *S. pneumoniae*, *B. fragilis*, and *N. meningitidis*. Because of its penetration into the central nervous system, chloramphenicol is a particularly important alternative therapy for meningitis. It is not recommended for the treatment of urinary tract infections because 5% to 10% of the unconjugated form is excreted in the urine. Chloramphenicol is also used for the treatment of rickettsial infections, such as Rocky Mountain spotted fever.

Because it is bitter, this antibiotic is administered orally either in capsules or as the palmitate ester. Chloramphenicol palmitate is insoluble in water and may be suspended in aqueous vehicles for liquid dosage forms. The ester forms by reaction with the hydroxyl group on C-3. In the alimentary tract, it is hydrolyzed slowly to the active antibiotic. Chloramphenicol is administered parenterally as an aqueous suspension of very fine crystals or as a solution of the sodium salt of the succinate ester of chloramphenicol. Sterile chloramphenicol sodium succinate has been used to prepare aqueous solutions for intravenous injection.

Chloramphenicol Palmitate

Chloramphenicol palmitate is the palmitic acid ester of chloramphenicol. It is a tasteless prodrug of chloramphenicol intended for pediatric use. The ester must hydrolyze in vivo following oral absorption to provide the active form. Erratic serum levels were associated with early formulations of the palmitate, but the manufacturer claims that the bioavailability of the current preparation is comparable to that of chloramphenicol itself.

Chloramphenicol Sodium Succinate

Chloramphenicol sodium succinate is the water-soluble sodium salt of the hemisuccinate ester of chloramphenicol. Because of the low solubility of chloramphenicol, the sodium succinate is preferred for intravenous administration. The availability of chloramphenicol from the ester following intravenous administration is estimated to be 70% to 75%; the remainder is excreted unchanged.^{269,270} Poor availability of the active form from the ester following intramuscular injection precludes attaining effective plasma levels of the antibiotic by this route. Orally administered chloramphenicol or its palmitate ester actually gives higher plasma levels of the active antibiotic than does intravenously administered chloramphenicol sodium succinate.^{270,271} Nonetheless, effective concentrations are achieved by either route.

Novobiocin Sodium

In the search for new antibiotics, three different research groups independently isolated novobiocin, streptonivicin (Albamylin) from *Streptomyces* spp. It was reported first in 1955 as a product of *S. spheroides* and *S. niveus*. Currently, it is produced from cultures of both species. Until the common identity of the products obtained by the different research groups was ascertained, the naming of this compound was confused. Its chemical identity was established as 7-[4-(carbamoyloxy)tetrahydro-3-hydroxy-5-methoxy-6,6-dimethylpyran-2-yloxy]-4-hydroxy-3-[4-hydroxy-3-(3-methyl-2-butenyl)benzamido]-8-methylcoumarin by Shunk et al.²⁷² and Hoeksema et al.²⁷³ and confirmed by Spencer et al.^{274,275}

Chemically, novobiocin has a unique structure among antibiotics, though, like several others, it possesses a glycosidic sugar moiety. The sugar in novobiocin, devoid of its carbamate ester, has been named *noviose* and is an aldose with the configuration of L-lyxose. The aglycon moiety has been termed *novobiocic acid*.

Novobiocin is a pale yellow, somewhat photosensitive compound that crystallizes in two chemically identical forms with different melting points (polymorphs). It is soluble in methanol, ethanol, and acetone but is quite insoluble in less polar solvents. Its solubility in water is affected by pH. It is readily soluble in basic solutions, in which it deteriorates, and is precipitated from acidic solutions. It behaves as a diacid, forming two series of salts.

The enolic hydroxyl group on the coumarin moiety behaves as a rather strong acid (pK_a 4.3) and is the group by which the commercially available sodium and calcium salts are formed. The phenolic -OH group on the benzamido moiety also behaves as an acid but is weaker than the former, with a pK_a of 9.1. Disodium salts of novobiocin have been prepared. The sodium salt is stable in dry air but loses activity in the presence of moisture. The calcium salt is quite water insoluble and is used to make aqueous oral suspensions. Because of its acidic characteristics, novobiocin combines to form salt complexes with basic antibiotics. Some of these salts have been investigated for their combined antibiotic effect, but none has been placed on the market, as they offer no advantage.

The action of novobiocin is largely bacteriostatic. Its mode of action is not known with certainty, though it does inhibit bacterial protein and nucleic acid synthesis. Studies indicate that novobiocin and related coumarin-containing antibiotics bind to the subunit of DNA gyrase and possibly interfere with DNA supercoiling²⁷⁶ and energy transduction in bacteria.²⁷⁷ The effectiveness of novobiocin is confined largely to Gram-positive bacteria and a few strains of *P. vulgaris*. Its low activity against Gram-negative bacteria is apparently because of poor cellular penetration.

Although cross-resistance to other antibiotics is reported not to develop with novobiocin, resistant *S. aureus* strains are known. Consequently, the medical use of novobiocin is reserved for the treatment of staphylococcal infections resistant to other antibiotics and sulfas and for patients allergic to these drugs. Another shortcoming that limits the usefulness of novobiocin is the relatively high frequency of adverse reactions, such as urticaria, allergic rashes, hepatotoxicity, and blood dyscrasias.

Mupirocin

Mupirocin (pseudomonic acid A, Bactroban) is the major component of a family of structurally related antibiotics, pseudomonic acids A to D, produced by the submerged fermentation of *Pseudomonas fluorescens*. Although the antimicrobial properties of *P. fluorescens* were recorded as early as 1887, it was not until 1971 that Fuller et al.²⁷⁸ identified the metabolites responsible for this activity. The structure of the major and most potent metabolite, pseudomonic acid A (which represents 90%–95% of the active fraction from *P. fluorescens*), was later confirmed by chemical synthesis²⁷⁹ to be the 9-hydroxy-nonanoic acid ester of monic acid.

The use of mupirocin is confined to external applications.²⁸⁰ Systemic administration of the antibiotic results in rapid hydrolysis by esterases to monic acid, which is inactive in vivo because of its inability to penetrate bacteria. Mupirocin has been used for the topical treatment of impetigo, eczema, and folliculitis secondarily infected by susceptible bacteria, especially staphylococci and β -hemolytic streptococci. The spectrum of antibacterial activity of mupirocin is confined to Gram-positive and Gram-negative cocci, including staphylococci, streptococci, *Neisseria* spp., and *M. catarrhalis*. The activity of the antibiotic against most Gram-negative and Gram-positive bacilli is generally poor, with the exception of *H. influenzae*. It is not effective against enterococci or anaerobic bacteria.

Mupirocin interferes with RNA synthesis and protein synthesis in susceptible bacteria.^{281,282} It specifically and reversibly binds with bacterial isoleucyl tRNA synthase to prevent the incorporation of isoleucine into bacterial proteins.²⁸² High-level, plasmid-mediated mupirocin resistance in *S. aureus* has been attributed to the elaboration of a modified isoleucyl tRNA that does not bind mupirocin.²⁸³ Inherent resistance in bacilli is likely because of poor cellular penetration of the antibiotic.²⁸⁴

Mupirocin is supplied in a water-miscible ointment containing 2% of the antibiotic in polyethylene glycols 400 and 3350.

Quinupristin/Dalfopristin

Quinupristin/dalfopristin (Synercid) is a combination of the streptogramin B quinupristin with the streptogramin A dalfopristin in a 30:70 ratio.

Both of these compounds are semisynthetic derivatives of two naturally occurring pristinamycins produced in fermentations of *Streptomyces pristinaspiralis*. Quinupristin and dalfopristin are solubilized derivatives of pristinamycin Ia and pristinamycin IIa, respectively, and therefore are suitable for intravenous administration only.

The spectrum of activity of quinupristin/dalfopristin is largely against Gram-positive bacteria. The combination is active against Gram-positive cocci, including *S. pneumoniae*, β -hemolytic and α -hemolytic streptococci, *Enterococcus faecium*, and coagulase-positive and coagulase-negative staphylococci. The combination is mostly inactive against Gram-negative organisms, although *M. catarrhalis* and *Neisseria* spp. are susceptible. The combination is bactericidal against streptococci and many staphylococci, but bacteriostatic against *E. faecium*.

Quinupristin and dalfopristin are protein synthesis inhibitors that bind to the 50S ribosomal subunit. Quinupristin, a type B streptogramin, binds at the same site as the macrolides and has a similar effect, resulting in inhibition of polypeptide elongation and early termination of protein synthesis. Dalfopristin binds to a site near that of quinupristin. The binding of dalfopristin results in a conformational change in the 50S ribosomal subunit, synergistically enhancing the binding of quinupristin at its target site. In most bacterial species, the cooperative and synergistic binding of these two compounds to the ribosome is bactericidal.

Synercid should be reserved for the treatment of serious infections caused by multidrug-resistant Gram-positive organisms such as vancomycin-resistant *E. faecium*.

Quinupristin

Dalfopristin

Pristinamycin 1A

Pristinamycin 2A

Linezolid

Linezolid (Zyvox) is an oxazolidinone-type antibacterial agent that inhibits bacterial protein synthesis. It acts in the early translation stage, preventing the formation of a functional initiation complex. Linezolid binds to the 30S and 70S ribosomal subunits and prevents initiation complexes involving these subunits. Collective data suggest that the oxazolidinones partition their ribosomal interaction between the two subunits. Formation of the early tRNA^{fMet}-mRNA-70S or 30S is prevented. Linezolid is a newer synthetic agent, and hence, cross-resistance between the antibacterial agent and other inhibitors of bacterial protein synthesis has not been seen.

Linezolid possesses a wide spectrum of activity against Gram-positive organisms, including MRSA, penicillin-resistant pneumococci, and vancomycin-resistant *Enterococcus faecalis* and *E. faecium*. Anaerobes such as *Clostridium*, *Peptostreptococcus*, and *Prevotella* spp. are sensitive to linezolid.

Linezolid is a bacteriostatic agent against most susceptible organisms but displays bactericidal activity against some strains of pneumococci, *B. fragilis*, and *Clostridium perfringens*.

The indications for linezolid are for complicated and uncomplicated skin and soft-tissue infections, community- and hospital-acquired pneumonia, and drug-resistant Gram-positive infections.

Fosfomicin Tromethamine

Fosfomicin tromethamine (Monurol) is a phosphonic acid epoxide derivative that was initially isolated from fermentations of *Streptomyces* spp. The structure of the drug is shown next. Making the tromethamine salt greatly expanded the

therapeutic utility of this antibacterial because water solubility increased enough to allow oral administration.

Fosfomycin is a broad-spectrum, bactericidal antibacterial that inhibits the growth of *E. coli*, *S. aureus*, and *Serratia*, *Klebsiella*, *Citrobacter*, *Enterococcus*, and *Enterobacter* spp. at a concentration less than 64 mg/L. Currently fosfomycin is recommended as single-dose therapy for uncomplicated urinary tract infections. It possesses in vitro efficacy similar to that of norfloxacin and trimethoprim-sulfamethoxazole.

Fosfomycin covalently inactivates the first enzyme in the bacterial cell wall biosynthesis pathway, UDP-*N*-acetylglucosamine enolpyruvyl transferase (MurA) by alkylation of the cysteine-115 residue. The inactivation reaction occurs through nucleophilic opening of the epoxide ring. Resistance to fosfomycin can occur through chromosomal mutations that result in reduced uptake or reduced MurA affinity for the inhibitor. Plasmid-mediated resistance mechanisms involve conjugative bioinactivation of the antibiotic with glutathione. The frequency of resistant mutants in in vitro studies has been low, and there appears to be little cross-resistance between fosfomycin and other antibacterials.

NEWER ANTIBIOTICS

Tigecycline

Tigecycline (Tygacil) is a first-in-class (a glycylicycline) intravenous antibiotic that was designed to circumvent many important bacterial resistance mechanisms. It is not affected by resistance mechanisms such as ribosomal protection, efflux pumps, target site modifications, β -lactamases, or DNA gyrase mutations. Tigecycline binds to the 30S ribosomal subunit and blocks peptide synthesis. The glycylicyclines bind to the ribosome with five times the affinity of common tetracyclines. Tigecycline also possesses a novel mechanism of action, interfering with the mechanism of ribosomal protection proteins. Tigecycline, unlike common tetracyclines, is not expelled from the bacterial cell by efflux pumping processes.

Tigecycline is recommended for the treatment of complicated skin and skin structure infections caused by *E. coli*, *E. faecalis* (vancomycin-susceptible isolates), *S. aureus* (methicillin-susceptible and methicillin-resistant isolates), *S. pyogenes*, and *B. fragilis* among others. Tigecycline is also indicated for complicated intra-abdominal infections caused by strains of *Clostridium*, *Enterobacter*, *Klebsiella*, and *Bacteroides*. To reduce the development of resistance to tigecycline, it is recommended that this antibiotic be used only for those infections caused by proven susceptible bacteria.

Glycylicyclines are structurally similar to tetracyclines, and appear to have similar adverse effects. These may include photosensitivity, pancreatitis, and pseudotumor cerebri. Nausea and vomiting have been reported.

Aztreonam

Azactam (aztreonam for injection, intravenous or intramuscular) contains the active ingredient aztreonam, which is a member of the monobactam class of antibiotics. A true antibiotic, aztreonam was originally isolated from cultures of the bacterium *Chromobacterium violaceum*. Now, the antibiotic is prepared by total synthesis. Monobactams possess a unique monocyclic β -lactam nucleus, and are structurally unlike other β -lactams like the penicillins, cephalosporins, carbapenems, and cephamycins. The β -lactam arrangement of aztreonam is unique, possessing an *N*-sulfonic acid functionality. This group activates the β -lactam ring toward attack. The side chain (3-position) aminothiazolyl oxime moiety and the 4-methyl group specify the antibacterial spectrum and β -lactamase resistance.

The mechanism of action of aztreonam is essentially identical to that of other β -lactam antibiotics. The action of aztreonam is inhibition of cell wall biosynthesis resulting from a high affinity of the antibiotic for penicillin binding protein 3 (PBP-3). Unlike other β -lactam antibiotics, aztreonam does not induce bacterial synthesis of β -lactamases. The structure of aztreonam confers resistance to hydrolysis by penicillinases and cephalosporinases synthesized by most Gram-negative and Gram-positive pathogens. Because of these properties, aztreonam is typically active against Gram-negative aerobic microorganisms that resist antibiotics hydrolyzed by β -lactamases. Aztreonam is active against strains that are multiply-resistant to antibiotics such as cephalosporins, penicillins, and aminoglycosides. The antibacterial activity is maintained over a broad pH range (6–8) in vitro, as well as in the presence of human serum and under anaerobic conditions.

Aztreonam for injection is indicated for the treatment of infections caused by susceptible Gram-negative microorganism, such as urinary tract infections (complicated and uncomplicated), including pyelonephritis and cystitis (initial and recurrent) caused by *E. coli*, *K. pneumoniae*, *P. mirabilis*, *P. aeruginosa*, *E. cloacae*, *K. oxytoca*, *Citrobacter* sp., and *S. marcescens*. Aztreonam is also indicated for lower respiratory tract infections, including pneumonia and bronchitis caused by *E. coli*, *K. pneumoniae*, *P. aeruginosa*, *H. influenzae*, *P. mirabilis*, *S. marcescens*, and *Enterobacter* species. Aztreonam is also indicated for septicemia caused by *E. coli*, *K. pneumoniae*, *P. aeruginosa*, *P. mirabilis*, *S. marcescens*, and *Enterobacter* spp. Other infections responding to aztreonam include skin and skin structure infections, including those associated with postoperative wounds and ulcers and burns. These may be caused by *E. coli*, *P. mirabilis*, *S. marcescens*, *Enterobacter* species, *P. aeruginosa*, *K. pneumoniae*, and *Citrobacter* species. Intra-abdominal infections, including peritonitis caused by *E. coli*, *Klebsiella* species including *K. pneumoniae*, *Enterobacter* species including *E. cloacae*, *P. aeruginosa*, *Citrobacter* species including *C. freundii*, and *Serratia* species including *S. marcescens*. Some gynecologic infections, including endometritis and pelvic cellulitis caused by *E. coli*, *K. pneumoniae*, *Enterobacter* species including *E. cloacae*, and *P. mirabilis* also respond to aztreonam.

Ertapenem

Ertapenem (Invanz, for injection) is a synthetic 1- β -methyl carbapenem that is structurally related to β -lactam antibiotics, particularly the thienamycin group. Its mechanism of action is the same as that of other β -lactam antibiotics. The structure resists β -lactamases and dehydropeptidases.

Ertapenem is indicated for the treatment of moderate to severe infections caused by susceptible strains causing complicated intra-abdominal infections such as *Escherichia*, *Clostridium*, *Peptostreptococcus*, and *Bacteroides*. The antibiotic is also indicated for complicated skin and skin structure infections including diabetic foot infections (without osteomyelitis). Treatable strains include *Staphylococcus* (MSSA), *Streptococcus*, *Escherichia*, *Klebsiella*, *Proteus*, and *Bacteroides*. Ertapenem is also indicated for community-acquired pneumonia caused by *S. pneumoniae*, *Haemophilus influenzae*, and *M. catarrhalis*. Complicated urinary tract infections and acute pelvic infections round out the indications for ertapenem.

Telithromycin

Telithromycin (Ketek) is an orally bioavailable macrolide. The antibiotic is semisynthetic. Telithromycin is classified as a *ketolide*, and it differs chemically from the macrolide group of antibacterials by the lack of α -L-cladinose at 3-position of the erythronolide A ring, resulting in a 3-keto function. It is further characterized by imidazolyl and pyridyl rings inked to the macrolide nucleus through a butyl chain. The mechanism of action of telithromycin is the same as that of the macrolide class.

Telithromycin causes a blockade of protein synthesis by binding to domains II and V of 23S rRNA of the 50S ribosomal subunit. Because telithromycin binds at domain II, activity against Gram-positive cocci is retained in the presence of resistance mediated by methylases that alter the domain V binding site. The antibiotic is also believed to inhibit the assembly of ribosomes. Resistance to telithromycin occurs because of riboprotein mutations.

Telithromycin is active against aerobic Gram-positive microorganisms such as *S. pneumoniae* (including multidrug-resistant isolates), aerobic Gram-negative organisms such as *H. influenzae* and *M. catarrhalis*, and *M. pneumoniae*. Ketek is recommended for use in patients 18 years of age or older.

Telithromycin is metabolized by cytochrome P450. It therefore possesses several drug-drug interactions because of its ability to interact with various P450 isoforms. CYP3A4 inhibitors such as itraconazole caused the C_{max} of telithromycin to increase by 22% and the area under the curve (AUC) to increase by 54%. Ketoconazole and grapefruit juice demonstrated similar patterns. CYP3A4 substrates such as cisapride caused a dramatic increase in

telithromycin plasma concentration. Simvastatin and midazolam also demonstrated increases in AUC when telithromycin was added. CYP2D6 substrates showed no effect on drug kinetics when administered with telithromycin. Other drug–drug interactions with telithromycin include digoxin (plasma peak and trough levels increased by 73% and 21%, respectively), theophylline (16% and 17% in steady-state C_{max} and AUC, respectively), and some oral contraceptives.

NEW DIRECTIONS IN ANTIBIOTIC DISCOVERY

Considering the rapid development of multidrug resistance to the antibiotics currently in our armamentarium, research into new agents is crucial. Multidrug resistant bacteria have become a major public health crisis because existing antibiotics are no longer effective in many cases. Antibiotics like vancomycin that have traditionally been drugs of last resort are becoming the first line of treatment of resistant infections. Unfortunately, in recent times very few novel antibiotics have been reported, and the development of new compounds by the pharmaceutical industry has been slow. Some consider that the reason for this situation is that industry is more concerned with developing drugs for chronic use in patients, instead of agents like antibiotics that are used acutely. The situation may be getting better. The Pharmaceutical Research and Manufacturing Association reports that in 2008, there are about 80 new antibiotics and antibacterial agents in various stages of development (it wasn't specified how many of these 80 agents are actually antibiotics). It is safe to assume that screening in nature for novel antibiotics is proceeding. Unfortunately, many agents that are isolated from nature are compounds that are mechanistically the same as antibiotics currently on the market.

It is essential to discover antibiotics that act through the disruption of a novel target. One success story is found in the research of scientists at Merck, who conducted high-throughput screenings of specialized metabolites against FabF, an enzyme that is involved in bacterial fatty acid biosynthesis. These screenings led to the discovery of a new antibiotic hitting a new target, platensimycin. Isolated

from *Streptomyces platensis* cultures, platensimycin^{285,286} represents a new structural class of antibiotics with very potent broad-spectrum activity against Gram-positive bacteria. It is interesting that to date, no cross-resistance has been observed. This feature is probably because of platensimycin's unique mechanism of action.

Platensimycin

In nature there are two distinct types of fatty acid biosynthesis pathways. Type 1 is referred to as the *associated system*, whereas type 2 is referred to as the *dissociated system*. Associated systems are found in higher organisms. These are composed of a large multidomain protein that is capable of catalyzing all of the steps of fatty acid biosynthesis. Dissociated systems are found in plants and bacteria. In these systems a set of discrete enzymes each catalyze a single step in the biosynthetic pathway. Hence, type 2 biosynthesis represents a good target for novel antibiotics. Moreover, two enzymes of the dissociated pathway, FabH and FabF/B, are well-conserved across many bacterial strains. This fact goes hand in hand with broad spectrum activity.

In vitro, platensimycin compares favorably with linezolid. No cross-resistance to MRSA, vancomycin-intermediate *S. aureus*, and vancomycin-resistant enterococci has been observed. An efflux mechanism appears to preclude platensimycin's activity in Gram-negative bacteria.

The total synthesis of platensimycin has been reported²⁸⁷ and a congener, carbaplatensimycin,²⁸⁸ has been synthesized as well. The activity of carbaplatensimycin is similar to that of the parent platensimycin.

It is safe to assume that if any success is to be had against the rapidly developing multidrug-resistant bacteria, novel targets will have to be found. The platensimycin story is just the first case of this kind of antibiotic development.

REVIEW QUESTIONS

1. Compare and contrast the mechanisms of action of the tetracyclines and the macrolides.
2. Give the correct definition of an “antibiotic.”
3. Can penicillins and aminoglycosides be used synergistically? If so, how?
4. What are “PBPs”? How do they work in the mechanism of action of the penicillins?
5. What is an aglycone?
6. How does spectinomycin differ from the other aminoglycoside antibiotics?
7. What bacterial genus synthesizes most of the clinically used antibiotics?
8. What are multidrug-resistant bacteria? Why are they of concern to medicine?
9. What is the unique mechanism of action of platensimycin?
10. Why do we say that cephalosporins possess “intrinsic β -lactamase resistance”?

Antiviral Agents

JOHN M. BEALE, JR.

CHAPTER OVERVIEW

Viral diseases constitute a set of difficult-to-treat conditions. Over the years, many different antiviral agents have been discovered and synthesized, and these have provided various means of treatment of viral conditions. This chapter will begin with some concepts of viral taxonomy and the steps in the infectious cycle of viruses, as well as biochemical steps that can be used as targets in antiviral therapy. We will then move into the arena of prevention of viral infection through the use of chemoprophylaxis. Chemoprophylaxis is accomplished through the use of immunization with vaccines, agents such as amantadine and rimantidine for influenza prophylaxis, and the neuraminidase inhibitors zanamivir and oseltamivir. Interferons (IFNs) will then be discussed as chemoprophylactic agents. Nucleoside antimetabolites will be discussed as compounds that inhibit polymerases and are incorporated into viral nucleic acids, causing these macromolecules to become unstable. An extended discussion of reverse transcriptase (RT) inhibitors and nonnucleoside reverse transcriptase inhibitors (NNRTIs) follows. The chapter concludes with a discussion of human immunodeficiency virus (HIV), protease inhibitors (PIs), combination therapy, and short-interfering RNA (siRNA) and RNA interference.

Objectives of this chapter are to understand the biochemistry of viruses, to learn the mechanisms of action of the antiviral agents, and to develop a knowledge of which antiviral agent should be used in any given infection.

THE CLASSIFICATION AND BIOCHEMISTRY OF VIRUSES

Viruses are unique organisms. They are the smallest of all self-replicating organisms, able to pass through filters that retain the smallest bacteria.¹ The simplest viruses contain a small amount of DNA or RNA surrounded by an uncomplicated protein coat. Some of the more complex viruses have a lipid bilayer membrane surrounding the nucleic acid.² Viruses must replicate in living cells, which has led many to argue that viruses are not even living organisms but that they somehow exist at the interface of the living and the nonliving.¹ The most basic requirement is for the virus to induce either profound or subtle changes in the host cell, so that viral genes are replicated and viral proteins are expressed. This will result in the formation of new viruses, usually many more than the number that infected the cell initially. Viruses conduct no metabolic processes on their own; they

depend totally on a host cell, which they invade and parasitize to subvert subcellular machinery. They use part of the cell's equipment for replication of viral nucleic acids and expression of viral genes, all of the cell's protein synthesis machinery, and all of the cell's energy stores that are generated by its own metabolic processes. The virus turns the biochemical systems of the host cell to its own purposes, completely subverting the infected cell. An infection that results in the production of more viruses than initiation of infection is called a *productive infection*. The actual number of infectious viruses produced in an infected cell is termed the *burst size*. This number can range from 10 to more than 10,000, depending on the type of cell infected, the nature of the virus, and other factors.³

Viruses are known to infect every form of life.¹ A typical DNA virus will enter the nucleus of the host cell, where viral DNA is transcribed into messenger RNA (mRNA) by host cell RNA polymerase. mRNA is then translated into virus-specific proteins that facilitate assembly, maturation, and release of newly formed virus into surrounding tissues. RNA viruses are somewhat different, in that their replication relies on enzymes in the virus itself to synthesize mRNA.

An adult virus possesses only one type of nucleic acid (either a DNA or an RNA genome). This feature differentiates viruses from other intracellular parasites, such as *Chlamydia* (which possesses both DNA and RNA when replicating within a cell) and the *Rickettsiae* (which, in addition to DNA and RNA, have autonomous energy-generating systems). Viruses are very different from these other intracellular parasites. Another unique feature of viruses is that their organized structure is completely lost during replication within the host cell; the nucleic acid and proteins exist dispersed in the cytoplasm.

CLASSIFICATION OF VIRUSES

Viruses are classified on the basis of several features:

- Nucleic acid content (DNA or RNA)
- Viral morphology (helical, icosahedral)
- Site of replication in cell (cytoplasm or nucleus)
- Coating (enveloped or nonenveloped)
- Serological typing (antigenic signatures)
- Cell types infected (B lymphocytes, T lymphocytes, monocytes)

The Baltimore Classification Scheme⁴ (Table 9.1) gives an alternate means of relating the different virus types.

TABLE 9.1 Baltimore Classification Scheme for Viruses

- I) Single-stranded RNA viruses
 - A) Positive sense (virion RNA-like cellular mRNA)
 - 1) Nonenveloped
 - (a) Icosahedral
 - (i) Picornaviruses (polio, hepatitis A, rhinovirus)
 - (ii) Calicivirus
 - (iii) Plant virus relatives of Picornavirus
 - (iv) MS2 bacteriophage
 - (b) Enveloped
 - (i) Togaviruses (rubella, equine encephalitis, Sindbis)
 - (ii) Flaviviruses (yellow fever, dengue fever)
 - (b) Helical
 - (i) Coronavirus
 - B) Positive sense but requires RNA to be converted to DNA via a virion-associated enzyme (reverse transcriptase)
 - 1) Enveloped
 - (a) Retroviruses
 - (i) Oncornaviruses
 - (ii) Lentiviruses
 - C) Negative-sense RNA (opposite polarity to cellular mRNA, requires a virion-associated enzyme to begin the replication cycle)
 - 1) Enveloped
 - (a) Helical
 - (i) Mononegaviruses (rabies, vesicular stomatitis virus, paramyxovirus, filovirus)
 - (ii) Segmented genome (orthomyxovirus-influenza, bunyavirus, arenavirus)
- II) Double-stranded RNA viruses
 - A) Nonenveloped
 - 1) Icosahedral
 - (a) Reovirus
 - (b) Rotavirus
- III) Single-stranded DNA viruses
 - A) Nonenveloped
 - 1) Icosahedral
 - (a) Parvoviruses (canine distemper, adeno-associated virus)
 - (b) Bacteriophage Φ X174
- IV) Double-stranded DNA viruses
 - A) Nuclear replication
 - 1) Nonenveloped
 - (a) Icosahedral
 - (i) Small circular DNA genome (papoviruses, SV40, polyomaviruses, papillomaviruses)
 - (ii) "Medium" sized, complex morphology, linear DNA (adenovirus)
 - (b) Enveloped-nuclear replicating
 - (a) Icosahedral
 - (i) Herpesviruses (linear DNA)
 - (ii) Hepadnavirus (virion encapsidates RNA that is converted to DNA by reverse transcriptase)
 - B) Cytoplasmic replication
 - 1) Icosahedral
 - (a) Iridovirus
 - 2) Complex symmetry
 - (a) Poxvirus
 - C) Bacterial viruses
 - 1) Icosahedral with tail
 - (a) T-series bacteriophages
 - (b) Bacteriophage λ

The following lists some virus types together with diseases that they cause:

- RNA viruses: picornaviruses (polio, hepatitis A, rhinovirus); togavirus (rubella, equine encephalitis); flavivirus (yellow fever, dengue fever, St. Louis encephalitis); bunyaviruses (encephalitis, hemorrhagic fever); rhabdoviruses (vesicular stomatitis); myxoviruses (mumps, measles); reoviruses or rotaviruses (diarrhea); filovirus (Ebola, Marburg); arenaviruses (lymphocytic choriomeningitis); retroviruses (HIV)
- DNA viruses: herpesviruses (herpes, cold sores); papovaviruses (polyoma, warts); adenoviruses (respiratory complaints); poxvirus (smallpox); parvovirus (canine distemper)

It has been estimated that viruses cause more than 60% of the infectious diseases that occur in the developing countries. Bacterial infections account for only 15%. Table 9.2 provides a synopsis of virus types with their possible therapeutic modalities.

TARGETS FOR THE PREVENTION OF VIRAL INFECTIONS—CHEMOPROPHYLAXIS

Immunization

Prevention of viral infections by conferring artificially acquired active immunity with vaccines is the main approach for preventing most viral diseases. Safe and highly

TABLE 9.2 Classification of Viruses Causing Disease in Humans

Family Agent	Disease	Vaccine	Chemotherapy
RNA Viruses			
Picornavirus			
Enterovirus	Polio; three serotypes cause meningitis, paralysis	Live and killed vaccines (very effective)	None
Coxsackie viruses	Variety of symptoms	None	None
Rhinovirus	Common cold, pneumonia (more than 10 serotypes)	None	None
Hepatitis A virus	Hepatitis (usually mild and rarely chronic)	Inactivated virus (effective)	None
Calicivirus			
Norwalk virus	Gastroenteritis	None	None
Togavirus			
Alphaviruses (group A arboviruses)	Encephalitis, hemorrhagic fevers	Attenuated virus (generally effective)	None
Rubivirus	Rubella (German measles)	Attenuated virus	None
Flavivirus			
Flaviviruses (group B arboviruses)	Yellow fever, dengue, encephalitis, hemorrhagic fevers	Attenuated virus (generally effective)	None
Hepatitis C virus	Hepatitis	None	None
Coronavirus	Respiratory infection	None	None
Rhabdovirus			
Rabies virus	Rabies	Inactivated virus (effective)	None
Vesicular stomatitis virus		None	None
Filovirus			
Marburg virus	Marburg disease	None	None
Ebola virus	Hemorrhagic fever	None	None
Paramyxovirus			
Parainfluenza virus	Respiratory infection	None	None
Respiratory syncytial virus	Respiratory infection	Attenuated virus (effectiveness uncertain)	Ribavirin
Morbillivirus	Measles (rubeola)	Attenuated virus (90% effective)	None
Mumps virus	Mumps	Attenuated virus	None
Orthomyxovirus			
Influenza virus	Influenza (A, B, C serotypes)	Attenuated virus (70% effective)	Amantadine
Bunyavirus			
Hantavirus	Fever, renal failure	None	None
Arboviruses	Encephalitis, hemorrhagic fever	None	None
Arenavirus			
Lymphocytic choriomeningitis virus	Meningitis	None	None
Junin, Machupo viruses	Hemorrhagic fever	None	None
Lassa virus	Hemorrhagic fever	None	Ribavirin
Reovirus			
Human rotavirus	Gastroenteritis in infants	None	None
Orbivirus	Colorado tick fever	Inactivated virus (effectiveness unknown)	None
Retrovirus			
Human immunodeficiency viruses (HIV-1, HIV-2)	AIDS and AIDS-related complex (ARC)	None	AZT, ddl, ddC, stavudine
Human T-cell lymphotropic viruses (HTLV-1, HTLV-2)	T-cell leukemia, lymphoma	None	None
DNA Viruses			
Herpesvirus			
Herpes simplex 1	Stomatitis, eye infections, encephalitis	Inactivated virus (efficacy uncertain)	Iudr, ara-A
Herpes simplex 2	Genital herpes, skin eruptions	None	Acyclovir
Varicella zoster	Chickenpox (children), shingles (adults)	None	Acyclovir
Cytomegalovirus	Infections in the immunocompromised, neonates	None	Ganciclovir, foscarnet
Epstein-Barr virus	Infectious mononucleosis, Burkitt's lymphoma	None	None
Papovavirus			
Papillomavirus	Warts	None	Podophyllin
Polyomavirus (JC virus)	Progressive leukoencephalopathy	None	None
Adenovirus			
Human adenovirus	Upper respiratory tract and eye infections	None	None
Hepadnavirus			
Hepatitis B virus	Hepatitis (may become chronic)	Inactivated subunit (very effective)	None
Poxvirus			
Variola	Smallpox	Vaccinia (cowpox) (very effective)	Methisazone
Parvovirus			
Human parvovirus B19	Erythema, hemolytic anemia	None	None

effective vaccines are available for the prevention of polio, rubella, measles, mumps, influenza, yellow fever, encephalitis, rabies, smallpox (now considered to be eradicated worldwide, but still of interest from a biological warfare standpoint), and hepatitis B. Vaccines developed to prevent infection with herpesvirus, Epstein-Barr virus, cytomegalovirus (CMV), respiratory syncytial virus (RSV), and HIV have so far proved ineffective or unreliable. The development of a new vaccine that is effective against a chronic disease-causing virus such as HIV (acquired immunodeficiency syndrome [AIDS]) can be a daunting task. The primary principles of vaccine development apply: the vaccine must be sufficiently antigenic to induce an effective antibody response, even in very young patients; the vaccine must not cause the disease that it is designed to prevent or cause some other toxic manifestation as the early killed vaccines did; and, ideally, the vaccine should produce a lasting form of immunity, with a minimum requirement for booster doses. These requirements are difficult enough to meet for viruses that cause acute infections. The chronic cases are much more complicated. It is difficult to overcome the tendency of some viruses to undergo rapid mutation, leading to multiple antigenic epitopes; this makes development of a broadly effective vaccine much more difficult.

Biochemical Targets for Antiviral Therapy

With the discovery of antibiotics and anti-infective agents, the science of treating bacterial infections moved forward at a rapid rate. The development of useful antiviral agents (antibiotics and antiviral agents), in contrast, has historically lagged behind. There are several reasons for this. Unlike bacteria, viruses will not grow in simple synthetic culture media. They must infect human or animal cells to propagate.⁵ For example, the most commonly used cell cultures in virology derive from primates (including humans and monkeys), rodents (including hamsters and mice), and birds (especially chickens). These culture methods are very reliable⁶ and are in widespread use for the propagation of virus particles, but they are more difficult to perform than their bacterial counterparts. Hence, drug-screening techniques with viruses have taken longer to catch up with those in bacteria. Another possible reason for the lag in antiviral drug development lies in the comparative biochemical simplicity of viruses vis-à-vis bacteria and their use of the biochemical processes of a host cell. There are fewer specialized targets for potential attack by chemotherapeutic agents. The rapid, spectacular successes of immunization procedures for the prevention of certain viral diseases may have contributed to a relative lack of interest in antiviral chemotherapy. Another feature of mild viral infections, such as the common cold, is that clinical symptoms do not appear until the infection is well established and the immune processes of the host have begun to mount a successful challenge. Thus, for many common viral infections, chemotherapy is simply not an appropriate choice of treatment. Chemotherapeutic agents are needed, however, to combat viruses that cause severe or chronic infections, such as encephalitis, AIDS, and herpes, particularly in patients with compromised immune systems.

THE INFECTIOUS PROCESS FOR A VIRUS

Despite their simplicity relative to bacteria, viruses still possess various biochemical targets for potential attack by chemotherapeutic agents. An appropriate chemical compound may interrupt each of these. Hence, a thorough understanding of the specific biochemical events that occur during viral infection of the host cell should guide the discovery of site-specific antiviral agents. The process of viral infection can be sequenced in seven stages:

1. *Adsorption*, attachment⁷ of the virus to specific receptors on the surface of the host cells, a specific recognition process.
2. *Entry*, penetration⁷ of the virus into the cell.
3. *Uncoating*, release⁷ of viral nucleic acid from the protein coat.
4. *Transcription*, production of viral mRNA from the viral genome.⁸
5. *Translation*, synthesis⁸ of viral proteins (coat proteins and enzymes for replication) and viral nucleic acid (i.e., the parental genome or complimentary strand). This process uses the host cell processes to express viral genes, resulting in a few or many viral proteins involved in the replication process. The viral proteins modify the host cell and allow the viral genome to replicate by using host and viral enzymes. The mechanisms by which this occurs are complex. This is often the stage at which the cell is irreversibly modified and eventually killed.
6. *Assembly* of the viral particle. New viral coat proteins assemble into capsids (the protein envelope that surrounds nucleic acid and associated molecules in the core) and viral genomes.⁸
7. *Release* of the mature virus from the cell by budding from the cell membrane or rupture of the cell and repeat of the process, from cell to cell or individual to individual.⁸ Enveloped viruses typically use budding on the plasma membrane, endoplasmic reticulum, or Golgi membranes. Nonenveloped viruses typically escape by rupture of the host cell.

Life cycles of different viruses provide many different possible schemes. To show the typical complexity, the life cycle of the influenza type A virus is shown in Figure 9.1.

Step 1: The virion attaches to the host cell membrane via hemagglutinin and enters the cytoplasm via receptor-mediated endocytosis, forming an *endosome*. A cellular trypsinlike enzyme cleaves HA into products HA1 and HA2 (not shown). HA2 promotes fusion of the virus envelope and the endosomal membranes. A minor virus envelope protein M2 acts as an ion channel, thereby making the interior of the virion more acidic. As a result, major envelope M1 dissociates from the nucleocapsid.

Step 2: In Step 2, viral nucleoproteins are translated into the nucleus by interaction between the nucleoproteins and cellular transport machinery.

Step 3: In the nucleus, the viral polymerase complexes transcribe (Step 3a) and replicate (Step 3b) the viral RNAs.

Step 4: Newly synthesized mRNAs migrate to cytoplasm where they are translated.

Figure 9.1 • Diagram depicting the life cycle of an influenza type A virus. (Reprinted with permission from http://en.wikipedia.org/wiki/Influenza#Types_of_influenza-virus.)

- Step 5: Posttranslational processing of HA, NA, and M2 includes transport via the Golgi apparatus to the cell membrane (Step 5b). Structural regulatory proteins and nuclear export proteins move to the nucleus (Step 5a).
- Step 6: The newly formed nucleocapsids migrate into the cytoplasm in a nuclear export protein-dependent process and eventually interact via M1 with a region of the cell membrane where neuraminidase, hemagglutinin, and M2 have been inserted.
- Step 7: The newly synthesized virions bud from the infected cell. Neuraminidase destroys the sialic acid moiety of cellular receptors, thereby releasing the progeny virions.

The initial attachment of viral particles to cells probably involves multiphasic interactions between viral attachment protein(s) and host cell surface receptors. For instance, in the case of the alphaherpesviruses, internalization involves a cascade of events that involve different glycoproteins and different cell surface molecules at different stages. Different cell surface proteins may be used for the initial attachment and entry into target cells and for cell-to-cell spread across closely apposed populations of cells.⁹ The pattern of systemic illness produced during an acute viral infection in large part depends on the specific organs infected and, in many cases, on the capacity of the viruses to infect discrete populations of cells within these organs. This property is called *tissue tropism*.^{10,11} The tissue tropism of a virus is influenced by the interaction between various hosts and viral factors.

Although the specific viral attachment proteins and specific receptors on target cells are important, a variety of other virus–host interactions can play an important role in

determining the tropism of a virus. Increasing attention is being focused on *coreceptors* in mediating viral binding. For instance, entry of HIV-1 into target cells requires the presence of both CD4⁺ and a second coreceptor protein that belongs to the G-protein-coupled seven-transmembrane receptor family, including the chemokine receptor proteins CCR5 and CXCR4. Cells that express CD4⁺ but not the coreceptor are resistant to HIV infection. Host cellular receptors can be integrins, heparans, sialic acids, gangliosides, ceramides, phospholipids, and major histocompatibility antigens (to name a few). There is substantial evidence that the cellular receptor for influenza viruses is the peptidoglycan component *N*-acetylmuramic acid, which binds a protein molecule, hemagglutinin, projecting from the viral surface.¹² The binding of *N*-acetylmuramic acid and hemagglutinin sets in motion a sequence of events, whereby the viral envelope and the host cell membrane dissolve into each other, and the viral contents enter the cell. Initiation of HIV-1 infection involves the interaction of specific glycoprotein molecules (gp120) that stud the viral cell surface with an antigenic CD4⁺ receptor molecule on helper T lymphocytes along with a cytokine coreceptor.^{13–16} Substantial evidence indicates that viruses enter cells by *endocytosis*, a process that involves fusion of the viral envelope with the cell membrane, intermixing of components, and dissolution of the membranes of virus and cell. Various receptors and coreceptors facilitate this reaction.^{17–19}

Before a virus can begin a replication cycle within a host cell, its outer envelope and capsid must be removed to release its nucleic acid genome. For complex DNA viruses such as vaccinia (its binding receptor is the epidermal

growth factor receptor), the uncoating process occurs in two stages¹⁷:

1. Host cell enzymes partially degrade the envelope and capsid to reveal a portion of the viral DNA, which serves as a template for mRNA synthesis.
2. mRNAs code for the synthesis of viral enzymes, which complete the degradation of the protein coat, allowing the virus to fully enter the host.

The proteins of the viral envelope and capsule are the primary targets for antibodies synthesized in response to immunization techniques. Protein synthesis inhibitors such as cycloheximide and puromycin inhibit the uncoating process, but they are not selective enough to be as useful as antiviral agents.

In the critical fourth and fifth stages of infection, the virus usurps the energy-producing and synthetic functions of the host cell to replicate its own genome and to synthesize viral enzymes and structural proteins.²⁰ Simple RNA viruses conduct both replication and protein synthesis in the cytoplasm of the host cell. These contain specific RNA polymerases (RNA replicases) responsible for replication of the genome. Some single-stranded RNA viruses, such as poliovirus, have a (+)-RNA genome that serves the dual function of messenger for protein synthesis and template for the synthesis of a complementary strand of (–)-RNA, from which the (+)-RNA is replicated. In poliovirus (a picornavirus), the message is translated as a single large open reading frame whose product is cleaved enzymatically into specific viral enzymes and structural proteins.^{18,21} Other RNA viruses, such as influenza viruses, contain (–)-RNA, which serves as the template for the synthesis of a complementary strand of (+)-RNA. The (+)-RNA strand directs viral protein synthesis and provides the template for the replication of the (–)-RNA genome. Certain antibiotics, such as the rifamycins, inhibit viral RNA polymerases *in vitro*, but none has yet proved clinically useful. Bioactivated forms of the nucleoside analog ribavirin variously inhibit ribonucleotide synthesis, RNA synthesis, or RNA capping in RNA viruses. Ribavirin has been approved for aerosol treatment of severe lower respiratory infections caused by RSV.

Retroviruses constitute a special class of RNA viruses that possess an RNA-dependent DNA polymerase (*reverse transcriptase*) required for viral replication. In these viruses, a single strand of complementary DNA (cDNA) is synthesized on the RNA genome (*reverse transcription*), duplicated, and circularized to a double-stranded proviral DNA. The proviral DNA is then integrated into the host cell chromosomal DNA to form the template (*provirus* or *virogene*) required for the synthesis of mRNAs and replication of the viral RNA genome. During the process of cDNA biosynthesis, a ribonuclease (RNase) degrades the RNA strand, leaving only DNA. *Oncogenic* (cancer-causing) viruses, such as the human T-cell leukemia viruses (HTLV) and the related HIV, are retroviruses. Retroviral RT is a good target for chemotherapy, being inhibited by the triphosphates of certain dideoxynucleosides, such as 2',3'-deoxy-3'-azidothymidine (AZT, zidovudine), 2',3'-dideoxycytidine (ddCyd, zalcitabine), and 2',3'-dideoxy-2',3'-didehydrothymidine (D4T, stavudine), all of which have been approved for the treatment of AIDS. The nomenclature of these agents is straightforward. A 2',3'-dideoxynucleoside is referred to as ddX, whereas the unsaturated 2',3'-dideoxy-2',3'-didehydronucleosides are named

d4X. The dideoxynucleoside triphosphates are incorporated into viral DNA in place of the corresponding 2'-deoxynucleoside (i.e., 2'-deoxythymidine, 2'-deoxycytidine, or 2'-deoxyadenosine) triphosphate.^{22,23} This reaction terminates the viral DNA chain, because the incorporated dideoxynucleoside lacks the 3'-hydroxyl group required to form a 3',5'-phosphodiester bond with the next 2'-deoxynucleotide triphosphate to be incorporated.

The DNA viruses constitute a heterogeneous group whose genome is composed of DNA. They replicate in the nucleus of a host cell. Some of the DNA viruses are simple structures, consisting of a single DNA strand and a few enzymes surrounded by a capsule (e.g., parvovirus) or a lipoprotein envelope (e.g., hepatitis B virus). Others, such as the herpesviruses and poxviruses, are large, complex structures with double-stranded DNA genomes and several enzymes encased in a capsule and surrounded by an envelope consisting of several membranes. DNA viruses contain DNA-dependent RNA polymerases (*transcriptases*), DNA polymerases, and various other enzymes (depending on the complexity of the virus) that may provide targets for antiviral drugs. The most successful chemotherapeutic agents discovered thus far are directed against replication of herpesviruses. The nucleoside analogs idoxuridine, trifluridine, and vidarabine block replication in herpesviruses by three general mechanisms: first, as the monophosphates, they interfere with the biosynthesis of precursor nucleotides required for DNA synthesis; second, as triphosphates, they competitively inhibit DNA polymerase; and third, the triphosphates are incorporated into the growing DNA itself, resulting in DNA that is brittle and does not function normally. Acyclonucleosides (e.g., acycloguanosine) are bioactivated sequentially by viral and host cell kinases to the acyclonucleotide monophosphate and the acyclonucleoside triphosphate, respectively. The latter inhibits viral DNA polymerase and terminates the viral DNA strand, since no 3'-hydroxyl group is available for the subsequent formation of a 3',5'-phosphodiester bond with the next nucleoside triphosphate. The structure of acyclovir with the acyclosugar chain rotated into a pentose configuration shows clearly the absence of the 3'-hydroxyl group.

Late stages in viral replication require important virus-specific processing of certain viral proteins by viral or cellular proteases. Retroviruses, such as HIV, express three genes as precursor polyproteins. Two of these gene products, designated the p55gag and p160gag-pol proteins for their location on the genome, undergo cleavage at several sites by a virally encoded protease to form structural (viral coat) proteins (p17, p24, p8, and p7) and enzymes required for replication (RT, integrase, and protease). The demonstration that HIV protease, a member of the aspartyl protease family of enzymes, is essential for the maturation and infectivity of HIV particles²⁴ has stimulated major research efforts to develop effective inhibitors of this step. These

efforts have led to several candidates, some that are on the market and many that are in clinical trials.

To complete the replication cycle, the viral components are assembled into the mature viral particle, or *virion*. For simple, nonenveloped viruses (e.g., the picornavirus poliovirus), the genome and only a few enzymes are encased by capsid proteins to complete the virion. Other, more complex viruses are enveloped by one or more membranes containing carbohydrate and lipoprotein components derived from the host cell membrane.

Once the mature virion has been assembled, it is ready for release from the cell. The release of certain viruses (e.g., poliovirus) is accompanied by lysis of the host cell membrane and cell death. Some of the enveloped viruses, however, are released by *budding* or *exocytosis*, a process involving fusion between the viral envelope and the cell membrane. This process is nearly a reversal of the entry process; the host cell membrane remains intact under these conditions, and the cell may survive.

Chemoprophylaxis is an alternative to active immunization for the prevention of viral infection. With chemoprophylaxis, one uses a chemical agent that interferes with a step in early viral infectivity. The immune system is not directly stimulated by the drug but is required to respond to any active infection. It would seem that the most successful chemoprophylactic agents would be those that prevent penetration of the virus into the host cell. In principle, this can be achieved by blocking any of three steps prior to the start of the replication cycle: (a) attachment of the virion to the host cell via its receptor complex, (b) its entry into the cell via endocytosis, or (c) release of the viral nucleic acid from the protein coat. At present, only a single class of agents affects these early stages of replication.^{13–16} The adamantanamines (amantadine and rimantadine) have been approved for controlling influenza type A infection. These drugs appear to interfere with two stages of influenza type A viral replication: preventing the early stage of viral uncoating and disturbing the late stage of viral assembly. Clinical studies have shown that amantadine and rimantadine are effective in both prophylaxis and treatment of active influenza type A infection.

Chemoprophylaxis Influenza

Amantadine and Rimantadine

Amantadine and rimantadine are both drugs that interfere with penetration of host cells by viruses and block early-stage replication. Amantadine, 1-adamantanamine hydrochloride (Symmetrel), and its α -methyl derivative rimantadine, α -methyl-1-adamantanamine hydrochloride (Flumadine), are unusual caged tricyclic amines with the following structures:

Amantadine

Rimantadine

Amantadine has been used for years as a treatment for Parkinson disease. Both of these agents will specifically inhibit replication of the influenza type A viruses at low concentrations. Rimantadine is generally 4 to 10 times more active than amantadine. The adamantanamines have two mechanisms in common: (a) they inhibit an early step in viral replication, most likely viral uncoating,²⁵ and (b) in some strains, they affect a later step that probably involves viral assembly, possibly by interfering with hemagglutinin processing. The main biochemical locus of action is the influenza type A virus M2 protein, which is an integral membrane protein that functions as an ion channel. The M2 channel is a proton transport system. By interfering with the function of the M2 protein, the adamantanamines inhibit acid-mediated dissociation of the ribonucleoprotein complex early in replication. They also interfere with transmembrane proton pumping, maintaining a high intracellular proton concentration relative to the extracellular concentration and enhancing acidic pH-induced conformational changes in the hemagglutinin during its intracellular transport at a later stage. The conformational changes in hemagglutinin prevent transfer of the nascent virus particles to the cell membrane for exocytosis.

Resistant variants of influenza type A have been recovered from amantadine- and rimantadine-treated patients. Resistance with inhibitory concentrations increased more than 100-fold have been associated with single nucleotide changes that lead to amino acid substitutions in the transmembrane domain of M2. Amantadine and rimantadine share cross-susceptibility and resistance.^{25,26}

Amantadine and rimantadine are approved in the United States for prevention and treatment of influenza type A virus infections. Seasonal prophylaxis with either drug is about 70% to 90% protective²⁷ against influenza type A. The drugs have no effect on influenza type B. The primary side effects are related to the central nervous system and are dopaminergic. This is not surprising, because amantadine is used in the treatment of Parkinson disease. Rimantadine has significantly fewer side effects, probably because of its extensive biotransformation. Less than 50% of a dose of rimantadine is excreted unchanged, and more than 20% appears in the urine as metabolites.²⁸ Amantadine is excreted largely unchanged in the urine.

