A report describes a child being given **cytarabine** and **daunorubicin** who developed significant bradycardia after receiving a bolus dose of propofol.[3]

Mechanism

Both cytarabine and propofol may cause bradycardia by blocking the sinoatrial node, and an additive or synergistic effect may have caused the bradycardia in the child described above.[3]

Importance and management

The general applicability of these reports remains to be determined. The use of propofol alone may cause pain and it should be noted that the manufacturer of propofol recommends that local pain associated with propofol during the induction phase can be minimised by the use of the larger veins on the forearm and antecubital fossa.[4]

Antineoplastics + Protease inhibitors

There is limited evidence that the incidence of chemotherapy-induced toxicities (with CDE or CHOP regimens) might be increased by protease inhibitor-based antiretroviral therapy; however, there is also limited evidence of a lack of increased toxicity. Cyclophosphamide clearance might be modestly reduced by protease inhibitor-based therapy, whereas doxorubicin pharmacokinetics do not seem to be affected. Indinavir levels were modestly increased by CHOP chemotherapy (cyclophosphamide, doxorubicin and vincristine).

Clinical evidence

(a) CDE

When compared with historical controls, the mucositis experienced by 12 patients who were receiving **saquinavir** and CDE (**cyclophosphamide**, **doxorubicin** and **etoposide**) was more severe than without **saquinavir** (grade 3 or 4, 67% versus 12%). However, the use of **saquinavir** was not associated with an effect on haematological toxicity (myelosuppression, neutropenia). All patients also received stavudine and 10 also received didanosine.[1]

In a retrospective study in 46 patients with HIV-associated non-Hodgkin's lymphoma who had been receiving CDE, the incidence of neutropenia and infection in those also taking protease inhibitor-based antiretroviral regimens was compared with that of regimens without protease inhibitors. Eleven patients were taking protease inhibitor-based antiretroviral treatment (not specifically named) and 35 were receiving non-protease inhibitor regimens (mostly NNRTI-based). There was a higher incidence of infections requiring hospitalisation in the group taking a protease inhibitor than in the NNRTI-based treatment group (48% compared with 25%). There was a similar difference in the incidence of grade 4 neutropenia (54% compared with 38%), and day-10 and day-14 neutrophil counts were significantly lower in patients receiving protease inhibitors, resulting in delays in giving chemotherapy in 16% of cycles (compared with 9% with NNRTIs). Overall, however, there was no difference in response rate, disease-free survival or overall survival between the two groups.[2]

Conversely, in an earlier study in 98 patients who had received CDE for HIV-associated non-Hodgkin's lymphoma, those patients receiving a protease inhibitor and two nucleoside analogues experienced less toxicity (including grade 4 neutropenia and infections) than the 43 patients who received didanosine alone (these were patients treated early on in the study, before combined antiretroviral regimens became accepted practice).[3]

(b) CHOP

When compared with historical controls, the clearance of cyclophosphamide, as part of CHOP (**cyclophosphamide**, **doxorubicin** and **vincristine**) was about 35 to 40% lower in a study in patients taking stavudine, lamivudine and **indinavir**. There was no significant difference in the clearance of doxorubicin, and no significant difference in **indinavir** levels. Excessive haematological toxicity was not noted when compared with historical controls.[4]

Conversely, in a retrospective study, there was a higher incidence of anaemia, a need for colony-stimulating factor support, and neurotoxicity in patients who received antiretrovirals (most including protease inhibitors) with CHOP compared with those receiving CHOP alone.[5] Nevertheless, in a subsequent crossover study by this research group, no significant changes were noted in the pharmacokinetics of doxorubicin, given as part of CHOP, during a cycle when given with antiretrovirals, when compared with a cycle when no antiretrovirals were given. In addition, when analysed by the protease inhibitors given, **indinavir**, **nelfinavir**, or **saquinavir**, the pharmacokinetics of doxorubicin did not differ.[6]

In a prospective study, in 7 patients receiving indinavir-based antiretroviral therapy the **indinavir** AUC was 38% higher when they were receiving CHOP than when they were not (either before CHOP or 2 weeks after the last CHOP cycle). However, the **indinavir** plasma levels with CHOP were the same as those expected from historical controls given indinavir alone, whereas the levels of **indinavir** given without CHOP were lower than expected. There was a trend towards higher **nelfinavir** plasma levels in 3 patients who also received CHOP when compared with **nelfinavir** alone.[7]

(c) Hyper-CVAD

In a study in patients with AIDS-associated Burkitt lymphoma or acute lymphoblastic leukaemia, the incidence of toxicity with the use of hyper-CVAD (**cyclophosphamide**, **dexamethasone**, **doxorubicin** and **vincristine** alternating with **methotrexate** and **cytarabine**) given with antiretrovirals (including **amprenavir**, **indinavir**, **nelfinavir**, or **ritonavir**) was similar to that usually seen with this regimen when used in HIV-negative patients.[8]

Mechanism

Unknown. It has been speculated that protease inhibitors might reduce the metabolism or transport of antineoplastics by inhibiting cytochrome P450 enzymes or P-glycoprotein, and thereby increase the toxicity of chemotherapy.[2]

Importance and management

No interaction is established. None of these studies on the possible effect of protease inhibitors on the toxicity of CDE or CHOP were randomised prospective studies, therefore the findings are difficult to interpret, especially as they differ in whether they found toxicity to be increased, and which toxicities in particular were assessed. There is limited evidence that cyclophosphamide clearance might be modestly reduced by protease inhibitor-based therapy, although the relevance of this is uncertain since no increase in toxicity was noted. In one prospective study, the pharmacokinetics of doxorubicin were not altered by protease inhibitor-based antiretroviral regimens. In another, indinavir levels appeared to be modestly raised by CHOP, but the increase seen was unlikely to be clinically relevant.

For the lack of effect of protease inhibitors on the pharmacokinetics of liposomal daunorubicin, see 'Anthracyclines; Daunorubicin + Protease inhibitors', p.700. For limited evidence that the toxicity of taxanes and irinotecan might be increased by protease inhibitors, see 'Taxanes + Protease inhibitors', p.769, and 'Irinotecan + Protease inhibitors', p.740.

Antineoplastics + Semaxanib

The combination of semaxanib, cisplatin and gemcitabine has caused an unexpectedly high incidence of thromboembolic events.

Clinical evidence, mechanism, importance and management

The pharmacokinetics of semaxanib (SU5416), **cisplatin** and **gemcitabine** were unaltered when they were given together in a phase I study but investigation of the combination was terminated after 8 of the 19 patients had thromboembolic events (transient ischaemic attacks, cerebrovascular accidents, deep vein thromboses). **Gemcitabine** 1250 mg/m^2 was given on day one, immediately followed by **cisplatin** 80 mg/m^2, then semaxanib 85 mg/m^2 (escalated to 145 mg/m^2 in some patients). **Gemcitabine** then semaxanib were given on day 8, and semaxanib alone on days 4, 11, 15, and 18. The cycle was repeated every 3 weeks.[1] The incidence of thromboembolic events in this study (42%) was much higher than that seen with **cisplatin** and **gemcitabine** (0%) or semaxanib alone (2.2%), and was thought to be a result of the drug combination.[1] **Cisplatin** in particular, due to its effects on platelets and its vasoconstrictive effects, may be the drug interacting with the semaxanib.[2] Preliminary results of other studies of semaxanib with: **irinotecan**; **fluorouracil** and folinic acid; **irinotecan**, **fluorouracil** and folinic acid; or **paclitaxel** and **carboplatin** did not report this complication.[3-6] The authors of the first study[1] caution against further clinical studies of antineoplastics with angiogenesis inhibitors such as semaxanib until the exact cause of the thromboembolic events has been elucidated.

Antineoplastics + Tamoxifen

Antineoplastics and tamoxifen are associated with an increased risk of thrombosis and there is the possibility that their combined use may further increase this risk.

Clinical evidence

A retrospective analysis of data from various Eastern Cooperative Oncology Group studies suggested that venous thromboembolic complications were more common in women given tamoxifen with adjuvant chemotherapy (CMF; **cyclophosphamide**, **methotrexate**, **fluorouracil**) than women given CMF alone (3.8% versus 0% in one study).[1] In another study of patients given tamoxifen 30 mg daily for 2 years the incidence of thromboembolic events was 2.6% compared with 13.6% in those also given 8 cycles of CMF. The authors of this study considered the rate of thromboembolic events with the combination to be higher than that usually seen

with CMF, and suggested that this occurred as a result of an interaction between tamoxifen and CMF.[2] In contrast, in another study, in the first 12 weeks of therapy, thrombosis occurred in 5 of 103 patients given tamoxifen with chemotherapy (**cyclophosphamide**, **methotrexate**, **fluorouracil**, **vincristine**, prednisone, **doxorubicin**) compared with 4 of 102 given the same chemotherapy alone, suggesting that tamoxifen made no significant contribution to the rate of thromboembolic events.[3]

Mechanism

Tamoxifen alone is known to carry a small risk of thromboembolic events when used for primary prevention of breast cancer,[4] which may be a result of tamoxifen causing an increased calcium uptake by platelets, leading to platelet activation.[5] Antineoplastic chemotherapy also increases the risk of thrombosis,[3] and cancer *per se* increases the risk, as does surgery for cancer.[6]

Importance and management

To what extent, if any, tamoxifen further increases the risk of thrombosis with cytotoxic antineoplastics is unclear from the above studies. However, some authors recommend that serious consideration be given to the use of prophylactic anticoagulants if adjuvant CMF is given with tamoxifen in women with breast cancer,[2] and the UK manufacturer endorses this for any adjuvant chemotherapy.[7] This may be prudent with antineoplastic chemotherapy in any case.

Antineoplastics + Vaccines

The immune response of the body is suppressed by cytotoxic antineoplastics. The effectiveness of vaccines may be poor, and generalised infection may occur in patients immunised with live vaccines.

Clinical evidence, mechanism, importance and management

As cytotoxic antineoplastics are immunosuppressant, they reduce the response of the body to immunisation. A study[1] in 53 patients with Hodgkin's disease found that chemotherapy reduced the antibody response to a **pneumococcal vaccine** by 60% when measured 3 weeks after immunisation. The patients were taking **chlormethine** (mechlorethamine), **vincristine**, prednisone and **procarbazine**. A few of them had also been given **bleomycin**, **vinblastine** or **cyclophosphamide**. Subtotal radiotherapy reduced the response by a further 15%.

The response to **influenza immunisation** in children with various malignancies was also markedly suppressed by chemotherapy. The regimen included prednisone and the cytotoxic drugs **mercaptopurine**, **methotrexate**, and **vincristine**. Some of them were also given **dactinomycin** and **cyclophosphamide**.[2] In another study only 9 out of 17 children with leukaemia or other malignant diseases and taking **methotrexate**, **cyclophosphamide**, **mercaptopurine** and prednisone developed a significant response to immunisation with **inactivated measles vaccine**.[3]

Furthermore, immunisation with **live vaccines** may result in a potentially life-threatening infection. For example, a woman taking **methotrexate** 15 mg once a month for psoriasis developed a generalised vaccinial infection after vaccination against **smallpox**.[4] Studies in *animals* given **smallpox vaccine** confirmed that they were more susceptible to infection if they had been given **methotrexate**, **mercaptopurine** or **cyclophosphamide**.[5]

Live vaccines should not be given to patients who are receiving cytotoxics or other immunosuppressant antineoplastics. The UK Department of Health states that live vaccines should not be given during or within at least 6 months of treatment with immunosuppressive chemotherapy or radiotherapy for malignant disease.[6] Attenuated vaccines are also unlikely to be used during cytotoxic chemotherapy, but, bear in mind that they might have reduced efficacy if they have to be given.

Bevacizumab + Miscellaneous

Bevacizumab did not alter the pharmacokinetics of capecitabine, cisplatin, interferon alfa-2a, irinotecan and its active metabolite, SN-38, or oxaliplatin. A possible association between the use of bevacizumab with sunitinib and microangiopathic haemolytic anaemia has been suggested. There might be an increased risk of congestive heart failure in patients receiving bevacizumab who have previously received cardiotoxic antineoplastics such as the anthracyclines.

Clinical evidence, mechanism, importance and management

(a) Anthracyclines

A case report describes a patient who, after being given bevacizumab and capecitabine, developed severe cardiac failure. She had previously received two different courses of **epirubicin**-based chemotherapy, and also radiotherapy.[1]

Bevacizumab use alone can cause congestive heart failure, principally in patients with metastatic breast cancer, as in this case. The manufacturer notes that the previous use of an anthracycline and/or chest radiation might be a risk factor.[2] Bear this possibility in mind when using bevacizumab. The relation of capecitabine to this case is unknown.

(b) Capecitabine

The manufacturer states that in a study in patients with metastatic colorectal cancer given capecitabine with oxaliplatin, the pharmacokinetics of capecitabine were not significantly altered when bevacizumab was given.[2] For a case of heart failure in a patient receiving capecitabine and bevacizumab, see *Anthracyclines*, above.

(c) Interferon

Bevacizumab had no effect on the pharmacokinetics of interferon alfa-2a in patients with renal cancer.[2]

(d) Irinotecan and IFL

The manufacturers note that, in a specific drug interaction study, bevacizumab did not appear to significantly alter the pharmacokinetics of irinotecan and its active metabolite, SN-38.[2,3] However, the manufacturer of irinotecan states that bevacizumab appeared to increase the plasma levels of SN-38, the active metabolite of irinotecan, by about 33% in patients who received bevacizumab with **irinotecan**, **fluorouracil** and **folinic acid** (IFL), compared with IFL alone, but because there was a wide variability between patients, it is uncertain if this was due to bevacizumab. Nevertheless, more irinotecan dose reductions were needed in the bevacizumab recipients.[4] In addition, there was no difference in the clearance of bevacizumab when it was given with bolus IFL, when compared with its use alone.[2]

(e) Platinum compounds

The manufacturer states that in a study in patients with metastatic colorectal cancer also given capecitabine the pharmacokinetics of **oxaliplatin** were not significantly altered when it was given with bevacizumab. In addition, the pharmacokinetics of **cisplatin** were not affected by bevacizumab in patients with lung cancer.[2]

(f) Sunitinib

In two studies in patients with metastatic renal carcinoma, 7 of 19 patients given bevacizumab 10 mg/kg every 2 weeks and sunitinib 50 mg daily developed microangiopathic haemolytic anaemia, which was reversible upon discontinuation of bevacizumab and sunitinib.[2] It is unclear whether this was related to an interaction of the two drugs, or an adverse effect of either drug alone. Bear the possibility of this effect in mind if these two drugs are used together.

Bexarotene + Miscellaneous

Gemfibrozil raises bexarotene plasma levels. The manufacturers warn that, theoretically, inhibitors of CYP3A4 (azoles, grapefruit juice, protease inhibitors and some macrolides) may possibly raise bexarotene levels, whereas CYP3A4 inducers (phenytoin, phenobarbital, rifampicin (rifampin)) may possibly reduce them. They also suggest that the efficacy of hormonal contraceptives may be reduced, and increased blood glucose-lowering effects may occur with insulin or oral antidiabetic drugs. Food increases the oral absorption of bexarotene. No interaction seems to occur between bexarotene and atorvastatin or levothyroxine.
Systemic drug interactions are unlikely to occur with topical bexarotene, but it should not be used with topical diethyltoluamide.

Clinical evidence, mechanism, importance and management

(a) CYP3A4 inducers, inhibitors and substrates

Because it is known that bexarotene is metabolised by the cytochrome P450 isoenzyme CYP3A4, the manufacturers point out that there is a theoretical risk that drugs that inhibit CYP3A4 might increase bexarotene levels when it is given orally. They name **clarithromycin**, **erythromycin**, **itraconazole**, **ketoconazole**, **protease inhibitors** and **grapefruit juice**. They also suggest that CYP3A4 inducers, namely **dexamethasone**, **phenytoin** [and therefore probably **fosphenytoin**], **phenobarbital** [and therefore probably **primidone**] and **rifampicin** (**rifampin**), may theoretically increase the metabolism of bexarotene and reduce its levels.[1,2] Note, however, that **dexamethasone** does not usually cause a clinically relevant interaction by this mechanism.

The US manufacturer notes that, based on interim data, the concurrent use of bexarotene capsules and **tamoxifen** reduced the plasma concentrations of tamoxifen by about 35%.[2] They say that this is an indication that bexarotene might induce CYP3A4,[2] and that it may theoretically increase the metabolism of other substances metabolised by CYP3A4 such oral or other systemic **hormonal contraceptives**, thereby reducing both their serum levels and their efficacy.[1,2] For this reason they advise the use of additional non-hormonal contraception (e.g. a barrier method) to avoid the risk of contraceptive failure. They point out that this is particularly important because if failure were to occur, the foetus might be exposed to the teratogenic effects of bexarotene.[1,2]

Due to the low systemic exposure to bexarotene after *topical* use, any increases that occur with CYP3A4 inhibitors are unlikely to be sufficient to result in adverse effects with a low to moderate intensity topical bexarotene regimen.[3]

(b) Diethyltoluamide (DEET)

The manufacturers advise that patients using bexarotene gel should avoid the use of insect repellents containing diethyltoluamide because *animal* studies have shown increased diethyltoluamide toxicity.[3]

(c) Food

Oral administration of bexarotene 75 to 300 mg with a fat-containing meal resulted in an increase in the AUC and maximum plasma level of bexarotene of 35% and 48%, respectively, compared with administration with a glucose solution.[1] It is therefore recommended that bexarotene capsules are taken with food.[1,2]

(d) Other drugs

A population analysis of patients with cutaneous T-cell lymphoma found that the concurrent use of **gemfibrozil** in 3 patients substantially increased the plasma levels of bexarotene after oral administration, and caused dose-limiting hypertriglyceridaemia. The reasons for this effect are unknown, although it was suggested that inhibition of CYP3A4 by **gemfibrozil** may be partially responsible.[4] The manufacturers state that the concurrent use of gemfibrozil with oral bexarotene is not recommended,[1,2] but note that fibrates are not generally recognised as inhibitors of this isoenzyme, see 'Lipid regulating drugs', (p.1313). Under similar conditions, they say that bexarotene levels were not affected by **atorvastatin** or **levothyroxine**. Changes in thyroid function caused by bexarotene have been successfully treated with **thyroid hormones**.[1,2,4]

The manufacturers recommend that because bexarotene is related to **vitamin A**, any **vitamin A** supplements should be limited to 15 000 units or less daily to avoid potentially additive toxic effects.[1-3] They also say that, although no cases of hypoglycaemia have been seen, because of the known mode of action of bexarotene, it should be used with caution if given with **insulin** or drugs that enhance insulin secretion (e.g. **sulfonylureas**) or insulin sensitisers (e.g. **thiazolidinediones**).[1,2] For a list of these drugs see 'Table 13.1', (p.534).

Bicalutamide + CYP3A4 inhibitors or substrates

Bicalutamide is a weak inhibitor of CYP3A4, as assessed by a minor to modest increase in the AUC of midazolam, and is unlikely to result in clinically relevant interactions with CYP3A4 substrates. Nevertheless, the UK manufacturer contraindicates concurrent use with astemizole, cisapride and terfenadine, and cautions use with ciclosporin and calcium-channel blockers. Theoretically, inhibitors of CYP3A4 might increase bicalutamide levels, but there is no evidence of this.

Clinical evidence, mechanism, importance and management

(a) CYP3A4 inhibitors

Bicalutamide is extensively metabolised by the cytochrome P450 enzyme system, possibly by CYP3A4.[1] Although there are no specific data, the manufacturer advises caution when bicalutamide is given with other drugs that may inhibit drug oxidation. They suggest that bicalutamide plasma levels may be increased, which could increase the risk of adverse effects. They specifically name **cimetidine** and **ketoconazole**.[2] However, steady-state levels of bicalutamide are known to vary up to about 15-fold,[1] and there is just one recommended dose of bicalutamide.[2] Any effect of a weak inhibitor of CYP3A4 such as **cimetidine** is therefore very unlikely to be clinically relevant. There does not appear to be any published evidence of any interactions of bicalutamide with drugs that are known inhibitors of CYP3A4.

(b) CYP3A4 substrates

In vitro, the active isomer of bicalutamide is an inhibitor of various cytochrome P450 isoenzymes, particularly CYP3A4. In an early 12-week study with **phenazone** (largely used as an investigational marker drug of enzyme induction or inhibition), there were only minor changes in phenazone pharmacokinetics (half-life reduced by 16% with bicalutamide 50 mg, AUC reduced by 19% with bicalutamide 150 mg. This suggests that clinically bicalutamide has little effect on the cytochrome P450 system.[3]

In a further study, a single oral dose of **midazolam** was given to men who had been randomised to receive bicalutamide 150 mg twice daily or placebo at least 3 months previously.[1] The mean AUC of midazolam was 27% higher,[1] with a maximum increase of 80%,[2] in the bicalutamide recipients, although this difference was not statistically significant.[1] Midazolam is used as a probe drug to assess the effects of CYP3A4, and this study therefore suggests that, clinically, bicalutamide is only a weak CYP3A4 inhibitor, and is unlikely to cause clinically relevant interactions with substrates of this isoenzyme. Nevertheless, the UK manufacturer suggests that an interaction might occur with drugs that have a narrow

therapeutic range. They specifically contraindicate the concurrent use of **astemizole**, **cisapride** and **terfenadine**. They advise caution when bicalutamide is given with **ciclosporin**, and suggest that plasma concentrations of **ciclosporin** should be monitored closely both during and after concomitant treatment. They also advise caution with **calcium-channel blockers**.[2] The US manufacturer[4] advises caution with drugs that are substrates of CYP3A4; however, this seems over cautious. There does not appear to be any published evidence of any interactions of bicalutamide with drugs that are substrates of CYP3A4.

4. Casodex (Bicalutamide). AstraZeneca. US Prescribing information, December 2008.

Bicalutamide + Food

In a study in 15 healthy subjects, there was no clinically relevant difference in bicalutamide pharmacokinetics when a single 50-mg dose of bicalutamide was taken after an overnight fast or after a high-fat cooked breakfast.[1] Bicalutamide can therefore be taken with or without meals.

Bicalutamide + Tamoxifen and other anti-oestrogens

Tamoxifen and anastrozole do not appear to alter bicalutamide levels.

Clinical evidence, mechanism, importance and management

The mean trough levels of *R*- and *S*-bicalutamide did not differ between 7 men taking bicalutamide 150 mg daily alone and men also taking tamoxifen 20 mg daily (7 subjects) or anastrozole 1 mg daily (7 subjects). The plasma levels of tamoxifen and anastrozole were similar to those usually seen. The findings of this small study suggest that tamoxifen and anastrozole do not have a marked effect on bicalutamide pharmacokinetics, although a more minor effect cannot be ruled out.[1]

Bleomycin + Cisplatin

Cisplatin can increase the pulmonary toxicity of bleomycin by reducing its renal excretion. Digital ischaemia and arterial thrombosis have also been described in patients receiving both drugs.

Clinical evidence

Thirty patients with carcinoma of the cervix and 15 patients with germ cell tumours were given combination chemotherapy including bleomycin and cisplatin. Cisplatin was given by infusion on day one, followed by bleomycin given intramuscularly every 12 hours for 4 days or by continuous infusion over 72 hours. Nine of the patients with normal renal function and no previous pulmonary disease developed serious pulmonary toxicity and 6 died from respiratory failure.[1]

In a study of 18 patients given cisplatin and bleomycin for the treatment of disseminated testicular non-seminoma, 2 patients developed pneumonitis, and it was found that the cisplatin-induced reduction in renal function was paralleled by an increase in bleomycin-induced pulmonary toxicity.[2] Similar results were found by the same group in a much larger study of 54 patients.[3] A study in 2 children found that the total plasma clearance of bleomycin was halved (from 39 to 18 mL/minute/m^2) when they were also given cisplatin in cumulative doses exceeding 300 mg/m^2. The renal clearance in one of the children fell by 73% (from 30 to 8.2 mL/minute/m^2) although there was no evidence of severe bleomycin toxicity in either child.[4] Two cases of fatal bleomycin toxicity have been described in patients with cisplatin-induced renal impairment.[5,6]

A case report describes arterial thrombosis associated with pathological vascular changes in the arteries of a man receiving cisplatin, bleomycin and etoposide.[7] Another man developed fatal thrombotic microangiopathy (characterised by microangiopathic haemolytic anaemia, thrombocytopenia, renal impairment), which was attributed to the use of bleomycin and cisplatin.[8]

In an earlier study, digital ischaemia occurred in 41% of patients given cisplatin, bleomycin and vinblastine, compared with 21% of patients given only cisplatin and vinblastine.[9]

Mechanism

Renal excretion accounts for almost half of the total body clearance of bleomycin. Cisplatin is nephrotoxic and reduces the glomerular filtration rate so that the clearance of bleomycin is reduced. The accumulating bleomycin apparently causes the pulmonary toxicity.

Importance and management

Pulmonary toxicity with bleomycin and cisplatin is an established reaction with a potentially serious, sometimes fatal, outcome. Concurrent use should be very closely monitored and renal function checked. One of the problems is that levels of creatinine may not accurately indicate the extent of renal damage both during and after cisplatin treatment. The renal toxicity of cisplatin may also develop rapidly. Other toxic effects on the vascular system can also occur.

Bleomycin + Colony-stimulating factors

The concurrent use of granulocyte colony-stimulating factor or granulocyte-macrophage colony-stimulating factor has been linked with an increased occurrence of bleomycin-induced pulmonary toxicity.

Clinical evidence, mechanism, importance and management

Pulmonary toxicity that developed at low cumulative bleomycin doses (70 to 130 units/m^2) in at least 3 of 5 patients given standard ABVD treatment (doxorubicin, bleomycin, vinblastine, and dacarbazine) was attributed by the author of the report to the synergistic action of the concurrent use of **G-CSF** (granulocyte colony-stimulating factor).[1] In another report 8 out of 40 patients with malignant non-Hodgkin's lymphoma given **G-CSF** developed drug-induced pneumonia. Three of these patients were given chemotherapy regimens including bleomycin (MACOB-B, COP-BLAM III), and all 3 died of respiratory failure. None of 35 other patients, similarly treated but without **G-CSF**, developed pneumonia.[2] Non-infectious interstitial pneumonitis developed in a patient given doxorubicin, cyclophosphamide, bleomycin, vinblastine, methotrexate and prednisone with **GM-CSF** (granulocyte-macrophage colony-stimulating factor).[3] Five further reports have identified a total of 23 other patients who developed bleomycin-pulmonary toxicity probably potentiated by **G-CSF** or **GM-CSF**, including at least 7 fatalities.[4-8]

In contrast, analysis of two placebo-controlled studies of the use of adjuvant **G-CSF** (**filgrastim** or **lenograstim**) with combination chemother-

apy including bleomycin found no evidence of an increase in pulmonary complications. Overall 7 of 139 patients given placebo and 9 of 139 given **G-CSF** had pulmonary complications possibly related to bleomycin.[9,10] Similarly, another retrospective analysis found that 34% of patients given bleomycin and **G-CSF** developed pulmonary toxicity, compared with 33% of those given bleomycin alone.[11]

These interactions are not firmly established, but good pulmonary function monitoring appears to be advisable when colony-stimulating factors are used with antineoplastics causing pulmonary toxicity, such as bleomycin. If interstitial pneumonia occurs, the drugs should be discontinued and high-dose corticosteroids started immediately.[7]

Bleomycin + Oxygen

Serious and potentially fatal pulmonary toxicity can develop in patients given bleomycin who are exposed to conventional oxygen concentrations during anaesthesia.

Clinical evidence

Five patients given bleomycin, exposed to oxygen concentrations of 35 to 42% during and immediately following anaesthesia, developed a severe respiratory distress syndrome and died. Bleomycin-induced pneumonitis and lung fibrosis were diagnosed at post-mortem. Another group of 12 matched patients who underwent the same procedures but with lower oxygen concentrations (22 to 25%) had an uneventful postoperative course.[1]

Another comparative study[2] similarly demonstrated that adult respiratory distress syndrome (ARDS) in patients receiving bleomycin was reduced by a technique allowing the use of lower oxygen concentrations of 22 to 30%. Bleomycin-induced pulmonary toxicity, apparently related to oxygen concentrations, has also been described in other case reports.[3-7] Studies in *animals* have also confirmed that the severity of bleomycin-induced pulmonary toxicity is increased by oxygen.[8-10] However, in two other series of patients given bleomycin and undergoing surgery there was no obvious increase in pulmonary complications despite the use of usual concentrations of oxygen.[11,12]

Mechanism

Not understood. One suggestion is that bleomycin-injured lung tissue is less able to scavenge free oxygen radicals, which may be present, and damage occurs as a result.[3]

Importance and management

An established, well-documented, serious and potentially fatal interaction. It is advised that any patient receiving bleomycin and undergoing general anaesthesia should have their inspired oxygen concentrations limited to less than 30%, and the fluid replacement should be carefully monitored to minimise the crystalloid load. This is clearly very effective because one author has treated 700 patients following these guidelines without a single case of pulmonary failure.[13] It has also been suggested that reduced oxygen levels should be continued during the recovery period and at any time during hospitalisation.[3] If an oxygen concentration equal to or greater than 30% has to be used, the short-term use of prophylactic corticosteroids should be considered. Intravenous corticosteroids should be given at once if bleomycin toxicity is suspected.[3]

Bortezomib + Ciclosporin

Preliminary evidence suggests that patients who have received long-term ciclosporin might be at increased risk of severe neuropathy when given bortezomib.

Clinical evidence

In a review of 24 patients with multiple myeloma who had received bortezomib after relapse following allografting, the incidence of severe peripheral neuropathy was far higher than usually seen in non-transplant patients. Fourteen patients developed neurotoxicity; in 7 patients it was severe and 6 patients required treatment discontinuation as the neurotoxicity did not resolve following a bortezomib dose reduction. In an analysis of possible risk factors, prolonged ciclosporin use (median of 15 months) was found to be a risk factor for the development of severe neurotoxicity.[1]

Mechanism

Ciclosporin can cause neurotoxicity. Bortezomib is also very commonly associated with peripheral neuropathy, which can be dose-limiting. It was suggested that long-term ciclosporin might have caused subclinical neurotoxicity that became apparent after bortezomib was given.[1]

Importance and management

An interaction between bortezomib and ciclosporin is not established, but until more is known, be aware of the possibility of this effect if bortezomib is used in patients taking ciclosporin. The authors also suggest considering using a lower bortezomib dose in these patients.[1] Note that, any patients receiving bortezomib should be carefully monitored for symptoms of neuropathy such as a burning sensation, hyperaesthesia, hypoaesthesia, paraesthesia, discomfort, neuropathic pain or weakness. Patients experiencing new or worsening peripheral neuropathy should undergo neurological evaluation and may require the dose and schedule of bortezomib to be modified.

Bortezomib after allografting in multiple myeloma: association between neurotoxicity and cyclosporine treatment. *Biol Blood Marrow Transplant* (2007) 13, 497–9.

Bortezomib + Miscellaneous

Plasma levels of bortezomib were modestly increased by ketoconazole, and are predicted to be similarly affected by other potent CYP3A4 inhibitors. Omeprazole did not alter bortezomib levels, and no clinically relevant effect was seen with melphalan plus prednisone. Cases of hyper- and hypoglycaemia have been reported in clinical studies in patients taking antidiabetics and bortezomib. Hypotension is common in patients taking bortezomib,

and the effects may be additive if used with antihypertensives or other drugs that can cause hypotension.

Clinical evidence, mechanism, importance and management

(a) Antidiabetics

The manufacturers note that during clinical studies with bortezomib, some patients who were taking oral antidiabetics (none specifically named) experienced hyper- or hypoglycaemia.[1,2] Bortezomib commonly causes hyperglycaemia (sometimes requiring treatment discontinuation[2]) and uncommonly causes hypoglycaemia,[1] and it is therefore likely that this is a drug-disease interaction rather than a drug-drug interaction. The manufacturers advise that patients taking oral antidiabetics may require close monitoring of their blood glucose and adjustment of the dose of antidiabetic drugs accordingly.[1,2]

(b) CYP2C19 inhibitors and substrates

In *in vitro* studies bortezomib is metabolised by cytochrome P450 isoenzymes, including CYP2C19. However, the pharmacokinetics of bortezomib were unaltered in 17 patients who also received **omeprazole**, an inhibitor of CYP2C19.[1,2] Nevertheless, the UK manufacturer continues to advise that patients should be monitored carefully when given bortezomib with other drugs which are inhibitors of CYP2C19, and they name **fluoxetine**.[1] However, note that of the SSRIs, only **fluvoxamine** is an established CYP2C19 inhibitor. For a list of CYP2C19 inhibitors, see 'Table 1.3', (p.6).

The US manufacturer predicts that exposure to CYP2C19 substrates may be increased on the basis of *in vitro* data showing that bortezomib is an inhibitor of this isoenzyme.[2] This requires confirmation.

(c) CYP3A4 inducers

Bortezomib has been shown *in vitro* to be metabolised by cytochrome P450 isoenzymes, including CYP3A4. The manufacturers advise that in the absence of any studies investigating the interaction of bortezomib with inducers of CYP3A4, patients taking such drugs should be closely monitored.[1,2] They specifically name **rifampicin** (**rifampin**).[1]

(d) CYP3A4 inhibitors

The manufacturers note that the AUC of bortezomib was increased by 35% in 12 patients who also took **ketoconazole**, a known inhibitor of the cytochrome P450 isoenzyme CYP3A4. They advise close monitoring when bortezomib is given with **ketoconazole** or other drugs that inhibit CYP3A4, and name **ritonavir**.[1,2] For a list of CYP3A4 inhibitors, see 'Table 1.4', (p.6).

(e) Drugs causing hypotension

Bortezomib commonly causes orthostatic/postural hypotension, which may occur throughout treatment, and not just during administration. The manufacturers advise caution when treating patients receiving drugs known to be associated with hypotension. They say that management of orthostatic hypotension may include adjustment of **antihypertensives**. Patients should be instructed to seek medical advice if they experience symptoms of dizziness, light-headedness or fainting spells.[1,2]

(f) Melphalan with Prednisone

The manufacturers note that data from 21 patients show that the concurrent use of bortezomib with melphalan and prednisone resulted in an increase in the AUC of bortezomib of 17%, which is not considered to be clinically relevant.[1,2] Bortezomib is often used with melphalan and prednisone in patients with multiple myeloma.