NEURAMINIDASE INHIBITORS: ZANAMIVIR AND OSELTAMIVIR

Sheathing the protein coat of the influenza virus is a lipid envelope. Two macromolecules, surface glycoproteins, are embedded in the lipid envelope: hemagglutinin and neuraminidase. These glycoproteins fulfill separate functions in the viral cycle. Hemagglutinin is important for binding of the virus to the host cell membrane by a terminal sialic acid residue. Neuraminidase is an enzyme. It functions in several of the early activation steps of the virus and occurs in both influenza A and B viruses. Neuraminidase is believed to be a sialidase, cleaving a bond between a terminal sialic acid unit and a sugar. This action is important in enhancing the penetration of viruses into host cells, and hence enhances the infectivity of the virus. If the sialic acid–sugar bond is prevented from being cleaved, the viruses tend to aggregate and the migration of viruses into host cells is inhibited. Hence, drugs that inhibit neuraminidase should be useful in interfering with infection caused by influenza virus type A and B.

The importance of neuraminidase in the infectivity of influenza types A and B suggests that it should be a good target for the development of antiviral drugs. Indeed, neuraminidase inhibitors are clinically useful agents in blocking the spread of the viruses. The x-ray crystal structure of neuraminidase has been determined, and it shows that the sialic acid-binding site of neuraminidase is nearly identical in influenza types A and B. The transition state of sialic acid cleavage is believed to proceed through a stabilized carbonium ion. Drug molecules that have been developed strongly resemble the transition state. The first of these, 2-deoxy-2,3-dehydro-*N*-acetylneuraminic acid, is a highly active neuraminidase inhibitor but it is not specific for the viral enzyme. This compound has served as a starting point for the development for virus-specific agents. These molecules, zanamivir and oseltamivir, are effective agents in interfering with infection and spread of influenza virus types A and B (recall that amantadine and rimantadine are only effective against type A).

2-deoxy-2,3-dehydro-*N*-acetylneuraminic acid

Zanamivir

X-ray crystallography of 2-deoxy-2,3-dehydro-*N*-acetylneuraminic acid bound to neuraminidase showed the three-dimensional structure of the receptor site at which the sialic acid units on the virus bind. Zanamivir is identical to 2-deoxy-2,3-dehydro-*N*-acetylneuraminic acid except that it possesses a guanidino group at position 4 instead of a hydroxyl group. At positions 119 and 227 of the receptor site, there exist glutamic acid residues. Zanamivir has been shown to form a salt bridge with the guanidine and Glu-119 and a charge transfer interaction with Glu-227. These interactions increase the interaction strength with the enzyme and create an excellent competitive inhibitor and an effective antiviral agent for influenza types A and B.

Human studies have shown that zanamivir is effective when administered before or after exposure to the influenza virus. If administered before exposure to the virus, the drug reduced viral propagation, infectivity, and disease symptoms. If administered after exposure, the drug reduces propagation, viral titer, and illness. Zanamivir is marketed as a dry powder for oral inhalation. It is used in adolescents and adults who

have been exposed and are symptomatic for not more than 2 days. Zanamivir is also indicated for prophylactically treating family members of a person who has developed influenza.

Oseltamivir Phosphate

The x-ray crystal structures of neuraminidase and the viral receptor site showed clearly that additional binding sites exist for the C-5 acetamido carbonyl group and the arginine residue at position 152 of the receptor site. In addition, the C-2 carboxyl group of sialic acid binds to Arg 118, Arg 292, and Arg 371. Position C-6 is capable of undergoing a hydrophobic interaction with various amino acids, including Glu, Ala, Arg, and Ile. Maximum binding to neuraminidase occurs when the C-6 substituent is substituted with a nonpolar chain. In oseltamivir, this nonpolar group is 3-pentyl. An important feature of oseltamivir is the ethyl ester, which makes the drug orally efficacious. This drug is the first orally active agent for use against influenza A and B. It is also indicated for the treatment of acute illness. If administered within 2 days after the onset of influenza symptoms, the drug is effective.

Oseltamivir is actually a prodrug in its ethyl ester form. Ester hydrolysis releases the active oseltamivir molecules.

INTERFERONS: INTERFERON ALFA (INTRON A, ROFERON A) AND INTERFERON BETA (BETASERON)

IFNs are extremely potent cytokines that possess antiviral, immunomodulating, and antiproliferative actions.²⁹ IFNs are synthesized by infected cells in response to various inducers (Fig. 9.2) and, in turn, elicit either an antiviral state in neighboring cells or a natural killer cell response that destroys the initially infected cell (Fig. 9.3). There are three classes of human IFNs that possess significant antiviral activity. These are IFN- α (more than 20 subtypes), IFN- β (2 subtypes), and IFN- γ . IFN- α is used clinically in a recombinant form (called *interferon alfa*). IFN- β (Betaseron) is a recombinant form marketed for the treatment of multiple sclerosis.

IFN- α and IFN- β are produced by almost all cells in response to viral challenge. However, interferon production is not limited to viral stimuli. Various other triggers, including cytokines such as interleukin-1, interleukin-2, and tumor necrosis factor, will elicit the production of IFNs. Both IFN- α and IFN- β are elicited by exposure of a cell to double-stranded viral RNA. IFN- α is produced by lymphocytes and macrophages, whereas IFN- β is biosynthesized in fibroblasts and epithelial cells. IFN- γ production is restricted to T lymphocytes and natural killer cells responding to antigenic stimuli, mitogens, and specific cytokines. IFN- α and IFN- β bind to the same receptor, and the genes for both are encoded on chromosome 9. The receptor for IFN- γ is unique,

Figure 9.2 • Types of interferon.

and only one subtype has been identified. The genes for this molecule are encoded on chromosome 12. IFN- γ has less antiviral activity than IFN- α and IFN- β but more potent immunoregulatory effects. IFN- γ is especially effective in activating macrophages, stimulating cell membrane expression of class II major histocompatibility complexes (MHC-II), and mediating the local inflammatory responses. Most animal viruses are sensitive to the antiviral actions of IFNs. The instances in which a virus is insensitive to IFN typically involve DNA viruses.¹³

On binding to the appropriate cellular receptor, the IFNs induce the synthesis of a cascade of antiviral proteins that contribute to viral resistance. The antiviral effects of the IFNs are mediated through inhibition of³⁰:

- Viral penetration or uncoating
- Synthesis of mRNA
- Translation of viral proteins
- Viral assembly and release

With most viruses, the IFNs predominantly inhibit protein synthesis. This takes place through the intermediacy of IFN-induced proteins such as 2',5'-oligoadenylate (2',5'-OA) synthetases (Fig. 9.4) and a protein kinase, either of which can inhibit viral protein synthesis in the presence of double-stranded RNA. 2',5'-OA activates a cellular endoribonuclease (RNase) (Fig. 9.5) that cleaves both cellular and viral RNA. The protein kinase selectively phosphorylates and inactivates eukaryotic initiation factor 2 (eIF2), preventing initiation of the mRNA-ribosome complex. IFN also induces a specific phosphodiesterase that cleaves a portion of

transfer RNA (tRNA) molecules and thereby interferes with peptide elongation.³⁰ The infection sequence for a given virus may be inhibited at one or several steps. The principal inhibitory effect differs among virus families. Certain viruses can block the production or activity of selected IFN-inducible proteins and thus counter the IFN effect.

IFNs cannot be absorbed orally; to be used therapeutically, they must be given intramuscularly or subcutaneously. The biological effects are quite long, so pharmacokinetic parameters are difficult to determine. The antiviral state in peripheral blood mononuclear cells typically peaks 24 hours after a dose of IFN- α and IFN- β , then decreases to baseline in 6 days.³¹ Both recombinant and natural IFN- α and IFN- β are approved for use in the United States for the treatment of condyloma acuminatum (venereal warts), chronic hepatitis C, chronic hepatitis B, Kaposi sarcoma in HIV-infected patients, other malignancies, and multiple sclerosis.

Attempts have been made to produce drugs that selectively induce interferon production. One such molecule, tilorone induces interferon in murine models but is not effective in humans.

Figure 9.3 • Interferon mechanisms.

Figure 9.4 • IFNs predominantly inhibit protein synthesis.

NUCLEOSIDE ANTIMETABOLITES: INHIBITING VIRAL REPLICATION

Inhibitors of DNA Polymerase

Idoxuridine

Idoxuridine, 5-iodo-2'-deoxyuridine (Stoxil, Herplex), was introduced in 1963 for the treatment of herpes simplex keratitis.³² The drug is an iodinated analog of thymidine that inhibits replication of several DNA viruses in vitro. The

susceptible viruses include the herpesviruses and poxviruses (vaccinia).

The mechanism of action of idoxuridine has not been completely defined, but several steps are involved in the activation of the drug. Idoxuridine enters the cell and is phosphorylated at O-5 by a viral thymidylate kinase to yield a monophosphate, which undergoes further biotransformation to a triphosphate. The triphosphate is believed to be both a substrate and an inhibitor of viral DNA polymerase, causing inhibition of viral DNA synthesis and facilitating the synthesis of DNA that contains the iodinated pyrimidine. The altered DNA is more susceptible to strand breakage and leads to faulty transcription. When the iodinated DNA is transcribed, the results are miscoding errors in RNA and faulty protein synthesis. The ability of idoxuridylic acid to substitute for deoxythymidylic acid in the synthesis of DNA may be a result of the similar van der Waals radii of iodine (2.15 Å) and the thymidine methyl group (2.00 Å).

In the United States, idoxuridine is approved only for the topical treatment of herpes simplex virus (HSV) keratitis;

Figure 9.5 • Structure of 2',5'-oligoadenylate.

although outside the United States, a solution of idoxuridine in dimethyl sulfoxide is available for the treatment of herpes labialis, genitalis, and zoster. The use of idoxuridine is limited because the drug lacks selectivity; low, subtherapeutic concentrations inhibit the growth of uninfected host cells. The effective concentration of idoxuridine is at least 10 times greater than that of acyclovir.

Idoxuridine occurs as a pale yellow, crystalline solid that is soluble in water and alcohol but poorly soluble in most organic solvents. The compound is a weak acid, with a pK_a of 8.25. Aqueous solutions are slightly acidic, yielding a pH of about 6.0. Idoxuridine is light and heat sensitive. It is supplied as a 0.1% ophthalmic solution and a 0.5% ophthalmic ointment.

Cytarabine

Cytarabine is a pyrimidine nucleoside drug that is related to idoxuridine. This agent is primarily used as an anticancer agent for Burkitt lymphoma and myeloid and lymphatic leukemias. Cytarabine blocks the cellular utilization of deoxycytidine, hence inhibiting the replication of viral DNA. Before it becomes active, the drug is converted to monophosphates, diphosphates, and triphosphates, which block DNA polymerase and the C-2 reductase that converts cytidine diphosphate into the deoxy derivative.

The antiviral use of cytarabine is in the treatment of herpes zoster (shingles), herpetic keratitis, and viral infections that resist idoxuridine. Cytarabine is usually administered topically. Toxicity occurs on bone marrow, the gastrointestinal (GI) tract, and the kidneys.

Trifluridine

Trifluridine, 5-trifluoromethyl-29-deoxyuridine (Viroptic), is a fluorinated pyrimidine nucleoside that demonstrates *in vitro* inhibitory activity against HSV-1 and HSV-2, CMV, vaccinia, and some adenoviruses.³³ Trifluridine possesses a trifluoromethyl group instead of an iodine atom at the 5-position of the pyrimidine ring. The van der Waals radius of the trifluoromethyl group is 2.44 Å, somewhat larger than that of the iodine atom.

Like idoxuridine, the antiviral mechanism of trifluridine involves inhibition of viral DNA synthesis. Trifluridine monophosphate is an irreversible inhibitor of thymidylate

synthetase, and the biologically generated triphosphate competitively inhibits thymidine triphosphate incorporation into DNA by DNA polymerase. In addition, trifluridine in its triphosphate form is incorporated into viral and cellular DNA, creating fragile, poorly functioning DNA.

Trifluridine is approved in the United States for the treatment of primary keratoconjunctivitis and recurrent epithelial keratitis caused by HSV types 1 and 2. Topical trifluridine shows some efficacy in patients with acyclovir-resistant HSV cutaneous infections. Trifluridine solutions are heat sensitive and require refrigeration.

Vidarabine

Chemically, vidarabine (Vira-A), is 9- β -D-arabinofuranosyladenine. The drug is the 2' epimer of natural adenosine. Introduced in 1960 as a candidate anticancer agent, vidarabine was found to have broad-spectrum activity against DNA viruses.³⁴ The drug is active against herpesviruses, poxviruses, rhabdoviruses, hepadnavirus, and some RNA tumor viruses. Vidarabine was marketed in the United States in 1977 as an alternative to idoxuridine for the treatment of HSV keratitis and HSV encephalitis. Although the agent was initially prepared chemically, it is now obtained by fermentation with strains of *Streptomyces antibioticus*.

The antiviral action of vidarabine is completely confined to DNA viruses. Vidarabine inhibits viral DNA synthesis. Enzymes within the cell phosphorylate vidarabine to the triphosphate, which competes with deoxyadenosine triphosphate for viral DNA polymerase. Vidarabine triphosphate is also incorporated into cellular and viral DNA, where it acts as a chain terminator. The triphosphate form of vidarabine also inhibits a set of enzymes that are involved in methylation of uridine to thymidine: ribonucleoside reductase, RNA polyadenylase, and *S*-adenosylhomocysteine hydrolase.

At one time in the United States, intravenous vidarabine was approved for use against HSV encephalitis, neonatal herpes, and herpes or varicella zoster in immunocompromised patients. Acyclovir has supplanted vidarabine as the drug of choice in these cases.

In the treatment of viral encephalitis, vidarabine had to be administered by constant flow intravenous infusion because of its poor water solubility and rapid metabolic conversion to a hypoxanthine derivative *in vivo*. These problems, coupled with the availability of less toxic and more effective agents, have caused intravenous vidarabine to be withdrawn from the U. S. market.

Vidarabine occurs as a white, crystalline monohydrate that is soluble in water to the extent of 0.45 mg/mL at 25°C. The drug is still available in the United States as a 3% ointment for the treatment of HSV keratitis.

Adefovir Dipivoxil

Adefovir is an orally active prodrug that is indicated for the treatment of the chronic form of hepatitis B. The dipivoxil

moieties are hydrolyzed by ubiquitous esterases to yield adefovir, which is phosphorylated by adenylate kinase to yield adefovir diphosphate. This compound is inhibitory at HBV DNA polymerase. In addition, adefovir undergoes incorporation into viral DNA and causes chain termination. Adefovir is poorly absorbed by the oral route, but the dipivoxil ester groups cause the bioavailability to increase to approximately 60%.

Acyclovir

Acyclovir, 9-[2-(hydroxyethoxy)methyl]-9H-guanine (Zovirax), is the most effective of a series of acyclic nucleosides that possess antiviral activity. In contrast with true nucleosides that have a ribose or a deoxyribose sugar attached to a purine or a pyrimidine base, the group attached to the base in acyclovir is similar to an open chain sugar, albeit lacking in hydroxyl groups. The clinically useful antiviral spectrum of acyclovir is limited to herpesviruses. It is most active (in vitro) against HSV type 1, about two times less against HSV type 2, and 10 times less potent against varicella-zoster virus (VZV). An advantage is that uninfected human cells are unaffected by the drug.

The ultimate effect of acyclovir is the inhibition of viral DNA synthesis. Transport into the cell and monophosphorylation are accomplished by a thymidine kinase that is encoded by the virus itself.³⁵ The affinity of acyclovir for the viral thymidine kinase is about 200 times that of the corresponding mammalian enzyme. Hence, some selectivity is attained. Enzymes in the infected cell catalyze the conversion of the monophosphate to acyclovir triphosphate, which is present in 40 to 100 times greater concentrations in HSV-infected than uninfected cells. Acyclovir triphosphate competes for endogenous deoxyguanosine triphosphate (dGTP); hence, acyclovir triphosphate competitively inhibits viral DNA polymerases. The triphosphorylated drug is also incorporated into viral DNA, where it acts as a chain terminator. Because it has no 3'-hydroxyl group, no 3',5'-phosphodiester bond can form. This mechanism is essentially a suicide inhibition because the terminated DNA template containing acyclovir as a ligand binds to, and irreversibly inactivates, DNA polymerase. Resistance to acyclovir can occur, most often by deficient thymidine kinase activity in HSV isolates. Acyclovir

resistance in vesicular stomatitis virus (VSV) isolates is caused by mutations in VSV thymidine kinase or, less often, by mutations in viral DNA polymerase.

Two dosage forms of acyclovir are available for systemic use: oral and parenteral. Oral acyclovir is used in the initial treatment of genital herpes and to control mild recurrent episodes. It has been approved for short-term treatment of shingles and chickenpox caused by VZV. Intravenous administration is indicated for initial and recurrent infections in immunocompromised patients and for the prevention and treatment of severe episodes. The drug is absorbed slowly and incompletely from the GI tract, and its oral bioavailability is only 15% to 30%. Nevertheless, acyclovir is distributed to virtually all body compartments. Less than 30% is bound to protein. Most of the drug is excreted unchanged in the urine, about 10% excreted as the carboxy metabolite.

Acyclovir occurs as a chemically stable, white, crystalline solid that is slightly soluble in water. Because of its amphoteric properties (pK_a values of 2.27 and 9.25), solubility is increased by both strong acids and bases. The injectable form is the sodium salt, which is supplied as a lyophilized powder, equivalent to 50 mg/mL of active acyclovir dissolved in sterile water for injection. Because the solution is strongly alkaline ($pH \sim 11$), it must be administered by slow, constant intravenous infusion to avoid irritation and thrombophlebitis at the injection site.

Adverse reactions are few. Some patients experience occasional GI upset, dizziness, headache, lethargy, and joint pain. An ointment composed of 5% acyclovir in a polyethylene glycol base is available for the treatment of initial, mild episodes of herpes genitalis. The ointment is not an effective preventer of recurrent episodes.

Valacyclovir Hydrochloride

Valacyclovir (Valtrex) is the hydrochloride salt of the L-valyl ester of acyclovir. The compound is a water-soluble crystalline solid, and it is a prodrug intended to increase the bioavailability of acyclovir by increasing lipophilicity. Valacyclovir is hydrolyzed rapidly and almost completely to acyclovir following oral administration. Enzymatic hydrolysis of the prodrug is believed to occur during enterohepatic cycling. The oral bioavailability of valacyclovir is three to five times that of acyclovir, or about 50%.³⁶

Valacyclovir has been approved for the treatment of herpes zoster (shingles) in immunocompromised patients. The side effect profile observed in valacyclovir is comparable with bioequivalent doses of acyclovir. Less than 1% of an administered dose of valacyclovir is recovered in the urine. Most of the dose is eliminated as acyclovir.

Ganciclovir

Ganciclovir, 9-[(1,3-dihydroxy-2-propoxy)methyl]guanine) or DHPG (Cytovene), is an analog of acyclovir, with

an additional hydroxymethyl group on the acyclic side chain.

This structural modification, while maintaining the activity against HSV and VSV possessed by acyclovir, greatly enhances the activity against CMV infection.

After administration, similar to acyclovir, ganciclovir is phosphorylated inside the cell by a virally encoded protein kinase to the monophosphate.³⁷ Host cell enzymes catalyze the formation of the triphosphate, which reaches more than 10-fold higher concentrations in infected cells than in uninfected cells. This selectivity is caused by the entry and monophosphorylation step. Further phosphorylation with cellular enzymes occurs, and the triphosphate that is formed selectively inhibits viral DNA polymerase. Ganciclovir triphosphate is also incorporated into viral DNA causing strand breakage and cessation of elongation.³⁸

The clinical usefulness of ganciclovir is limited by the toxicity of the drug. Ganciclovir causes myelosuppression, producing neutropenia, thrombocytopenia, and anemia. These effects are probably associated with inhibition of host cell DNA polymerase.³⁹ Potential central nervous system side effects include headaches, behavioral changes, and convulsions. Ganciclovir is mutagenic, carcinogenic, and teratogenic in animals.

Toxicity limits its therapeutic usefulness to the treatment and suppression of sight-threatening CMV retinitis in immunocompromised patients and to the prevention of life-threatening CMV infections in at-risk transplant patients.²¹

Oral and parenteral dosage forms of ganciclovir are available, but oral bioavailability is poor. Only 5% to 10% of an oral dose is absorbed. Intravenous administration is preferable. More than 90% of the unchanged drug is excreted in the urine. Ganciclovir for injection is available as a lyophilized sodium salt for reconstitution in normal saline, 5% dextrose in water, or lactated Ringer solution. These solutions are strongly alkaline (pH ~11) and must be administered by slow, constant, intravenous infusion to avoid thrombophlebitis.

Famciclovir and Penciclovir

Famciclovir is a diacetyl prodrug of penciclovir.⁴⁰ As a prodrug, it lacks antiviral activity. Penciclovir, 9-[4-hydroxy-3-hydroxymethylbut-1-yl] guanine, is an acyclic guanine

Guanosine

Penciclovir

Famciclovir

Penciclovir

nucleoside analog. The structure is similar to that of acyclovir, except in penciclovir, a side chain oxygen has been replaced by a carbon atom and an extra hydroxymethyl group is present. Inhibitory concentrations for HSV and VSV are typically within twice that of acyclovir. Penciclovir also inhibits the growth of hepatitis B virus.

Penciclovir inhibits viral DNA synthesis. In HSV- or VSV-infected cells, penciclovir is first phosphorylated by viral thymidine kinase⁴¹ and then further elaborated to the triphosphate by host cell kinases. Penciclovir triphosphate is a competitive inhibitor of viral DNA polymerase. The pharmacokinetic parameters of penciclovir are quite different from those of acyclovir. Although penciclovir triphosphate is about 100-fold less potent in inhibiting viral DNA polymerase than acyclovir triphosphate, it is present in the tissues for longer periods and in much higher concentrations than acyclovir. Because it is possible to rotate the side chain of penciclovir into a pseudopentose, the triphosphorylated metabolite possesses a 3'-hydroxyl group. This relationship is shown on page 342 with guanosine. Penciclovir is not an obligate chain terminator,⁴¹ but it does competitively inhibit DNA elongation. Penciclovir is excreted mostly unchanged in the urine.

Penciclovir (Denvir) has been approved for the topical treatment of recurrent herpes labialis (cold sores) in adults. It is effective against HSV-1 and HSV-2.⁴² It is available as a cream containing 10% penciclovir.

Cidofovir

Cidofovir, (*S*)-3-hydroxy-2-phosphonomethoxypropyl cytosine (HPMPC, Vistide), is an acyclonucleotide analog that possesses broad-spectrum activity against several DNA viruses. Unlike other nucleotide analogs that are activated to nucleoside phosphates, Cidofovir is a phosphonic acid derivative. The phosphonic acid is not hydrolyzed by phosphatases in vivo but is phosphorylated by cellular kinases to yield a diphosphate. The diphosphate acts as an antimetabolite to deoxycytosine triphosphate (dCTP). Cidofovir diphosphate is a competitive inhibitor of viral DNA⁴³ polymerase and can be incorporated into the growing viral DNA strand, causing DNA chain termination.

Cidofovir possesses a high therapeutic index against CMV and has been approved for treating CMV retinitis in patients with AIDS. Cidofovir is administered by slow, constant intravenous infusion in a dose of 5 mg/kg over a 1-hour period once a week for 2 weeks. This treatment is followed by a maintenance dose every 2 weeks. About 80% of a dose of Cidofovir is excreted unchanged in the urine, with a $t_{1/2elim}$ of 2 to 3 hours. The diphosphate antimetabolite, in contrast, has an extremely long half-life (17–30 hours).

The main dose-limiting toxicity of cidofovir involves renal impairment. Renal function must be monitored closely. Pretreatment with probenecid and prehydration with intravenous normal saline can be used to reduce the nephrotoxicity of the drug. Patients must be advised that

cidofovir is not a cure for CMV retinitis. The disease may progress during or following treatment.

Foscarnet Sodium

Trisodium phosphonoformate is an inorganic pyrophosphate analog that inhibits replication in herpesviruses (CMV, HSV, and VSV) and retroviruses (HIV).⁴⁴ Foscarnet (Foscavir) is taken up slowly by the cells and does not undergo significant intracellular metabolism. Foscarnet is a reversible, noncompetitive inhibitor at the pyrophosphate-binding site of the viral DNA polymerase and RT. The ultimate effect is inhibition of the cleavage of pyrophosphate from deoxynucleotide triphosphates and a cessation of the incorporation of nucleoside triphosphates into DNA (with the concomitant release of pyrophosphate).⁴⁵ Because the inhibition is noncompetitive with respect to nucleoside triphosphate binding, foscarnet can act synergistically with nucleoside triphosphate antimetabolites (e.g., zidovudine and didanosine triphosphates) in the inhibition of viral DNA synthesis. Foscarnet does not require bioactivation by viral or cellular enzymes and, hence, can be effective against resistant viral strains that are deficient in virally encoded nucleoside kinases.⁴⁵

Foscarnet is a second-line drug for the treatment of retinitis caused by CMV in patients with AIDS. The drug causes metabolic abnormalities including increases or decreases in blood Ca^{2+} levels. Nephrotoxicity is common, and this side effect precludes the use of foscarnet in other infections caused by herpesvirus or as single-agent therapy for HIV infection. Foscarnet is an excellent ligand for metal ion binding, which undoubtedly contributes to the electrolyte imbalances observed with the use of the drug.⁴⁶ Hypocalcemia, hypomagnesemia, hypokalemia, and hypophosphatemia and hyperphosphatemia are observed in patients treated with foscarnet. Side effects such as paresthesias, tetani, seizures, and cardiac arrhythmias may result. Because foscarnet is nephrotoxic, it may augment the toxic effects of other nephrotoxic drugs, such as amphotericin B and pentamidine, which are frequently used to control opportunistic infections in patients with AIDS.

Foscarnet sodium is available as a sterile solution intended for slow intravenous infusion. The solution is compatible with normal saline and 5% dextrose in water but is incompatible with calcium-containing buffers such as lactated Ringer solution and total parenteral nutrition (TPN) preparations. Foscarnet reacts chemically with acid salts such as midazolam, vancomycin, and pentamidine. Over 80% of an injected dose of foscarnet is excreted unchanged in the urine.⁴⁴ The long elimination half-life of foscarnet is thought to result from its reversible sequestration into bone.⁴⁶

Reverse Transcriptase Inhibitors

An early event in the replication of HIV-1 is reverse transcription, whereby genomic RNA from the virus is converted into a cDNA–RNA complex, then into double-stranded DNA ready for integration into the host chromosome. The enzyme that catalyzes this set of reactions is *reverse tran-*

scriptase. RT actually operates twice prior to the integration step. Its first function is the creation of the cDNA–RNA complex; RT acts alone in this step. In the second step, the RNA chain is digested away by RNase H, whereas RT creates the double-stranded unintegrated DNA.

All of the classical antiretroviral agents are 2',3'-dideoxynucleoside analogs. These compounds share a common mechanism of action in inhibiting the RT of HIV. Because RT acts early in the viral infection sequence, inhibitors of the enzyme block acute infection of cells but are only weakly active in chronically infected ones. Even though the RT inhibitors share a common mechanism of action, their pharmacological and toxicological profiles differ dramatically.

Zidovudine

Zidovudine, 3'-azido-3'-deoxythymidine or AZT, is an analog of thymidine that possesses antiviral activity against HIV-1, HIV-2, HTLV-1, and several other retroviruses. This nucleoside was synthesized in 1978 by Lin and Prusoff⁴⁷ as an intermediate in the preparation of amino acid analogs of thymidine. A screening program directed toward the identification of agents potentially effective for the treatment of patients with AIDS led to the discovery of its unique antiviral properties 7 years later.⁴⁸ The next year, the clinical effectiveness of AZT in patients with AIDS and AIDS-related complex (ARC) was demonstrated.⁴⁹ AZT is active against retroviruses, a group of RNA viruses responsible for AIDS and some kinds of leukemia. Retroviruses possess a RT or an RNA-directed DNA polymerase that directs the synthesis of a DNA copy (proviral DNA) of the viral RNA genome that is duplicated, circularized, and incorporated into the DNA of an infected cell. The drug enters the host cells by diffusion and is phosphorylated by cellular thymidine kinase. Thymidylate kinase then converts the monophosphate into diphosphates and triphosphates. The rate-determining step is conversion to the diphosphate, so high levels of monophosphorylated AZT accumulate in the cell. Low levels of diphosphate and triphosphate are present. Zidovudine triphosphate competitively inhibits RT with respect to thymidine triphosphate. The 3'-azido group prevents formation of a 5',3'-phosphodiester bond, so AZT causes DNA chain termination, yielding an incomplete proviral DNA.⁵⁰ Zidovudine monophosphate also competitively inhibits cellular thymidylate kinase, thus decreasing intracellular levels of thymidine triphosphate. The antiviral selectivity of AZT is caused by its greater (100×)⁵¹ affinity for HIV RT than for human DNA polymerases. The human γ -DNA polymerase of mitochondria is more sensitive to zidovudine; this may contribute to the toxicity associated with the drug's use. Resistance is common and is a result of point mutations at multiple sites in RT, leading to a lower affinity for the drug.⁵²

Zidovudine is recommended for the management of adult patients with symptomatic HIV infection (AIDS or ARC) who have a history of confirmed *Pneumocystis carinii* pneumonia or an absolute CD4⁺ (T4 or T_H cell) lymphocyte count below 200/mm³ before therapy. The hematological toxicity of the drug precludes its use in asymptomatic patients. Anemia and granulocytopenia are the most common toxic effects associated with AZT.

For oral administration, AZT is supplied as 100-mg capsules and as a syrup containing 10 mg AZT per mL. The injectable form of AZT contains 10 mg/mL and is injected intravenously. AZT is absorbed rapidly from the GI tract and distributes well into body compartments, including the cerebrospinal fluid (CSF). It is metabolized rapidly to an inactive glucuronide in the liver. Only about 15% is excreted unchanged. Because AZT is an aliphatic azide, it is heat and light sensitive. It should be protected from light and stored at 15°C to 25°C.

Didanosine

Didanosine (Videx, ddI) is 2',3'-dideoxyinosine (ddI), a synthetic purine nucleoside analog that is bioactivated to 2',3'-dideoxy-ATP (ddATP) by host cellular enzymes.⁵³ The metabolite, ddATP, accumulates intracellularly, where it inhibits RT and is incorporated into viral DNA to cause chain termination in HIV-infected cells. The potency of didanosine is 10- to 100-fold less than that of AZT with respect to antiviral activity and cytotoxicity, but the drug causes less myelosuppression than AZT causes.⁵⁴

Didanosine is recommended for the treatment of patients with advanced HIV infection who have received prolonged treatment with AZT but have become intolerant to, or experienced immunosuppression from, the drug. AZT and ddI act synergistically to inhibit HIV replication in vitro, and ddI is effective against some AZT-resistant strains of HIV.⁵⁵ Painful peripheral neuropathy (tingling, numbness, and pain in the hands and feet) and pancreatitis (nausea, abdominal pain, elevated amylase) are the major dose-limiting toxicities of didanosine. Didanosine is given orally in the form of buffered chewable tablets or as a solution prepared from the powder. Both oral dosage forms are buffered to prevent acidic decomposition of ddI to hypoxanthine in the stomach. Despite the buffering of the dosage forms, oral bioavailability is quite low and highly variable. Less than 20% of a dose is excreted in the urine, which suggests extensive metabolism.⁵⁶ Food interferes with absorption, so the oral drug must be given at least 1 hour before or 2 hours after meals. High-dose therapy can cause hyperuricemia in some patients because of the increased purine load.

Zalcitabine

Zalcitabine, 2',3'-dideoxycytidine or ddCyd, is an analog of cytosine that demonstrates activity against HIV-1 and HIV-2,

including strains resistant to AZT. The potency (in peripheral blood mononuclear cells) is similar to that of AZT, but the drug is more active in populations of monocytes and macrophages as well as in resting cells.

Zalcitabine enters human cells by carrier-facilitated diffusion and undergoes initial phosphorylation by deoxycytidine kinase. The monophosphorylated compound is further metabolized to the active metabolite, dideoxycytidine-5'-triphosphate (ddCTP), by cellular kinases.⁵⁷ ddCTP inhibits RT by competitive inhibition with dCTP. Most likely, ddCTP causes termination of the elongating viral DNA chain.

Zalcitabine inhibits host mitochondrial DNA synthesis at low concentrations. This effect may contribute to its clinical toxicity.⁵⁸

The oral bioavailability of zalcitabine is over 80% in adults and less in children.⁵⁹ The major dose-limiting side effect is peripheral neuropathy, characterized by pain, paresthesias, and hypesthesia, beginning in the distal lower extremities. These side effects are typically evident after several months of therapy with zalcitabine. A potentially fatal pancreatitis is another toxic effect of treatment with ddC. The drug has been approved for the treatment of HIV infection in adults with advanced disease who are intolerant to AZT or who have disease progression while receiving AZT. ddC is combined with AZT for the treatment of advanced HIV infection.

Stavudine

Stavudine, 2',3'-didehydro-2'-deoxythymidine (D4T, Zerit), is an unsaturated pyrimidine nucleoside that is related to thymidine. The drug inhibits the replication of HIV by a mechanism similar to that of its close congener, AZT.⁶⁰ Stavudine is bioactivated by cellular enzymes to a triphosphate. The triphosphate competitively inhibits the incorporation of thymidine triphosphate (TTP) into retroviral DNA by RT.⁶¹ Stavudine also causes termination of viral DNA elongation through its incorporation into DNA.

Stavudine is available as capsules for oral administration. The drug is acid stable and well absorbed (about 90%) following oral administration. Stavudine has a short half-life (1–2 hours) in plasma and is excreted largely unchanged (85%–90%) in the urine.⁶² As with ddC, the primary dose-limiting effect is peripheral neuropathy. At the recommended dosages, approximately 15% to 20% of patients ex-

perience symptoms of peripheral neuropathy. Stavudine is recommended for the treatment of adults with advanced HIV infection who are intolerant of other approved therapies or who have experienced clinical or immunological deterioration while receiving these therapies.

Abacavir

Abacavir is a nucleoside reverse transcriptase inhibitor NRTI that has been approved for use in combination therapies for the treatment of HIV and AIDS. Once in the tissues, it is metabolized by stepwise phosphorylation to the monophosphate, diphosphate, and triphosphate. Abacavir is highly bioavailable (>75%) and is effective by the oral route. It penetrates the blood-brain barrier efficiently. Abacavir has been reported to produce life-threatening hypersensitivity reactions in some patients.

Tenofovir Disoproxil

Tenofovir disoproxil is a prodrug analogously with abacavir. Plasma and tissue esterases cleave the phosphate protecting groups, releasing the active drug. The bioavailability of tenofovir is about 35% when administered with food. The drug is approved by the Food and Drug Administration (FDA) for the treatment of HIV infections in adult patients. Recommendations are for the drug to be administered with other RT inhibitors or PIs to achieve synergism.

Lamivudine

Lamivudine is (–)-2',3'-dideoxy-3'-thiacytidine, (–)-β-L-(2*R*,5*S*)-1,3-oxathiolanylcytosine, 3TC, or (–)-(*S*)-ddC. Lamivudine is a synthetic nucleoside analog that differs from 2',3'-dideoxycytidine (ddC) by the substitution of a sulfur atom in place of a methylene group at the 3'-position of the ribose ring. In early clinical trials, lamivudine exhibited highly promising antiretroviral activity against HIV and low toxicity in the dosages studied.^{63,64} Preliminary pharmacokinetic studies indicated that it exhibited good oral bioavailability ($F = \sim 80\%$) and a plasma half-life of 2 to 4 hours.⁶³

It is interesting that the unnatural stereoisomer (–)-(*S*)-ddC exhibits greater antiviral activity against HIV than the natural enantiomer (+)-(*S*)-ddC.⁶⁵ Both enantiomers are bioactivated by cellular kinases to the corresponding triphosphates.⁶⁶ Both SddCTP isomers inhibit HIV RT and are incorporated into viral DNA to cause chain termination. (+)-*S*-ddCTP inhibits cellular DNA polymerases much more strongly than (–)-SddCTP, explaining the greater toxicity associated with (+)-(*S*)-ddC. Initial metabolic comparison of SddCTP isomers has failed to explain the greater potency of the (–)-isomer against HIV. Therefore, although the intracellular accumulation of (–)-*S*-ddCTP was twice that of (+)-*S*-ddCTP, the latter was one and a half times more potent as an inhibitor of HIV RT, and the two isomers were incorporated into viral DNA at comparable rates. The puzzle was solved with the discovery of a cellular 3',5'-exonuclease, which was found to cleave terminal (+)-*S*-ddCMP incorporated into viral DNA 6 times faster than (–)-*S*-ddCMP from the viral DNA terminus.

Resistance to lamivudine develops rapidly as a result of a mutation in codon 184 of the gene that encodes HIV-RT when the drug is used as monotherapy for HIV infection.⁶⁴ When combined with AZT, however, lamivudine caused substantial increases in CD4⁺ counts. The elevated counts were sustained over the course of therapy.⁶⁷ The codon mutation that causes resistance to lamivudine suppresses AZT resistance,⁶⁷ thus increasing the susceptibility of the virus to the drug combination.

Emtricitabine

Emtricitabine is an orally active NRTI whose pharmacokinetics are favorable for once-daily administration.

Miscellaneous Nucleoside Antimetabolites

Ribavirin

Ribavirin is 1-β-D-ribofuranosyl-1,2,4-thiazole-3-carboxamide. The compound is a purine nucleoside analog with a modified base and a D-ribose sugar moiety.

Ribavirin inhibits the replication of a very wide variety of RNA and DNA viruses,⁶⁸ including orthomyxoviruses, paramyxoviruses, arenaviruses, bunyaviruses, herpesviruses, adenoviruses, poxvirus, vaccinia, influenza virus (types A and B), parainfluenza virus, and rhinovirus. In spite of the broad spectrum of activity of ribavirin, the drug has been approved for only one therapeutic indication—the treatment of severe lower respiratory infections caused by RSV in carefully selected hospitalized infants and young children.

The mechanism of action of ribavirin is not known. The broad antiviral spectrum of ribavirin, however, suggests multiple modes of action.⁶⁹ The nucleoside is bioactivated by viral and host cellular kinases to give the monophosphate (RMP) and the triphosphate (RTP). RMP inhibits inosine monophosphate (IMP) dehydrogenase, thereby preventing the conversion of IMP to xanthine monophosphate (XMP). XMP is required for guanosine triphosphate (GTP) synthesis. RTP inhibits viral RNA polymerases. It also prevents the end capping of viral mRNA by inhibiting guanyl-*N'*-methyltransferase. Emergence of viral resistance to ribavirin has not been documented.

Ribavirin occurs as a white, crystalline, polymorphic solid that is soluble in water and chemically stable. It is supplied as a powder to be reconstituted in an aqueous aerosol containing 20 mg/mL of sterile water. The aerosol is administered with a small-particle aerosol generator (SPAG). Deterioration in respiratory function, bacterial pneumonia, pneumothorax, and apnea have been reported in severely ill infants and children with RSV infection. The role of ribavirin in these events has not been determined. Anemia, headache, abdominal pain, and lethargy have been reported in patients receiving oral ribavirin.

Unlabeled uses of ribavirin include aerosol treatment of influenza types A and B and oral treatment of hepatitis, genital herpes, and Lassa fever. Ribavirin does not protect cells against the cytotoxic effects of the AIDS virus.

NEWER AGENTS FOR THE TREATMENT OF HIV INFECTION

When HIV-1 was characterized and identified as the causative agent of AIDS in 1983,^{70,71} scientists from all over the world joined in the search for a prevention or cure for the disease. Mapping the HIV-1 genome and elucidating the replication cycle of the virus have supplied key information.⁷² Biochemical targets, many of which are proteins involved in the replication cycle of the virus, have been cloned and sequenced. These have been used to develop rapid, mechanism-based assays for the virus to complement tissue culture screens for whole virus. Several of the biochemical steps that

have been characterized have served as targets for clinical candidates as well as for successfully licensed drugs.^{73,74}

Despite the many advances in the understanding of the HIV virus and its treatment, there is not yet a cure for the infection. Emergent resistance⁷⁵ to clinically proven drugs such as the RT inhibitors and the PIs has complicated the picture of good therapeutic targets. The idea of using a vaccine as a therapeutic tool has been complicated by the fact that the vaccine apparently can modulate its antigenic structures in its chronic infectious state.⁷⁶

Vaccines

The chronology of vaccine development and use in the 20th century is nothing short of a medical miracle. Diseases such as smallpox and polio, which once ravaged large populations, have become distant memories. The technique of sensitizing a human immune system by exposure to an antigen so that an anamnestic response is generated on subsequent exposure seems quite simple on the surface. Hence, it is natural that a vaccine approach to preventing AIDS be tried. The successes achieved so far have involved live/attenuated or killed whole-cell vaccines and, in more recent times, recombinant coat proteins.

Successes with vaccines of the live/attenuated (low-virulence), killed whole virus or the recombinant coat protein types have primarily involved acute viral diseases in which a natural infection and recovery lead to long-term immunity.

This type of immunity is of the humoral or antibody-mediated type, and it is the basis for successes in immunizing the human population. Causative organisms of chronic infections do not respond to vaccines. The AIDS virus causes a chronic disease in which infection persists despite a strong antibody response to the virus (at least initially, HIV can circumvent the humoral response to infection by attacking and killing CD4⁺ T cells). These T cells, also known as *T-helper cells*, upregulate the immune response. By eradicating the CD4⁺ cells, the HIV virus effectively destroys the immune system. Cell-mediated immune responses are critical to the prevention and treatment of HIV infection. To be effective, a vaccine against HIV must elicit an appropriate cellular immune response in addition to a humoral response. In other words, the vaccine must have the potential to act on both branches of the immune system.

The initial work on vaccine development focused on isotopic variants of the HIV envelope glycoprotein gp120 obtained by recombinant DNA techniques. This target was chosen because of concerns about the safety of live/attenuated vaccines. The gp120 glycoprotein is a coat protein, and if great care is taken, a virus-free vaccine is obtainable. Moreover, glycoprotein gp120 is the primary target for neutralizing antibodies associated with the first (attachment) step in HIV infection.⁷⁷ Early vaccines were so ineffective that the National Institutes of Health suspended plans for massive clinical trials in high-risk individuals.⁷⁸ There are several reasons why the vaccine failed.⁷⁹ There are multiple subtypes of the virus throughout the world; the virus can infect by means of both cell-free and cell-associated forms; the virus has demonstrated its own immunosuppressive, immunopathological, and infection-enhancing properties of parts of the envelope glycoprotein; and vaccines have not been able to stimulate and maintain high enough levels of immunity to be effective.

The failure of the first generation of AIDS vaccines led to a reexamination of the whole AIDS vaccine effort.⁷⁹ As a guide for research efforts, several criteria for an “ideal” AIDS vaccine have been developed. The ideal AIDS vaccine should (a) be safe, (b) elicit a protective immune response in a high proportion of vaccinated individuals, (c) stimulate both cellular and humoral branches of the immune system, (d) protect components against all major HIV subtypes, (e) induce long-lasting protection, (f) induce local immunity in both genital and rectal mucosa, and (g) be practical for worldwide delivery and administration. It is not yet known how well the second-generation AIDS vaccines will satisfy the previously described criteria or when one might receive approval for widespread use in humans.

A new era in the treatment of AIDS and ARC was ushered in with the advent of some clinically useful, potent inhibitors of HIV. For the first time in the history of AIDS, the death rate reversed itself. There are several different classes of drugs that can be used to treat HIV infection. These are the NRTIs, the NNRTIs, the HIV PIs, the HIV entry inhibitors, and the HIV integrase inhibitors (IN). At present, at least 14 antiretroviral agents belonging to three distinct classes (NRTIs, NNRTIs, PIs) have been licensed for use in patients in the United States. All of these agents are limited by rapid development of resistance and cross-resistance; so commonly, three drugs are used at the same time, each acting at a different point in HIV replication. These drugs can effect dramatic reductions in viral load, but eventually, as resistance develops, the virus reasserts itself.

Nonnucleoside Reverse Transcriptase Inhibitors

Cloned HIV-1 RT facilitates the study of the effects of a novel compound on the kinetics of the enzyme. Random screening of chemical inventories by the pharmaceutical industry has led to the discovery of several NNRTIs of the enzyme. These inhibitors represent several structurally distinct classes. The NNRTIs share several common biochemical and pharmacological properties.^{74,80,81} Unlike the nucleoside antimetabolites, the NNRTIs do not require bioactivation by kinases to yield phosphate esters. They are not incorporated into the growing DNA chain. Instead, they bind to an allosteric site that is distinct from the substrate (nucleoside triphosphate)-binding site of RT. The inhibitor can combine with either free or substrate-bound enzyme, interfering with the action of both. Such binding distorts the enzyme, so that it cannot form the enzyme-substrate complex at its normal rate, and once formed, the complex does not decompose at the normal rate to yield products. Increasing the substrate concentration does not reverse these effects. Hence, NNRTIs exhibit a classical noncompetitive inhibition pattern with the enzyme.

The NNRTIs are extremely potent in *in vitro* cell culture assays and inhibit HIV-1 at nanomolar concentrations. NNRTIs inhibit RT selectively; they do not inhibit the RTs of other retroviruses, including HIV-2 and simian immunodeficiency virus (SIV). The NNRTIs have high therapeutic indices (in contrast to the nucleosides) and do not inhibit mammalian DNA polymerases. The NRTIs and NNRTIs are expected to exhibit a synergistic effect on HIV, because they interact with different mechanisms on the enzyme. The

chief problem with the NNRTIs is the rapid emergence of resistance among HIV isolates.⁷⁵ Resistance is a result of point mutations in the gene coding for the enzyme. Cross-resistance between structurally different NNRTIs is more common than between NNRTIs and NRTIs. In the future, clinical use of the NNRTIs is expected to use combinations with the nucleosides to reduce toxicity to the latter, to take advantage of additive or synergistic effects, and to reduce the emergence of viral resistance.^{75,80} The tricyclic compound nevirapine (Viramune),⁸² the bis(heteroacyl)piperazine (BHAP) derivative delavirdine (Rescriptor),⁸³ and efavirenz⁸⁴ have been approved for use in combination with NRTIs such as AZT for the treatment of HIV infection. Numerous others, including the quinoxaline derivative GW-420867X,⁸⁴ the tetrahydroimidazobenzodiazpinone (TIBO) analog R-82913,⁸⁵ and calanolide-A⁸⁴ are in clinical trials.

Nevirapine

Nevirapine (Viramune)⁸² is more than 90% absorbed by the oral route and is widely distributed throughout the body. It distributes well into breast milk and crosses the placenta. Transplacental concentrations are about 50% those of serum. The drug is extensively transformed by cytochrome P450 (CYP) to inactive hydroxylated metabolites; it may undergo enterohepatic recycling.

The half-life decreases from 45 to 23 hours over a 2- to 4-week period because of autoinduction. Elimination occurs through the kidney, with less than 3% of the parent compound excreted in the urine.⁸² Dosage forms are supplied as a 50 mg/5 mL oral suspension and a 200-mg tablet.

Delavirdine

Delavirdine (Rescriptor)⁸³ must be used with at least two additional antiretroviral agents to treat HIV-1 infections. The oral absorption of delavirdine is rapid, and peak plasma concentrations develop in 1 hour. Extensive metabolism occurs in the liver by CYP isozyme 3A (CYP3A) or possibly CYP2D6. Bioavailability is 85%. Unlike nevirapine, which is 48% protein bound, delavirdine is more than 98% protein bound. The half-life is 2 to 11 hours, and elimination is 44% in feces, 51% in urine, and less than 5% unchanged in urine. Delavirdine induces its own metabolism.⁸³ Oral dosage forms are supplied as a 200-mg capsule and a 100-mg tablet.

Efavirenz

Efavirenz (Sustiva)⁸⁴ is also mandated for use with at least two other antiretroviral agents. The compound is more than 99% protein bound, and CSF concentrations exceed the free fraction in the serum. Metabolism occurs in the liver. The half-life of a single dose of efavirenz is 52 to 76 hours, and 40 to 55 after multiple doses (the drug induces its own metabolism). Peak concentration is achieved in 3 to 8 hours. Elimination is 14% to 34% in urine (as metabolites) and 16% to 41% in feces (primarily as efavirenz).⁸⁴ The oral dosage form is supplied as a capsule.

HIV Protease Inhibitors

A unique biochemical target in the HIV-1 replication cycle was revealed when HIV protease was cloned and expressed^{86,87} in *Escherichia coli*. HIV protease is an enzyme that cleaves gag-pro propeptides to yield active enzymes that function in the maturation and propagation of new virus. The catalytically active protease is a symmetric dimer of two identical 99 amino acid subunits, each contributing the triad Asp-Thr-Gly to the active site.^{86,87} The homodimer is unlike monomeric aspartyl proteases (renin, pepsin, cathepsin D), which also have different substrate specificities. The designs of some inhibitors^{86,87} for HIV-1 protease exploit the C₂ symmetry of the enzyme. HIV-1 protease has active site specificity for the triad Tyr-Phe-Pro in the unit Ser-(Thr)-Xaa-Xaa-Tyr-Phe-Pro, where Xaa is an arbitrary amino acid.

HIV PIs are designed to mimic the transition state of hydrolysis at the active site; these compounds are called *analog inhibitors*. Hydrolysis of a peptide bond proceeds through a transition state that is sp³ hybridized and, hence, tetrahedral. The analog inhibitors possess a preexisting sp³ hybridized center that will be drawn into the active site (one hopes with high affinity) but will not be cleavable by the enzyme. This principle has been used to prepare hundreds of potentially useful transition state inhibitors.^{86,87} Unfortunately, very few of these are likely to be clinically successful candidates for the treatment of HIV infection. Because HIV PIs are aimed at arresting replication of the virus at the maturation step to prevent the spread of cellular infection, they should possess good oral bioavailability and a relatively long duration of action. A long half-life is also desirable because of the known development of resistance by HIV under selective antiviral pressure.^{74,75} Resistance develops by point mutations.

Most of the early PIs are high-molecular-weight, dipeptide- or tripeptide-like structures, generally with low water solubility. The bioavailability of these compounds is low, and the half-life of elimination is very short because of hydrolysis or hepatic metabolism.⁸⁸ Strategies aimed at in-

creasing water solubility and metabolic stability have led to the development of several highly promising clinical candidates. Saquinavir (Invirase),⁸¹ indinavir (Crixivan),⁸⁹ ritonavir (Norvir),⁹⁰ nelfinavir (Viracept),⁹¹ and amprenavir (Agenerase)⁹² have been approved for the treatment of HIV-infected patients. Several others are in clinical trials.

There is an important caution for the use of PIs. As a class, they cause dyslipidemia, which includes elevated cholesterol and triglycerides and a redistribution of body fat centrally to cause the “protease paunch” buffalo hump, facial atrophy, and breast enlargement. These agents also cause hyperglycemia.

Saquinavir

Saquinavir (Invirase)⁸⁹ is well tolerated following oral administration. Absorption of saquinavir is poor but is increased with a fatty meal. The drug does not distribute into the CSF, and it is approximately 98% bound to plasma proteins. Saquinavir is extensively metabolized by the first-pass effect. Bioavailability is 4% from a hard capsule and 12% to 15% from a soft capsule. Saquinavir lowers p24 antigen levels in HIV-infected patients, elevates CD4⁺ counts, and exerts a synergistic antiviral effect when combined with RT inhibitors such as AZT and ddC.^{93–95} Although HIV-1 resistance to saquinavir and other HIV PIs occurs in vivo, it is believed to be less stringent and less frequent than resistance to the RT inhibitors.⁹⁶ Nevertheless, cross-resistance between different HIV PIs appears to be common and additive,⁹⁷ suggesting that using combinations of inhibitors from this class would not constitute rational prescribing. The drug should be used in combination with at least two other antiretroviral drugs to minimize resistance. Dosage forms are Invirase (hard capsule) and Fortovase (soft capsule).