Busulfan + Azoles

Itraconazole, but not fluconazole, modestly reduces the clearance of busulfan. There is some limited evidence to suggest that the use of busulfan with ketoconazole may increase the risk of hepatic veno-occlusive disease.

Clinical evidence, mechanism, importance and management

The pharmacokinetics of busulfan were compared in 26 bone marrow transplant patients, who had received busulfan without concurrent antifungal therapy, in 13 similar patients given busulfan with **itraconazole**, and in another 13 patients given busulfan with **fluconazole**. The busulfan clearance was decreased by 20% by **itraconazole** (probably because **itraconazole** inhibits the metabolism of busulfan by the liver) but busulfan clearance was not affected by the **fluconazole**.[1] The expected rise in serum busulfan levels is only likely to be moderate, but until more information is available it would be prudent to monitor for any signs of increased busulfan toxicity if **itraconazole** is used, but no special precautions seem to be needed with **fluconazole**. Concurrent **ketoconazole** has been identified as a possible risk factor for hepatic veno-occlusive disease after the use of high-dose busulfan.[2] Further study is needed to confirm or refute this.

1. Buggia I, Zecca N, Alessandrino EP, Locatelli F, Rosti G, Bosi A, Pession A, Rotoli B, Majolino I, Dallorso A, Regazzi MB. Itraconazole can increase systemic exposure to busulfan in patients given bone marrow transplantation. *Anticancer Res* (1996) 16, 2083–8.
2. Méresse V, Hartmann O, Vassal G, Benhamou E, Valteau-Couanet D, Brugieres L, Lemerie J. Risk factors for hepatic veno-occlusive disease after high-dose busulfan-containing regimens followed by autologous bone marrow transplantation: a study in 136 children. *Bone Marrow Transplant* (1992) 10, 135–41.

Busulfan + Benzodiazepines

Diazepam and lorazepam do not appear to alter the pharmacokinetics of busulfan.

Clinical evidence, mechanism, importance and management

In a study in patients receiving high-dose busulfan, no pharmacokinetic changes were seen in 8 patients given **diazepam**, apart from a steady decline in steady-state serum levels in just one.[1] Similarly, in another study, **lorazepam** did not alter the absorption and clearance of high-dose busulfan in children undergoing stem-cell transplantation.[2] Benzodiazepines may therefore be a suitable alternative to phenytoin for seizure prophylaxis during high-dose busulfan treatment.[2]

1. Hassan M, Öberg G, Björkholm M, Wallin I, Lindgren M. Influence of prophylactic anticonvulsant therapy on high-dose busulphan kinetics. *Cancer Chemother Pharmacol* (1993) 33, 181–6.
2. Chan KW, Mullen CA, Worth LL, Choroszy M, Koontz S, Tran H, Slopis J. Lorazepam for seizure prophylaxis during high-dose busulfan administration. *Bone Marrow Transplant* (2002) 29, 963–5.

Busulfan + Ketobemidone

Ketobemidone may increase busulfan levels.

Clinical evidence, mechanism, importance and management

A patient with acute myeloid leukaemia was given busulfan 1 mg/kg four times daily for 4 days followed by cyclophosphamide for 2 days before bone marrow transplantation. At the time he was also receiving ketobemidone 1 g daily for a rectal fissure. Busulfan plasma levels after the first dose were elevated (AUC increased by about one-third). Later, when the dose of ketobemidone was reduced and morphine substituted, busulfan levels decreased.[1] The authors suggest that ketobemidone should not be used with high-dose busulfan unless monitoring is possible: dose adjustments may be required to prevent busulfan toxicity. An alternative analgesic should be considered.

1. Hassan M, Svensson J-O, Nilsson C, Hentschke P, AL-Shurbaji A, Aschan J, Ljungman P, Ringdén O. Ketobemidone may alter busulfan pharmacokinetics during high-dose therapy. *Ther Drug Monit* (2000) 22, 383–5.

Busulfan + Metronidazole

Metronidazole increases the trough levels of high-dose busulfan, and increases its toxicity.

Clinical evidence

In a study, patients were given oral high-dose busulfan 1 mg/kg every six hours for 4 days (adjusted to achieve a target trough level) as part of a stem cell transplant procedure. It was found that the dose-adjusted trough

levels of busulfan were 87% higher in 5 patients who also received metronidazole 400 mg three times daily than in 10 patients who did not take metronidazole. Furthermore, all 5 patients who had received metronidazole with busulfan developed elevated liver function tests and mucositis, and three developed veno-occlusive disease (moderate to severe in two, with one death). In the 10 patients who did not receive metronidazole, only 3 had elevated liver function tests, one had mucositis, and none had veno-occlusive disease.[1]

In a further group of 9 patients who received busulfan alone for 2 days then in combination with metronidazole for 2 days the trough level of busulfan increased by 78% when given metronidazole.[1]

Mechanism

The reason why metronidazole might increase busulfan levels is unknown, but it might be something to do with glutathione depletion.[1]

Importance and management

Although information is limited, this pharmacokinetic interaction would appear to be established and clinically important. The authors considered that metronidazole should not be given at the same time as high-dose busulfan,[1] and this would appear to be prudent, and is included in some manufacturers' advice.[2] If the drugs are used together in a patient taking conventional dose busulfan, one manufacturer recommends weekly blood counts to detect any increase in toxicity.[2].

1. Nilsson C, Aschan J, Hentschke P, Ringdén O, Ljungman P, Hassan M. The effect of metronidazole on busulfan pharmacokinetics in patients undergoing hematopoietic stem cell transplantation. *Bone Marrow Transplant* (2003) 31, 429–35.
2. Myleran (Busulfan). GlaxoSmithKline UK. UK Summary of product characteristics, October 2006.

Busulfan + Paracetamol (Acetaminophen)

Paracetamol is predicted to decrease the clearance of busulfan

Clinical evidence, mechanism, importance and management

Busulfan is conjugated with glutathione as part of its metabolism, and, as paracetamol is known to reduce the blood levels of glutathione it is predicted to reduce the clearance of busulfan. The manufacturers of busulfan therefore advise caution when paracetamol is given during the 72-hour period before busulfan is given, and during the use of busulfan.[1,2] Note that the clinical relevance of this proposed interaction is unclear, and only the manufacturers of intravenous busulfan appear to mention it.

1. Busilvex (Busulfan). Pierre Fabre Ltd. UK Summary of product characteristics, July 2008.
2. IVBusulfex (Busulfan). Otsuka America Pharmaceutical, Inc. US Prescribing information, August 2009.

Busulfan + Phenytoin

Phenytoin modestly increases the clearance of busulfan and lowers its levels. Subtherapeutic levels of phenytoin may occur in the presence of busulfan.

Clinical evidence

Seven patients receiving high-dose busulfan (1 mg/kg four times daily for 4 days) before bone marrow transplantation had a 19% increase in busulfan clearance, a 16% lower AUC and a shorter half-life (reduced from 3.94 to 3.03 hours) when they were given phenytoin 2.5 to 5 mg/kg daily. A continuous decline in the steady-state plasma levels of busulfan was also seen in 4 of the patients.[1]

In a study in 51 patients given busulfan and prophylactic phenytoin 300 mg daily for 5 days, 3 patients developed convulsions, and plasma phenytoin levels analysed in 2 of them were found to be subtherapeutic.[2]

Mechanism

It seems likely that phenytoin (a well recognised enzyme inducer) increases the metabolism of busulfan by the liver (possibly by induction of glutathione-S-transferase), thereby decreasing its levels. In an *animal* study, phenytoin was found to reduce the myelosuppressive effects of busulfan.[3]

Importance and management

Evidence for an interaction between phenytoin and busulfan appears to be limited to these two reports. However, the effects of phenytoin on busulfan are in line with the way phenytoin is known to interact with a number of other drugs, so an interaction would appear to be established. The authors of one study suggest that antiepileptics with fewer enzyme-inducing properties than phenytoin should be used as prophylaxis if busulfan is given for bone marrow transplant pretreatment.[1] One UK manufacturer recommends prophylaxis with a benzodiazepine rather than phenytoin if high-dose busulfan is given.[4] Clobazam has been suggested as a possible alternative to phenytoin.[5] Lorazepam and diazepam appear not to interact with busulfan (see 'Busulfan + Benzodiazepines', p.709) and they may therefore be suitable alternatives. The UK manufacturer of parenteral busulfan found no evidence that phenytoin increased its clearance, and notes that all adult patients given busulfan also received phenytoin.[6] However, the US manufacturer of parenteral busulfan gives a dose assuming that phenytoin will also be given, and notes that if other antiepileptics are used instead, the busulfan plasma levels may be increased and monitoring is recommended.[7]

To overcome the problem of reduced phenytoin levels, the authors recommended a loading dose of phenytoin 18 mg/kg on the day before the first dose of busulfan, then 300 mg daily until 48 hours after the last busulfan dose. A further loading dose was given if the phenytoin level was subtherapeutic 48 hours after the initial dose (required in 35% of patients).[2]

Busulfan + Tioguanine

The long-term use of busulfan with tioguanine appears to increase the risk of nodular regenerative hyperplasia of the liver, portal hypertension and oesophageal varices.

Clinical evidence, mechanism, importance and management

Five patients receiving continuous busulfan 2 mg and tioguanine 80 mg five days weekly for chronic myeloid leukaemia (CML) developed oesophageal varices and abnormal liver function tests. Three of them had gastrointestinal haemorrhages and one died. Liver biopsy of 4 of the patients showed nodular regenerative hyperplasia, which was the cause of portal hypertension and varices.[1] A later analysis of the Medical Research Council study comparing busulfan with busulfan and tioguanine in 675 patients with CML, revealed a total of 18 cases of portal hypertension and oesophageal varices (including 4 described in the first report[1]), all 18 of which occurred in patients receiving both drugs. In addition, there was no survival advantage with the combination.[2] The risk of portal hypertension may be related to the long-term use of tioguanine, or to its combination with busulfan. It has been suggested that this drug combination should not be routinely used for the long-term maintenance of CML.[2]

Cetuximab + Irinotecan

No pharmacokinetic interaction occurs between cetuximab and irinotecan.

Clinical evidence, mechanism, importance and management

Cetuximab is used with irinotecan in the treatment of metastatic colorectal cancer. In a study, 14 patients with advanced epidermal growth factor responsive (EGFR) positive adenocarcinoma were given either irinotecan 350 mg/m^2 every 3 weeks and cetuximab 400 mg/m^2 at week 2 then 250 mg/m^2 each week, or cetuximab each week starting at week one and irinotecan starting at week 4. There was at least a one-hour period between the end of the cetuximab infusion and the start of the irinotecan infusion. No evidence was found of a pharmacokinetic interaction between cetuximab and irinotecan, nor was there any significant increase in serious toxicities for the combination, when compared with treatment with either drug alone.[1] Similar results were found in a crossover study in 8 patients who received irinotecan 350 mg/m^2 every 3 weeks and cetuximab 400 mg/m^2 on day 2, then 250 mg/m^2 each week.[2]

Chlorambucil + Prednisone

An isolated report describes seizures in a patient, which were possibly caused by the use of chlorambucil with prednisone.

Clinical evidence, mechanism, importance and management

A patient with non-Hodgkin's lymphoma experienced a syncopal episode with generalised tonic-clonic seizures 8 days after completing an initial 5-day course of chlorambucil 12 mg daily and prednisone 50 mg daily. The seizures were controlled with intravenous clonazepam. Four weeks later, on the third day of a second course, she again had generalised tonic-clonic seizures, which resolved spontaneously.

Chlorambucil-induced seizures have occurred in children with nephrotic syndrome. Cases in adults usually involve high-dose chlorambucil or are in patients with a history of seizures. The seizures in this patient may have been due to the additive effects of both drugs in reducing the seizure threshold.[1]

Note that chlorambucil and prednisone or prednisolone have been widely used together, but this case report highlights the need to assess the risk of seizures when giving drugs that lower the seizure threshold.

Cisplatin and other platinum compounds + Aminoglycosides

The renal toxicity of cisplatin is potentiated by aminoglycosides such as gentamicin and tobramycin. In one retrospective analysis in patients taking cisplatin, hearing loss was not associated with the concurrent use of ototoxic drugs, including tobramycin.

Clinical evidence

(a) Hypomagnesaemia

Both cisplatin and the aminoglycosides can cause excessive loss of magnesium, and it has been suggested that combined use increases this loss.[1]

(b) Nephrotoxicity

Early after the introduction of cisplatin it became apparent that aminoglycosides could increase the nephrotoxicity of this drug. In one report, 4 patients given cisplatin, in doses ranging from low to very high (eight doses of 0.5 mg/kg, one or two doses of 3 mg/kg or a single-dose of 5 mg/kg), and who were subsequently given **gentamicin** and cefalotin developed acute and fatal renal failure. Autopsy revealed extensive renal tubular necrosis.[2] Two similar cases of severe renal toxicity, attributed to the use of **gentamicin** and cefalotin in patients who had previously been given cisplatin, are described elsewhere.[3,4] Another patient given cisplatin and **gentamicin** developed acute renal failure.[5] A further 3 patients given cisplatin then **gentamicin** or **tobramycin** had greater decreases in creatinine levels than 12 others receiving cisplatin alone.[5] A retrospective comparative study confirmed that the incidence of abnormal renal function was higher in patients who had received cisplatin and an aminoglycoside than in patients who had received cisplatin alone (12 of 17 versus 19 of 50 patients, respectively), but the renal impairment was described as usually mild and not clinically significant.[6] Similarly, a brief report stated that aminoglycoside use was associated with a greater decline in renal function in children receiving high-dose cisplatin.[7] There is also evidence from a study in children to show that previous treatment with cisplatin is a risk factor for the delayed elimination of aminoglycosides (**gentamicin**, **amikacin**, **tobramycin**).[8]

Conversely, in another study, aminoglycosides were not found to be a significant factor in the development of renal impairment after the use of high-dose cisplatin-based therapy, and use of appropriate supportive care (hydration and mannitol diuresis) probably played a part in this.[9]

(c) Ototoxicity

In one small retrospective analysis of patients with cancer, the risk of developing hearing loss after low-dose, slow-infusion cisplatin did not correlate significantly with the concurrent use of other ototoxic drugs, such as furosemide or **tobramycin**.[10] Enhanced renal toxicity and ototoxicity have been reported in *guinea pigs* given cisplatin and **kanamycin** for 2 weeks.[11] In another *animal* study **gentamicin** was given for 14 days. A single dose of cisplatin given early in the course enhanced the ototoxic effects of **gentamicin** but no increase in ototoxicity occurred when cisplatin was given at the end of the **gentamicin** course.[12]

Mechanism

Cisplatin (and other platinum compounds such as **carboplatin**) are nephrotoxic and it would appear that its damaging effects on the kidney are additive with the nephrotoxic effects of the aminoglycoside. Both gentamicin and cisplatin may cause ototoxicity.[13] Previous exposure to cisplatin may delay the elimination of the aminoglycosides.

Importance and management

An established and potentially serious interaction. However, aminoglycosides remain an important group of antibacterials for the empirical treatment of febrile neutropenia in patients receiving chemotherapy,[14,15] including cisplatin-based regimens. However, in selecting an initial antibacterial regimen, it has been suggested that concurrent use of some drugs, including cisplatin and aminoglycosides, should be avoided if possible because of additive renal toxicity.[16] Good supportive care is required (e.g. pre and post-treatment hydration with mannitol diuresis), and renal function should be well monitored. Audiometric tests should be carried out when cisplatin is used, particularly when other ototoxic drugs are also given. Similar precautions would seem advisable with **carboplatin**.

Cisplatin + Cannabis

A case report describes a fatal stroke when a young man receiving cisplatin smoked cannabis.

Clinical evidence, mechanism, importance and management

A 27-year-old man who smoked cannabis and tobacco daily developed tinnitus and paraesthesias after receiving the first course of chemotherapy consisting of cisplatin, etoposide and bleomycin for testicular cancer. Following the second course of chemotherapy, the patient reported distal paresis of the right arm and, 2 days later, about 30 minutes after cannabis inhalation, he developed headache, paresis of his right leg and aphasia. A large thrombus was found in the carotid artery. The patient died the next day. He had no cardiovascular risk factors apart from the smoking (about 4 cigarettes per day).[1]

Cisplatin is known to carry a small risk of stroke, and cases have also been reported for cannabis smoking alone. In this case it was suggested that the use of cannabis may have also contributed to the adverse outcome in this patient.[1] It might be prudent for patients receiving cisplatin to avoid smoking cannabis.

Cisplatin + Diuretics

A single report describes the development of renal failure in a patient given furosemide and other antihypertensives during the use of cisplatin. However, note that furosemide can be used to promote diuresis in patients given cisplatin to reduce the risk of nephrotoxicity. A small retrospective review found that cisplatin-induced nephrotoxicity was associated with hydrochlorothiazide use. Although *animal* studies show that the damaging effects of cisplatin on the ear can be markedly increased by the concurrent use of etacrynic acid or furosemide a retrospective analysis in patients did not find this effect.

Clinical evidence, mechanism, importance and management

(a) Nephrotoxicity

1. Loop diuretics. Three hours after receiving intravenous cisplatin 70 mg/m^2 a patient experienced severe nausea and vomiting and his blood pressure rose from 150/90 mmHg to 248/140 mmHg. This was managed with **furosemide** 40 mg intravenously, hydralazine 10 mg intramuscularly, diazoxide 300 mg intravenously and propranolol 20 mg orally twice daily for 2 days. Nine days later the patient had evidence of renal impairment (creatinine raised from about 88 micromol/L to 283 micromol/L), which resolved within 3 weeks. The patient was subsequently similarly treated on two occasions with cisplatin and again developed hypertension, but no treatment was given and there was no evidence of renal impairment.[1]

The reasons for the renal impairment are not known, but a study in *rats*[2] indicates that kidney damage may possibly be related to the concentrations of cisplatin, and that **furosemide** can increase cisplatin levels in the kidney. However, another study in patients found that there was no difference in the toxicity or pharmacokinetics of cisplatin when **furosemide** was used to induce diuresis, compared with mannitol.[3] Two other studies have also found that **furosemide** does not alter cisplatin pharmacokinetics.[4,5] Another study found that sodium chloride solution with or without **furosemide** was associated with less cisplatin nephrotoxicity than sodium chloride solution with mannitol.[6]

For **furosemide**, information seems to be limited to the case cited and its general clinical importance is uncertain. Although mannitol is by far the more usual drug used to induce diuresis during the use of cisplatin in order to reduce the risk of nephrotoxicity, **furosemide** may also be used for this indication.[7]

2. Thiazides. A retrospective review of 62 patients who had received cisplatin found that there was an association between those patients who had also received **hydrochlorothiazide**, and those who developed nephrotoxicity (an increase in serum creatinine of about 44 micromol/L or more). All 5 patients who had taken **hydrochlorothiazide** developed nephrotoxicity after one cycle of cisplatin.[8] It was suggested that hydrochlorothiazide and cisplatin might have additive effects on renal magnesium wasting. The mechanism for any of these associations is unclear.

The data from these sorts of analyses require confirmation in a controlled study, because it is possible that the findings are due to chance alone. The general relevance of this report is therefore uncertain.

(b) Ototoxicity

Both cisplatin and loop diuretics (particularly **etacrynic acid**) given alone can be ototoxic in man. A study[9] in *guinea pigs* found that when cisplatin 7 mg/kg or **etacrynic acid** 50 mg/kg were given alone their ototoxic effects were reversible, but when given together the damaging effects on the ear were profound, prolonged and possibly permanent. Similarly, while cisplatin-induced ototoxicity was potentiated by **furosemide** in *guinea pigs* in one study[10] in another this was only seen when a very high dose of **furosemide** was used.[11] In one small retrospective analysis of patients with cancer, the risk of developing hearing loss after low-dose slow-infusion cisplatin did not correlate significantly with concurrent use of other ototoxic drugs, such as **furosemide**.[12] Audiometric tests should be carried out when cisplatin is used, and this is of particular importance when other ototoxic drugs are also given.

Cisplatin + H_2-receptor antagonists

Cimetidine and ranitidine probably do not have a clinically relevant effect on the renal clearance of cisplatin.

Clinical evidence, mechanism, importance and management

Some *animal* studies have shown that organic cations such as **cimetidine** and **ranitidine** may compete with the renal tubular transport of cisplatin and thus could be useful in reducing cisplatin nephrotoxicity.[1,2] However, in a study of 10 children receiving cisplatin, **ranitidine** had no effect on the total body disposition or renal clearance of cisplatin. This finding and further studies in *dogs* showed that cisplatin may not share transport systems with organic cations to a clinically relevant extent.[3] Although information is limited, it appears that there is no pharmacokinetic interaction between cisplatin and **cimetidine** or **ranitidine**.

Cisplatin + Probenecid

The available clinical data suggest that the nephrotoxicity of cisplatin is reduced by probenecid, but uncertainty remains.

Clinical evidence, mechanism, importance and management

In a randomised study in patients with cancer, probenecid 2 to 4 g daily reduced the fractional clearance of free platinum after a single 60- to 100-mg/m^2 dose of cisplatin given as a 24-hour infusion, and no cases of renal impairment were seen.[1] Similarly, in a further phase I dose-escalation study, no renal impairment was seen in patients given cisplatin at doses from 100 to 160 mg/m^2 when they were also given probenecid 1 g every 6 hours for 12 doses (beginning 24 hours before the cisplatin infusion, and continuing for 24 hours after).[2] It was concluded that probenecid may protect against cisplatin-induced renal toxicity. An earlier study in *rats* had also suggested that giving probenecid before cisplatin reduced nephrotoxicity, as assessed by blood urea levels and serum creatinine.[3] Subsequently, a study in *dogs* has found that probenecid decreases the renal clearance of free cisplatin,[4] and another study in *mice* found that probenecid reduces the renal tubular damage seen with cisplatin alone.[5]

Conversely, some researchers have suggested that the combination of probenecid and cisplatin is potentially more toxic than cisplatin alone. They found that probenecid increased the fractional clearance of free platinum from cisplatin in *rats*, and that pretreatment with probenecid increased nephrotoxicity, as assessed by blood urea levels.[6] Other authors similarly reported that probenecid increased cisplatin clearance in *rats*.[7]

It is unclear why some *animal* studies show that probenecid increases cisplatin-induced nephrotoxicity whereas others show a decrease. Although the available clinical data suggest that there is a decrease, some uncertainty remains. The combination should be used with caution.

Cyclophosphamide + Allopurinol

There is some evidence to suggest that the incidence of serious bone marrow depression caused by cyclophosphamide can be increased by allopurinol, but this was not confirmed in a controlled study.

Clinical evidence

A retrospective epidemiological survey of patients in four hospitals who, over a 4-year period, had been taking cyclophosphamide, found that the incidence of serious bone marrow depression was 58% in 26 patients who had also taken allopurinol, and 19% in 32 patients who had not taken allopurinol.[1] A pharmacokinetic study in 9 patients with malignant disease and 2 healthy subjects found that while taking allopurinol 600 mg daily the concentration of the cytotoxic metabolites of cyclophosphamide increased by an average of about 38% (range 2 to 110%).[2] Another pharmacokinetic study reported that the half-life of cyclophosphamide was more than twofold longer in 3 children also receiving allopurinol 300 mg/m^2, when compared with that in children not given allopurinol.[3] However, another study found that although allopurinol pre-treatment increased the half-life of cyclophosphamide, the plasma alkylating activity and urinary metabolite and cyclophosphamide excretion were unchanged.[4] Moreover, a randomised controlled study,[5] designed as a follow-up to the survey cited above,[1] failed to confirm that allopurinol increased the toxicity of cyclophosphamide in 81 patients with Hodgkin's or non-Hodgkin's lymphoma. In this study, there was no difference in nadirs for white blood cells and platelets during 3 cycles of cyclophosphamide-containing chemotherapy in 44 patients receiving allopurinol and in 37 patients not receiving allopurinol.

Mechanism

Not understood. Cyclophosphamide itself is inactive, but it is converted by the liver into cytotoxic metabolites.[4] Allopurinol or its metabolite oxypurinol may inhibit their renal excretion, or may alter hepatic metabolism.[2,3]

Importance and management

This interaction is not established with any certainty. The authors of the randomised study consider that, if necessary, allopurinol can be safely used to prevent hyperuricaemia with the chemotherapy regimens used for lymphomas,[5] and allopurinol is standardly given for the prevention of tumour lysis syndrome.[6]

Cyclophosphamide + Amiodarone

Early-onset pulmonary toxicity occurred in one patient taking amiodarone after high-dose cyclophosphamide was given. Fatal pulmonary toxicity occurred in another patient taking amiodarone after a single dose of cyclophosphamide.

Clinical evidence

A patient with dendritic cell carcinoma who had been taking amiodarone for 18 months, and who had received 6 cycles of chemotherapy including cyclophosphamide over the previous 12 months, was admitted to hospital with progressive shortness of breath 18 days after being given a single 4-g/m^2 dose of cyclophosphamide. He was found to have interstitial pneumonitis and a lung biopsy indicated drug-induced pulmonary toxicity. The patient's condition improved rapidly over the following 10 days with discontinuation of amiodarone and treatment with prednisolone 60 mg daily. Over the previous year he had also received vincristine, etoposide and prednisone, cisplatin, cytarabine and dexamethasone as part of his chemotherapy.[1] Similarly, another patient with non-Hodgkin's lymphoma, who had been taking amiodarone 300 mg twice daily for 4 years, developed acute respiratory distress 2 days after being given a single dose of cyclophosphamide. This was eventually fatal. Autopsy revealed lung damage consistent with the effects of amiodarone and cyclophosphamide, with the cyclophosphamide the major cause. Other drugs used as part of the chemotherapy regimen were rituximab, doxorubicin, vincristine and prednisone.[2]

Mechanism

Pulmonary toxicity may occur in about 10% of patients given amiodarone.[3,4] Pulmonary toxicity due to cyclophosphamide may occur between one to 6 months after exposure or occur as a more insidious form after about 6 months. The early onset of symptoms in the patients described above suggests accelerated mechanisms of pulmonary toxicity. Both cyclophosphamide and amiodarone pulmonary toxicity appear to be enhanced by oxygen and the combination of cyclophosphamide with amiodarone may enhance oxidative stress and therefore pulmonary toxicity.

Importance and management

Although information seems to be limited to the two case reports cited, the potential for both cyclophosphamide and amiodarone to cause pulmonary toxicity is established. Be alert to the possibility of enhanced pulmonary toxicity if these drugs are given together.

Cyclophosphamide + Azathioprine

A report describes liver damage in four patients given cyclophosphamide and who had previously taken azathioprine. However, other studies have found that liver function improved when cyclophosphamide was substituted for azathioprine.

Clinical evidence, mechanism, importance and management

Four patients (two with systemic lupus erythematosus, one with Sjögren's syndrome, and one with Wegener's granulomatosis) developed liver injury when given cyclophosphamide and 3 of them had liver cell necrosis. All had previously been taking azathioprine and 2 of them had received cyclophosphamide previously without apparent liver damage. It was suggested that azathioprine and cyclophosphamide may have interacted.[1] However, in a retrospective study of heart transplant recipients, substitution of cyclophosphamide for azathioprine was associated with improvement in liver function tests in 29 patients with suspected azathioprine-induced liver impairment.[2] In a similar report 10 patients with kidney transplants who developed hepatic impairment while taking azathioprine, had an improvement in liver function when the treatment was changed to cyclophosphamide.[3]

Cyclophosphamide or Ifosfamide + Azoles

Fluconazole and itraconazole both inhibit the metabolism of cyclophosphamide, but itraconazole might cause greater increases in cyclophosphamide toxicity. Ketoconazole inhibits the metabolism of ifosfamide: efficacy could be reduced.

Clinical evidence

(a) Cyclophosphamide

Twenty-two children with established cyclophosphamide metabolism profiles, who were not receiving other treatment known to affect drug metabolism, were included in a retrospective case series investigation. The clearance of cyclophosphamide was reduced by 43% in 9 children who were given oral or intravenous **fluconazole** 5 mg/kg daily compared with the remaining 13 children who did not receive **fluconazole**.[1] A study in patients given either intravenous or oral **fluconazole** 400 mg daily or **itraconazole** (either 200 mg daily intravenously or 2.5 mg/kg three times daily orally) for prophylaxis after allogeneic stem cell transplantation found that those given **itraconazole** developed higher bilirubin and creatinine levels in the first 20 days after transplantation than those given **fluconazole**. Highest values were in patients who received **itraconazole** with cyclophosphamide. In this study, analysis of cyclophosphamide pharmacokinetics in 9 **itraconazole** recipients and 140 **fluconazole** recipients revealed that **itraconazole** recipients had a 20% greater clearance of cyclophosphamide than fluconazole recipients, leading to greater exposure to the active metabolite of cyclophosphamide, 4-hydroxycyclophosphamide, and its metabolites.[2]

(b) Ifosfamide

Eight patients undergoing chemotherapy were also given (for the first or second cycle of treatment) **ketoconazole** 200 mg twice daily for 4 days starting one day before ifosfamide. The concurrent use of **ketoconazole** modestly decreased the clearance of ifosfamide by 11%, increased its AUC by 14%, and increased urinary elimination by 26%. The fraction of ifosfamide metabolised to the inactive, neurotoxic, dechloroethylated metabolite was not affected, whereas the fraction metabolised to the active, hydroxylated metabolite was modestly decreased.[3]

Mechanism

Cyclophosphamide is oxidised to the active metabolite 4-hydroxycyclophosphamide by the cytochrome P450 isoenzymes CYP2B6, CYP3A4, CYP2C9, and CYP2A6, and then 4-hydroxycyclophosphamide undergoes further metabolism to produce several toxic metabolites. It is also metabolised by CYP3A4 to an inactive metabolite, deschloroethylcyclophosphamide (DCCP). Itraconazole is a more potent inhibitor of CYP3A4 than fluconazole, but unlike itraconazole, fluconazole can also inhibit CYP2C9. It has been suggested that inhibition of CYP2C9 by fluconazole may decrease the formation of 4-hydroxycyclophosphamide and result in increased levels of DCCP and fewer toxic metabolites.[2] Further study is required to determine whether the inhibition of active metabolite formation by fluconazole reduces the therapeutic effect of cyclophosphamide.[1]

Ketoconazole is an inhibitor of the cytochrome P450 isoenzyme CYP3A4, an enzyme that is involved in the production of active and inactive-toxic metabolites of ifosfamide. See *Mechanism*, under 'Cyclophosphamide or Ifosfamide + Barbiturates', below, for more on the balance of production of these metabolites.

Importance and management

Until more is known it may be prudent to encourage caution when azoles are used in patients receiving cyclophosphamide, other than therapies established in randomised clinical studies, being alert for unexpected toxicity or reduced efficacy.

In the clinical study cited, ketoconazole modestly decreased the proportion of ifosfamide undergoing activation. It was suggested that concurrent use should be avoided, as it might result in decreased ifosfamide efficacy,[3] although this is not established.

Cyclophosphamide or Ifosfamide + Barbiturates

Evidence suggests that neither the toxicity nor the therapeutic effects of cyclophosphamide and ifosfamide are significantly altered by the concurrent use of barbiturates. However, an isolated report describes a girl taking phenobarbital who developed encephalopathy when given ifosfamide.

Clinical evidence

(a) Cyclophosphamide

In 4 patients **phenobarbital** 180 mg daily in divided doses for 10 days increased the mean plasma levels of cyclophosphamide total metabolites by 50% and increased their rate of urinary excretion.[1] Similarly, another study in 11 patients given cyclophosphamide reported that the peak level of normustard-like substances was increased by 50% after pretreatment with **phenobarbital**.[2] Similar changes in cyclophosphamide pharmacokinetics have been described in *animal* studies, and these have generally also shown that **phenobarbital** has no effect on the antitumour activity of cyclophosphamide (one study is cited as an example[3]) although some have shown a reduction in its effects (one study is cited as an example[4]). Another study found that the auto-induction of cyclophosphamide clearance in a patient taking **phenobarbital** with subsequent chemotherapy courses was similar to that in patients not taking **phenobarbital**.[5]

Cyclophosphamide was reported to inhibit the clearance and increase the effects of **pentobarbital** in a study in *rats*.[6]

(b) Ifosfamide

A 15-year-old girl who had been taking **phenobarbital** for epilepsy since infancy developed confusion and gradually became unconscious 6 hours after being given a first dose of ifosfamide for metastatic rhabdomyosarcoma. Her chemotherapy regimen was ifosfamide 3 g/m^2, mesna 3.6 g/m^2, vincristine 2 mg and dactinomycin. An EEG revealed signs of severe diffuse encephalopathy. She remained unconscious for 24 hours but was asymptomatic after 48 hours.[7] In a pharmacokinetic study, **phenobarbital** 60 mg daily for 3 days had no effect on the pharmacokinetics of high-dose ifosfamide (4 g/m^2 over one hour each day for 3 days). The AUC for ifosfamide decreased from day one to day 3 irrespective of **phenobarbital** use.[8]

Mechanism

Cyclophosphamide and ifosfamide are prodrugs that undergo hepatic metabolism, and it seems that they are able to induce their own metabolism. Cyclophosphamide appears to be hydroxylated by the cytochrome P450 subfamilies CYP2B and CYP2C, in particular, to form active metabolites, whereas ifosfamide appears to be principally hydroxylated by CYP3A. Both drugs also undergo dechloroethylation to produce inactive but neurotoxic metabolites, which can cause encephalopathy. For cyclophosphamide, this seems to be primarily catalysed by CYP3A, whereas for ifosfamide both CYP3A and CYP2B appear to be involved. Ifosfamide has a higher incidence of encephalopathy than cyclophosphamide.[9] Phenobarbital and other barbiturates are inducers of both CYP2B and CYP3A. Therefore it is unlikely that barbiturates will generally alter the balance between dechloroethylation and hydroxylation for cyclophosphamide,[3] although there is some evidence from *animal* studies they may do so for ifosfamide.[10]

Importance and management

The relationship between the case of encephalopathy and the use of ifosfamide with phenobarbital is not established, but it serves to emphasise the need for particular caution and good monitoring if concurrent use is undertaken. Although barbiturates can cause an increase in the rate of metabolism of cyclophosphamide, this does not appear to alter the AUC and the efficacy of this drug.

Cyclophosphamide or Ifosfamide + Benzodiazepines

***Animal* studies suggest that the benzodiazepines may possibly increase the metabolic activation and the toxicity of high doses of cyclophosphamide and ifosfamide. However, diazepam did not alter the pharmacokinetics of high-dose cyclophosphamide in a clinical study. Note also that lorazepam is widely used for chemotherapy-induced nausea and vomiting.**

Clinical evidence, mechanism, importance and management

Studies in *mice* found that pretreatment with benzodiazepines (**chlordiazepoxide**, **diazepam**, **oxazepam**) increased the levels of the active metabolites and the lethality of high-dose cyclophosphamide[1] and similarly increased the levels of active metabolites and enhanced the toxicity of high-dose ifosfamide.[2] However, a clinical study found that the prophylactic use of **diazepam** 5 mg daily as an antiepileptic had no effect on the pharmacokinetics of very high-dose cyclophosphamide (60 mg/kg intravenously over 2 hours for 2 days) or its neurotoxic (dechloroethylated) metabolites in 3 patients receiving cyclophosphamide and busulfan before bone marrow transplantation.[3]

In the *animal* studies, it was suggested that benzodiazepines may induce the liver enzymes concerned with the metabolism of cyclophosphamide and ifosfamide to its active cytotoxic products.

There are very limited data on this potential interaction. The widespread use of the benzodiazepine **lorazepam** in antiemetic regimens for chemotherapy-induced nausea and vomiting suggest that a significant increase in toxicity or alteration in efficacy of cyclophosphamide and ifosfamide does not occur clinically, but there do not appear to be any studies directly addressing this question.

Cyclophosphamide + Busulfan

The levels of cyclophosphamide may be increased, and those of its active metabolite decreased, if it is given within 24 hours of busulfan.

Clinical evidence, mechanism, importance and management

In one study, the ratio of the AUC of cyclophosphamide and that of its active metabolite 4-hydroxycyclophosphamide (HCY) was higher in patients also receiving phenytoin and busulfan than in those receiving irradiation (suggesting reduced cyclophosphamide activation), but variability between patients was high.[1] In a similar study, 23 bone marrow transplant patients were pretreated with busulfan 4 mg/kg daily for 4 days, followed by cyclophosphamide 60 mg/kg daily for 2 days. The interval between the last dose of busulfan and starting cyclophosphamide was 24 to 50 hours in 12 patients [group A] and 7 to 15 hours in the remaining 11 [group B]. Nine others pretreated with cyclophosphamide and total body irradiation acted as the controls. In group A the AUCs of cyclophosphamide and HCY were similar to those in the controls but in group B the AUC of cyclophosphamide was more than doubled and the AUC of HCY significantly lower (representing a reduced ratio of HCY to cyclophosphamide). In addition group B had greater toxicity.[2]

Busulfan may directly inhibit the hepatic activation of cyclophosphamide or may act indirectly by depleting glutathione. Phenytoin (given in the first study) induces the metabolism of cyclophosphamide (see 'Cyclophosphamide or Ifosfamide + Phenytoin', p.718).

It seems therefore that if the cyclophosphamide is given at least 24 hours after the last busulfan dose, its serum levels will not be greatly affected, whereas if the interval is short, activation may be decreased and toxicity increased. Further study is required to determine the optimum timing to achieve maximum efficacy and minimum drug toxicity while taking into account other concurrent medication such as phenytoin.

Cyclophosphamide + Chloramphenicol

Some limited evidence suggests that chloramphenicol may reduce the production of the active metabolites of cyclophosphamide.

Clinical evidence, mechanism, importance and management

Cyclophosphamide itself is inactive, but after administration it is metabolised to active alkylating metabolites. A study in *animals*[1] found that pretreatment with chloramphenicol reduced the effects of cyclophosphamide and reduced the production of its active metabolites. Although another *animal* study also found a reduction in the lethality of cyclophosphamide with chloramphenicol, the immunosuppressive effect of cyclophosphamide was unchanged.[2] A study in 4 patients found that chloramphenicol 1 g twice daily for 12 days prolonged the mean serum half-life of a single intravenous dose of cyclophosphamide from 7.5 hours to 11.5 hours, but did not significantly affect the AUC of the metabolites.[3]

Chloramphenicol is an inhibitor of the cytochrome P450 isoenzyme subfamily CYP2B, which is partially responsible for the activation of cyclophosphamide. It therefore seems possible that a reduction in the activity of cyclophosphamide may occur, but the extent to which this affects treatment with cyclophosphamide is uncertain. Concurrent use need not be avoided, but be alert for evidence of a reduced response.

Cyclophosphamide or Ifosfamide + Cisplatin

The renal toxicity of ifosfamide may be greater when used with cisplatin or in those who have had previously been given cisplatin. Ifosfamide may increase the hearing loss due to cisplatin.

Clinical evidence

(a) Nephrotoxicity

A comparative study in 36 children with malignant solid tumours taking a range of drugs including some known to be potentially nephrotoxic (high dose methotrexate, aminoglycosides, cyclophosphamide), indicated that the previous use of cisplatin increased their susceptibility to ifosfamide toxicity (neurotoxicity, severe leucopenia or acute renal tubular damage).[1] Similarly, in another study the cumulative cisplatin dose given before high-dose ICE (ifosfamide, carboplatin, and etoposide) was found to be a strong risk factor for the development of nephrotoxicity.[2] The nephrotoxicity may not be reversible; 3 cases requiring long-term haemodialysis have been described.[3]

Other studies also suggested that the concurrent use of ifosfamide with cisplatin appeared to increase nephrotoxicity; one found an increase in depletion of phosphate reabsorption,[4] whereas the other found increased microglobulin excretion.[5]

(b) Ototoxicity

A retrospective comparative study found that when ifosfamide was given with cisplatin, the hearing loss caused by cisplatin was exacerbated.[6]

Mechanism

Both cisplatin and ifosfamide are commonly associated with nephrotoxicity. It is thought that concurrent or possibly previous use of cisplatin damages the renal tubules so that the clearance of the ifosfamide metabolites is reduced and their toxic effects are thereby increased. Damaged renal tubules may also be less capable of converting mesna to its active kidney-protecting form. The increase in the hearing loss is not understood.

Importance and management

These interactions appear to be established. The authors of the paper cited[1] point out that the majority of patients who develop toxicity have persistently high urinary NAG concentrations (*N*-acetyl-β-D-glucosaminidase, an enzyme released by renal tubular cells), even though serum creatinine levels remain within the acceptable range for ifosfamide treatment. They suggest that evidence of subclinical renal tubular damage should be sought for by monitoring the excretion of urinary NAG. Note that cisplatin and ifosfamide are widely used in combination, and the related drug **cyclophosphamide** is also routinely used with cisplatin. Amifostine may be useful in reducing the nephrotoxicity of this combination.[7] The authors who reported on hearing loss advised that serial audiograms should be done in patients given both drugs.[6]

Cyclophosphamide + Colony-stimulating factors

Granulocyte colony-stimulating factor (G-CSF) used with cyclophosphamide has been associated with an increased occurrence of pulmonary toxicity.

Clinical evidence, mechanism, importance and management

A one-year-old boy with a neuroblastoma Evans stage III died of respiratory failure after being given **filgrastim** (a **G-CSF**) and normal doses of cyclophosphamide and doxorubicin. The authors of the report suggest that the pulmonary toxicity of the cyclophosphamide (normally only seen with high cumulative doses) is potentiated by **filgrastim**.[1] Six of 53 patients given CHOP (cyclophosphamide, doxorubicin, vincristine and prednisolone) and **G-CSF** developed pulmonary toxicity, which was considered a much higher incidence than is usually seen with CHOP alone. The development of toxicity correlated with the mean peak leucocyte count.[2] Another 10 cases of interstitial pneumonitis have occurred with cyclophosphamide-based regimens (not including bleomycin or methotrexate) and **G-CSF**.[3,4]

These interactions are not firmly established, but good pulmonary function monitoring appears to be advisable when colony-stimulating factors are used with antineoplastics causing pulmonary toxicity, such as cyclophosphamide. If interstitial pneumonitis occurs, the drugs should be discontinued and high-dose corticosteroids started immediately.[2] Note however, because of the increased risk of myelosuppression, colony stimulating factors should not be given within 24 hours of myelosuppressive chemotherapy, see 'Antineoplastics + Colony-stimulating factors', p.702.

Cyclophosphamide or Ifosfamide + Corticosteroids

There is limited and conflicting evidence on the effect of prednisone and prednisolone on the metabolic activation of cyclophosphamide. Synergistic increases in enzyme induction may occur if cyclophosphamide is given with dexamethasone. Dexamethasone does not appear to alter ifosfamide metabolism.

Clinical evidence

(a) Dexamethasone

In an *in vitro* study it was noted that the combination of cyclophosphamide with dexamethasone resulted in a greater induction of the cytochrome P450 isoenzyme CYP3A4 than with cyclophosphamide alone; the extent of induction being dependent on baseline CYP3A4 activity.[1] In *rats*,[2] dexamethasone pretreatment caused a fourfold increase in the AUC of the inactive, neurotoxic, dechloroethylated metabolite of cyclophosphamide, and caused a 60% decrease in the AUC of the active, hydroxylated metabolite. In an earlier study in patients receiving high-dose cyclophosphamide and dexamethasone for 2 days, the total clearance of both cyclophosphamide and dexamethasone were higher on the second day than the first day, with higher concentrations of cyclophosphamide metabolites.[3]

In *rats*, dexamethasone pretreatment had no net impact on the fraction of ifosfamide undergoing activation.[4] Similarly, in a clinical study, ifosfamide metabolism was no different when patients were given dexamethasone 4 mg every 8 hours with ifosfamide for 3 days than when they received ifosfamide alone.[5]

(b) Prednisone or Prednisolone

In an early study, single doses of prednisone were found to inhibit the metabolic activation of cyclophosphamide,[6,7] whereas another study briefly mentioned that massive single doses of prednisolone given just before cyclophosphamide did not inhibit cyclophosphamide metabolism.[8] Longer-term prednisone treatment (50 mg daily for 1 to 2 weeks) increased the rate of activation of cyclophosphamide in the first study.[6,7] Conversely, another study in 7 patients with systemic vasculitis given prednisone 1 mg/kg daily and cyclophosphamide 600 mg/m^2 intravenously every 3 weeks for 6 cycles found that, by the last cycle, the AUC of cyclophosphamide had significantly increased, while that of its active metabolites had significantly decreased.[9]

Mechanism

Cyclophosphamide and ifosfamide are prodrugs that undergo hepatic metabolism to active and inactive-neurotoxic metabolites, and it appears they induce their own metabolism (see also 'Cyclophosphamide or Ifosfamide + Barbiturates', p.714). Corticosteroids are said to be inducers of the cytochrome P450 isoenzyme CYP3A4. For cyclophosphamide, the CYP3A subfamily is thought to be principally involved in the production of inactive-neurotoxic metabolites, whereas, for ifosfamide, CYP3A catalyses both the production of active and inactive-neurotoxic metabolites. On this basis, corticosteroids are predicted decrease the efficacy and increase the neurotoxicity of cyclophosphamide (although this does not take account of auto-induction), whereas for ifosfamide they would not be expected to alter the balance between efficacy and toxicity.

Importance and management

The documentation is very limited. It appears that dexamethasone does not have any appreciable effect on the metabolism of ifosfamide. The information about cyclophosphamide is conflicting, and the clinical importance of any changes remains to be established. However, it should be noted that prednisone and prednisolone have a long established use as part of chemotherapy regimens including cyclophosphamide and are also often combined in various autoimmune diseases, and dexamethasone is widely used as an antiemetic with cancer chemotherapy.

Cyclophosphamide + H_2-receptor antagonists

Ranitidine, and probably famotidine, appear not to increase the bone marrow toxicity of cyclophosphamide. *Animal* studies suggest that cimetidine might.

Clinical evidence, mechanism, importance and management

A study in 7 patients with cancer found that although oral **ranitidine** 300 mg daily significantly prolonged the half-life and increased the AUC of intravenous cyclophosphamide 600 mg/m^2, it did not significantly affect the AUCs of the two major alkylating metabolites of cyclophosphamide, nor did it affect its bone marrow toxicity (leucopenia, granulocytopenia). The authors of the study concluded that **ranitidine** can safely be given with cyclophosphamide.[1] The same authors previously reported that **cimetidine**, when given with cyclophosphamide, increased the AUC of total alkylating metabolites of cyclophosphamide, and resulted in greater toxicity to normal bone marrow, but increased survival in leukaemia-bearing *mice*.[2,3] Other studies in *mice* have found that **cimetidine**, but not **famotidine**, increases the toxicity of cyclophosphamide to normal bone marrow cells.[4]

Cimetidine inhibits the cytochrome P450 isoenzyme CYP2C9, which has a minor role in the activation of cyclophosphamide (see 'Cyclophosphamide or Ifosfamide + Barbiturates', p.714). These results suggest that no special precautions are likely to be needed when **ranitidine** or **famotidine** are given with cyclophosphamide. The relevance of the findings with **cimetidine** is uncertain.

Cyclophosphamide + Indometacin

A single case report describes acute water intoxication when a patient taking indometacin was given low-dose intravenous cyclophosphamide.

Clinical evidence, mechanism, importance and management

A patient with multiple myeloma taking indometacin 50 mg every 8 hours, developed acute water intoxication and salt retention after being given a single bolus intravenous injection of cyclophosphamide 500 mg (less than 10 mg/kg). The reasons for this effect are not understood, but it is suggested that it was due to the additive or synergistic effects of the two drugs, because water intoxication had not been noted before with this low-dose of cyclophosphamide.[1] There do not appear to be any further reports or studies on this potential interaction but water intoxication has subsequently been reported with low-dose intravenous cyclophosphamide alone.[2] The evidence does not justify any special precautions when both drugs are used.

2. McCarron MO, Wright GD, Roberts SD. Water intoxication after low dose cyclophosphamide. *BMJ* (1995) 311, 292.

Cyclophosphamide + Metronidazole

A case report describes encephalopathy in a girl given cyclophosphamide and metronidazole.

Clinical evidence, mechanism, importance and management

After the fourth dose of pulse intravenous cyclophosphamide, a 9-year-old girl developed pancytopenia and gastrointestinal bleeding. She was then given metronidazole for presumptive *Clostridium difficile* colitis. Within 6 hours she developed encephalopathy with seizures and visual hallucina-

tions, requiring antipsychotics. Metronidazole is thought to cause disulfiram-like reactions by inhibiting aldehyde dehydrogenase (see 'Alcohol + Metronidazole and related drugs', p.76), and it was suggested that inhibition of this enzyme may cause toxic metabolites of cyclophosphamide to accumulate (see also 'Cyclophosphamide or Ifosfamide + Barbiturates', p.714).[1] This appears to be the only report of this potential interaction, and its general relevance is unclear.

Cyclophosphamide + Pentostatin

Two patients had an acute and fatal cardiovascular collapse when pentostatin was added to high-dose cyclophosphamide. Some studies have found the combination to be effective and safe in patients with chronic lymphocytic leukaemia.

Clinical evidence, mechanism, importance and management

A clinical study that was started to find out if pentostatin would improve the immunosuppressive effects of an ablative regimen of high-dose cyclophosphamide, carmustine and etoposide in bone marrow transplant patients was stopped when acute and fatal cardiovascular collapse developed in the first 2 patients. Both patients had been given cyclophosphamide 800 mg/m^2 and etoposide 200 mg/m^2, both every 12 hours for 8 doses, and carmustine 112 mg/m^2 daily for 4 doses. On day 3 pentostatin 4 mg/m^2, given over 4 hours, was added. Within 8 to 18 hours after completion of chemotherapy both patients developed confusion, hypothermia, hypotension, respiratory distress, pulmonary oedema, and eventually fatal ventricular fibrillation within 45 to 120 minutes of the first symptoms. A later study in *rats* similarly found that pentostatin markedly increased the acute toxicity of cyclophosphamide. The reasons for this cardiotoxicity are not understood. Neither of the 2 patients had previously shown any evidence of cardiac abnormalities.[1] In view of these findings, the UK manufacturer advises against the use of pentostatin with high-dose cyclophosphamide.[2]

Note that pentostatin 4 mg/m^2 plus cyclophosphamide 600 mg/m^2, with or without subsequent rituximab 375 mg/m^2, has been used for chronic lymphocytic leukaemia[3-5] or Waldenstrom's macroglobulinaemia[6] with acceptable toxicity, and without any cases similar to that described in the first report.[1]

Cyclophosphamide or Ifosfamide + Phenytoin

Phenytoin increases the metabolism of cyclophosphamide and ifosfamide, but the clinical relevance of this is uncertain. Efficacy and toxicity has been suggested to be both unchanged and increased.

Clinical evidence

(a) Cyclophosphamide

In another case report, a 42-year-old man received two courses of CTC (high-dose cyclophosphamide, thiotepa and carboplatin) with phenytoin 150 mg twice daily started 5 days before the second course for seizures. When compared with the first course, phenytoin appeared to cause a 51% increase in the AUC of 4-hydroxycyclophosphamide, the active metabolite of cyclophosphamide, and a sixfold increase in its maximum plasma level. In addition, the AUC of cyclophosphamide was reduced by 67%. On the basis of these data, the dose of cyclophosphamide was almost halved for the remaining 2 days of this course of chemotherapy, and this resulted in plasma levels within the therapeutic range.[1]

In a small pharmacokinetic study, the use of prophylactic phenytoin increased the formation of *S*-dechloroethylated cyclophosphamide in 3 patients receiving cyclophosphamide and busulfan compared with 3 patients given diazepam with the same cytotoxic regimen.[2] In yet another study, the ratio of the AUC of active 4-hydroxycyclophosphamide to cyclophosphamide was 166% higher in patients receiving phenytoin and busulfan than in those receiving irradiation.[3] It is likely that phenytoin was responsible for this effect because busulfan alone decreases cyclophosphamide metabolism (see 'Cyclophosphamide + Busulfan', p.715). In an earlier study, in patients receiving enzyme-inducing drugs (2 of whom received phenytoin), the peak plasma levels of the alkylating metabolites of cyclophosphamide were raised, but declined rapidly, so that the overall exposure was not different from those not taking these drugs.[4] Another study reported that a patient taking phenytoin had a high clearance rate for cyclophosphamide during her first chemotherapy course, and that autoinduction of cyclophosphamide clearance was not apparent during her second course.[5]

(b) Ifosfamide

A child taking phenytoin and also given ifosfamide and etoposide had a neurotoxic reaction. The plasma levels of the dechloroethylated metabolites of ifosfamide were subsequently found to be markedly altered compared with those previously seen in 14 other children receiving the same chemotherapy but not taking phenytoin. The child recovered uneventfully after 3 days, and achieved clinical remission (she had not responded to first-line chemotherapy).[6]

Mechanism

The alteration in the pattern of ifosfamide metabolites suggested that phenytoin had induced the activity of the cytochrome P450 isoenzyme CYP2B6, and to a lesser extent CYP3A4.[6] The pattern of the increase in cyclophosphamide clearance is also consistent with induction of CYP2B and CYP3A.[2] See also *Mechanism*, under 'Cyclophosphamide or Ifosfamide + Barbiturates', p.714, for more detail on the metabolism of cyclophosphamide and its metabolites.

Importance and management

The alteration in the metabolism of cyclophosphamide and ifosfamide caused by phenytoin is not surprising, but the clinical importance of any changes remains to be established. The authors of the study from the 1970s concluded that phenytoin was unlikely to have much effect on the antitumour and toxic effects of cyclophosphamide.[4] Conversely, the authors of the more recent studies suggest that phenytoin may increase the therapeutic efficacy of cyclophosphamide and ifosfamide.[2,6] Moreover, the authors of the latest case report suggest that it is preferable to avoid using phenytoin with cyclophosphamide. They suggest that, when concurrent use is unavoidable, the starting dose of cyclophosphamide should be reduced, and the levels of active metabolite should be monitored to guide further doses.[1] Further study is needed.

Note that reduced phenytoin levels and seizures have been reported in a patient receiving chemotherapy including cyclophosphamide, see 'Table 14.1', (p.594).

Cyclophosphamide or Ifosfamide + Rifampicin (Rifampin)

Rifampicin induced the metabolism of cyclophosphamide and ifosfamide *in vitro*. For ifosfamide, this did not improve the ratio of active to inactive-toxic metabolites in a clinical study.

Clinical evidence, mechanism, importance and management

In a clinical study, rifampicin doubled the clearance of ifosfamide. In this study, patients were given rifampicin 300 mg twice daily for 3 days before ifosfamide, for 3 days concurrently for one cycle, and then for another cycle they were given the ifosfamide alone. The fraction of ifosfamide metabolised to the inactive-neurotoxic, dechloroethylated metabolite was increased, but elimination of this metabolite was also increased resulting in reduced exposure. The fraction of ifosfamide metabolised to the active, hydroxylated metabolite, and its exposure, were not altered appreciably.[1]

An *in vitro* study in human liver cells found that rifampicin was a potent inducer of the activation (hydroxylation) of cyclophosphamide and ifosfamide.[2] Rifampicin is a clinically relevant inducer of the cytochrome P450 isoenzymes CYP3A4 and CYP2B6, which are involved in the metabolism of cyclophosphamide and ifosfamide (see also 'Cyclophosphamide or Ifosfamide + Barbiturates', p.714). In the clinical study cited,[1] rifampicin did not have a positive effect on the proportion of ifosfamide undergoing activation. In addition, as rifampicin increased metabolism overall, there is the possibility of decreased efficacy,[1] although this remains to be shown.

Cyclophosphamide + Sulfonamides

Some very limited evidence suggests that sulfaphenazole may modestly inhibit the metabolism of cyclophosphamide to its active metabolite.

Clinical evidence, mechanism, importance and management

A study in 7 patients given a 50-mg dose of cyclophosphamide with **sulfaphenazole** 1 g twice daily for 9 to 14 days found that the half-life of cyclophosphamide was unchanged in 3 patients, longer in 2 patients, and shorter in 2 patients.[1] **Sulfaphenazole** and **sulfamethoxazole** are inhibitors of the cytochrome P450 isoenzyme CYP2C9, which shows genetic polymorphism (i.e. some people produce very little, while others produce larger quantities). This enzyme has a minor role in the metabolism (and therefore activation) of cyclophosphamide, and the extent of its involvement varies between patients. For example, an *in vitro* study found that **sulfaphenazole** inhibited cyclophosphamide activation by 17 to 27% in one human liver sample, but insignificant inhibition occurred in two other samples.[2] Thus, sulfonamides such as **sulfaphenazole** and **sulfamethoxazole** may moderately inhibit the activation of cyclophosphamide in some patients, but the clinical relevance of this is uncertain. Note that **co-trimoxazole** is sometimes used for prophylaxis of infection in patients receiving chemotherapy. One study found that this did not *increase* the myelotoxicity of CAE (cyclophosphamide, doxorubicin, and etoposide).[3]

Cyclophosphamide or Ifosfamide + Taxanes

The clearance of ifosfamide is higher when it is given after docetaxel. This results in less toxicity, but the effect on efficacy is unknown. Ifosfamide did not alter the pharmacokinetics of docetaxel. Results from one study indicate that docetaxel pharmacokinetics are unaltered by cyclophosphamide. The sequence of ifosfamide followed by paclitaxel was antagonistic *in vitro*, and there is some evidence to suggest that the toxicity associated with combinations of paclitaxel and cyclophosphamide is dependent on the order of administration.

Clinical evidence, mechanism, importance and management

(a) Docetaxel

The AUCs of ifosfamide and its metabolites were lower when ifosfamide was given immediately after docetaxel than when it was given 24 hours before docetaxel, due to increased clearance. Docetaxel pharmacokinetics were unaltered by ifosfamide.[1] This supports the evidence that the maximum tolerated dose of ifosfamide is greater when it is given after docetaxel.[2] The mechanism of this effect is unknown, but it has been suggested[3] that docetaxel may competitively inhibit the activation of ifosfamide by the cytochrome P450 isoenzyme CYP3A4. These results show that the toxicity, and possibly efficacy, of the combination are schedule-dependent, but more study is needed to determine this.

In a phase I study, the pharmacokinetics of docetaxel were not altered by pretreatment with an intravenous bolus dose of cyclophosphamide.[4]

(b) Paclitaxel

In vitro studies in human liver microsomes found that additive or synergistic cytotoxicity occurred when activated ifosfamide (hydroxyifosfamide) and paclitaxel were given together or when paclitaxel was given first followed by hydroxyifosfamide. In contrast pronounced antagonism was seen when hydroxyifosfamide was given before paclitaxel.[5] The mechanism for this effect is unknown. These results suggest that the scheduling of this combination may be important for efficacy.

A study in patients given paclitaxel as a 24-hour infusion and cyclophosphamide as an infusion over one hour found that neutropenia and thrombocytopenia were more severe when paclitaxel preceded cyclophosphamide.[6] Similarly, in another study, the concurrent use of a continuous 72-hour infusion of paclitaxel and a daily bolus of cyclophosphamide had acceptable toxicity. However, when the cyclophosphamide was given as a single intravenous dose after the end of the 72-hour paclitaxel infusion, severe haematological and gastrointestinal toxicity occurred.[7] Whether the clinical efficacy of this combination is also altered by the schedule and sequence has not been determined.

Cyclophosphamide + Thiotepa

Pretreatment with thiotepa may inhibit the metabolism of cyclophosphamide to its active metabolite and decrease both its efficacy and toxicity. Cyclophosphamide might slightly increase the metabolism of thiotepa to TEPA (triethylenephosphamide), but the relevance of this is uncertain.

Clinical evidence

(a) Effect on cyclophosphamide

The proportion of cyclophosphamide excreted unchanged in the urine (i.e. never metabolically activated) was found to be higher when cyclophos-

phamide was given as a 96-hour infusion with thiotepa and novobiocin than when it was given alone. The authors suggested that the potential of thiotepa to inhibit the metabolism of cyclophosphamide should be investigated.[1] Later, other authors observed that the concentration of the active metabolite of cyclophosphamide, 4-hydroxycyclophosphamide, decreased sharply after thiotepa was given to 20 patients.[2] In a study to investigate this effect further, 3 patients were given high-dose cyclophosphamide 1 or 1.5 g/m^2 as a one-hour infusion, followed by carboplatin and thiotepa for 4 days. The order of infusion was reversed on one treatment day in each of 4 courses. Giving thiotepa one hour before cyclophosphamide resulted in decreases in the peak plasma levels and AUC of 4-hydroxycyclophosphamide of 62% and 26%, respectively, when compared with thiotepa given one hour after cyclophosphamide.[2]

(b) Effect on thiotepa

In an *in vitro* study using human microsomes, cyclophosphamide had no effect on the metabolism of thiotepa to TEPA (triethylenephosphamide) by cytochrome P450 at therapeutic concentrations.[2,3] However, the metabolism of thiotepa to TEPA was modestly increased in the presence of cyclophosphamide in two patients who received treatment with thiotepa and carboplatin with and then without cyclophosphamide.[4] A subsequent population pharmacokinetic modelling study found that incorporation of induction of thiotepa metabolism by cyclophosphamide improved the model. According to this model, the total clearance of thiotepa is increased by 10 to 25% with cyclophosphamide.[4]

Mechanism

In human microsomes, thiotepa was found to inhibit the conversion of cyclophosphamide to its active metabolite, 4-hydroxycyclophosphamide,[2] most likely because it is a potent inhibitor of the cytochrome P450 isoenzyme CYP2B6.[5] See also *Mechanism*, under 'Cyclophosphamide or Ifosfamide + Barbiturates', p.714, for further detail on the metabolism of cyclophosphamide and its metabolites. Cyclophosphamide may have induced the metabolism of thiotepa by cytochrome P450 enzymes, but the exact enzymes involved are not clear.[4]

Importance and management

These results suggest that thiotepa can decrease both the efficacy and toxicity of cyclophosphamide, and that the order of administration may be of critical importance. The authors of one study question the practice of giving cyclophosphamide and thiotepa simultaneously.[2] Cyclophosphamide may also slightly increase the metabolism of thiotepa to an active metabolite, although the clinical relevance of this remains to be determined.[4]

Cytarabine + Dipyridamole

A fatal case of increased cytarabine toxicity has been attributed to the concurrent use of dipyridamole.

Clinical evidence

A case report describes a 52-year-old man who experienced a relapse of acute myeloid leukaemia and was given idarubicin daily for 3 days and cytarabine daily for 7 days. Amikacin and cefepime were also given for febrile neutropenia. In addition he was given dipyridamole 75 mg three times daily for 5 days for occlusion of the peroneal and tibialis anterior arteries. His liver function deteriorated, most notably his bilirubin increased almost 10-fold by day 5, and he died 10 days after starting treatment due to multiple organ failure.[1]

Mechanism

Dipyridamole is reported to inhibit the nucleoside transporter responsible for the extracellular transport of cytarabine and its metabolites, thus increasing the intracellular retention of cytarabine within the hepatocytes.[1] One *in vitro* study in *mouse* leukaemic cells has shown that use of dipyridamole *after* cytarabine resulted in an increase in cytarabine retention and an increase in cytotoxicity.[2] However, in a similar study using human acute myeloid leukaemia blasts, dipyridamole had little effect, possibly because these cells had few nucleoside transport carriers.[3] In yet another *in vitro* study, *pretreatment* with dipyridamole inhibited the uptake of cytarabine into both normal and leukaemic *mouse* and human cells, which suggests that dipyridamole may reduce the toxicity of cytarabine when used first.[4]

Importance and management

This appears to be the only report of an interaction between dipyridamole and cytarabine, but consider an interaction as a possible cause should unexpected toxicity occur in patients receiving both drugs.

Dasatinib + Miscellaneous

The AUC of dasatinib was markedly increased by ketoconazole, a CYP3A4 inhibitor, and markedly reduced by rifampicin (rifampin), a CYP3A4 inducer. Other CYP3A4 inhibitors and inducers are expected to interact similarly. Dasatinib modestly increased simvastatin levels, and may increase the levels of other substrates of CYP3A4. Antacids and drugs that reduce gastric pH reduce the absorption of dasatinib. Dasatinib commonly causes thrombocytopenia and bleeding, and its effects may be additive with antiplatelet drugs and anticoagulants and NSAIDs. Dasatinib prolongs the QT interval and its effect may be additive when given with other drugs that also prolong the QT interval.

Clinical evidence, mechanism, importance and management

(a) Anticoagulants, Antiplatelet drugs and NSAIDs

Dasatinib adverse effects reported in clinical studies include haemorrhages, with severe gastrointestinal haemorrhage occurring in 4% of patients, and CNS bleeds (some of which were fatal) in less than 1% of patients.[1,2] Most of these effects are thought to be due to dasatinib-induced thrombocytopenia, which is a dose-limiting toxicity.[2] In general, patients were excluded from clinical studies if they were taking antiplatelet drugs or anticoagulants, and in the cases where they were permitted, it was only if the platelet count was above 50×10^9/L.[1,2] Similarly, NSAIDs were only permitted when platelet count was above 50×10^9/L.[1,2] The manufacturers therefore advise caution when drugs that have antiplatelet or anticoagulant activity are given with dasatinib.[1,2] This seems a sensible precaution.

(b) CYP3A4 inducers

The manufacturer reports that **rifampicin** (**rifampin**) 600 mg daily for 8 days, markedly decreased the AUC of dasatinib, by 82%. They predict that other CYP3A4 inducers may also reduce dasatinib levels, and specifically name **carbamazepine**, **dexamethasone**, **phenobarbital** [and therefore probably **primidone**], **phenytoin** [and therefore probably **fosphenytoin**], **rifabutin**, and **St John's wort**.[1,2] They advise that the use of potent inhibitors of CYP3A4 should be avoided,[1,2] or, if this is not possible, the dose of dasatinib should be increased, and the patient monitored for toxicity.[2]

(c) CYP3A4 inhibitors

In a study in 18 patients with solid tumours, **ketoconazole** 200 mg twice daily with dasatinib 20 mg daily markedly increased the dasatinib maximum level and AUC by four- and fivefold, respectively.[2] Dasatinib has been shown *in vitro* to be a substrate of CYP3A4 and ketoconazole inhib-

its this isoenzyme. Other drugs that are potent inhibitors of CYP3A4 would be expected to interact similarly, and the manufacturers advise against concurrent use. They specifically mention **atazanavir**, **clarithromycin**, **erythromycin**, **indinavir**, **itraconazole**, **nefazodone**, **nelfinavir**, **ritonavir**, **saquinavir**, **telithromycin** and **voriconazole**[1,2] (for a list of CYP3A4 inhibitors, see 'Table 1.4', (p.6)). They advise that if an alternative is not suitable, the dose of dasatinib should be reduced to 20 mg daily. If this is not tolerated, then treatment with dasatinib should be interrupted until one week after the inhibitor is stopped.[2]

(d) CYP3A4 substrates

Following a single 100-mg dose of dasatinib, the AUC and maximum plasma concentration of **simvastatin** were increased by 20% and 37%, respectively. It is possible that the effect might be greater after multiple dasatinib doses.[1] Dasatinib is an inhibitor of CYP3A4,[1,2] of which simvastatin is a substrate. Dasatinib may therefore increase the plasma levels of other drugs that are substrates of CYP3A4, and the manufacturers recommend caution with CYP3A4 substrates that have a narrow therapeutic range. They specifically mention **alfentanil**, **astemizole**, **ciclosporin**, **cisapride**, **ergot derivatives**, **fentanyl**, **pimozide**, **quinidine**, **sirolimus**, **tacrolimus** and **terfenadine**.[1,2]

(e) Drugs that prolong the QT interval

The manufacturer warns that dasatinib may cause prolongation of the QT interval (a mean increase of 4 to 6 milliseconds was seen in clinical studies, and QTc prolongation has been reported as an adverse effect).[2] Therefore, they recommend that dasatinib should be used with caution with other drugs that may also prolong the QT interval, or with cumulative high-dose **anthracycline** chemotherapy.[1,2]

(f) Drugs that reduce gastric pH

1. Antacids. The solubility of dasatinib is altered by changes in pH. In a single-dose study, the AUC and maximum plasma level of dasatinib 50 mg were reduced by 55% and 58%, respectively, when it was given at the same time as 30 mL of an **aluminium/magnesium hydroxide** antacid. However, when the antacid was given 2 hours before dasatinib, there was no change in the pharmacokinetics of dasatinib.[1,2] Therefore, if needed, antacids may be given 2 hours before or 2 hours after a dose of dasatinib.[1]

2. H_2-receptor antagonists or Proton pump inhibitors. In a single-dose study, **famotidine**, given 10 hours before dasatinib markedly reduced the exposure to dasatinib by 61%. This is thought to be because the acid suppressant effect of famotidine decreases the solubility of dasatinib. The H_2-receptor antagonists and proton pump inhibitors should therefore be avoided in patients taking dasatinib. The manufacturers advise that antacids (see above) should be used instead.[1,2]

(g) Grapefruit juice

The US manufacturer predicts that grapefruit juice may increase the plasma levels of dasatinib and advises avoidance.[2] Grapefruit is a modest CYP3A4 inhibitor, having the greatest effect on drugs that are poorly bioavailable. Until more is known about its possible effect on dasatinib, given the marked effect of the CYP3A4 inhibitor, ketoconazole, see *CYP3A4 inhibitors*, above, this seems a sensible precaution.