Indinavir

When administered with a high-fat diet, indinavir (Crixivan)⁹⁰ achieves a maximum serum concentration of 77% of the administered dose. The drug is 60% bound in the plasma. It is extensively metabolized by CYP3A4, and seven metabolites have been identified. Oral bioavailability is good, with a t_{\max} of 0.8 ± 0.3 hour. The half-life of elimination is 1.8 hour, and the elimination products are detectable in feces and urine. Indinavir also causes dyslipidemia. The available dosage forms are capsules of 200 mg, 333 mg, and 400 mg.

Ritonavir, Amprenavir, and Nelfinavir

Ritonavir (Norvir),⁹⁸ amprenavir (Agenerase),⁹⁹ and nelfinavir (Viracept)¹⁰⁰ have similar properties and cautionary statements. All cause dyslipidemia, and they have a host of drug interactions, mainly because they inhibit CYP3A4. These agents must always be used with at least two other antiretroviral agents. Used properly, the PIs are an important part of HIV therapy.

Lopinavir

Lopinavir is a protease inhibitor that has been approved for use in combination with ritonavir for patients with HIV who have not responded to other treatment modalities. Lopinavir is used in excess over ritonavir. Ritonavir at amounts given has no antiretroviral activity. Ritonavir inhibits lopinavir's metabolism by CYP3A4, causing a higher level of lopinavir in the system. The combination is the first protease inhibitor approved for patients as young as 6 months of age.

Ritonavir

Amprenavir

Nelfinavir

Atazanavir

Atazanavir is an antiretroviral agent that has been approved by the FDA for use in combination with other anti-RT agents for the treatment of HIV infections. The drug is always used in combination with RT inhibitors.

**Fosamprenavir**

Fosamprenavir is used in combination with other HIV drugs in adult patients. Like the other PIs, this compound is a prodrug that produces the active drug upon hydrolysis. In this case, the active drug is amprenavir, a peptidomimetic transition state inhibitor. Fosamprenavir is typically administered in combination with RT inhibitors.

Tipranavir

Tipranavir is unique among the PIs because it is not a peptidomimetic compound. It does appear to bind to the active site of HIV-1 protease the same as the peptidomimetics do. The benefit of this agent is that, because it is a different chemical structure, cross-resistance does not develop to the same extent as seen with the peptidomimetics. The drug is administered with a booster dose of ritonavir. This protocol inhibits CYP3A4, causing the levels of tipranavir to increase.

Several other nonpeptide inhibitors of HIV protease have been developed as a result of two very different approaches. For example, the C_2 symmetry of the active site of the enzyme was exploited in the structure-based design of the symmetric cyclic urea derivative DMP-323.¹⁰¹ This inhibitor exhibited potent activity against the protease in vitro, excellent anti-HIV activity in cell culture, and promising bioavailability in experimental animals. In phase I clinical trials, however, the bioavailability of DMP-323 was poor and highly variable, possibly because of its low water solubility and a high fraction of hepatic metabolism. Subsequent synthesis of nonsymmetric derivatives DMP-850¹⁰¹ (page 351) and DMP-851¹⁰¹ yielded in vitro antiviral potency comparable with that of the already-approved PIs. These were selected as clinical candidates on the basis of their favorable pharmacokinetics in dogs. In a second approach, random screening of chemical inventories yielded the 5,6-dihydropyran-2-one-based inhibitor¹⁰² PD-178390 (page 351). This compound, in addition to having good potency against HIV protease and good anti-HIV activity in cell culture, exhibits high bioavailability in experimental animals. PD-178390 appears not to share the resistance profile of the other PIs, and no virus resistant to the compound emerged, even during the prolonged in vitro selection.

DMP-850

PD-178390

Dipeptide PIs containing 2-hydroxy-3-amino-4-arylbutanoic acid in their scaffold showed promising preclinical results. JE-2147¹⁰³, containing the allophenylnorstatin moiety, exhibited potent in vitro anti-HIV activity. JE-2147 appears to fully retain its susceptibility against various HIV strains resistant to multiple approved PIs and exhibits good oral bioavailability and a good pharmacokinetic profile in two animal species. Also, emergence of resistance was considerably delayed with JE-2147.

JE-2147

HIV Entry Inhibitors

Entry of HIV into a cell is a complex process that involves several specific membrane protein interactions. Initially, viral glycoprotein gp120 mediates the virus attachment via its binding to at least two host membrane receptors, CD4⁺ and the chemokine coreceptor. This bivalent interaction induces a conformational change in the viral fusion protein gp41. Protein gp41 acts as the anchor for gp120 in the virus. With the conformational change, the viral envelope fuses with the

host cell membrane. In addition to gp120–chemokine receptor interaction, the fusion activity of gp41 is currently being explored as a novel target for antiretroviral therapy. At least one agent from each class is in clinical testing.

Chemokine Receptor Binders

Most HIV-1 isolates rely on the CCR5 coreceptor for entry (R5 strains). In later stages of the disease, however, more pathogenic selection variants of the virus emerge in about 40% of individuals, which use the CXCR4 coreceptor in addition to CCR5 (R5X4 strains) or the CXCR4 receptor only (X4 strains). Bicyclam compound AMD-3100¹⁰⁴ was the first compound identified as a CXCR4-specific inhibitor that interferes with the replication of X4 but not R5 viruses. The compound is currently in phase II clinical evaluations. It is used as an injectable agent because of its limited bioavailability.

R =

AMD-3100

Several positively charged 9- to 14-mer peptides have been described as capable of blocking the CXCR4 coreceptor. A small molecule, TAK-779,¹⁰⁵ exhibits high-affinity binding to the CCR5 coreceptor, specifically blocking R5 isolates.

TAK-779

Inhibitors of GP41 Fusion Activity

The fusion of the HIV-1 viral envelope with host plasma membrane is mediated by gp41, a transmembrane subunit of the HIV-1 glycoprotein subunit complex. Pentafuside¹⁰⁶ (T-20) is a 36-mer peptide that is derived from the C-terminal repeat of gp41. Pentafuside appears to inhibit the formation of the fusion-competent conformation of gp41 by interfering with the interaction between its C- and N-terminal repeat. Pentafuside is a potent inhibitor of HIV-1 clinical isolates, and it is currently in clinical trials.

Integrase Inhibitors

Two closely related types of small molecules that block strand transfer catalyzed by recombinant integrase have been identified. Both types show *in vitro* antiviral activity. The diketo acids¹⁰⁷ inhibit strand transfer catalyzed by recombinant integrase with an IC_{50} less than $0.1 \mu\text{m}$. Mutations that conferred resistance to the diketo acids mapped near conserved residues in the IN enzyme. This finding demonstrates that the compounds have a highly specific mechanism of action. X-ray crystallography of the bound tetrazole¹⁰⁸ derivative revealed that the inhibitor was centered in the active site of IN near acidic catalytic residues.

Short-Interfering RNA

RNA interference is a phenomenon that has been recently used as a way to silence genes that are part of viral replication cycles. The siRNAs very specifically interrupt gene function and switch off some aspect of a disease. The siRNAs are found in higher organisms (eukaryotes) and are typically double-stranded duplexes of RNA of about 21 base

pairs. In nature, these siRNAs are produced by excision from a parent duplex RNA molecule. The siRNAs instruct the cell to split specific mRNAs that have identical sequences as the siRNAs. As antiviral therapy, the idea would be for the siRNAs to stop synthesis of mRNAs of a pathogenic organism. Antiviral siRNA therapies can be tailored for any given pathogen. The use of siRNAs as potential therapeutic modalities is a highly active area of research at the present time.

Combination Antiviral Therapy

Combination antiviral therapy, in which a mixture of drugs possessing different mechanisms of action, has been shown to be advantageous for several reasons. The antiviral effect of the combination is excellent, toxicities are decreased, and resistance to any drug in the combination is slow to develop. Resistance to single drugs such as amantadine, ganciclovir, and acyclovir is problematic. Administered of a given agent in combination with other types of drugs retards the development of such resistance. Combination treatment is especially important in antiretroviral therapy.

Typical antiretroviral therapy, as exemplified by HIV treatment, includes combinations of NRTI or NNRTI along with PIs. The key that makes the combination work is that the drugs act to inhibit HIV virus replication at different stages of the viral infective cycle. The RT inhibitors (NRTIs or NNRTIs) prevent RNA formation or viral protein synthesis or inactivate the catalytic site of RT (NNRTIs). The PIs act once the provirus integrates into the host's genes. Protease is necessary to split viral precursor polypeptides into new virus. The combination of RTs and PIs is synergistic. There are many two- and three-drug combinations that have been reported to be useful in various viral infections.

CHAPTER 10

Antineoplastic Agents

FORREST T. SMITH AND C. RANDALL CLARK

CHAPTER OVERVIEW

Antineoplastic agents describe the chemistry, use, metabolism, and adverse effect profiles for the alkylating agents, antibiotics, natural products, antimetabolites, and tyrosine kinase (TK) inhibitors used in the treatment of cancer. Emphasis has been placed on understanding how cell division and cell death are regulated and how drugs may influence these processes as well as how cancer cells may become resistant to the actions of the antineoplastics. Topics such as apoptosis, DNA alkylation, reactive oxygen species (ROS), and the role of growth factors in controlling transcription and translation are especially important in the discussion of antineoplastic agents; however, in a wider sense, it is important for pharmacists to appreciate the role of these subjects in several other areas such as neurodegenerative diseases, mutagenicity, cardiovascular toxicity, and cell signaling.

INTRODUCTION

The American Cancer Society defines cancer as a group of diseases characterized by uncontrolled growth, and the spread of abnormal cells that left untreated may lead to death. Related to this definition is the term *neoplasia*, which is the uncontrolled growth of new tissue, the product of which is known as a *tumor*, and these tumors may be either malignant or benign. Malignant tumors have the capability of invading surrounding tissues and moving to distant locations in the body in a process known as *metastasis*; characteristics that benign tumors do not possess. Treatment of malignant tumors or cancer has generally involved initially surgical removal followed by radiation and/or chemotherapy, if necessary. In those cases where complete surgical removal is not feasible, radiation and chemotherapy become the only available options. The term *chemotherapy*, in the strictest sense, refers to drugs that are used to kill cells and includes both antibiotics and agents used in the treatment of cancer, but it is often used to refer exclusively to anticancer agents also known as *antineoplastics*. Traditional chemotherapy has been based on the principle of selective toxicity; however, this has been difficult to achieve in the case of cancer cells because these cells utilize the biochemical pathways used by normal cells. In many cases, the agents have attempted to exploit the increased proliferative rates of cancer cells compared with normal cells. This has been difficult to achieve even in a relative sense because, in part, of the fact that not all normal tissue is slowly proliferative and, conversely, not all cancer cells are highly proliferative.

Increased knowledge of intercellular and intracellular communication has led to the development of several newer agents that have shown some effectiveness in treating several cancers, especially when used in combination with more traditional agents. These have included several monoclonal antibodies that target the overproduction of growth factor receptors and TK inhibitors that target the transduction process involved in growth factor stimulation.

Progress against neoplastic disease has also been greatly aided by early detection resulting from increased public awareness and improved diagnostics. As a result, neoplasms are often detected before they have a chance to metastasize and become more difficult to treat. Surgery followed by chemotherapy is often effective in accomplishing a 5-year survival in cancers that are discovered early and have not metastasized. The approach to treatment depends on the extent of the disease and the so-called stage. There are several methods of staging including the commonly used TNM system, where T—tumor, N—lymph node involvement, and M—metastasis. In this system, T and N are followed by numbers (1, 2, 3, etc.) to indicate the size of the tumor and the extent of lymph node involvement, respectively, where higher numbers are associated with more advanced disease. M is followed by either “0” to indicate metastasis has not occurred or “1” to indicate that it has. An alternative system utilizes stage 0 through stage IV designations, with higher numbers indicating progression of the disease. In this system, stage IV indicates that the primary tumor has metastasized.

Even with all the advancements, progress in many cases has been very slow. In comparing 5-year survival rates for patients with pancreatic cancer diagnosed between 1975 and 1977, with those diagnosed between 1996 and 2003, the rate increased from 2% to only 5%. Five-year survival rates for lung cancer patients increased from 13% to 16% during the same interval. It is obvious that these results do not represent tremendous progress in these types of cancer, and some of the increase may be ascribed to increased public awareness and better diagnostic methods that have allowed for earlier detection. This is important because the starting date in calculating a 5-year survival rate is the day of initial detection. This lack of progress in lung cancer is especially ominous since the American Cancer Society estimates that lung cancer will account for the greatest percentage of cancer deaths in 2008.¹

As part of the definition, cancer is a group of diseases and these have been traditionally grouped together based on the organ in which the cancer originated. Even this grouping is somewhat misleading, because all cancers of a particular organ may not be caused by the same genetic alterations. This has important consequences for therapy,

because the ability to respond to a chemotherapeutic agent is partly dependent on the genetic abnormality occurring in the cell.

The primary risk factor for most cancers is age. There are certainly other risk factors such as exposure to environmental toxins, but generally, as aging occurs, the chance of developing cancer increases. This is related to the genetic component of cancer so that every time a cell divides, there is a small chance that an aberrant cancer cell may arise as a result of mutation or translocation of DNA. This is cumulative so that the chances increase with an increasing number of cell divisions and, hence, age.

Normal cellular growth and proliferation are generally driven by factors external to the cell. Mitogenic signals such as hormones and growth factors direct the cell to undergo mitosis and are generally released from other tissues setting up a system of checks and balances where any one cell type is not allowed to proliferate in an uncontrolled manner. In cancer cells, this system may become disrupted in several ways. For example, some cells may acquire the ability to synthesize their own growth factors in a process known as *autocrine signaling*. It is also possible for cells to lose the requirements for growth factors altogether and still be capable of proliferating. There are numerous ways in which this may come about. For example, the signal transduction processes in which the interaction of a growth factor and its receptor is translated into cellular division may become permanently activated at any one point along the chain or at multiple points. Central to this idea is the concept of oncogenes or cancer-producing genes, the products of which may be responsible for these types of alterations. Oncogenes themselves are not normally present in the genome; however, precursors known as *proto-oncogenes* are commonly seen. Alterations in these proto-oncogenes by mutation or translocation may result in their transformation to an oncogene and the development of cancer. Several of these are listed in Table 10.1, but it should be kept in mind that although conversion of any particular proto-oncogene to an oncogene may be associated with a particular cancer, it is not seen in all patients that develop this type of cancer.

The process of cell division occurs through a series of phases that collectively are known as the *cell cycle*. Starting in the G_1 for gap 1 or growth 1 phase, the enzymes necessary for the replication of DNA are synthesized (Fig. 10.1). Alternatively, cells may enter the G_0 phase in which they do not prepare for cell division but carry on normal metabolic processes. Entry into G_0 (sometimes referred to as *senescence*) is not an irreversible process; however, some

Figure 10.1 • Cyclins and the cell cycle.

cells such as nerve cells never divide. If the cell is to undergo division, it will progress to the S phase where DNA is replicated. This is followed by the G_2 phase, during which additional protein synthesis occurs including the formation of the microtubules. The M phase, which is further subdivided into prophase, metaphase, anaphase, and telophase, follows in which the DNA is segregated and cell division occurs. During the entire cycle, movement from one phase to the next is driven by proteins known as *cyclins* and their associated cyclin-dependent kinases (CDKs). There are several subtypes of cyclins with their CDKs, the concentrations of which change or cycle as the cell moves from G_1 through M phase, and this concentration change is associated with moving the cell into the next phase. The D-type cyclins paired with CDK4/6 are in high concentration during the G_1 phase, and their formation is under the control of external growth factors. Subsequent to this, the D-type cyclins help drive the formation of cyclin E with its CDK2, which drives the cell from the G_1 to the S phase. This is followed by formation of A- and B-type cyclins with their CDKs, which push the cell into G_2 and subsequently into M, respectively.

The progression through the cell cycle is a highly regulated process, and the cell is constantly monitoring itself to make sure that the necessary enzymes are present and the genome is intact. If problems are encountered, the cell may be slowed from progressing or undergo programmed cell death also known as *apoptosis*. Regulation of the cell through the cell cycle is the function of the tumor suppressor proteins such as retinoblastoma protein (Rb), p21^{Cip1}, and p53.² Especially important in this regard is p53, sometimes referred to as the guardian of the cell, it functions as a transcription factor and may activate genes, the products of which are involved in the repair of DNA. When damage becomes too severe to be repaired, p53 may direct the cell to die. One of the best examples of this is seen during overexposure to the sun. The UV damage that the skin has suffered is detected by p53 and the cells undergo apoptosis with the resulting peeling away of the dead skin.³ Activation of p53 may occur in response to various stresses that cause damage to the genome, but it has been found that in many cancer cells, p53 and other tumor suppressor genes are not

TABLE 10.1 Selected Oncogenes and the Associated Human Cancer

Oncogene	Oncogene Product	Associated Human Cancer

<i>RAF</i>	Serine-threonine kinase	Bladder
<i>KIT</i>	Receptor tyrosine kinase	Colon
<i>SIS</i>	Growth factor	Various
<i>TP53</i>	Transcription factor (p53)	Various

functioning. Although a normal cell would undergo apoptosis in this situation, the cancerous cells continue to survive and may mutate more readily because the system of genetic checks and balances is no longer in place.

The process of apoptosis can occur by both an intrinsic and extrinsic pathway (Fig. 10.2). The intrinsic pathway begins when cytochrome *c* is released from the mitochondria via channels present in the mitochondrial membrane. The state of this channel is controlled by several different proteins such that opening is stimulated by the proapoptotic p53 products Bad, Bax, and Bid and closure is stimulated by the antiapoptotic Bcl-2 and Bcl-X_L proteins. Opening of the channel releases cytochrome *c* into the cytoplasm where it combines with apoptotic protease activating factor-1 (apaf-1) molecules to form a wheel-like structure of seven spokes known as the *apoptosome*. This then binds and activates caspase-9, which activates additional caspase enzymes in a cascade fashion. The caspase enzymes cleave numerous proteins within the cell, leading to profound morphological changes and cell death.

The extrinsic pathway is activated when ligands of the tumor necrosis factor family of proteins (TNF- α , FasL, TRAIL) interact with the so-called death receptors (FAS, DR3-5, TNFR1) present on the cell surface. This interaction serves to convert procaspase to active caspase-8/10, which is capable of activating the executioner caspases directly, and in this process, the proapoptotic Bid is activated by caspase-8, which opens the mitochondrial channel allowing for the release of cytochrome *c*. This then functions as it had in the intrinsic pathway to form the apoptosome.

The ability of drugs to kill cancer cells is generally believed to be because of their ability to induce the process of apoptosis. In high-dose therapy, cell death may occur by necrosis but this is also toxic to the patient. In a general sense, the antineoplastics target DNA or the process of DNA replication and stimulate apoptosis but the exact mechanisms by which this stimulation occurs are not known with certainty. The effectiveness of the agents is reduced in cells where apoptosis fails to occur properly, and this is a property of many cancer cells. Normal cells with fully functioning apoptotic

Figure 10.2 • Intrinsic and extrinsic pathways of cellular apoptosis.

mechanisms may then become susceptible to the action of the antineoplastics increasing the toxicity of the agents.

DRUG CLASSES

Alkylating Agents

The alkylating agents are a class of drugs that are capable of forming covalent bonds with important biomolecules. The major targets of drug action are nucleophilic groups present on DNA (especially the 7-position of guanine); however, proteins and RNA among others may also be alkylated. Alkylation of DNA is thought to lead to cell death, although the exact mechanism is uncertain. Potential mechanisms of cell death include activation of apoptosis caused by p53 activation and disruption of the template function of DNA. In many cases, however, the cancer cells have dysfunctional p53 so that even though the cell has been unable to replicate DNA error free, cell death via apoptosis does not occur. In this way, cancer cells may become resistant to the effects of alkylating agents. Another possibility is that the cancer cells, like normal cells, have various mechanisms by which alkylated DNA bases can be excised.

Disruption of the template function of DNA may have several effects. There are several potential nucleophilic sites on DNA, which are susceptible to electrophilic attack by an alkylating agent (N-2, N-3, and N-7 of guanine, N-1, N-3, and N-7 of adenine, 0-6 of thymine, N-3 of cytosine). The most

important of these for many alkylating agents is the N-7 position of guanine whose nucleophilicity may be enhanced by adjacent guanine residues. Alkylation converts the base to an effective leaving group so that attack by water leads to depurination and the loss of genetic information if the resulting depurination is not repaired by the cell (Scheme 10.1). Additionally, alkylation has been proposed to result in altered base pairing away from the normal G-C: A-T hydrogen bonds because of alterations in tautomerization.⁴ The alkylation also leads to increased acidity of the N-1 nitrogen reducing the pK_a from 9 to 7 to 8 giving rise to a zwitterionic form that may also mispair. For those agents that possess two reactive functionalities, both interstrand and intrastrand cross-linking becomes possible. When interstrand links occur, separation of the two strands during replication is prevented and therefore replication is blocked.

Most of the currently used alkylating agents are nonselective regarding the sequence of DNA with which they react. Therefore, it is uncertain whether alkylation will lead to a cytotoxic event. Some alkylation reactions may lead to inconsequential results, and others may be easily repaired by the cell. Recent efforts have been directed at producing more sequence-selective alkylators that could be used at lower concentrations in an effort to reduce the significant side effects associated with this group of agents.

The general mechanism for alkylation involves nucleophilic attack by $-N=$, $-NH_2$, $-OH$, $-O-PO_3H$ of DNA and RNA, while additional nucleophiles ($-SH$, $COOH$, etc.) present on proteins may also react (Scheme 10.2). Anion

Scheme 10.1 • Alkylation of guanine N-7 and subsequent depurination of DNA.

Scheme 10.2 • General reaction for alkylation and inactivation of alkylating agents.

Where X = a leaving group

formation increases the reactivity of the nucleophile compared with the un-ionized form (—O^- is more nucleophilic than OH). Reaction with water is also possible, because it represents the nucleophile in greatest abundance in the body and this becomes more likely as the electrophile becomes more reactive. Reaction involves displacement of a leaving group on the electrophile by the nucleophile. The reactivity of the electrophile is dependent in part on the ability of the leaving group to stabilize a negative charge.

Along with a common mechanism, there are other characteristics that the alkylating agents share. Mechanisms by which cells may become resistant to these agents are thought to be similar and include decreased cellular uptake, increased inactivation by detoxifying nucleophilic thiols such as glutathione, increased DNA repair processes, and decreased drug activation when this is necessary for generation of an alkylating species. Functioning apoptotic mechanisms are thought to be important for the effectiveness of these agents at normal doses, and those cells that do not possess these mechanisms may not respond. In high-dose therapy involving bone marrow transplants, the cell may be overwhelmed by the damage caused by these agent and die because of necrosis. The alkylating agents are thought to be effective from $\text{G}_0\text{--M}$ and are, therefore, not considered cell cycle-specific agents. Many of the toxicities seen with the various agents are similar. Myelosuppression and gastrointestinal (GI) disruption, which often present as nausea and vomiting are commonly seen and are caused by the highly proliferative nature of these tissues, and therefore susceptibility to the effects of the alkylating agents. It is interesting to note that although cancer cells may develop resistance to the alkylating agents, this is not generally seen for cells of the bone marrow and GI tract because of

the genetic stability and functioning DNA repair mechanisms present in these cells. However, an additional long-term consequence of the administration of these agents is the emergence of secondary cancers that are associated with the mutagenic effects of the alkylating agents themselves.

NITROGEN MUSTARDS

The nitrogen mustards are compounds that are chemically similar to sulfur mustard or mustard gas developed and used in World War I. The term “mustard” comes from the similarity in the blisters produced by the compound and those seen upon exposure to the oil of black mustard seeds. Investigation of sulfur mustard revealed that it possessed antineoplastic properties but because the compound existed as a gas at room temperature, handling and administration of the material were difficult. Conversion of the sulfide to a tertiary amine allowed for the formation of salts, which exist as solids at room temperature allowing for easier handling and dosing. The term mustard was then extended to the nitrogen analogs (nitrogen mustards) given their chemical similarity.

Mustards such as mechlorethamine are classified as dialkylating agents in that one mustard molecule can alkylate two nucleophiles.⁵ The initial acid-base reaction is necessary to release the lone pair of electrons on nitrogen, which subsequently displaces chloride to give the highly reactive aziridinium cation (Scheme 10.3). Nucleophilic attack can then occur at the aziridinium carbon to relieve the small ring strain and neutralize the charge on nitrogen. This process can then be repeated provided a second leaving group is present.⁶

Mechlorethamine is highly reactive, in fact, too reactive and therefore nonselective, making it unsuitable for oral

Scheme 10.3 • Alkylation of nucleophilic species by nitrogen mustards.

Scheme 10.4 • Thiosulfate inactivation of mechlorethamine.

administration and necessitating direct injection into the tumor. In cases of extravasation (drug escapes from the tumor into the underlying tissue), the antidote sodium thiosulfate ($\text{Na}_2\text{S}_2\text{O}_3$), a strong nucleophile, may be administered. It is capable of reacting with electrophilic sites on the mustard, and once reaction has occurred, the resulting adduct has increased water solubility and may be readily eliminated (Scheme 10.4). Cancer patients are at an increased risk of extravasation because of the fragility of their veins resulting from radiation, previous chemotherapy treatments, or malnutrition.

The lack of selectivity of mechlorethamine led to attempts to improve on the agent. One rationale was to reduce the reactivity by reducing the nucleophilicity of nitrogen, thereby slowing aziridinium cation formation. This could be accomplished by replacement of the weakly electron-donating methyl group with groups that were electron withdrawing (-I). This is seen in the case of chlorambucil and melphalan by attachment of nitrogen to a phenyl ring (Fig. 10.3).⁷ Reactivity was reduced such that these compounds could be administered orally. In the case of melphalan, attachment of the mustard functionality to a phenylalanine moiety was not only an attempt to reduce reactivity but also an attempt to increase entry into cancer cells by utilization of carrier-mediated uptake.⁸ Melphalan was found to utilize active transport to gain entry into cells, but selective uptake by cancer cells has not been demonstrated.⁹

Attachment of more highly electron-withdrawing functionalities was utilized in the case of cyclophosphamide and ifosfamide (Fig. 10.4). In these cases, aziridinium cation formation is not possible until the electron-withdrawing

function has been altered. In the case of cyclophosphamide, it was initially believed that the drug could be selectively activated in cancer cells because they were believed to contain high levels of phosphoramidase enzymes. This would remove the electron-withdrawing phosphoryl function and allow aziridine formation to occur. However, it turned out that the drug was activated by cytochrome P450 (CYP) isozymes CYP2B6 and CYP3A4/5 to give a carbinolamine that could undergo ring opening to give the aldehyde.^{10,11} The increased acidity of the aldehyde α -hydrogen facilitates a retro-Michael decomposition (Scheme 10.5). The ionized phosphoramidate is now electron-releasing via induction and allows aziridinium cation formation to proceed. Acrolein is also formed as a result of this process, which may itself act as an electrophile that has been associated with bladder toxicity. Alternatively, the agent may be inactivated by alcohol dehydrogenase-mediated oxidation of the carbinolamine to give the amide or by further oxidation of the aldehyde intermediate to give the acid by aldehyde dehydrogenase.

To decrease the incidence of kidney and bladder toxicity, the sulfhydryl ($-\text{SH}$) containing agent mesna may be administered and functions to react with the electrophilic species that may be present in the kidney. The sulfonic acid functionality serves to help concentrate the material in the urine, and the nucleophilic sulfhydryl group may react with the carbinolamine, aziridinium cation, the chloro substituents of cyclophosphamide, or via conjugate addition with acrolein (Scheme 10.6). This inactivation and detoxification may also be accomplished by other thiol-containing proteins such as

Figure 10.3 • Structure of chlorambucil and melphalan.

Figure 10.4 • Structures of cyclophosphamide and ifosfamide.

glutathione. Increased levels of these proteins may occur as cancer cells become resistant to these alkylating agents.

Ifosfamide contains similar functionality and also requires activation by CYP2B6 and CYP3A4/5 (Scheme 10.7). Although the agents are similar, there are differences in the metabolism and activity of the agents.^{12,13} Both are administered as racemic mixtures as a result of the presence of a chiral phosphorus atom. There appears to be little difference in the metabolic fate of the *R*- and *S*-isomers of cyclophosphamide, but in the case of ifosfamide, the *R*-isomer is converted to the required 4-hydroxy-ifosfamide 2 to 3 times faster than the *S*-isomer.¹⁴ The *S*-isomer undergoes preferential oxidation of the side chain to give *N*-dechloroethylation, which removes the ability of the agent to cross-link DNA and also produces the neurotoxic and urotoxic chloroacetaldehyde. An additional difference between cyclophosphamide and ifosfamide is the larger alkylating species that ultimately

results after metabolic activation of ifosfamide. This results in the reactive form of ifosfamide having a higher affinity for DNA than the analogous form of cyclophosphamide and differences in the interstrand and intrastrand links that ultimately result. The differential metabolism also results in increased formation of the urotoxic chloroacetaldehyde in the case of ifosfamide such that bladder toxicity that normally presents as hemorrhagic cystitis becomes dose limiting with this agent.

THIOTEPA

The early success of the nitrogen mustards led researchers to investigate other compounds that contained a preformed aziridine ring, and thiotepa resulted from this work. Thiotepa containing the thiophosphoramidate functionality was found to be more stable than the oxa-analog (TEPA) but is metabolically converted to TEPA by desulfuration *in vivo*.¹⁵ Thiotepa incorporates a less reactive aziridine ring compared with that formed in mechlorethamine. The adjacent thiophosphoryl is electron withdrawing and, therefore, reduces the reactivity of the aziridine ring system. Although thiotepa is less reactive than many other alkylating agents, it has been shown to form cross-links. This is believed to occur by sequential reactions of thiotepa itself with DNA (Scheme 10.8).¹⁶ Monoalkylation is also possible as a result of aziridine formation via hydrolysis of thiotepa. Thiotepa is also metabolized by oxidative desulfuration mediated by CYP2B1 and CYP2C11.¹⁷ The decreased stability of the resulting TEPA undergoes hydrolysis to give aziridine, which may function to monoalkylate

Scheme 10.5 • Metabolic and chemical activation of cyclophosphamide.

Scheme 10.6 • Detoxification of cyclophosphamide by mesna.

DNA.¹⁸ The conclusion that aziridine is the active alkylating agent once thiotepa has been converted to TEPA is based on the fact that when TEPA is incubated with DNA, no cross-links are formed and only monoadducts are generated. The reactivity of aziridine generated by either route may be somewhat enhanced within cancer cells, where the pH is normally reduced 0.2 to 0.4 pH units resulting in an increase in reactivity toward nucleophilic attack.

BUSULFAN

As an alternative to utilizing aziridines as electrophilic species, it was found that simply utilizing a carbon chain terminated at both ends by leaving groups gave compounds capable of acting as cross-linking agents (Scheme 10.9).¹⁹ Busulfan utilizes two sulfonate functionalities as leaving groups separated by a four-carbon chain that reacts with DNA to primarily form intrastrand cross-link at 5'-GA-3' sequences.²⁰ The sulfonates are also subject to displacement by the sulfhydryl functions found in cysteine and glutathione, and metabolic products are formed as a result of nucleophilic attack by these groups to generate sulfonium species along with methane sulfonic acid.²¹ This is followed by conversion to tetrahydrothiophene, and further oxidation products are subsequently produced to give the sulfoxide and sulfone. The cyclic sulfone known as *sulfolane* may be further oxidized to give 3-hydroxysulfolane.

ORGANOPLATINUM COMPOUNDS

There are several organometallic compounds based on platinum that play a central role in many cancer treatment

protocols (Fig. 10.5). The first of these, cisplatin, was discovered by Barnett Rosenberg as a result of experiments investigating the role of electrical current on cell division. *Escherichia coli* cells in an ammonium chloride solution had an electrical current applied through platinum electrodes.²² It was subsequently found that cell division was inhibited but not as a result of the current but from the reaction of the ammonium chloride with what was thought to be an inert platinum electrode. Further investigation led to the identification of *cis*-[PtCl₂(NH₃)₂] as the active species and mechanistic studies revealed that after administration of the agent to mammals, the dichloro species is maintained in the blood stream as a result of the relatively high chloride concentration (Scheme 10.10).²³ Movement into the tumor cells is accomplished by passive diffusion or carrier-mediated transport. Once inside the tumor cell, the drug encounters a lower chloride concentration and one chloro group is substituted by a water molecule in a process known as *aquation*. This serves to “trap” the molecule in the cell as a result of ionization. Reaction with DNA occurs preferentially at the N-7 of guanine of two adjacent guanine residues resulting in primarily (95%) intrastrand cross-links.²⁴

Platinum (II) is considered to be a “soft” electrophile and as a result, its complexes are subject to attack by “soft” nucleophiles such as thiol groups found on proteins. This can result in significant protein binding (88%–95%) and inactivation caused by the presence of thiols in albumin, glutathione, and other proteins.²⁵ Cisplatin administration is also associated with significant nephrotoxicity and neurotoxicity that is dose limiting. These factors lead to the development of less

Scheme 10.7 • Metabolic and chemical activation of ifosfamide.

reactive platinum compounds such as carboplatin and oxaliplatin in which the leaving group was incorporated into a chelate. More recently, there has been interest in the development of Pt(IV) compounds, which are much less reactive and believed to function as prodrugs requiring reduction to the Pt(II) species prior to reaction with nucleophiles. One such agent, satraplatin is currently in clinical trials. One advantage of these agents is the possibility of oral administration. Satraplatin has shown similar activity when given orally to that of cisplatin given by injection.

Tumor cells may become resistant to the platins by mechanisms that are seen with other chemotherapeutic agents such as decreased uptake, increased inactivation by

thiol-containing proteins and increased DNA repair. However, a deficiency in a type of DNA repair known as *mismatch repair* (MMR) has also been implicated in resistance to cisplatin and carboplatin.²⁶ The process of MMR involves several enzymes that are responsible for maintaining the integrity of the genome, and interest has focused on the interaction of these enzymes with repeating units found throughout DNA known as *microsatellites*. When MMR processes are not operating, these microsatellites may become longer or shorter and this is known as *microsatellite instability*. This can result in frame shift errors such that tumor suppressor genes may become less effective, and the tumor cells therefore fail to undergo apoptosis even if

Scheme 10.8 • Metabolic and chemical interactions of thiotepa with DNA.

alkylation has occurred. The binding of cisplatin- and carboplatin-DNA adducts by the MMR enzymes results in increased cytotoxicity of these agents. Several rationales have been put forward as to why this occurs, including the involvement of MMR enzymes in downstream signaling that activates apoptosis. A second rationale involves the ability

of MMR enzymes to remove replication errors that occur past the point of adduct formation, and in the process of removing these errors, gaps in the DNA are created, which lead to cell death. When there is a deficiency in the MMR enzymes, cells may be resistant to cisplatin and carboplatin because both of these agents produce the same DNA adduct.

Scheme 10.9 • Metabolic and chemical reactions of busulfan.

Figure 10.5 • Platinum-containing antineoplastics.

The bulkier oxaliplatin-DNA adduct does not seem to be recognized by the same enzymes and does not depend on MMR enzymes for its cytotoxicity, and several cell lines that are resistant to cisplatin and carboplatin are still susceptible to oxaliplatin. In addition, several DNA polymerases are unable to replicate past cisplatin-DNA adducts but are able to replicate past oxaliplatin-DNA adducts.²⁷ This difference has been used to explain the greater mutagenicity that is seen with cisplatin compared with oxaliplatin. These two compounds both form primarily intrastrand links between adjacent guanine residues or adjacent guanine-adenine residues; however, nuclear magnetic resonance (NMR) analysis has recently shown that the amount of DNA bending is much greater, and the minor groove is widened for the cisplatin-DNA adduct compared with the oxaliplatin-DNA adduct. The greater bending associated with cisplatin-DNA adducts is recognized by MMR enzymes possibly explaining the differential effects of cisplatin and oxaliplatin on these enzymes.

NITROSOUREAS

The nitrosoureas were discovered as a result of drug screening by the Cancer Chemotherapy National Service Center, which identified *N*-methyl-*N'*-nitroguanidine as having activity against L1210 leukemia.²⁸ Further development of this lead compound was based on the idea that its chemical decomposition was leading to the formation of diazomethane (CH₂N₂) and subsequent alkylation of DNA. This led to the nitrosoureas, where it was found that activity could be enhanced by attachment of a 2-haloethyl substituent to both nitrogens (Fig. 10.6).

These compounds are reasonably stable at pH = 4.5 but undergo both acid and base catalyzed decomposition at lower and higher pH, respectively. There are several pathways of decomposition that are possible for these compounds, but the one that appears to be most important for alkylation of DNA involves abstraction of the NH proton, which is relatively acidic (pK_a = 8–9), followed by rearrangement to give an isocyanate and a diazohydroxide. The diazohydroxide, upon protonation followed by loss of water, yields a diazo species that decomposes to a reactive carbocation (Scheme 10.11).²² The isocyanate functions to carbamylate proteins and RNA, whereas the carbocation is believed to be the agent responsible for DNA alkylation.^{29–31} Alternative mechanisms of decomposition have also been proposed involving formation of chlorovinyl carbocations. In those cases where there is a chloroethyl moiety attached to the *N*-nitroso urea functionality, cross-linking of DNA occurs. Alkylation occurs preferentially at the N-7 position of guanine with minor amounts of alkylation at guanine O-6.³²

Detoxification pathways of the nitrosoureas are also possible and can play a role in resistance to this group of agents. Two major routes of inactivation have been identified and are indicated in Scheme 10.12. The first of these involves dechlorination, which is facilitated by CYP participation and involves cyclization to give 4,5-dihydro-[1,2,3]oxadiazole and the isocyanate, which is still capable of carbamylating proteins.³³ The oxadiazole can be further degraded by hydrolysis to give several inactive products. The second route involves denitrosation, which in the case of BCNU (carmustine) has been shown to be catalyzed by CYP monooxygenases and glutathione-*S*-reductase.³⁴

Scheme 10.10 • Mechanism of cisplatin activation and formation of DNA adducts.

Figure 10.6 • Nitrosoureas antineoplastics.

PROCARBAZINE, DACARBAZINE, AND TEMOZOLOMIDE

Procarbazine is an antineoplastic agent that was originally developed as a result of efforts to find new inhibitors of monoamine oxidase. Subsequent screening revealed antineoplastic activity.³⁵ It was initially believed that the cytotoxicity was related to the ability of the compound to undergo auto-oxidation to give hydrogen peroxide, which in the presence of Fe^{+2} would produce hydroxide radicals capable of cleaving DNA.^{36,37} Subsequent work showed that although this did occur, sufficient amounts of hydrogen peroxide were not produced to account for the observed effects. Metabolism studies revealed that oxidation of procarbazine does occur in the liver and is mediated by CYP and monoamine oxidase to give azo-procarbazine. This compound may also be generated nonenzymatically in an aerobic environment (Scheme 10.13).^{38–40} There are several chemical and metabolic pathways that azo-procarbazine may then undergo, and there is some disagreement regarding the exact structure of the active alkylating species. One such route involves CYP-mediated oxidation of the benzylic methylene carbon with subsequent decomposition to give methyl diazine and the aldehyde. The methyl diazine may then decompose by homolytic bond cleavage to give methyl and hydrogen radicals along with nitrogen gas or be further oxidized to give the diazo compound, which can decompose to give the methyl carbocation. Methyl diazine may also be produced by a minor route involving isomerization of

azo-procarbazine to give the hydrazone, which subsequently undergoes hydrolysis to give the aldehyde and methylhydrazine. Methylhydrazine may react with oxygen to give methyl diazine, which then decomposes as before. Studies utilizing radiolabeled procarbazine indicated that the terminal methyl group was found covalently bound to the N-7 position of guanine especially on tRNA disrupting its function and preventing protein, RNA, and DNA synthesis.⁴¹ There was also a small amount of methylation at the O-6 position of guanine.⁴² Hydrazines are also capable of inhibiting monoamine oxidase as seen with isocarboxazid and phenelzine; however, procarbazine is only a weak inhibitor of this enzyme. The agent is also capable of inhibiting aldehyde dehydrogenase and producing a disulfiram-like reaction. Given the involvement of the CYP system in its activation, the action of procarbazine is subject to drug interactions with both inducers and inhibitors of this system.

Somewhat related is dacarbazine, which was initially thought to act as an inhibitor of purine biosynthesis, but later was shown to be an alkylating agent.⁴³ Activation of the agent occurs through the action of CYP (isozymes 1A1, 1A2, and 2E1) to give the demethylated product monomethyl triazeno imidazole carboxamide (MTIC) (Scheme 10.14).⁴⁴ Tautomerization allows for decomposition to give the amino-carboxamido-imidazole and diazomethane, which is capable of alkylating DNA.⁴⁵ An alternative pathway involves acid catalyzed or photoinduced loss of dimethylamine to give an alternative diazo compound (diazo-IC), which may not only

Scheme 10.11 • Mechanism of DNA alkylation by nitrosoureas.

Scheme 10.12 • Metabolic and chemical inactivation of nitrosoureas.

generate a carbocation but also undergoes internal cyclization to give 2-azo-hypoxanthine.⁴⁶ Formation of diazo-IC has been associated with pain at the injection site, which is often seen during dacarbazine administration.⁴⁷ Methylation of DNA occurs at N-7, N-3 and O-6 of guanine among other sites.⁴⁸ Dacarbazine proved to be more active against murine tumors than against human tumors. This was attributed to the enhanced ability of mice to metabolize the agent to MTIC

and the subsequent conversion to a methylating species.⁴⁹ Building on this idea was temozolomide, which undergoes conversion to the same intermediate, MTIC, as dacarbazine, but it does not require metabolic activation to do so.^{50,51} Hydrolysis of temozolomide gives the carboxy-triazene, which spontaneously loses CO₂ to give MTIC. Dacarbazine must be administered intravenously; however, the related temozolomide may be administered orally.

Scheme 10.13 • Metabolic and chemical activation of procarbazine.

Scheme 10.14 • Metabolic and chemical activation of dacarbazine and temozolomide.

Individual Agents

MECHLORETHAMINE HYDROCHLORIDE (NH₂, MUSTARGEN)

Mechlorethamine is available in 10-mg vials for intravenous (IV) administration in the treatment of Hodgkin's lymphoma. It is part of the MOPP regimen used in treating this condition, which is comprised of mechlorethamine, vincristine (*Oncovin*), procarbazine, and prednisone. The agent is also used topically in the treatment of mycosis fungoides, a rare type of cancer but the most common type of cutaneous T-cell lymphoma. Additional uses have included treatment of cancers that have resulted in pleural effusion. Although the compound is a potent alkylating agent, resistance may develop as a result of increased inactivation by sulfhydryl containing proteins such as glutathione and increased expression of DNA repair mechanisms. Adverse effects include dose-limiting myelosuppression and nausea/vomiting. There is a significant risk of extravasation upon IV administration, and the agent may produce pain at the injection site. Additional adverse effects include

alopecia, azoospermia, amenorrhea, hyperuricemia, and an increased risk of secondary cancers.

CHLORAMBUCIL (AMBOCHLORIN, ABMOCLORIN, LEUKERAN)

Chlorambucil is available as 2-mg tablets for oral administration in the treatment of Hodgkin's lymphoma, and chronic lymphocytic leukemia in combination with prednisone and as a single agent. The mechanisms of resistance are the same as those seen for other agents of the class such as mechlorethamine. The agent is well absorbed (75%) upon oral administration and highly protein bound. Metabolism is mediated by CYP and occurs extensively to give several metabolites, including the active phenylacetic acid–nitrogen mustard. The drug is eliminated via the kidneys with a terminal elimination half-life of 1.5 hours. Adverse effects include dose-limiting myelosuppression, which are seen as both leucopenia and thrombocytopenia. Nausea and vomiting occur less often than for mechlorethamine. Additional adverse effects include hyperuricemia, azoospermia, amenorrhea, seizures, pulmonary fibrosis, and skin rash.

MELPHALAN (L-PAM, ALKERAN, L-PHENYLALANINE MUSTARD)

Melphalan is available in 2-mg tablets and 50-mg vials for oral and IV administration, respectively in the treatment of multiple myeloma, breast and ovarian cancer, and in high-dose therapy when bone marrow transplant is being utilized. The mechanisms of resistance are the same as those seen for mechlorethamine. The agent is poorly absorbed when given by the oral route. Melphalan is highly plasma protein bound (80%–90%) and inactivated in the blood by water to give the hydroxy metabolites. Elimination occurs primarily in the feces with an elimination half-life of 38 to 108 minutes. The commonly seen adverse effects are myelosuppression, nausea, and vomiting. Nausea is normally mild with normal doses but becomes severe when high doses are used during bone marrow transplant. Less commonly seen adverse effects are hypersensitivity reactions, skin rash, and alopecia. Secondary cancers are also of concern with the use of the agent.

CYCLOPHOSPHAMIDE (CTX, CPM, CPA, CLAFEN, CYTOXAN, NEOSAR)

Cyclophosphamide is available in 25- and 50-mg tablets for oral administration and 100-, 200-, 500-, 1,000-, and 2,000-mg vials for IV use in the treatment of a wide variety of cancers, including breast cancer, non-Hodgkin's lymphoma, chronic lymphocytic leukemia, ovarian cancer, bone and soft tissue sarcoma, rhabdomyosarcoma, neuroblastoma, and Wilms tumor. Coadministration of mesna is recommended. The alkylating agent is cell cycle–nonspecific, and mechanisms of resistance are similar to those seen for other alkylating agents including decreased uptake and activation and increased inactivation by glutathione and oxidase enzymes (aldehyde dehydrogenase and alcohol dehydrogenase) as well as increased DNA repair mechanisms. The agent is well absorbed when given orally. Metabolism by CYP2B6 and 3A4/5 is required for activation of the agent, and metabolites are formed as a result of this activation by subsequent reactions that are shown in Scheme 10.5. The major metabolite seen in plasma is the phosphoramidate mustard, although there is a small amount of material (10%) arising from the dechloroethylation, which is primarily mediated by 3A4/5. This metabolic pathway gives rise to a small amount of chloroacetaldehyde, which is both neurotoxic and nephrotoxic. The parent compound and metabolites are eliminated in the urine with an elimination half-life of 4 to 6 hours. Adverse effects include dose-limiting myelosuppression, which normally presents as leucopenia. Bladder toxicity, which presents as hemorrhagic cystitis, is related to the formation of electrophilic species in the kidney including acrolein and may be treated by administration of mesna and increased water intake. Additionally, amenorrhea may be seen and sterility may be permanent. Other effects include alopecia, cardiotoxicity, inappropriate secretion of antidiuretic hormone, and an increased risk of secondary cancers.

IFOSFAMIDE (IPHOSPHAMIDE, IFO, CYFOS, IFEX, IFOSFAMIDUM)

Ifosfamide is available in 1- and 3-g vials for IV administration as Food and Drug Administration (FDA)-approved third-line therapy in the treatment of testicular cancer. It has

also been utilized (although not FDA approved) in the treatment of a wide variety of cancers including Hodgkin's and non-Hodgkin's lymphoma, soft tissue sarcoma, germ cell tumors, small cell lung cancer, non–small cell lung cancer (NSCLC), cancers of the head and neck, bladder cancer, cervical cancer, and Ewing sarcoma. Coadministration of mesna is recommended. The mechanisms of resistance are identical to those seen with cyclophosphamide. The drug is widely distributed with a low extent of protein binding (20%). Metabolism primarily by CYP3A4/5 and CYP2B6 is required for activation of the compound (Scheme 10.7). The agent is administered as the racemic mixture as a result of the presence of the chiral phosphorus atom, and differential metabolism of the *R*- and *S*-isomers has been observed. In contrast to cyclophosphamide, there is a greater amount of deactivation of the agent by *N*-dechloroethylation and subsequently more chloroacetaldehyde is produced, which may result in a greater amount of neurotoxicity and nephrotoxicity than seen with cyclophosphamide. The *N*-dechloroethylated metabolites are the predominate species seen in the plasma. The parent and metabolites are eliminated in the urine with an elimination half-life of 3 to 10 hours. The major components found in the urine are the dechloroethylated metabolites. Dose-limiting toxicities include myelosuppression and bladder toxicity. Other adverse effects include nausea, alopecia, amenorrhea, inappropriate secretion of antidiuretic hormone, as well as the production of secondary cancers. Neurotoxicity, which is associated with the production of chloroacetaldehyde presents as confusion, seizure, weakness, and hallucination, and coma may occur.

THIOTEPA (TRIETHYLENETHIOPHOSPHORAMIDE, GIROSTAN, STEPA, TESPA, THIOPLEX, TIFOSYL)

Thiotepa is available in 15-mg vials for IV administration in the treatment of bladder cancer, ovarian cancer, and breast cancer. It has been used in the past in the treatment of lymphomas such as Hodgkin's and non-Hodgkin's lymphoma but has now mostly been replaced by other agents. The agent is widely distributed after infusion, and 40% is bound to plasma proteins. Metabolism mediated by CYP2B1 and CYP2C11 effects desulfurization to give TEPA from which aziridine may arise. Metabolites have also been identified as arising from glutathione conjugation of thiotepa followed by formation of the mercapturic acid derivative. However, the excretion profile has only accounted for a small percentage (10%–22%) of the administered dose. The elimination half-life of the compound is 2 to 3 hours. Adverse effects include dose-limiting myelosuppression and mucositis. Additionally, nausea, vomiting, skin rash, hemorrhagic cystitis, and secondary cancers may occur.

BUSULFAN (BUSULFEX, MYLERAN)

Busulfan is available as 2-mg tablets for oral administration and 10-mL vials for IV administration in the treatment of chronic myelogenous leukemia (CML) and in high-dose therapy for refractory leukemia with bone marrow transplant. The agent is well absorbed when given orally, well distributed into tissues, and crosses the blood-brain barrier. Metabolism occurs in the liver as shown in Scheme 10.9 to give mainly methane sulfonic acid by the action of glutathione-*S*-transferase. Other identified metabolites in humans have included tetrahydrothiophene-1-oxide, sulfalene,

and 3-hydroxysulfolane. The metabolites are excreted primarily in the urine, and the terminal elimination half-life is 2.5 hours. Adverse effects include dose-limiting myelosuppression; nausea and vomiting that occur commonly but are generally mild; and pulmonary symptoms including interstitial pulmonary fibrosis, which is referred to as "busulfan lung," occurs belatedly (1–10 years posttreatment) and although rare, it is severe. Other adverse effects include mucositis, skin rash, impotence, amenorrhea, infertility, hepatotoxicity, insomnia, anxiety, and an increased risk of secondary malignancies. At normal doses, the agent is well tolerated except for the myelosuppression that occurs. This has allowed for high-dose therapy with the agent when accompanied by bone marrow transplant to counter the myelosuppressive effects.