Enzastaurin + Antineoplastics

Capecitabine, cisplatin and gemcitabine did not alter the pharmacokinetics of enzastaurin, and enzastaurin did not appear to alter the pharmacokinetics of these antineoplastics.

Clinical evidence, mechanism, importance and management

In a study in 30 patients who received enzastaurin alone, followed by enzastaurin, **gemcitabine**, and **cisplatin**, the pharmacokinetics of enzastaurin were not altered to a clinically significant extent by cisplatin and gemcitabine. The pharmacokinetics of gemcitabine or cisplatin were not affected by enzastaurin, when compared with historical data.[1] Similarly, in a study in patients who received enzastaurin alone, or enzastaurin with **capecitabine**, there were no significant changes in the pharmacokinetics of enzastaurin in the 6 patients for whom pharmacokinetic data were available. In addition, the pharmacokinetics of capecitabine were similar to those previously reported for capecitabine alone.[2]

Erlotinib + Antiepileptics; Enzyme-inducing

Enzyme-inducing antiepileptics reduce the plasma levels of erlotinib. A single case report describes increased phenytoin levels in a patient given erlotinib.

Clinical evidence

(a) Effect on erlotinib levels

As part of a study in 33 patients with glioma, the pharmacokinetics of erlotinib 100 mg daily increasing to 500 mg daily were compared in patients taking enzyme-inducing antiepileptics and those not taking these antiepileptics. There was a 33 to 71% lower exposure to erlotinib when it was given with an enzyme-inducing antiepileptic drug. Antiepileptic drugs taken were **carbamazepine**, **oxcarbazepine**, **phenytoin**, **fosphenytoin**, **phenobarbital** and **primidone**. Patients taking these drugs tolerated a higher dose of erlotinib.[1]

(b) Effect on antiepileptic levels

A case report describes a 52-year-old woman, stable taking **phenytoin** 100 mg twice daily, with a plasma level of 5 to 6 mg/dL, who experienced signs of **phenytoin** toxicity, and an elevated plasma **phenytoin** level (19.8 mg/dL) after starting to take erlotinib 150 mg daily. Despite a reduction in her **phenytoin** dose, to 100 mg daily alternating with 200 mg daily, her **phenytoin** level rose to 25.3 mg/dL. Three weeks after a further reduction in her **phenytoin** dose, to 100 mg daily, the phenytoin level was 13.5 mg/dL.[2]

Mechanism

Erlotinib is a substrate of the cytochrome P450 isoenzyme CYP3A4, and therefore its levels are reduced by the enzyme-inducing antiepileptics, which induce this isoenzyme. The reason for the increase in phenytoin levels is uncertain as erlotinib would not be expected to alter the pharmacokinetics of phenytoin by inhibiting CYP2C9, by which phenytoin is metabolised.

Importance and management

The effect of enzyme-inducing antiepileptics is established, and likely to be clinically important. The manufacturers of erlotinib recommend using alternatives to these antiepileptics if possible.[3,4] If this is not possible, the starting dose of erlotinib should be increased (the UK manufacturers suggest 300 mg) with close monitoring, and, if tolerated, further increased after 2 weeks, to a maximum of 450 mg.[3,4] When stopping the enzyme-inducing drug, they recommend immediately reducing the erlotinib dose to the indicated starting dose.[3] The authors of the glioma study suggest that, for further studies in this disease, the dose of erlotinib should be at least 500 mg daily in those already taking enzyme-inducing antiepileptics and 200 mg daily in those patients not taking these drugs.[1] Note that, **primidone** is metabolised to phenobarbital, and **fosphenytoin** is metabolised to phenytoin, and so similar precautions may be prudent with these drugs.

The case of raised phenytoin levels with erlotinib appears to be the only report of such an interaction, and its general relevance is unclear.[2]

4. Tarceva (Erlotinib). Roche Products Ltd. UK Summary of product characteristics, May 2009.

Erlotinib + Antineoplastics

Temozolomide appears to have dose-related effects on erlotinib levels. Erlotinib pharmacokinetics are not affected by carboplatin, gemcitabine, docetaxel or paclitaxel, but capecitabine may increase erlotinib exposure, although this was not seen in a pharmacokinetic study. The pharmacokinetics of gemcitabine and carboplatin were not affected to a clinically relevant extent by erlotinib. The effect of erlotinib on docetaxel pharmacokinetics is unclear.

Clinical evidence, mechanism, importance and management

(a) Capecitabine

The manufacturer notes that erlotinib has no effect on the pharmacokinetics of capecitabine, but the AUC of erlotinib may be increased by capecitabine (amount not stated).[1] However, a study in which patients received capecitabine, docetaxel and erlotinib found no clinically significant changes in the pharmacokinetics of erlotinib when it was given with these two cytotoxics.[2]

(b) Carboplatin

In a study in patients given paclitaxel and carboplatin the AUC of platinum was increased by about 10% when erlotinib was given, but this is not considered to be clinically significant. The pharmacokinetics of erlotinib were not altered by carboplatin when compared with historical controls.[1,3]

(c) Gemcitabine

The manufacturer notes that there was no change in the pharmacokinetics of gemcitabine or erlotinib on concurrent use in a phase 1 study.[1,4]

(d) Taxanes

In a study in which patients received capecitabine, **docetaxel** and erlotinib, there was no change in the pharmacokinetics of erlotinib when it was given with these two cytotoxics. A trend towards a modest reduction in the AUC and maximum concentration of **docetaxel** (with capecitabine) was seen when erlotinib was also given compared with docetaxel and capecitabine without erlotinib. However, the authors state that this did not confirm an interaction due to variability in docetaxel pharmacokinetics. The relevance of this is therefore uncertain and further study is needed.[2]

The pharmacokinetics of **paclitaxel** were not altered by erlotinib in a study in patients given **paclitaxel** and carboplatin, nor were the pharmacokinetics of erlotinib affected by **paclitaxel** when compared with historical controls.[1,3]

(e) Temozolomide

As part of a phase I study, 16 patients with glioma were given erlotinib 100 mg daily increasing to 250 mg daily alone, and 14 patients were given erlotinib with temozolomide 150 mg/m^2 increasing to 200 mg/m^2 for 5 days in each 28 day cycle. There was some variability in the pharmacokinetics of erlotinib between the patients taking the combination and those taking erlotinib alone at the different dose levels. For example, at the lowest dose of erlotinib 100 mg daily, the group also taking temozolomide (3 patients) had a 49% lower maximum plasma level of erlotinib, and almost 50% lower AUC of both erlotinib and its metabolite OSI-420. Whereas, at a dose of erlotinib of 200 mg daily, the difference was reversed with the temozolomide group (3 patients) having a 45% higher AUC of erlotinib. However, with erlotinib 150 mg and 250 mg no differences were apparent.[5] The reason for these paradoxical findings is unclear, and could be attributed to the small group sizes and an imbalance in some factor between the groups. Further study is needed to assess whether an interaction actually occurs and if it does, the clinical significance of this.

Erlotinib + Food

Food increases the extent of absorption of erlotinib.

Clinical evidence, mechanism, importance and management

In a pharmacokinetic study, 18 healthy subjects received a single 150-mg dose of erlotinib after a 10-hour fast and 4 hours before food, or with a high-fat, high-calorie breakfast. When taken with food, the maximum plasma concentration and AUC of erlotinib were increased by 52% and 97%, respectively. The effects of food on multiple doses of erlotinib were then investigated in 22 healthy subjects who took erlotinib 100 mg daily for 7 days after either a 10-hour fast and 4 hours before food, or with a high-fat, high-calorie breakfast. At day 7 of the study, there was a 34% increase in AUC of erlotinib when it was taken with food, but this was not statistically significant.[1]

It is thought that the increase in exposure to erlotinib is due to increased absorption in the presence of food.[1] However, this appears to be less significant after multiple dosing. Nevertheless, it is recommended that erlotinib is taken on an empty stomach, at least one hour before or 2 hours after any food.[2,3]

2. Tarceva (Erlotinib). OSI Pharmaceuticals, Inc., and Genentech, Inc. US Prescribing information, April 2009.
3. Tarceva (Erlotinib). Roche Products Ltd. UK Summary of product characteristics, May 2009.

Erlotinib + Miscellaneous

The metabolism of erlotinib is markedly affected by drugs that are potent inhibitors (such as ketoconazole) or inducers (such as rifampicin) of CYP3A4. CYP1A2 inhibitors such as ciprofloxacin also increase erlotinib exposure. Drugs that decrease gastric acidity (omeprazole, ranitidine) decrease erlotinib exposure.

Clinical evidence, mechanism, importance and management

(a) CYP1A2 inhibitors

The AUC of erlotinib was increased by 39% when it was given with **ciprofloxacin**, but its maximum plasma level was increased by just 17%.[1,2] The AUC and maximum plasma levels of the active metabolite of erlotinib were increased by 60% and 48%, respectively.[2] Erlotinib is partially metabolised by the cytochrome P450 isoenzyme CYP1A2, of which ciprofloxacin is a moderate inhibitor.

The UK manufacturer notes that the clinical relevance of these pharmacokinetic changes is unclear, but advises caution when **ciprofloxacin** or potent inhibitors of CYP1A2 are given with erlotinib, and they specifically name **fluvoxamine**.[2] It may be necessary to reduce the dose of erlotinib if adverse effects occur.[1,2] This seems a sensible precaution. For a list of CYP1A2 inhibitors, see 'Table 1.2', (p.4).

(b) CYP3A4 inducers

Pretreatment with **rifampicin** (**rifampin**) 600 mg daily for 7 days reduced the AUC of erlotinib by about 66%.[1,2] In another study, the AUC of a single 450-mg dose of erlotinib, taken after 11 days of treatment with **rifampicin** was about 57% of that of erlotinib 150 mg taken without rifampicin.[1,2] Rifampicin is a potent inducer of the metabolism of erlotinib, probably because of its effects on the cytochrome P450 isoenzyme CYP3A4.

The manufacturers advise that alternative treatments with no CYP3A4-inducing activity should be considered. If this is not possible, the starting dose of erlotinib should be increased (the UK manufacturers suggest 300 mg) with close monitoring, and if tolerated, further increased after 2 weeks, to a maximum of 450 mg.[1,2] When stopping the enzyme-inducing drug, they recommend immediately reducing the erlotinib dose to the indicated starting dose.[1] They also advise caution with other CYP3A4 inducers, and specifically name **rifabutin**,[1] **rifapentine**,[1] and **St John's wort**.[1,2] For a list of CYP3A4 inducers, see 'Table 1.4', (p.6).

(c) CYP3A4 inhibitors

In a study, 12 healthy subjects were given **ketoconazole** 200 mg twice daily for 5 days, with a single 100-mg dose of erlotinib on day 2. The AUC of erlotinib was increased by 86% and its maximum plasma level was

increased by 52%. There was no change in the elimination half-life. For the active metabolite, OSI-420, the AUC was 30% higher but the maximum level was 23% lower.[3]

Erlotinib is a substrate for the cytochrome P450 isoenzyme CYP3A4, of which ketoconazole is an inhibitor. The lack of change in elimination half-life suggests that ketoconazole increases erlotinib bioavailability, and it is possible that P-glycoprotein inhibition may also be involved.

This interaction is established, and the marked increase in erlotinib levels is likely to be clinically important. The manufacturers advise caution on concurrent use, and recommend that the dose of erlotinib should be reduced if severe adverse reactions occur when given with any potent CYP3A4 inhibitors. They specifically name **clarithromycin**,[1,2] **erythromycin**,[2] **grapefruit** and **grapefruit juice**,[1] **itraconazole**,[1,2] **ketoconazole**,[1,2] **nefazodone**,[1] **protease inhibitors**[2] (**atazanavir**, **indinavir**, **nelfinavir**, **ritonavir**, **saquinavir**)[1], **telithromycin**,[1] **troleandomycin**[1] and **voriconazole**.[1,2] For a list of CYP3A4 inhibitors, see 'Table 1.4', (p.6).

(d) CYP3A4 substrates

The manufacturer states that erlotinib did not alter the clearance of **midazolam**, a substrate of CYP3A4, but the bioavailability of oral **midazolam** was reduced by up to 24%.[2] *In vitro*, erlotinib is a moderate inhibitor of CYP3A4,[2] therefore this finding is the opposite of that expected, and the mechanism is not clear. However, this modest reduction in the AUC of midazolam is not clinically relevant, and suggests that clinically relevant interactions with other drugs that are substrates of CYP3A4 are unlikely.[2]

(e) Drugs that affect gastrointestinal pH

Omeprazole reduces the AUC and maximum plasma concentration of erlotinib by 46% and 61%, respectively.[1,2] The time taken to reach maximum plasma levels and the half-life of erlotinib were unaffected by **omeprazole**.[2] Similarly, giving erlotinib with **ranitidine** 300 mg decreased the erlotinib AUC and maximum levels by 33% and 54%, respectively.[2] However, when erlotinib was given 2 hours before or 10 hours after **ranitidine** 150 mg twice daily, the erlotinib AUC and maximum levels decreased by only 15% and 17%, respectively.[2]

Drugs that reduce gastric acidity are thought to reduce the solubility of erlotinib (which has a decreased solubility above pH 5), thereby reducing its absorption. Therefore, the manufacturers of erlotinib advise against the concurrent use of **proton pump inhibitors** and **H_2-receptor antagonists**.[1,2] If the use of **ranitidine** is essential, administration should be separated with the erlotinib taken 2 hours before or 10 hours after the ranitidine.[2] Although **antacids** are also predicted to interact, antacid interactions can usually be minimised by separation of administration. The manufacturer recommends that, if treatment with **antacids** is essential, they should be taken at least 4 hours before or 2 hours after erlotinib.[2]

(f) NSAIDs

Infrequent cases of gastrointestinal bleeding have been reported in patients taking erlotinib, and some cases have occurred in patients also taking NSAIDs.[1,2]

(g) P-glycoprotein inhibitors

Erlotinib is a substrate for the drug transporter protein P-glycoprotein. The manufacturer suggests that drugs that are inhibitors of P-glycoprotein may alter the pharmacokinetics (absorption and/or distribution) of erlotinib. They specifically mention **ciclosporin** and **verapamil**, and advise caution.[2] Note that, many CYP3A4 inhibitors, see (a) above, are also inhibitors of P-glycoprotein, and both mechanisms may be involved in their interactions with erlotinib.

(h) Warfarin

Raised INRs and infrequent bleeding have been reported in patients taking warfarin with erlotinib. Patients taking these drugs, and other coumarins, should be closely monitored for INR changes.[1,2]

Erlotinib + Tobacco

Smoking increases the metabolism of erlotinib.

Clinical evidence

In a study, 12 smokers and 14 non-smokers were given oral erlotinib 150 mg on day one and 300 mg on day 15. The subjects who smoked had lower maximum plasma levels of erlotinib; 35% lower after the 150 mg dose and 20% lower after the 300 mg dose. The AUC of erlotinib was also reduced, by 65% and 57%, respectively.[1]

In addition, the manufacturer notes that in a phase 3 study, the steady-state trough plasma concentrations of erlotinib were about twofold less in smokers than in former smokers or patients who had never smoked, and erlotinib clearance was 24% higher.[2]

Mechanism

Cigarette smoking induces the cytochrome P450 isoenzymes CYP1A1 and CYP1A2, which are involved in the metabolism of erlotinib.

Importance and management

Consideration should be given to the smoking status of a patient when planning treatment with erlotinib.[1] The manufacturer says that these decreases are likely to be clinically important, and that patients should be encouraged to stop smoking[2,3] as early as possible before starting treatment with erlotinib.[3] In patients who continue to smoke, the dose of erlotinib should be cautiously increased to a maximum of 300 mg. In patients who stop smoking during treatment, the erlotinib dose should be immediately reduced to the recommended starting dose.[2]

Estramustine + ACE inhibitors

Angioedema occurred in a man taking cilazapril after starting estramustine. The concurrent use of estramustine and ACE inhibitors might increase the risk of angioedema.

Clinical evidence, mechanism, importance and management

A patient who had taken an ACE inhibitor for 20 years experienced four episodes of swelling of the tongue and epiglottis over a period of 40 days, approximately 2 months after starting to take estramustine. Three of the episodes resolved after hydrocortisone was given; one episode was unresponsive to hydrocortisone and required a tracheotomy. After stopping the estramustine and while continuing the **cilazapril**, the patient experienced no further episodes of angioedema. He had never had angioedema while taking the ACE inhibitor.[1]

Angioedema is a rare adverse effect of both estramustine and the ACE inhibitors, and it is possible that concurrent use might increase the risk. The UK manufacturer of estramustine notes that, in many of the reported cases of angioedema with estramustine, including a fatal one, patients were also taking ACE inhibitors.[2] They recommend that treatment with estramustine should be stopped immediately if angioedema occurs.[2]

Estramustine + Calcium compounds

The absorption of estramustine is reduced by milk, foods, and drugs containing calcium.

Clinical evidence

A randomised three-way crossover study in 6 patients with prostate cancer found that the absorption of single-doses of estramustine disodium (equivalent to 140 mg of estramustine) was reduced by 59% when taken with 200 mL of **milk**, and by 33% when taken with a standardised breakfast (2 pieces of white bread with margarine, ham, tomato, marmalade and water). Peak serum estramustine levels were reduced by 68% and 43%, respectively.[1]

Mechanism

In vitro studies suggest that estramustine combines with calcium ions in milk and food to form a poorly-soluble complex that is not as well absorbed as the parent compound.[1]

Importance and management

An established interaction although the information is limited. The manufacturers recommend that estramustine should be taken at least one hour before or 2 hours after meals, and that it should not be taken at the same time as milk, milk products, calcium-rich foods, or drugs containing calcium (such as **calcium-containing antacids**).[2,3]

Estramustine + Clodronate

Clodronate markedly increases the levels of estramustine.

Clinical evidence, mechanism, importance and management

In 12 patients, the bioavailability of estramustine was increased by about 80% when clodronate 800 mg four times daily was given with estramustine 280 mg twice daily for 5 days. The serum levels and AUC of clodronate were not changed by estramustine.[1] Documentation appears to be limited to this study. However, the toxicity of estramustine should be more closely monitored if clodronate is also given. The effects of other bisphosphonates do not appear to have been studied.

Etoposide + Antiepileptics; Enzyme-inducing

Etoposide clearance appears to be increased by phenobarbital, phenytoin, and probably carbamazepine, and this may result in reduced efficacy.

Clinical evidence, mechanism, importance and management

The clearance of etoposide was found to be highly variable in children given etoposide 320 to 500 mg/m^2 over 6 hours on alternate days for a total of 3 doses. However, it was 77% higher in 7 children taking antiepileptics (**phenobarbital**, **phenytoin** or both) than in 22 others not taking antiepileptics.[1] In a retrospective survey, long-term antiepileptic use (**phenytoin**, **phenobarbital**, **carbamazepine**, or a combination) was associated with worse event-free survival, and greater haematological and/or CNS relapse in children receiving chemotherapy for B-lineage acute lymphoblastic leukaemia. The authors considered that the increased clearance of etoposide induced by the antiepileptics was a likely factor in these findings.[2] Be alert for the possible need to give larger doses of etoposide if these antiepileptics (and probably **primidone**, which is metabolised to phenobarbital, or **fosphenytoin**, which is metabolised to phenytoin) are used. More study is needed to establish the magnitude and clinical effects of the interaction.

Note that reduced valproate levels and phenytoin levels have been reported in patients receiving chemotherapy including etoposide, see 'Antiepileptics + Antineoplastics; Cytotoxic', p.593.

Etoposide + Atovaquone

The concurrent use of atovaquone with etoposide may modestly increase exposure to the metabolite, etoposide catechol.

Clinical evidence, mechanism, importance and management

A study in 9 children with acute lymphoblastic leukaemia or non-Hodgkin's lymphoma found that the AUC of etoposide and its metabolite, etoposide catechol, were slightly increased, by 9% and 28%, respectively, following atovaquone 45 mg/kg daily, when compared with co-trimoxazole (trimethoprim with sulfamethoxazole) 150/750 mg/m^2 daily. The mechanism by which this occurs is unclear, but the authors suggested that atovaquone may affect the metabolism of etoposide by the cytochrome P450 isoenzyme CYP3A4 or its transport by P-glycoprotein.[1] The authors considered that an interaction with co-trimoxazole was unlikely, so used it as a control; however, ideally this requires confirmation. The relevance of the minor changes seen is unclear. The authors note that the risk of etoposide-related secondary acute myeloid leukaemia has been linked to minor changes in therapy, therefore, they advise caution if atovaquone is given with etoposide, particularly if it is used with other substrates of CYP3A4 or P-glycoprotein.[1] They also say it may be possible to avoid the interaction by separating the administration by one to 2 days,[1] but this requires confirmation.

Etoposide + Ciclosporin

High-dose ciclosporin markedly raises etoposide levels and increases the suppression of white blood cell production. Severe toxicity has been reported in one patient.

Clinical evidence

In a comparative study, 16 patients with multidrug-resistant advanced cancer were given 20 paired courses of etoposide alone or with ciclosporin. Ciclosporin levels were measured at the end of a 2-hour infusion: ciclosporin levels of greater than 2000 nanograms/mL were defined as high-dose and ciclosporin levels less than 2000 nanograms/mL were defined as low-dose. High and low-dose ciclosporin, respectively, increased the etoposide AUC by 80% and 50%, decreased the total clearance by 38% and 28%, increased its half-life by 108% and 40%, reduced the leucocyte count nadir by 64% and 37%, and altered the volume of distribution at steady state by 46% and 1.4%.[1] The patients were given 150 to 200 mg/m^2 of etoposide daily as a 2-hour intravenous infusion for 3 consecutive days and ciclosporin in doses ranging from 5 to 21 mg/kg daily as a 3-day continuous infusion.[1]

In another study, 18 children with recurrent or refractory tumours who had previously received etoposide were given high-dose ciclosporin (either a continuous infusion of 15 mg/kg per 24 hours for 60 hours (13 patients) or 30 mg/kg over 3 hours on 3 consecutive days (5 patients) with etoposide 150 mg/m^2 over one hour for 3 days, starting one hour after the beginning of the ciclosporin infusion. The AUC and half-life of etoposide were increased by 89% and 78%, respectively, and the clearance was decreased by 48%.[2] In a further study in children, the pharmacokinetics of etoposide 100 mg/m^2 daily were compared with etoposide 60 mg/m^2 (a 40% reduction in dose) with high-dose ciclosporin. Despite the dose reduction, recipients of ciclosporin had a 71% reduction in etoposide clearance and a 47% increase in the etoposide AUC, although toxicity was similar.[3]

The leukaemic cells in the bone marrow of a patient with acute T-lymphocyte leukaemia were totally cleared when ciclosporin 8.3 mg/kg orally twice daily was given with etoposide 100 to 300 mg daily for 2 to 5 days, but the adverse effects were severe (mental confusion, renal and hepatic toxicity). The patient died from respiratory failure precipitated by a chest infection.[4]

A patient with chronic myeloid leukaemia who had responded poorly to treatment with etoposide, mitoxantrone and cytarabine for blast crisis, returned to the chronic phase when given etoposide with ciclosporin.[5] An *in vitro* study by the same authors showed that etoposide was partially toxic to blast cells but that its effect on blast cells was increased sixfold when it was given with ciclosporin.[5]

Mechanism

It is suggested that the ciclosporin inhibits the metabolism of etoposide by cytochrome P450 isoenzymes,[6] and inhibits hepatic P-glycoprotein, as

well as some unknown non-renal clearance mechanism.[1] The total effect is to cause the retention of etoposide in the body, thereby increasing its effects.

Importance and management

An established interaction. Ciclosporin alters the pharmacokinetics of etoposide resulting in increased levels. This pharmacokinetic interaction has complicated the study of the value of using ciclosporin to modulate multidrug resistance in tumours to improve the response to chemotherapy: any benefit could just be attributed to dose intensification. Consequently, some,[1-3] including one manufacturer,[7] have suggested reducing the dose of etoposide by 40% or 50% in the presence of ciclosporin.[1-3] In one study, a continuous infusion of ciclosporin was better tolerated than an intermittent regimen, but it was associated with similar hepatic and renal impairment as the short schedule (transient hyperbilirubinaemia, and elevated creatinine or urea).[2] The use of high-dose ciclosporin for multidrug-resistant tumour modulation remains experimental and should only be undertaken in clinical studies. Concurrent use should be very well monitored. More study is needed to find out the possible effects of low-dose ciclosporin.

Etoposide + Cisplatin and other platinum compounds

The clearance of etoposide may be modestly reduced by carboplatin and cisplatin.

Clinical evidence, mechanism, importance and management

(a) Carboplatin

In one study in 4 patients, the pharmacokinetics of etoposide were unchanged when carboplatin was also given.[1] However, in another study of 14 young patients receiving etoposide and carboplatin the clearance of etoposide was lower than in previous reports in adults and children. They had been given an escalating dose regimen starting with etoposide 960 mg/m^2, and increasing to 1200 mg/m^2, and 1500 mg/m^2, given in three divided doses on alternate days, with carboplatin 400 to 700 mg/m^2 given on the other days, followed by autologous marrow rescue. The authors point out that the dose and the timing of carboplatin may be important determinants for any interaction.[2] In yet another study,[3] carboplatin did not affect the pharmacokinetics of etoposide during the first cycle of chemotherapy (etoposide was given on days 1, 2 and 3, and carboplatin on day 2, and the AUC of etoposide was compared for days 1 and 2). However, during a second cycle of chemotherapy, the etoposide AUC was 8% higher on day 2 than day 1. These changes were considered unlikely to be clinically important.[3]

(b) Cisplatin

A study in 17 children with neuroblastoma found that when intravenous cisplatin 90 mg/m^2 was given immediately before etoposide, the clearance of etoposide 780 mg/m^2 fell by 20% and its serum levels rose. However, after a cumulative dose of 360 mg/m^2 cisplatin had no effect on the clearance of etoposide.[4] In another study, cisplatin did not affect the pharmacokinetics of etoposide during the first cycle of chemotherapy (etoposide was given on days 1, 2 and 3, and cisplatin on day 2, and the AUC of etoposide was compared for days 1 and 2). However, during a second cycle of chemotherapy, the etoposide AUC was 28% higher on day 3 than day 1. These changes were considered unlikely to be clinically important.[3]

Etoposide + CYP3A4 inducers or inhibitors

Ketoconazole modestly increased the AUC and decreased the clearance of etoposide in one study. Etoposide clearance was markedly increased by prednisone in one study. Etoposide bioavailability was modestly (and unexpectedly) decreased by grapefruit juice.

Clinical evidence

(a) CYP3A4 inducers

In a study, 102 children with acute lymphoblastic leukaemia were given **prednisone** 40 mg/m^2 daily for 28 days with etoposide 300 mg/m^2 on day 29. Forty-eight of the children with high risk disease were given continuation therapy and received etoposide 300 mg/m^2 at week 54, two weeks or more after the last **prednisone** dose. Etoposide clearance was 62% higher on day 29 than at week 54 and the AUC for the catechol metabolite was significantly lower (27%) on day 29 compared with week 54.[1]

(b) CYP3A4 inhibitors

1. Grapefruit juice. In a single-dose study, 6 patients were given etoposide 50 mg intravenously or orally, either alone or after drinking 100 mL of **grapefruit juice**. The bioavailability of oral etoposide was unexpectedly *reduced* by about 25% by **grapefruit juice**, but there was wide inter-individual variation in the findings.[2]

2. Ketoconazole. In a study in 27 patients, ketoconazole 200 mg daily was given with oral etoposide (escalating doses of 50 mg every other day increasing to 50 mg alternating with 100 mg daily) in cycles of 3 out of 5 weeks. The median AUC of etoposide was increased by about 20%, and its clearance reduced by about 18%, and inter-individual variation was greater than seen with etoposide alone. However, the toxicity profile of etoposide did not appear to be altered by ketoconazole, when compared with historical data.[3]

Mechanism

Etoposide is a substrate for the cytochrome P450 isoenzyme CYP3A4. *In vitro* studies using human liver microsomes showed that ketoconazole, **prednisolone**, **troleandomycin**, **verapamil** and **vincristine** can inhibit the metabolism (3′-demethylation) of etoposide by CYP3A4.[4] The clinical study found that ketoconazole modestly inhibited etoposide metabolism; however, unexpectedly, grapefruit juice (another CYP3A4 inhibitor) appeared to decrease etoposide bioavailability. The reason for this is unknown, but may be a concentration effect, or an effect via P-glycoprotein. Also, somewhat in contrast to the *in vitro* findings, prednisone (a metabolite of prednisolone) induced etoposide metabolism, but note that corticosteroids are more usually known to be clinical inducers of CYP3A4 and possibly also P-glycoprotein.

Importance and management

There seems to be little clinical confirmation that the potential interactions with CYP3A4 inhibitors or inducers, other than prednisone have clinical relevance, but good monitoring would be a prudent precaution. Ketoconazole had only a modest and variable effect on etoposide, and grapefruit juice seemed to reduce rather than increase oral etoposide bioavailability. Further study is needed.

For mention that the protease inhibitors (CYP3A4 inhibitors) have been associated with an increased risk of infection when used with various antineoplastic regimens, including those containing etoposide, see also 'Antineoplastics + Protease inhibitors', p.703.

Etoposide + Food

In 8 patients with extensive small cell lung carcinoma the pharmacokinetics of a 100-mg oral dose of etoposide were unaffected when it was taken with a full breakfast, when compared with the fasting state.[1] However, the UK manufacturer recommends that oral etoposide should be taken on an empty stomach.[2]

2. Vepesid Capsules (Etoposide). Bristol-Myers Pharmaceuticals. UK Summary of product characteristics, March 2008.

Etoposide + Levamisole

The manufacturers of an intravenous etoposide *phosphate* product warn that the administration with drugs known to inhibit phosphatase activity (they name levamisole) should be undertaken with caution.[1,2] This is presumably because this might reduce the conversion of etoposide phosphate to etoposide in the plasma. There does not seem to be any information on whether this interaction is clinically relevant.

1. Etopophos Injection (Etoposide phosphate). Bristol-Myers Squibb Pharmaceuticals Ltd. UK Summary of product characteristics, September 2007.
2. Etopophos Injection (Etoposide phosphate). Bristol-Myers Squibb Company. US Prescribing information, March 2005.

Etoposide + Other antineoplastics

The use of doxorubicin with cyclophosphamide has no clinically relevant effects on the pharmacokinetics of oral or intravenous etoposide. Similarly, cyclophosphamide with methotrexate, doxorubicin with procarbazine and procarbazine alone do not affect the pharmacokinetics of oral etoposide.

Clinical evidence, mechanism, importance and management

(a) Cyclophosphamide with Doxorubicin

A pharmacokinetic study in 7 patients with small cell lung cancer given cyclophosphamide 800 mg/m^2, doxorubicin 40 mg/m^2 and etoposide 100 mg/m^2 (all given intravenously) found that the protein binding, metabolism and renal clearance of etoposide were unaffected by the other antineoplastics.[1] Similarly, another study found only modest changes in the pharmacokinetics of intravenous etoposide when it was given with cyclophosphamide and doxorubicin, compared with use alone, and these changes were considered unlikely to be clinically relevant. Specifically, the AUC of etoposide was 9% higher and the clearance was 10% lower on day one of the CAE cycle (cyclophosphamide, doxorubicin, and etoposide) compared with days 2 and 3 (etoposide alone).[2] This is a commonly used regimen, and these data suggest there is no pharmacokinetic interaction.

(b) Cyclophosphamide with Methotrexate

No changes in etoposide pharmacokinetics were seen when oral etoposide 100 mg was given immediately after oral cyclophosphamide 100 mg/m^2 and oral methotrexate 12.5 mg/m^2 in 8 patients with small cell lung cancer.[3]

(c) Doxorubicin with Procarbazine

No changes in etoposide pharmacokinetics were seen when oral etoposide 400 mg was given 15 minutes after intravenous doxorubicin 35 mg/m^2 with oral procarbazine 60 mg/m^2 or after oral procarbazine alone, when compared with etoposide alone.[3]

(d) Imatinib

For the possible effect of imatinib on etoposide, see 'Imatinib + Antineoplastics', p.734.

(e) Platinum compounds

For the lack of effect of platinum derivatives on etoposide pharmacokinetics, see 'Etoposide + Cisplatin and other platinum compounds', p.725.

Exemestane + CYP3A4 inducers or inhibitors

Ketoconazole appears not to interact with exemestane. Rifampicin reduces exemestane levels and other CYP3A4 inducers are predicted to interact similarly.

Clinical evidence, mechanism, importance and management

The manufacturers say that *in vitro* evidence shows that while exemestane is metabolised by both the cytochrome P450 isoenzyme CYP3A4 and aldoketoreductases, a clinical study found that **ketoconazole** (a specific inhibitor of CYP3A4) had no significant effects on the pharmacokinetics of exemestane. The manufacturers therefore suggest that interactions with CYP3A4 inhibitors are unlikely.[1,2]

However, in an interaction study the potent enzyme inducer **rifampicin** (**rifampin**) reduced the AUC and maximum plasma levels of exemestane by 54% and 41%, respectively.[1,2] The manufacturers therefore caution the use of exemestane with CYP3A4 inducers such as **carbamazepine**, **phenobarbital**, **phenytoin** and **St John's wort**,[1,2] and the US manufacturer recommends that the dose of exemestane should be doubled to 50 mg daily in patients taking CYP3A4 inducers such as **rifampicin** (**rifampin**) and **phenytoin**.[2] The clinical relevance of these potential interactions is unknown, but it would seem prudent to monitor the outcome of concurrent use for both exemestane efficacy and toxicity, if the dose is increased. Note that, **primidone** is metabolised to phenobarbital, and **fosphenytoin** is metabolised to phenytoin, and so similar precautions may be prudent with these drugs.