CISPLATIN (CIS-DIAMINEDICHLOROPLATINUM, DDP, PLATINOL, PLATINOL-AQ)

Cisplatin is available in 10- and 50-mg vials for IV administration in the treatment of a wide variety of cancers including non-Hodgkin's lymphoma, bladder cancer, ovarian cancer, testicular cancer, and cancers of the head and neck. A liposomal form is also available as well as an injectable collagen matrix gel containing cisplatin. Compared with other platins, cisplatin is the most reactive and therefore the most effective in platinating DNA. After IV administration, the agent is widely distributed, highly protein bound (90%), and concentrates in the liver and kidney. After infusion, covalent attachment to plasma proteins occurs such that after 4 hours, 90% of drug is protein bound. The elimination of platinum from the blood is a slow process with a terminal elimination half-life of 5 to 10 days. Metabolism involves aquation, which occurs to a greater extent once distribution out of the plasma has occurred. Additional metabolites have been seen resulting from reaction with glutathione and cysteine. The greater reactivity of cisplatin gives rise to significant toxicities compared with other platins. These include dose-limiting nephrotoxicity, which normally presents as elevated blood urea nitrogen (BUN) and creatinine. This effect is cumulative upon repeated dosing and may progress further to necrosis, altered epithelial cells, cast formation, and thickening of the tubular basement membranes but is generally reversible upon discontinuation of drug treatment. Sodium thiosulfate may be given to reduce the nephrotoxicity. Neurotoxicity may also be dose limiting, normally presenting initially as numbness but may progress to seizure. Other adverse effects include myelosuppression, nausea, vomiting, alopecia, ototoxicity, ocular toxicity, azoospermia, impotence, myocardial infarction, thrombotic events, and inappropriate secretion of antidiuretic hormone.

CARBOPLATIN (CBDCA, PARAPLAT, PARAPLATIN)

Carboplatin is available in 50-, 150-, and 450-mg vials for IV administration in the treatment of ovarian cancer, bladder cancer, germ cell tumors, head and neck cancers, small cell lung cancer, and NSCLC. Activation of the agent occurs by aquation in a manner similar to that seen for cisplatin. The presence of the chelating 1,1-cyclobutane-dicarboxylate slows this reaction 100-fold and reduces the toxicity of the agent. The sites of alkylation and mechanisms of resistance are like those seen for cisplatin, and the two agents show cross-resistance. The agent is widely distributed upon IV

administration but, because of its greater stability, it binds slowly to plasma proteins, requiring 24 hours to reach 90% bound drug compared with 4 hours for cisplatin. The agent is eliminated in the urine with a terminal elimination half-life of 2 to 6 hours. Adverse effects include myelosuppression, which is dose limiting. Other adverse effects include renal toxicity, nausea, vomiting, and peripheral neuropathy, but these occur much less frequently than with cisplatin.

OXALIPLATIN (DIAMINOCYCLOHEXANE PLATINUM, DACH-PLATINUM, ELOXATIN)

Oxaliplatin is available in 50- and 100-mg vials for IV administration in the treatment of ovarian cancer, metastatic colorectal cancer, and early stage colon cancer in combination with 5-fluorouracil/leucovorin. The activation of the agent occurs in low-chloride environments to give the aquated species, which subsequently reacts with DNA in a manner similar to cisplatin. The mechanisms of resistance are similar for the two agents; however, oxaliplatin is not recognized by MMR enzymes and does not show cross-resistance with cisplatin. The agent is widely distributed, highly protein bound (85%–88%), and irreversibly binds to erythrocytes. Numerous metabolites have been identified many of which are produced as a result of nonenzymatic processes and include chloro-, dichloro-, monoquo-, and diaquo-species. The parent and metabolites are eliminated primarily in the urine with a long terminal elimination half-life of 240 hours. Neurotoxicity is dose limiting and normally presents as peripheral neuropathy, which may be exacerbated by exposure to low temperatures. The neurotoxicity is normally reversible in contrast to that seen with cisplatin, which may be irreversible. Other adverse effects include nausea, vomiting, diarrhea, myelosuppression, and hypersensitivity reactions. Ototoxicity and renal toxicity occur only rarely in contrast to cisplatin.

CARMUSTINE (BIS-CHLOROETHYL-NITROSOUREA, BCNU, BECENUM, CARMUBRIS, BICNU, GLIADEL)

Carmustine is available in a 100-mg vial for IV administration in the treatment of several types of brain tumors, Hodgkin's and non-Hodgkin's disease, and multiple myeloma. The agent is also available as an implantable wafer containing 7.7 mg of drug for intracavity implantation in the treatment of glioblastoma multiforme. Cytotoxicity is associated with cross-linking of DNA and RNA and carbamoylation of glutathione reductase. Cross-resistance is not seen with other alkylating agents. The agent is very lipid soluble and easily crosses the blood-brain barrier, achieving concentrations greater than 50% of those seen in plasma. Metabolism involves both the nonenzymatic formation of reactive intermediates that may react with glutathione and other thiol-containing proteins, as well as enzymatic reductive denitrosation and dechlorination. The half-life of the agent in plasma is short (15–20 minutes) because of rapid decomposition. Myelosuppression is dose limiting and may present as thrombocytopenia, leucopenia, or more rarely as anemia. This is generally seen 24 to 48 days after treatment. Pulmonary toxicity occurs rarely at low doses but at high doses such as those seen during bone marrow transplant may present as dyspnea, cough, pulmonary infiltrates, and progress to respiratory failure. This may be seen years after the completion of therapy. Other toxicities include nausea,

vomiting, pain at the injection site, impotence, sterility, amenorrhea, and infertility. Hepatotoxicity may initially present as elevations in serum transaminase levels. There is also an increased risk of secondary cancers as is often seen with the alkylating agents.

LOMUSTINE (CHLOROETHYL-CYCLOHEXYL-NITROSOUREA, CCNU, CEENU)

Lomustine is available in 10-, 40-, and 100-mg capsules for oral administration in the treatment of primary and metastatic brain cancers and Hodgkin's lymphoma. This lipophilic agent is well absorbed, widely distributed, and crosses the blood-brain barrier. Lomustine undergoes extensive hepatic metabolism, which is mediated by CYP3A4 to give several hydroxylated metabolites, which arise as a result of oxidation of the cyclohexyl ring. Several of these are more active than the parent compound. Denitrosation and dechlorination have also been demonstrated to occur for lomustine as well. The intact drug was not found in plasma when the agent was administered orally. Elimination occurs primarily in the urine with an elimination half-life of 16 to 72 hours. Myelosuppression is dose limiting and presents in a manner similar to that seen with carmustine. Other toxicities include nausea, vomiting, anorexia, impotence, sterility, amenorrhea, and infertility. Pulmonary and renal toxicity are rarely seen during standard-dose therapy but increase during high-dose therapy.

STREPTOZOCIN (STREPTOZOTOCIN, STZ, ZANOSAR)

Streptozocin is available in 1-g vials for IV administration in the treatment of metastatic islet cell carcinoma of the pancreas, colon cancer, and Hodgkin's disease. Activation results in the formation of methyl carbonium ions, which alkylate DNA, but the agent is less effective in alkylating DNA and carbamylating proteins than other nitrosoureas, which is because in part of an intramolecular carbamoylation. The internal carbamate group migration occurs via the hydroxyl groups of the glucose portion of the molecule. There is a reduced effect on RNA function compared with other nitrosoureas as well. The hydrophilic agent is rapidly cleared from the plasma with an elimination half-life of 35 minutes. The presence of the glucose moiety allows for utilization of glucose transporters, which concentrate the compound in the β -cells of the pancreas. The metabolism of the agent has not been well characterized. Renal toxicity is dose limiting and may present initially as proteinuria and azotemia but may progress to renal failure. Nausea and vomiting may be severe with the agent, whereas myelosuppression is generally mild. Normal glucose metabolism may be altered so that hypoglycemia or hyperglycemia may be seen. In some animal species, streptozocin produces diabetes but much milder effects are seen in man.

PROCARBAZINE HYDROCHLORIDE (PCZ, PCB, MATULANE)

Procarbazine is available in 50-mg tablets for oral administration in the treatment of Hodgkin's (part of MOPP) and non-Hodgkin's disease, brain cancer, and mycosis fungoides. The major mechanisms of resistance appear to be enhanced activity of DNA-repair enzymes including enhanced *O*-6-alkylguanine DNA transferase (AGAT),

which removes the methyl group from the *O*-6 of guanine. The agent is rapidly and completely absorbed after oral administration and extensively metabolized in the liver to give azo-procarbazine followed by further oxidation to methyldiazine and the aldehyde. The parent drug and metabolites cross the blood-brain barrier. Elimination occurs in the urine mostly as metabolites with an elimination half-life of 1 hour. Myelosuppression is dose limiting, generally presenting as thrombocytopenia that may be followed by leucopenia. Glucose-6-phosphate dehydrogenase deficient patients may develop hemolytic anemia during procarbazine therapy. Other adverse effects include nausea, vomiting, hypersensitivity, flulike symptoms, amenorrhea, and azoospermia. Central nervous system effects may be seen, including lethargy, confusion, neuropathies, and seizure.

DACARBAZINE (DTIC, DTIC-DOME)

Dacarbazine is available in 100- and 200-mg vials for IV administration in the treatment of Hodgkin's disease, malignant melanoma, carcinoid cancer, neuroblastoma, and soft tissue sarcoma. Resistance to dacarbazine has been primarily attributed to enhanced activity of AGAT. The volume of distribution exceeds the amount of water in the body suggesting the compound distributes into body tissues possibly the liver. The agent is not highly protein bound (20%) and is metabolized in the liver by CYP to give MTIC and 4-amino-5-imidazole-carboxamide (AIC). The demethylation reaction is mediated by isozymes CYP1A1/2 and CYP2E1. Elimination occurs via the urine with 40% to 50% occurring as unchanged drug. Dose-limiting myelosuppression presents as both leucopenia and thrombocytopenia. Other adverse effects include nausea, vomiting, flulike symptoms, photosensitivity, and pain at the injection site.

ALTRETAMINE (HMM, HEXALEN, HEXAMETHYLMELAMINE)

Altretamine (Fig. 10.7) is available in 50-mg capsules for oral administration as a second-line treatment for ovarian cancer. The mechanism of action has not been firmly established, although the spectrum of activity is similar to that for other alkylating agents; however, cross-resistance is not seen. Cytotoxicity has been correlated with metabolism to give the carbinolamines, which may form imines capable of cross-linking, or decompose to give formaldehyde, which may react with nucleophiles on DNA or proteins. The agent is well absorbed upon oral administration, well distributed, and highly (90%) plasma protein bound. The agent is extensively metabolized in the liver by CYP to give demethylated metabolites

Altretamine

Figure 10.7 • Chemical structure of altretamine.

via the previously mentioned carbinolamines. Elimination occurs primarily in the urine as mostly demethylated metabolites with a terminal elimination half-life of 4 to 10 hours. Myelosuppression and nausea/vomiting are dose-limiting toxicities. Other adverse effects include lethargy, agitation, hallucinations, skin rash, and elevations in transaminase levels, flulike symptoms, abdominal cramps, and diarrhea.

ANTIMETABOLITES

Antimetabolites are compounds closely related in structure to a cellular precursor molecule, yet these imposter substances are capable of preventing the proper use or formation of the normal cellular product. These antimetabolites are similar enough in structure in many cases to interact with the normal cellular process but differ in a manner sufficient to alter the outcome of that pathway. Most antimetabolites are effective cancer chemotherapeutic agents via interaction with the biosynthesis of nucleic acids. Therefore, several of the useful drugs used in antimetabolite therapy are purines, pyrimidines, folates, and related compounds. The antimetabolite drugs may exert their effects by several individual mechanisms involving enzyme inhibition at active, allosteric, or related sites. Most of these targeted enzymes and processes are involved in the regulatory steps of cell division and cell/tissue growth. Often the administered drug is actually a prodrug form of an antimetabolite and requires activation *in vivo* to yield the active inhibitor. The administration of many purine and pyrimidine antimetabolites requires the formation of the nucleoside and finally the corresponding nucleotide for antimetabolite activity. An antimetabolite and its transformation products may inhibit several different enzymes involved in tissue growth. These substances are generally cell cycle specific with activity in the S phase.

The purine and pyrimidine antimetabolites are often compounds incorporated into nucleic acids and the nucleic acid polymers (DNA, RNA, etc.). The antifolates are compounds designed to interact at cofactor sites for enzymes involved in the biosynthesis of nucleic acid bases. The biosynthesis of these nucleic acid bases depend heavily on the availability of folate cofactors, hence antimetabolites of the folates find utility as antineoplastic agents. The antitumor effects of all these compounds attempting to masquerade as the natural precursor compound may occur because of a malfunction in the biosynthesis of the corresponding macromolecules. Classic examples of pyrimidine and purine antimetabolites are 5-fluorouracil and 6-mercaptopurine, respectively, and the classic antifolate is methotrexate.

The purine analog 6-mercaptopurine and its bioactivation products interact with many enzymes in the various stages of cell division.⁵² The activity of 6-mercaptopurine requires bioactivation to its ribonucleotide, 6-thioinosinate, by the enzyme hypoxanthine-guanine phosphoribosyl transferase (HGPRT). 6-Thioinosinate is a potent inhibitor of the conversion of 5-phosphoribosylpyrophosphate into 5-phosphoribosylamine. The ribose diphosphate and triphosphates of 6-mercaptopurine are active enzyme inhibitors, and the triphosphate can be incorporated into DNA and RNA to inhibit chain elongation.

The pyrimidine analog 5-fluorouracil was designed based on the observation that in certain tumors, uracil was

used for nucleic acid pyrimidine biosynthesis.⁵³ Fluorine, at the 5-position of uracil, blocks the conversion of uridylylate to thymidylate, thus diminishing DNA biosynthesis. The fluorine induced increase in acidity (inductive effect) was expected to cause the molecule to bind more strongly to enzymes of the various stages of pyrimidine biosynthesis. Thymidine is a logical target, because it is only found in DNA and not in RNA. 5-Fluorouracil is activated by anabolism to 5-fluoro-2-deoxyuridylic acid, and this activated species is a strong inhibitor of thymidylate synthetase, the enzyme that converts 2'-deoxyuridylic acid to thymidylic acid.

Methotrexate inhibits the binding of the substrate folic acid to the enzyme dihydrofolate reductase (DHFR), resulting in reductions in the synthesis of nucleic acid bases, perhaps most importantly, the conversion of uridylylate to thymidylate as catalyzed by thymidylate synthetase, which requires folate cofactors.

The pathways for the normal biosynthesis of the pyrimidine and purine bases are summarized in Schemes 10.15 and 10.16, respectively. The biosynthesis of pyrimidine and purine monomers is a central component for DNA and RNA formation in mammalian cells. The process of cell division and tissue growth is a very complex set of biochemical events with many feedback controls. Thus, antimetabolite drugs based on pyrimidine, purine, and related structures may exert their effects by altering many metabolic processes and pathways. The final step in Figure 10.15 illustrates the conversion of ribonucleotides to deoxyribonucleotides catalyzed by ribonucleotide reductase. The substrate for this enzyme is the ribonucleotide diphosphate, and the process is the same for both purine and pyrimidine bases.

Pyrimidine Drugs

The anticancer drugs based on pyrimidine structure are shown in Figure 10.8. The pyrimidine derivative 5-fluorouracil (5-FU) was designed to block the conversion of uridine to thymidine. The normal biosynthesis of thymidine involves methylation of the 5-position of the pyrimidine ring of uridine. The replacement of the hydrogen at the 5-position of uracil with a fluorine results in an antimetabolite drug, leading to the formation of a stable covalent ternary complex composed of 5-FU, thymidylate synthase (TS), and cofactor (a tetrahydrofolate species). The normal pathway for the formation of thymidine from uridine catalyzed by the enzyme TS is shown in Scheme 10.17. Anticancer drugs targeting this enzyme should selectively inhibit the formation of DNA because thymidine is not a normal component of RNA.

TS is responsible for the reductive methylation of deoxyuridine monophosphate (dUMP) by 5,10-methylenetetrahydrofolate to yield dTMP and dihydrofolate.⁵⁴ Because thymine is unique to DNA, the TS enzyme system plays an important role in replication and cell division. The tetrahydrofolate cofactor species serves as both the one-carbon donor and the hydride source in this system. The initial step of the process involves the nucleophilic attack by a sulfhydryl group of a cysteine residue at the 6-position of dUMP. The resulting enolate adds to the methylene of 5,10-CH₂-THF perhaps activated via the very reactive *N*-5-iminium ion (see Scheme 10.17). The iminium ion likely forms at *N*-5 and only after 5,10-CH₂-THF binds to TS.⁵⁴

Scheme 10.15 • Biosynthetic pathway for pyrimidine nucleotides.

The iminium ion is likely formed at N-5 because it is the more basic of the two nitrogens, whereas N-10 is the better leaving group. The loss of the proton at the 5-position of dUMP and elimination of folate yields the exocyclic methylene uracil species. The final step involves hydride transfer from THF and elimination to yield the enzyme, DHF, and dTMP.

5-Fluorouracil is activated by conversion to the corresponding nucleotide species,⁵³ 5-fluoro-2-deoxyuridylic acid (see Scheme 10.18). The resulting 5-fluoro-2'-deoxyuridylic acid is a powerful inhibitor of thymidylate synthetase, the enzyme that converts 2'-deoxyuridylic acid to thymidylic acid. In the inhibiting reaction, the sulfhydryl group of TS adds via conjugate addition to the 6-position of the fluorouracil moiety (Scheme 10.19). The carbon at the 5-position then binds to the methylene group of 5,10-methylenetetrahydrofolate following initial formation of the more electrophilic form of folate the N-5-iminium ion. In the normal process, this step is followed by the elimination of dihydrofolate from the ternary complex, regeneration of

the active enzyme species, and the product thymidine. Central to this process is the loss of the proton at the 5-position of uracil to form the exocyclic methylene uracil species. The 5-fluorine is stable to elimination, and a terminal product results, involving the enzyme, cofactor, and substrate, all covalently bonded (Scheme 10.19).

The chemical mechanism of inhibition of thymidylate synthetase by 5-fluorouracil is shown in Scheme 10.19. This process clearly shows that in order to inactivate the TS enzyme, both 5-FU and the tetrahydrofolate species are required to form the ternary complex. Some clinical studies have shown that administration of a tetrahydrofolate source prior to treatment with 5-FU results in greater inhibition of total TS activity. The administered source of active 5,10-methylenetetrahydrofolate is leucovorin, *N*-5-formyltetrahydrofolate.

TS is the most obvious and well-documented mechanism of action for 5-FU cytotoxic activity. However, other mechanisms may play a role in the overall value of this drug in the treatment of human cancer. The triphosphate of 5-FU

Scheme 10.16 • Biosynthetic pathway for purine nucleotides. (THF, tetrahydrofolate.)

Figure 10.8 • Anticancer drugs based on pyrimidine and related compounds.

nucleotide is a substrate for RNA polymerases, and 5-FU is incorporated into the RNA of some cell lines. The incorporation of 5-FU into DNA via DNA polymerase occurs in some tissue lines even though uracil is not a common component of human DNA. The 5-FU in DNA likely serves as substrate for the editing and repair enzymes involved in DNA processing for cell division and tissue growth. The actual addition of 5-FU into RNA and/or DNA may not be the direct cytotoxic event, but the incorporation may lead to less efficient utilization of cellular resources. The significance of these various mechanisms on the overall cytotoxic effects of 5-FU may vary with cell line and tissue.

The metabolic activation (anabolism) of 5-FU required to produce the anticancer effects accounts for no more than 20% of the administered amount of drug in most patients. Catabolic inactivation via the normal pathways for uracil consumes the remaining approximate 80% of the dose. The major enzyme of pyrimidine catabolism is dihydropyrimidine dehydrogenase (DPD), and 5-FU is a substrate for this enzyme.⁵⁵ The DPD catabolism of 5-FU is shown in Scheme 10.20. The formation of dihydro-5-FU (5-FU-H₂) occurs very rapidly and accounts for the majority of the total 5-FU dose in most patients. Thus, α -fluoro- β -alanine is the major human metabolite of 5-FU.⁵⁶ Uracil is a substrate for this enzyme system also and has been dosed with 5-FU and 5-FU prodrugs in an attempt to saturate DPD and conserve active drug species. Variability in the levels of DPD activity among the patient population is a major factor in the bioavailability of 5-FU. Inhibitors of DPD such as uracil or 5-chloro-2,4-dihydropyridine (CDHP)⁵³ increase the plasma concentration–time curve of 5-FU by preventing 5-FU catabolism. One mechanism of drug resistance in 5-FU-treated patients may be caused by increased levels of DPD in the target tissue. The

observed low bioavailability of 5-FU as a result of the catabolic efficiency of DPD and other enzymes has led to the development of unique dosing routes and schedules as well as the development of prodrug forms of 5-FU.⁵³

Attempts at chemical modification of 5-FU to protect from catabolic events have produced several prodrug forms, which are converted via *in vivo* metabolic and/or chemical transformation to the parent drug 5-FU.⁵⁷ Figure 10.8 shows the structure of the more common prodrug forms of 5-FU. The carbamate derivative of 5'-deoxy-5-fluorocytidine is known as *capecitabine*, and it is converted to 5-FU through a series of activation steps. The activation sequence is shown in Scheme 10.21. The initial step is carbamate hydrolysis followed by deamination, then hydrolysis of the sugar moiety to yield 5-FU. Some of these activation steps take place at a higher rate in tumor tissue leading to selective accumulation in those cells.⁵³ The last step in the sequence shown in Scheme 10.21 is catalyzed by phosphorolases, and these enzymes occur in higher levels in colorectal tumors. Despite this complex activation process, capecitabine still exhibits some of the significant toxicities of 5-fluorouracil. The tetrahydrofuran derivative tegafur is slowly converted to 5-FU but requires quite high doses to reach therapeutic plasma concentrations. Esters of the *N*-hydroxymethyl derivative of tegafur show greater anticancer activity than tegafur.⁵⁸

Pyrimidine analogs as antimetabolites for cancer therapy have been developed based on the cytosine structure as well. Modification of the normal ribose or deoxyribose moiety has produced useful drug species such as cytarabine (ara-C) and gemcitabine, see Figure 10.8. Cytosine arabinoside (ara-C or cytarabine) is simply the arabinose sugar instead

(text continues on page 378)

of ribose, and the only difference in structure is the epimeric hydroxyl group at the 2'-position of the pentose sugar. This epimeric sugar is similar enough to the natural ribose to allow ara-C to be incorporated into DNA, and its mechanism of action may include a slowing of the DNA chain elongation reaction via DNA polymerase or cellular inefficiencies in DNA processing or repair after incorporation.

Gemcitabine⁵⁹ is the result of fluorination of the 2'-position of the sugar moiety. Gemcitabine is the 2',2'-difluoro deoxycytidine species and after its anabolism to diphosphate and triphosphate metabolites, it inhibits ribonucleotide reductase and competes with 2'-deoxycytidine triphosphate for incorporation into DNA. The mechanism of action for gemcitabine is likely similar to that of ara-C including alteration of the rate of incorporation into DNA as well as the rate of DNA processing and repair.

Modification of the pyrimidine ring has also been explored for the development of potential anticancer drugs based on antimetabolite theory. Several pyrimidine nucleoside analogs have one more or one less nitrogen in the heterocyclic ring. They are known as *azapyrimidine* or *deazapyrimidine nucleosides*. 5-Azacytidine is an example of a drug in this category (see Fig. 10.8). This compound was developed via organic synthesis and later found as a natural product of fungal metabolism. The mode of action of this compound is complex involving reversible inhibition of DNA methyltransferase, and this lack of methylated DNA activates tumor suppressor genes. In certain tumor systems, it is incorporated into nucleic acids, which may result in misreading or processing errors.

Purine Drugs

The anticancer drugs based on purine structure are shown in Figure 10.9. The design of antimetabolites based on purine structure began with isosteric thiol/sulphydryl group to replace the 6-hydroxyl group of hypoxanthine and guanine. One of the early successes was 6-mercaptapurine (6-MP), the thiol analog of hypoxanthine.⁶⁰ This purine requires bioactivation to its ribonucleotide, 6-thioinosinate (6-MPMP), by the enzyme HGPRT. The resulting nucleotide (Scheme 10.22) is a potent inhibitor of an early step in basic purine biosynthesis, the conversion of 5-phosphoribosylpyrophosphate into 5-phosphoribosylamine (see Scheme 10.16). The ribose diphosphate and triphosphates of 6-mercaptapurine are active enzyme inhibitors, and the triphosphate can be incorporated into DNA and RNA to inhibit chain elongation.⁶¹ However, the major antineoplastic action of 6-MP appears to be related to the inhibition of purine biosynthesis.

Thioguanine (6-TG) is the 6-mercapto analog of guanine, analogous to 6-MP. Thioguanine is converted into its ribonucleotide by the same enzyme that acts on 6-mercaptapurine. It is converted further into the diphosphates and triphosphates. These species inhibit most of the same enzymes that are inhibited by 6-mercaptapurine.⁶² Thioguanine is also incorporated into RNA, and its 2'-deoxy metabolite is incorporated into DNA. The incorporation into RNA and DNA and the subsequent disruption of these polymers may account for a greater portion of the antineoplastic activity of thioguanine compared with 6-MP.⁶³

Figure 10.9 • Anticancer drugs based on purines and related compounds.

Scheme 10.22 • Conversion of 6-MP to active 6-thioinosine-5-monophosphate (6-MPMP) by HGPRT and inactivation by xanthine oxidase and thiopurine methyl transferase.

The antineoplastic activity of these purines as well as most antimetabolites depends on the relative rates of enzymatic activation and inactivation of these compounds in various tissues and cells. Drug resistance in certain cell lines may be caused by lower activity of activating enzymes or higher activity of catabolic enzymes.⁶⁴ For the classic purine antimetabolites 6-MP major pathways of inactivation (see Scheme 10.22) include *S*-methylation via thiopurine-*S*-methyl-transferase (TPMT) and oxidation by the enzyme xanthine oxidase (XO).⁶² Xanthine oxidase converts the drugs to the inactive thiouric acid, and inhibition of the enzymes responsible for the catabolic breakdown of the purine drugs can potentiate the drug's antineoplastic activity. Allopurinol is a potent inhibitor of xanthine oxidase and is often used as an adjuvant in purine anticancer drug therapy. Allopurinol increases both the potency and the toxicity of 6-mercaptopurine. Its main importance is that it prevents the uric acid kidney toxicity caused by the release of purines from destroyed cancer cells.

Heterocyclic derivatives of 6-mercaptopurine, such as azathioprine, were designed to protect it from catabolic reactions. Although azathioprine has antitumor activity, it is not significantly better than 6-mercaptopurine. It has an important role, however, as an immunosuppressive agent in organ transplants. Adenine arabinoside (Vidarabine) contains the sugar, *D*-arabinose, which is epimeric with *D*-ribose at the 2'-position. This structural change makes it a competitive inhibitor of DNA polymerase, and this activity accounts for its antineoplastic activity as well as its antiviral action. Adenine arabinoside and some of its derivatives are limited in their antitumor effect by susceptibility to adenosine deaminase. This enzyme converts them into the inactive hypoxanthine arabinoside derivatives. High levels of adenosine deaminase accounts for resistance of certain tumors to the action of adenine arabinoside.

The addition of fluorine to the sugar moiety has produced some purine-based drugs with resistance to the catabolic activity of adenosine deaminase. In contrast to the susceptibility of adenosine arabinoside to adenosine deaminase, its 2-fluoro derivative, fludarabine, is stable to this enzyme. The antineoplastic activity of fludarabine depends on its anabolic conversion to the corresponding triphosphate. 2-Chloro-2'-deoxyadenosine (cladribine) also is resistant to adenosine deaminase. It is phosphorylated in cells to the

triphosphate by cytidine kinase, and the triphosphate inhibits enzymes required for DNA repair.

Folates

Folic acid and the structures of the major antifolate anticancer drugs are shown in Figure 10.10. Methotrexate is the classic antimetabolite of folic acid structurally derived by *N*-methylation of the para-aminobenzoic acid residue (PABA) and replacement of a pteridine hydroxyl by the bioisosteric amino group. The conversion of —OH to —NH₂ increases the basicity of N-3 and yields greater enzyme affinity. This drug competitively inhibits the binding of the substrate folic acid to the enzyme DHFR, resulting in reductions in the synthesis of nucleic acid bases, perhaps most importantly, the conversion of uridylate to thymidylate as catalyzed by thymidylate synthetase.⁶⁵ In addition, purine synthesis is inhibited because the *N*-10-formyl tetrahydrofolic acid is a formyl donor involved in purine synthesis. The interconversion of the various folate species is shown in Scheme 10.23. Recall that in Scheme 10.16, THFs are cofactors in at least two key steps in the normal biosynthesis of purines.

Methotrexate⁶⁶ is a broad-spectrum antineoplastic agent commonly used in the treatment of acute lymphoblastic and myeloblastic leukemia and other lymphomas and sarcomas. The major side effects seen are bone marrow suppression, pulmonary fibrosis, and GI ulceration. Leucovorin is often given 6 to 24 hours after methotrexate to prevent the long-term effects on normal cells by preventing the inhibition of DNA synthesis. Related to this is Pemetrexed, but its scope is greater in that it not only inhibits DHFR but also TS and glycinamide ribonucleotide formyltransferase (GARFT), which is involved in purine biosynthesis (see Fig. 10.16). The material is taken into tumor cells by the reduced folate-carrier systems and subsequently converted to the polyglutamate, which is retained in the cell.

Products

5-FLUOROURACIL (5-FU, EFUDEX, ADRUCIL, FLUOROPLEX)

The drug is available in a 500-mg or 10-mL vial for IV use and as a 1% and 5% topical cream. 5-FU is used in the treatment of several carcinoma types including breast cancer,

Folic Acid

Methotrexate

Pemetrexed

Trimetrexate

Figure 10.10 • Structures of folic acid and antifolate anticancer drugs.

colorectal cancer, stomach cancer, pancreatic cancer, and topical use in basal cell cancer of the skin. The mechanism of action includes inhibition of the enzyme TS by the deoxyribose monophosphate metabolite, 5-FdUMP. The triphosphate metabolite is incorporated into DNA and the ribose triphosphate into RNA. These incorporations into growing chains result in inhibition of synthesis and function of DNA and RNA. Resistance can occur as a result of increased expression of TS, decreased levels of reduced folate substrate 5,10-methylenetetrahydrofolate, or increased levels of dihydropyrimidine dehydrogenase. Dihydropyrimidine dehydrogenase is the main enzyme responsible for 5-FU catabolism.

Bioavailability following oral absorption is erratic. Administration of 5-FU by IV yields high drug concentrations in bone marrow and liver. The drug does distribute into the central nervous system (CNS). Significant drug interactions include enhanced toxicity and antitumor activity of 5-FU following pretreatment with leucovorin. Toxicities include dose-limiting myelosuppression, mucositis, diarrhea, and hand-foot syndrome (numbness, pain, erythema, dryness, rash, swelling, increased pigmentation, nail changes, pruritus of the hands and feet).

CAPECITABINE (XELODA)

The drug is available in a 150- and 500-mg tablets for oral use. This drug is a fluoropyrimidine carbamate prodrug form of 5-fluorouracil (5-FU). It is used to treat breast cancer and colorectal cancer. The drug is converted to 5-FU by the enzyme thymidine phosphorylase following esterase ac-

tivity to hydrolyze the carbamate moiety and deamination. Capecitabine is readily absorbed by the GI tract, and peak plasma levels of 5-FU occur about 2 hours after oral administration. Indications, drug interactions, and toxicities are equivalent to those of 5-FU.

CYTARABINE (CYTOSINE ARABINOSIDE, ARA-C, CYTOSAR-U, TARABINE)

The drug is available in 100-, 500-, 1,000-, and 2,000-mg multidose vials for IV use. Cytarabine is used in the treatment of acute myelogenous leukemia and CML. This drug is a deoxycytidine analog originally isolated from the sponge *Cryptothethya crypta*. It is active following intracellular activation to the nucleotide metabolite ara-CTP. The resulting ara-CTP is incorporated into DNA resulting in chain termination and inhibition of DNA synthesis and function. Resistance can occur because of decreased activation or transport and increased catabolic breakdown. Metabolic breakdown within the GI tract leads to poor bioavailability. The drug distributes rapidly into tissues and total body water with cerebrospinal fluid (CSF) levels reaching 20% to 40% of those in plasma. Cytidine deaminase is the primary catabolic enzyme involved in the inactivation of cytarabine. Drug interactions include antagonism of the effects of gentamicin, decreasing the oral bioavailability of digoxin, as well as enhancing the cytotoxicity of various alkylating agents, cisplatin, and ionizing radiation. Pretreatment with methotrexate enhances the formation of ara-CTP metabolites resulting in enhanced cytotoxicity.

Scheme 10.23 • Interconversion of various folate species. (DHFR, dihydrofolate reductase.)

Toxicities include myelosuppression, leukopenia and thrombocytopenia, nausea and vomiting, anorexia, diarrhea, and mucositis. Neurotoxicity is usually expressed as ataxia, lethargy, and confusion. An allergic reaction often described in pediatric patients includes fever, myalgia, malaise, bone pain, skin rash, conjunctivitis, and chest pain.

FLOXURIDINE (FLUORODEOXYURIDINE, FUDR)

The drug is available as a 500-mg vial of lyophilized powder. The drug is used to treat metastatic GI adenocarcinoma. The mechanism of action of this fluoropyrimidine deoxynucleoside analog involves metabolic conversion to 5-fluorouracil (5-FU) metabolites resulting in inhibition of TS thus disrupting DNA synthesis, function, and repair. Resistance can occur because of increased expression of TS,

decreased levels of reduced folate 5,10-methylenetetrahydrofolate, increased activity of DNA repair enzymes, and increased expression of dihydropyrimidine dehydrogenase (the major catabolic enzyme). The drug is poorly absorbed from the GI tract and is extensively metabolized to 5-FU and 5-FU metabolites. Dihydropyrimidine dehydrogenase is the main enzyme responsible for 5-FU catabolism, and it is present in liver, GI mucosa, white blood cells, and kidney. The drug interaction and toxicity profiles are equivalent to those of 5-FU.

GEMCITABINE (DFDC, GEMZAR)

The drug is available as the hydrochloride salt in 200- and 1,000-mg lyophilized single-dose vials for IV use. Gemcitabine is used to treat bladder cancer, breast cancer,

pancreatic cancer, and NSCLC. Gemcitabine is a potent radiosensitizer, and it increases the cytotoxicity of cisplatin. The mechanism of action of this fluorine-substituted deoxycytidine analog involves inhibition of DNA synthesis and function via DNA chain termination. The triphosphate metabolite is incorporated into DNA inhibiting several DNA polymerases and incorporated into RNA inhibiting proper function of mRNA. Resistance can occur because of decreased expression of the activation enzyme deoxycytidine kinase or decreased drug transport as well as increased expression of catabolic enzymes. Drug oral bioavailability is low because of deamination within the GI tract, and the drug does not cross the blood-brain barrier. Metabolism by deamination to 2', 2'-difluorouridine (dFdU) is extensive. Drug toxicity includes myelosuppression, fever, malaise, chills, headache, myalgias, nausea, and vomiting.

CLADRIBINE (2-CHLORODEOXYADENOSINE, 2-CDA, LEUSTATIN)

The drug is available in a 10-mg or 10-mL single-use vial for IV use. Cladribine is used for chronic lymphocytic leukemia, hairy cell leukemia, and non-Hodgkin's lymphoma. The mechanism of action of this purine deoxyadenosine analog involves incorporation into DNA resulting in inhibition of DNA chain extension and inhibition of DNA synthesis and function. This incorporation into DNA occurs via the triphosphate metabolite active species. The 2-chloro group on the adenine ring produces resistance to breakdown by adenosine deaminase. Resistance to the anticancer effects can occur because of decreased expression of the activating enzyme or overexpression of the catabolic enzymes. Oral bioavailability is variable and averages about 50%. The drug crosses the blood-brain barrier; however, CSF concentrations reach only 25% of those in plasma. The drug is selectively activated inside the cell, and intracellular concentrations of phosphorylated metabolites exceed those in plasma. Toxicities include myelosuppression, neutropenia, immunosuppression, fever, nausea, and vomiting.

FLUDARABINE (2-F-ARA-AMP, FLUDARA)

The drug is available as the phosphate salt in a 50-mg vial for IV use. Fludarabine is used to treat chronic lymphocytic leukemia and non-Hodgkin's lymphoma. The mechanism of action involves the triphosphate metabolite and its inhibition of DNA chain elongation. The 2-fluoro group on the adenine ring renders fludarabine resistant to breakdown by adenosine deaminase. The drug is rapidly dephosphorylated to 2-fluoro-ara-adenosine (F-ara-A) after administration. F-ara-A is taken into the cell and subsequently re-phosphorylated to yield the triphosphate (F-ara-ATP), the active drug species. Resistance can occur via decreased expression of the activating enzymes and decreased drug transport. Fludarabine is orally bioavailable and is distributed throughout the body reaching high levels in liver, kidney, and spleen. The drug is metabolized to F-ara-A, which enters cells via the nucleoside transport system and is rephosphorylated by deoxycytidine kinase to fludarabine monophosphate and finally fludarabine triphosphate, the active species. About 25% of F-ara-A is excreted unchanged in urine. Drug interactions include an increased incidence of fatal pulmonary toxicity when fludarabine is used in combination with pentostatin. Additionally, fludarabine may

potentiate the effects of several other anticancer drugs including cytarabine, cyclophosphamide, and cisplatin. Toxicities include myelosuppression, immunosuppression, fever, nausea, and vomiting.

MERCAPTOPURINE (6-MP, MERCAPTOPURINUM, PURINETHOL)

The drug is available as a 50-mg tablet for oral use. The primary uses of mercaptopurine are in the treatment of lymphoblastic leukemia, acute lymphocytic leukemia, and Crohn disease. The mechanism of action includes incorporation of mercaptopurine into DNA and RNA via the triphosphate metabolite. This incorporation inhibits synthesis and function of the resulting modified DNA or RNA. The parent drug is inactive and requires phosphorylation for activity. Resistance can occur via decreased expression of the activating enzymes or increased expression of the major catabolic enzymes. Oral absorption is generally incomplete (about 50%) and the drug does not enter the CNS in therapeutic quantities. Mercaptopurine is metabolized by methylation, and the methylated product has anticancer activity. Oxidation by xanthine oxidase yields inactive metabolites. The concurrent use of xanthine oxidase inhibitors such as allopurinol can enhance the potency of mercaptopurine by inhibiting its catabolic breakdown. The toxicities for mercaptopurine include myelosuppression, immunosuppression, nausea, vomiting, diarrhea, dry skin, urticaria, and photosensitivity.

THIOGUANINE (6-THIOGUANINE, 6-TG, TABLOID)

The drug is available in 40-mg tablets for oral use. Thioguanine is used to treat acute nonlymphocytic leukemia. The mechanism of action involves incorporation of the triphosphate into DNA and RNA, resulting in inhibition of processing and function. Intracellular phosphorylation is required for activity and inhibition of purine biosynthesis. Resistance can include decreased expression of the activating enzyme, decreased drug transport, and/or increased expression of catabolic enzymes. The oral absorption of thioguanine is poor, and the drug does not appear to cross the blood-brain barrier. Major metabolic pathways involve deamination or methylation. Thioguanine is not a substrate for the enzyme xanthine oxidase in contrast to mercaptopurine. Toxicities include myelosuppression, immunosuppression, nausea, vomiting, mucositis, and diarrhea.

PENTOSTATIN (2'-DEOXYCOFORMYCIN, DCF, NIPENT)

The drug is available in 10-mg vials for IV use. The drug is used to treat leukemias such as hairy cell leukemia, chronic lymphocytic leukemia, and lymphoblastic leukemia. The mechanism of action involves inhibition of the enzyme adenosine deaminase yielding increased cellular levels of deoxyadenosine and deoxyadenosine triphosphate (dATP). The increased levels of dATP are cytotoxic to lymphocytes. Pentostatin is a fermentation product of *Streptomyces antibioticus*. Resistance appears to involve decreased cellular transport or increased expression of catabolic enzymes. Acid instability prevents oral administration, and the drug is only administered by IV. The drug is distributed in total body water but does not enter the CNS. The majority of the dosage is excreted unchanged in the urine. Fatal pulmonary

toxicity has occurred when pentostatin and fludarabine are used in combination. Toxicities include myelosuppression, immunosuppression, nausea, vomiting, headache, lethargy, and fatigue.

METHOTREXATE (MTX, ABITREXATE, MEXATE, FOLEX)

The drug is available in 50-, 100-, 200-, and 1,000-mg vials for IV use. Methotrexate is used to treat several cancer types including breast cancer, bladder cancer, colorectal cancer, and head and neck cancer. The mechanism of action of methotrexate involves inhibition of DHFR leading to a depletion of critical reduced folates. The reduced folates are necessary for biosynthesis of several purines and pyrimidines. Resistance to methotrexate can occur because of decreased carrier-mediated transport of drug into cells or increased expression of the target enzyme DHFR. Oral bioavailability varies with dose because of saturable uptake processes, and high doses are required to reach therapeutic levels in the CNS. The majority of drug dosage is excreted unchanged in the urine. The renal excretion of methotrexate is inhibited by several carboxylic acid drugs such as penicillins, probenecid, nonsteroidal anti-inflammatory agents, and aspirin. Methotrexate enhances 5-FU antitumor effects when given 24 hours prior to the fluoropyrimidine. Methotrexate toxicity includes myelosuppression, mucositis, nausea, vomiting, severe headaches, renal toxicity, acute cerebral dysfunction, skin rash, and hyperpigmentation.

PEMETREXED (MTA, ALIMTA)

The drug is available in a 100-mg sterile vial for IV use. The drug appears to be effective against a range of tumors including mesothelioma, NSCLC, colorectal cancer, bladder cancer, and lung cancer. The mechanism of action involves inhibition of TS resulting in inhibition of thymidylate and DNA synthesis. This drug is a pyrrolopyrimidine analog of folate with antifolate activity. Resistance can occur by increased expression of TS, decreased binding affinity for TS, or decreased drug transport into cells. The drug is administered only via the IV route and distributes to all tissues. Cellular activation to the more potent polyglutamated forms occurs, and the majority of the dose is excreted unchanged in the urine. The drug interaction and toxicity profiles are similar to that of methotrexate.

TRIMETREXATE (TMTX, NEUTREXIN)

The drug is available as a lyophilized powder in 5- or 30-mg vials for IV use. The drug is used to treat colorectal cancer, head and neck cancer as well as NSCLC. The mechanism of action of trimetrexate involves folate antagonism and inhibition of thymidylate synthesis. Trimetrexate does not form intracellular polyglutamate adducts as does methotrexate and other related compounds. Resistance can occur by increased expression of the target enzyme, decreased binding affinity for the target enzyme, or decreased intracellular drug transport. Trimetrexate is administered only by the IV route and distributed throughout the body with extensive binding to plasma proteins. The major catabolic pathways involve *O*-demethylation followed by glucuronide conjugation. The drug interaction and toxicity profiles are similar to those for methotrexate.

HYDROXYUREA (DROXIA, HYDREA)

HONH-CO-NH₂. The drug is available in a 500-mg capsule for oral use. Hydroxyurea is often considered an antimetabolite drug, and it is used to treat myelogenous leukemia, ovarian cancer, and essential thrombocytosis. The mechanism of action of hydroxyurea involves inhibition of DNA biosynthesis by inhibition of the enzyme ribonucleotide reductase (see Fig. 10.15). Resistance can occur via increased expression of ribonucleotide reductase. The oral bioavailability is quite high approaching 100% and the drug is distributed to all tissues. Hydroxyurea readily enters the CNS and distributes to human breast milk. A major portion of the total dose is excreted unchanged in the urine. The drug has been shown to increase the toxicity of 5-FU, and hydroxyurea may increase the effectiveness of some antimetabolite HIV drugs. The toxicity profile includes myelosuppression, leucopenia, nausea, vomiting, pruritus hyperpigmentation, headache, drowsiness, and confusion.

ANTIBIOTICS AND NATURAL PRODUCTS

A variety of the anticancer agents available today are derived from natural sources with several of these being obtained from microbial sources (antibiotics). Many of the antineoplastic antibiotics are produced by the soil fungus *Streptomyces*. Both the antibiotic and natural product classes have multiple inhibitory effects on cell growth; however, they primarily act to disrupt DNA function and cell division.

There are several mechanisms by which these agents target DNA, including intercalation, alkylation, and strand breakage either directly or as a result of enzyme inhibition. Intercalation is a process by which a planar molecule of the appropriate size inserts itself between adjacent base pairs of DNA and in so doing, it causes a local unwinding that may disrupt the normal template function of DNA. Intercalation requires that the drug induce a cavity between base pairs so that insertion may occur. The interaction of the intercalator and the adjacent base pairs occurs by the overlap of *p*-orbitals of the intercalator and the base pairs. The *p*-orbitals of the intercalation species are provided by a combination of aromatic and conjugated systems that impart the planarity required for intercalation. The drug–DNA interaction is further stabilized by side chains attached to the intercalation species. The side chains often include a cationic moiety, which may form ionic bonds with the anionic phosphate backbone. Alternative modes of stabilization may occur through a combination of van der Waals interaction or hydrogen bonds. The overall result of these interactions is to cause a local bend or kink in DNA resulting in a local shape distortion. This may produce several effects but is often associated with inhibition of normal DNA function.

By virtue of their ability to induce bends or kinks in DNA, intercalators may also result in inhibition of topoisomerase enzymes. In order for the cell to store the nearly 2 m of DNA that it contains, it is necessary to fold the genetic material into a more compact form and in the process, knots and tangles are produced. Topoisomerase enzymes are responsible for the unwinding and relaxation of DNA so that transcription may occur.⁶⁷ There are two major types of topoisomerase enzymes, which are important sites

of action for antineoplastics. Topoisomerase I makes a single-strand break in DNA and subsequently allows the other strand to spin, relieving any tension associated with the packing process and subsequently reseals the broken strand. Topoisomerase II makes double-strand breaks in DNA allowing an intact chain to pass through and then subsequently reseals the double-strand break. In this way, it can relieve the knotting that occurs upon folding of the DNA. Both enzymes are believed to recognize sequences of DNA, bind and function by formation of a transient phosphodiester bond between the DNA strand and a tyrosine residue present on the protein. Inhibition may occur at different steps in the process such that if there is stabilization of the cleavable complex, the resealing step may be delayed or prevented resulting in strand breakage. This may then activate the apoptotic cascade.

There are several natural products that are capable of disrupting the formation and function of the mitotic spindle. These include the epipodophyllotoxins, the taxanes, and the vinca alkaloids. The mitotic spindle forms during the M phase of the cell cycle and is responsible for moving the replicated DNA to opposite ends of the cell in preparation for cell division. During prophase, the cytoskeleton made of proteins, which gives the cell its shape, begins to breakdown providing the building blocks for the mitotic spindle. The cell then progresses to prometaphase, where the nuclear membrane begins to disappear and the spindle begins to form attaching the centrosomes to the kinetochores, which are proteins joining the two sister chromatids. Tension is then applied to the spindle so that during metaphase, the chromatids align near the center of the cell. In anaphase, a further increase in tension separates the sister chromatids at the kinetochore, and they are pulled to opposite ends of the cell. Ultimately, the microtubules will disintegrate and reform the cytoskeleton. The process is highly controlled and there are several proteins including "motor proteins," which are involved in coordinating the process.

Actinomycins

The actinomycins are a group of compounds that are isolated from various species of *Streptomyces*, all of which contain the same phenoxazone chromophore but differ in the attached peptide portion. Originally, these materials were investigated for use as antibiotics, but they proved to be too toxic. From this group emerged actinomycin D, which is known as *dactinomycin* and contains identical pentapeptides bound through an amide linkage utilizing the amino group of L-threonine with carbonyls at positions 1 and 9.⁶⁸ The pentapeptides namely L-threonine, D-valine, L-proline, sarcosine, and L-methylvaline form a lactone via the side chain hydroxyl of L-threonine and the carboxyl group of L-methylvaline (Fig. 10.11).

Dactinomycin binds noncovalently to double-stranded DNA by partial intercalation between adjacent guanine-cytosine bases resulting in inhibition of DNA function. The structural feature of dactinomycin important for its mechanism of cytotoxicity is the planar phenoxazone ring, which facilitates intercalation between DNA base pairs. The peptide loops are located within the minor groove and provide for additional interactions (Fig. 10.12). The preference for GpC base pairs is thought to be partly related to the formation of a hydrogen bond between the 2-amino groups of

Figure 10.11 • Structure of dactinomycin.

guanine and the carbonyls of the L-threonine residues.⁶⁹ Additional hydrophobic interactions and hydrogen bonds are proposed to form between the peptide loops and the sugars and base pairs within the minor groove. In all, actinomycin D spans four to five DNA base pairs (Fig. 10.12). This results in high affinity with the molecule only slowly dissociating from DNA. Additional modes of binding are also possible for the molecule. The primary effect of this interaction is the inhibition of DNA-directed RNA synthesis and specifically RNA polymerase. DNA synthesis may also be inhibited, and the agent is considered cell cycle specific for the G₁ and S phases. The drug has been found to bind to single-stranded DNA and double-stranded DNA without adjacent GpC sequences.⁷⁰ It has been suggested that binding to single-stranded DNA may occur as the strands separate during transcription, and this may be responsible for the inhibition of RNA polymerase.⁷¹ Those genes that were being actively transcribed, which would require strand separation, would be more susceptible to this type of binding. Inhibition of topoisomerase II also occurs such that the enzyme-DNA complex is stabilized and strand breakage may be seen. Resistance is caused by a decreased ability of tumor cells to take up the drug and P-glycoprotein (Pgp)-mediated efflux.

Figure 10.12 • Representation of the dactinomycin-DNA complex. (Reprinted with permission from Hou, M. H., et al.: *Nucleic Acids Res.* 30:4910, 2002.)

Figure 10.13 • Structure of the anthracycline antibiotics.

Anthracyclines

The anthracycline antibiotics (Fig. 10.13) are characterized by a planar oxidized anthracene nucleus fused to a cyclohexane ring that is subsequently connected via a glycosidic linkage to an amino sugar. Initially discovered in the early 1960s when they were isolated from *Streptomyces peucetius*, hundreds of compounds belonging to this class have subsequently been discovered of which five are used clinically in the United States (doxorubicin, daunorubicin, idarubicin, epirubicin, and valrubicin). The conjugated systems found in these molecules impart a red color, which is reflected in the name.

Studies of the mechanism by which the anthracyclines exhibit their cytotoxic effects initially focused on the ability of the compounds to associate with DNA resulting from intercalation of their planar ring system reinforced by auxiliary binding of the amino sugar. Subsequent work focused on the ability of these compounds to generate free radicals.

Although free radical generation is thought to be important in the toxicity, it was not shown to occur in the nucleus and therefore not likely associated with their antiproliferative effects. Currently, the accepted mechanism involves intercalation followed by inhibition of topoisomerase II resulting in strand breakage leading to apoptosis.⁷² The anthracyclines are considered specific for the S phase of the cell cycle. There is data to support increased binding of p53 with DNA when anthracyclines are administered, which would stimulate the apoptotic process, although some studies have failed to confirm this.^{73,74} Several of these agents have been cocrystallized with B-DNA oligomers and the three-dimensional structure determined by x-ray crystallography. The general features show rings B and C intercalating between CpG base pairs and ring D protruding into the major groove. The sugar moiety lies within the minor groove and along with ring A is important for interaction and inhibition of topoisomerase II by stabilization of the cleavable complex. The amino sugar

seems to play an especially important role and compounds lacking this functionality failed to inhibit the enzyme. In the case of doxorubicin and daunorubicin, specificity is provided by the hydrogen bonding between O-9 of the anthracycline and N-2 and N-3 of guanine. The x-ray data also suggested that the interaction with DNA is stabilized by the formation of several hydrogen bonds through bridging water molecules.⁷⁵ The formation of covalent bonds between anthracyclines and DNA also is supported by several studies in which formaldehyde is produced by oxidation of cellular components or other anthracycline molecules. This oxidation results from the production of ROS such as H_2O_2 , which are generated during redox cycling of anthracyclines (Scheme 10.24). The generated formaldehyde may then form a methylene bridge between the 4'-amino group of the anthracycline and the 2-amino group of guanine in DNA.⁷⁶

Although the anthracyclines produce several adverse effects that are typical for antineoplastics, cardiotoxicity is a special concern with this class of agents. The associated cardiomyopathies and congestive heart failure (CHF) have been related to the ability of these compounds to undergo redox cycling.⁷⁷ This is most notable in the case of daunorubicin and doxorubicin and less of a problem in the newer derivatives, idarubicin and epirubicin. The C ring of the anthracy-

clines is subject to a one or two electron reduction by several different enzymes including NAD(P)H-oxidoreductases and CYP reductases to give the semiquinone or hydroquinone. The case of the one electron reduction is shown in Scheme 10.25. This may undergo reversion to the starting quinone in futile redox cycling accompanied by the production of superoxide radical. The radical is normally converted to H_2O_2 by superoxide dismutase and H_2O_2 is then converted to H_2O and O_2 by catalase. However, the production of superoxide ($\text{O}_2^{\cdot-}$) is also associated with the release of iron from intracellular stores, which may be chelated by the anthracycline. The iron then diverts the normal detoxification pathway by catalase so that more potent radicals such as hydroxyl radical ($\cdot\text{OH}$) are produced. Myocardial cells possess lower levels of catalase and therefore are less able to detoxify the H_2O_2 that results from redox cycling. This results in increasing levels of $\cdot\text{OH}$ for which a detoxification pathway does not exist and therefore cellular damage occurs. Materials such as $\text{O}_2^{\cdot-}$, $\cdot\text{OH}$, and H_2O_2 are known as *reactive oxygen species* or ROS and in sufficiently high concentration produce cellular damage. Hydroxyl radicals cause single-strand breaks in DNA, which would activate p53 and enhance apoptosis in cardiac cells. Studies have also shown that doxorubicin administration stimulates both the intrinsic and extrinsic pathways of

Scheme 10.24 • Formation of anthracycline-DNA adduct.

apoptosis in numerous ways, and this has been linked to the increased production of H₂O₂ and hydroxyl radical. One proposed mechanism involves damage to the mitochondrial membrane by H₂O₂ and •OH resulting in the release of cytochrome c, which would activate the intrinsic pathway (Fig. 10.2).⁷⁸ This sequence of events would be desirable in a cancer cell but not in a normal cardiac cell.

Additional mechanisms of cardiotoxicity have been proposed, which involve the metabolic reduction of the anthracycline C-13 ketone to the alcohol.⁷⁹ Several pharmacological effects have been associated with the resulting alcohols including loss of Ca²⁺ homeostasis and inhibition of Na⁺/K⁺-ATPase in cardiac cells. The formation of doxorubicin C-13 alcohol, doxorubicinol has been associated with conversion of iron regulatory protein-1 (IRP-1) into a null protein that is no longer able to maintain iron homeostasis.⁸⁰ It has been proposed that the loss of iron regulation may contribute to the cardiotoxicity seen with doxorubicin. However, compared with doxorubicin, daunorubicin and idarubicin form greater amounts of the alcohol metabolites and exhibit similar and reduced cardiotoxicity, respectively. This suggests that metabolism to the alcohols is not solely responsible for the cardiotoxicity.

Several strategies have been developed to reduce the cardiotoxicity associated with the anthracyclines. Slow infusion over 48 to 96 hours versus administration of a bolus given over 15 minutes was implemented in the 1980s and has proven to be effective in reducing the toxicity without adversely affecting the antineoplastic effects. Given the proposed mechanism of toxicity, it is not surprising that several antioxidants have been investigated including vitamins A, C, and E and also thiol-containing reducing agents such as acetylcysteine. These, however, have not proved effective in large measure. An alternative strategy is to chelate the iron required for the activation of H₂O₂, and for this, dexrazoxane (Totect) is used.⁸¹ Radiolabeling experiments have shown that dexrazoxane is rapidly taken up into myocardial cells, where it is subsequently hydrolyzed by a two-step

process to yield the diamide acid (Scheme 10.26), which chelates free iron and iron bound to the anthracycline and is similar to the chelating agent ethylenediaminetetraacetic acid (EDTA). This has been proven effective and has allowed patients to tolerate higher doses and increased numbers of cycles of the anthracyclines. Dexrazoxane is also an inhibitor of topoisomerase II that, unlike the anthracyclines, does not result in strand breaks.⁸² This additional property is important in its utility as antidote in cases of anthracycline extravasation.⁸³ The anthracyclines are often administered with other antineoplastics such as the taxanes and trastuzumab, which may have cardiotoxicities themselves leading to an increased risk despite the precautions mentioned.

Related to the anthracyclines is mitoxantrone, which is shown in Figure 10.14. Although mitoxantrone is a synthetic agent, it is included with the natural products because it is mechanistically similar to the anthracyclines. Produced in the late 1970s, it is a derivative of a synthetic dye and is classified as an anthracenedione.⁸⁴ The mechanism involves intercalation by the chromophore, which is stabilized by the 2-[(2-aminoethyl)amino]ethanol side chain presumably as a

Scheme 10.26 • Aqueous hydrolysis of dexrazoxane to yield the iron-chelating metabolite.

Mitoxantrone

Figure 10.14 • Structure of mitoxantrone.

result of an ionic interaction of the protonated amines with the phosphate backbone of DNA. The formation of covalent adducts with DNA have also been demonstrated to occur in a manner similar to the anthracyclines. In this case, however, other enzymes such as myeloperoxidase are responsible for the generation of formaldehyde.⁸⁵ Topoisomerase II is inhibited, and strand breakage occurs similar to that seen with the anthracyclines. In contrast to the anthracyclines, mitoxantrone is not a substrate for the reductase enzymes responsible for the conversion to the semiquinone so that ROS are not generated by this process.⁸⁶ This lack of activation has been attributed to the presence of the side chains. This has the effect of reducing the cardiotoxicity but not completely eliminating it, and caution should be used especially in those patients with existing cardiovascular problems.

Individual Agents

DACTINOMYCIN-D (ACT-D, ACTINOMYCIN-D, COSMEGEN, LYOVAC COSMEGEN)

Dactinomycin is available in vials containing 0.5 mg of drug for reconstitution in sterile water for IV administration. This antibiotic is most effective in the treatment of rhabdomyosarcoma and Wilms tumor in children as well as in the treatment of choriocarcinoma, Ewing sarcoma, Kaposi sarcoma, and testicular carcinoma. The pharmacokinetics of dactinomycin has not been well characterized, but it appears to concentrate in nucleated blood cells. The agent is 5% to 15% plasma protein bound and is excreted mostly unchanged in urine and bile. Other metabolites have not been characterized. The terminal elimination half-life is 30 to 40 hours. Myelosuppression is dose limiting with both leucopenia and thrombocytopenia being the most likely presentation. Nausea and vomiting occur shortly (2 hours) after treatment and may be severe. Mucositis and diarrhea also result from irritation of the GI tract. Hair loss is commonly associated with the agent as is hyperpigmentation of the skin and erythema.

DOXORUBICIN HYDROCHLORIDE (ADM, ADR, ADRIA, ADRIAMYCIN)

Doxorubicin is available as both the conventional dosage form and a liposomal preparation, both of which are administered by infusion. Doxorubicin HCl powder is available in 10-, 20-, 50-, and 150-mg vials and is widely used in treating various cancers, including leukemias, soft and bone tissue sarcomas, Wilms tumor, neuroblastoma, small cell lung cancer, and ovarian and testicular cancer. Resistance to the agent involves decreased expression of topoisomerase II and

mutations in this enzyme that decrease binding of the drug. The agent may also be actively secreted from cancer cells by Pgp. The agent is rapidly taken up into tissues following injection with a distributive half-life of 5 minutes followed by a slow elimination half-life of 20 to 48 hrs. The primary route of elimination is in the bile and feces. Metabolism involves reduction of the C-13 ketone to yield doxorubicinol (active) along with cleavage of the amino sugar to give the aglycone. The aglycones are also capable of undergoing redox cycling and producing ROS.

The toxicities associated with doxorubicin include dose-limiting cardiotoxicity and myelosuppression. Most patients will experience alopecia and nausea. Cardiotoxicity is a limiting factor in the administration of doxorubicin, which, in its most severe form, may progress to CHF. This may occur during therapy or during months or years following the termination of therapy. The percentage of patients that progress to CHF increases with increasing cumulative dose.

The liposomal form of doxorubicin (Doxil) offers several advantages including an improved pharmacokinetic profile with slower plasma clearance giving a distributive half-life of 45 hours versus 5 minutes for doxorubicin and a smaller volume of distribution of 4 L versus 254 L for doxorubicin.⁸⁷ There is also reportedly an increased uptake of doxorubicin in tumor cells, which has been attributed to the ability of the liposomes to break down in the more acidic environment associated with tumor cells or by the release of enzymes from the tumor cells that degrade the liposomes. The liposomes decrease uptake by myocardial tissue, so cardiotoxicity is less common. The liposomes also reduce conversion to doxorubicinol, which has been implicated in the cardiotoxicity of doxorubicin. Additionally, there is a decrease in the incidence of extravasation. Other adverse effects are also decreased including less nausea, alopecia, and stomatitis although skin toxicity, which is normally seen as a rash on the feet and hands, may occur frequently.

DAUNORUBICIN HYDROCHLORIDE (DAUNOMYCIN, DNM, DNR, CERUBIDINE, RUBIDOMYCIN)

Daunorubicin is available in 20- and 100-mg vials for reconstitution. The agent is given intravenously for the treatment of acute nonlymphocytic and lymphocytic leukemia. Other unlabeled uses include CML and Kaposi sarcoma. In general, its use is more limited than that of doxorubicin. Daunorubicin lacks the hydroxyl groups found at C-14 of doxorubicin. This leads to an increase in the amount of the alcohol metabolite daunorubicinol (active) arising as a result of reduction of the side chain ketone. This, however, does not appear to lead to a significant increase in the occurrence of cardiotoxicity compared with doxorubicin. The mechanisms of resistance and toxicities of daunorubicin are similar to that of doxorubicin; the major difference between the two agents being the spectrum of cancers that they are used treat.

A liposomal form of daunorubicin is also available known as *DaunoXome*. The drug offers the same advantages as those seen for the liposomal form of doxorubicin.

EPIRUBICIN HYDROCHLORIDE (4'-EPIADRIAMYCIN, EPI-ADR, ELLENCE)

Epirubicin is available in 50- and 200-mg vials for IV administration for the treatment of breast cancer. It also has

several unlabeled uses in various cancers in combination with other agents including therapy for small cell lung cancer, NSCLC, Hodgkin's lymphoma, and non-Hodgkin's lymphoma. Epirubicin is the 4'-epimer of doxorubicin, which exhibits a lower level of cardiotoxicity compared with doxorubicin. The reduced cardiotoxicity has been attributed to the epimerization of 4'-OH, which places this -OH function in an equatorial position resulting in increased glucuronidation, faster clearance, and reduced metabolic reduction to epirubicinol, the C-13 alcohol (compared with doxorubicin). The glucuronide, which forms via glucuronidation of the 4'-alcohol, is the major metabolite found in plasma and urine.⁸⁸ Epirubicinol that does form has little cytotoxic activity. Other minor metabolites that are seen are the aglycones of epirubicin and epirubicinol. These factors have allowed epirubicin to be used in larger doses than doxorubicin with less cardiotoxicity. Other toxicities typical of the class are also seen with epirubicin. Like doxorubicin, it has a short distributive half-life of 5 minutes; however, plasma levels are 20% to 30% lower with an increased volume of distribution. The agent has an elimination half-life of 16 hours, which is shorter than that of doxorubicin. Epirubicin is eliminated primarily by biliary excretion.

IDARUBICIN HYDROCHLORIDE (4-DEMETHOXYDAUNOMYCIN, DMDR, IDAMYCIN)

Idarubicin is available in 5-, 10-, and 20-mL vials for IV administration in the treatment of acute myeloid leukemia and acute nonlymphocytic leukemia. The compound lacks the 4-methoxy group and terminal side-chain alcohol of doxorubicin making it the most lipophilic of the four major anthracyclines (doxorubicin, daunorubicin, epirubicin, idarubicin), and it is considered less cardiotoxic than doxorubicin. The removal of the 4-methoxy group also increases inhibition of topoisomerase II. The drug has a fast distributive phase and a high volume of distribution reflecting binding to tissue. Concentrations in blood and bone marrow cells are 100 times higher than those found in plasma, reflecting its use in treating leukemias. Metabolism of the agent primarily occurs by conversion to idarubicinol via reduction of the side chain ketone to the alcohol, which retains activity as an antineoplastic. Elimination occurs primarily in the bile. Adverse effects are similar to those found for doxorubicin; however, there is a lower incidence of cardiotoxicity.

VALRUBICIN (AD 32, VALSTAR)

Valrubicin is available in 200-mg vials for intravesicular administration in the treatment of bladder cancer (orphan drug status). The increased lipophilicity associated with the valeric acid ester and trifluoro acetate functionalities increases tissue penetration and remains intact because, in large measure, of the lack of exposure to hydrolyzing enzymes caused by direct delivery into the bladder followed by voiding of the instilled solution. This local action also minimizes cardiotoxicity and other adverse effects seen with other anthracyclines. The major adverse effects that are seen are bladder irritation and reddening of the urine.

MITOXANTRONE HCL (DHAD, NOVANTRONE)

Mitoxantrone is supplied as a blue aqueous solution in 10- and 20-mg vials for IV administration in the treatment of

acute lymphoid leukemia, acute myeloid leukemia, breast cancer, prostate cancer, non-Hodgkin's lymphoma, and multiple sclerosis. The mechanisms of resistance are the same as those seen for the anthracyclines. The distribution half-life is 1.1 to 3.1 hours, and the drug has a large volume of distribution (11 L/kg). The elimination half-life ranged from 23 to 215 hours, and elimination was primarily via the bile. Metabolism of the agent involves oxidation of the side-chain alcohols to give the monocarboxylic and dicarboxylic acids.⁸⁹ Other toxicities are those seen for the anthracyclines and include myelosuppression, nausea, vomiting, mucositis, diarrhea, and alopecia. The intense color of the parent drug and metabolites may turn the urine blue.

Epipodophyllotoxins

The epipodophyllotoxins (Fig. 10.15) are semisynthetic derivatives of podophyllotoxin, which is isolated from the mayapple (mandrake) root and functions as an inhibitor of microtubule function.^{90,91} Chemical modification has led to compounds with a different mechanism of action, which involves inhibition of topoisomerase enzymes.^{92,93} The change in mechanism was associated with removal of the 4'-methyl group of podophyllotoxin. Further alteration in podophyllotoxin involved the addition of the glycosidic portion of the molecules.

Etoposide acts on topoisomerase II stabilizing the cleavable complex leading to single- and double-strand breaks. If enough breaks are initiated, apoptosis is activated. Etoposide is believed to bind to topoisomerase II in the absence of DNA, because it shows little tendency to interact with DNA alone.^{94,95} The etoposide-topoisomerase II complex then binds DNA, and strand cleavage occurs; however, the ligation step is inhibited. Binding of the drug occurs near the site at which the cleaved phosphodiester bond is held by the enzyme. One etoposide molecule stabilizes the cleavable complex of one chain, and therefore two etoposide molecules are necessary to mediate double-strand breaks.⁹⁶ The concentration of the agent will then determine whether single- or double-strand breaks occur. The resulting breaks in normal cells may lead to mutations and translocations that have been associated with the development of leukemias posttreatment. The agents are considered cell cycle specific and act in the late S and G₂ phases of the cell cycle.

The glycosidic moiety of the epipodophyllotoxins, which is lacking in podophyllotoxin, is associated with converting these compounds from tubulin binders to topoisomerase inhibitors. Replacement of the glycosidic 8-methyl group with thiophene gives tenoposide, which is 10-fold more potent than etoposide. The glycosidic moiety is not an absolute requirement for activity, and other more active compounds are known in which it has been replaced. The 4'-OH group is important for the activity of the compounds, and loss of this functionality results in greatly reduced levels of strand breaks. Removal of one of the adjacent methoxy groups by CYP3A4 mediated oxidative-O-dealkylation gives the catechol analogs, which are more potent than the parent molecules.^{97,98} The catechol analogs may be further oxidized to give the quinones, which are also more active than the parent (Scheme 10.27). There are several mechanisms by which cells become resistant to the epipodophyllotoxins including increased efflux by Pgp as seen for many of the other natural products. Additionally, topoisomerase II levels may decrease

Figure 10.15 • Structures of the epipodophyllotoxins.

or develop altered binding sites with lower affinity for these agents. Increased DNA repair mechanisms may also decrease the effectiveness of these agents. There are mechanisms by which double-strand breaks in DNA can be repaired. If for example a strand break occurs in the late portion of the S phase or in the G₂ phase after DNA has been replicated, the sister chromatid can be utilized as a template to make the repair in a process known as *homologous recombination* without the loss of genetic material. However, if a sister chromatid is not available, then a process known as *nonhomologous end joining* may be utilized. In this process, after a double-strand break has occurred, exonucleases remove additional base pairs from each strand creating overhangs. If complementary sequences are present in the overhangs, the strands can associate and the missing bases can be filled in. This process, however, results in the loss of some genetic material.

ETOPOSIDE (VP-16, VEPESID, TOPOSAR)

Etoposide is available in 50- and 100-mg capsules for oral use and in 100-mg vials for IV use. The agent is approved for use in testicular cancer and small cell lung cancer. It has also been used in a wide variety of cancers including NSCLC,

Hodgkin's and non-Hodgkin's disease, Kaposi sarcoma, acute lymphocytic leukemia, neuroblastoma, choriocarcinoma, and epithelial, ovarian, testicular, gastric, endometrial, and breast cancers. Etoposide is one of the few natural product derivatives that can be administered orally. When given by this route, bioavailability is 50%. Administration by the IV route is also utilized, and the drug is widely distributed when given by either route. The agent is highly protein bound (90%) primarily to albumin. Low albumin levels may lead to an increase in free drug and require a lowering of the dose. The drug does not penetrate the blood-brain barrier at normal doses but does during high-dose therapy. Elimination occurs primarily in the urine with 30% to 40% of an IV dose appearing as unchanged drug. The elimination half-life is 5 to 10 hours. Metabolism involves opening of the lactone ring to give the hydroxy acid as the major metabolite. Epimerization occurs at C-3 to give the *cis*-lactone, which may also undergo hydrolysis to give the hydroxy acid. Glucuronidation and sulfation of the 4'-OH give products that are inactive. Active metabolites are formed as a result of CYP3A4 mediated oxidative-*O*-demethylation of the 3'-methoxy group to give the catechol followed by oxidation to give the quinone. The toxicities of etoposide include dose-limiting myelosuppression,

Scheme 10.27 • Metabolism of epipodophyllotoxins.

which normally presents as leucopenia. In addition, the drug produces nausea and vomiting in 30% to 40% of patients, which is more commonly seen when the drug is administered orally. The agent also produces anorexia, alopecia, mucositis, and hypersensitivity reactions that may be caused by etoposide or Cremophor EL (polyoxyethylated castor oil), which is used as a vehicle for IV administration of the drug. Leukemia, especially acute myelogenous leukemia, has been associated with the drugs' ability to produce strand breaks with resultant translocation of genetic material. The leukemias are generally seen 5 to 8 years posttreatment and have been associated with translocation of several different genes resulting in break-points around the mixed lineage leukemia (*MLL*) gene. Transcription and translation of this altered DNA gives chimeric proteins, which form partly from the translocated gene and partly from the *MLL* gene. Exactly how these chimeric proteins lead to leukemia is not known, but similar alterations are seen with other topoisomerase inhibitors.

Etoposide phosphate is a prodrug of etoposide and is converted to the parent by the action of phosphatases. The increased water solubility does not require Cremophor EL or

other vehicles to be used. The agent is administered IV and used in the treatment of germ cell tumors, small cell lung cancers, and NSCLCs.

TENIPOSIDE (VM-26, VUMON)

Teniposide is available in 50-mg ampules with Cremophor EL for IV administration in the treatment of acute lymphoblastic leukemia (ALL). The agent is more potent as an inhibitor of topoisomerase II. The pharmacokinetics of teniposide is similar to that of etoposide; however, the more lipophilic teniposide is more highly protein bound (99%) and less is excreted unchanged in the urine (10%–20%). There is also greater overall metabolism of teniposide; however, CYP3A4-mediated conversion to the active catechol is slower compared with etoposide. Elimination occurs primarily in the urine with a terminal elimination half-life of 5 hours.

Camptothecins

The camptothecins (Fig. 10.16) are inhibitors of topoisomerase I and are used clinically for the treatment of various

Figure 10.16 • Structures of topoisomerase I inhibitors.

cancers.⁹⁹ The lead drug for this class of agents was camptothecin, which was discovered in the 1960s by Wani and Wall¹⁰⁰ who isolated the material from *Camptotheca acuminata*, an ornamental tree found in China. Initial testing of the isolated material revealed promising antitumor activity, but testing in phase II trials gave disappointing results. The reason for this outcome was that camptothecin had low water solubility, and to overcome this, the sodium salt had been prepared and used during the trials. This was accomplished by hydrolysis of the E-ring lactone to give the carboxylate salt (Scheme 10.28). The resulting ring-opened material was 10 times less active and more toxic producing inflammation of the small intestines, blood in the urine, and myelosuppression.^{101,102} Interest in the material subsided until it was revealed that the mechanism of antitumor action was inhibition of topoisomerase I.¹⁰³ Subsequently, the incorporation of side chains containing basic amines led to the more water-soluble derivatives, topotecan and irinotecan (Fig. 10.16).^{104,105} These agents could be administered as the lactone giving better clinical results. Topoisomerase I produces single-strand breaks in DNA, utilizing a similar mechanism to topoisomerase II.^{106,107} The enzyme binds to supercoiled DNA and cleaves a single strand resulting in the formation of a cleavable complex with formation of a transient phosphodiester bond between DNA and a tyrosine residue of topoisomerase I. The complementary strand of the double helix then passes through the break, and the enzyme then reseals the initial strand break. In this way, local supercoils are removed from DNA. The camptothecin analogs bind to the enzyme DNA complex after strand cleavage has occurred, such that the planar structure of the drug can intercalate between DNA base pairs and then

stabilize the cleavable complex. The binding site for this intercalation is only formed after the enzyme is bound to DNA, and once this site is occupied by the drug, it prevents the realignment necessary for resealing of the initial strand break.

X-ray crystal structures have been solved for several camptothecin analogs bound to DNA and topoisomerase I.¹⁰⁸ In the case of topotecan, the results indicate that the planar portion of the drug intercalates between base pairs at the DNA cleavage site. In this process, the 5'-OH of the cleaved strand is shifted away from the phosphotyrosine bond formed between the enzyme and DNA. This shift prevents the 5'-OH from attacking the phosphotyrosine bond and resealing the strands after supercoiling has been removed. The result is strand breakage. Other key interactions involve a direct hydrogen bond between Asp-533 of topoisomerase I and the 20-OH of topotecan. There is a water-bridged hydrogen bond between the lactone carbonyl at C-21 of the drug and the phosphotyrosine of the covalent topoisomerase I-DNA adduct. An additional water-bridged hydrogen bond forms between Asn-722 and the pyridine carbonyl at C-16a of topotecan. Arg-364 is located in proximity to the quinoline nitrogen at N-1, although the interatomic distance was not close enough to allow for a specific interaction in the case of topotecan. Subsequent work with camptothecin, which binds with a slight twist of the planar ring system relative to topotecan, allowed for the formation of a hydrogen bond between Arg-364 and the N-1 nitrogen.¹⁰⁹ The drugs orient such that C-7, C-9, and C-10 are directed into the major groove so that bulky substituents can be tolerated at these positions. These interactions are summarized in Figure 10.17. The result of

Scheme 10.28 • Chemical hydrolysis of camptothecin lactone.

Figure 10.17 • Interactions between camptothecins and topoisomerase I.

this binding is the formation of single-strand breaks most notably at replication forks that occur during the S phase. Strand breakage of the leading strand of DNA during replication results in double-strand breakage and ultimately leads to cell death.

Several mechanisms of resistance to the camptothecin analogs are known. Different neoplasms express different levels of topoisomerase I, and this is thought to explain the susceptibility of any specific cancer to these agents. It is also possible for cells to decrease their expression of this enzyme or develop altered forms to which these compounds can no longer bind. Increased DNA-repair enzymes may limit the damage to DNA, and these agents are susceptible to Pgp-mediated efflux. The agents have also been shown to activate nuclear factor- κ B (NF- κ B), which has an antiapoptotic effect so that strand breaks may not initiate apoptosis.

Irinotecan undergoes hydrolysis of its carbamate moiety by irinotecan-converting enzyme to give SN-38, which is 1,000 times more potent than the parent compound (Scheme 10.29).¹¹⁰ There is wide interpatient variability in the extent of this transformation, which may explain differential responses to the agent. Further metabolism involves the glucuronidation (isozyme UGT1A1) of the resulting phenolic function of SN-38 to give SN-38G, which is inactive. An additional metabolite forms as a result of CYP3A4-mediated conversion to [4-*N*-(5-aminopentanoic acid)-1-piperidino]carbonylcamptothecin (APC), which is 100 times less active than SN-38. There is also the additional complication that the parent and metabolites may exist as the lactones or as the inactive hydroxy acid forms.

IRINOTECAN HYDROCHLORIDE (CPT-11, CAMPTOSAR)

Irinotecan is available in 100-mg or 5-mL vials for IV administration and is used in combination with 5-FU and leucovorin as first-line treatment of metastatic colon cancer. The agent may also be used as a single agent in colorectal cancer as a second-line therapy when 5-FU therapy has failed. Additional uses include small cell lung cancer, NSCLC, cervical cancer, esophageal cancer, and gastric can-

cer. Irinotecan is 30% to 60% plasma protein bound, whereas the active metabolite SN-38 is 95% protein bound. Binding of SN-38 as the lactone stabilizes the material to ring opening. The elimination of the agent occurs primarily in the bile with a minor amount of renal elimination. The excretion of active metabolites or inactive metabolites such as the glucuronide SN-38G, which may be converted back to SN-38 in the bile, has been associated with severe diarrhea. Irinotecan and SN-38 have half-lives of 8 and 14 hours, respectively. Irinotecan has two dose-limiting toxicities, myelosuppression and diarrhea. The diarrhea occurs in two forms, early and late. The early form occurs within the first 24 hours after administration. It has been associated with inhibition of acetylcholinesterase, which results in increased gut motility. This early phase is also associated with flushing, abdominal pain, and excessive sweating. Atropine can be used to relieve these symptoms but it is not recommended for prophylactic use unless there has been a prior episode. The late-phase diarrhea occurs after 24 hours and has been associated with the presence of active material, particularly SN-38 in the gut, and may last 3 to 10 days. The prolonged nature may lead to dehydration and electrolyte imbalances. Loperamide therapy is recommended at the first appearance of a loose stool. If the diarrhea persists, additional agents may be used including antibiotics that decrease β -glucosidase-producing bacteria in the gut and prevent the overgrowth of pathogenic bacteria.¹¹¹ Other toxicities include emesis and alopecia.

TOPOTECAN HYDROCHLORIDE (HYCAMPTAMINE, TOPO, HYCAMTIN)

Topotecan is supplied in 4-mg vials and administered IV for the treatment of ovarian cancer, cervical cancer, and small cell lung cancer in those patients who did not respond to first-line therapy. Following IV administration, the drug is widely distributed with 10% to 35% of the agent bound to plasma proteins. There is evidence that the agent may cross the blood-brain barrier to some extent. In plasma, an equilibrium is established between the lactone and the less active hydroxy acid with 20% of the drug present as the lactone 1 hour after the infusion is complete. In contrast to irinotecan,

Scheme 10.29 • Metabolism of irinotecan.

both the lactone and the hydroxy acid bind equally well to human serum albumin. *N*-Demethylation of the tertiary amine to give the secondary amine is mediated by CYP3A4 and represents a minor route of metabolism. Glucuronidation of the parent and the phase I metabolites also occurs to a limited (10%) extent.¹¹² Elimination occurs primarily in the urine, with 30% of the dose being recovered as unchanged drug. The terminal elimination half-life is 2 to 3 hours. The major toxicity seen for topotecan is dose-limiting myelosuppression. Nausea and vomiting are seen in most (70%–80%) patients, along with diarrhea and abdominal pain. Other toxicities include headache myalgias, alopecia and elevation of serum transaminases, alkaline phosphatases, and bilirubin. Microscopic hematuria (blood in the urine) may also be seen.

Bleomycin

Bleomycin is a glycopeptide antibiotic complex isolated from *Streptomyces verticillus* initially by Umezawa.¹¹³ At least 13 different fractions of bleomycin have been isolated with the clinically used product (Blenoxane) being a mixture of predominantly A₂ (55%–70%) and B₂ (25%–32%) fractions (Fig. 10.18). Of these fractions, A₂ appears to possess the greatest antineoplastic activity. Copper is found in the naturally occurring material, and its removal is important for the material used clinically because it significantly reduces activity.

Bleomycin binds Fe⁺² through multiple interactions with the amino terminal end of the peptide chain (Fig. 10.19).¹¹⁴ Bleomycin may itself initiate the release of iron necessary for this complexation. Interaction with DNA subsequently occurs through the bithiazole portion of the molecule, which intercalates between G-C base pairs with a preference for genes undergoing transcription. Held in proximity to DNA by this interaction, in an aerobic environment, Fe⁺² is oxidized to Fe⁺³ in a one-electron process with the electron being transferred to molecular oxygen.¹¹⁵ This gives the activated form of bleomycin, which has been formulated as HOO⁻Fe(III)-bleomycin, which is believed to possess square bipyramidal geometry. This then results in the production of ROS in the form of superoxide and hydroxide radical, which initiate single-strand breakage of the phosphodiester backbone and release of DNA bases by oxidative cleavage of the 3'-4' bond of the deoxyribose moiety.¹¹⁶ This activity may be enhanced in the presence of mercaptans such as glutathione, which can facilitate the action of reductase enzymes in reducing the Fe⁺³ that is generated back to Fe⁺² so that the process may continue. The agent is most active in the G₂ and M phases of the cell cycle.

NMR studies of bleomycin complexed with cobalt have confirmed the intercalation of the bithiazole with adjacent G-C base pairs with the dimethylsulfonium chain (bleomycin A₂) projecting into the major groove where the sulfonium cation may interact with the phosphate backbone

Figure 10.18 • Structure of bleomycins.

or N-7 of a purine base adjacent to the site of intercalation (Fig. 10.20).^{117,118} Additional stabilization is provided by hydrogen bonding of the amino-pyrimidine ring with a guanine residue in the minor groove. This also serves to orient the coordinated metal and the hydroperoxide ligand toward the minor groove.

Bleomycin is notable for its lack of myelotoxicity, and this allows it to be combined with other myelosuppressants without a resulting additive effect. The acute toxicities seen with bleomycin are erythema (reddening of the skin), hyperpigmentation (skin darkening) found predominately on the extremities, and pulmonary toxicity. The pulmonary toxicity may first occur as pneumonitis (inflammation of lung tissue), which normally responds to glucocorticosteroid therapy. Chronic pulmonary toxicity is expressed as pulmonary fibrosis, which is irreversible and limits utility of the agent.

Figure 10.19 • Structure of the bleomycin-Fe-O₂ complex.

The toxicity profile of bleomycin is explained by its route of inactivation. Hydrolysis of the N-terminal amide to the carboxylic acid increases the pK_a of the amine at C-2 from 7.3 to 9.4, resulting in a greater degree of ionization and decreased binding to DNA.¹¹⁹ The enzyme responsible for this conversion is known as *bleomycin hydrolase*, and it is present in most tissue but found in low concentration in skin and lung tissue. Tumor cells that are resistant to bleomycin may contain high levels of this enzyme.

BLEOMYCIN SULFATE (BLEO, BLM, BLENOXANE)

Bleomycin occurs as a white powder and is available in 15- and 30-U vials for reconstitution in water. It may be given intravenously, intramuscularly, or subcutaneously. It is used

Figure 10.20 • Representation of the bleomycin-DNA complex. (Reprinted with permission from Zhao, C., et al.: *J. Inorgan. Biochem.* 91:259, 2002.)

in the treatment of squamous cell carcinoma of the head neck, cervix, penis, and vulva. It is also used in Hodgkin's and non-Hodgkin's lymphoma as well as testicular carcinoma. Unlabeled uses include the treatment of mycosis fungoides, osteosarcoma, and AIDS-related Kaposi sarcoma.

Bleomycin given intravenously has a distribution half-life of 10 to 20 minutes with a small volume of distribution of 20 L. The major metabolite results from hydrolysis of the amide at C-1 to give the inactive carboxylic acid. The drug is primarily eliminated in the kidneys with 60% to 70% of the drug recovered in the urine as unchanged drug. The serum elimination is related to glomerular filtration rate, such that those patients with a creatinine clearance greater than 35 mL/min have a serum total elimination half-life of 115 minutes, and in those with a creatinine clearance less than 35 mL/min, the serum total elimination half-life exponentially increases with decreasing creatinine clearance.

Dermatological reactions are the most commonly seen adverse effect with erythema, hyperpigmentation, rash, and tenderness occurring in 50% of the patients taking the drug. The most serious adverse effect is the pulmonary fibrosis previously mentioned. Treatment with bleomycin can increase the risk of pulmonary toxicity that may occur if the patient is subsequently administered oxygen during surgery.

Vinca Alkaloids

The vinca alkaloids (Fig. 10.21) are extracted from the leaves of *Catharanthus roseus* (periwinkle), and were originally investigated for their hypoglycemic properties but later found to possess antineoplastic actions.¹²⁰ The alkaloids are composed of a catharanthine moiety containing the indole subunit and the vindoline moiety containing the dihydroindole subunit joined by a carbon-carbon bond. Vincristine and vin-

blastine differ only in the group attached to the dihydroindole nitrogen, which is a methyl group in vinblastine and a formyl group in vincristine. Vinorelbine is a semisynthetic material resulting from loss of water across the 3',4' bond and first prepared by the use of a modified Polonovski reaction of vinblastine followed by hydrolysis.¹²¹

The vinca alkaloids were initially believed to gain entry into the cell by an energy-dependent process, but more recent work suggests that entry occurs by an energy- and temperature-independent mechanism similar to passive diffusion. The agents then begin to accumulate in cells with intracellular concentrations 5- to 500-fold higher than extracellular concentrations. Once in the cell, the vincas bind to tubulin disrupting formation and function of the mitotic spindle.

The mitotic spindle is composed of the microtubules, which function as part of the cell's cytoskeleton and are important in maintaining cellular shape. They are also involved in transport within the cell and cell signaling as well as playing a pivotal role in the movement of chromosomes during mitosis. The microtubules are composed of heterodimers of α -tubulin and β -tubulin, which may arrange as alternating heterodimers around a hollow axis to form the protofilaments of the microtubule. The behavior of the microtubules are regulated in part by microtubule-associated proteins (MAPs), which may bind to soluble tubulin or the microtubules themselves.¹²² As part of the mitotic process, the length of the microtubule will change because of polymerization and depolymerization of the associated tubulin. Tubulin is capable of binding guanosine-5'-triphosphate (GTP) and hydrolyzing it to guanosine diphosphate (GDP) and inorganic phosphate (P_i). When this hydrolysis occurs and P_i dissociates another tubulin-GTP complex adds to the microtubule. This forms the GTP cap and as long as tubulin-GTP or tubulin-GDP with associated P_i is present at the end

Figure 10.21 • Structures of vinca alkaloids.

of the microtubule, shortening or depolymerization is prevented. The ends of the microtubules are differentiated by the activity that is occurring and are designated as plus and minus. When the microtubule elongates and shortens, it does so primarily at the plus end. The minus end undergoes less pronounced changes in length and is normally attached to a microtubule-organizing center. In a process known as “dynamic instability,” the ends go through phases of slow prolonged growth and rapid shortening, such that the overall length changes. In the process of treadmilling, there is growth at one end counterbalanced by shortening at the other, such that the overall length does not change appreciably. Both of these processes are important for the cell to successfully complete mitosis.¹²³

As the cell prepares for mitosis, the microtubules that make up the cytoskeleton are degraded and reassembled into the mitotic spindle. During prometaphase, the microtubules grow out from the spindle poles to connect to the kinetochores of the individual chromosomes. This involves both polymerization of tubulin and depolymerization as the microtubule seeks out the chromosome representing a period of dynamic instability. These processes continue as the chromosomes are aligned at the metaphase plate, and during this alignment, treadmilling occurs.¹²⁴ Chromosomes are subsequently moved to the spindle poles during anaphase as microtubules attached to the spindle poles shorten and other microtubules known as *interpolar microtubules* lengthen.

The vincas bind to tubulin in a reversible manner at sites different from those at which other inhibitors of spindle function bind including the podophyllotoxins and the taxanes. Combinations of these agents may give synergistic effects because of their unique binding sites. X-ray studies indicate that vinblastine binds between the α - and β -tubulin heterodimers and other studies have shown that there are both high-affinity binding sites located at the end of the spindle and low-affinity sites located along the intact spindle.^{125,126} Binding at the high-affinity sites prevents both lengthening and shortening of the spindle and thereby disrupts its function. Both dynamic instability and treadmilling are inhibited by the vinca alkaloids. Binding at low-affinity sites, which occurs at higher drug concentration, leads to breakdown of the spindle as tubulin depolymerizes. Initial binding at these low-affinity sites leads to an alteration in structure that exposes additional vinca-binding sites. The intracellular concentration of the drug then determines which of these effects is seen. As a result of these actions, the mitotic spindle fails to form properly, chromosomes do not move to the metaphase plate, anaphase fails to occur, and the cell undergoes apoptosis.¹²⁷ The agents are considered specific for the M phase of the cell cycle. Other activities have been observed including antimetabolite activity, inhibition of protein synthesis, and altered lipid metabolism, but these are only seen at very high concentrations of the drugs. Inhibition of angiogenesis has also been associated with the vinca alkaloids.¹²⁸

Microtubules also play important roles in axons or nerve fibers, and disruption of this function is thought to be responsible for the neuropathies seen with this group of compounds. This seems to be most pronounced for vincristine and presumably represents a greater affinity for this type of microtubule. The specific effects the vincas have on axonal microtubules is not as well defined as it is for the mitotic spindle.

Resistance to the vinca alkaloids occurs by several different mechanisms that are also associated with resistance to several high-molecular-weight molecules with diverse mechanisms of action also used in treating cancer.¹²⁹ This multidrug resistance (MDR) is also seen with the taxanes, epipodophyllotoxins, and the anthracyclines although the resistance is usually greatest to the principal agent to which the patient was exposed. The MDR has been associated with several proteins including permeability glycoprotein (Pgp) and multidrug resistance protein (MRP1), which function to actively secrete the molecules from the cell. There are several inhibitors of Pgp such as calcium channel blockers and cyclosporine, which have been investigated to decrease drug efflux; however, these first-generation inhibitors were not successful in reducing drug efflux. There are several newer agents that have proven to be more potent inhibitors of Pgp, but none is currently approved. An additional mechanism of resistance involves altered forms of tubulin to which the vincas fail to bind.

VINBLASTINE SULFATE (VLB, VELBAN, VELSAR)

Vinblastine sulfate is available as a powder in 10-mg vials and as a solution in 10- and 25-mL vials for IV administration in the treatment of various cancers including Hodgkin's disease, lymphocytic lymphoma, histiocytic lymphoma, advanced mycosis fungoides, advanced testicular carcinoma, and Kaposi sarcoma. It has also been used in treating choriocarcinoma and breast cancer when other therapies have failed. Vinblastine is part of the ABVD (adriamycin, bleomycin, vinblastine, and dacarbazine) regimen used in the treatment of Hodgkin's lymphoma. This may be alternated with the MOPP regimen. Extravasation is a concern with the vincas and is treated by administration of hyaluronidase and application of heat. Hyaluronidase hydrolyzes hyaluronic acid, a polysaccharide component of the connective tissue. In so doing, the drug may increase diffusion out of the area of extravasation more quickly, preventing the buildup of toxic levels. Vinblastine is highly protein bound and metabolized by CYP to the 4-*O*-desacetyl metabolite, which has been shown to be active although only small amounts have been recovered in the bile and feces. The metabolism of the vinca alkaloids has not been well characterized. Vinblastine is eliminated primarily in the feces; however, little of the unchanged drug has been recovered. Metabolism appears to involve CYP3A but other than the desacetyl derivative, other metabolites have not been characterized. The elimination half-life for vinblastine is 25 hours. Like vinorelbine, myelosuppression is commonly seen with vinblastine and is dose limiting. Inflammation of the GI tract is more commonly seen with vinblastine than vincristine. Nausea and vomiting may also occur. Other adverse effects include alopecia, secretion of antidiuretic hormone, headache, and depression. Neurotoxicity is mild compared with vincristine, but peripheral neuropathy may be seen. An additional manifestation of this neurotoxicity is hypertension related to disruption of autonomic function.

VINCRIStINE SULFATE (LCR, VCR, LEUCROStINE, ONCOVIN)

Vincristine sulfate is available as a 1-mg/mL solution in 1-, 2-, and 5-mL vials for IV administration in acute leukemia and as part of a multidrug regime for Hodgkin's and

Figure 10.22 • Structures of the taxanes.

non-Hodgkin's lymphoma as well as rhabdomyosarcoma, neuroblastoma, Ewing sarcoma, Wilms tumor, soft tissue sarcoma, testicular cancer, liver cancer, and head and neck cancers. It has also been utilized in treating pediatric cancer. Vincristine is highly protein bound (75%) and may also bind to platelets that contain large amounts of tubulin. Numerous metabolites have been detected and several have been identified, one of which is the 4-*O*-desacetyl derivative. The metabolism that does occur is believed to largely be mediated by CYP3A. Elimination occurs primarily in the bile with a terminal elimination half-life of 23 to 85 hours. The most commonly seen toxicity for vincristine is a dose-limiting neurotoxicity caused by effects on axonal microtubules. Symptoms are variable and include peripheral neuropathy, ataxia, seizure, bone pain, and coma. Constipation is also a commonly seen toxicity, and laxatives may be used prophylactically. Other toxicities include alopecia, skin rash, mild myelosuppression, secretion of antidiuretic hormone, azospermia, and amenorrhea.

VINORELBINE DITARTRATE (VNB, VRL, NAVELBINE)

Vinorelbine ditartrate is available in 1- and 5-mL vials at a concentration of 10 mg/mL for IV use. It is FDA approved for the treatment of NSCLC. The agent has also been used in treating metastatic breast cancer, cervical cancer, uterine cancer, and lung cancer especially in older patients or those with physical difficulties. Vinorelbine is the most lipophilic of the vinca alkaloids because of modifications of the catharanthine ring system and dehydration of the piperidine ring. This allows the agent to be quickly taken up into cells including lung tissue where concentrations are 300-fold higher than plasma concentrations. This is 3 to 13 times higher than the lung concentrations seen with vincristine. The agent is highly protein bound (80%–91%) and metabolized by CYP3A. The major metabolite seen is the 4-*O*-desacetyl derivative, which is equally active with the parent but only formed in small quantities. The agent is eliminated primarily (33%–88%) in the bile with some appearing in the urine (16%–30%). The elimination half-life is 27 to 43 hours. The toxicities seen for vinorelbine include myelosuppression, which is dose limiting but ceases upon discontinuation of drug. This is most commonly seen as a neutropenia, and patient's neutrophil count should be monitored prior to and during therapy to decrease the chance of infection. Additional toxicities include nausea/vomiting, elevation of liver function tests, alopecia, generalized fa-

tigue, and inappropriate secretion of antidiuretic hormone. Neurotoxicity is seen with vinorelbine but occurs to a lesser degree compared with other vinca alkaloids because of its decreased affinity for axonal microtubules.

Taxanes

The taxanes, specifically, taxol (or paclitaxel) was discovered in the 1960s as part of a large-scale screening program conducted by the National Cancer Institute on plant extracts.¹³⁰ Taxol (Fig. 10.22), isolated from the bark of the pacific yew tree, proved to be active against various cancer models; however, interest in the material waned because of the lack of available material and formulation problems. Interest was renewed as the mechanism of action was elucidated, new sources of material were identified, and the formulation problems were resolved.

The formulation problems seen in the early development of paclitaxel were caused by poor water solubility, which was addressed by the use of Cremophor EL and ethanol as vehicles. Cremophor EL is a polyoxyethylated castor oil, and early experience with this formulation resulted in a high percentage of hypersensitivity reactions including rash, bronchospasm, and hypotension, which were associated with the ability of Cremophor EL to cause histamine release. Administration of antihistamines and corticosteroids prior to paclitaxel administration reduces the percentage of patients experiencing hypersensitivity reactions to 1% to 3%.¹³¹

The taxanes bind to tubulin at a site distinct from the vinca alkaloids. In the absence of x-ray crystal structures of bound drug, photoaffinity probes of paclitaxel have identified two sites at which binding may occur to β -tubulin. The first site was located at the N-terminus and involved residues 1 to 31. The second site involved residues 217 to 231 of β -tubulin and although these two sites are widely separated in the primary structure, they are close to each other in the tertiary structure.¹³² The binding site is located on the luminal side of the microtubule and located in the middle of the β -tubulin subunit. Docetaxel binds to the same site with greater affinity. Binding of taxanes at low concentration results in stabilization of the microtubule and prevents depolymerization. At higher concentrations, polymerization is enhanced, and the normal equilibrium between free tubulin and polymer is modified. The taxanes inhibit both treadmilling and dynamic instability, and cells are most affected in the M phase when microtubule dynamics are undergoing the greatest change. Mitosis is blocked at the

metaphase anaphase boundary, and cells undergo apoptosis.¹³³ Paclitaxel has also been shown to enhance phosphorylation of a serine residue of Bcl-2, an antiapoptotic protein resulting in inhibition of Bcl-2's ability to block apoptosis. The proapoptotic proteins Bad and Bax are stimulated and in a similar manner, docetaxel has been shown to induce apoptosis by activation of caspase enzymes.¹³⁴

Resistance to the taxanes is like that seen for the vinca alkaloids and other agents and involves Pgp-mediated efflux. Alterations in the structure of β -tubulin may also occur and result in decreased binding of taxanes to the microtubules and therefore reduced cytotoxicity.

PACLITAXEL (TAX, TAXOL)

Paclitaxel is available in single-dose vials of 30 mg/5 mL and 100 mg/16.7 mL for IV administration in the treatment of breast, ovarian, NSCLC, and AIDS-related Kaposi sarcoma. Other uses have included treatment of head, neck, esophageal, cervical, prostate, and bladder cancers.

Paclitaxel is highly plasma protein bound (>90%) and does not penetrate the CNS. Metabolism involves CYP-mediated oxidation to give 6 α -hydroxypaclitaxel (CYP2C8) and para hydroxylation of the phenyl group attached to the 3'-position (CYP3A4). The 6 α -hydroxy metabolite normally predominates, but the para hydroxy metabolite may occur to a greater degree in those patients with liver disease or when CYP3A4 has been induced. Both metabolites are less active than the parent and do not undergo phase II conjugation reactions. Elimination occurs primarily in the feces, and the elimination half-life is 9 to 50 hours depending on the infusion period.

The major toxicity seen with paclitaxel is a dose-limiting myelosuppression that normally presents as neutropenia. The previously mentioned hypersensitivity reactions occur but are greatly reduced by antihistamine pretreatment. Interaction with the axonal microtubules such as that seen for the vincas also occurs and leads to numbness and paresthesias (abnormal touch sensations including burning and prickling). The agent is also available as an albumin-bound formulation (Abraxane) to eliminate the need for the solubilizing agents associated with the hypersensitivity reactions. Other adverse effects include bradycardia, which may progress to heart block, alopecia, mucositis, and/or diarrhea. Paclitaxel produces moderate nausea and vomiting that is short-lived.

DOCETAXEL (TXT, TAXOTERE)

Docetaxel is available in single-dose vials of 20 mg/0.5 mL and 80 mg/2 mL for IV administration in the treatment of

breast, NSCLC, and prostate cancers. It has also been utilized in non-FDA-approved treatment of head, neck, gastric, bladder, and refractory ovarian cancers.

Docetaxel is highly plasma protein bound (80%) and widely distributed with the highest concentration in the hepatobiliary system, but it does not appear to cross the blood-brain barrier. The metabolism of docetaxel has been less well studied than that of paclitaxel. The use of human liver microsomes has indicated that metabolism involves oxidation of one of the *tert*-butyl methyl groups of the C-13 side chain to initially give the alcohol. Further oxidation to the aldehyde and carboxylic acid both of which may cyclize with the carbamate nitrogen to give stereoisomeric hydroxoxazolidinones and an oxazolidinedione, respectively. No active metabolites have been identified. The major enzyme involved is CYP3A4. The drug is primarily eliminated in the feces with a terminal half-life of 11 hours.

The adverse effects profile for docetaxel is similar to that of paclitaxel but also includes reversible fluid retention that is dose related. This has been associated with an initial increase in capillary permeability followed by a decrease in lymphatic drainage later in the therapy. Restriction of sodium intake and pretreatment with corticosteroids is usually successful in minimizing this adverse effect. Peripheral neuropathy is seen with docetaxel but occurs less often than with paclitaxel. Fatigue and muscle pain are commonly seen, and fever may occur in up to 30% of patients who are infection free.

IXABEPILONE (AZAEPOTHILONE B, IXEMPRA)

The epothilones are macrocyclic lactones that have a mechanism of action similar to that of the taxanes but offer several advantages (Fig. 10.23).¹³⁵ Ixabepilone is the semisynthetic amide analog of epothilone B that is isolated from the myxobacterium *Sorangium cellulosum*. The epothilones showed potent *in vitro* activity but greatly decreased activity *in vivo* caused by metabolic instability via hydrolysis of the macrocyclic lactone. Conversion to the lactam increased stability and maintained *in vivo* activity. Ixabepilone has been recently (2007) approved for the treatment of metastatic breast cancer that is resistant to the taxanes. The agent is believed to bind to the same site occupied by the taxanes. Molecular modeling studies have been utilized to identify a common pharmacophore between the taxanes and epothilones.¹³⁶ Key structural components that assume comparable relative position are indicated in Table 10.2. Like the taxanes, ixabepilone binds to β -tubulin and stabilizes microtubules resulting in cell death. The agent is useful in cancers that have become resistant to the taxanes, because it is not removed by Pgp and is still capable of binding

Figure 10.23 • Structures of epothilones.

TABLE 10.2 Functional Groups Yielding Analogous Microtubule Binding in Paclitaxel and Epothilone B

Paclitaxel	Epothilone B
C-15 gem-dimethyl	C-4 gem-dimethyl
C-1 OH	C-3 OH
C-9 carbonyl	C-7 OH
C-5 oxetane-oxygen	C-12,13 epoxide oxygen
C-3' phenyl ring	C-17 thiazole ring

to altered beta tubulin to which the taxanes no longer bind. Increased water solubility also allows the agent to be administered without the need for Cremophor EL, reducing the chance of hypersensitivity reactions. The current indications for the agent are in metastatic breast cancer in combination with capecitabine after the failure of an anthracycline and a taxane and as monotherapy in metastatic breast cancer after failure of an anthracycline, a taxane, and capecitabine. The agent is extensively metabolized in the liver primarily by CYP3A4 to give over 30 different metabolites. Elimination occurs primarily in the feces (65%) with a smaller amount (21%) occurring in the urine. The terminal elimination half-life is 52 hours. Major toxicities associated with the use of ixabepilone have included peripheral neuropathy and myelosuppression occurring as neutropenia. Occurring less frequently are alopecia, nausea, vomiting, mucositis, diarrhea, and muscle pain.