1. Aromasin (Exemestane). Pharmacia Ltd. UK Summary of product characteristics, May 2009.
2. Aromasin (Exemestane). Pfizer. US Prescribing information, October 2008.

Exemestane + Food

Food increases the bioavailability of exemestane.

Clinical evidence, mechanism, importance and management

In a single-dose study in 12 healthy postmenopausal women, a high-fat meal increased the AUC of exemestane 25 mg by 40%, but had no significant effect on its maximum plasma levels. In addition, its pharmacodynamics (estrone sulfate suppressant effect) were unaffected.[1] The manufacturers recommend that exemestane is taken after food.[2,3]

3. Aromasin (Exemestane). Pfizer. US Prescribing information, October 2008.

Fludarabine + Busulfan

In 16 patients with haematological malignancies the pharmacokinetics of intravenous fludarabine were unaltered by oral high-dose busulfan.[1]

1. Bonin M, Pursche S, Bergeman T, Leopold T, Illmer T, Ehninger G, Schleyer E, Bornhauser M. F-ara-A pharmacokinetics during reduced-intensity conditioning therapy with fludarabine and busulfan. *Bone Marrow Transplant* (2007) 39, 201–6.

Fludarabine + Dipyridamole

Because fludarabine phosphate is an analogue of adenine, the UK manufacturers warn that drugs that are adenosine uptake inhibitors, such as dipyridamole, may prevent the uptake of fludarabine into cells and reduce its efficacy.[1,2] Until more is known, some caution would seem to be appropriate on concurrent use.

1. Schering Health Care Ltd. Personal communication, February 1995.
2. Fludara Tablets (Fludarabine phosphate). Genzyme Therapeutics. UK Summary of product characteristics, February 2009.

Fludarabine + Food

Food does not affect the pharmacokinetics of oral fludarabine.

Clinical evidence, mechanism, importance and management

In a randomised, crossover study, 16 patients were given fludarabine 90 mg orally either on a full stomach or after fasting on the first day of their chemotherapy cycle, followed 2 days later by intravenous fludarabine 25 mg/m^2 daily for 4 days. There was no clinically significant effect of food on the pharmacokinetics of oral fludarabine.[1] The manufacturer advises that oral fludarabine may be taken with or without food.[2]

1. Oscier D, Orchard JA, Culligan D, Cunningham D, Johnson S, Parker A, Klein M, Gieschen H. The bioavailability of oral fludarabine phosphate is unaffected by food. *Hematol J* (2001) 2, 316–21.
2. Fludara Tablets (Fludarabine phosphate). Genzyme Therapeutics. UK Summary of product characteristics, February 2009.

Fludarabine + Pentostatin

When fludarabine phosphate and pentostatin were used in the treatment of chronic lymphoid leukaemia, 4 out of 6 patients developed pulmonary toxicity consistent with interstitial pneumonitis, and 3 of them died.[1] Pentostatin should therefore not be given with fludarabine.[2,3]

2. Fludara Tablets (Fludarabine phosphate). Genzyme Therapeutics. UK Summary of product characteristics, February 2009.
3. Fludara (Fludarabine phosphate). Bayer HealthCare Pharmaceuticals Inc. US Prescribing information, February 2009.

Fludarabine with Cytarabine + Voriconazole

A case of fatal peripheral neuropathy was tentatively attributed to the use of voriconazole with fludarabine and cytarabine.

Clinical evidence, mechanism, importance and management

A patient experienced severe peripheral neuropathy, which progressed to poor respiratory effort and death, after receiving treatment with cytarabine, fludarabine and tretinoin. During his first course he had developed probable pulmonary invasive fungal infection, and was treated with broad-spectrum antibacterials and liposomal amphotericin B. He then started taking prophylactic voriconazole, which was stopped after a total of 7 days, two days after starting his second course of chemotherapy, because he again had a fever. After 14 days, severe distal peripheral neuropathy became apparent, which progressed, and he died after 23 days.[1] The exact cause of the neurological effects was not clear. Both cytarabine and fludarabine uncommonly cause neurological toxicity, and it has been reported with the combination.[1] In the case described, it was considered that voriconazole might have altered the metabolism of the antineoplastics, and increased the risk of toxicity.[1] However, neither cytarabine nor fludarabine are metabolised by the cytochrome P450 system, which voriconazole inhibits. The clinical relevance of this single case report is uncertain and no general recommendations can be made.

Fluorouracil + Allopurinol

Allopurinol has been studied as a modulator of the effects of fluorouracil, but has not gained an established clinical use in this setting.

Clinical evidence, mechanism, importance and management

Some early studies found that allopurinol 300 mg two to four times daily allowed the usual maximum tolerated dose of fluorouracil to be increased up to twofold.[1-3] The hope was that allopurinol would prove useful to decrease the toxicity and/or improve the activity of fluorouracil. However, most studies have found no increase in response rates in colorectal cancer with allopurinol,[4,5] even when the fluorouracil dose was escalated,[2,4] and some have also found no reduction in toxicity.[5-7] These are by no means all the studies, and are just cited as examples. Allopurinol mouthwash has also been investigated to reduce the incidence of stomatitis with fluorouracil. Some controlled studies have found a benefit,[8] whereas others have not.[9] Allopurinol clearly modulates some of the effects of fluorouracil; however, this has not been shown to be obviously beneficial or harmful in the clinical setting.

Fluorouracil + Aminoglycosides; Oral

Neomycin can delay the gastrointestinal absorption of fluorouracil, but the clinical importance of this is uncertain.

Clinical evidence, mechanism, importance and management

Some preliminary information from a study in 12 patients treated for metastatic adenocarcinoma found that the use of oral **neomycin** 500 mg four times daily for a week delayed the absorption of fluorouracil, but the effects were generally too small to reduce the therapeutic response, except possibly in one patient.[1] It seems probable that this interaction occurs because **neomycin** can induce a malabsorption syndrome. If **neomycin**, and most probably also **paromomycin** or **kanamycin**, are used in patients receiving fluorouracil, the possibility of this interaction should be borne in mind.

Fluorouracil + Cisplatin and other platinum compounds

Giving low-dose cisplatin with a fluorouracil infusion markedly increased toxicity in one study. Cardiotoxicity may possibly be increased if high doses of cisplatin are given with fluorouracil. Oxaliplatin appears to moderately raise fluorouracil levels, without increasing its toxicity.

Clinical evidence, mechanism, importance and management

(a) Cisplatin

In 18 patients with advanced cancers giving low-dose cisplatin 20 mg/m^2 weekly with continuous ambulatory fluorouracil infusions of 300 mg/m^2 daily considerably increased the toxicity (nausea, vomiting, anorexia, diarrhoea, stomatitis, myelosuppression). More than half of the patients developed multiple toxicities, and severe toxicity occurred in two-thirds of the patients. Leucopenia occurred in 28% given both drugs whereas it was virtually nonexistent with fluorouracil alone. Toxicity requiring treatment interruption or dose reduction was seen in 55% of patients receiving fluorouracil alone, and this rose to 94% in the presence of cisplatin.[1]

In another study, signs of cardiotoxicity (chest pain, ST-T wave changes, arrhythmias) were seen in 12 of 80 patients given fluorouracil with cisplatin for carcinoma of the head, neck, oesophagus and stomach.[2] Studies in humans and *rats* have shown that there is a prolonged elevation of filterable platinum levels associated with the concurrent use of cisplatin and fluorouracil.[3]

The combination of a platinum compound and fluorouracil is widely used, but the optimum schedule to improve activity and reduce toxicity is not firmly established. In one study of bolus cisplatin and continuous infusion fluorouracil, modifying the dose of fluorouracil based on its AUC reduced toxicity while still maintaining response rates.[4] In another study, cisplatin pharmacokinetics were said to be optimum when it was given as a continuous infusion with a continuous infusion of fluorouracil.[5] Further study is needed.

(b) Oxaliplatin

In one study, 28 patients with advanced or metastatic colorectal cancer were given fluorouracil alone, or immediately following an 85 mg/m^2 dose of oxaliplatin given over 2 hours. Oxaliplatin did not significantly affect the pharmacokinetics of fluorouracil (either 2 cycles of a 400 mg/m^2 bolus followed by a 46-hour infusion of 2400 mg/m^2 given to 10 patients, with pharmacokinetic sampling over 46 hours; or a single cycle of a 400 mg/m^2 bolus followed by 600 mg/m^2 over 22 hours given to 18 patients, with pharmacokinetic sampling over 22 hours).[6] Similarly, a study in which patients received fluorouracil 200 mg/m^2 daily as a continuous infusion, and oxaliplatin 30 mg/m^2 daily as a 12-hour infusion on days one to 4 of each 14 day cycle found that the pharmacokinetics of both oxaliplatin or fluorouracil were unaffected by concurrent use.[7] However, in another study, 29 patients with advanced colorectal cancer were given fluorouracil in a dose adjusted to give levels of 2.5 to 3 mg/L (dose range 750 to 3500 mg/m^2 per week) either alone, or immediately after a 2-hour infusion of oxaliplatin 130 mg/m^2. In this study pharmacokinetic samples were taken on days one, 8 and 15. Oxaliplatin raised the plasma levels of fluorouracil by about one-third, with the effect appearing to last for 15 days; however, fluorouracil toxicity was not increased.[8]

The combination of fluorouracil and oxaliplatin is widely used, but one of the studies cited here suggests that the schedules could still be adjusted to optimise efficacy and minimise toxicity.[8] As of 2005, the recommended schedule for use of oxaliplatin in the management of colon and colorectal cancer is that it is given before fluorouracil.[9]

Fluorouracil + Dipyridamole

One study suggested that *intravenous* dipyridamole may reduce the steady-state plasma levels of fluorouracil, whereas others found that *oral* dipyridamole caused no important changes in fluorouracil pharmacokinetics.

Clinical evidence, mechanism, importance and management

Numerous preclinical studies found that dipyridamole enhanced the activity of fluorouracil, leading to its investigation as a biomodulator.[1] However, unexpectedly, in one phase I study of the combination, the use of dipyridamole was associated with a lower steady state plasma level of fluorouracil, suggesting an increase of about 30% in the total body clearance or volume of distribution of fluorouracil.[2] In this study, 47 patients with advanced cancer were given fluorouracil in escalating doses ranging from 185 mg/m^2 daily to 3600 mg/m^2 daily with or without dipyridamole as a continuous infusion of 7.7 mg/kg daily for 72 hours.[2] In contrast, in a later randomised study, oral dipyridamole 75 mg three times daily for 5 days did not significantly alter the pharmacokinetics of fluorouracil, except for prolonging the half-life and slightly increasing the dose-intensity: over 5 cycles the average dose of fluorouracil was 479 mg/m^2 alone, compared with 533 mg/m^2 in the presence of dipyridamole. In this study, oral dipyridamole did not improve the antineoplastic activity of fluorouracil with folinic acid.[3] Similarly, another clinical study found that oral dipyridamole did not significantly alter the pharmacokinetics of fluorouracil.[4] Thus, despite the promise of preclinical studies, the benefits of combining dipyridamole with fluorouracil have not been realised clinically.

Fluorouracil + Folic acid

Two patients developed severe fluorouracil toxicity while taking multivitamin preparations containing folic acid.

Clinical evidence

A woman who underwent surgery for carcinoma of the rectum was, a month later, given intravenous fluorouracil 500 mg/m^2 daily for 5 days. At the end of this chemotherapy she was admitted to hospital with anorexia, severe mouth ulceration, bloody diarrhoea and vaginal bleeding, which was interpreted as fluorouracil toxicity. Her concurrent medication included folic acid 5 mg daily (in *Multi-B forte*) along with loperamide, sulfasalazine, vitamins B_{12} and K, and HRT. A month later, when she was given fluorouracil without the folic acid, her treatment was well tolerated and without toxicity. A man similarly treated with fluorouracil for colonic cancer was admitted to hospital 2 days later with severe mouth ulceration and bloody diarrhoea. He too was found to be taking a multivitamin preparation, containing folic acid 500 micrograms (amount taken daily not known). Subsequent courses of fluorouracil at the same dose, but without the folic acid, were well tolerated.[1]

Mechanism

It would seem that folic acid increases fluorouracil inhibition of thymidine formation which is important for DNA synthesis, and thereby increases fluorouracil toxicity.

Importance and management

Direct information seem to be limited to these two cases and a case of fatal toxicity associated with concurrent folic acid and capecitabine, a prodrug of fluorouracil (see 'Fluorouracil prodrugs; Capecitabine + Folinates', p.731) but the interaction would appear to be established. What happened is consistent with the way folinic acid, another source of folate, is used therapeutically to increase the potency of fluorouracil. Patients given fluorouracil should therefore not be given folic acid, and should be told to avoid multivitamin preparations containing folic acid to prevent the development of severe fluorouracil adverse effects.

Fluorouracil + Gemcitabine

Pharmacokinetic analysis has shown that gemcitabine enhances the systemic exposure of fluorouracil in patients with pancreatic carcinoma given folinic acid, fluorouracil, and gemcitabine.[1,2] In addition, *in vitro*, gemcitabine increases both the accumulation of fluorouracil and its cytotoxicity.[1] The use of fluorouracil with gemcitabine is being investigated for its therapeutic potential, particularly in pancreatic cancer.

Fluorouracil + H_2-receptor antagonists

Some data indicate that four weeks, but not one week, of treatment with cimetidine can markedly increase plasma fluorouracil levels. The combination may have increased activity in colorectal cancer.

Clinical evidence, mechanism, importance and management

A study in 6 patients with carcinoma given fluorouracil (15 mg/kg daily for 5 days, repeated every 4 weeks) found that **cimetidine** 1 g daily for 4 weeks increased the AUC and peak plasma levels of fluorouracil by 72% and 74%, respectively, when fluorouracil was given orally. When fluorouracil was given intravenously, **cimetidine** increased its AUC by 27% and reduced its total body clearance by 28%. In this small group, no increased toxicity was noted. The pharmacokinetics of fluorouracil were unaltered when **cimetidine** was given for only one week.[1] **Cimetidine** had similar effects in *animal* studies but **ranitidine** had no effect on fluorouracil metabolism.[2] It is suggested that **cimetidine** reduces the hepatic metabolism of fluorouracil.[1,2] At least three clinical studies have shown some treatment benefits from giving fluorouracil with long-term **cimetidine** in colorectal cancer.[3-5] However, this benefit has been attributed to immunomodulation[3] or inhibition of adhesion,[4] rather than any pharmacokinetic interaction. Whatever the mechanism, it appears that **cimetidine** can increase the activity of fluorouracil. Concurrent treatment should be undertaken with care. **Cimetidine** can be obtained without a prescription in some countries, therefore patients may unwittingly increase the toxicity of fluorouracil. **Ranitidine** does not appear to interact.

Fluorouracil + Interferon alfa

Interferon alfa has increased plasma fluorouracil levels in some, but not other, studies.

Clinical evidence, mechanism, importance and management

In a pharmacokinetic study, 26 patients with colorectal cancer were given a 5-day continuous infusion of fluorouracil 750 mg/m^2 daily repeated in week 4 followed by a bolus intravenous injection of 750 mg/m^2 weekly with or without subcutaneous interferon alfa-2a (*Roferon*) 9 million units three times a week. There was considerable within-patient variation but no significant differences in steady-state plasma levels were found between the two groups.[1] Similarly, others have also reported that interferon alfa does not significantly alter fluorouracil pharmacokinetics;[2,3] however, other studies[4-8] have found a significant increase in the peak levels of fluorouracil and/or its AUC when interferon alfa is given. Despite promising early pre-clinical and clinical data indicating that interferon may improve the response to fluorouracil, this has not yet been demonstrated in randomised studies.[9]

Fluorouracil + Metronidazole

The toxicity, but not the efficacy of fluorouracil, is increased by metronidazole.

Clinical evidence

A marked increase in fluorouracil toxicity was noted in 27 patients with metastatic colorectal cancer when they were given intravenous metronidazole 750 mg/m^2 one hour before receiving intravenous fluorouracil 600 mg/m^2 five days per week, every 4 weeks. Granulocytopenia occurred in 74% of patients, nausea and vomiting in 48%, anaemia in 41%, stomatitis and oral ulceration in 34%, and thrombocytopenia in 19%.[1] A related pharmacokinetic study in 10 patients found that metronidazole reduced the clearance of fluorouracil by 27% over the 5-day period and increased the AUC by 34%. *In vitro* studies with human colon cancer cells did not show any increased efficacy.[1]

Studies using another nitroimidazole, **misonidazole**, in patients with colorectal cancer also found an increased incidence and severity of gastrointestinal toxicity with concurrent use,[2,3] a slightly increased incidence of leucopenia[2] and a reduction in the clearance of fluorouracil.[3]

Mechanism

Metronidazole reduces the clearance of fluorouracil, thereby increasing its toxic effects.

Importance and management

Information is limited but the interaction between fluorouracil and metronidazole appears to be established. It was hoped that metronidazole or misonidazole (no longer in clinical use) might increase the efficacy of fluorouracil. However, the studies above show that the toxicity of fluorouracil is increased without an obvious increase in its therapeutic efficacy. Care should be taken if metronidazole is required for its antimicrobial effects in a patient receiving fluorouracil. Whether other nitroimidazoles (e.g. tinidazole) behave similarly appears not to have been studied.

Fluorouracil + Miscellaneous

A retrospective analysis of studies in a total of 250 patients given fluorouracil for the treatment of gastrointestinal cancer found that chlorprothixene, cinnarizine, prochlorperazine, sodium pentobarbital, thiethylperazine, trimethobenzamide (in antiemetic doses) did not significantly increase toxicity or decrease therapeutic effects of fluorouracil, when compared with a placebo.[1]

Fluorouracil prodrugs + Food

Food modestly to markedly reduces the AUC and plasma levels of capecitabine, but has a minor to modest effect on the pharmacokinetics of the active metabolites. Food markedly reduces the plasma levels and modestly reduces the AUC of fluorouracil derived from tegafur.

Clinical evidence, mechanism, importance and management

(a) Capecitabine

In a crossover study in 11 patients with colorectal cancer, oral capecitabine was given either after an overnight fast, or 30 minutes after breakfast. When normalised to a dose of capecitabine of 1255 mg/m^2, the time to reach maximum plasma levels was prolonged from 30 minutes to 2 hours when capecitabine was taken with food, and the maximum plasma level and AUC were reduced by 60% and 31%, respectively. The maximum plasma level and AUC of fluorouracil derived from capecitabine were reduced by 33% and 16%, respectively. The clinical relevance of these findings remains to be determined.[1] Note that, it is recommended that capecitabine is taken within 30 minutes after a meal,[1-3] because this is how it was used in clinical efficacy studies.[1]

(b) Tegafur with uracil

In a crossover study, 22 patients received a single 200-mg dose of *Uftoral* (tegafur with uracil) with a single 30-mg dose of folinic acid after an overnight fast, or 5 minutes after a high-fat breakfast. The maximum plasma level and AUC of fluorouracil derived from tegafur were reduced by 70% and 37%, respectively, when tegafur with uracil was given with food, and the time to maximum fluorouracil levels was delayed from 30 minutes to 2 hours.[4] This reduction is quite marked, and might result in reduced efficacy. It is recommended that tegafur with uracil is taken one hour before or one hour after meals,[5] as was the procedure in clinical efficacy studies.[4]

Fluorouracil prodrugs + Sorivudine

Marked and rapidly fatal toxicity, attributed to fluorouracil toxicity, has been seen in patients given tegafur or other fluorouracil prodrugs with sorivudine.

Clinical evidence

In 1993, the Japanese Ministry of Health reported that 15 Japanese patients with cancer and a viral disease died several days after being given a fluorouracil prodrug (e.g. **tegafur**) and sorivudine. Before death most of them developed severe toxicity including severe anorexia, marked damage to the bone marrow with decreases in white cell and platelet counts, and marked atrophy of the intestinal membrane, with diarrhoea and loss of blood. Eight other patients given both drugs developed symptoms of severe toxicity.[1,2]

Mechanism

Sorivudine appears to be converted in the gut to a metabolite (BVU or bromovinyluracil) that is a potent inhibitor of dihydropyrimidine dehydrogenase (DPD), an enzyme involved in the metabolism of fluorouracil (which is derived from tegafur and other fluorouracil prodrugs).[1,3] There is some evidence that DPD activity is genetically determined, and that there are poor fluorouracil metabolisers with low DPD activity, who would be expected to be more susceptible to this interaction.[4]

Importance and management

Information appears to be limited to these reports but the interaction appears to be established and of clinical importance. The concurrent use of inhibitors of dihydropyrimidine dehydrogenase (such as sorivudine and **brivudine**) with oral fluorouracil prodrugs such as **capecitabine**[5] and **tegafur**[6] is contraindicated. The manufacturers of tegafur with uracil suggest that it should not be given until 4 weeks after brivudine is stopped, to allow recovery of enzyme activity.[6] Note that sorivudine was withdrawn from the market following confirmation of this interaction.

Fluorouracil prodrugs + Taxanes

There are no clinically significant pharmacokinetic interactions between capecitabine and paclitaxel, and probably not between capecitabine and docetaxel. A case report describes hand-foot syndrome in a patient who received docetaxel two days after stopping tegafur with uracil.

Clinical evidence, mechanism, importance and management

(a) Capecitabine

1. Docetaxel. A study in patients with advanced solid tumours found that the use of capecitabine with docetaxel resulted in an almost twofold decrease in the maximum plasma concentration and AUC of fluorouracil. The authors suggest that more study is needed to assess the significance of this finding. Other pharmacokinetic parameters of capecitabine were not affected by docetaxel, and the pharmacokinetics of docetaxel were not significantly affected by capecitabine or its metabolites.[1]

Another study in similar patients also found that capecitabine did not alter the pharmacokinetics of docetaxel.[2] However, in a multiple regression analysis, the clearance of docetaxel appeared to be modestly increased in 32 patients who had received treatment with capecitabine and docetaxel when compared with 27 other patients who had received docetaxel alone,[3] but this was probably not clinically significant.

2. Paclitaxel. In a study in 17 patients, the concurrent use of paclitaxel and capecitabine did not significantly alter the pharmacokinetics of either drug.[4]

(b) Tegafur with uracil

A 30-year old patient received treatment with **docetaxel** 50 mg/m^2 two days after stopping tegafur with uracil, which she had been taking for the previous 14 months. Seven days later she developed hand-foot syndrome which increased to such an extent that she could not walk due to severe pain. A later subsequent dose of **docetaxel** did not result in hand-foot syndrome. Both fluoropyrimidines and taxanes have been associated with hand-foot syndrome. The authors suggested that a longer period of time is required between the two drugs to reduce the risk of this adverse effect occurring.[5] However, the combination of tegafur and docetaxel is being investigated, and other fluoropyrimidines are used with docetaxel in established regimens, suggesting that any additive interaction is rare.

Fluorouracil prodrugs; Capecitabine + Allopurinol

The activity of capecitabine is predicted to be decreased by allopurinol.

Clinical evidence, mechanism, importance and management

Capecitabine is a prodrug, which is activated by several enzymatic steps to produce active fluorouracil within the body. Because allopurinol is reported to modulate fluorouracil, with possible decreased efficacy (although note an adverse effect is not established, see 'Fluorouracil + Allopurinol', p.727), the UK manufacturers of capecitabine say that the concurrent use of allopurinol should be avoided.[1]

1. Xeloda (Capecitabine). Roche Products Ltd. UK Summary of product characteristics, October 2008.

Fluorouracil prodrugs; Capecitabine + Antacids

The absorption of capecitabine was not affected by an aluminium/magnesium hydroxide antacid.

Clinical evidence, mechanism, importance and management

A study in 12 patients found that 20 mL of an **aluminium/magnesium hydroxide** antacid (*Maalox*) caused a small increase in the plasma levels of a single 1250-mg/m^2 oral dose of capecitabine and one metabolite (5′-DFCR) but it had no effect on the other 3 major metabolites (5′-DFUR, 5-FU and FBAL).[1] There would therefore seem to be no reason for taking special precautions if capecitabine and an antacid of this type are used concurrently.

Fluorouracil prodrugs; Capecitabine + Folinates

A patient died after treatment with capecitabine possibly because the concurrent use of folic acid enhanced capecitabine toxicity. The maximum tolerated dose of capecitabine is decreased by folinic acid.

Clinical evidence, mechanism, importance and management

(a) Folic acid

A 51-year-old woman with metastatic breast cancer started treatment with capecitabine 2500 mg/m^2 daily for 14 days every 21 days. Treatment was stopped after 8 days because she developed diarrhoea, vomiting and hand-foot syndrome. She improved with parenteral hydration and symptomatic treatment, but 3 weeks later still had diarrhoea, leg oedema and hand-foot syndrome. She was found to have been taking folic acid 15 mg daily for several weeks before starting capecitabine and had continued to take it during and after capecitabine treatment. The patient's condition improved when the folic acid was stopped, but she then developed diarrhoea and fever followed by necrotic colitis and she died from septic shock and vascular collapse. It is possible that the concurrent use of folic acid enhanced the toxicity of capecitabine.[1]

(b) Folinic acid

Studies in patients with refractory advanced cancer have found that folinic acid 30 mg twice daily does not have a major effect on the pharmacokinetics of capecitabine.[2] However, the pharmacodynamics of capecitabine were affected as determined by the more frequent occurrence of dose-limiting gastrointestinal disorders or hand-foot syndrome.[2] The UK manufacturers say that the maximum tolerated capecitabine dose when used alone in the intermittent regimen is 3 g/m^2, but this is reduced to 2 g/m^2 if folinic acid 30 mg twice daily is also given.[3]

3. Xeloda (Capecitabine). Roche Products Ltd. UK Summary of product characteristics, October 2008.

Fluorouracil prodrugs; Capecitabine + Miscellaneous

The maximum tolerated dose of capecitabine is decreased by interferon alfa. No pharmacokinetic interaction appears to occur between capecitabine and oxaliplatin.

Clinical evidence, mechanism, importance and management

(a) Interferon alfa

The UK manufacturer[1] says that the maximum tolerated capecitabine dose when used alone is 3 g/m^2, but when combined with interferon alfa-2a (3 million units/m^2 daily) the maximum tolerated dose is 2 g/m^2. Capecitabine is a prodrug of fluorouracil, the activity of which is thought to be modulated by interferon alfa. See also 'Fluorouracil + Interferon alfa', p.729.

(b) Oxaliplatin

The manufacturer notes there were no changes in the pharmacokinetics of capecitabine and its metabolites, or of platinum when capecitabine was given with oxaliplatin.[1]

1. Xeloda (Capecitabine). Roche Products Ltd. UK Summary of product characteristics, October 2008.

Fluorouracil prodrugs; Capecitabine + Vinorelbine

The concurrent use of vinorelbine and capecitabine does not appear to affect the pharmacokinetics of either drug.

Clinical evidence, mechanism, importance and management

A study in which 44 patients received escalating doses of oral capecitabine for 14 days every 3 or 4 weeks and vinorelbine weekly, or on days one and 8 of a 3- or 4-week cycle, found that the pharmacokinetics of vinorelbine were unaffected by capecitabine, when compared with historical data. The pharmacokinetics of capecitabine and its metabolites were highly variable, but were unchanged by the use of vinorelbine. Although the AUC of

fluorouracil was lower on day one, (when capecitabine was given with vinorelbine) than on day 7 (when capecitabine was given alone), this was expected after repeated dosing of capecitabine, and was not considered to have been affected by vinorelbine.[1] No pharmacokinetic drug interaction appears to occur.

Fluorouracil prodrugs; Tegafur + Miscellaneous

Tegafur is partially metabolised by CYP2A6, and the manufacturer advises caution with CYP2A6 inhibitors (e.g. tranylcypromine and methoxsalen).

Clinical evidence, mechanism, importance and management

In vitro studies indicate that tegafur is partially metabolised by the cytochrome P450 isoenzyme CYP2A6.[1,2] In one report, a patient who was a CYP2A6 poor metaboliser (that is lacking in this isoenzyme) had fourfold higher levels of tegafur than other patients.[3] Therefore, it is possible that tegafur might not be as effective in patients such as this, or if it is given with drugs that are inhibitors of CYP2A6, because of reduced metabolism to active fluorouracil. In addition, the toxicity profile might be different. However, tegafur is also metabolised to fluorouracil by cytosolic thymidine phosphorylase and some other isoenzymes (e.g. CYP1A2 and CYP2C8), so it is likely that fluorouracil can still be produced in the absence of CYP2A6.[1,4] Nevertheless, the manufacturer advises that tegafur should not be used in patients with a known deficiency of hepatic CYP2A6,[1] although note that they do not advise testing for this, and a patient's P450 phenotype is rarely known outside of the clinical research situation. The manufacturer also advises caution if tegafur is given with other drugs that are substrates or inhibitors of CYP2A6. They specifically name **coumarin**, **methoxsalen** and the azole antifungals **clotrimazole**, **ketoconazole**, and **miconazole**.[1] The clinical relevance of any of these interactions and of CYP2A6 metaboliser status remains to be determined. However, note that important pharmacokinetic interactions do not usually occur between two drugs that are just substrates for the same isoenzyme, and so no interaction would be expected with **coumarin**. Moreover, **ketoconazole** did not inhibit the formation of fluorouracil from tegafur *in vitro*,[2] and is therefore unlikely to do so clinically. **Methoxsalen** is an inhibitor of CYP2A6,[5] and so might theoretically interact with tegafur, but as it has a specialist use in phototherapy it is unlikely to be used with tegafur. Another CYP2A6 inhibitor is the MAOI, **tranylcypromine**.

5. Kharasch ED, Hankins DC, Taraday JK. Single-dose methoxsalen effects on human cytochrome P-450 2A6 activity. *Drug Metab Dispos* (2000) 28, 28–33.

Fulvestrant + Miscellaneous

The pharmacokinetics of intravenous fulvestrant were not affected by rifampicin (rifampin), an inducer of the cytochrome P450 isoenzyme CYP3A4, or ketoconazole, an inhibitor of CYP3A4. In addition, intramuscular fulvestrant did not affect the pharmacokinetics of midazolam, a substrate of CYP3A4. It is therefore unlikely that fulvestrant will be affected by drug interactions involving this isoenzyme.[1]

1. Robertson JFR, Harrison M. Fulvestrant: pharmacokinetics and pharmacology. *Br J Cancer* (2004) 90 (Suppl. 1), S7–S10.

Gefitinib + Miscellaneous

The pharmacokinetics of gefitinib are affected by the concurrent use of drugs that induce (e.g. rifampicin) or inhibit (e.g. itraconazole) CYP3A4. Inhibitors of CYP2D6 may increase levels of gefitinib. Based on data with metoprolol, gefitinib is not expected to affect the pharmacokinetics of drugs that are metabolised by CYP2D6. The concurrent use of cisplatin, carboplatin or paclitaxel with gefitinib did not affect the pharmacokinetics of either drug. High-dose gefitinib slightly increased the exposure to gemcitabine. Anastrozole and tamoxifen do not alter gefitinib levels.

Clinical evidence, mechanism, importance and management

(a) Anastrozole

In a study in which 53 patients received gefitinib alone or with anastrozole, the authors briefly mention that the pharmacokinetics of gefitinib were not affected by anastrozole. The addition of anastrozole did not exacerbate the adverse effects of gefitinib.[1]

A case report describes an increase in liver transaminases in a woman given gefitinib and anastrozole, which resolved when gefitinib was stopped and recurred on rechallenge. However, the authors concluded that this was likely to be an adverse effect of gefitinib, and not due to a pharmacokinetic drug interaction with anastrozole.[2] Note that, although anastrozole weakly inhibited the cytochrome P450 isoenzyme CYP3A4 *in vitro*, (gefitinib is a CYP3A4 substrate), this was not considered likely to be important at clinically attainable levels.[3]

(b) Carboplatin and Paclitaxel

In 24 patients with advanced non-small cell lung cancer there was no change in the pharmacokinetics of carboplatin or paclitaxel when gefitinib 250 or 500 mg daily was also given. There was a slight increase in exposure to gefitinib, but no increase in toxicity was noted.[4]

(c) Cisplatin and Gemcitabine

Eighteen patients were given gemcitabine 1250 mg/m^2 on day one and 8 of a 21-day cycle, with cisplatin 80 mg/m^2 on day one, and gefitinib 250 mg or 500 mg daily. The pharmacokinetics of gefitinib were unchanged by the combination chemotherapy, and cisplatin pharmacokinetics were not affected by gefitinib. However, the exposure to gemcitabine was slightly increased when gefitinib was also given (day 8) at only the 500 mg dose, when compared with gemcitabine with cisplatin or with both cisplatin and gefitinib.[4]

(d) CYP2D6 inhibitors

The manufacturer predicts that potent inhibitors of the cytochrome P450 isoenzyme CYP2D6 may increase gefitinib levels. They advise that patients should be closely monitored for adverse effects. Note that, *in vitro* studies have shown that gefitinib is metabolised to its major metabolite by CYP2D6, and that exposure to gefitinib was twofold higher in CYP2D6 poor metabolisers (that is, those lacking this isoenzyme) than in CYP2D6 extensive metabolisers (those with normal levels of this isoenzyme).[5]

(e) Itraconazole and other CYP3A4 inhibitors

In a randomised, crossover study, 48 healthy subjects were given gefitinib 250 mg or 500 mg, alone and on day 4 of a 12-day course of itraconazole 200 mg daily. Itraconazole increased the maximum plasma concentration of gefitinib 250 mg and 500 mg by 51% and 32%, respectively, and increased the AUC of these two doses by 78% and 61%, respectively.[6] Itraconazole is a potent inhibitor of the cytochrome P450 isoenzyme CYP3A4, by which gefitinib is partly metabolised. Concurrent use therefore raises gefitinib levels. It seems likely that other potent inhibitors of CYP3A4 will also increase the levels of gefitinib and might increase its toxicity.[5,7] The manufacturers specifically name the azoles **ketoconazole**, **posaconazole**, and **voriconazole**; the macrolides **clarithromycin** and **telithromycin**, and **protease inhibitors**.[5,7] Monitor patients carefully when taking CYP3A4 inhibitors with gefitinib. For a list of CYP3A4 inhibitors, see 'Table 1.4', (p.6).