MITOMYCIN C

Mitomycin C (Fig. 10.24) was isolated from *Streptomyces caespitosus* in 1958 by Japanese workers and is considered the prototype of the bioreductive alkylating agents.^{137–139} Mitomycin is sometimes included as an alkylating agent but is included here because it is a naturally occurring material. The drug contains what would appear to be reactive functionalities, including the quinone and aziridine functionalities, both of which would be thought to be susceptible to nucleophilic attack; however, the reactivity of these functionalities is reduced because of steric and electronic effects in the parent molecule. It was reasoned that selective activation could be achieved in a reductive environment such as that found in an area of low oxygen content. This is known to occur in tumors where the fast-growing cells often grow beyond the blood supply that would normally provide oxygen.¹⁴⁰ A normal cell would undergo apoptosis under these conditions, but because cancer cells often have their apoptotic mechanisms inhibited they continue to survive with little or no oxygen available. Mitomycin C is capable of being activated and alkylating DNA in an anaerobic environ-

Figure 10.24 • Structure of mitomycin C.

ment, but there is actually little selectivity for hypoxic cells. Activation can occur enzymatically by both one- and two-electron processes. Reductive enzymes such as NADPH-CYP reductase and DT-diaphorase have been implicated in these processes.¹⁴¹ Involvement of one-electron processes such as those seen for the anthracyclines result in redox cycling and the production of ROS that may result in DNA damage, but the cytotoxicity of mitomycin C is primarily associated with its ability to alkylate DNA. The hydroquinone can result from a single two-electron process or a one-electron process followed by disproportionation to give the hydroquinone (Scheme 10.30).^{142–144} The electrons of the amine are no longer withdrawn by the quinone system and are now free to expel methoxide followed by loss of a proton to give the leuco-aziridinomitosenone. This reduction renders positions C-1 and C-10 reactive to nucleophilic attack because of the fact that there are leaving groups attached, and they are now benzylic positions so that the intermediate carbocations can be stabilized. Several pathways are possible from this point, and the specific route is dependent on the conditions in the cell. Shown in Scheme 10.30 is one possible pathway that occurs under more acidic conditions and results in the formation of interstrand and intrastrand cross-links. Protonation of the aziridine is followed by ring opening to give the carbocation, which can be stabilized by resonance involving the hydroquinone system. Nucleophiles on DNA may attack at C-1 with concomitant electron movement. This can be repeated in a similar manner at C-10, which allows for cross-linking. There are several other possibilities under different conditions. DNA is alkylated by mitomycin C at both the N-2 and N-7 positions of guanine

MITOMYCIN C (MITC, MTC, MUTAMYCIN)

Mitomycin C is available in 5-, 20-, and 40-mg vials for IV administration in the treatment of cancers of the stomach and pancreas when other treatments have failed. Other uses have included breast, NSCLC, cervical, bladder, and head and neck cancers. Mechanisms of resistance include increased synthesis of nucleophilic detoxifying compounds such as glutathione, decreased expression of activating enzymes such as DT-diaphorase, and increased efflux by Pgp. The drug is rapidly cleared from the plasma after administration and widely distributed but does not cross the blood-brain barrier. The parent and metabolites are excreted mainly in the feces with an elimination half-life of 50 minutes. Adverse effects include dose-limiting myelosuppression, mild nausea and vomiting, mucositis, anorexia, fatigue, and interstitial pneumonitis.

PROTEIN KINASE INHIBITORS

In the last several years, several new treatment options have become available based on increased knowledge of growth factors and cell signaling. Although these agents have provided great benefit in some cases and their utility is still being determined, it is important to remember that in many cases they are used in combination with more traditional chemotherapeutic agents to achieve a better outcome. The traditional agents are often used in combination as well in attempts to increase success and prevent resistance.

Scheme 10.30 • Alkylation of DNA by mitomycin C.

It was realized early on that the growth and proliferation of many tissues was under the control of the endocrine system, in which endocrine glands secreted hormones and that hormones or their antagonists were useful in controlling the overgrowth of these tissues. It was found later that other growth factors, many of which were secreted by nearby cells, were also involved in controlling the growth and proliferation of the target tissue and this became known as *paracrine control*. Many of these growth factors have been identified and several along with their receptors are indicated in Table 10.3.¹⁴⁴

These receptors have become targets for several different monoclonal antibodies that have been recently introduced.

TABLE 10.3 Growth Factors and Receptors of Paracrine Origin

Growth Factor	Designation	Receptor
Epidermal growth factor	EGF	EGF-R
Platelet-derived growth factor	PDGF	PDGF-R
Nerve growth factor	NGF	Trk
Vascular endothelial growth factor	VEGF	VEGF-R
Stem cell factor	SCF	Kit
Glial cell line-derived neurotropic factor	GFL	RET

Further work identified the pathways by which interaction with these cell surface receptors resulted in growth and proliferation of cells. There are various mechanisms by which these processes occur, but a generalized pathway involves interaction of a growth factor with a growth factor receptor occurring as a monomer present in the phospholipid bilayer of the cell membrane, which results in dimerization of the receptors (Scheme 10.31). The receptors themselves possess an extracellular-binding domain for interaction with the growth factors, an intracellular domain, and a connecting transmembrane region. The intracellular domain of these receptor proteins often function as kinases, many of which are TKs that phosphorylate residues on the other monomer receptor. The resulting phosphorylated residues are recognized by the Src homology 2 domain (SH2) of cytoplasmic proteins such as Shc, Grb-2, and Sos, which activate Ras. These cytoplasmic proteins then serve to transmit the growth signals from the growth factor receptors to Ras (Fig. 10.25). Ras is a G protein tethered to the cytoplasmic membrane, which may bind GTP resulting in activation of Ras or bind GDP resulting in Ras inactivation. Ras also normally has the ability to hydrolyze GTP to inactivate itself. Many cancers are found to have altered forms of Ras, which is present in a hyperactive state. Ras, in its activated form activates a series of kinases, many of which are TKs with various effects on cells. Notable is the Ras-Raf-MEK-ERK pathway also known as the *mitogen-activated protein kinase* (MAPK) pathway. This is a

Scheme 10.31 • Schematic of the activation of growth factor receptors.

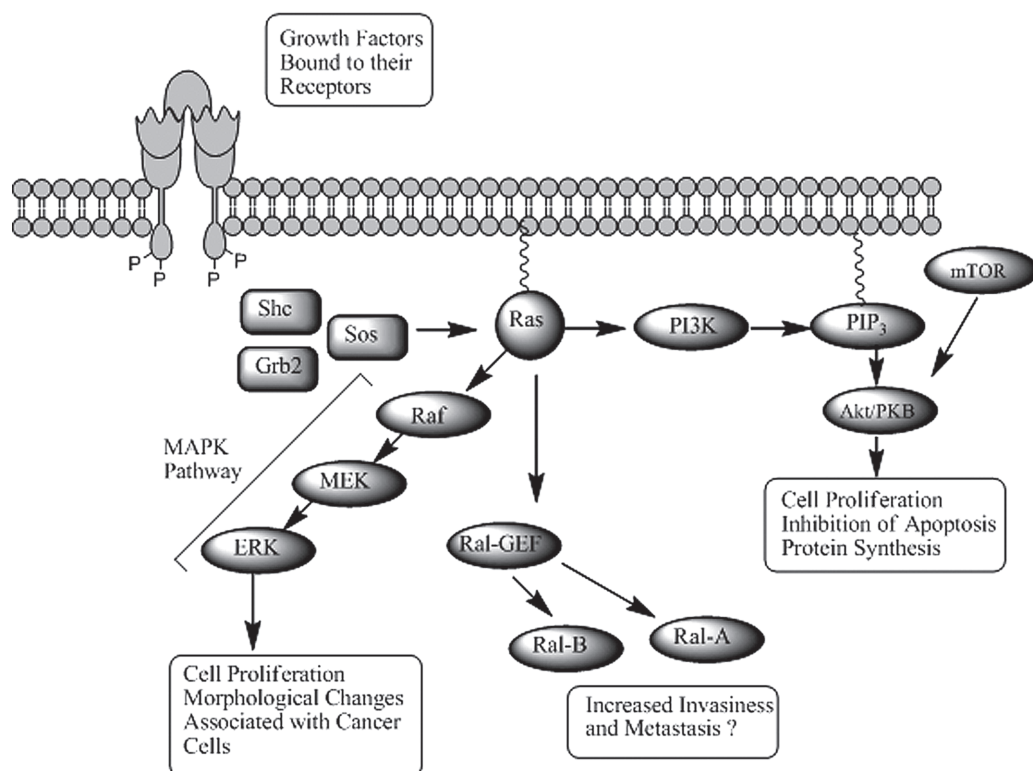

Figure 10.25 • Schematic of the Ras pathways leading to uncontrolled cell proliferation.

cascade effect, whereby one kinase phosphorylates and activates more of the next kinase in the pathway amplifying the signal in the process. Stimulation of this pathway results in the activation of several transcription factors involved in the expression of growth factors, cyclin D1 (involved in controlling cell division, see Fig. 10.1), and transcription factors Fos and Jun, which were first discovered as viral oncogenes and are known to be elevated in several human cancers. In addition, overactivation of this pathway may result in loss of contact inhibition, loss of anchorage dependence, and changes in cell shape, all of which are characteristic of cancer cells.

The second major pathway activated by Ras is PI3K-PIP3-Akt/PKB whose activation increases cell proliferation but perhaps most importantly, inhibits apoptosis. When Ras is activated, phosphatidylinositol(4,5)-diphosphate (PIP₂) is further phosphorylated to give phosphatidylinositol(3,4,5)-triphosphate PIP₃, which remains embedded in the plasma membrane but attracts and activates other kinases namely protein kinase B (PKB), a serine-threonine kinase. Overactivity of this pathway results in decreased apoptosis, increased proliferation and increased cell size. Specific effects include inactivation of the proapoptotic protein Bad (Fig. 10.2) and activation of antiapoptotic NF- κ B.

The third pathway involves Ras-mediated activation of Ral-GEF (Guanine nucleotide exchange factor), which acts on Ral-A and Ral-B to stimulate their exchange of GDP for GTP and hence their activation. The activation of this pathway, although less well understood, seems to allow cancer cells to metastasize and invade.

Overactivity of these pathways is present in several different cancers, and consequently, several agents have been developed to correct this. One such approach is the inhibition of kinases whose normal activity has been amplified.

Working in Philadelphia in the 1960s, scientists discovered a genetic abnormality present in 95% of patients with CML.¹⁴⁵ The abnormality was a translocation between chromosomes 22 and 9 in which the *ABL* gene (analogous to the Abelson proto-oncogene found in mice) originally on chromosome 9 was translocated to chromosome 22, such that it was fused with BCR gene (breakpoint cluster region). The new chromosome was designated as the Philadelphia translocation or the Philadelphia chromosome (Ph¹).¹⁴⁶ The fusion of these two genes resulted in a protein that encoded the entire *ABL* gene and as many as three additional proteins from BCR. The product of this fusion was found to be a TK that was always activated. This altered TK utilizes ATP to phosphorylate and activate numerous pathways including MAPK and Akt/PKB along with several others. This leads to proliferation of white cells that normally lasts about a year, when the disease becomes more difficult to treat and eventually to the terminal blast phase lasting several months.

Imatinib (Fig. 10.26) was developed to specifically inhibit this unique TK and does so rather selectively by binding to the ATP-binding pocket and stabilizing an inactive form of the enzyme. Protein kinases have similar structures and consist of C- and N-terminal lobes with the active site formed by a cleft between the two lobes. The activity of the enzyme is regulated by an activation loop that is extended in the active form of the enzyme and provides for substrate binding. X-ray crystal studies of imatinib binding to Abl show that the drug binds in the

cleft formed by the two lobes of the enzyme through the formation of several hydrogen bonds and hydrophobic interactions with the pyridine ring assuming the position occupied by ATP in the active enzyme.¹⁴⁷ Imatinib binding locks the enzyme in a conformation in which the activation loop is oriented so as to block substrate binding. Specificity for the BCR-ABL kinase is not complete because of structural similarity of TKs, and those associated with the PDGF receptor and the receptor for SCF known as KIT are also inhibited (Table 10.3). The agent has been found to be effective in 90% of patients in the chronic stage (the chronic stage last 4–6 years and precedes the proliferation stage mentioned previously). Blast-phase patients respond at a rate of 60% but usually relapse after several months.¹⁴⁸

The tremendous success of imatinib led to other agents that could be used in the case of resistance. Specifically, dasatinib can bind to either an active or inactive form of the enzyme and is 100 times more potent compared with imatinib. It has the ability to overcome resistance associated with amino acid alterations that leads to decreased affinity for imatinib. As the structure is altered, binding to other TKs (BCR-ABL, PDGF, SRC, KIT) is manifested, which may eventually lead to other indications but at this time, it is used primarily in those cases when patients fail to respond to imatinib.¹⁴⁹

This general idea of targeting TKs was extended to the EGF receptor. It was hoped that by targeting EGF TKs the inhibitors would be applicable to a wide range of cancers. Recall that after the receptors dimerize, they transphosphorylate each other and act as TKs. Currently, there are two structurally similar agents in use, gefitinib and erlotinib, which bind to the ATP-binding site and thereby inhibit the resulting cascade that would normally occur from activation of the EGF receptor.^{150,151} The benefit of the agents was hoped to be caused by inhibition to the Ras pathway so that ultimately, all three arms could be affected (MAPK, Akt/PKB, and Ral-GEF). The agents are modestly selective for this kinase. Currently both compounds have indications for NSCLC generally as alternatives after the failure of more traditional therapy, and gefitinib has an additional indication against pancreatic cancer. Initial results have not been as dramatic as that seen with imatinib. There are also several known mutations and deletions in the EGF receptor of cancer patients and this may affect the activity of these compounds. Specifically, point mutations in the *KRAS* gene (a member of the Ras family) have been associated with resistance to these agents and tests have become available to detect this prior to initiating therapy.

The activation of numerous tyrosine and serine-threonine kinases offers many theoretical targets for drug intervention when these pathways become overactive as is often the case in neoplastic cells. These kinase enzymes are all thought to have evolved from a common ancestor and as such possess a great deal of structural similarity that complicates the development of agents, which are selective for a single kinase. This has led to the strategy of simultaneously inhibiting numerous kinase enzymes, and consequently there are several multikinase inhibitors now available. Sorafenib was originally developed using high-throughput testing and parallel synthesis as an inhibitor of the serine-threonine kinase Raf.¹⁵² It proved to be a potent inhibitor of this enzyme with an IC₅₀ = 6 nM and acted by stabilizing an inactive form of

Figure 10.26 • Protein kinase inhibitors.

the enzyme similar to imatinib. Subsequent x-ray analysis of the drug receptor complex showed that the pyridine ring occupied the ATP-binding site of Raf, whereas the trifluoromethyl-chloro-substituted phenyl ring occupied a hydrophobic pocket in the cleft formed by the two lobes of the protein.¹⁵³ The urea moiety forms two hydrogen bonds, one through interaction of the amide proton with the carboxylate of Glu500 and the second through interaction of the carbonyl oxygen with the peptide amide N-H of Asp593. The compound also has the capacity to inhibit several other TKs associated with growth factor receptors including PDGF-R, VEGF-R, RET-kinase, and c-Kit with IC₅₀s in the range of 20 to 90 nM. In some cancer models, the compound has been shown to be effective even though the MAPK pathway was not inhibited and this has been explained by the com-

pounds inhibition of angiogenesis. This has been attributed to the effects on inhibition of PDGF-R and VEGF-R phosphorylation and the role these growth factor receptors play in the creation of new blood vessels. The agent was investigated and subsequently approved for use in renal cell carcinoma (RCC) because of the fact that this particular cancer is often associated with increased activity of the targets inhibited by sorafenib and the high level of neovascularization that is seen in this cancer.

As a group of agents, the protein kinase inhibitors have the advantage of oral administration and better patient tolerability. The major adverse effects include a skin rash that normally appears early in therapy on the upper torso and is generally mild but may become more serious in some cases. Mild diarrhea and nausea are also commonly seen but are

generally controlled with the administration of antiemetics and antidiarrheals. Mild myelosuppression is also seen with several of these agents. There has been concern about cardiotoxicity associated with protein kinase inhibitors because of the fact that multiple kinases may be inhibited. This could potentially have several effects on signaling processes in cardiac tissue. For example if the Akt/PKB pathway was blocked, apoptosis may become activated and cardiac cells would die (Table 10.3). There has been some evidence for cardiotoxicity in this class and the agents have been ranked with imatinib, dasatinib, sorafenib, and sunitinib having known or likely cardiotoxicity and gefitinib, erlotinib, and lapatinib having low cardiotoxicity. Concern of cardiotoxicity is also a result of the fact that other drugs such as the anthracyclines and several of the monoclonal antibodies directed against the EGF-R are known to have cardiotoxicity associated with their use.¹⁵⁴ Therefore, patients who have already been exposed to these agents may experience additional adverse effects to their cardiovascular system if a protein kinase inhibitor were utilized and it also produced significant cardiotoxicity. Studies for the most part have not evaluated the cardiotoxicity of these agents and the given ranking is based on preliminary data, but there is concern about the cardiovascular effects of this class of agents.

IMATINIB MESYLATE (STI-571, GLEEVEC)

Imatinib is available in 100- and 400-mg capsules for oral administration and is indicated for the treatment of CML, gastrointestinal stromal tumors (GIST) that express Kit and acute lymphoblastic leukemia that is positive for the Philadelphia chromosome.

Bioavailability of the agent is nearly 100% by the oral route. The agent is highly protein bound and metabolized to the *N*-desmethyl derivative by CYP3A4-mediated removal of the piperaziny methyl group. The resulting metabolite is similar to the parent in activity. Elimination occurs primarily in the feces, and the terminal half-life is 18 hours for the parent and 40 hours of the *N*-desmethyl metabolite. Resistant forms of the TK are known, which have altered amino acids that prevent binding. In addition, there may be increased levels of the kinase itself. The drug is also a substrate for Pgp and an additional efflux transporter known as *breast cancer resistance protein* (BCRP), both of which remove the drug from the cell. These transporters are also inhibited by the agent as well. Severe side effects include ascites, neutropenia, thrombocytopenia, skin rash, and pulmonary edema. Less serious side effects include nausea/vomiting, heartburn, and headache but overall, the agent is better tolerated than most other medications used in treating the disease.

DASATINIB (BMS-354825, SPRYCEL)

Dasatinib is available in 20-, 50-, and 70-mg tablets for oral administration in the treatment of CML and ALL that are Ph¹ positive. Although dasatinib is more potent than imatinib, bioavailability is much lower with values ranging between 14% to 34%. The agent is extensively metabolized with as many as 29 metabolites seen as result of oxidation by primarily CYP3A4 and phase II conjugation. The agent may act as an inhibitor of CYP3A4 and CYP2C8. Metabolism does give an active metabolite, but

this accounts for only 5% of the total and is not believed to be important for the overall activity of the agent. Dasatinib is 95% protein bound with a terminal half-life of 3 to 5 hours. The majority of the drug and metabolites are eliminated in the feces. The most common side effects are skin rash, nausea, diarrhea, and fatigue. Serious side effects include myelosuppression appearing as neutropenia and thrombocytopenia, bleeding of the brain and GI tract, and fluid retention.

GEFITINIB (ZD1839, IRESSA)

Gefitinib is available as 250-mg tablets for oral administration in the treatment of NSCLC for those patients who have failed to respond to platinum-based therapies and docetaxel and has also been used against squamous cell cancers of the head and neck. The agent is an inhibitor of the TK of EGF-R and possibly other TKs as well. Gefitinib is both a substrate and inhibitor of Pgp and BCRP. The agent is absorbed slowly after being administered orally with 60% bioavailability. Metabolism occurs in the liver and is mediated primarily by CYP3A4 to give eight identified metabolites resulting from defluorination of the phenyl ring, oxidative-*O*-demethylation, and multiple products arising as a result of oxidation of the morpholine ring. The *O*-demethylated product represents the predominate metabolite and is 14-fold less active compared with the parent. The parent and metabolites are eliminated in the feces with a terminal elimination half-life of 48 hours. The drug appears to be well tolerated with the most commonly reported side effects being rash and diarrhea. It may also cause elevations in blood pressure especially in those patients with preexisting hypertension, elevation of transaminase levels, and mild nausea and mucositis.

ERLOTINIB HYDROCHLORIDE (CP-358,774, TARCEVA)

Erlotinib is available as 25-, 100-, and 150-mg tablets for oral administration and is used after failure of first-line therapy in metastatic NSCLC and as first-line therapy in combination with gemcitabine in the treatment of metastatic pancreatic cancer, and in treating malignant gliomas. The structural similarity to gefitinib imparts similar pharmacokinetic behavior with bioavailability of 60% and protein binding of 93%. The agent is extensively metabolized primarily by CYP3A4. Three major metabolic pathways have been identified, involving oxidative-*O*-demethylation of the side chains followed by further oxidation to give the carboxylic acids, oxidation of the acetylene functionality to give a carboxylic acid, and aromatic hydroxylation of the phenyl ring para to the electron-donating nitrogen. The metabolites are primarily eliminated in the feces, and the terminal half-life is 36 hours.¹⁵⁵ The major toxicities seen with the agent are dose-limiting skin rash and diarrhea. Other common adverse effects include shortness of breath, fatigue, and nausea.

SORAFENIB TOSYLATE (BAY 43-9006, NEXAVAR)

Sorafenib is available in 200-mg tablets for oral administration and is used in the treatment of RCC and colon cancer. The agent is classified as a multikinase inhibitor because of its action on numerous kinase enzymes including the PDGF-R, VEGF-R, Kit, and Raf. Sorafenib is 39% to 48%

bioavailable and CYP3A4-mediated metabolism gives eight identified metabolites including the *N*-oxide, which is equally active with the parent. However, the majority of the drug in plasma is present as the parent compound. Sorafenib is highly protein bound (99.5%). The drug is eliminated primarily in the feces (77%) with 19% appearing in the urine as glucuronides (UGT1A1) and has a elimination half-life of 24 to 48 hours. The most commonly seen toxicity is skin rash that normally occurs within the first 6 weeks of therapy. Other adverse effects include hypertension, fatigue, increased wound healing time, and increased risk of bleeding.

LAPATINIB DITOSYLATE (GSK572016, TYKERB)

Lapatinib is available in 250-mg tablets for oral administration and is used in combination with capecitabine in the treatment of breast cancer for those patients that over express the type 2 EGF-R and who have previously received taxane, anthracycline, and trastuzumab therapy. The type 2 EGF-R is one subtype of this receptor and is also known as HER2 or ErbB-2. The agent is a receptor TK inhibitor targeting the ErbB-1 and ErbB-2 subtypes. Binding occurs at the ATP-binding site and thereby prevents phosphorylation and the subsequent activation of other kinase enzymes. ErbB-1 overexpression occurs in approximately 27% to 30% of breast cancers, while ErbB-2 is over expressed in 20% to 25% of cases.¹⁵⁶ The agent has demonstrated IC₅₀ values of <0.2 μM against ErbB-1 and 2 from several different cancer cell lines and dissociates slowly (*t*_{1/2} = 300 min) from these receptor TKs.¹⁵⁷ The drug is both a substrate and an inhibitor of the efflux transporters Pgp and BCRP. It is also an inhibitor of the hepatic uptake transporter OATP1B1, which is an organic anion transporter.¹⁵⁸ The absorption of lapatinib is incomplete and variable after oral administration. The agent is extensively metabolized by CYP3A4 and CYP3A5, with minor contributions from CYP2C19 and CYP2C8. Lapatinib inhibits CYP3A and CYP2C8 at clinically relevant concentrations. The agent is highly (99%) protein bound and eliminated primarily in the feces. The half-life of the agent increase upon repeated dosing, taking 6 days to reach steady state that gives an effective half-life of 24 hours. The most commonly seen adverse effects of lapatinib therapy are skin rash and diarrhea. Skin rash is commonly seen with many of the other TK inhibitors and agents that target ErbB-1. Lapatinib-induced diarrhea is usually mild to moderate. There have been reports of decreases in left ventricular ejection fraction associated with the agent, although this appears to occur only rarely and is reversible upon discontinuation of therapy.

SUNITINIB MALATE (SU11248, SUTENT)

Sunitinib is available in 12.5-, 25-, and 50-mg capsules for oral administration for the treatment of advanced RCC and GIST upon the failure of imatinib. The agent is a multikinase inhibitor and has been shown to inhibit PDGF-R, VEGF-R, Kit, RET, and the colony-stimulating factor receptor (CSR-1R). The result of this spectrum of activity is a slowing of tumor progression and inhibition of angiogenesis both of which are useful in the highly vascularized cancers, RCC and GIST. The median TTP (time to tumor progression) was 27.3 weeks for sunitinib and 6.4 weeks

for placebo. Progression-free survival was also significant with a median time of 24.1 weeks for sunitinib and 6 weeks for placebo. The agent is well absorbed upon oral administration, and both the parent and major metabolite are highly (90%–95%) protein bound. Metabolism is mediated primarily by CYP3A4 to give the *N*-desethyl derivative, which is the major metabolite (23%–37%), equally active with the parent and undergoes further metabolism by CYP3A4. The terminal elimination half-life for the parent and *N*-desethyl derivative are 40 to 60 hours and 80 to 110 hours, respectively. Elimination occurs primarily via the feces. Common adverse effects of sunitinib include fatigue, diarrhea, yellow skin discoloration, anorexia, nausea, and mucositis. Mild myelosuppression has been reported in patients with GIST including neutropenia, lymphopenia, thrombocytopenia, and anemia. There have been reports of cardiotoxicity including decreases in left ventricular ejection fraction, which occurred in 11% of patients during a GIST study.

MISCELLANEOUS COMPOUNDS

TEMSIROLIMUS (CCI-779, TORISEL)

Temsirolimus (Fig. 10.27) is an esterified derivative of rapamycin and in a similar manner binds initially to the protein FKBP-12(FK506-binding protein).¹⁵⁹ This complex then acts to inhibit the mammalian target of rapamycin (mTOR), a serine-threonine kinase that plays a crucial role in cell division. It is somewhat unique in its method of kinase inhibition, because it actually binds to an allosteric modulator of the kinase rather than just binding to the ATP-binding site like most other kinase inhibitors. Binding of temsirolimus inhibits the phosphorylating activity of mTOR. As shown in Table 10.3, mTOR regulates the Akt/PKB pathway, and therefore, one way in which the agent acts is to inhibit this pathway. An additional mechanism involves the ability of mTOR to initiate protein synthesis independent of the Akt/PKB pathway. Blockade of mTOR results in inhibition of protein synthesis and prevents the cell from moving past the G₁ phase into the S phase. More specifically, mTOR is prevented from phosphorylating 4E-binding protein-1(4E-BP1) an initiating factor and 40S ribosomal protein S6 kinase (p70S6 kinase), both of which are involved in initiating protein synthesis necessary for the cell cycle. In addition, mTOR is involved in the control of several growth factors such VEGF, PDGF, and TGF, which are involved in cell growth and angiogenesis. Temsirolimus is available as a 25-mg/mL injection for IV administration in the treatment of advanced RCC. The agent is extensively metabolized and undergoes rapid hydrolysis of the ester function to give rapamycin that retains activity.¹⁶⁰ Additional metabolism is mediated primarily by CYP3A4 to give several hydroxylated and demethylated metabolites that are inactive. The agent and metabolites are eliminated primarily in the feces with half-lives of 17 and 55 hours for temsirolimus and rapamycin, respectively. This agent, like rapamycin, possesses immunosuppressant properties and there is an increased risk of infection. The most serious side effects are interstitial lung disease, perforation of the bowel, and acute renal failure although these occur only rarely. The most commonly seen side

Figure 10.27 • Miscellaneous antineoplastic agents.

effects are rash, weakness, mucositis, nausea, edema, and anorexia.

BORTEZOMIB (VELCADE)

Proteasomes normally function to degrade proteins that are no longer needed by the cell. Such proteins are normally marked by the addition of ubiquitin, a 76 amino acid protein that is added to the ϵ -amino group of lysine residues on the target proteins. The marked proteins are then hydrolyzed by the large barrel-shaped proteasomes to give peptides of 7 to 8 residues that may be further hydrolyzed and reutilized by the cell. This process serves to regulate protein levels within the cell, remove defective proteins, and becomes important in maintaining normal signal transduction. Inhibition of the proteasomes results in the build up of ubiquitylated proteins, which disrupts cell-signaling processes and cell growth (Fig. 10.28). The signaling by transcription factor NF- κ B (nuclear factor κ B) appears to be especially sensitive to bortezomib. NF- κ B is associated with the transcription of antiapoptotic and proliferative genes but is under the control of I κ B (inhibitor of NF- κ B). I κ B can itself be phosphorylated by IKK (I κ B kinase), which marks I κ B for ubiquitylation and destruction allowing NF- κ B to mediate its antiapoptotic and proliferative ef-

fects. In the presence of the competitive inhibitor bortezomib (IC₅₀ = 0.6 nM), the 26S proteasome is inhibited and the ubiquitylated I κ B is still capable of inhibiting NF- κ B, preventing its effects.¹⁶¹

The agent is used primarily in treating multiple myeloma, where NF- κ B is thought to be especially important because of its regulation of VEGF and adhesion molecules, which play important roles in this cancer. The agent is also used in treating non-Hodgkin's lymphoma.

Bortezomib is available in 10-mL vials containing 3.5 mg that is administered intravenously for the treatment of multiple myeloma. The agent contains the unique boronic acid group, which serves as a bioisosteric replacement for an aldehyde functionality and forms a tetrahedral complex with a threonine hydroxyl group present on the proteasome. Several aldehydes were known to be proteasome inhibitors, but their incorporation resulted in racemization of the α -carbon. The boronic acids were not susceptible to the same racemization, and stereochemistry was preserved in vivo giving maximal inhibition. The agent has a half-life of 9 to 15 hours with the major metabolizing enzymes being CYP3A4 and CYP2C19.¹⁶² Metabolism involves the oxidative removal of boron from the agent to give two diastereomeric carbinolamines. Both of the metabolites are inactive, the boronic acid functionality

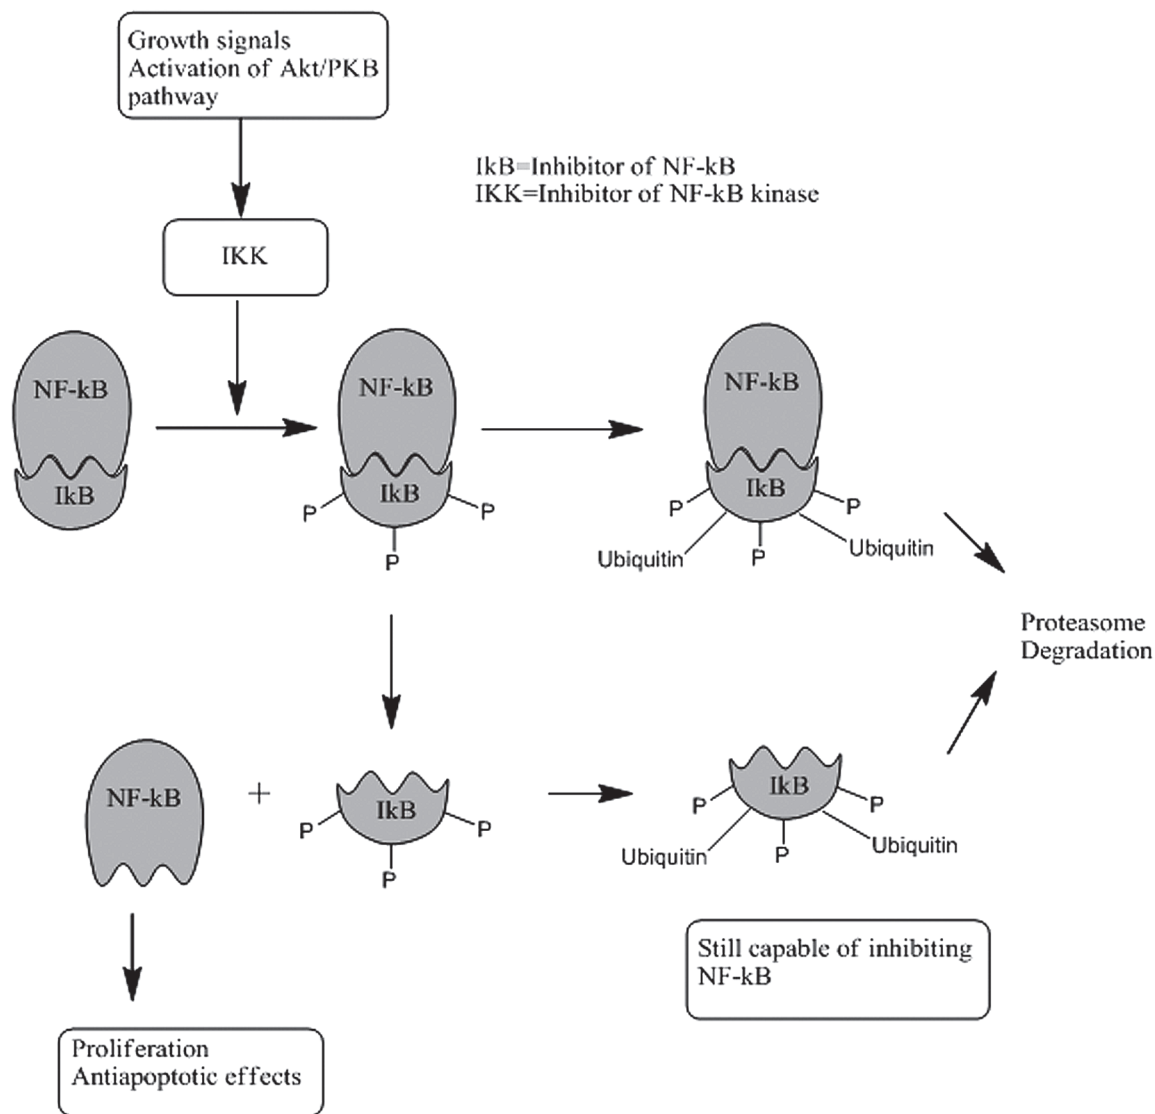

Figure 10.28 • Actions of proteasomes on NF- κ B.

being necessary for binding of the proteasome. The elimination of the agent has not been well characterized.

The major toxicities seen with the agent are generalized weakness, nausea, vomiting, diarrhea, peripheral neuropathy, fever, and orthostatic hypotension. Myelosuppression also occurs normally as thrombocytopenia and neutropenia.

VORINOSTAT (SUBEROYLANILIDE HYDROXAMIC ACID, SAHA, ZOLINZA)

Histones are proteins around which DNA is wound in the process of packing DNA into the nucleus. They also have a role in regulating the transcription of genes, and this is controlled by the covalent modifications acetylation, phosphorylation, and methylation to which they are subject. The specific modifications present on the histones or histone code has been proposed to determine which transcription factors associate with specific genes and result in their replication.¹⁶³ Acetylation occurs at the ϵ -amino group of lysine and is accomplished by histone acetyltransferase enzymes, whereas deacetylation is accomplished by histone deacetylase enzymes. The result of inhibition of histone

deacetylase is hyperacetylation of lysine residues of the histone proteins. The positively charged ϵ -amino groups of the lysine residues are believed to interact with the negatively charged phosphate backbone of DNA. Once acetylation has occurred, this interaction is prevented, and the binding of transcription factors is favored. Therefore, the inhibition of deacetylation by vorinostat, a histone deacetylase inhibitor (HDACi), results in the increased transcription of certain genes. Specifically, this has been associated with upregulation of a regulatory protein known as p21, which serves to inhibit progression past the G₁ phase of the cell cycle. Other genes and their proteins are also effected by vorinostat such as Hsp90 (heat shock protein 90) and BCL6.

Vorinostat fits the basic pharmacophore for the HDACis (Fig. 10.29), which consists of a hydrophobic cap region connected to a zinc coordinating functionality by a hydrophobic linker.¹⁶⁴ The hydroxamic acid functionality is capable of bidentate binding to zinc present in the enzyme and is a major factor in the overall binding of the compound. The compound inhibits HDAC1, 2, 3, and 6 classes of this enzyme with nanomolar (<86 nM) IC₅₀ values.¹⁶⁵

Figure 10.29 • Pharmacophore for histone deacetylase inhibitors.

The agent is given orally and is available in 100-mg capsules for the treatment of cutaneous T-cell lymphoma. The bioavailability is 43%, and the agent is 71% bound to plasma proteins. Extensive metabolism of the agent occurs to give the *O*-glucuronide of the hydroxamic acid function and 4-anilino-4-oxobutanoic acid with minimal involvement of isozymes of CYP. The metabolites, both of which are inactive, are eliminated in the urine and the drug has a terminal elimination half-life of 2 hours. The most commonly reported adverse effects are fatigue, diarrhea, and nausea. Elevations in glucose and triglyceride levels are commonly seen with the agent. The agent has been associated with thrombocytopenia, an increased risk of clotting resulting in pulmonary embolism and possibly prolongation of the QTc interval.

ARSENIC TRIOXIDE (AS₂O₃, TRISENOX)

Arsenic trioxide is available in 10-mL vials for IV administration as second-line therapy in the treatment of acute promyelocytic leukemia (APL). The mechanism of the agent has not been well characterized; however, work has indicated that the agent may cause the degradation of a protein that blocks myeloid differentiation. Acute lymphocytic leukemia is associated with a translocation in which the promyelocytic leukemia (PML) gene is fused with the retinoic acid receptor gene (RAR α), and the protein that results from this genetic rearrangement prevents myeloid differentiation.¹⁶⁶ Arsenic trioxide is capable of degrading this protein and allowing the cells to differentiate. Additional effects have included stimulation of apoptosis by decreasing Bcl-2 activity and stimulation of caspase enzymes and p53. Angiogenesis is inhibited by the inhibition of VEGF at the protein level.¹⁶⁷ The agent is widely distributed after IV administration; however, the pharmacokinetics of the agent have not been well characterized. Metabolism studies have shown that the agent undergoes reduction to trivalent arsenic followed by methylation to give monomethylarsonic and dimethylarsinic acids, which are eliminated in the urine. Unlike most other antineoplastic agents, myelosuppression does not occur in fact many patients (50%–60%) experience leukocytosis in which white blood cell count increases. APL differentiation syndrome is seen in many patients (30%) and presents as fever, shortness of breath, weight gain, pulmonary infiltrates, and pleural or pericardial effusions. This may be fatal and is commonly treated with high-dose dexamethasone upon initial suspicion. The presentation of APL differentiation syndrome are identical for arsenic trioxide and retinoic acid. Additional adverse effects include fatigue, a prolonged QT interval, dizziness, mild hyperglycemia, and mild nausea and vomiting.

TRETINOIN (ALL-TRANS-RETINOIC ACID, ATRA, RETIN-A, VESANOID)

Tretinoin is available in 10-mg capsules for oral administration in the treatment of APL. The mechanism of action involves passive diffusion through the cell membrane and then movement to the nucleus where it interacts with the retinoic acid receptor (RAR) portion of the PML-RAR α fusion protein. Binding of tretinoin allows the cell to differentiate and has also been shown to result in the destruction of the PML-RAR α fusion protein. Resistance to tretinoin is problematic and associated with an increase in cellular retinoic acid-binding proteins (CRABPs) located in the cytosol. The complexation with tretinoin prevents movement into the nucleus and may present the drug to metabolizing enzymes that inactivate it. Amino acid mutation of the PML-RAR α protein has also been established as a mechanism of resistance. The agent is well absorbed upon oral administration and highly (95%) protein bound. Metabolism occurs in the liver and several inactive metabolites have been identified including 13-*cis*-retinoic acid, 4-*oxo cis*-retinoic, 4-*oxo trans*-retinoic acid and 4-*oxo trans*-retinoic acid glucuronide. Elimination occurs in the urine (63%) and feces (31%) with an elimination half-life of 40 to 120 minutes. Vitamin A toxicity is seen in nearly all patients and presents as headache, fever, dryness of the skin, skin rash, mucositis, and peripheral edema. APL differentiation syndrome such as that seen for arsenic trioxide also occurs. Cardiovascular effects include flushing, hypotension, CHF, stroke, and myocardial infarction have been reported but occur only rarely. There are also several CNS and GI effects that have been associated with the agent as well.

BEXAROTENE (TARGRETIN)

Bexarotene is available in 75-mg capsules for oral administration in the treatment of refractory cutaneous T-cell lymphoma. The agent is also available as a gel that may be used topically. The mechanism of action has not been fully established but is thought to involve binding to retinoid receptors resulting ultimately in the formation of transcription factors that promote cell differentiation and regulate cellular proliferation.¹⁶⁸ Bexarotene has been demonstrated to activate apoptosis as a result of stimulation of caspase 3 and inhibition of survivin, an antiapoptotic protein that would normally inhibit caspase activity.¹⁶⁹ Apoptosis is also stimulated because of cleavage of poly(ADP-Ribose) polymerase, which is antiapoptotic. Reduced expression of the retinoid receptor subtypes RXR α and RAR α has also been demonstrated for the agent. Absorption is nearly complete after oral administration and plasma protein binding is high (<99%).¹⁷⁰ There is extensive metabolism in the liver to give 6- and 7-hydroxy-bexarotene and 6- and 7-oxo-bexarotene as well as glucuronides of these metabolites and the parent. Elimination occurs via the feces with an elimination half-life of 7 hours. Adverse effects include hypercholesterolemia, hypertriglyceridemia, hypothyroidism, myelosuppression, nausea, and skin rash.

ASPARAGINASE (L-ASPARAGINASE, ELSPAR, L-ASNASE, CRISTANASPASE)

Asparaginase is available in 10-mL vials for intramuscular and IV use in the treatment of acute lymphocytic leukemia.

Tumor cells are unable to synthesize asparagine, and therefore must utilize what is available in the extracellular environment. The agent acts by hydrolyzing extracellular asparagine to aspartate and ammonia. The tumor cells are then deprived of a necessary nutrient, and protein synthesis is inhibited leading to cell death. The agent is specific for the G₁ phase of the cell cycle. Resistance occurs because of the development of the tumor cells ability to produce asparagine synthetase that allows them to synthesize the required amino acid. Antibody production directed at asparaginase may be stimulated by the agent as well. The agent remains in the extracellular space after parental administration and is 30% protein bound. The metabolism of the agent has not been well characterized and the plasma half-life depends on the formulation of the drug. The *E. coli*-derived agent has a plasma half-life of 40 to 50 hours, whereas polyethylene glycol-asparaginase's half-life is 3 to 5 days. Adverse effects include hypersensitivity reactions, fever, chills, nausea, lethargy, confusion, hallucinations, and possibly coma. Myelosuppression is not generally seen. An increased risk of bleeding and clotting is seen in half of the patients taking the agent.

ESTRAMUSTINE PHOSPHATE SODIUM (EM, EMCYT)

Estramustine as the phosphate is available in 140-mg capsules for the treatment of prostate cancer. Although originally designed as an alkylating agent, it has been shown to be devoid of alkylating activity and functions as an inhibitor of microtubule function by binding to microtubule associate

proteins (MAPs) and also binds to tubulin at a site that is distinct from that of the vinca alkaloids but thought to partially overlap with that of paclitaxel.¹⁷¹ The major mechanism by which cells become resistant to the agent involves increased efflux, although this is not mediated by Pgp as is the case with other microtubule inhibitors such as the taxanes and vinca alkaloids. Therefore, the agent does not show cross-resistance with these agents. As an inhibitor of microtubules, it is cell cycle specific acting in the M phase. The agent is well absorbed upon oral administration with hydrolysis of the water solubilizing phosphate beginning to occur in the GI tract. Metabolism involves the formation of the active estromustine, which arises from oxidation of the C17 alcohol to give the ketone. Additional inactive metabolites result from carbamate hydrolysis to give estradiol and estrone. The parent and metabolites are primarily eliminated in the feces with a terminal elimination half-life of 20 hours. The adverse effects of the agent are nausea and vomiting, which is generally mild but the severity may increase upon prolonged administration. Gynecomastia also commonly occurs, and diarrhea may also be seen. Less commonly seen effects include myelosuppression, skin rash, and cardiovascular abnormalities including CHF.

There are several agents that manipulate the endocrine system to inhibit cell growth that are used in treating cancers that are endocrine dependent. Additionally, there are also several monoclonal antibodies that have been developed and are currently used in treating cancer. Both of these groups of agents are discussed elsewhere in this text.

REVIEW QUESTIONS

1. The agent shown is most likely to result from which of these agents?

- methotrexate and temozolomide
 - temozolomide and streptozocin
 - streptozocin and cyclophosphamide
 - cyclophosphamide and methotrexate
 - 5-fluorouracil and streptozocin
2. The following agent is capable of chelating iron and generating ROS. It has been associated with pulmonary toxicity, which is related to reduced levels of an enzyme in lung tissue that normally inactivates the compound.
- bleomycin
 - doxorubicin
 - mitoxantrone
 - procarbazine

3. The following agent is an inhibitor of a topoisomerase enzyme and binds to both DNA and the enzyme itself. It has been associated with the production of cardiotoxicity that may progress to CHF related to the production of ROS.

- mitoxantrone
- mechlorethamine
- daunorubicin
- epirubicin
- topotecan

4. For the agent shown below, what would be the effect of coadministration of a CYP inducer and an inhibitor of alcohol dehydrogenase?

Ifosfamide

- increased cytotoxicity and bladder toxicity
- increased cytotoxicity and decreased bladder toxicity
- decreased cytotoxicity and increased bladder toxicity
- decreased cytotoxicity and decreased bladder toxicity

Agents for Diagnostic Imaging

JEFFREY J. CHRISTOFF

CHAPTER OVERVIEW

Diagnostic medical imaging encompasses a group of techniques often used in the diagnosis and subsequent treatment of disease. Medical imaging procedures are typically considered low-risk events in comparison to direct surgical visualization and often provide information or treatment methods that are simply not available by any other means. Medical imaging techniques use electromagnetic radiation to pass through tissue and convey the internal information necessary to create an image of the tissue or organ. The different types of medical imaging techniques diverge in their physical means, methods, and the information that they can provide. All of the techniques can provide anatomical and/or functional information that is often displayed as an image for interpretation by a physician trained to evaluate the meaning of the image in the context of the disease state.

Medical imaging began with Roentgen's discovery of x-rays in 1895, and it has been the domain of diagnostic radiology ever since. In its earliest days, the specialty of radiology used x-rays to produce images of the chest and skeleton. At the present time, diagnostic imaging uses decaying radioactive tracers (nuclear medicine), ionizing radiation (x-rays and computed tomography [CT]), radio waves (magnetic resonance imaging [MRI]), and high-frequency sound waves (ultrasound) to produce diagnostic images of the body. Today, radiologists and other physicians can use these imaging techniques to facilitate interventional procedures, such as organ biopsy or abscess drainage.

Nuclear medicine procedures utilize radioactive tracers, (i.e., radiopharmaceuticals) and specialized radiation detectors to follow these compounds as they distribute to various organs or tissues. The other imaging modalities, x-rays, CT, MRI, and ultrasound, often utilize contrast agents to enhance information obtained about the organs or organ systems during imaging. This chapter is a discussion of the chemistry and physics of selected agents used in various medical imaging procedures.

RADIOPHARMACEUTICALS

Radioactivity and Nuclear Medicine

Atomic nuclei are either stable or radioactive. Stable nuclei generally have a proton-to-neutron ratio near 1:1. As this ratio deviates significantly away from unity, atomic nuclei become unstable and have a greater amount of internal nuclear energy. Such unstable nuclei are radioactive and obtain stability by emitting energy in the form of particulate and/or electromagnetic radiation that propagates through

space or matter. Selected radioactive nuclei are present in nature, while many other radioactive nuclei are produced by bombarding stable nuclei with high-energy particles.

Ionizing radiation is radiation, that when interacting with matter, can cause changes in the atomic or nuclear structure. The first type of ionizing radiation is particulate radiation, which includes alpha (α), beta (β^- or β^+), proton (p), and neutron (n) particles. Particulate radiation is energy in the form of mass with kinetic energy. On the atomic scale, energy is usually measured in electron volts (eV). By definition, an *electron volt* is the energy needed to accelerate an electron across a potential difference of 1 V. The second type of ionizing radiation is called *electromagnetic radiation*. Electromagnetic radiation is an electric and magnetic disturbance that is propagated through space at the speed of light.

Electromagnetic radiation is unaffected by either an electrical or magnetic field because it has no charge. These properties are shared by radio waves (10^{-10} – 10^{-6} eV), microwaves (10^{-6} – 10^{-2} eV), infrared (10^{-2} –1 eV), visible light (1–2 eV), ultraviolet (2–100 eV), x-rays (100 – 10^4 eV) and gamma (γ) rays (100 – 10^6 eV). The various forms of electromagnetic radiation differ in their frequency and, therefore, their energy. The energy of electromagnetic radiation can be calculated in electron volts from the following equation:

$$E = hv = hc / \lambda$$

where h is Planck constant (4.13×10^{-15} eV*sec), v is the frequency (hertz), c is the speed of light (cm/sec), and λ is the wavelength (cm). The difference between x-rays and γ -rays is based on where they originate; x-rays come from outside the nucleus via the electron orbitals, whereas γ -rays originate in the nucleus via nuclear transformations. These highly energetic x-rays and γ -rays have properties resembling both waves and particles. Therefore, x-rays and γ -rays are often referred to as *photons*.

Radionuclides are unstable nuclei that undergo processes called *decay*. In many cases, the composition of the nucleus transforms from one element into another element. A nucleus may undergo a single transformation or several decays before finally reaching a stable configuration. Nuclear particles, either a proton or a neutron, are called *nucleons*. A species of atom with a specified number of neutrons and protons in its nucleus is called a *nuclide*. Nuclides with the same number of protons and a different number of neutrons are called *isotopes*. Nuclides with the same number of neutrons and a different number of protons are called *isotones*. Nuclides with same atomic mass are called *isobars*. Nuclides with the same number of protons and atomic mass but at two energy levels are called *isomers*.

The atomic nucleus has discrete energy levels. In a stable atom, the energy level is called the *ground (g) state*. An unstable, high-energy nucleus or a stable nucleus that is excited to a higher level by interaction with high-speed particles can emit this excess energy by decaying to the ground state. If this decay process is delayed, the excited state may be referred to as a *metastable (m) state*. During decay, energy is released from the nucleus. Depending on the properties of the nuclide, this may occur by simply releasing the energy in the form of a γ -ray or ejecting an energetic particle from the nucleus with or without γ -ray emission.

Nuclides are characterized by the following notation:

where X is the symbol of the chemical element to which the nuclide belongs, A represents the atomic mass (number of neutrons plus the number of protons), and Z represents the atomic number (number of protons). The right side of the element is reserved for the oxidation state (valence), and N represents the number of neutrons. In most medical references, various notations indicating the element and mass number are used (e.g., ${}^{131}\text{I}$, I-131, or iodine-131).

The nuclide at the beginning of the decay sequence is referred to as the *parent*. The nuclide produced by decay is referred to as the *daughter*. Daughter nuclei may be stable or unstable. There are five types of radioactive decay processes described below that are distinguished according to the nature of the primary radiation event. A particular radioactive nucleus may decay by more than one process. The type of decay that occurs for a particular isotope generally depends on the balance of protons and neutrons in the nucleus.

1. **Isomeric transition (IT).** IT is a decay process where the nucleus simply changes from a higher energy level to a lower energy level by emitting γ -rays. Therefore, both mass number and atomic number remain unchanged. The daughter nucleus is the same chemical element as the original nucleus. The original nucleus, before the transition, is said to be in a metastable (m) state if the transition from the higher energy level to the lower level is delayed by a measurable period of time. Depending on the decaying nuclide, this delay could last from fractions of a second to months. The predominant isotope used in nuclear medicine procedures, Tc-99m, has a half-life of 6 hours. Since no particles are emitted during this nuclear transformation, Tc-99m is considered a pure gamma emitter.

2. **Electron capture (EC).** The nucleus captures an electron (e^-) from the electron cloud of the atom (mainly the K shell). This electron combines with a proton (p) to produce a neutron (n). The excess energy from this transformation can be liberated in the form of a γ -ray and/or a neutrino (ν , a highly energetic, chargeless particle of extremely small mass). Therefore, no charged nuclear particles are emitted during this transformation. Other events occurring within the vacant electron orbital can lead to the production of secondary x-rays.

3. **Positron emission (β^+).** An alternative decay process in a proton rich nucleus is the conversion of a proton to a neutron with the subsequent ejection of an energetic *positron* and a neutrino. Positrons are considered antimatter and exist only for very short periods of time. The positron loses its kinetic energy, by interacting with surrounding atoms. The positron ultimately combines with a free electron from one of the surrounding atoms in an interaction in which the rest masses of both particles are converted to two γ -rays of 511 keV emitted approximately 180° to each other. This combination is called *annihilation radiation*. This characteristic decay process is utilized for the specialized imaging technique called *positron emission tomography* (PET).

4. **Negatron emission (β^-).** A neutron-rich nucleus decays by the conversion of a neutron to a proton with subsequent emission of an energetic *negatron* and an antineutrino ($\bar{\nu}$, a highly energetic, chargeless particle of extremely small mass) with or without γ -ray emission.

5. **Alpha-particle emission (${}^4_2\text{He}^{+2}$).** A heavy, unstable nucleus may decay to a daughter nuclide and an *alpha particle* consisting of two protons and two neutrons, essentially the equivalent to a charged helium nucleus. If the particle has sufficient energy, it may escape the nucleus in an excited energy state with/without the emission of excess energy in the form of a γ -ray.

These decay processes are random events. It is impossible to predict when an individual atom of a particular radionuclide will spontaneously decay. In quantitative terms, however, this process follows first-order kinetics. The *radioactive decay law* is the number of atoms that decay per unit time. Radioactive decay is proportional to the number of atoms (N) present and a decay constant (λ) characteristic for the particular radionuclide.

$$\frac{-dN}{dt} = \lambda N$$

To obtain the number of decaying atoms for a measurable period of time, the differential equation must be integrated. Therefore, the basic equation for radioactive decay is expressed as follows in terms of atoms:

$$N_t = N_0 e^{-\lambda t}$$

where N_t (number of atoms at time t) and N_0 (number of atoms at time 0). Activity (A) of a radionuclide is also expressed as the number of atoms disintegrating per unit of time ($A = \lambda N$). With the substitution of A/λ into the equation above for N and simplifying the result,

$$A_t = A_0 e^{-\lambda t}$$

where A_t is the activity at time t , A_0 is the original activity, and λ is the decay constant.

A radionuclide's decay is routinely expressed as its physical half-life, the time in which one half of the atoms decay. Mathematically, this is expressed as

$$t_{1/2} = \frac{\ln 2}{\lambda}$$

where $t_{1/2}$ is the physical half-life and λ is the decay constant. Substitution into the previous equation for the decay constant, λ , provides

$$A_t = A_0 e^{-(\ln 2)t/t_{1/2}}$$

which is simplified to

$$A_t = A_0(0.5)^{t/t_{1/2}}$$

where A_t is the activity at time t , A_0 is the original activity, t is the elapsed time interval, and $t_{1/2}$ is the physical half-life of the radionuclide of interest. This equation is frequently utilized directly or indirectly in daily operations of a nuclear pharmacy or nuclear medicine department.

The activity (A) of radionuclides can be expressed in the following three ways: (a) in disintegrations per unit time (usually disintegrations per second [dps] or disintegrations per minute [dpm]), (b) in curies (Ci), and (c) in becquerels (Bq; 1 Bq = 1 dps). A *curie* is defined as the quantity of any radionuclide that decays at a rate of 3.7×10^{10} dps, a number closely approximating the historically calculated number of dps in 1 g of pure radium. More recently, the International System of Units (SI) has adopted the becquerel as the official unit of radioactivity. The curie is still traditionally utilized in clinical practice, and the relevant conversion factor to remember is the following:

$$1 \text{ millicurie (mCi)} = 37 \text{ megabecquerels (MBq)}$$

An example of a routine radioactive decay calculation follows:

A sample of sodium iodide (^{123}I) is calibrated by the manufacturer at 200 μCi on May 14 at 12 PM C.S.T. What is the activity remaining on May 15 at 3 PM E.S.T.? The $t_{1/2}$ of ^{123}I is 13.2 hours. (Note: Calculations of elapsed time must also indicate variations in time zones incurred during transport).

$$(t_{1/2} = 13.2 \text{ hours})$$

$$A = (200 \mu\text{Ci}) (0.5)^{(26/13.2)}$$

$$A = (200 \mu\text{Ci}) (0.255)$$

$$A = 51.1 \mu\text{Ci}$$

Radionuclide Production

Radionuclides utilized in nuclear medicine are artificially produced. This is accomplished when small charged or uncharged particles bombard atomic nuclei and initiate a process of nuclear change. The artificial production of a radionuclide requires preparation of target nuclei (parent), irradiation of the target, and chemical separation of the daughter radionuclide produced from the nuclear reaction. The daughter radionuclide is converted to the desired radiopharmaceutical form. Quality assurance tests of the physical, chemical, and pharmaceutical qualities (i.e., sterility and apyrogenicity) of the final product are per-

formed. The systems used for practical production of radionuclides are a nuclear reactor, cyclotron, or radioisotope generator.

The shorthand nuclear physics notation of artificial nuclear transformation reaction is as follows:

where Cd-112 is the stable target nuclei, a proton (p) is the bombarding particle, two neutrons (2n) are emitted from the nucleus during the transformation, and In-111 is the daughter radionuclide produced.

The introduction of radionuclide generators into nuclear medicine arose from the need to administer larger doses of a short half-life radionuclide to obtain higher quality images. The general principle of the radionuclide generator is that a long-lived parent is bound to some adsorbent material in a chromatographic ion exchange column and the daughter is eluted from the column with some solvent or gas. When considering potential radioactive parent and daughter pairs, two scenarios can be envisioned depending on the magnitude of difference in half-lives between the long-lived parent and the short-lived daughter. If the parent nuclide has a sufficiently longer half-life than the daughter nuclide (10-fold to 100-fold), a state of transient equilibrium is ultimately reached when the daughter nuclide is being produced from the parent at the same rate as the daughter decays. In the situation where the parent half-life is much longer than that of the daughter (>1,000-fold), a state of secular equilibrium is reached when the daughter nuclide is being produced from the parent at the same rate as the parent decays.

There are many possible parent–daughter generator systems for clinical use, but there is only one in routine use in nuclear medicine, the molybdenum-99/technetium-99m system. All of the molybdenum-99 at the present time is obtained as a fission product of uranium-235 from nuclear reactors.

Inorganic radiochemistry techniques separate molybdenum-99 from the other radionuclides. Molybdenum-99 ($t_{1/2} = 66$ hours) decays by negatron emission to technetium-99m ($t_{1/2} = 6$ hours), which decays by IT to technetium-99 by emitting a γ -ray (140 keV). Anionic molybdate ($^{99}\text{MoO}_4^{-2}$) is loaded on a column of alumina (Fig. 11.1). The molybdate ions adsorb firmly to the alumina, and the generator column is autoclaved to sterilize the system. Then the rest of the generator is assembled under aseptic conditions into its final form in a lead-shielded container. Each generator is eluted with sterile normal saline (0.9% sodium chloride). The alumina column is an inorganic ion exchange column where chloride ions (Cl^-) exchange for pertechnetate ions ($^{99\text{m}}\text{TcO}_4^-$) but not molybdate ions (MoO_4^{-2}). The column eluate contains sodium pertechnetate as well as sodium chloride. Elution efficiency of contemporary molybdenum-99/technetium-99m generators is approximately 80% to 90% per elution.

The method for calculating how much daughter ion present on the column at any given time is complex because it must consider the decay rates of parent and daughter nuclides, the abundance daughter nuclide produced from the parent, as well as any daughter nuclide initially present or remaining on the column after previous elution

Figure 11.1 • Cross-sectional diagram of a molybdenum-99/technetium-99m generator. (Reprinted with permission from Bushberg, J. T., et al.: The Essential Physics of Medical Imaging, 2nd ed. Philadelphia: Lippincott Williams and Wilkins, 2002.)

(Fig. 11.2). In the case of Mo-99 ($t_{1/2} = 66$ hours), only 86% of the atoms decay to Tc-99m ($t_{1/2} = 6$ hours). Typical elution efficiencies of commercially available generators are approximately 80% to 90%. The equation for the theoretical activity of the daughter nuclide present at any time (t) after a previous elution is as follows:

$$A_d^t = (A_p^0)\lambda_d[(e^{-\lambda_p t} - e^{-\lambda_d t})/(\lambda_d - \lambda_p)] + A_d^0 e^{-\lambda_d t}$$

where A_p^0 is the activity of the parent at the time of the previous elution, A_d^0 is the activity of the daughter at the time of the previous elution, λ_p and λ_d are their respective decay constants, and t is the time since the last elution of the generator. The generator system can be eluted several times each day to obtain collective radioactivity because Tc-99m is constantly produced by Mo-99 decay. The time interval since the last elution will determine the maximal amount of Tc-99m available for elution. Approximately 40% of maximal Tc-99m is available after 6 hours, whereas maximal Tc-99m activity is achieved in 23 hours.¹

Biological Effects of Radiation

The absorption of ionizing radiation by living cells always produces effects potentially harmful to the irradiated organism. An undesirable aspect to the medical use of radiation is that a small number of the atoms in the body tissues will have electrons removed as a result of the photons. Radiation that does this is called *ionizing radiation* and is potentially damaging to body tissues. Therefore, in using ionizing radiation, as in using other pharmaceutical agents, the risks must be balanced with the medical benefits provided for the patient.

The amount of radiation energy absorbed by tissue is called *radiation absorbed dose* and is specified in rads or millirads. A dose of 1 rad implies 100 ergs of energy absorbed

per gram of any tissue. The unit of exposure for x-rays and γ radiation in air, the *roentgen*, is used to specify radiation levels in the environment. One roentgen is the amount of radiation that produces 1 electrostatic unit (ESU) of charge of either sign per 0.001293 g of air at standard temperature and pressure (STP). The SI has adopted the gray (Gy) to replace the rad (1 Gy = 100 rads). Again, the more traditional unit is still used in clinical medicine. In the case of electromagnetic radiation such as x-rays or γ -rays, the roentgen and rad are equivalent.

Figure 11.2 • Time-activity curve of a molybdenum-99/technetium-99m generator system demonstrating the in-growth of technetium-99m and subsequent elution. (Reprinted with permission from Bushberg, J. T., et al.: The Essential Physics of Medical Imaging, 2nd ed. Philadelphia: Lippincott Williams and Wilkins, 2002.)

The major difference between electromagnetic radiation (x-rays or γ -rays) and particulate radiation (β^+ , β^- , and α particles) lies in the ability of electromagnetic rays to penetrate matter. Whereas particles travel only a few millimeters before expending all their energy, x-rays and γ -rays distribute their energy more diffusely and can travel through several centimeters of tissue.

Particle emitters deliver highly localized radiation doses to biological molecules. Damage results from the direct absorption of this radiation energy. This is known as the *direct effect* of radiation damage. The radiation dose of particle emitters is generally clinically useful for therapeutic use, with limited benefits for diagnostic use.

X-rays and γ -rays deliver more uniform doses in a less concentrated way throughout the irradiated volume of tissue. Damage is indirectly produced by formation of free radicals (atoms or molecules with an unpaired electron). The *indirect effect* of radiation damage generally involves aqueous free radicals as intermediaries in the transfer of radiation energy to the biological molecules.

All biological systems contain water as the most abundant molecule (~80%). Radiolysis of water is the most likely event in the initiation of biological damage from diagnostic x-rays and γ -rays. The absorption of energy by a water molecule results in the ejection of an electron with the formation of a free radical ion ($\text{H}_2\text{O}^{\cdot+}$). The free radical ion dissociates to yield a hydrogen ion (H^+) and a hydroxyl free radical (HO^{\cdot}). The hydroxyl free radicals combine to form hydrogen peroxide (H_2O_2), which is an oxidizing agent. In addition, hydrogen free radicals (H^{\cdot}) can form, which can combine with oxygen (O_2) and form a hydroperoxy-free radical (HO_2^{\cdot}). These free radical intermediates are very reactive chemically and can attack and alter chemical bonds.

The only significant “target” molecule for biological damage is DNA. Types of DNA damage include single- and double-chain breakage as well as intermolecular or intramolecular cross-linking of double-stranded DNA. With the direct effect of radiation, the damage makes cell replication impossible. Cell death occurs. For the indirect effect of radiation, if the damage is not lethal but changes the genetic sequence or structure, mutations occur that may lead to cancer or birth of genetically damaged offspring. Some effects of radiation may develop within a few hours; others may take years to become apparent. Consequently, the effects of ionizing radiation on human beings may be classified as somatic (affecting the irradiated person) or genetic (affecting progeny).

Radiation dose can only be estimated, and its “measurement” is called *radiation dosimetry*. In the case of x-ray exposure, most radiation “doses” in the literature are described as the entrance exposure (in roentgens per minute) to the patient. In diagnostic nuclear medicine procedures, patients are irradiated by radiopharmaceuticals localized in certain organs or distributed throughout their bodies. Because the radionuclides are taken internally, there are many variables, and the radiation absorbed dose (rad) to individual patients cannot be measured. It can only be estimated by calculation. Under normal circumstances, no radiation worker or patient undergoing diagnostic investigation by radiopharmaceutical or radiographic procedures should ever suffer from any acute or long-term injury. Typical radiation doses to patients from radiopharmaceuticals are similar to, or less than, those from radiographic procedures.

Radiopharmaceuticals

Medical science provides a framework or paradigm in which to understand disease and to maintain health. Nuclear medicine is the branch of medical science that contributes to medicine by the use of the radiotracer method for diagnosis, and the use of in vivo radioactivity for therapy.

Nuclear medicine generally involves the administration of radioactively labeled compounds to *trace* a biological process. This process may be mechanical (gastric emptying, blood flow, cardiac wall motion) or a variety of other physiological functions. Within the concept of a “radiotracer” is the implication that the agent administered will not disturb the functional aspects of the process you wish to examine. In nuclear medicine, this concept is used to trace physiological processes in vivo and then compare them with known normal images or levels. These images are interpreted within the context of relevant pathophysiology to allow diagnosis of disease. The information obtained from diagnostic images can also be used to follow the patient for improvement following treatment. In clinical practice, nuclear medicine also makes use of in vitro diagnostic methods (radioimmunoassay) as well as in vivo radiopharmaceutical therapy.

The most common application of nuclear medicine is to image the distribution of radiopharmaceuticals in specific tissues or organ systems with a scintillation (Anger) camera for diagnostic purposes. Fundamentally, these instruments or cameras allow in vivo detection and localization of radiotracers. The purpose of the gamma camera is to record the location and intensity of the radiation within the imaging field (Fig. 11.3).

Radiation in the form of gamma photons (occasionally x-rays) initially enters the camera through the collimator, which usually is a sheet of lead with multiple small, precisely made holes. The collimator covers the detector’s crystal. The purpose of the collimator is to decrease scattered radiation and to increase the overall resolution of the system. Photons that are not blocked by the collimator then enter a large sodium iodide (with a small amount of thallium) crystal that absorbs γ -rays. The absorbed energy in the crystal is emitted as a flash of light (called a *scintillation*), which is proportional to the

Figure 11.3 • Patient being imaged with a scintillation (Anger) camera. (Reprinted with permission from Bushberg, J. T., et al.: *The Essential Physics of Medical Imaging*, 2nd ed. Philadelphia: Lippincott Williams and Wilkins, 2002.)

energy of the γ -ray. Coupled to the back of the NaI(Tl) crystal are photomultiplier (PM) tubes that convert the light flashes to electrical pulses proportional to the amount of light. To localize the original source of the photon (and create an image), a computer assigns x - y spatial coordinates to the various γ -rays coming from the patient and stores this information in a matrix. After data collection, the image is converted into a signal for display on a video monitor. The images obtained with the scintillation camera are called *scintigrams*, *scintigraphs*, or *scans*.

Nuclear medicine imaging studies involve the generation of images that represent the functional status of various organs in the body. When interfaced with computer systems, information regarding dynamic physiological parameters such as organ perfusion, metabolism, excretion, and the presence or absence of obstruction can be obtained. Images can be focused on a portion of the body, or an image of the whole body can be acquired by moving the camera from head to toe.

Cross-sectional images of organs can be obtained by rotating a position-sensitive scintillation camera detector about the patient. This type of procedure is called *single photon emission computed tomography* (SPECT), which is the counterpart of CT or computed axial tomography (CAT) scans in diagnostic radiology. Most SPECT systems (Fig. 11.4) use one to three scintillation detectors that rotate about the patient.

Figure 11.4 • Schematic diagram of a rotating triple-detector scintillation camera system for single photon emission computed tomography (SPECT).

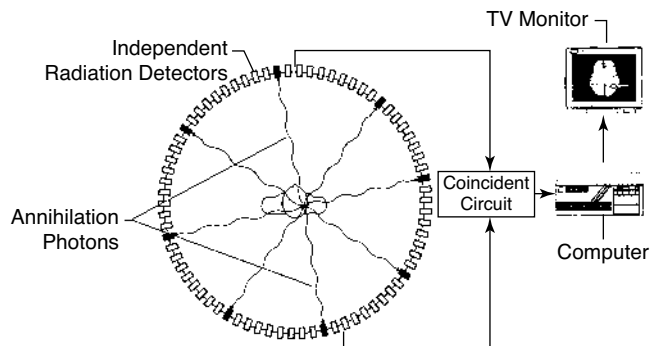

Figure 11.5 • Schematic diagram of a PET imaging system with multiple scintillation detectors that localize positron decay by coincident detection of annihilation photons.

SPECT is routinely used when imaging the brain or heart to demonstrate three-dimensional distribution of radioactivity in these organs.

A newer modality for imaging uses multiple detector heads to image positron-emitting radiopharmaceuticals by PET (Fig. 11.5). The physics associated with annihilation radiation allow PET cameras to utilize coincident circuitry to facilitate the acquisition of high resolution images for the two photons emitted approximately 180 degrees from each other during positron decay. When the photon pair is detected by two detectors, it is known that a decay event took place along a straight line between those detectors. Computer models will calculate a three-dimensional image of the subsequent data set to prepare PET images of the area of interest. Although various positron emitting nuclides can be covalently attached to numerous biologically important molecules for development of PET radiopharmaceuticals, ^{18}F -fluorodeoxyglucose (^{18}F -FDG) is by far, the major clinical PET agent.

The incidence of adverse reactions to radiopharmaceuticals is very low. Most adverse events are allergic reactions and occur within minutes of intravenous injection. In the case of radiolabeled murine antibodies, an anaphylactic reaction may occur on rare occasions.

Fluorine Radiochemistry

The clinically useful radioisotope of fluorine for organ imaging is fluorine-18. Fluorine-18 is produced in a cyclotron according to the $^{18}\text{O}(p,n)^{18}\text{F}$ nuclear reaction. Fluorine-18 ($t_{1/2} = 110$ min) decays predominantly by positron emission to oxygen-18 with γ -ray emissions of 511 keV (194%). Fluorine-18 can be attached to several physiologically active molecules and, with the great strength of the C-F bond, appears to be a very useful label for radiopharmaceuticals.² Radiotracer production involves relatively complicated synthetic pathways, and the preparation of high-specific-activity compounds presents many problems. The short half-life of fluorine-18 makes it necessary to complete the synthetic and purification procedure quickly.

FLUORINE RADIOPHARMACEUTICALS

2-Fluoro-2-Deoxy-D-Glucose (^{18}F). The only F-18 radiopharmaceutical presently available is fluorine ^{18}F -FDG, the structure of which is shown on next page. Synthesis of ^{18}F -FDG by nucleophilic displacement of a protected

mannose triflate derivative, hydrolysis of the protecting groups, and purification by solid phase extraction is the typical method of production.³ The synthetic cascade and subsequent purification is routinely accomplished in about 50 minutes by an automated synthesizer.^{4,5}

The high glycolytic rate of many neoplasms compared with that of the surrounding tissues facilitates tumor imaging with this glucose analog. Both glucose and ^{18}F -FDG are transported into the cell and phosphorylated; however, ^{18}F -FDG does not get catabolized as an energy source, nor is it effectively degraded by glucose-6-phosphatase. Thus, energetically active tissues accumulate ^{18}F -FDG. Because of the widespread anatomical distribution of metastases, a whole-body imaging technique using a tumor-specific radiopharmaceutical, such as ^{18}F -FDG, is very useful for tumor detection and mapping to evaluate the extent and relative metabolic activity of the disease.

^{18}F -FDG can also be used for diagnostic imaging of myocardial viability and in the evaluation of seizure disorders.⁶

(^{18}F)-2-Fluoro-2-deoxy-D-glucose

Gallium Radiochemistry

The only radioisotope of gallium that is presently used is gallium-67, which is produced in a cyclotron by proton bombardment of a zinc metal target according to the $^{68}\text{Zn}(p,2n)^{67}\text{Ga}$ nuclear reaction. Gallium-67 ($t_{1/2} = 78.2$ hours) decays by EC to stable zinc-67 with principal γ -ray emissions of 93 keV (38%), 185 keV (24%), and 300 keV (16%). The radiotracer is isolated by dissolution of the target in hydrochloric acid followed by isopropyl ether extraction of the gallium-67 from the zinc and other impurities. Gallium-67 is back-extracted from the isopropyl ether into 0.2 M hydrochloric acid, evaporated to dryness, and dissolved in sterile, pyrogen-free 0.05 M hydrochloric acid.⁷ Gallium is an amphoteric element that acts as a metal at low pH but forms insoluble hydroxides when the pH is raised above 2 in the absence of chelating agents. At high pH, gallium hydroxide acts as a nonmetal and dissolves in ammonia to form gallates. Gallium forms compounds of oxidation states +1, +2, and +3; however, only the Ga^{+3} state is stable in aqueous solutions.

GALLIUM RADIOPHARMACEUTICALS

Gallium Citrate (^{67}Ga). The gallium (III)-citrate complex is formed by adding the required amount of sodium citrate (0.15 M) to gallium (III) chloride and adjusting the pH to 4.5 to 8.0 with sodium hydroxide. Recent studies have proposed a 1:2 gallium: citrate complex.^{8,9}

The patient receives an intravenous injection of 5 to 10 mCi (185–370 MBq) of gallium (^{67}Ga) citrate, and whole-body images are then obtained 24, 48, and 72 hours after injection. Gallium localizes at sites of inflammation or infection as well as various tumors. It is used in clinical practice in the staging

and evaluation of recurrence of lymphomas. Gallium localizes normally in the liver and spleen, bone, nasopharynx, lacrimal glands, and breast tissue. There is also some secretion in the bowel; consequently, the patient may require a laxative and/or enemas to evacuate enteric radioactivity prior to the 48-hour image. As more specific radiotracers have been developed, the nonspecific normal localization of gallium radioactivity has limited its clinical use.

Gallium (^{67}Ga) Citrate

Indium Radiochemistry

The most commonly used radioisotope of indium is indium-111, which is produced in a cyclotron by proton bombardment of a cadmium target according to the $^{112}\text{Cd}(p,2n)^{111}\text{In}$ nuclear reaction. Indium-111 ($t_{1/2} = 67.3$ hours) decays by EC to stable cadmium-111 with principal γ -ray emissions of 171 keV (91%) and 245 keV (94%). The radiotracer is isolated by dissolution in hydrochloric acid to form indium chloride (^{111}In). In aqueous solution, lower valence states of indium have been described, but they are unstable and are rapidly oxidized to the trivalent state. In acid solution, indium hexaqua complexes $[\text{In}(\text{H}_2\text{O})_6]^{+3}$ are stable at low pH but are hydrolyzed (above pH 3.5) to form a precipitate of indium hydroxide $\text{In}(\text{OH})_3$.⁵ Indium is stabilized in solution above pH 3.5 if it is complexed with a weak chelating agent such as sodium citrate and stronger chelating agents such as 8-hydroxyquinoline (oxine) or diethylenetriamine pentaacetic acid (DTPA). Monoclonal antibodies and peptides are radiolabeled with indium by using compounds called *bifunctional chelating agents*. Bifunctional chelating agents are molecules that can be attached to the antibody or peptide as well as to the radionuclide.

INDIUM RADIOPHARMACEUTICALS

Indium (^{111}In) Capromab (ProstaScint). Capromab pentetide is a murine monoclonal immunoglobulin G (IgG) antibody conjugated to the linker-chelator, glycyl-tyrosyl-(*N*,diethylenetriamine pentaacetic acid)-lysine hydrochloride (Gly-Tyr-Lys-DTPA·HCl). This conjugated antibody is directed against the glycoprotein expressed on prostate epithelium, prostate-specific membrane antigen. It is indicated in the evaluation of newly diagnosed patients with biopsy-proven prostate cancer who are at high risk for pelvic lymph

Indium (^{111}In) Capromab Pendetide

node metastases as well as postprostatectomy patients with a rising prostate-specific antigen (PSA), whom there is a high clinical suspicion of metastatic disease.

The kit utilized to prepare this radiotracer contains capromab pendetide, sodium acetate buffer, and a 0.22- μm filter. A portion of the sodium acetate buffer is added to a vial of indium (^{111}In) chloride to stabilize the radiolabel as an indium (^{111}In) acetate complex for subsequent reaction with the conjugated antibody. The buffered indium (^{111}In) acetate complex is added to the capromab pendetide and allowed to incubate for 30 minutes at room temperature. After incubation is complete, the remaining sodium acetate buffer is added to the capromab (^{111}In) pendetide mixture. The patient dose is drawn into a syringe that was fitted with the 0.22- μm filter. The tagged product must be used within 8 hours of preparation. A schematic representing the bifunctional IgG antibody modified is shown.

The patient receives an intravenous injection of 5 mCi (185 MBq). Since the radiotracer accumulates in both the bladder and bowel, patient preparation includes a cathartic laxative the night before imaging, an enema 1 hour prior to imaging, and the patient is likely to be catheterized. Images of the pelvis are taken 30 minutes after the injection to assess the blood pool distribution, and whole-body or spot images as well as specific pelvic/abdomen images are acquired between 72 and 120 hours after administration.

Indium Chloride (^{111}In). Indium (III) chloride is a sterile, colorless solution that is isolated from the production of radiolabeled indium-111 from cadmium-112 by dissolution in hydrochloric acid solution (0.05 M) and has a pH of 1.4. It is primarily used to radiolabel pharmaceuticals such as monoclonal antibodies and peptides that are used for cancer imaging.

Indium (^{111}In) Oxyquinoline. Indium (^{111}In) oxyquinoline (Indium [^{111}In] oxine) is formed by adding the required amount of 8-hydroxyquinoline sulfate to indium (III) chloride (^{111}In). Other ingredients include polysorbate 80 as a stabilizer and HEPES buffer to adjust the pH range to 6.5 to 7.5. The structure of indium (^{111}In) oxyquinoline is shown.¹⁰

This radiochemical is indicated for the preparation of patient-specific radiolabeled leukocytes to assess the presence or absence of a suspected infection that is unable to be confirmed by other imaging modalities. Approximately 50 mL of a patient's blood is drawn. The blood will be processed to separate the leukocytes from the plasma and other cellular components. The leukocytes will be incubated with indium (^{111}In) oxyquinoline for 20 minutes, washed with saline, re-suspended in the patient's own plasma, and reinfused to the patient within 5 hours of the initial blood draw. The goal in leukocyte preparation is to achieve 200 to 500 μCi of activity in the tagged cells. Images are acquired 2 to 48 hours after reinjection of the radiolabeled cells, allowing the cells to localize at the suspected site of infection.

Indium (^{111}In) Oxyquinoline

Indium (^{111}In) Pentetate. Indium (^{111}In) pentetate is formed by adding the required amount of calcium or sodium pentetate (DTPA) to the indium (^{111}In) chloride and adjusting the pH to 7 to 8 with sodium hydroxide and/or hydrochloric acid. A proposed structure of ^{111}In -DTPA is shown on next page.^{11,12}

This tracer is indicated for use in cisternography. The patient undergoes a lumbar puncture under sterile conditions

and receives an intrathecal injection of 0.5 mCi (18.5 MBq) of indium (^{111}In) pentetate, which distributes into the cerebrospinal fluid (CSF). Initial images are obtained to ensure a good intrathecal injection. Images of the spinal canal and CSF spaces of the brain are acquired intermittently to assess CSF flow or leakage from the normal CSF space.

Another use for ^{111}In -DTPA is in dual isotope gastric emptying studies. After a 6-hour fast, the patient ingests a solid meal of oatmeal or scrambled egg mixed with 1 mCi (37 MBq) of $^{99\text{m}}\text{Tc}$ -sulfur colloid along with a liquid meal of water mixed with 0.5 mCi (18.5 MBq) of ^{111}In -DTPA. The patient's stomach is imaged 5 minutes after the meal as the initial gastric image utilizing appropriate camera settings to detect each isotope separately. Imaging continues every 5 to 15 minutes until the recorded activity is reduced to one half the initial gastric activity. Normal values are 50 to 80 minutes for solid meals and 10 to 15 minutes for liquid meals⁴; however, these values can vary based on the size and composition of the meal.⁵

Indium (^{111}In) Pentetate

Indium (^{111}In) Pentetreotide (OctreoScan). Pentetreotide is a modified peptide hormone that consists of a bifunctional chelating agent, DTPA, linked to octreotide, a long-acting analog of the endogenous hormone somatostatin. Somatostatin is a 14-amino acid peptide hormone that binds to the somatostatin receptor. These receptors have been found on many cells of neuroendocrine origin and are expressed in large numbers on nearly all tumors of such origin. The drug is indicated in the imaging of primary and metastatic neuroendocrine tumors bearing somatostatin receptors.

The kit utilized to prepare this radiotracer contains pentetreotide, a solution of indium (^{111}In) chloride/ferric chloride, and a transfer needle. The addition of ferric chloride and the use of the transfer needle are necessary to increase the labeling yield. The radiolabeled solution is added to the pentetreotide vial and incubated at room temperature for 30 minutes. The tagged product must be used within 6 hours of preparation. The structure of labeled radiopharmaceutical, indium (^{111}In) pentetreotide, is shown.¹³

The patient receives an intravenous injection of 3 to 6 mCi (111–222 MBq) of indium (^{111}In) pentetreotide depending on the type of imaging camera that will be used to obtain images. Whole-body images are obtained 4 to 48 hours after injection to localize the primary tumor and sites of metastases.

Indium (In-111) Pentetreotide

Iodine Radiochemistry

Iodine is in group VIIB with the other halogens (fluorine, chlorine, bromine, and astatine). In aqueous solution, compounds of iodine are known with at least five different oxidation states; however, in nuclear medicine, the -1 and $+1$ oxidation states are the most significant. The -1 oxidation state represented as sodium iodide (NaI) is important for thyroid studies and, when obtained in a reductant-free solution (no sodium thiosulfate), is a starting material for the radiolabeling of iodinated radiopharmaceuticals. The common methods for introducing radioiodine into organic compounds are isotope exchange reactions, electrophilic substitution of hydrogen in activated aromatic systems, nucleophilic substitution, and addition to double bonds.¹⁴ Electrophilic substitution on tyrosine side chains is commonly used for protein labeling. The electrophilic species (I^+) can be generated from iodide (I^-) by various oxidizing agents, including (a) chloramine-T (*N*-chloro-*p*-toluene sulfonamide) sodium, (b) enzyme oxidation of (lactoperoxidase), and (c) Iodo-Gen (1,3,4,6-tetrachloro-3 α -6 α -diphenylglycoluril).

The useful radioisotopes of iodine for organ imaging are iodine-123 and iodine-131. Iodine-123 is produced in a cyclotron by bombarding a xenon-124 target with a proton according to the $^{124}\text{Xe}(\text{p},2\text{n})^{123}\text{Cs} \rightarrow ^{123}\text{Xe} \rightarrow ^{123}\text{I}$ sequence. Iodine-123 is isolated in the iodide form. Cesium-123 ($t_{1/2} = 5.9$ min) decays by EC to xenon-123 ($t_{1/2} = 2.1$ hours), which decays to iodine-123. Iodine-123 ($t_{1/2} = 13.3$ hours) decays by EC to tellurium-123, with a principal γ -ray emission of 159 keV (83%), which makes it the ideal radioisotope of iodine for organ imaging because of increased detection efficiency and reduced radiation burden to the patient. The main disadvantage of I-123 is the need for daily delivery from commercial suppliers because of its short half-life.

Iodine-131 is obtained from a reactor by production of tellurium-131. It is prepared by nuclear bombardment of $^{235}\text{U}(\text{n,fission})^{131}\text{Te} \rightarrow ^{131}\text{I}$ or $^{130}\text{Te}(\text{n},\gamma)^{131}\text{Te} \rightarrow ^{131}\text{I}$. I-131 is isolated in the iodide form. Tellurium-131 ($t_{1/2} = 25$ minutes) decays by β^- emission to iodine-131. Iodine-131 ($t_{1/2} = 8.04$ days) decays by β^- emission to stable xenon-131, with five significant γ -ray emissions ranging from 80 to 723 keV. The major γ -ray of 364 keV (82%) provides good tissue penetration for organ imaging. I-131 properties are either desirable or undesirable based on one's perspective. The high radiation dose from the β^- particles may be undesirable when used for diagnostic purposes, but highly desirable for therapeutic use. The long half-life provides sufficient time for radiolabeling syntheses, but can be problematic in terms of waste disposal. Finally, poor quality images are obtained

by current gamma cameras because the high-energy γ -rays are not efficiently recorded by the detector.

IODINE PHARMACEUTICALS

Sodium Iodide (^{123}I). The major indications for thyroid imaging with sodium iodide (^{123}I) are for evaluation of thyroid function (uptake) and/or morphology (imaging). The patient fasts before receiving the oral dose of 0.1 to 0.4 mCi (3.7–14.8 MBq) of sodium iodide (^{123}I) typically in an encapsulated dosage form. Images are obtained of the thyroid and surrounding area 4 to 6 hours after ingestion.

Sodium Iodide (^{131}I). Diagnostic use of sodium iodide (^{131}I) with microcurie doses for evaluating thyroid function and/or morphology is no longer preferred because of the higher radiation dose associated with particle decay from this isotope. Doses from 1 to 10 mCi (37–370 MBq) are used for whole-body imaging to detect metastatic thyroid cancer and/or residual thyroid tissue following thyroidectomy. Whole-body images are obtained 48 to 72 hours later.

Therapeutic use of sodium iodide (^{131}I) occurs in hyperthyroidism or differentiated types of thyroid cancers. A patient with hyperthyroidism will receive an oral dose of 5 to 10 mCi (185–370 MBq) of sodium iodide (^{131}I). The dose could be higher for patients with toxic nodular goiter or other special situations. Treatment doses for differentiated thyroid carcinoma with or without metastases range from 30 to 200 mCi (1,110–7,400 MBq). Seven days after the therapeutic dose, a whole-body scan is performed in an effort to detect metastases not seen on the pretherapy diagnostic images. Thyroid hormone medication will be discontinued for several weeks prior to radiotherapy and thyroid-stimulating hormone (TSH) levels must be evaluated to ensure maximal uptake of the radiotracer for therapy.¹⁵

Iodine (^{131}I) Tositumomab (Bexxar). Tositumomab is a murine IgG monoclonal antibody directed against the CD20 antigen found on the surface of normal and malignant B lymphocytes. Iodine tositumomab (^{131}I) is a radioiodinated derivative of the antibody indicated for the treatment of patients with CD20 antigen-expressing relapsed or refractory, non-Hodgkin lymphoma. A schematic representing an IgG antibody labeled with covalently linked I-131 is shown. The exact number and position of the covalently linked I-131 is not described.

The treatment regimen occurs in two discrete steps: the dosimetric (diagnostic distribution) and therapeutic steps. Each step consists of a sequential infusion of unlabeled Tositumomab followed by iodine (^{131}I) tositumomab. The patient is premedicated with a thyroid protective agent (either potassium iodide or Lugol solution) for at least 24 hours, and will also receive acetaminophen and diphenhydramine shortly before the infusions begin. The dosimetric step administers 450-mg unlabeled tositumomab followed by 5 mCi (185 MBq) of iodine (^{131}I) tositumomab.

The patient is imaged three times over the next 7 days to assess the biodistribution of the radiolabeled antibody. Imaging occurs within 1 hour following the radiolabeled antibody infusion, 2 to 4 days after the infusion, and also 6 to 7 days after the infusion. If the dosimetric dose's biodistribution is altered, no further drug will be administered. If the dosimetric dose's biodistribution is as expected, the thera-

peutic dose can be administered 7 to 14 days after the dosimetric infusion.

The therapeutic dose is calculated based on the assessment of the patient's biodistribution and elimination of the dosimetric infusion as well as the patient's platelet count. Clinical studies have reported calculated therapeutic doses of 450-mg unlabeled tositumomab followed by 50 to 200 mCi (1,300–5,900 MBq) of iodine (^{131}I) tositumomab. Thyroid protective agents are administered daily until 2 weeks after the last radioiodine dose.¹⁶

Technetium Radiochemistry

The most commonly used radioisotope of technetium is technetium-99m, which is produced by molybdenum-99 β^- decay in a molybdenum-99/technetium-99m generator. Technetium-99m ($t_{1/2} = 6$ hours) decays by IT to technetium-99 ($t_{1/2} = 2.1 \times 10^5$ years) with principal γ -ray emissions of 140 keV (100%). The radiotracer is collected as pertechnetate ions ($^{99\text{m}}\text{TcO}_4^-$) from the generator by elution from the alumina column with sterile normal saline (0.9% sodium chloride). Long-lived radioactive impurities such as molybdate ions ($^{99}\text{MoO}_4$) that coelute from the generator column with pertechnetate ions ($^{99\text{m}}\text{TcO}_4^-$) theoretically may shorten the manufacturer's recommended expiration time of each elution since the Nuclear Regulatory Commission (NRC) and *United States Pharmacopeia (USP)* limits molybdenum-99 breakthrough to no more than 0.15 μCi of ^{99}Mo per 1 mCi of $^{99\text{m}}\text{Tc}$ in the preparation.⁵ In clinical practice, molybdenum-99 breakthrough is a rare occurrence.

Technetium, is a transition state metal and is the only "artificial" element with a lower atomic number than uranium. No stable isotopes exist in nature. All known isotopes of technetium are radioactive, and as such, has hindered the study of technetium's chemistry. However, milligram quantities of Tc-99 (a weak β^- emitter; $t_{1/2} = 2.1 \times 10^5$ years) are now available for characterization of technetium complexes. Technetium can exist in eight oxidation states, from -1 to $+7$. The $+7$ ($^{99\text{m}}\text{TcO}_4^-$) and $+4$ state ($^{99\text{m}}\text{TcO}_2$, or hydrolyzed-reduced technetium-99m) are the most stable forms.⁴

The chemistry of technetium is similar to that of rhenium and is dominated by forming compounds by bonding between the electron-deficient metal and electronegative

groups, which are capable of donating electron pairs. Some examples of these electronegative groups include amines, carboxylic acids, hydroxyls, isonitriles, oximes, phosphates, phosphines, and sulfhydryls. Various oxidation states (e.g., +1, +3, +5, etc.) are prepared in the presence of the reducing agent and stabilized by complexation with available ligands.

Tc-99m radiopharmaceuticals are by far the most commonly used radiotracers in day-to-day diagnostic nuclear medicine practice. Almost all technetium radiopharmaceuticals are metal–electron donor complexes. Compounds that contain two or more electron donor groups and bind to a metal are called *chelating agents*. As the pertechnetate ($^{99m}\text{TcO}_4^-$) ion, technetium will not form metal–donor complexes. However, the pertechnetate ion can be reduced by a stannous salt or other methods to an oxidation state that will complex with various monodentate, bidentate, or polydentate ligands. The most common reducing agent used in clinical practice is the stannous ion.

Technetium-99m radiopharmaceuticals are prepared by combining sodium pertechnetate ($\text{Na}^{99m}\text{TcO}_4$) with nonradioactive components in a sterile reaction vial. The primary chemical substances in the vial are the complexing agent (ligand) and a stannous salt-reducing agent (stannous chloride, stannous fluoride, or stannous tartrate). The oxidation state of technetium in various complexes as well as the actual chemical structure of many radiopharmaceuticals has yet to be characterized. Several reviews of technetium chemistry are available for further study.^{17–20}

After preparation of the radiopharmaceutical, tests for radiochemical purity should be carried out to ensure that the radiotracer is in the correct radiochemical form. Analytical quality control methods include paper and thin-layer chromatography, column chromatography, and solvent extraction. Likely, radiochemical impurities include unreacted sodium pertechnetate ($\text{Na}^{99m}\text{TcO}_4$), hydrolyzed-reduced technetium ($^{99m}\text{TcO}_2$) colloid, technetium–tin colloid, and possibly radiochemical complexes different from the one expected (e.g., ^{99m}Tc -monodentate rather than ^{99m}Tc -bidentate ligand, etc.). The sterile vials containing the stannous salt and the ligand are lyophilized under a sterile inert gas atmosphere (i.e., nitrogen or argon). The ligand in the reaction vial determines the final chemical structure of the ^{99m}Tc -complex and the biological fate after intravenous injection of the radiopharmaceutical.

TECHNETIUM RADIOPHARMACEUTICALS

Sodium Pertechnetate (^{99m}Tc). Sodium pertechnetate (^{99m}Tc) is a sterile, colorless solution in normal saline (0.9% NaCl), obtained by elution of the sterile Mo-99/Tc-99m generator. The major use of sodium pertechnetate (^{99m}Tc) is the preparation of various technetium-99m radiopharmaceuticals either in a nuclear pharmacy or nuclear medicine department. On-site preparation of radiolabeled red blood cells (RBCs) requires the availability of sodium pertechnetate since the radiolabeled cells must be reinfused to the patient within 30 minutes of preparation.

The pertechnetate ion ($^{99m}\text{TcO}_4^-$), which has an ionic radius and charge similar to the iodide ion (I^-) and is concentrated in the thyroid, salivary glands, kidneys, stomach, and choroid plexus in the brain. It can be used in a diluted solution from the Mo-99/Tc-99m generator elution to image the

thyroid, Meckel's diverticulum (stomach tissue in the intestine), salivary glands, and to detect processes that disrupt the blood-brain barrier (i.e., tumors, abscesses, strokes).

Like iodide, pertechnetate is trapped by the thyroid. Pertechnetate, however, cannot be utilized to prepare thyroid hormone. The patient receives an intravenous injection of 5 to 10 mCi (185–370 MBq) of Tc-99m pertechnetate, and thyroid images are obtained 20 to 30 minutes after injection. The usual dose for other imaging procedures such as Meckel's diverticulum and salivary gland imaging is also 5 to 10 mCi (185–370 MBq), whereas 20 mCi (740 MBq) is used for blood-brain barrier imaging.

Sodium Pertechnetate (^{99m}Tc)

Technetium (^{99m}Tc) Bicisate (Neurolite). Technetium (^{99m}Tc) bicisate is a neutral, lipophilic complex that crosses the blood-brain barrier and is selectively retained in the brain.

The kit used to prepare the product contains two vials. Vial “A” contains the ligand, tin, and other components that must be protected from light, whereas vial “B” contains a buffer solution. The radiopharmaceutical is prepared by adding sodium pertechnetate (^{99m}Tc) to the shielded “B” vial containing the buffer. The vial A containing lyophilized bicisate, EDTA, mannitol, and stannous chloride is reconstituted with 3 mL of normal saline (0.9% NaCl). Within 30 seconds, 1 mL of the saline solution from vial A is transferred to vial B and allowed to incubate at room temperature for 30 minutes. The tagged product must be used within 6 hours of preparation. The structure of the technetium complex is $[\text{N}_2\text{N}'\text{-ethylene-di-L-cysteinato}(3-)]\text{o}[\text{oxo } ^{99m}\text{Tc}]$ technetium(V) diethyl ester.²¹

After intravenous injection of 20 mCi (740 MBq) of Tc-99m bicisate, about 5% of the injected dose is localized within the brain cells 5 minutes after injection. Ester hydrolysis traps the radiotracer within the brain. This radiotracer is indicated for the evaluation of stroke, but it is used off-label to clinically evaluate various brain disorders, especially brain perfusion (“brain death”).

Technetium (^{99m}Tc) Bicisate

Technetium (^{99m}Tc) Disofenin (Hepatolite). Technetium (^{99m}Tc) disofenin is a 2:1 complex of ligand:metal that is rapidly eliminated via the hepatobiliary system. Clearance from the blood is delayed by high bilirubin levels. The primary clinical indication for this product is possible acute cholecystitis. In acute cholecystitis, there is

Technetium (^{99m}Tc) Disofenin

obstruction of the cystic duct leading to the gallbladder. The gallbladder is not visualized because the radiotracer cannot enter it. Some other clinical conditions that can be diagnosed by biliary images are common bile duct obstruction, biliary leak following surgery, biliary atresia, and a choledochal cyst.

The product is prepared by adding sodium pertechnetate (^{99m}Tc) to the shielded vial containing disofenin and stannous chloride. The preparation is allowed to incubate for 4 minutes. The product should be used within 6 hours of preparation. The structure of the technetium complex is shown.^{22,23} Hepatobiliary agents are commonly referred to as *HIDA agents*, or *hepatobiliary aminodiacetic acids*.

The fasting patient receives an intravenous injection of 5 mCi (185 MBq), which is taken up by the hepatocytes in the liver by active anionic transport. Patients with bilirubin levels greater than 5 mg/dL require an 8 mCi (296 MBq) dose. Then the radiopharmaceutical is excreted in bile, via the biliary canaliculus, into the bile ducts, with accumulation in the gallbladder and finally excretion via the common bile duct into the small bowel. The normal patient exhibits early accumulation of the radiopharmaceutical in the liver and the gallbladder.

Technetium (^{99m}Tc) Exametazime (Ceretek).

Technetium (^{99m}Tc) exametazime⁵ is a mixture of unstable lipophilic enantiomers that rapidly cross the blood-brain barrier and is trapped in the tissues. The proposed trapping mechanism for localization includes reduction by glutathione. A similar diffusion and trapping process occurs with autologous lymphocytes *in vitro*.

Exametazime is also known as *hexamethylpropyleneamine oxime* or HMPAO. The radiolabeled complex is in-

dicated for cerebral perfusion in stroke, but is most commonly used for the radiolabeling of autologous leukocytes as an adjunct in the localization of intra-abdominal infection and inflammatory bowel disease.

Each kit includes several components: (a) reaction vials containing a mixture of exametazime, stannous chloride, and sodium chloride; (b) vials of 1% methylene blue; (c) vials of phosphate buffer in 0.9% NaCl; and (d) 0.45- μm syringe filters. Product preparation depends on the intended use.

For use as a cerebral perfusion agent, the kit can be prepared with or without stabilizer. Shelf life is 4 hours with stabilizer, but only 30 minutes without stabilizer. Stabilizer is prepared by injecting 0.5 mL of 1% methylene blue in the phosphate buffer vial. Fresh sodium pertechnetate (^{99m}Tc) elution (<2 hours old) is added to the shielded vial containing exametazime. The vial is gently agitated for 10 seconds and used immediately because this unstabilized complex has a shelf life of approximately 30 minutes. For stabilization, 2 mL of the methylene blue/phosphate buffer mixture is added to the reconstituted exametazime vial within 2 minutes of the technetium (^{99m}Tc) exametazime vial reconstitution. Since the stabilized product is dark blue, a syringe filter is utilized to prevent inadvertent administration of particulate matter. Unstabilized product should be visually inspected for a clear, colorless appearance prior to administration. The patient receives an intravenous dose of 10 to 20 mCi (370–740 MBq). Dynamic imaging begins immediately following injection for up to 10 minutes. Static imaging may be performed from 15 minutes to 6 hours after injection.

For the radiolabeling of autologous leukocytes, approximately 50 mL of a patient's blood is drawn. The blood will be processed to separate the leukocytes from the

Technetium (^{99m}Tc) Exametazime

plasma and other cellular components. Fresh sodium pertechnetate (^{99m}Tc) elution (<2 hours old) is added to the shielded vial containing exametazime. The vial is gently agitated for 10 seconds and used immediately. The leukocytes will be incubated with technetium (^{99m}Tc) exametazime for 15 minutes, washed with saline, resuspended in the patient's own plasma, and reinfused to the patient as soon as possible. The goal in leukocyte preparation is to achieve 7 to 25 mCi of activity in the tagged cells. Images are acquired 2 to 4 hours after reinjection of the radiolabeled cells, allowing the cells to localize at the suspected site of infection.

Technetium (^{99m}Tc) Macroaggregated Albumin.

Technetium (^{99m}Tc) macroaggregated albumin (^{99m}Tc -MAA) is a sterile white suspension of human albumin aggregates formed by denaturing human albumin at 80°C for 30 minutes at pH 5 (isoelectric point of albumin).⁴ The particle size and number of particles can be estimated with a hemocytometer grid. The particle composition within the suspension should be between 10 and 100 μm , with no particles greater than 150 μm . Commercial manufacturing practices provide a consistent range for the number of particles per vial as well as a consistent range of particle size. This primary use of this agent is for the imaging of the pulmonary microcirculation to assess potential pulmonary emboli. Another much less common indication is to evaluate peritoneovenous (LeVeen) shunt patency.

In general, the kit is prepared by adding sodium pertechnetate (^{99m}Tc) to the shielded vial containing albumin, aggregated albumin, and stannous chloride, gently inverting the reconstituted suspension (to prevent foaming), and allowing the mixture to incubate at room temperature for 15 minutes. Gentle inversion of the vial is recommended to provide a uniform suspension prior to withdrawing a patient dose into a syringe. If the syringe is not used immediately, it should be gently inverted to resuspend the particles prior to injection. The tagged product is to be used within 12 hours of preparation. The precise structure of the radiolabeled complex is unknown at this time.

The patient receives an intravenous injection of 2 to 5 mCi (74–185 MBq) of the Tc-99m albumin aggregates, which lodge in some of the small pulmonary arterioles and capillaries. The number of aggregates recommended for good image quality and patient safety is 100,000 to 500,000 particles; thus, only a small fraction of the 280 billion capillaries are occluded. Multiple images of the lung are obtained to assess lung perfusion. The distribution of the particles in the lung is a function of regional blood flow; consequently,

in the normal lung, the particles are distributed uniformly throughout the lung. When blood flow is occluded because of emboli, multiple segmental “cold” (decreased radioactivity) defects are seen. This procedure is almost always combined with a xenon-133 gas or technetium-99m DTPA aerosol lung ventilation scan (should be normal in pulmonary embolism) and same-day chest radiograph x-ray (should be normal).

Technetium (^{99m}Tc) Mebrofenin (Choletec).

Technetium (^{99m}Tc) mebrofenin^{22,23} is a 2:1 complex of ligand:metal that is rapidly eliminated via the hepatobiliary system. The presence of bromine within the structure of mebrofenin makes the drug more lipophilic, and thus it has higher hepatic extraction than other hepatobiliary iminodiacetic acids (HIDA). Clearance from the blood is also affected by bilirubin levels, but generally to a much lesser extent because of the higher hepatic extraction. The clinical indication for this product is hepatobiliary imaging.

The product is prepared by adding sodium pertechnetate (^{99m}Tc) to the shielded vial containing mebrofenin, stannous fluoride and preservatives, and allowing the mixture to incubate for 15 minutes. The presence of preservatives allows this kit to be used for up to 18 hours after preparation.

The fasting patient receives an intravenous injection of 5 mCi (185 MBq), which is taken up by the hepatocytes in the liver by active anionic transport. Patients with bilirubin levels greater than 1.5 mg/dL may require a 10 mCi (370 MBq) dose.