(f) Metoprolol and other CYP2D6 substrates

In a study, 15 patients were given gefitinib 500 mg daily for 28 days, with a single 50-mg dose of metoprolol on day 15. The maximum plasma concentration of metoprolol was increased by about 10% by gefitinib. There was a 35% increase in the AUC of metoprolol, but this was not statistically

significant.[6]These changes are not clinically relevant, and it was suggested that gefitinib is unlikely to have a clinically relevant effect on the pharmacokinetics of CYP2D6 substrates. Nevertheless, the UK manufacturer warns that such an increase may be relevant for CYP2D6 substrates with a narrow therapeutic index and that a dose modification may be necessary;[5] this seems extremely cautious.

(g) Rifampicin (Rifampin) and other CYP3A4 inducers

In a study, 18 healthy subjects were given rifampicin 600 mg daily for 16 days, with a single 500-mg dose of gefitinib on day 10. Rifampicin reduced the maximum plasma concentration of gefitinib by 65%, and reduced its AUC by 83%, when compared with gefitinib alone.[6] The US manufacturer advises that, in the absence of severe adverse reactions, the usual daily dose of gefitinib should be increased to 500 mg daily in patients taking potent CYP3A4 inducers, such as rifampicin or **phenytoin**.[7] In contrast, the UK manufacturer states that inducers of CYP3A4 should be avoided. They additionally name **barbiturates**, **carbamazepine** and **St John's wort**.[5] For a list of CYP3A4 inducers, see 'Table 1.4', (p.6).

(h) Tamoxifen

In a study, 18 healthy male subjects were given tamoxifen 60 mg daily for 4 days then 20 mg daily for at least 10 days with a single 250-mg dose of gefitinib on day 14. The pharmacokinetics of gefitinib were not significantly altered by tamoxifen.[8]

Gemcitabine + Anthracyclines

The concurrent use of gemcitabine and doxorubicin or epirubicin does not appear to affect the pharmacokinetics of either drug. An *in vitro* study found that the efficacy of the combination of gemcitabine and epirubicin may be schedule-dependent.

Clinical evidence, mechanism, importance and management

(a) Doxorubicin

The pharmacokinetics of gemcitabine did not differ when it was given immediately before doxorubicin, when compared with historical data of its use alone in patients with breast cancer.[1] Similarly the pharmacokinetics of gemcitabine were unchanged when it was given with paclitaxel the day after liposomal doxorubicin, when compared with historical data.[2] Another study also found that when doxorubicin was given immediately before gemcitabine on day one, the pharmacokinetics of gemcitabine were unaltered, when compared with gemcitabine alone on day 8. However, the activation of gemcitabine to its phosphorylated forms in peripheral blood mononuclear cells was reduced by doxorubicin. As the combination was poorly tolerated and no more effective than doxorubicin alone, the authors suggested that this sequence of dosing should not be further investigated in sarcomas.[3]

(b) Epirubicin

Gemcitabine pharmacokinetics were unchanged by the concurrent use of epirubicin and paclitaxel in patients with breast cancer,[4] and gemcitabine did not alter the interaction between epirubicin and paclitaxel (see 'Anthracyclines + Taxanes', p.698).

An *in vitro* study using human bladder cancer cells found that both gemcitabine and epirubicin alone exerted a cytotoxic effect but the efficacy of the combination of epirubicin and gemcitabine depended on the schedule used. When the drugs were given concurrently or if gemcitabine was given before epirubicin, there was an antagonistic interaction. There was synergistic cytotoxic activity when epirubicin was used before gemcitabine. This schedule is being investigated in clinical studies.[5]

Gemcitabine + Cisplatin and other platinum compounds

The toxicity and pharmacokinetics of gemcitabine combined with platinum drugs such as cisplatin is dependent upon the order in which they are given.

Clinical evidence, mechanism, importance and management

(a) Carboplatin

Gemcitabine 1 g/m^2 on days one, 8, and 15 has been given with carboplatin (maximum tolerated dose, giving an AUC of 5.2 mg/mL per minute) on day one, in a monthly cycle. No difference was detected in toxicity or tolerated dose when the gemcitabine was given before or after the carboplatin.[1] However, subsequent authors reported that this same dose schedule, with carboplatin given immediately after the gemcitabine, caused unexpected and severe thrombocytopenia, and could not be recommended.[2] Nevertheless, in clinical use,[3] it is recommended that carboplatin is given after gemcitabine 1 g/m^2.

(b) Cisplatin

When gemcitabine was given 4 hours before or after cisplatin there were no major differences in the plasma pharmacokinetics of gemcitabine, deaminated gemcitabine and platinum. Similarly, cisplatin given 24 hours before gemcitabine did not significantly change gemcitabine and deaminated gemcitabine levels, although there was a trend towards an increased AUC of gemcitabine triphosphate.[4] Gemcitabine given 24 hours before cisplatin decreased the platinum AUC twofold,[4] and caused the least leucopenia of the schedules.[5] Anaemia, thrombocytopenia, nausea and vomiting, and fatigue were not sequence dependent.[5] On the basis of these findings, the authors further evaluated the schedule of cisplatin given 24 hours before gemcitabine but found no clear evidence for the best sequence of these drugs.[6] Note that the combination of cisplatin and gemcitabine is commonly used for the treatment of various cancers, usually with cisplatin given after gemcitabine on the same day.[3]

(c) Oxaliplatin

The pharmacokinetics of gemcitabine 800 to 1500 mg/m^2 and its main metabolite did not appear to be affected by oxaliplatin 70 to 100 mg/m^2 when oxaliplatin was given immediately after gemcitabine once every 2 weeks.[7] Similarly, in a study in 10 patients with advanced solid tumours,[8] the pharmacokinetics of gemcitabine did not differ when it was given immediately before oxaliplatin on day one and when it was given alone on day 8. Furthermore, in a study in which 10 patients received either gemcitabine followed 24 hours later by oxaliplatin, or the two drugs in the reverse order, the sequence of administration had no effect on the pharmacokinetics of either gemcitabine or oxaliplatin.[9]

Gemcitabine + Taxanes

One study found that giving paclitaxel before gemcitabine increased gemcitabine levels, but other studies did not find a pharmacokinetic interaction. Gemcitabine distribution may be altered by docetaxel, but docetaxel pharmacokinetics are not affected by gemcitabine. The clinical response to the combination of gemcitabine and a taxane may depend on the sequence of administration.

Clinical evidence, mechanism, importance and management

(a) Docetaxel

In a study of gemcitabine and docetaxel, given on days one and 8 of a 21 day cycle, drug toxicity and pharmacokinetics were unaffected by the relative order of their administration.[1] However, in another study, it appeared that while docetaxel pharmacokinetics were unaffected, the distribution of gemcitabine was altered by docetaxel, although there was no clear relationship between this and toxicity.[2]

A favourable response rate of 43% was reported in a study in which 35 patients with sarcomas were given gemcitabine 675 mg/m^2 over 90 minutes on days one and 8, followed by docetaxel 100 mg/m^2, given over 60 minutes, on day 8. The possible synergistic antitumour effect may have been secondary to both the prolonged gemcitabine infusion and the sequence of drug administration.[3] More study is needed.

(b) Paclitaxel

A study in 18 patients with non small cell lung cancer found that when they were given gemcitabine 1000 mg/m^2 on days one and 8 and paclitaxel 150 to 200 mg/m^2 on day one as a 3-hour infusion immediately before the gemcitabine, the plasma levels of gemcitabine and the AUC of its deaminated metabolite were unchanged, as was the AUC of paclitaxel. However, paclitaxel increased gemcitabine triphosphate levels, potentially improving efficacy.[4] In a study in 14 patients with non small cell lung cancer, gemcitabine 800 mg/m^2 was given on days one and 8 of a 21-day cycle and paclitaxel 110 mg/m^2 was given 3 hours before the second dose of gemcitabine on day 8. When paclitaxel was given first the clearance, volume of distribution and interpatient pharmacokinetic variability of gemcitabine were decreased. Plasma levels of gemcitabine were increased by 25%, but there was no correlation between these changes and toxicity, and the clinical significance of the interaction is uncertain.[5] In another study, no pharmacokinetic interactions were detected between gemcitabine and paclitaxel given weekly, although gemcitabine showed saturation kinetics at higher doses.[6,7] Another study in patients with advanced breast cancer given gemcitabine, epirubicin and paclitaxel also found no pharmacokinetic interaction between gemcitabine and paclitaxel:[8] a similar lack of pharmacokinetic interaction was found in a further study in patients receiving liposomal doxorubicin, gemcitabine and paclitaxel.[9]

The high overall response rate of 71% in a phase II study[10] in patients with advanced breast cancer given gemcitabine and paclitaxel, prompted an *in vitro* study,[11] which found that giving paclitaxel followed by gemcitabine resulted in synergistic cytotoxic activity, whereas gemcitabine followed by paclitaxel had antagonistic activity. Phase III studies are being carried out to further evaluate the effects of order of administration of these drugs in patients with metastatic breast cancer.[12] As of 2009, paclitaxel is given before gemcitabine, with both drugs given on the same day.[13,14]

Hydroxycarbamide + Interferon alfa

When hydroxycarbamide is used with interferon alfa, the risk of vasculitis might be increased.

Clinical evidence, mechanism, importance and management

Hydroxycarbamide alone has been associated with cutaneous vasculitic ulceration and gangrene, and interferons alone have also been associated with vasculitis. In one review of serious vasculopathic adverse effects associated with interferon alfa in 13 patients, 5 patients were also taking hydroxycarbamide, 4 of whom had digital ulcerations and gangrene, and one of whom had pulmonary vasculitis. Most cases improved on stopping interferon alfa and adding immunosuppressants. The authors considered that the distribution of the ulcers was different from that seen with hydroxycarbamide alone. They say that whether the use of hydroxycarbamide, concurrently or use at any time, can potentiate these vascular events is a matter of debate.[1] Nevertheless, the manufacturer of hydroxycarbamide notes that the risk of cutaneous vasculitis may be increased when interferon is given with or before hydroxycarbamide,[2,3] and one UK manufacturer of interferon alfa also includes a similar warning.[4] Bear this possibility in mind. Hydroxycarbamide should be stopped if cutaneous vasculitic ulcers occur.[2,3]

Imatinib + Antineoplastics

Data from *animal* studies suggest that imatinib markedly increases etoposide levels and modestly increases ifosfamide levels. The use of imatinib with asparaginase might be associated with increased hepatotoxicity.

Clinical evidence, mechanism, importance and management

(a) Asparaginase

The UK manufacturer states that the concurrent use of imatinib with asparaginase could be associated with increased hepatotoxicity. They therefore recommend caution with concurrent use.[1]

(b) Etoposide and Ifosfamide

In a study in *mice*, a fivefold increase in the maximum plasma levels of etoposide and a 60% increase in the maximum plasma level of ifosfamide occurred when they were given by intraperitoneal injection with imatinib, compared with when they were given alone. In a further study, there was a 3.4-fold increase in the $AUC_{0\text{-}3}$ of etoposide when it was given with imatinib. In yet another study, the AUC of etoposide was increased by 92% and its clearance reduced by about 50% when it was given with imatinib. In a lymphoma model, an increased antitumour effect was observed with the combination, but this was not seen in a small cell lung cancer model.[2]

Imatinib is an inhibitor of the cytochrome P450 isoenzyme CYP3A4, and it seems likely that it increased the levels of etoposide and ifosfamide, which are metabolised by this isoenzyme, by this mechanism.

Although these data are from *animals*, and therefore preliminary, they suggest that caution is necessary if imatinib were used, particularly with etoposide, and possibly with ifosfamide.

Imatinib + CYP3A4 inducers

Rifampicin (rifampin) and enzyme-inducing antiepileptics (e.g. carbamazepine, phenobarbital) markedly lower serum imatinib levels, and St John's wort (*Hypericum perforatum*) modestly lowers imatinib levels; other CYP3A4 inducers are predicted to do the same.

Clinical evidence

(a) Enzyme-inducing antiepileptics

The manufacturer reports that, in a study in patients with malignant gliomas, the AUC of imatinib was 73% lower in patients taking enzyme-inducing antiepileptics (such as **carbamazepine**, **oxcarbazepine** and **phenytoin**) than in patients not taking these drugs.[1]

(b) Rifampicin (Rifampin)

In a study in healthy subjects, rifampicin 600 mg daily for 11 days decreased the maximum serum levels and AUC of a 400-mg dose of imatinib given on day 8 by 54% and 74%, respectively.[2]

(c) St John's wort (Hypericum perforatum)

In a study in 12 healthy subjects, the pharmacokinetics of a single dose of imatinib was determined before and on day 12 of two weeks of treatment with St John's wort (*Hypericum perforatum*) extract (Kira [LI 160], Lichtwer Pharma) 300 mg three times daily. The AUC and maximum plasma level of imatinib was decreased by 30% and 15%, respectively. Imatinib clearance was increased by 43% and its half-life was decreased from 12.8 hours to 9 hours.[3] Similar results were found in another study.[4]

Mechanism

Rifampicin is a known potent inducer of many cytochrome P450 isoenzymes, including CYP3A4, by which imatinib is metabolised. Therefore rifampicin increases imatinib metabolism and decreases its levels. Enzyme-inducing antiepileptics interact similarly. St John's wort induces intestinal CYP3A4 and it therefore also modestly reduces imatinib levels.

Importance and management

Subtherapeutic levels of imatinib may occur if rifampicin or the enzyme-inducing antiepileptics [**carbamazepine**, **phenobarbital** (and therefore **primidone**), **phenytoin** (and therefore **fosphenytoin**)], are given. The manufacturers therefore reasonably recommend caution, and suggest that concurrent use with potent enzyme-inducing drugs should be avoided.[1,5] They also name **dexamethasone**,[1,5] and **rifabutin**,[5] (but note that, clinically, these drugs generally appear to have weak effects on this isoenzyme). If concurrent use cannot be avoided, it would be prudent to monitor the outcome, and increase the imatinib dose as necessary. An increase of at least 50% has been suggested by the US manufacturer.[5]

St John's wort has smaller effects, but they may be sufficient to impair the effects of imatinib, and are more likely to be variable, and it has therefore been suggested that concurrent use should also be avoided.[1,3]

Imatinib + CYP3A4 inhibitors

Single-dose ketoconazole modestly raised single-dose imatinib levels; however, ritonavir (given for three days) had little effect on imatinib levels at steady-state. There is a case report of an adverse skin reaction attributed to a pharmacokinetic interaction between voriconazole and imatinib.

Clinical evidence

(a) Ketoconazole

In a single-dose study in 14 healthy subjects, the maximum serum levels and AUC of imatinib rose by 26% and 40%, respectively, when ketoconazole 400 mg was given at the same time as imatinib 200 mg.[1]

(b) Ritonavir

In a study, 11 patients who had been taking imatinib 400 to 800 mg daily for at least 2 month were also given ritonavir 600 mg daily for 3 days, with a 50% reduction in the imatinib dose. Unexpectedly, the dose-normalised pharmacokinetics of imatinib were unaltered by ritonavir. However, the AUC of the active metabolite of imatinib was increased by about 40%.[2]

(c) Voriconazole

A patient with chronic myeloid leukaemia developed a pustular eruption while taking imatinib 800 mg daily, 12 weeks after starting to take voriconazole for pulmonary aspergillosis. His imatinib plasma levels were about twice the predicted levels while taking both drugs. His condition improved within 3 weeks of stopping both voriconazole and imatinib, and did not recur with the use of voriconazole alone.[3]

Mechanism

Ketoconazole, voriconazole, and ritonavir are potent inhibitors of the cytochrome P450 isoenzyme CYP3A4, which is involved in the metabolism of imatinib. The single-dose study with ketoconazole appears to confirm that CYP3A4 inhibitors increase imatinib levels. However, the multiple-dose study with ritonavir did not find this. This might be because imatinib is also a CYP3A4 inhibitor, so at steady-state it is less affected by other CYP3A4 inhibitors. However, it could also be due to specific effects of ritonavir, which can act as a CYP3A4 inducer. Further studies are needed. Adverse skin reactions occur frequently with imatinib and may be associated with high doses of imatinib and/or increased levels due to an interaction with CYP3A4 inhibitors, such as voriconazole.[3]

Importance and management

The pharmacokinetic interaction has not been fully established. The single-dose study with ketoconazole suggests a moderate increase in single-dose imatinib levels, which could possibly be greater with multiple-dose ketoconazole. However, the ritonavir study shows minimal effect on imatinib at steady-state. Further studies are needed to assess the extent and clinical relevance of these pharmacokinetic interactions at steady-state. At present, the manufacturers advise caution with ketoconazole and with other CYP3A4 inhibitors (examples listed are **atazanavir**, **clarithromycin**, **erythromycin**, **indinavir**, **itraconazole**, **nefazodone**, **nelfinavir**, **ritonavir**, **saquinavir**, **telithromycin** and **voriconazole**),[4,5] and the US manufacturer advises avoidance of **grapefruit juice**.[5] For a list of CYP3A4 inhibitors see 'Table 1.4', (p.6). The authors of the one case report suggest

monitoring plasma levels of imatinib to identify patients at risk of severe toxicity.[3]

Imatinib + Miscellaneous

In one case, adverse cutaneous drug reactions developed when lansoprazole was used with imatinib. In two cases, relapse during treatment with imatinib occurred in patients who also abused cocaine. One patient who took paracetamol with imatinib developed acute liver failure. Interactions are predicted to occur with warfarin. Imatinib is an inhibitor of CYP3A4, and caution is recommended with CYP3A4 substrates that have a narrow therapeutic window.

Clinical evidence, mechanism, importance and management

(a) Cocaine

Two patients with chronic myeloid leukaemia took imatinib and achieved a complete haematological response after 3 and 7 weeks, but then relapsed after 12 and 14 weeks and also experienced more severe imatinib adverse effects. Both patients had started to abuse cocaine 2 to 4 weeks before they relapsed. It was suggested that cocaine might have interfered with imatinib metabolism; however, the mechanism for this possible interaction is unclear.[1]

(b) CYP3A4 substrates

Imatinib is an inhibitor of the cytochrome P450 isoenzyme CYP3A4, as shown by the fact that it raises 'simvastatin', (p.1337), levels. The manufacturers of imatinib therefore predict that it may raise the levels of other CYP3A4 substrates and they mention **triazolo-benzodiazepines** (e.g. **triazolam**, **midazolam**)[2,3] and dihydropyridine calcium-channel blockers. They specifically advise caution with CYP3A4 substrates that have a narrow therapeutic index,[2,3] and name, **alfentanil**, **di[hydro]ergotamine**, **ergotamine**, **fentanyl**, **pimozide**, **quinidine** and some immunosuppressants [this would be expected to include ciclosporin and tacrolimus].[3] The clinical relevance of these interactions is not known, but caution would be appropriate.

(c) Lansoprazole

A patient with a recurrence of a gastrointestinal stromal tumour was given imatinib 400 mg daily without adverse effect. However, after 2 months, lansoprazole 15 mg daily was also given for dyspepsia and the patient developed bilateral eyelid oedema with hyperaemic conjunctivae and labial oedema. Both drugs were stopped, but on reintroduction the symptoms reappeared and she developed Stevens-Johnson syndrome. Both drugs were again stopped and she recovered after treatment with methylprednisolone and desloratadine for one month. Two months later, she took a single dose of lansoprazole on the day before taking imatinib 300 mg daily (with prednisone and desloratadine). One day later she developed eyelid and labial oedema and a generalised rash. She recovered after imatinib was stopped.[4]

Although the adverse effects could be attributed to either imatinib or lansoprazole alone, the authors suggested it was possible that the effects may have been the result of an interaction in which the levels of imatinib were increased by lansoprazole, which they said is a weak inhibitor of CYP3A4.[4] However, CYP3A4 inhibition was based on *in vitro* data, which indicated that clinically relevant CYP3A4 inhibition is unlikely. This has been borne out by the fact that lansoprazole has not caused interactions with CYP3A4 substrates in clinical use. Therefore, this mechanism seems unlikely.

(d) Paracetamol (Acetaminophen)

During clinical studies one patient regularly taking paracetamol for fever, died of acute liver failure 11 days after starting to take imatinib.[5] The manufacturers report that imatinib inhibits paracetamol *O*-glucuronidation *in vitro*. Although this potential interaction has not been studied in humans, the manufacturers recommend caution during concurrent use, especially with high doses of paracetamol.[2,3]

(e) Warfarin

The manufacturers say that patients needing anticoagulation should be given low-molecular-weight or standard **heparin** instead of warfarin. This recommendation is based on an observation in one patient[6] and *in vitro* studies[2,3] that show that imatinib can inhibit the cytochrome P450 isoenzyme CYP2C9, by which warfarin is extensively metabolised. There seems to be no other evidence that a clinically relevant interaction is likely to occur. However, note that, from a disease perspective, when treating venous thromboembolic disease in patients with cancer, warfarin is generally inferior (higher risk of major bleeds and recurrent thrombosis) to low-molecular-weight heparins.[7]

Irinotecan + Antiepileptics

In patients with malignant gliomas, enzyme-inducing antiepileptics (carbamazepine, phenobarbital, phenytoin) markedly increase the clearance of irinotecan and its active metabolite. A number of case reports support these suggestions. Limited evidence suggests that non-enzyme inducing antiepileptics (particularly gabapentin) might also be associated with modestly increased irinotecan clearance. One case report with valproate found hepatotoxicity and *decreased* active irinotecan metabolite levels.

Clinical evidence

(a) Enzyme-inducing antiepileptics

In a study in adult patients with malignant glioma, the clearance of irinotecan was 60% higher in 18 patients taking enzyme-inducing antiepileptics (**phenytoin**, **carbamazepine**, **phenobarbital**, or combinations) than in 22 patients who were not taking these drugs. The maximum tolerated dose of irinotecan in these patients was double that in those not receiving enzyme-inducing antiepileptics, but there was no relationship between the dose and the AUC of the active metabolite, SN-38.[1] In a similar study in paediatric patients, the clearance of irinotecan lactone was 49% higher and the AUC of the lactone forms of irinotecan and SN-38 were 27% and 51% lower, respectively, in 10 children taking enzyme-inducing antiepileptics than in 21 children not taking these antiepileptics.[2] The enzyme-inducing antiepileptics used were **phenytoin** alone in 6 children, **carbamazepine**, **oxcarbazepine** and **phenobarbital** in one child each, and **phenytoin** with **carbamazepine** in one child. In a subsequent study by these authors, increasing the dose of irinotecan increased the AUC of the active metabolite, SN-38, in 3 of 5 children taking stable doses of enzyme-inducing antiepileptics, but no increase was seen in 2 children, despite a three- to fourfold increase in the irinotecan dose.[3]

1. Carbamazepine. In a preliminary report of studies in patients with malignant glioma, the clearance of irinotecan was increased almost twofold in the presence of carbamazepine. The peak plasma levels and AUCs of irinotecan and SN-38 were significantly decreased.[1]

2. Phenobarbital. In a preliminary report of studies in patients with malignant glioma, the clearance of irinotecan was increased by about 70% in the presence of phenobarbital. The AUC and peak plasma levels of irinotecan and SN-38 were significantly decreased.[1]

In a phase I study in patients given ciclosporin and irinotecan, giving phenobarbital 90 mg daily for 2 weeks before irinotecan allowed a dose escalation of irinotecan from 75 mg/m^2 to 144 mg/m^2. Phenobarbital increased

irinotecan clearance by 27% and reduced the AUC of SN-38 by 75%, when compared to irinotecan pharmacokinetics in patients given irinotecan with ciclosporin. Further clinical studies are needed to assess the effects of phenobarbital on the antitumour response and toxicity of irinotecan.[4]

3. Phenytoin. A 14-year-old girl with glioblastoma was given irinotecan 20 to 60 mg/m^2 daily for 5 days on 2 consecutive weeks every 21 days for 2 cycles. During the first cycle she also received phenytoin 300 mg and dexamethasone 6 mg daily. Irinotecan clearance was increased 2.5-fold compared with that in other patients receiving irinotecan alone, and there was decreased exposure to the active metabolite of irinotecan, SN-38. The effect on clearance decreased slowly over 8 days after stopping phenytoin.[5] Another patient taking phenytoin and irinotecan was found to have much lower AUCs for irinotecan and SN-38, when compared with data from patients not taking phenytoin.[6] Similarly, a third patient had a three-fold increase in irinotecan clearance and about a 60% reduction in the AUCs of irinotecan and SN-38 after starting phenytoin.[7] In a preliminary report of studies in patients with malignant glioma, the clearance of irinotecan was increased about twofold in the presence of phenytoin. The peak plasma levels and AUCs of irinotecan and SN-38 were significantly decreased.[1]

(b) Non-enzyme-inducing antiepileptics

A preliminary report of studies in patients with malignant gliomas found that in patients also taking non-enzyme-inducing antiepileptics (**gabapentin**, **lamotrigine**, **levetiracetam**, **tiagabine**, **topiramate**, **valproate**, or **zonisamide**, mostly in combination) there was a small but statistically significant increase (about 40%) in irinotecan clearance when compared with patients not taking any antiepileptics. The authors said that this was especially so for **gabapentin**. They also noted that in the four patients taking **valproate** (also in combination with other non-enzyme-inducing antiepileptics), there was no difference in irinotecan clearance or the AUC of SN-38.[1]

1. Valproate. A patient who was taking sodium valproate 600 mg and received an irinotecan 600 mg infusion, experienced dose-limiting hepatotoxicity. During a subsequent, uneventful, course, the dose of irinotecan was reduced to 300 mg, and in further courses the valproate was discontinued and the irinotecan dose returned to 600 mg. Pharmacokinetic analysis found that during valproate treatment the AUC of SN-38, the active metabolite of irinotecan, was 42% lower, and there were no changes in the pharmacokinetics of the valproate.[8] Conversely, preclinical data from *rats*[9] found that sodium valproate increased the AUC of SN-38 because valproate inhibits its subsequent glucuronidation.[1]

Mechanism

Irinotecan (which is inactive) is metabolised to an inactive metabolite by the cytochrome P450 isoenzyme CYP3A. In addition, the active metabolite SN-38 (which is formed by carboxylesterases) is inactivated by glucuronidation (UGT1A1). Enzyme-inducing antiepileptics probably induce both of these routes of metabolism, leading to decreased exposure to the active metabolite.[6,9]

Conversely, *animal* data show that valproate inhibits glucuronidation and therefore is likely to increase the AUC of the active metabolite of irinotecan, SN-38,[9] although a decrease was seen in the one case report of this interaction.

Importance and management

An established interaction. The enzyme-inducing antiepileptics induce the metabolism of irinotecan and reduce the availability of its active metabolite, SN-38. Increasing the dose of irinotecan may not increase the exposure to SN-38. Further study is needed to establish the most appropriate dose of irinotecan to use in patients requiring treatment with these drugs. The manufacturers advise that their use with irinotecan should be avoided,[10,11] and that, where possible, non-enzyme-inducing drugs should be substituted at least 2 weeks before irinotecan is given.[11] This would seem prudent. Note that as **fosphenytoin** is metabolised to phenytoin, and **primidone** is metabolised to phenobarbital, similar advice should probably apply.

With valproate, the apparently conflicting information from the *animal* study, and the case study in a single patient is difficult to interpret. It would seem wise to monitor patients carefully for any signs of toxicity or treatment failure.

Irinotecan + Azoles

Ketoconazole markedly increases the levels of the active metabolite of irinotecan. Other azoles may interact similarly.

Clinical evidence

A study in 7 patients found that ketoconazole 200 mg given one hour before and 23 hours after an infusion of irinotecan 100 mg/m^2 decreased the dose-normalised AUC of the inactive metabolite APC by 87% and increased the AUC of the active metabolite, SN-38, by 109%, when compared with irinotecan 350 mg/m^2 given alone. There was no difference in degree of myelosuppression despite the large reduction in the irinotecan dose.[1]

Mechanism

Ketoconazole is a potent inhibitor of the cytochrome P450 isoenzyme CYP3A4, which is involved in the metabolism of irinotecan (itself inactive) to its inactive metabolite APC. More irinotecan would therefore be available to be metabolised by carboxylesterases to the active moiety SN-38. Ketoconazole had no effect on the subsequent glucuronidation of SN-38.[1] Other azoles are, to varying degrees, inhibitors of CYP3A4, and would therefore be expected to interact similarly.

Importance and management

The pharmacokinetic interaction between ketoconazole and irinotecan is established, and likely to be clinically important. Excess toxicity (potentially fatal[1]) would be expected if the dose of irinotecan were not markedly reduced on concurrent use. The manufacturers of irinotecan recommend that the concurrent use of ketoconazole should be avoided.[2,3] The US manufacturers recommend stopping ketoconazole at least one week before starting irinotecan.[3] It is likely that other drugs that are potent inhibitors of CYP3A4, such as **itraconazole** and possibly some other azoles (see 'azole antifungals', (p.233)), will also affect the metabolism of irinotecan, and the UK manufacturer advises avoidance of all potent CYP3A4 inhibitors.[2]

3. Camptosar (Irinotecan hydrochloride). Pfizer Inc. US Prescribing information, July 2008.

Irinotecan + Cannabis

The pharmacokinetics of irinotecan are not altered by a herbal tea containing cannabis.

Clinical evidence

In a crossover study, 24 patients were given intravenous irinotecan 600 mg before and 12 days after starting a 15-day course of 200 mL daily of a herbal tea containing cannabis 1 g/L. This was prepared from medicinal-grade cannabis (*Cannabis sativa* L. Flos, Bedrocan®) containing the cannabinoids Δ^9-tetrahydrocannabinol 18% and cannabidiol 0.8%. The clearance and the AUC of irinotecan and its metabolites, SN-38 and SN-38G, were not significantly altered by the presence of cannabis.[1]

Mechanism

Irinotecan is metabolised by the cytochrome P450 isoenzyme CYP3A4, and this does not appear to be affected by oral cannabis.

Importance and management

This study suggests that cannabis taken orally will not affect the pharmacokinetics of irinotecan. No dose adjustments are likely to be needed if irinotecan is given with cannabis tea. It is not known if this applies to other drugs metabolised by CYP3A4, or to other preparations and routes of administration of cannabis.

Irinotecan + Celecoxib

Celecoxib slightly increased irinotecan clearance in one study, and decreased it in another.

Clinical evidence, mechanism, importance and management

In a phase I study in patients given docetaxel followed by irinotecan on days one and 8 of a 21-day cycle, the addition of celecoxib 400 mg twice daily started on day 2 appeared to slightly increase the clearance of irinotecan by 18% and decreased the AUC of its active metabolite, SN-38, by 22% (day one of the first cycle compared with day one of the second cycle). Docetaxel pharmacokinetics were unaffected.[1] Conversely, in a similar study in 4 patients given FOLFIRI (irinotecan, fluorouracil and folinic acid), the addition of continuous celecoxib 400 mg twice daily started on day 2 appeared to slightly decrease the clearance of irinotecan by 31% and of SN-38 by 18%.[2] The reason for these changes is unclear. The authors considered that the changes are probably not large enough to be of clinical significance.[1,2]

Irinotecan + Ciclosporin

Ciclosporin reduces the clearance of irinotecan and increases the exposure of its active metabolite, SN-38, but ciclosporin appears to reduce irinotecan-induced gastrointestinal toxicity.

Clinical evidence

In a phase I study in patients with refractory solid tumours or lymphomas, ciclosporin 5 to 10 mg/kg was given as a 6-hour infusion beginning 3 hours before irinotecan (initial dose 25 mg/m^2 increased to 72 mg/m^2 weekly). Ciclosporin increased the AUC of SN-38 (the active metabolite of irinotecan) by 23 to 630% and reduced irinotecan clearance by 39 to 64%, when compared with historical controls.[1] Similar pharmacokinetic findings have been reported in further phase I and II studies using intravenous or oral ciclosporin, and these studies have generally found a reduction in the irinotecan-induced gastrointestinal toxicity (diarrhoea), when compared with historical controls.[2-4]

Mechanism

The effects of ciclosporin on irinotecan pharmacokinetics may be due to inhibition of irinotecan- and SN-38-related biliary transporters,[1,3] and this suggestion is supported by a study in *rats*.[5] It is suggested that this results in a reduction in the gastrointestinal toxicity of irinotecan.

Importance and management

Ciclosporin clearly alters the pharmacokinetics of irinotecan. In the studies described, ciclosporin was being used to try to improve the toxicity profile of irinotecan without affecting its efficacy. If this is confirmed, this will be of clinical benefit rather than an adverse drug interaction. However, bear this pharmacokinetic interaction in mind if irinotecan is used in a patient already taking ciclosporin for other reasons: in this situation, the toxicity profile and drug levels might be different from that expected.

Irinotecan + Dexamethasone

In one small study, dexamethasone did not appear to alter the pharmacokinetics of irinotecan or its active metabolite, SN-38.

Clinical evidence, mechanism, importance and management

In a study in paediatric patients with gliomas, there did not appear to be any differences in irinotecan pharmacokinetics (in the AUC of irinotecan and its active metabolite, SN-38, and in the clearance of irinotecan) between 17 patients receiving dexamethasone (1 to 16 mg daily) and 4 patients not receiving dexamethasone. None of these 21 patients were taking enzyme-inducing antiepileptics.[1] Although this study was small and non-randomised, it provides some reassurance that dexamethasone might not have an important effect on irinotecan pharmacokinetics.

Irinotecan + Fluorouracil

Some studies suggest that giving fluorouracil after irinotecan reduces the conversion of irinotecan to its active metabolite, whereas others have found no interaction.