Technetium (^{99m}Tc) Medronate. Technetium (^{99m}Tc) Medronate (^{99m}Tc -MDP)²⁴ is a diphosphonate complex with technetium-99m indicated for bone imaging to identify areas of altered osteogenesis. The clinical use of this agent is for investigation of skeletal problems such as metastatic disease to the bones, osteomyelitis, Paget disease, fractures, primary bone tumors, avascular necrosis, metabolic bone disease, and loose or infected hip prostheses. Stress fractures can be diagnosed by bone imaging when x-rays are completely normal. Bone radioscintigraphy is one of the most commonly performed nuclear medicine diagnostic procedures because the whole-body survey allows evaluation of the entire skeleton, which cannot be done as cost-effectively by any other imaging modality.

The relatively weak complex is prepared by adding sodium pertechnetate (^{99m}Tc) to the shielded vial containing medronic acid, a stannous salt (varies among manufacturers) with or without an antioxidant stabilizer. Radiolabeling

Technetium (^{99m}Tc) Mebrofenin

requires an incubation of 1 to 2 minutes, and the recommended shelf life is 6 hours.

The patient receives an intravenous injection of 10 to 20 mCi (370–740 MBq) of Tc-99m medronate, which localizes in bone according to the degree of metabolic activity. Tc-99m medronate is absorbed onto hydroxyapatite crystals at sites of new bone formation with about 50% to 60% of the injected dose distributed throughout the skeleton within 3 hours; the rest is excreted by the kidneys. The patient should void immediately prior to imaging to minimize interference from the bladder. Images are obtained 1 to 4 hours postinjection.

Technetium (^{99m}Tc) Medronate

Technetium (^{99m}Tc) Mertiatide (Technescan MAG3).

Technetium (^{99m}Tc) mertiatide complex is the radiopharmaceutical agent of choice to provide information about relative function of the kidneys and urine outflow because of its high renal extraction efficiency. Indications include renal artery stenosis in nonperfused kidneys, renal transplant assessment, and outflow obstruction.

The kit includes a reaction vial containing betiatide (a mertiatide prodrug), stannous chloride dihydrate, sodium tartrate, and lactose monohydrate sealed under argon. A filter-containing vented needle is also included. Betiatide must be protected from light. The generator elution utilized for the preparation of this complex should be no more than 6 hours old. The complex is prepared by inserting the venting needle through the shielded reaction vial's rubber stopper and then adding sodium pertechnetate (^{99m}Tc) to the shielded reaction vial. Before the pertechnetate syringe is removed, the plunger should be pulled back so that 2 mL of room air replaces the argon in the vial. Room air is required to for oxidation of excess stannous ion to ensure high radiochemical purity. The reaction vial is heated at 100°C for 10 minutes and then allowed to cool for 15 minutes. Initially, a weak ^{99m}Tc -tartrate complex is formed followed by ligand exchange with mertiatide (formed by the hydrolysis of betiatide) to form the desired technetium (^{99m}Tc) mertiatide complex.²⁵

The patient receives a bolus intravenous injection of 10 mCi (370 MBq) and dynamic images are obtained every 3 to 5 seconds to study blood flow to the kidneys. Sequential static images are then obtained for 20 to 30 minutes to evaluate renal cortical uptake, excretion, and tubular clearance. Delayed images may be required to evaluate patients with obstruction or renal failure. Normally, there is prompt symmetric bilateral perfusion, good bilateral cortical accumulation with visualization of the collecting systems by 3 to 5 minutes post injection, and rapid excretion into the bladder, with no delay to indicate partial or complete obstruction.

Technetium (^{99m}Tc) Mertiatide

Technetium (^{99m}Tc) Oxidronate Injection.

Technetium (^{99m}Tc) oxidronate (^{99m}Tc -HDP)²⁴ is a hydroxylated diphosphonate complex with technetium-99m also indicated for bone imaging to identify areas of altered osteogenesis. The additional hydroxyl group on the methylene spacer connecting the phosphonate groups of medronate provides higher binding affinity for hydroxyapatite crystals in bone; however, subjective criteria indicate no advantage to use of this agent.

The relatively weak complex is prepared by adding sodium pertechnetate (^{99m}Tc) to the shielded vial containing oxidronate sodium, stannous chloride, sodium chloride, and gentisic acid. Radiolabeling requires an incubation of 30 to 60 seconds, and the recommended shelf life is 8 hours.

The recommended dose is an intravenous injection of 10 to 20 mCi (370–740 MBq). The patient should void immediately prior to imaging to minimize interference from the bladder. Images are obtained 1 to 4 hours postinjection.

Technetium (^{99m}Tc) Oxidronate

Technetium (^{99m}Tc) Pentetate. Technetium (^{99m}Tc) pentetate (^{99m}Tc DTPA) is a complex between DTPA and technetium-99m. The precise structure of Tc-99m pentetate is unknown; evidence suggests the central metal atom may be at a +4 oxidation state.^{5,12} The clinical indications for this agent are renal imaging, renal functional studies (perfusion and GFR), and brain imaging. An additional clinical use of ^{99m}Tc DTPA is as an aerosol for pulmonary studies.

The complex is formed when sodium pertechnetate (^{99m}Tc) is added to a shielded vial containing DTPA (or a pentasodium or a calcium trisodium salt thereof) with or without an antioxidant and a stannous salt. Recommended incubation times vary from a few minutes up to 15 minutes in length, and the shelf life is between 6 and 12 hours depending on the absence or presence of an antioxidant, respectively.

For renal imaging and GFR studies, the patient receives an intravenous injection of 3 to 5 mCi (111–185 MBq) and the kidneys are imaged for 20 to 30 minutes. The GFR is calculated by a quantitative method using a combination of imaging and counting the radioactivity in serum and urine samples. Renal and brain perfusion studies use doses from 10 to 20 mCi (370–740 MBq). Both dynamic and static images are usually acquired for perfusion studies. For lung studies, 30 to 50 mCi (1.11–1.85 GBq) is placed in a closed, disposable nebulizer system. After 5 to 10 minutes of inhalation by the patient, the nebulizer is detached and patient images from various projections are obtained. Images are comparable to those obtained with xenon-133.

Technetium (^{99m}Tc) Pentetate

Technetium (^{99m}Tc) Pyrophosphate. Technetium (^{99m}Tc) pyrophosphate ($^{99m}\text{Tc-PYP}$)²⁰ is a pyrophosphate complex with technetium-99m indicated for bone, cardiac, and blood pool imaging. The primary current clinical uses are for cardiac and blood pool imaging.

For cardiac imaging, the complex is prepared by adding sodium pertechnetate (^{99m}Tc) to the shielded vial containing sodium pyrophosphate and stannous fluoride. Radiolabeling requires an incubation of 30 to 60 seconds, and the recommended shelf life is 6 hours. For blood pool imaging, the vial is reconstituted with normal saline (0.9% NaCl) and used within the next 30 minutes without further processing. The unlabeled pyrophosphate/stannous fluoride solution is administered to the patient intravenously 15 to 60 minutes prior to sodium pertechnetate (^{99m}Tc) for in vivo labeling of RBCs.

The recommended dose for cardiac imaging is an intravenous injection of 10 to 15 mCi (370–555 MBq) of technetium (^{99m}Tc) pyrophosphate within 24 to 144 hours after the onset of symptoms. The mechanism of radiotracer accumulation in damaged myocardium is unclear, but it is assumed that the radiotracer may bind to an ongoing calcification process that occurs in the damaged cells. For blood pool imaging (gated cardiac blood pool or gastrointestinal [GI] bleeding), the stannous salt is administered and allowed to accumulate by binding to hemoglobin in the RBCs. Then, 20 to 30 mCi (740–1,110 MBq) of sodium pertechnetate (^{99m}Tc) is administered. The pertechnetate ion also penetrates the RBC, but encounters the stannous salt for in vivo reduction and entrapment within the RBCs.

Technetium (^{99m}Tc) Pyrophosphate

Technetium (^{99m}Tc) Red Blood Cells (UltraTag RBC Kit). An in vitro method is available to radiolabel a patient's donated RBCs for use in blood pool imaging (gated cardiac blood pool or GI bleeding) studies. A sterile reaction vial containing stannous chloride is used to radiolabel a patient's own RBCs with sodium pertechnetate (^{99m}Tc). Briefly, the patient's blood (1–3 mL) is drawn with acid citrate dextrose (ACD) or heparin (100 units) used as an anticoagulant. The blood is labeled with the patient's name and hospital number and added to the sterile reaction vial. After mixing and incubation for 5 minutes, sodium hypochlorite (6 mg) is added to the vial to oxidize excess stannous ions (Sn^{+2}) to stannic ions (Sn^{+4}). Then, a citrate buffer is added to adjust the pH to about 7.4. Finally, 30 mCi (1,110 MBq) of sodium pertechnetate (^{99m}Tc) is added to the vial, mixed and incubated for 20 minutes. Without further preparation, the patient receives an intravenous injection of 25 mCi (925 MBq) of his or her own radiolabeled RBCs.

Technetium (^{99m}Tc) Sestamibi (Cardiolite and Micaluma). Technetium (^{99m}Tc) sestamibi is a lipophilic cation complex represented as $^{99m}\text{Tc}-(\text{MIBI})_6^+$, where MIBI is 2-methoxyisobutyl isonitrile.²⁶ It is clinically indicated as a myocardial perfusion agent for detecting coronary artery disease and evaluation of myocardial function (accomplished by imaging during rest and during cardiovascular stress with either exercise or pharmacologic stress) as well as a second line diagnostic drug after mammography to assist in the evaluation of breast lesions in patients with an abnormal mammogram or a palpable breast mass. An additional clinical use is the evaluation of hyperparathyroidism.

Preparation of ^{99m}Tc sestamibi begins with the addition of sodium pertechnetate (^{99m}Tc) to shielded reaction vial containing tetrakis (2-methoxyisobutyl isonitrile) copper (I) tetrafluoroborate, sodium citrate, L-cysteine hydrochloride, mannitol, and stannous chloride. Initially, the reduced technetium-99m forms a weak complex with citrate, which undergoes a ligand exchange with the isonitrile during a 10-minute heating period in a boiling water bath. The reaction vial requires cooling for 15 minutes before use. The recommended shelf life is 6 hours.

Technetium (^{99m}Tc) sestamibi accumulates in the myocardium by facilitated diffusion from the Na^+/H^+ antiporter.²⁷ There is no "redistribution," or movement of the tracer out of the myocardium and back into the bloodstream. This tracer has several advantages as a myocardial perfusion agent when compared with thallous (^{201}Tl) chloride. The shorter half-life of technetium-99m (6 hours) when compared with thallium-201 (73 hours) allows administration of a larger dose for shorter imaging times. The

Technetium (^{99m}Tc) Sestamibi

higher energy γ -ray (140 keV) also provides better quality images with contemporary gamma cameras.

Myocardial perfusion imaging is, by far, the most common nuclear medicine procedure. Various myocardial perfusion protocols utilize ^{99m}Tc sestamibi for one or both procedures: 1-day rest first, stress second, 1-day stress first, rest second, 1-day stress first, rest if ischemia is present, 2-day protocols, and dual-isotope studies. The 1-day rest first, stress second protocol utilizes 8 to 10 mCi (296–370 MBq) while the patient is at rest (normal blood flow). Imaging occurs 30 to 60 minutes later. Sufficient time is needed for the radiotracer to clear the liver before imaging. One to four hours after the rest study, 25 to 30 mCi (925–1,110 MBq) is injected at peak stress (treadmill or pharmacologic stress with increased blood flow demand), and imaging occurs 15 to 60 minutes later. Two-day protocols typically utilize 20 to 25 mCi (740–925 MBq) doses for both the rest and stress images. Dual-isotope protocols typically perform a thallium rest study first, followed shortly thereafter with a ^{99m}Tc stress study.¹⁵

The recommended dose for ^{99m}Tc sestamibi when used for breast imaging is 20 to 30 mCi (740–1,110 MBq). When used for parathyroid imaging, the recommended dose is 25 to 30 mCi (925–1,110 MBq).

Technetium (^{99m}Tc) Succimer Injection. 2,3-dimercaptosuccinic acid (DMSA, succimer) forms a hydrophilic complex when labeled with technetium-99m that is useful in evaluating renal function, especially in children.

The pH-dependent preparation of ^{99m}Tc -DMSA begins with the addition of sodium pertechnetate (^{99m}Tc) to shielded reaction vial containing 2,3-dimercaptosuccinic acid, stannous chloride, ascorbic acid, and inositol at a pH range of 2 to 3. Various metal-DMSA complexes are initially formed, but over the 10-minute incubation period at this acidic pH, the hexacoordinate complex²⁸ of three carboxylic acids and three sulfhydryls produces a tracer with the highest renal uptake.⁵ Localization of such a complex prepared at a certain pH is not altered if the environmental pH is subsequently changed.²⁹ This complex has a shelf life of 4 hours.

The patient is injected with 2 to 6 mCi (74–222 MBq) of ^{99m}Tc -DMSA and images are taken 1 to 2 hours later.

Technetium (^{99m}Tc) Succimer

Technetium (^{99m}Tc) Sulfur Colloid. Technetium (^{99m}Tc) sulfur colloid (^{99m}Tc -SC) is a dispersion of particles larger than those found in solution, but small enough to remain suspended in the delivery matrix for a very long time. It is indicated for use by injection to assess functional capacity of reticuloendothelial cells of the liver, spleen, and bone marrow, to evaluate peritoneovenous (LeVeen) shunt patency. It is indicated orally to assess gastric emptying. Another use involves the intralymphatic or peritumoral administration for radioguided sentinel lymph node biopsy.

Kits for the preparation of ^{99m}Tc -SC include the following three vials: (a) a reaction vial containing sodium thiosulfate, edentate disodium, and gelatin; (b) "vial A," which is an aqueous solution of dilute hydrochloric acid; and (c) "vial B," which is an aqueous solution of sodium biphosphate and sodium hydroxide. Sodium pertechnetate (^{99m}Tc) solution is added to the shielded reaction vial followed by the addition of the dilute hydrochloric acid. Upon heating in a water bath, the acid reacts with the thiosulfate and $^{99m}\text{TcO}_4^-$ to form the colloidal metal sulfide, $^{99m}\text{Tc}_2\text{S}_7$. Short heating periods provide a higher population of smaller colloid particles in the final preparation,³⁰ whereas extended heating periods produce larger particles with increasing amounts of colloidal sulfur.¹⁸ After the heating period has ended, the reaction vial is cooled for a brief period, and then the chemical reaction is quenched by the addition of the aqueous solution of sodium biphosphate and sodium hydroxide to the reaction vial. The inclusion of gelatin as an ingredient prevents colloid particles from clumping together. Particle sizes range from 0.1 to 1 μm , with a mean size of 0.3 μm .⁴

After intravenous injection of 1 to 12 mCi (37–444 MBq) of ^{99m}Tc -SC, the tracer is rapidly cleared from the blood by the reticuloendothelial cells of the liver, spleen, and bone marrow. Uptake depends on the relative blood perfusion rate and the functional capacity of the cells. In the normal patient, 85% of the radiocolloid is phagocytized by Kupffer cells in the liver, 7.5% by the spleen, and the remainder by the bone marrow, lungs, and kidneys. Liver-spleen images can be acquired within 20 minutes of administration. Bone marrow imaging studies are performed 1 hour after injection of 10 mCi (370 MBq) of ^{99m}Tc -SC. Normal bone marrow will take up the radiocolloid, but diseased bone marrow appears as “cold” defects in patients with tumor deposits in the marrow.

Technetium (^{99m}Tc) sulfur colloid use for GI studies includes gastroesophageal reflux (GER) and gastric emptying of solid food. Gastroesophageal reflux imaging is performed after having the patient swallow acidified orange juice mixed with 1 mCi (37 MBq) of ^{99m}Tc -SC. Normal patients do not demonstrate reflux. Gastric emptying imaging is performed after the patient swallows solid food (i.e., scrambled eggs or pancakes) radiolabeled with 1 mCi (37 MBq) of ^{99m}Tc -SC. In general, the normal gastric emptying half-time is less than 90 minutes for solid food.¹⁵ Imaging begins shortly after administration and monitors the migration of the colloid particles.

Identification of sentinel lymph nodes for subsequent biopsy in breast cancer³¹ and melanoma³² patients is accomplished by the administration of several injections totaling 0.5 to 1.5 mCi (19–56 MBq) of filtered (0.22- μm filter) or unfiltered ^{99m}Tc -SC. Smaller colloid particles may translocate more readily into the lymphatic system, whereas larger particles remain at the injection site.^{15,30} Imaging begins shortly after administration and monitors the migration of the colloid particles.

Technetium (^{99m}Tc) Tetrofosmin (Myoview). Technetium (^{99m}Tc) tetrofosmin is a lipophilic cation complex³³ clinically indicated as a myocardial perfusion agent for detecting regions of reversible myocardial ischemia in the presence or absence of infarcted myocardium, identifying changes in perfusion induced by pharmacologic stress in patients with coronary artery disease, and assessing left ventricular dysfunction.

Preparation of technetium (^{99m}Tc) tetrofosmin begins with the addition of sodium pertechnetate (^{99m}Tc) to shielded reaction vial containing tetrofosmin [6,9-bis(2-ethoxyethyl)-3,12-dioxa-6,9-diphosphatetradecane], stannous chloride, disodium sulphosalicylate, sodium D-gluconate, and sodium hydrogen carbonate. Initially, the reduced technetium-99m forms a weak complex with gluconate which undergoes a ligand exchange with tetrofosmin during a 15-minute incubation period at room temperature. The recommended shelf life is 8 hours.

Technetium (^{99m}Tc) tetrofosmin accumulates in the myocardium by facilitated diffusion from the Na^+/H^+ antiporter.²⁷ There is essentially no “redistribution,” or movement of the tracer out of the myocardium back into the bloodstream. Heart:liver ratios are somewhat higher for technetium (^{99m}Tc) tetrofosmin as compared with technetium (^{99m}Tc) sestamibi and allows for a shorter interval between injection and imaging for technetium (^{99m}Tc) tetrofosmin.³⁴

Various myocardial perfusion protocols utilize technetium (^{99m}Tc) tetrofosmin for 1-day, 2-day, and dual iso-

tope studies. One day protocols should utilize 5 to 12 mCi (185–444 MBq) for the first dose (rest or stress). Imaging can commence as early as 15 minutes later. One to four hours after the first study, 15 to 33 mCi (555–1,221 MBq) is injected for the second study. Two-day protocols typically utilize 30 mCi (1,110 MBq) doses for both the rest and stress images. Dual-isotope protocols typically perform a thallium rest study first, followed shortly thereafter with a technetium-99m stress study.¹⁵

Technetium (^{99m}Tc) Tetrofosmin

Thallium Radiochemistry

The clinically useful radioisotope of thallium is thallium-201. This isotope is produced in a cyclotron by proton bombardment of a thallium metal target according to a $^{203}\text{Tl}(p,3n)^{201}\text{Pb} \rightarrow ^{201}\text{Tl}$ sequence. Lead-201 ($t_{1/2} = 9.4$ hours) decays by EC to thallium-201. Thallium-201 ($t_{1/2} = 73$ hours) decays by EC to stable mercury-201, with principal γ -ray emissions of 135 keV (3%) and 167 keV (10%), and mercury-201 daughter x-rays from 69 to 80 keV (94.5%), all of which can be used for organ imaging.

The irradiated thallium target is dissolved in nitric acid, and the Pb-201 is separated from the thallium-203 by sequential ion exchange column chromatography with an EDTA containing mobile phase. Unbound lead-201 is allowed to decay for approximately 24 hours and passed through another ion exchanged column. Resin-bound thallium-201 (III) is eluted with hydrazine sulfate to provide thallium-201 (I). The elute containing thallium-201 ions are converted to the chloride salt form. The pH is adjusted to 4.5 to 7.0 with sodium hydroxide, made isotonic with sodium chloride containing benzyl alcohol as a preservative, and sterilized by filtration.^{4,35}

THALLIUM RADIOPHARMACEUTICALS

Thallous (^{201}Tl) Chloride. The most common clinical uses of this radiotracer are for the evaluation of myocardial perfusion and myocardial viability. It is also indicated for the localization of parathyroid hyperactivity. It is commercially available as a ready-to-use intravenous solution.

Thallous (^{201}Tl) chloride accumulates in viable myocardial tissue by Na^+/K^+ ATPase as well as $\text{Na}^+/\text{K}^+ / 2\text{Cl}^-$ symporter²⁷ much like potassium ions and is a dynamic exchange between the myocardial cell and the blood. Uptake is dependent on blood flow rates; at very high flow rates, extraction efficiency decreases. Thallous (^{201}Tl) chloride does not concentrate in scarred or infarcted myocardium.

These concepts are the basis for the stress/redistribution imaging strategy employed for the detection of coronary artery disease. To do this, the patient submits to either physiological “stress” (treadmill exercise) or pharmacological “stress” with an intravenous infusion of a vasodilator depending upon the patient’s physical condition. At maximum stress, the patient is injected with 3 to 4 mCi (111–148 MBq) of thallous (^{201}Tl) chloride. The “stress test” accentuates the myocardial perfusion abnormality because areas of significant arterial narrowing cannot respond to the increased blood flow demands of the stress as well as normal arteries. Images of the heart are obtained immediately after stress. Damaged or ischemic myocardium show less thallous (^{201}Tl) chloride uptake than surrounding normal heart muscle. Three hours after stress, the resting patient may be imaged again or will be injected with another 1.0 to 1.5 mCi (37–56 MBq) of thallous (^{201}Tl) chloride prior to imaging to provide information under normal (rest) conditions. Ischemic tissues will “fill in” during rest images demonstrating normal uptake, whereas infarcted tissue continues to demonstrate reduced uptake.

Dual isotope perfusion studies utilize thallous (^{201}Tl) chloride to first acquire rest images. Later, a technetium-99m perfusion agent is used to acquire the stress images.^{15,36}

Xenon Radiochemistry

The clinical radioisotope of xenon for organ imaging is xenon-133, a noble gas used in its elemental form. Xenon-133 is produced in a nuclear reactor as a byproduct of uranium fission by the nuclear reaction $^{235}\text{U}(n, \text{fission})^{133}\text{Xe}$. Xenon-133 ($t_{1/2} = 5.3$ days) decays by β^- emission to cesium-133, with γ -ray emission of 81 keV (37%). Gases used in lung ventilation studies must be chemically and physiologically inert at the concentrations used for imaging studies. Xenon-133 is chemically inert and insoluble in water, which makes it insoluble in body fluids. Unfavorable physical characteristics of xenon-133 include poor image quality because of the low tissue penetration of the low-energy γ -ray, increased patient dose due to β^- emission, and the low γ -ray emission yield (36 γ -rays/100 disintegrations).

XENON RADIOPHARMACEUTICALS

Xenon (^{133}Xe). Radioactive xenon (^{133}Xe) gas is supplied at standard pressure and room temperature in a septum-sealed glass vial in doses of 10 to 20 mCi (370–740 MBq) in either stable xenon carrier mixed with atmospheric air or 5% xenon carrier mixed with 95% carbon dioxide suitable for inhalation by the patient for diagnostic evaluation of pulmonary function and imaging of the lungs. The shelf life of the vials is 14 days because of the more rapid decay of xenon (^{133}Xe) gas when compared with the subsequent build-up of slower decaying impurities.

The general procedure involves mixing the vial contents of xenon-133 gas in air or oxygen in a closed-circuit spirometer system that delivers the radioactive gas, allowing the patient to breathe the gas mixture. The inhalation study consists of wash-in, equilibrium and washout phases, with the patient sitting or supine. The wash-in phase is the first breath of the xenon-133 bolus, the equilibrium phase consists of the patient breathing the mixture for 5 minutes,

and for the washout phase, the patient exhales xenon-133 gas into an activated charcoal trap. Images are obtained continuously for approximately 10 minutes with the gamma (γ -ray) camera. In the wash-in study, the patient inspires the bolus and holds their breath for several seconds. In the equilibrium study, there is an initial distribution of the radioactive gas throughout the lungs. In the washout phase, the xenon-133 gas clears readily from the lungs. In the abnormal study, the initial flow into the lungs of xenon-133 gas is delayed, and the outflow is also delayed. These abnormal lung ventilation findings add significant information in the evaluation of pulmonary embolism (blood clots in the lungs) when combined with the results of a lung blood perfusion study with Tc-99m macroaggregated albumin.

CONTRAST AGENTS

Radiography and Computed Tomography

A photographic film containing a radiographic image is properly called a *radiograph*, although it is commonly referred to as an *x-ray* or a *film*. The relative difference between the light and dark areas on a radiographic image reflects what is called *radiographic contrast*. Traditional radiographic images of the body, such as skeletal, abdominal, and chest x-rays, have four radiographic densities: air, fat, water (organs, muscle, soft tissue), and bone/metal. Organs and tissues are made visible according to how well they attenuate x-rays. The attenuation of x-rays by tissues is a complex process that depends on many factors, including, but not limited to, the energy of the x-ray beam and the density of the tissue. Bone has an average density of about 1.16 g/cm^3 , which accounts for its ability to absorb most of the radiation it encounters.

Whereas traditional radiological “film” studies have been used since 1895 and continue to be a mainstay of diagnostic medical imaging, they have their limitations. Many organs and tissues of the body are not easily discriminated from each other on traditional radiographic images. For example, the liver, spleen, kidneys, intestines, bladder, and abdominal musculature all have very similar radiographic densities and are difficult, if not impossible, to distinguish from each other.

To produce diagnostic x-rays, a very high voltage (20,000–150,000 volts) is applied to a glass vacuum tube that contains a cathode and a rotating anode (Fig. 11.6). The cathode is a filament that is heated to a very high temperature, which provides a copious source of electrons. These electrons are accelerated toward the positively charged anode. When the accelerated electrons strike the anode (called the *target*), x-rays are produced. The distribution of x-rays is as a continuous spectrum. Lower-energy x-rays are absorbed by an aluminum filter, while higher-energy x-rays travel through the patient, exposing the x-ray film, and producing a traditional radiograph. Digital radiography is the process of producing a digital radiographic image where a specialized phosphor plate is used in place of traditional film. Such digital images can be readily viewed on a monitor, stored, and transferred much like any other type of digital information.

Figure 11.6 • Schematic diagram of an x-ray tube for production of x-ray films.

Figure 11.7 • Schematic diagram of a fluoroscopic x-ray system for real-time imaging during medical procedures. (Reprinted with permission from Bushberg, J. T., et al.: *The Essential Physics of Medical Imaging*, 2nd ed. Philadelphia: Lippincott Williams and Wilkins, 2002.)

Figure 11.8 • Schematic diagram of a computerized axial tomography (CAT) system for producing cross-sectional images of the body.

An invaluable modification of the x-ray system is fluoroscopy (Fig. 11.7). This modality allows one to visualize organs in motion, position the patient for spot film exposures, instill contrast media into hollow cavities, and insert catheters into arteries.

CT (sometimes called CAT, Fig. 11.8) uses ordinary x-ray energies for imaging and applies complex mathematical reconstructions to produce multiple images of the body in the axial and other planes. This technique typically provides more detailed information about the anatomical region of interest because the images obtained are numerous thin slices of the imaged area. With this process, the reconstructed images increase the visibility of small differences in the radiographic densities between tissues to a far greater extent than traditional radiographic film.

RADIOLOGICAL CONTRAST AGENTS

From the earliest days of radiology, considerable effort has been devoted to developing compounds that if swallowed or injected would increase the radiographic contrast between various tissues and organs. Injection of air or other gases into a GI tube in the esophagus, stomach, or duodenum or into a rectal tube in the colon provides increased radiographic contrast for evaluating the gut; however, the information obtained by this technique is limited, and more opaque substances have been developed.

Any agent or compound administered to a patient to improve the visualization of an organ or tissue is called a *contrast agent*. Contrast agents can be classified as negative or positive. Air and other gases are negative contrast agents because they render a structure, such as the gut, more translucent. An agent that increases the radiographic opacity of an organ or tissue is a positive contrast agent. Most contrast

agents used in diagnostic radiology are positive contrast agents.

An ideal radiographic contrast agent should have the following properties: (a) readily available, (b) inexpensive, (c) excellent x-ray absorption characteristics at the x-ray energies used in diagnostic radiology, (d) minimal toxicity, (e) patient acceptance, (f) chemical stability, (g) high-water solubility with low viscosity and no significant osmotic effects, and (h) the ability to be administered for selective tissue uptake and excretion.

No compound has all of these characteristics. Barium sulfate and various iodine compounds, however, produce excellent radiological contrast with low patient toxicity and relatively low cost. The use of barium and iodine compounds as radiological contrast agents is based on their radiographic appearance, distribution, and elimination from the body. Contrast media are used in very large quantities and are usually administered over a brief period of time.

Barium sulfate is a nearly ideal contrast agent for oral and rectal studies of the GI tract. It produces a metal-like density on radiological studies, is inexpensive, and when properly utilized, has minimal patient morbidity and mortality. While various water-soluble barium compounds are quite toxic, barium sulfate is an insoluble white powder that is a colloidal suspension in water.

Most intravenous contrast agents used to opacify blood vessels and increase contrast in solid organs, such as the liver, are water-soluble organic iodides. Iodine absorbs x-rays effectively at many energy levels and produces opacities similar to bone density during radiographic studies. While iodine's radiographic density is somewhat less than that of barium sulfate, it is still very useful for radiographic contrast.

Early water-soluble contrast agents consisted of triiodinated benzoic acid salts. In solution, these salts dissociate into two particles: (a) a triiodinated anion and (b) a cation, usually sodium or methylglucamine (meglumine). These compounds, known as *high-osmolar contrast medium* (HOCM), have in effect three iodine atoms for every two ions in solution, a 3:2 ratio. They are often called *conventional, ionic ratio 1.5 contrast agents*, or *triiodinated monomers* and are represented by diatrizoate and iothalamate.³⁷ Various fixed ratios of sodium diatrizoate and meglumine diatrizoate are also available in proprietary products.

These water-soluble iodinated salts are administered in fairly high volumes and concentrations to achieve satisfactory radiological contrast. It is not unusual to administer as much as 100 mL or more of a 30% to 70% solution intravenously.³⁸ The typical concentrations used for various studies have an osmolality of 5 times or more to that of normal plasma. Administration of these HOCM agents can be associated with osmotoxic effects. Initially, water shifts rapidly from the interstitial and cellular spaces into the plasma after injection of an HOCM. This is typically accompanied by vasodilatation, local pain and warmth, a metallic taste in the mouth, and flushing. Later, there is an osmotic diuresis as these agents are excreted by the kidneys.

Various nonionic water-soluble compounds with a higher ratio of iodine content per osmotic particle have been developed. These types of agents, known as *low-osmolar contrast medium or isotonic contrast media* (LOCM or ICM), produce far fewer osmotic effects. Various monomers such as iohexol, iopamidol, iopramide, ioversol, and ioxilan as well

as dimers such as iodipamide, iodixanol, and ioxaglate have been described.³⁸

All of the water-soluble iodinated contrast media are clear, colorless, viscous liquids. Even though they are clear liquids, they are often called "dyes" when their administration is being explained to patients. Sodium salts are slightly less viscous than the meglumine salts, which are typically less viscous than nonionic monomers, which are typically less viscous than nonionic dimers. Viscosity is a function of temperature and can be reduced by warming the contrast agent to body temperature prior to its administration.

Water-soluble iodinated contrast media have relatively small molecular sizes and low chemical reactivity with body fluids and tissues. Their pharmacodynamic characteristics are similar to those of extracellular tracers. They have low lipid solubility and distribute throughout extracellular spaces. They do not significantly penetrate into intracellular spaces. Special attention must be given to ensure that iodinated contrast agents are not administered intrathecally unless they are indicated for such use. Inadvertent intrathecal administration can cause serious outcomes such as convulsions, cerebral hemorrhage, brain edema, and death.

Water-soluble iodinated contrast agents are cleared from the body by glomerular filtration. They are neither reabsorbed nor secreted by the renal tubules. When renal function is compromised, these contrast agents are eliminated in part or totally through the liver and gut. This alternate elimination pathway occurs at a much slower rate than elimination when compared with glomerular filtration in a healthy person.

Water-soluble organic iodides are the largest group of radiological contrast agents. In addition to water-insoluble barium sulfate, there is an iodinated fatty acid derivative of poppy seed oil that is occasionally utilized in the clinic. Unsaturated fatty acids are monoiodinated or diiodinated before conversion to an ester. These substances are susceptible to light-induced decomposition, and the oily nature of the formulation excludes intravascular use.

Radiological contrast agents that are administered orally or intravascularly in large amounts infrequently report adverse effects. Nevertheless, any radiological contrast material may produce an untoward patient reaction, even sudden death.³⁹⁻⁴²

Events can occur when contrast material is aspirated or when it leaks from the GI tract. Hypertonic ionic water-soluble contrast agents are potentially dangerous if aspirated into the tracheobronchial tree. They are irritating and can cause pulmonary edema. Contrast material that leaks out of the bowel into the abdomen, pelvis, or chest is potentially quite dangerous, especially barium sulfate. Barium sulfate is insoluble, and its particulate nature means it is poorly cleared from the mediastinum, peritoneum, and retroperitoneum. Water-soluble agents, on the other hand, are rapidly absorbed from these areas almost as quickly as if they had been injected intravenously. In general, water-soluble agents that leak from the GI tract rarely cause significant problems beyond transient inflammation.

The intravenous or intra-arterial injection of iodinated contrast material can lead to a diverse assortment of contrast reactions, most of which are minor and easily treated. Minor reactions include injection pain, a feeling of general body warmth and discomfort, mild nausea and vomiting, a strong metallic taste in the mouth, and mild urticaria (hives). Minor

reactions dissipate within a few minutes with patient reassurance and observation.

Intermediate or moderate reactions are those that require some form of therapy but are not life-threatening. These reactions include difficulty breathing, severe hives, severe nausea and vomiting, mild hypotension, wheezing, and other related reactions. Treatment ranges from administration of intravenous fluids to the use of intravenous diphenhydramine and/or corticosteroids. Epinephrine may be administered, and atropine is used if there is a vasovagal reaction with hypotension and bradycardia.

Severe reactions are those that are life-threatening. They include sudden cardiovascular collapse and death, as well as severe hypotension; severe shortness of breath, wheezing, or laryngedema; loss of consciousness; massive hives and angioneurotic edema; ventricular cardiac arrhythmias; angina; and myocardial infarction. Treatment depends on the patient's signs and symptoms and includes intravenous fluids, oxygen, various drugs (including epinephrine, diphenhydramine, and atropine), and possible cardiopulmonary resuscitation (CPR).

Barium Sulfate. Commercial preparations of barium sulfate differ in their density and ability to coat the bowel wall. These characteristics are determined by the particle size of the barium suspension, its viscosity, and concentration of the contrast agent. Flavoring agents, suspending agents, and other additives may be utilized in preparing various products.

Barium sulfate preparations are given orally or rectally and are used to study the esophagus, stomach, duodenum, entire small bowel, colon, or the total bowel. Most patients find the taste of these flavored mixtures tolerable, but they dislike the heavy texture of the barium.

Concentrated barium suspensions ranging from 50% to 210% weight/volume (wt/vol) are frequently used for traditional radiographic imaging. Dilute suspensions ranging from 1.5% to 5% weight/volume (wt/vol) are typically used for CT studies.

The quantity and concentration of barium sulfate suspension administered to the patient will depend on the selected procedure. In general, upper GI studies will administer the contrast agent just prior to imaging, whereas lower GI studies recommend intake several hours prior to the procedure. For total bowel opacification, the patient should consume contrast agent the night preceding the examination, additional agent a few hours prior to examination, and a third dose approximately 15 minutes prior to examination.

Diatrizoate. Diatrizoate is a water-soluble, ionic monomer. It is commercially available as the meglumine salt, sodium salt, or as fixed combinations of the two salt forms. These triiodobenzoic acid salts contain 47% organically bound iodine.

Numerous products with various concentrations of one or two of the salt forms are available for various imaging procedures. Indicated uses include angiography, venography, excretory urography, retrograde cystourethrography, retrograde or ascending pyelography, operative, T-tube, or percutaneous transhepatic cholangiography, splenoportography, arthrography; discography, radiographic examination of the GI tract when barium sulfate is contraindicated (i.e., suspected perforation of the GI tract), adjunct contrast enhancement in CT of the torso (dual contrast study), and hysterosalpingography.

Diatrizoate Meglumine

Ethiodized Oil (Ethiodol). This product is a mixture of iodinated fatty acid ethyl esters of poppy-seed oil, primarily as ethyl monoiodostearate and ethyl diiodostearate. It contains 37% organically bound iodine, has considerably reduced viscosity when compared with the triiodobenzoic acid derivatives, and is not miscible with plasma. Ethiodol is indicated for use as a radiopaque medium for hysterosalpingography and lymphography.

Iodipamide Meglumine. Iodipamide is a water-soluble, ionic dimer that is administered as the meglumine salt in combination with diatrizoate meglumine as the commercial product, Sinografin. Iodipamide has 50% bound iodine content. Intravenous use was associated with significant adverse effects, and the product is now indicated solely for use in hysterosalpingography.

Iodipamide Meglumine

Iodixanol

Iodixanol (Visipaque). Iodixanol is a viscous, isosmolar, nonionic, water-soluble dimer with 49% iodine content. It is formulated as an isotonic solution for intravascular injection and indicated for excretory urography, angiography, and CT procedures.

Iohexol (Omnipaque). Iohexol is a low-osmolar, nonionic monomer with 46% iodine content. Iohexol is one of the few iodinated contrast agents indicated for intrathecal use (myelography). Only selected concentrations of the product have this indication. Besides myelography, iohexol finds widespread use in excretory urography, angiography,

and CT procedures. Specific concentrations may have additional indications in adults and/or children for arthrography, hysterosalpingography, endoscopic retrograde pancreatography, cholangiopancreatography, herniography, voiding cystourethrography, oral pass-thru examination of the GI tract or CT of the abdomen.

Iopamidol (Isovue). Iopamidol is a low-osmolar, nonionic monomer with 49% organically bound iodine. It is indicated for use in angiography, excretory urography, and numerous CT procedures.

Iohexol

Iopamidol

Iopromide

Iopromide (Ultravist). Iopromide is a low-osmolar, nonionic monomer with 48% bound iodine content. It is indicated for use in angiography, excretory urography, and numerous CT procedures.

Iothalamate Meglumine (Conray). Iothalamate meglumine is a high-osmolar, ionic monomer with 47% bound iodine content. Conray is indicated for use in angiography,

excretory urography, arthrography, cholangiography, endoscopic retrograde cholangiopancreatography, and various CT procedures.

Ioversol (Optiray). Ioversol is a low-osmolar, nonionic monomer with 47% bound iodine content. It is indicated for angiography, excretory urography, ventriculography, and various CT procedures.

Iothalamate Meglumine

Ioversol

Ioxaglate

Ioxilan

Ioxaglate (Hexabrix). Ioxaglate is a high-osmolal, ionic dimer with 32% bound iodine content. It is commercially formulated as a mixture of its meglumine and sodium salts. Ioxaglate is indicated for angiography, excretory urography, and various CT procedures.

Ioxilan (Oxilan). Ioxilan is a low-osmolar, nonionic monomer with 48% bound iodine content. It is indicated for angiography, excretory urography, and various CT procedures.

Magnetic Resonance Imaging

MRI is a unique method of medical imaging. The strength of MRI as an imaging modality is its ability to detect small changes within soft tissues by using nonionizing radiation. The exquisite soft tissue images produced by MRI are analogous to the cross-sectional images of the body produced by CT with the benefit of MRI images being performed in any desired plane (coronal, axial, sagittal, oblique, etc.).

When a patient is placed in a large, strong, uniform magnetic field (Fig. 11.9), a population of hydrogen nuclei (protons) in all hydrogen-containing molecules align themselves with the magnetic field. Once aligned in the magnetic field, these nuclei will precess (spin like a gyroscope) with a characteristic spin frequency related to the magnetic field strength. The tesla (T) is the official unit of magnetic field strength, and MRI is normally performed between 0.5 to 1.5 T.

By directing low-energy, electromagnetic radiation to a defined region of the patient's body, the magnetized, precess-

ing hydrogen nuclei can selectively absorb this energy to become excited. The excitation is accomplished by a complex series of radiofrequency pulses at the same frequency as the precessing hydrogen nuclei. Each burst of energy displaces the magnetic orientation of precessing nuclei. When the excitation energy field is removed, the displaced nuclei will lose the acquired energy, returning to magnetic equilibrium. These decaying (i.e., relaxing) nuclei emit a weak, but detectable, radio wave (i.e., signal), whose strength and manner of relaxation can be used to generate diagnostic medical images.

The timing of data acquisition from the relaxing nuclei is just as important as the number of nuclei that are excited in the observed tissues. Early receiver detection of emitted proton signals following discontinuance of the radiofrequency pulse is called a T1-weighted sequence (longitudinal or spin-lattice relaxation). T1 images have good resolution and are useful for gaining anatomic information. Late receiver detection of emitted signals is called a T2-weighted sequence (transverse or spin-spin relaxation). T2 images are useful in identifying pathologies because T2 images have better contrast between water (high proton density) and soft tissue (relatively less proton density).⁴³⁻⁴⁵

MAGNETIC RESONANCE CONTRAST AGENTS

When a molecule is placed in a magnetic field, it displays a certain susceptibility to becoming magnetized and an ability to alter the magnetic field of the immediate environment into which it has been placed. The ability of a substance to produce additional magnetism within a magnetic field is known as its *susceptibility*. A vacuum has a susceptibility defined as

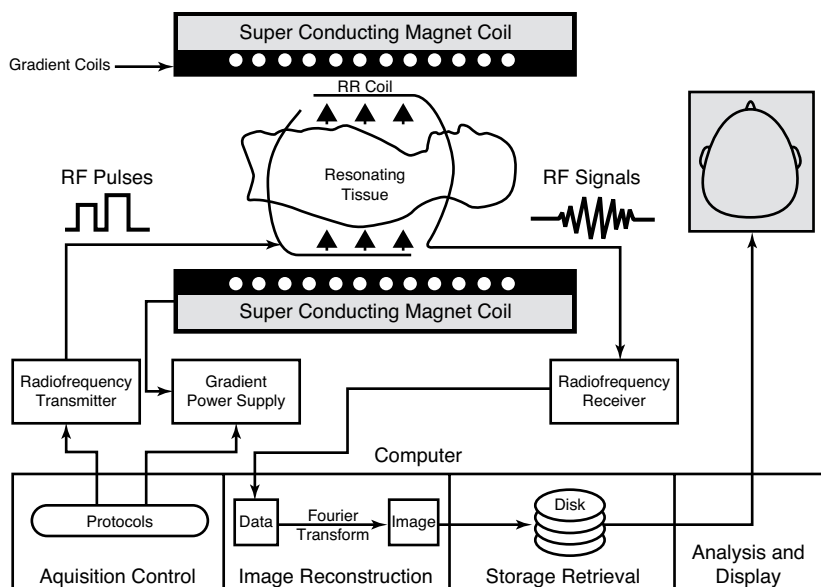

Figure 11.9 • Schematic diagram of an MRI system demonstrating radiofrequency pulses and the strong magnetic field.

zero in comparison with water. Many nonmetallic materials are diamagnetic; they have negative susceptibility and induce weaker magnetic fields in the local environment. Such substances generally have fully paired electrons. Materials with unpaired orbiting electrons are said to be paramagnetic, because when placed in an applied magnetic field, they strengthen the magnetic fields within their vicinity. The magnitude of paramagnetic influence is proportional to the strength of the applied field. A substance with many unpaired electrons will be superparamagnetic, because it produces a stronger supplementary magnetic field. Ferromagnetic materials have very large numbers of unpaired electrons and produce a large, supplementary magnetization to the applied field that remains once the magnetic field has been removed.

Gadolinium-containing contrast agents rely on unpaired electrons to produce magnetic changes in nearby water molecules. These paramagnetic agents predominantly decrease tissue T1 relaxation time, which increases tissue intensity on T1-weighted images. Such agents are known as positive contrast agents because they brighten tissues associated with the nearby paramagnetic substance.

Many contrast agents used for MRI are extracellular paramagnetic agents. The primary paramagnetic metal ion used is gadolinium, a rare earth element. Gadolinium ions (Gd^{+3}) form when prepared in 0.05 M hydrochloric acid and are extremely effective for enhancing water proton relaxation rates. The ion itself, however, is toxic for human use. The ion quickly binds to ferric (Fe^{+3}) protein-binding sites, most notably plasma transferrin, and has a long biological half-life of several weeks. In addition, the ion readily forms insoluble compounds by interacting with endogenous ions including phosphate, carbonate, and hydroxide.⁴⁶

Consequently, the development of gadolinium MRI contrast agents has mainly focused on chelated compounds that clear rapidly from the body through the kidneys and exhibit minimal toxicity. These include gadobenate dimeglumine (MultiHance), gadodiamide (Omniscan), gadopentetate dimeglumine (Magnevist), gadoteridol (ProHance), and gadoversetamide (Optimark).⁴⁷

All intravenous gadolinium complexes are hypertonic when compared with plasma. The most common side effects

are headache, nausea, dizziness, taste perversions, and vasodilation. A rare adverse event, nephrogenic systemic fibrosis, is more likely to occur in patients with severe acute or chronic renal insufficiency (<30 mL/min). Postmarketing reports identified such an event following single and multiple administrations of gadolinium-based contrast agents. These reports have not always identified a specific agent, and repetitive administration of the same or different agents carries similar risk if the time interval between the administrations precludes clearance of the contrast agent from the body.^{48,49}

Manganese (Mn^{2+}) is strongly paramagnetic and can be used to form complexes used as MRI contrast agents. At this time, the only parenteral manganese compound used in humans is mangafodipir trisodium. This compound is delivered to tissues with active metabolism, such as the pancreas, renal cortex, GI tract, heart, and adrenal glands. The effect of mangafodipir trisodium is to decrease T1 relaxation time, which enhances signal intensity on T1-weighted images.

Superparamagnetic iron oxide colloids (SPIO) contain a crystalline core composed of iron oxide complexes. The core may be coated with dextran, siloxanes, or another large polysaccharide. The particles vary in size from 1 and 10 μm , and their biological characteristics can be altered by changing their coating. Large particles accumulate in the liver and spleen, whereas smaller particles remain in the circulation longer and tend to aggregate in lymph nodes. Ferumoxides and ferumoxsil are examples of such agents.

Because the main MRI effect of the iron oxide particles is on T2-weighted images, they decrease the signal intensity of the tissue in which they accumulate. Such iron oxide agents are known as negative contrast agents, because they darken tissues associated with the accumulation of ferromagnetic particles. Enhancement of T1-weighted images is less dramatic, but can be obtained. SPIO contrast agents provide enhancement of the liver and/or spleen when injected intravenously or the bowel when administered orally.⁵⁰

Ferumoxides (Feridex). Ferumoxides is a black to reddish brown aqueous colloid of SPIO particles associated

Gadobenate Dimeglumine

with dextran. It is administered intravenously and taken up by cells of the reticuloendothelial system (RES). It is indicated to enhance T2-weighted images used to assess lesions of the liver. Hepatic tissues with decreased RES function retain their usual signal intensity, so the contrast between abnormal and normal tissue is enhanced.

Ferumoxsil (GastroMARK). Ferumoxsil is a turbid, slightly viscous, dark brown to orange-brown aqueous suspension of silicone-coated, SPIO for oral administration. The suspension distributes to the stomach and small intestine within 30 to 45 minutes and passes distally to the large intestine within 4 to 7 hours after ingestion. It is indicated to enhance the delineation of the bowel and to distinguish it from organs and tissues that are adjacent to the upper regions of the GI tract. Its usefulness in the distal GI regions is limited by transit time and dilution. Both T1- and T2-weighted images may be enhanced with ferumoxsil.

Gadobenate Dimeglumine (MultiHance). Gadobenate dimeglumine is an ionic, clear, colorless, gadolinium-containing solution. This salt solution has 6.9 times the osmolality of plasma. It is indicated to enhance the visualization of central nervous system (CNS) lesions associated with an abnormal blood-brain barrier or abnormal vascularity of the brain, spine, or associated tissues when using T1-weighted sequences.

Gadodiamide (Omniscan). Gadodiamide is a clear, colorless to slightly yellow, gadolinium-based contrast agent indicated to visualize lesions with abnormal vascularity in the CNS and body. It is a nonionic gadolinium complex administered by intravenous injection with an osmolality of 2.8 times that of plasma. Gadodiamide decreases both the T1 and T2 relaxation times in tissues where it is distributed. In clinical MRI, the effect is prima-

rily on the T1 relaxation time resulting in an increase in T1-weighted sequence signal intensity.

Gadodiamide

Gadopentetate Dimeglumine (Magnevist). Gadopentetate dimeglumine is an ionic, clear, colorless to slightly yellow, gadolinium-based contrast agent indicated to visualize lesions with abnormal vascularity in the CNS and body. This salt solution has 6.9 times the osmolality of plasma. Like other gadolinium-based contrast agents, the primary clinical effect is on T1 relaxation time.

Gadoteridol (ProHance). Gadoteridol is a nonionic clear, colorless to slightly yellow, gadolinium-based contrast agent indicated to visualize lesions with abnormal vascularity in the CNS, head, and neck. It is a hypertonic solution with an osmolality of 2.2 times that of plasma. Clinical enhancement of images occurs primarily when using T1-weighted sequences.

Gadopentetate dimeglumine

Gadoteridol

Gadoversetamide (OptiMARK). Gadoversetamide a nonionic clear, colorless to slightly yellow, gadolinium-based contrast agent indicated to visualize lesions with abnormal vascularity of the CNS or liver. It is a hypertonic solution with an osmolality of 3.9 times that of plasma. The primary clinical effect is on T1 relaxation time.

Mangafodipir Trisodium (Teslascan). Mangafodipir trisodium is a clear bright to dark yellow chelate of paramagnetic manganese for intravenous administration. Manganese is distributed to the liver and pancreas and shortens the T1-weighted relaxation time. It is indicated to detect metastatic lesions of the liver, focal pancreatic lesions, and hepatocellular carcinoma.

Gadoversetamide

Mangafodipir

Figure 11.10 • A portable ultrasound system. (Reprinted with permission from Bushberg, J. T., et al.: *The Essential Physics of Medical Imaging*, 2nd ed. Philadelphia: Lippincott Williams and Wilkins, 2002.)

Ultrasound Imaging

Diagnostic ultrasound imaging uses high-frequency sound waves from 1 to 20 MHz to produce cross-sectional images of the body. A small handheld transducer connected to a larger ultrasound unit is used to scan the body part of interest (e.g., the abdomen), and the resultant images are displayed on a monitor in real time (Fig. 11.10). Images may be stored digitally or printed later on film. Various body tissues reflect the sound waves in characteristic fashion, and diagnostic ultrasound is similar to the sonar imaging used by aquatic mammals and submarines. Differing tissues (e.g., the liver and the right kidney) have different acoustic properties. At the interface between tissues with different acoustic properties, the sound waves are reflected back to the transducer and are displayed on the screen, showing the tissues as well as the tissue interface. Unfortunately, gas-containing structures (lungs, bowel) as well as bones either absorb or scatter most of the sound waves and are not usually imaged satisfactorily by ultrasound. Solid organs (liver, spleen, kidneys), organs containing fluid (heart, gallbladder, urinary bladder), blood vessels, fatty tissue, and muscles, however, are usually amenable to diagnostic sonographic imaging.

Ultrasound finds widespread application in diagnostic radiology, obstetrics, gynecology, and cardiology because it produces diagnostic results comparable or even superior in some cases to other imaging techniques that require the use of

ionizing radiation. Ultrasound machines are often portable and may be taken to the patient's bedside. Moreover, diagnostic ultrasound has no known harmful effects.

ULTRASOUND CONTRAST AGENTS