Clinical evidence, mechanism, importance and management

A study in 33 patients with metastatic colorectal cancer found that the toxicity and pharmacokinetics of irinotecan given with fluorouracil depended upon the order of administration of the two drugs.[1] When irinotecan was given before fluorouracil, the AUC of the major active metabolite of irinotecan, SN-38, was about 40% lower, and toxicity was lower. In this study, patients were randomised to receive a 60-minute infusion of irinotecan (150 mg/m^2 starting dose, escalated by 50 mg/m^2 increments) immediately before or after a 48-hour infusion of fluorouracil 3500 mg/m^2 modulated by folinic acid in the first cycle, then given in the reverse sequence in the second cycle. Similarly, in a study using historical controls, the AUC of SN-38 was about 28% lower and the AUC of irinotecan about 35% higher when irinotecan was given over 90 minutes immediately before a 7-day fluorouracil infusion, compared with irinotecan alone.[2]

In contrast, a study found that fluorouracil did not substantially affect the metabolism of irinotecan to SN-38. The AUC of irinotecan and SN-38 did not differ between irinotecan alone, irinotecan immediately followed by folinic acid and fluorouracil, and irinotecan immediately after folinic acid and fluorouracil. In this study, irinotecan 100 to 150 mg/m^2 was given as

a 90-minute infusion, and fluorouracil 210 to 500 mg/m^2 by rapid intravenous injection.[3] Similarly, preliminary reports from another research group found that the clearance of irinotecan did not differ when it was given one day before or one day after 5 daily bolus doses of fluorouracil.[4,5]

From this information it is unclear whether or not fluorouracil alters the pharmacokinetics of irinotecan. A key difference between the main studies is the use of bolus[3] or continuous infusion[1] fluorouracil. The combination is in established clinical usage, where the recommendation is to give irinotecan before fluorouracil and folinic acid.[6,7] This combination has been shown to be more effective than fluorouracil and folinic acid alone.[6,7] Whether this is the optimal schedule remains to be determined.

Irinotecan + Fluorouracil prodrugs; Capecitabine

The pharmacokinetics of irinotecan and its active metabolite do not appear to be affected by capecitabine.

Clinical evidence, mechanism, importance and management

Irinotecan was given to 12 patients on days one and 8 of a 21-day cycle, alone, and with capecitabine on days one to 14. Capecitabine did not alter the pharmacokinetics of irinotecan or its active metabolite SN-38 (AUC, maximum levels unchanged). The time to reach maximum plasma levels of the active metabolite SN-38 was increased from 0.88 hours to 1.23 hours, suggesting a slight delay in conversion of irinotecan to SN-38.[1] Another study in 10 patients who received a weekly infusion of irinotecan for 6 weeks, and oral capecitabine twice daily for 2 weeks, starting the day after the first irinotecan infusion, also indicated that capecitabine might delay the conversion of irinotecan to SN-38, but that there was no significant effect on other irinotecan pharmacokinetic.[2]

Both irinotecan and capecitabine require activation by carboxylesterases, and it had been suggested that this might result in a pharmacokinetic interaction. The studies here suggest that no interaction of clinical relevance occurs.

Irinotecan + Food

In a study in 25 patients who received an *oral* preparation of irinotecan, formulated as a semi-solid matrix capsule, the pharmacokinetics of irinotecan and its active metabolite, SN-38, did not differ when the oral preparation was taken either with food or after an overnight fast.[1]

1. Soepenberg O, Dumez H, Verweij J, de Jong FA, de Jonge MJA, Thomas J, Eskens FALM, van Schaik RHN, Selleslach J, ter Steeg J, Lefebvre P, Assadourian S, Sanderink G-J, Sparreboom A, van Oosterom AT. Phase I pharmacokinetic, food effect, and pharmacogenetic study of oral irinotecan given as semisolid matrix capsules in patients with solid tumours. *Clin Cancer Res* (2005) 11, 1504–11.

Irinotecan + Gemcitabine

Gemcitabine appears not to alter the pharmacokinetics of the active metabolite of irinotecan.

Clinical evidence, mechanism, importance and management

In a phase I, dose-escalation study, a 24-hour infusion of gemcitabine, given before a 24-hour infusion of irinotecan, appeared to increase the AUC and maximum plasma levels of irinotecan at higher doses of gemcitabine. However, the pharmacokinetics of the active metabolite of irinotecan, SN-38, did not appear to be affected.[1]

1. Saif MW, Sellers S, Li M, Wang W, Cusimano L, Wang H, Zhang R. A phase I study of biweekly administration of 24-h gemcitabine followed by 24-h irinotecan in patients with solid tumours. *Cancer Chemother Pharmacol* (2007) 60, 871–82.

Irinotecan + Ifosfamide

Ifosfamide appears to markedly reduce the level of SN-38, the active metabolite of irinotecan, when ifosfamide is given daily immediately after irinotecan.

Clinical evidence, mechanism, importance and management

The pharmacokinetics of irinotecan were investigated in 3 paediatric patients who received irinotecan 20 mg/m^2 daily for 5 days, and ifosfamide 2.65 g/m^2 daily immediately after irinotecan on days one to 3. In all 3 patients, the AUC of the active metabolite of irinotecan, SN-38, was markedly lower on day 3 when compared with day one; in 2 patients the plasma levels of SN-38 were below the limit of detection. In two of the patients, the AUC of SN-38 on day 12 was still below that measured on day one. The AUC of the major inactive metabolite (APC) was also significantly reduced on day 3, but returned to day one levels by day 12. The study was stopped in view of the low exposure to SN-38.[1]

The reason for this possible interaction is unknown, but it was suggested that ifosfamide might have induced the metabolism of irinotecan.[1]

The authors concluded that the use of daily ifosfamide with daily irinotecan in a protracted regimen such as this should be avoided, because of this marked reduction in the levels of the active irinotecan metabolite. They note that other administration schedules might not cause the same interaction.[1]

Irinotecan + Milk thistle

Milk thistle does not appear to affect the pharmacokinetics of irinotecan.

Clinical evidence, mechanism, importance and management

A pharmacokinetic study was undertaken in 6 patients who were receiving intravenous irinotecan 125 mg/m^2 weekly for 4 weeks, followed by a 2-week rest period. Four days before the second dose of irinotecan, a 14-day course of 200 mg milk thistle seed extract (containing silymarin 80%) three times daily was started. The pharmacokinetics of irinotecan and its metabolites did not differ between week one (no milk thistle), week two (4 days of milk thistle) or week three (12 days of milk thistle).[1] No dose alterations would therefore be expected to be needed if milk thistle (standardised with silymarin 80%) is given with irinotecan.

1. van Erp NPH, Baker SD, Zhao M, Rudek MA, Guchelaar H-J, Nortier JWR, Sparreboom A, Gelderblom H. Effect of milk thistle (*Silybum marianum*) on the pharmacokinetics of irinotecan. *Clin Cancer Res* (2005) 11, 7800–6.

Irinotecan + Miscellaneous

Preclinical data suggest that vinorelbine and physostigmine may decrease the formation of the active metabolite of irinotecan, SN-38.

Clinical evidence, mechanism, importance and management

In studies in human liver microsomes, **nifedipine**, **clonazepam**, **methylprednisolone**, **omeprazole**, and **vinorelbine** had significant effects on the metabolism of irinotecan. However, only the effect of **vinorelbine** occurred at a concentration considered clinically relevant.[1] Similarly, of various potential carboxylesterase inhibitors, only **physostigmine** was considered sufficiently potent to possibly inhibit irinotecan activation.[2] Further study is needed to assess the clinical relevance of these findings.

Irinotecan + Oxaliplatin

An isolated report suggests that the cholinergic toxicity associated with irinotecan may be enhanced by oxaliplatin.

Clinical evidence, mechanism, importance and management

One of 15 patients given a one-hour infusion of irinotecan 80 mg/m^2 following an 2-hour infusion of oxaliplatin 85 mg/m^2 experienced hypersalivation and abdominal pain, which was successfully treated with atropine. In this patient, symptoms did not recur during subsequent treatment with irinotecan alone, nor when drugs were separated by one day, but rechallenge with the original regimen again produced cholinergic toxicity.[1] Two studies have found that the combination of irinotecan with oxaliplatin does not appear to alter the pharmacokinetics of either drug.[2,3]

The cholinergic effects in the patient may have been due to a pharmacodynamic interaction.[4] It has been suggested that the cholinergic effects of irinotecan, which is a potent inhibitor of acetylcholinesterase,[5] may be enhanced by oxaliplatin, which may, like other alkylating drugs, inhibit acetylcholinesterase.[4]

The clinical relevance of this report is unknown. The combination of irinotecan and oxaliplatin has been extensively evaluated in clinical studies, and this appears to be the only report of this problem. However, it has been noted that the prophylactic use of atropine with irinotecan could mask any increased cholinergic toxicity.[4,6]

Irinotecan + Protease inhibitors

Ritonavir-boosted lopinavir markedly increased levels of the active metabolite of irinotecan, SN-38, in one study. Other protease inhibitors would be expected to interact similarly.

Clinical evidence

A patient taking antiretrovirals including **ritonavir**-boosted **lopinavir** 135/400 mg twice daily received irinotecan 150 mg/m^2 alone after a 2-day protease inhibitor washout then irinotecan at a reduced dose of 75 mg/m^2 with his antiretrovirals. The dose-normalised AUC of the active metabolite of irinotecan, SN-38, was increased by 121%, and the AUC of the inactive metabolite, APC, was reduced by 93%. In this patient, a 50% reduction in irinotecan dose was necessary for the second cycle because of grade 2 neutropenia, and, because grade 2 neutropenia occurred again during the second cycle, no further irinotecan was given.[1]

Similar pharmacokinetic findings were later reported by the same researchers in 7 patients taking **ritonavir**-boosted **lopinavir** and irinotecan: this study found a 204% increase in the AUC of SN-38 and an 81% decrease in the AUC of APC. There was also a decrease in formation of the inactive glucuronide metabolite of SN-38.[2]

Mechanism

It appears that the metabolism of irinotecan to its inactive metabolite by the cytochrome P450 isoenzyme CYP3A4 was inhibited by the protease inhibitors. Therefore more irinotecan is available to be metabolised by carboxylesterases to the active metabolite, SN-38.[1] In addition, protease inhibitors inhibit glucuronosyltransferases, which are involved in the inactivation of SN-38, also resulting in greater SN-38 levels.

Importance and management

Although information is limited, what is known suggests that protease inhibitors are likely to markedly increase the AUC of the active metabolite of irinotecan. These changes suggest that an irinotecan dose reduction may be necessary to avoid toxicity. Note that the US manufacturer of **atazanavir** contraindicates concurrent use with irinotecan because of this predicted interaction.[3]

Irinotecan + Rifampicin (Rifampin)

A single case report found that rifampicin reduced the formation of the active metabolite of irinotecan.

Clinical evidence

A case report describes a 54-year-old man with small cell lung cancer and *Mycobacterium* infection who was uneventfully treated with rifampicin 450 mg daily, isoniazid, streptomycin and pyrazinamide. After 2 weeks of antimycobacterial treatment he was given 4 cycles of irinotecan 75 mg/m^2 on days one and 8, and cisplatin 60 mg/m^2 on day one, and during the first cycle rifampicin was stopped for a 4-day period. There was no difference in the pharmacokinetic profile of irinotecan with or without concurrent rifampicin; however, the AUC of the active metabolite of irinotecan, SN-38, and of its inactive glucuronide metabolite were reduced by 20% and 58%, respectively, in the presence of rifampicin.[1]

Mechanism

Irinotecan is metabolised by the cytochrome P450 isoenzyme CYP3A4 to an inactive metabolite, and rifampicin probably induces this pathway of metabolism. This would result in less irinotecan being available for conversion to the active metabolite SN-38.

Importance and management

The reduction in the levels of active metabolite of irinotecan in this patient taking rifampicin was only modest. However, note that the effects of rifampicin can persist for some time after it is stopped and therefore a 4-day period may not have been sufficient for any effect to have completely reversed. The UK manufacturer of irinotecan notes that the use of irinotecan with potent enzyme-inducers such as rifampicin should be avoided.[2] If concurrent use is unavoidable, it would seem wise to bear in mind the possibility of reduced irinotecan efficacy, and to closely monitor the patient accordingly.

Irinotecan + Selenium

Selenium at a dose of 2.2 mg daily does not appear to alter the pharmacokinetics of irinotecan, nor does it attenuate the toxicity of irinotecan.

Clinical evidence, mechanism, importance and management

In a study in 13 patients with metastatic or unresectable solid tumours **selenomethionine**, at a dose of elemental selenium 2.2 mg daily, was given with irinotecan weekly, in escalating doses from 125 mg/m^2 to 160 mg/m^2 for 4 weeks of a 6-week cycle. Irinotecan doses above the previously recommended maximum tolerated dose were still considered intolerable, with 3 of 4 patients receiving a dose of 160 mg/m^2 developing dose-limiting diarrhoea. There were no significant alterations in the pharmacokinetics of irinotecan or its metabolites, SN-38 and SN-38G. It was suggested that higher doses of selenomethionine should be investigated to see if they protect against irinotecan toxicity.[1]

Irinotecan + Sodium bicarbonate

Oral alkalinisation with sodium bicarbonate, and the concurrent use of domperidone and magnesium oxide, did not affect the pharmacokinetics of irinotecan or its metabolites, and patients tended to have less diarrhoea.

Clinical evidence, mechanism, importance and management

Ten patients with colorectal cancer who had not previously been treated with irinotecan were given irinotecan 120 mg/m^2 intravenously every 2 weeks until disease progression occurred. The study was a crossover design and patients also received oral alkalinisation with sodium bicarbonate 3 g daily, and also domperidone 30 mg daily, magnesium oxide up to 3 g daily and at least 1.5 litres of water daily, with either the first or second course of irinotecan. Sodium bicarbonate was given to alkalinise the gastrointestinal contents, domperidone to increase gastrointestinal motility, and magnesium oxide for its laxative effects. The aim was to try to reduce the delayed toxic effect of irinotecan on the bowel that can lead to severe diarrhoea.

The AUC of irinotecan and its inactive metabolite, SN-38G, were equivalent between the two groups, and there was no significant change in the AUC of the active metabolite, SN-38. The incidence of diarrhoea tended to be lower with oral alkalinisation (0 of 10 patients) than without (3 of 10 patients), although this was not significant, but there were no differences in the incidence of nausea and vomiting, anorexia and alopecia with or without oral alkalinisation. Concurrent alkalinisation is therefore unlikely to affect the efficacy of irinotecan and may reduce the incidence of delayed diarrhoea.[1]

Note that the current recommended treatment for delayed diarrhoea is prompt treatment with loperamide and fluid and electrolyte replacement.[2,3] The use of drugs with laxative properties [which would include magnesium oxide] should be avoided in case they exacerbate the diarrhoea.[3] Although oral alkalinisation is not an accepted from of therapy with irinotecan, it is worth knowing that sodium bicarbonate and domperidone did not alter the pharmacokinetics of irinotecan.

Irinotecan + Sorafenib

Sorafenib increases the levels of irinotecan and its major active metabolite. Irinotecan increases sorafenib levels.

Clinical evidence

In a phase I dose-escalation study, sorafenib 100 mg, 200 mg or 400 mg twice daily was given continuously from day 4 of the first cycle with irinotecan 125 mg/m^2 weekly for 4 out of 6 weeks as an intravenous infusion.[1,2] The pharmacokinetics of irinotecan and its major active metabolite, SN-38, were not affected by sorafenib at the two lower doses (100 mg and 200 mg twice daily). In addition, sorafenib pharmacokinetics at these dose levels were not affected by irinotecan.[1,2] However, the maximum plasma level of sorafenib was increased by 78% and its AUC was increased by 68% in the patients who received the highest dose of sorafenib (400 mg twice daily) with irinotecan 125 mg/m^2, but this was not seen with a lower fixed dose of irinotecan 140 mg. At both doses of irinotecan, the patients who had received the highest dose of sorafenib experienced a 26 to 42% increase in the AUC of irinotecan, and a 67 to 120% increase in the AUC of SN-38.[2]

Mechanism

In vitro, sorafenib strongly inhibits the glucuronidation of SN-38 by UGT1A1,[1] which would result in reduced metabolism of this active metabolite of irinotecan.

Importance and management

Usual clinical doses of irinotecan and sorafenib appear likely to increase the levels of each other, with a marked increase in levels of the active metabolite of irinotecan. The clinical significance of this finding is unknown, but increased toxicity might be expected. The authors of the study suggest that the dose of irinotecan for concurrent use should be 125 mg/m^2 or 140 mg, with close monitoring for toxicity.[2] The manufacturers of sorafenib recommend caution on concurrent use.[3,4]

Irinotecan + St John's wort (*Hypericum perforatum*)

St John's wort increases the metabolism of irinotecan, which may decrease its activity.

Clinical evidence

In a randomised, crossover study, St John's wort decreased the plasma levels of the active metabolite of irinotecan, SN-38, by 42%. Myelosuppression was also reduced; with irinotecan alone the leucocyte and neutrophil counts decreased by 56% and 63%, respectively, but in the presence of St John's wort the decreases were only 8.6% and 4.3%, respectively. In this study, irinotecan was given as a single 350-mg/m^2 intravenous dose every 3 weeks, and during one cycle a St John's wort preparation was given three times daily, beginning 14 days before and stopping 4 days after the irinotecan.[1]

Mechanism

St John's wort induces the cytochrome P450 isoenzyme CYP3A4 and P-glycoprotein, which are both involved in the metabolism and transport of irinotecan. The evidence suggests that St John's wort increases the metabolism of irinotecan to an unknown inactive metabolite, rather than the active SN-38, thereby reducing its effects.[1]

Importance and management

The evidence appears to be limited. Irinotecan has a narrow therapeutic range, and as irinotecan is a prodrug that is metabolised to its active metabolite SN-38, the lower levels of SN-38 suggest that its activity will be reduced in the presence of St John's wort. It would therefore seem sensible to warn patients who are about to receive irinotecan to avoid St John's

wort. It seems likely that **topotecan**, a related drug that is also a substrate for CYP3A4, will be similarly affected, but evidence for this is lacking.

Irinotecan + Temozolomide

Temozolomide does not appear to alter the pharmacokinetics of irinotecan or its active metabolite. Irinotecan does not alter the pharmacokinetics of temozolomide.

Clinical evidence, mechanism, importance and management

In a study in paediatric patients, there was no change in the pharmacokinetics of irinotecan, its active metabolite SN-38, or temozolomide when oral temozolomide 100 mg/m^2 daily was given one hour before irinotecan 10 or 15 mg/m^2 daily, both for 5 days.[1] Similarly, the pharmacokinetics of irinotecan and its active metabolite, SN-38, in 6 patients also taking enzyme-inducing antiepileptic drugs were not affected by temozolomide, when compared to historical data from patients taking irinotecan and enzyme-inducing antiepileptic drugs.[2] For details of the interaction of irinotecan with enzyme-inducing antiepileptic drugs see 'Irinotecan + Antiepileptics', p.736.

Irinotecan + Thalidomide

Thalidomide has both slightly increased and decreased irinotecan levels and slightly decreased the levels of the active metabolite of irinotecan.

Clinical evidence, mechanism, importance and management

Patients with solid tumours given irinotecan 350 mg/m^2 on day one of a 3-week cycle were also given thalidomide 400 mg daily from days one to 14 of the first cycle. Thalidomide slightly increased the AUC of irinotecan by 21% (not statistically significant) and its SN-38-glucuronide metabolite by 28%, but decreased the AUC of the active SN-38 metabolite of irinotecan by 26%. There was no difference in the toxicities seen when irinotecan was given with or without thalidomide.[1] In another study, patients were given intravenous irinotecan 125 mg/m^2 on days one and 8 of a 21-day cycle with oral thalidomide 200 mg or 400 mg given daily from day 3, at least one hour before the irinotecan. There was no change in the AUC of the active metabolite of irinotecan, SN-38, in 17 evaluable patients, although the maximum plasma levels of irinotecan and SN-38 were reduced by about 12%.[2] These changes are modest, and unlikely to be clinically relevant, but ideally this needs establishing in larger studies.

Irinotecan + Tobacco

Retrospective data suggests that tobacco smoking might increase the clearance of irinotecan and reduce the levels of its active metabolite, its toxicity, and presumably therefore, its efficacy.

Clinical evidence

In a retrospective analysis, the pharmacokinetics of irinotecan were compared between 49 patients who were smokers and 141 patients who were non-smokers, and who had received intravenous irinotecan 175 to 350 mg/m^2 (or a fixed dose of 600 mg) once every 3 weeks. The clearance of irinotecan was 18% faster in the group of patients who smoked, and these patients had a 40% lower AUC of the active metabolite of irinotecan, SN-38, and also had more extensive conversion of the active metabolite, SN-38, to the inactive glucuronide (SN-38G). Smokers experienced significantly less haematological toxicity than non-smokers (grade 3 to 4 neutropenia 6% versus 38%), possibly as a result of the increased rate of clearance.[1]

Mechanism

Uncertain. Irinotecan is metabolised to inactive metabolites by the cytochrome P450 subfamily CYP3A, which, although not the most commonly implicated isoenzyme in interactions involving tobacco smoking, may be induced by some of the components of tobacco smoke, resulting in increased clearance of irinotecan. In addition, smoking might induce glucuronyltransferases (which are responsible for glucuronidation of the active SN-38 metabolite).[1]

Importance and management

The findings of this retrospective analysis suggest that smoking might reduce the efficacy of irinotecan. However, the evidence is insufficient to make recommendations regarding smoking cessation or an increased irinotecan dose.[1] Further study is required.

Lapatinib + Antineoplastics

Lapatinib pharmacokinetics are not affected by fluorouracil, irinotecan or oxaliplatin, and fluorouracil and oxaliplatin pharmacokinetics are not affected by lapatinib. Lapatinib increased levels of the active metabolite of irinotecan, SN-38, and a reduction in the dose of the FOLFIRI regimen was required.

Clinical evidence, mechanism, importance and management

(a) Fluorouracil, Folinic acid and Irinotecan

The pharmacokinetics of lapatinib 1.25 g daily were unaffected when it was given with the FOLFIRI regimen (irinotecan, folinic acid and fluorouracil). In addition, there was no change in the steady-state level of fluorouracil or of the pharmacokinetics of irinotecan. However, there was a 41% increase in the AUC of the active metabolite of irinotecan, SN-38, and a 32% increase in its maximum level. A variety of mechanisms might be responsible for this effect, such as inhibition of transporters including OATP1B1 and P-glycoprotein. In this study, toxicity necessitated dose reductions rather than the planned dose escalations, and the optimally tolerated regimen was found to be FOLFIRI at 60% of the standard doses.[1] Bear these findings in mind if lapatinib is used with irinotecan.

(b) Fluorouracil, Folinic acid and Oxaliplatin

In 19 patients the pharmacokinetics of lapatinib 1.5 g daily were unaffected when it was given just before starting oxaliplatin in the FOLFOX4 regimen (**oxaliplatin**, folinic acid and **fluorouracil**), when compared with days when lapatinib was given alone. In addition, lapatinib had no effect on the pharmacokinetics of **fluorouracil** or **oxaliplatin**.[2] Lapatinib can be given with the full-dose FOLFOX regimen.

Lapatinib + Food

Food increases the bioavailability of lapatinib.

Clinical evidence, mechanism, importance and management

In a randomised, crossover study, 22 patients with cancer were given a single 1.5-g dose of lapatinib after a high-fat meal, a low-fat meal, or in the fasted state. The high-fat meal increased the AUC and maximum plasma concentration of lapatinib 4.2-fold and 3.1-fold, respectively, when compared with the fasted state. The low-fat meal increased the AUC and maximum plasma concentration of lapatinib by about 2.5-fold, when compared with the fasted state.[1]

This increase would be expected to be of clinical relevance, and therefore the manufacturers recommend taking lapatinib at least one hour before or one hour after food.[2,3]

Lapatinib + Miscellaneous

Ketoconazole increases lapatinib levels and carbamazepine reduces lapatinib levels. Other potent CYP3A4 inducers and inhibitors are predicted to interact similarly. Lapatinib is predicted to raise the levels of CYP3A4 substrates, but some evidence with midazolam suggests that this may not be clinically relevant. Additive QT prolongation may occur if lapatinib is given with other drugs that prolong the QT interval, and drugs that raise gastric pH may reduce lapatinib absorption. In theory lapatinib may affect the levels of P-glycoprotein substrates (such as digoxin), and have its levels affected by inducers and inhibitors of this drug transporter, but there is no clinical evidence to establish the relevance of these predictions.

Clinical evidence, mechanism, importance and management

(a) CYP2C8 and CYP3A4 substrates

In vitro, lapatinib is an inhibitor of CYP2C8 and CYP3A4, and the manufacturers therefore advise caution when it is given with other drugs that have a narrow therapeutic margin and are substrates of these isoenzymes. They specifically name **cisapride**, **pimozide** and **quinidine** (CYP3A4 substrates) and **repaglinide** (CYP2C8 substrate).[1,2] However, a study in 23 cancer patients found that lapatinib 1.5 g daily did not affect the pharmacokinetics of either oral or intravenous **midazolam**, a probe substrate of CYP3A4.[3] It therefore seems unlikely that lapatinib will have a clinically relevant effect on these drugs.

See 'Table 1.3', (p.6), for a list of substrates of CYP2C8.

(b) CYP3A4 inducers

A study in 23 healthy subjects who received **carbamazepine** 100 mg twice daily for 3 days followed by 200 mg twice daily for a further 17 days, with a single dose of lapatinib 250 mg on day 1 and day 21, found that the AUC and maximum plasma concentration of lapatinib were reduced by 72% and 58%, respectively.[4] Lapatinib is a substrate of the cytochrome P450 isoenzyme CYP3A4, and the manufacturer therefore advises that the concurrent use of **carbamazepine** and other strong inducers of CYP3A4 should be avoided. They specifically mention **dexamethasone**,[1] **phenobarbital**, **phenytoin**, **rifabutin**, **rifampicin** (**rifampin**), **rifapentine**, and **St John's wort**.[1,2] If concurrent use is necessary, the dose of lapatinib should be gradually increased to 4.5 g daily, depending on patient tolerability. The lapatinib dose should be reduced when the inducing drug is stopped.[1] However, note that clinically relevant interactions occurring as a result of dexamethasone inducing CYP3A4 appear rare.

For a list of CYP3A4 inducers, see 'Table 1.4', (p.6).

(c) CYP3A4 inhibitors

A randomised, crossover study in 22 healthy subjects found that **ketoconazole** 200 mg twice daily for 7 days increased the AUC and maximum plasma concentration of a single 100-mg dose of lapatinib taken on day 4 by 3.6-fold and 2.2-fold, respectively.[5] Lapatinib is a substrate of the cytochrome P450 isoenzyme CYP3A4, and the manufacturers therefore advise that the concomitant use of **ketoconazole**, and other strong inhibitors of CYP3A4 should be avoided. They specifically name the protease inhibitors **atazanavir**, **indinavir**, **nelfinavir**, **ritonavir**, and **saquinavir**; the macrolides **clarithromycin** and **telithromycin**; and the azoles **itraconazole**, **posaconazole**, and **voriconazole**.[1,2] If concurrent use with a strong inhibitor of CYP3A4 is unavoidable, a dose reduction of lapatinib to 500 mg daily should be considered.[1,2] A period of 1 week should be observed before increasing the lapatinib dose after stopping the CYP3A4 inhibitor.[1] The UK manufacturer also advises caution with moderate inhibitors of CYP3A4, which in practice probably means monitoring closely for lapatinib adverse effects. **Grapefruit juice** is also a CYP3A4 inhibitor and the manufacturers suggest that concurrent use should be avoided,[1,2] presumably as the effects of different grapefruit juice products may be variable.

For a list of CYP3A4 inhibitors, see 'Table 1.4', (p.6).

(d) Drugs that affect gastric pH

As lapatinib solubility is pH dependent, the UK manufacturer advises that drugs that increase gastric pH may reduce the bioavailability of lapatinib and should be avoided. This advice would apply to **antacids**, **H_2-receptor antagonists** and **proton pump inhibitors**; however, there does not appear to be any specific clinical data to confirm this prediction.[2]

(e) Drugs that prolong the QT interval

Lapatinib has been shown to prolong the QTc interval by more than 60 milliseconds in 13 of 81 patients, using Fridericia's correction. The manufacturers therefore advise caution when patients take lapatinib with antiarrhythmic drugs or other drugs that cause QT prolongation, and cumulative high-dose **anthracycline** treatment.[1]

Similar caution therefore seems appropriate with other drugs known to cause QT-prolongation, see 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290.

(f) P-glycoprotein inhibitors and substrates

Lapatinib is a substrate of P-glycoprotein, and the manufacturers therefore advise that caution is warranted with drugs that are inhibitors of P-glycoprotein as increased levels of lapatinib are likely to result.[1,2] See 'Table 1.6', (p.8), for a list of drugs that are inhibitors of P-glycoprotein.

As lapatinib is also an inhibitor of P-glycoprotein, it is predicted to increase the levels of P-glycoprotein substrates (**digoxin** is specifically named) and therefore caution is recommended. However there is no clinical information to clarify the relevance of this prediction.[1,2]

Lenalidomide + Miscellaneous

Lenalidomide may slightly increase digoxin levels. The concurrent use of lenalidomide and drugs that may increase the risk of thromboembolism (combined hormonal contraceptives, HRT, epoetins) should be avoided, or undertaken with caution. No interaction is anticipated when lenalidomide is taken with warfarin.

Clinical evidence, mechanism, importance and management

(a) Digoxin

The maximum level of a single 500-microgram dose of digoxin was very slightly increased by 14% by lenalidomide 10 mg daily, and the AUC of digoxin was unchanged.[1] This increase is not clinically relevant, but, as doses of lenalidomide can be higher than this (up to 25 mg daily), the possibility that higher doses might have a greater clinically relevant effect cannot be entirely excluded.[2] Note that lenalidomide is normally given with dexamethasone, consider also 'Digoxin and related drugs + Drugs that lower potassium levels', p.1099.

(b) Epoetins

Patients given lenalidomide and dexamethasone for multiple myeloma have an increased risk of deep vein thrombosis and pulmonary embolism. The use of epoetins may further increase this risk and therefore the UK manufacturer advises that these drugs should be used with caution.[2]

(c) Hormonal contraceptives

Lenalidomide is structurally related to thalidomide and may therefore be teratogenic. The manufacturers therefore give detailed advice about the use of adequate contraceptive measures.[1,2] However, the UK manufacturer considers that the increased risk of thromboembolic events in patients receiving lenalidomide might be further increased by the use of combined hormonal contraceptives, so they contraindicate these contraceptives. They recommend that, if a hormonal contraceptive is required, progestogen-only contraceptives should be used, and they specifically recommend implants, injections, the levonorgestrel intra-uterine system or oral desogestrel.[2] However, the US manufacturer makes no mention of this theoretical interaction, and does not exclude the use of combined hormonal contraceptives.[1] Moreover, the UK manufacturer suggests that, as lenalidomide should be taken with dexamethasone, the possibility that contraceptive efficacy of oral contraceptives may be reduced cannot be excluded, because dexamethasone is a weak to moderate inducer of the cytochrome P450 isoenzyme CYP3A4, by which contraceptive steroids are metabolised.[2] Nevertheless, they do not suggest any changes in their recommended hormonal contraceptives on the basis of this interaction. Note that, although this is a theoretical possibility there appear to be no examples of dexamethasone interacting with hormonal contraceptives in this way.

(d) Hormone replacement therapy

Patients receiving lenalidomide and dexamethasone for multiple myeloma have an increased risk of deep vein thrombosis and pulmonary embolism. The use of hormone replacement therapy may further increase this risk and therefore the UK manufacturer advises that it should be used with caution.[2]

(e) Warfarin

Lenalidomide 10 mg daily did not affect the pharmacokinetics of a single dose of warfarin, nor were the pharmacokinetics of lenalidomide affected by a single 25-mg dose of warfarin.[1,2] However, the UK manufacturer mentions that an interaction cannot be excluded in clinical use, because dexamethasone is also given, and the effect of dexamethasone on warfarin is unknown.[2] Consider also 'Coumarins and related drugs + Corticosteroids or Corticotropin', p.450.

Letrozole + Cimetidine

In 17 healthy subjects the pharmacokinetics of a single 2.5-mg dose of letrozole were unchanged by cimetidine 400 mg every 12 hours.[1]

1. Morgan JM, Palmisano M, Spencer S, Hirschhorn W, Piraino AJ, Rackley RJ, Choi L. Pharmacokinetic effect of cimetidine on a single 2.5-mg dose of letrozole in healthy subjects. *J Clin Pharmacol* (1996) 36, 852.

Melphalan + Cimetidine

Cimetidine modestly reduces the bioavailability of melphalan.

Clinical evidence, mechanism, importance and management

A study in 8 patients with multiple myeloma or monoclonal gammopathy found that pretreatment with cimetidine 1 g daily for 6 days reduced the bioavailability of a 10-mg oral dose of melphalan by 30%. The melphalan half-life was reduced from 1.94 hours to 1.57 hours. The interindividual variation in melphalan pharmacokinetics was high.[1] Note that, because of the variability in melphalan absorption, the dose of oral melphalan is usually cautiously increased until myelosuppression is seen, to ensure therapeutic levels. Therefore, this modest interaction with cimetidine is unlikely to have many clinical consequences.

1. Sviland L, Robinson A, Proctor SJ, Bateman DN. Interaction of cimetidine with oral melphalan. *Cancer Chemother Pharmacol* (1987) 20, 173–5.

Melphalan + Food

The absorption of melphalan can be reduced by food.

Clinical evidence, mechanism, importance and management

A study in 10 patients with multiple myeloma found that the half-life of oral melphalan 5 mg/m^2 was unaffected when it was taken with a standardised breakfast, but its AUC was reduced by 39%. In one patient, no melphalan was detectable in the plasma when it was given with food. In 8 of the patients who had also been given intravenous melphalan at the same dose, the bioavailability of oral melphalan was calculated to be 85% (range 26 to 96%) when fasting and 58% (7 to 99%) when given with food.[1] A similar reduction in absorption was noted in a study in 5 patients who were given melphalan orally with food, compared with doses given while fasting, or intravenously.[2]

The authors of these studies recommend that melphalan should not be taken with food,[1] or that it should be taken first thing in the morning on an empty stomach.[2] However, the manufacturers make no specific recommendations about intake in relation to food.[3,4] They note that absorption after oral administration is highly variable, and that the dose should be adjusted based on frequent monitoring of blood counts.[4]

Melphalan + Interferon alfa

Interferon alfa modestly decreases the AUC of melphalan, but melphalan cytotoxicity is possibly increased because of interferon-induced fever.

Clinical evidence, mechanism, importance and management

In 10 myeloma patients, the AUC of melphalan 250 microgram/kg was reduced by 13% when it was given 5 hours after the administration of human interferon alfa (7×10^6 units/m^2), possibly due to fever caused by the interferon.[1] The clinical importance of this is uncertain but the authors of the report suggest that, despite this small reduction in the AUC, the cytotoxicity of the melphalan may be increased by the fever. The use of interferon alfa with melphalan and prednisone in multiple myeloma has been associated with more adverse effects.[2-4]

Methotrexate + Amiodarone

An isolated case report tentatively attributes the development of methotrexate toxicity to the concurrent use of amiodarone.

Clinical evidence, mechanism, importance and management

An elderly woman, whose psoriasis was effectively controlled for 2 years with methotrexate, developed ulceration of the psoriatic plaques within

2 weeks of starting treatment with amiodarone. The reason for this effect is not understood. A modest increase in her dose of furosemide is a suggested contributory factor because it might have interfered with the excretion of the methotrexate.[1] This appears to be an isolated case, and therefore no general recommendations can be made.

Methotrexate + Antibacterials; Aminoglycosides, oral

Limited evidence suggests that the gastrointestinal absorption of methotrexate can be reduced by paromomycin, neomycin and possibly other oral aminoglycosides, but increased by kanamycin.

Clinical evidence

A study in 10 patients with small cell bronchogenic carcinoma taking methotrexate found that when they were also given a range of oral anti-infectives (**paromomycin**, vancomycin, polymyxin B, nystatin) the urinary recovery of methotrexate was reduced by over one-third (from 69% to 44%).[1] The **paromomycin** was believed to have been responsible. In another study the concurrent use of **neomycin** 500 mg four times daily for 3 days reduced the AUC of methotrexate and its 72-hour cumulative excretion by 50%.[2] In contrast, the same report suggests that **kanamycin** can *increase* the absorption of methotrexate, but no details are given.

Mechanism

Oral aminoglycosides reduce the activity of the gut flora, which metabolise methotrexate, so that more is available for absorption. However, paromomycin[3] and neomycin, in common with other oral aminoglycosides, can cause a malabsorption syndrome, which reduces drug absorption and presumably negates any effect altering the gut flora has. Kanamycin may possibly be different because it causes less malabsorption.

Importance and management

The documentation of these interactions is sparse, but it would seem prudent to be on the alert for a reduction in the response to methotrexate if patients are given oral aminoglycosides such as paromomycin or neomycin. An increased response may possibly occur with kanamycin. No interaction would be expected if aminoglycosides are given parenterally.

Methotrexate + Antibacterials; Cefotiam

Pancytopenia and pseudomembraneous colitis occurred when a patient taking low-dose methotrexate and loxoprofen was given cefotiam.

Clinical evidence, mechanism, importance and management

An elderly woman who had been taking low-dose methotrexate 5 mg weekly and loxoprofen for one month developed acute pyelonephritis. Intravenous cefotiam was started, and on day 7 she developed severe watery diarrhoea. Analysis showed pancytopenia and *Clostridium difficile* infection. Methotrexate and cefotiam were stopped, and vancomycin started, and the patient recovered.[1] It was suggested that the combination of the antineoplastic drug and the antibacterial increased the risk of *Clostridium difficile* diarrhoea. In addition, the NSAID (see 'Methotrexate + NSAIDs, Aspirin or other Salicylates', p.752) and renal impairment from the pyelonephritis could have contributed to the methotrexate toxicity.[1] This appears to be an isolated case, and any interaction between methotrexate and cefotiam is not established.

Methotrexate + Antibacterials; Ciprofloxacin

A report describes two patients who developed methotrexate toxicity when they were given ciprofloxacin.

Clinical evidence

Two patients with osteosarcoma, receiving high-dose methotrexate 12 g/m^2 per course, were given ciprofloxacin 500 mg twice daily, either during or 2 days before the start of the methotrexate course. Methotrexate elimination was delayed, resulting in raised serum levels, severe cutaneous toxicity and renal impairment. The first patient also had hepatic injury and haematological toxicity. Increased folinic acid rescue normalised methotrexate levels after several days. In earlier courses without ciprofloxacin in the first patient and subsequent courses without ciprofloxacin in the second patient, methotrexate elimination was normal.[1] This preliminary report has subsequently been published in full.[2,3]

Mechanism

Not fully understood. Ciprofloxacin may displace methotrexate from its plasma-protein binding sites resulting in a rise in levels of unbound methotrexate. Ciprofloxacin may also cause a decrease in the renal clearance of methotrexate.

Importance and management

Information about an interaction between methotrexate and ciprofloxacin appears to be limited to one report, but it would seem prudent to monitor for raised methotrexate levels if concurrent use is necessary. More study is needed.

Methotrexate + Antibacterials; Co-trimoxazole or Trimethoprim

Several cases of severe bone marrow depression (some of which were fatal) have been reported in patients given low-dose methotrexate and trimethoprim or co-trimoxazole (sulfamethoxazole with trimethoprim). Pancytopenia has also been reported in a few patients given co-trimoxazole shortly after stopping methotrexate.

Clinical evidence

A 61-year-old patient with rheumatoid arthritis, taking methotrexate 7.5 mg weekly, developed generalised bone marrow hypoplasia over 2 months after a 10-day course of treatment with co-trimoxazole for a urinary tract infection. She had taken a total of 775 mg of methotrexate when the hypoplasia appeared.[1] Twelve other cases of severe bone marrow depression, four of them fatal,[2-4] have been described in patients taking low-dose weekly methotrexate with co-trimoxazole[2,5-9] or trimethoprim.[3,7,10,11] Life-threatening complications (no details given) are said to have occurred in two other patients taking low-dose methotrexate with unnamed sulfonamides.[12] A 10-year (1981 to 1991) regional survey in Ottawa identified co-trimoxazole as one of four factors associated with serious pancytopenia in patients taking low-dose methotrexate. The other factors were elevated BUN or creatinine levels, increased mean corpuscular volumes and increasing age.[13]

Three cases of severe pancytopenia, one of them fatal, have been reported in patients given treatment dose co-trimoxazole for pneumocystis pneumonia shortly after stopping low-dose methotrexate.[14-16] A fatal case

of severe agranulocytosis and toxic epidermal necrolysis occurred in a patient receiving co-trimoxazole for prophylaxis of pneumocystis pneumonia after high-dose methotrexate.[17]

Mechanism

Not fully understood. Both drugs can suppress the activity of dihydrofolate reductase and it seems possible that they can act additively to produce folate deficiency, which could lead to some of the bone marrow changes seen. There may also be a pharmacokinetic mechanism. An early study found that the concurrent use of co-trimoxazole had no effect on the pharmacokinetics of methotrexate in children;[18] however, another study reported that co-trimoxazole caused an increase in 'free' methotrexate from about 37% to 52% while the renal clearance was more than halved.[19] This was calculated to increase the exposure to methotrexate by 66%.[19] Another sulfonamide, **sulfafurazole** (sulfisoxazole),[20] has been found to cause a small reduction in the clearance of methotrexate by the kidneys.

Importance and management

Information seems to be limited to the reports cited but the interactions between methotrexate and co-trimoxazole or trimethoprim are established. Low-dose co-trimoxazole is commonly given without problem to patients taking methotrexate as prophylaxis of pneumocystis pneumonia. This type of patient should be having regular blood monitoring as a matter of course. However, the situation with higher doses of either drug is potentially more hazardous. Some have recommended avoiding the combination. If both drugs must be used, the haematological picture should be very closely monitored because the outcome can be life-threatening.

Methotrexate + Antibacterials; Penicillins

Reduced methotrexate clearance and acute methotrexate toxicity has been attributed to the concurrent use of various penicillins (amoxicillin, benzylpenicillin, carbenicillin, dicloxacillin, flucloxacillin, mezlocillin, oxacillin, penicillin, phenoxymethylpenicillin, piperacillin, ticarcillin) in a small number of case reports.

Clinical evidence

Reduced methotrexate clearance and acute methotrexate toxicity has been attributed to the concurrent use of various penicillins in a number of patients. See 'Table 17.2', (p.747), for details.

A survey of the Wyeth/Lederle safety database in 1996 identified two additional unpublished cases of methotrexate toxicity (aplastic anaemia, thrombocytopenia, pneumonitis) in patients who had recently started penicillins.[1]

Mechanism

It is thought that weak acids such as the penicillins can possibly successfully compete with methotrexate in the kidney tubules for excretion so that the methotrexate is retained, thereby increasing its effects and its toxicity.[2] However, this was not demonstrated in a study with flucloxacillin,[3] and the mechanism has been disputed.[4]

Importance and management

Information seems to be limited to the reports given here, which would seem to indicate that serious interactions between methotrexate and penicillins are uncommon. It is not known why only a few patients have been affected and what other factors may have contributed, but the problem does not seem to be confined to patients receiving high-dose methotrexate. There is not enough evidence to forbid concurrent use (although some have advised against it[5]), but close monitoring is obviously advisable. One published recommendation is to carry out twice-weekly platelet and white cell counts for 2 weeks initially, with the measurement of methotrexate levels if toxicity is suspected. Folinic acid (leucovorin) rescue should be available.[6]

For the general guidelines given by the CSM in the UK on the use of methotrexate alone, see under *Importance and management* in 'Methotrexate + NSAIDs, Aspirin or other Salicylates', p.752.

Methotrexate + Antibacterials; Pristinamycin

An isolated report describes severe methotrexate toxicity in a patient also given pristinamycin.

Clinical evidence

A 13-year-old boy with acute lymphoblastic leukaemia had a relapse and began a series of regimens with high-dose methotrexate in combination with other drugs, including dexamethasone, mercaptopurine, vincristine, cytarabine and asparaginase, tioguanine and ifosfamide. During a late cycle when he was also taking pristinamycin 2 g daily for a staphylococcal infection, the clearance of methotrexate was markedly decreased (half-life prolonged from 6 hours to 203 hours). He developed severe methotrexate toxicity (oral mucositis, anusitis, balanitis, neutropenia and thrombocytopenia) and was given folinic acid rescue and haemodialysis.[1]

Mechanism

Not understood, but on the basis of experimental evidence the authors of the report excluded the possibilities of renal impairment or reduction of liver metabolism caused by the pristinamycin.[1]

Importance and management

This appears to be the first and only report of an interaction between methotrexate and pristinamycin. Its general importance is unknown but the au-

Table 17.2 Reports of reduced methotrexate clearance during penicillin use

Methotrexate	*Penicillin (dose)*	*Indication (number of patients)*	*Outcome*	*Refs*
High-dose intravenous regimen (with folinic acid rescue)				
Infusion of 8 g/m^2 over 6 hours	Amoxicillin (1 g every 6 hours orally)	Osteogenic sarcoma (1)	56% reduction in methotrexate clearance; prolonged and marked enhancement of methotrexate plasma levels; acute and subacute methotrexate toxicity	1
Infusion of 6 g/m^2 (10.8 g) over one hour, then 1.2 g/m^2 per hour for 23 hours	Carbenicillin (30 g daily)	Acute lymphoblastic leukaemia (1)	Elevated plasma methotrexate levels and decreased methotrexate clearance	2
Bolus of 15 to 60 mg/m^2, then 15 to 60 mg/m^2 infusion over 36 hours	Dicloxacillin (not stated) (Indometacin also given)	Oesophageal cancer (1)	93% reduction in methotrexate clearance; prolonged folinic acid rescue necessary	3
Infusion of 12 g/m^2 over 4 hours	Mezlocillin (330 mg/kg daily)	Osteogenic sarcoma (1)	Reduced methotrexate clearance; increased gastrointestinal toxicity	4
Infusion of 15 g over 6 hours	Oxacillin (1 g every 8 hours starting 6 hours after methotrexate infusion)	Osteogenic sarcoma (1)	Plasma methotrexate levels 53-fold higher than in previous cycles without oxacillin; fatal acute toxicity (renal failure and aplastic anaemia)	5
Bolus of 15 to 60 mg/m^2, then 15 to 60 mg/m^2 infusion over 36 hours	Penicillin [sic] (not stated)	Breast cancer (1)	36% reduction in methotrexate clearance; prolonged folinic acid rescue necessary	3
Bolus of 15 to 60 mg/m^2, then 15 to 60 mg/m^2 infusion over 36 hours	Piperacillin (not stated)	Chronic myeloid leukaemia (1)	67% reduction in methotrexate clearance; prolonged folinic acid rescue necessary	3
Infusion of 3 g/m^2 over 6 hours	Piperacillin (1 g every 6 hours intravenously)	Non-Hodgkin's lymphoma (1)	Reduced methotrexate clearance	6
High-dose methotrexate as part of CODOX-M regimen (Cyclophosphamide, Doxorubicin, Vincristine)	Piperacillin/tazobactam (not stated)	Burkitt's lymphoma (1)	Methotrexate clearance reduced by 97%. Plasma methotrexate levels remained at 0.2 micromols/L (reference less than 0.05 micromols/L) for 8 days until piperacillin stopped	7
Bolus of 15 to 60 mg/m^2, then 15 to 60 mg/m^2 infusion over 36 hours	Ticarcillin (not stated)	Acute myeloid leukaemia (1)	60% reduction in methotrexate clearance; prolonged folinic acid rescue necessary	3
Low-dose regimen				
7.5 mg weekly	Amoxicillin 500 mg orally three times daily for 7 days; from day 17, intravenous flucloxacillin 2 g every 4 hours, plus intravenous benzylpenicillin 2 million units every 4 hours	Rheumatoid arthritis	Neutropenia and thrombocytopenia probably as a result of reduced methotrexate clearance; folinic acid given, but patient died	8
10 mg weekly	Amoxicillin (route and dose not stated)	Not given (1)	Severe pancytopenia, sepsis, melaena, mucositis. Treatment also included aspirin and celecoxib. Treated with folinic acid and blood transfusion, but patient died	9
7.5 mg weekly	Co-amoxiclav (amoxicillin and clavulanic acid)	Psoriasis (1)	Neutropenia and thrombocytopenia, probably as a result of reduced methotrexate clearance	8
5 mg weekly	Flucloxacillin (4 g four times daily, intravenously then orally)	Rheumatoid arthritis (1)	Suspected methotrexate-induced pneumonitis	10
5 to 15 mg weekly	Flucloxacillin (500 mg four times daily orally)	Rheumatoid arthritis (10, and 10 not given flucloxacillin)	No significant effect on methotrexate pharmacokinetics	10
2.5 mg three times each week	Flucloxacillin (1 g every 6 hours intravenously) plus piperacillin (2 g every 6 hours intravenously)	Psoriasis (1)	Neutropenia and thrombocytopenia, probably as a result of reduced methotrexate clearance; folinic acid given, but patient died	8
5 mg twice weekly	Piperacillin (intravenous; dose not stated)	Psoriasis (1)	Neutropenia and thrombocytopenia, probably as a result of reduced methotrexate clearance; folinic acid given, but patient died	8

Continued

Table 17.2 Reports of reduced methotrexate clearance during penicillin use (continued)

Methotrexate	*Penicillin (dose)*	*Indication (number of patients)*	*Outcome*	*Refs*
Other regimen				
Intravenous 50 mg weekly	Phenoxymethylpenicillin 250 mg on alternate days	Dermatomyositis (also treated with prednisone; and prostatic cancer treated with diethylstilbestrol (stilboestrol); also receiving furosemide)	Methotrexate toxicity within a week of starting phenoxymethylpenicillin; treated with folinic acid and fluid replacement (and nafcillin and tobramycin)	11

Methotrexate + Antibacterials; Tetracyclines

Two case reports describe the development of methotrexate toxicity in patients also given tetracycline or doxycycline.

Clinical evidence, mechanism, importance and management

A man stable taking methotrexate 25 mg weekly for psoriasis was also given **tetracycline** 500 mg four times daily for a mycoplasmal infection. Within 5 days he developed recurrent fever, ulcerative stomatitis and diarrhoea, his white cell count fell to 1000, and his platelet count fell to 30 000 (units not stated, previous counts not given). These are all signs of methotrexate toxicity. The problem resolved when methotrexate was withdrawn, but the psoriasis returned.[1] A 17-year-old girl with osteosarcoma of the femur was given **doxycycline** 100 mg every 12 hours for an abscess in her left eye at the same time as her eleventh cycle of high-dose methotrexate with folinic acid rescue. She had elevated plasma methotrexate levels and she developed haematological toxicity and severe vomiting; requiring antiemetics, continued folinic acid, a prolonged stay in hospital and postponement of her next dose of methotrexate. **Doxycycline** had not been taken during the first 10 cycles of methotrexate and the pharmacokinetic changes and symptoms seen in the eleventh cycle were attributed to the concurrent use of **doxycycline**.[2] It was suggested that displacement of the methotrexate from its binding sites may be part of the explanation for the raised methotrexate levels. There appears to be the only two clinical reports of this interaction on record. Concurrent use need not be avoided, but it should be well monitored.

Methotrexate + Antibacterials; Vancomycin

Delayed methotrexate excretion and toxicity were seen when high-dose methotrexate was given to two patients recently treated with vancomycin. No significant interaction was found in eight other patients.

Clinical evidence, mechanism, importance and management

Two patients treated with a chemotherapy regimen containing high-dose methotrexate, cisplatin, doxorubicin and ifosfamide had delayed methotrexate excretion and methotrexate toxicity during a cycle soon after they had received vancomycin. Methotrexate levels took 170 to 231 hours to fall to 200 micromol/mL, and toxicity (mucositis) occurred. Subclinical renal impairment was found, which subsequently improved. In previous and subsequent cycles, where vancomycin was not given, serum methotrexate levels in both patients fell to 200 micromol/mL within 48 to 96 hours.[1] It was suggested that vancomycin caused subclinical nephrotoxicity, which resulted in delayed excretion of methotrexate, which is primarily renally excreted.[1] However, in another report of 8 patients who had received high-dose methotrexate following the use of vancomycin (all but one within 10 days) for previous neutropenia, there was no significant interaction in the absence of overt renal impairment. It was suggested that the difference in outcome may be due to slightly lower methotrexate doses and the fact that the drug regimen in the 8 patients did not include ifosfamide which, particularly in combination with cisplatin, may cause cumulative renal tubular damage.[2]

Vancomycin is commonly used in oncology patients with febrile neutropenia, and this appears to be the first report of this interaction. The authors of this report[1] suggest that it would be prudent to measure glomerular filtration rate with an EDTA renal scan before giving high-dose methotrexate to patients recently treated with vancomycin, to allow modification of the methotrexate dose if necessary.[1] However, the authors of the second report disagree and suggest such monitoring cannot be supported by their findings.[2] Further study is needed.

2. Shamash J, Joel S, Lundholm L, Millard L, Oliver T. High-dose methotrexate clearance following prior vancomycin administration: no significant interaction in the absence of overt renal impairment. *Ann Oncol* (2003) 14, 169–70.

Methotrexate + Antiepileptics; Enzyme-inducing

Enzyme-inducing antiepileptics appear to increase the clearance of methotrexate given as a 24-hour infusion, and their use is asso-

ciated with lower efficacy of combination therapy for B-lineage leukaemia.

Clinical evidence, mechanism, importance and management

In a retrospective survey, long-term antiepileptic use (**phenytoin**, **phenobarbital**, **carbamazepine**, or a combination) was associated with worse event-free survival, and greater haematological relapse and CNS relapse in children receiving chemotherapy for B-lineage acute lymphoblastic leukaemia. Faster clearance of high-dose methotrexate given as a 24-hour infusion was found in those receiving these enzyme-inducing antiepileptics; however, the clearance of short 4 to 6-hour methotrexate infusions and weekly low-dose methotrexate did not appear to be affected.[1] Further study is needed.

Note that reduced phenytoin ,carbamazepine and valproate levels, but unaltered phenobarbital levels, have been reported in various case reports of patients receiving chemotherapy including methotrexate, see 'Table 14.1', (p.594).

Methotrexate + Ascorbic acid (Vitamin C)

A study in a single patient found that the urinary excretion of methotrexate was not significantly changed by large amounts of vitamin C.

Clinical evidence, mechanism, importance and management

Vitamin C 1 g three times daily was found to have no effect on the urinary excretion of intravenous methotrexate 45 mg, given to a woman with breast cancer, despite the urine becoming more acidic at pH 5.9 (see also 'Methotrexate + Urinary alkalinisers', p.758). She was also receiving oral cyclophosphamide, propranolol, amitriptyline, perphenazine and prochlorperazine.[1] Although this is an isolated report, it appears that vitamin C is unlikely to affect methotrexate excretion.

1. Sketris IS, Farmer PS, Fraser A. Effect of vitamin C on the excretion of methotrexate. *Cancer Treat Rep* (1984) 68, 446–7.

Methotrexate + Caffeine

Caffeine may theoretically reduce the efficacy of low-dose methotrexate given for rheumatoid arthritis.

Clinical evidence

A study in 39 patients who had recently started taking methotrexate 7.5 mg weekly found that patients with a self-reported high caffeine intake (more than 180 mg of caffeine daily, 13 patients) had less relief in their symptoms of rheumatoid arthritis, such as swollen joints and joint pain, and smaller reductions from baseline in their erythrocyte sedimentation rate (ESR), a marker for inflammation, than patients with a low caffeine intake (less than 120 mg of caffeine daily, 13 patients).[1] A survey of 91 patients taking methotrexate 5 to 15 mg weekly for rheumatoid arthritis found that patients who were regular coffee drinkers (more than 7 cups a week) had a higher rate of methotrexate discontinuation (due to treatment failure in 80% of cases).[2]

In contrast, an analysis of data in a cohort study in 264 patients taking long-term methotrexate for rheumatoid arthritis found that the consumption of caffeinated beverages did not appear to affect the efficacy of methotrexate for rheumatoid arthritis in either low, moderate or high consumers of caffeinated drinks. The average dose of methotrexate was 16 mg weekly and the average intake of caffeine from caffeinated drinks was 212 mg daily. No difference in inflammatory markers or worsening of rheumatoid arthritis was found between the low-caffeine intake group and the high-caffeine intake group.[3] Similarly, a survey in 64 patients taking methotrexate (mean dose 13 mg weekly) for psoriasis and psoriatic arthritis found no effect on the efficacy or dose requirements of methotrexate between low caffeine intake (less than 120 mg daily) and high caffeine intake (more than 180 mg daily).[4]

Mechanism

It is not known exactly how methotrexate produces its effects in rheumatoid arthritis, but one theory is that it possibly increases the levels of adenosine by blocking a step in purine biosynthesis, leading to accumulation of adenosine, which results in anti-inflammatory effects.[1] Methotrexate also inhibits the enzyme 5-aminoimidazole-4-carboxamide ribonucleotide (AICAR) transformylase, raising levels of AICAR, which in turn increases adenosine levels. It may also contribute to the phosphorylation of adenosine nucleotides creating an accumulation of adenosine in tissues.[1,3] Caffeine is an adenosine receptor antagonist and therefore could reverse the effects of methotrexate.

Importance and management

There is limited information available regarding a potential interaction between caffeine consumption and methotrexate. The cohort study results and one patient survey seem to indicate that caffeine intake is not an issue, even with a high intake, whereas one study and another survey did find reduced efficacy in those with a higher caffeine intake. However, these results, particularly the surveys, were limited by a number of factors, including subjective reporting of caffeine consumption, lack of caffeine blood levels, and uncontrolled ingestion of both drugs. One UK manufacturer of intravenous methotrexate (licenced for rheumatoid arthritis) recommends avoiding the excessive consumption of caffeine-containing drinks.[5] There do not appear to be any case reports or studies indicating treatment failure as a result of high caffeine intake in patients receiving chemotherapy with high-dose methotrexate. More study is needed, but bear in mind that a high caffeine intake may be a factor in a reduced benefit from low-dose methotrexate given for rheumatoid arthritis.

Methotrexate + Chloroquine or Hydroxychloroquine

Single-dose chloroquine caused a moderate decrease in the AUC of methotrexate in one study, but another study in children found no interaction. Conversely, hydroxychloroquine caused a minor increase in the AUC of methotrexate in one study. Methotrexate does not appear to alter hydroxychloroquine pharmacokinetics.

Clinical evidence, mechanism, importance and management

Eleven patients with rheumatoid arthritis taking methotrexate 15 mg weekly were studied after they took a single dose of methotrexate alone and after they took methotrexate with a single 250-mg dose of **chloroquine**. The chloroquine *reduced* the maximum plasma levels of methotrexate by 20% and its AUC by 28%.[1] In contrast, in a study in patients with juvenile arthritis taking long-term methotrexate 150 micrograms/kg, the addition of **chloroquine** 4 mg/kg had no significant effect on the pharmacokinetics of methotrexate, when compared with similar patients taking methotrexate alone.[2]

In a randomised, crossover study in 10 healthy subjects, **hydroxychloroquine** 200 mg *increased* the AUC of methotrexate 15 mg by 52%, and slightly decreased the maximum methotrexate level by 17%.[3] In a population pharmacokinetic analysis the clearance of **hydroxychloroquine** did not appear to differ between 49 patients also taking methotrexate and 74 patients taking hydroxychloroquine alone.[4]

The reasons for the pharmacokinetic changes seen in some studies are unknown: just why the findings of these studies differ is unclear and their clinical relevance is uncertain. However, the changes seen were small, and the combination of methotrexate and chloroquine (or hydroxychloroquine) is used in the management of rheumatoid arthritis.

Methotrexate + Cisplatin

The risk of methotrexate toxicity appears to be markedly increased by the previous use of cisplatin. Methotrexate may inhibit the clearance of cisplatin.

Clinical evidence, mechanism, importance and management

Six out of 106 patients developed clinical signs of methotrexate toxicity and died 6 to 13 days after receiving standard doses of methotrexate (20 to 50 mg/m^2) in the absence of signs of renal impairment, and despite having previously been given methotrexate without serious toxicity. On this occasion all had previously been given cisplatin. Four of the patients were regarded as low-risk (i.e. methotrexate toxicity was not considered likely as they did not have renal or hepatic impairment, and their general condition was good).[1] A study in children and adolescents suggested that those who had received a cumulative dose of cisplatin greater than 360 mg/m^2 had delayed methotrexate clearance and a greater risk of methotrexate toxicity.[2] Similarly, a further report by the same authors, in 14 patients receiving high-dose methotrexate,[3] indicated that previous treatment with one course of cisplatin sharply increased the serum levels of methotrexate, particularly if the cumulative cisplatin dose exceeded 400 mg/m^2.

The picture is not totally clear but it seems possible that the previous use of cisplatin causes kidney damage that may not necessarily be detectable with the usual creatinine clearance tests. The effect is to cause a marked reduction in the clearance of the methotrexate. The serum methotrexate levels of such patients should be closely monitored so that any delay in its clearance is detected early and folinic acid rescue can be given.[2] This appears to prevent serious toxicity.[1-3]

There is also a report that suggests that methotrexate inhibits the renal clearance of cisplatin. The renal clearance of platinum in 4 of 5 patients with non-small-cell lung cancer given cisplatin 50 mg/m^2 and methotrexate 40 mg/m^2 was reduced in the first 6 hours after administration (50% lower in the first 3 hours). Apart from a transient increase in serum urea nitrogen and creatinine in one patient, there was no sign of nephrotoxicity with concurrent use.[4]

Methotrexate + Colestyramine

The serum levels of methotrexate, given by infusion, were markedly reduced by colestyramine in several patients.

Clinical evidence

An 11-year-old girl with osteosarcoma who developed colitis when given high-dose intravenous methotrexate, was subsequently given colestyramine 2 g every 6 hours from 6 to 48 hours after the methotrexate. Serum methotrexate levels at 24 hours were approximately halved. A marked fall in serum methotrexate levels was seen in another patient similarly treated.[1] Colestyramine also reduced methotrexate levels in cases of toxicity in two other patients.[2,3]

Mechanism

Methotrexate undergoes enterohepatic recirculation, that is to say it is excreted into the gut in the bile and re-absorbed further along the gut. If colestyramine is given orally, it can bind strongly to the methotrexate in the gut, thereby preventing its reabsorption and, as a result, its serum levels fall.[1,4]

Importance and management

The documentation seems to be limited. In the cases cited[1-3] the colestyramine was deliberately used to reduce serum methotrexate levels. However, in some circumstances it might represent an unwanted interaction. As methotrexate is excreted into the gut in the bile, separating the oral doses of colestyramine and methotrexate may not necessarily prevent their coming into contact and interacting together. Monitor concurrent use.

Methotrexate + Corticosteroids

Methotrexate clearance may be modestly reduced by the long-term use of prednisolone, but methotrexate does not alter prednisolone pharmacokinetics. Limited evidence suggests methotrexate may alter prednisone levels. Dexamethasone may increase the acute hepatotoxicity of high-dose methotrexate.

Clinical evidence, mechanism, importance and management

There is some evidence to suggest that **prednisolone** may reduce the clearance of methotrexate: patients taking long-term **prednisolone** 15 mg daily had a 20% lower clearance of intramuscular methotrexate 10 mg and a 30% higher AUC than patients given **prednisolone** 15 mg daily for just 4 days before the methotrexate, or those not given corticosteroids.[1] In another study, methotrexate had no effect on **prednisolone** pharmacokinetics in 7 patients, or **methylprednisolone** pharmacokinetics in one patient.[2] The preliminary findings of another study suggested that methotrexate may increase plasma methylprednisolone levels in response to a dose of **prednisone**: in 2 of 4 patients given methotrexate, plasma methylprednisolone levels remained stable despite a decrease in the **prednisone** dose.[3] These findings require confirmation. Their clinical relevance is uncertain.

Dexamethasone may increase the acute hepatotoxicity of high-dose methotrexate. A retrospective comparison in children with brain tumours given methotrexate alone (24 patients), or with **dexamethasone** (33 patients), found that no serious brain oedema occurred in either of the groups and there were no differences in bone marrow toxicity or mucositis, but liver enzymes were significantly higher in the **dexamethasone** group, indicating liver toxicity (AST levels 76 units/L compared with 19 units/L, ALT levels 140 units/L compared with 39 units/L). This effect was not due to differences in serum methotrexate levels.[4] The authors recommend that **dexamethasone** should not be included in high-dose methotrexate protocols for children with brain tumours when they are not glucocorticoid dependent.[4]

Methotrexate + Diuretics

Some very limited evidence suggests that triamterene may possibly increase the bone marrow suppressive effects of methotrexate. It seems doubtful if thiazides interact adversely with methotrexate.

Clinical evidence, mechanism, importance and management

A 57-year-old woman who had been treated for several years with daily doses of diclofenac 150 mg, atenolol 50 mg and **triamterene** with **hydrochlorothiazide** 50/25 mg, for rheumatoid arthritis and hypertension, additionally started taking methotrexate 5 mg weekly. After 2 months she was admitted to hospital with pancytopenia, extensive mucosal ulceration and renal impairment. The authors point out that **triamterene** is structurally similar to folate and has anti-folate activity, which may therefore have been additive with the effects of methotrexate,[1] but the diclofenac may also have contributed (see 'Methotrexate + NSAIDs, Aspirin or other Salicylates', p.752). In 1998, the manufacturer of methotrexate noted there were two other reports of pancytopenia in patients taking methotrexate and **triamterene**, but again the patients were also taking an NSAID.[2] These cases are isolated, and none of them can be directly attributed to an interaction. Nevertheless, it may be prudent to consider the use of triamterene as a possible cause of otherwise unexplained methotrexate toxicity.

A study in 9 patients found that **furosemide** and **hydroflumethiazide** did not effect the urinary clearance of methotrexate.[3] However, a study in women with breast cancer, taking methotrexate, **cyclophosphamide** and **fluorouracil** found that the concurrent use of a **thiazide diuretic** appeared to increase the myelosuppressant effects of the chemotherapy, but it is not clear which of the antineoplastics might have been affected.[4] This appears to be the only evidence of an interaction between the thiazides and methotrexate. An interaction is not established.

Methotrexate + Fluorouracil

Two patients taking low-dose methotrexate had a toxic skin reaction when they started to use a cream containing fluorouracil. The activity of systemic treatment with methotrexate and fluorouracil are said to be dependent on the order in which the two drugs are given.

Clinical evidence, mechanism, importance and management

(a) Topical fluorouracil

Two patients with rheumatoid arthritis taking low-dose methotrexate 7.5 to 12.5 mg weekly for 6 to 14 months were given 2% fluorouracil cream for actinic keratosis. Within 2 to 3 days both patients developed erythema, blister formation and necrosis. The cream was stopped and the lesions healed over the next 2 to 3 weeks.[1] It would seem that topical fluorouracil should be avoided in patients taking methotrexate.

(b) Systemic fluorouracil

In vitro and *animal* data indicate that methotrexate and fluorouracil can be mutually antagonistic under certain conditions.[2-4] Other studies indicate that the sequence (methotrexate first)[5,6] is important for additive or synergistic activity. However, the combination of cyclophosphamide, methotrexate and fluorouracil (CMF) has been the most commonly used adjuvant therapy in breast cancer, and the sequence of administration is said not to be important.[7]

Methotrexate + Folinates

Folic acid or folinic acid are sometimes added to low-dose methotrexate for rheumatoid arthritis or psoriasis to reduce adverse effects. Folinic acid is frequently used as an antidote to high-dose methotrexate.

Clinical evidence, mechanism, importance and management

Methotrexate acts as a folic acid antagonist by reversibly binding to the enzyme dihydrofolate reductase, so blocking the conversion of folic acid to tetrahydrofolate. Therefore folic acid and folinic acid (a derivative of tetrahydrofolate) would be expected to interfere with both the toxic and therapeutic effects of methotrexate.

Folic acid or folinic acid are commonly used to reduce the adverse effects of low-dose methotrexate used for rheumatoid arthritis and psoriasis, although the optimum doses and schedules to maximise tolerability and efficacy remain to be determined.

Similarly, folinic acid is used in conjunction with high-dose methotrexate for various cancers to minimise toxicity, when it is typically started 24 hours after methotrexate administration (folinic acid or 'leucovorin' rescue). In this setting, the antidote effect is clearly influenced by the dose of folinate in relation to the dose of methotrexate, and the timing of folinate administration in relation to methotrexate administration.

Patients taking methotrexate for any indication should avoid the inadvertent or unsupervised use of folates, which are commonly found in multivitamin preparations.

Methotrexate + Food

The absorption of low-dose oral methotrexate does not appear to be significantly affected by food.

Clinical evidence, mechanism, importance and management

In 10 children with lymphoblastic leukaemia the peak serum levels of a 15-mg/m^2 oral dose of methotrexate (measured at 1.5 hours) were reduced by about 40% when the methotrexate was taken with a milky meal (milk, cornflakes, sugar, white bread and butter). The $AUC_{0\text{-}4}$ was reduced by about 25%. A smaller reduction in methotrexate absorption was seen when it was taken after a citrus meal (orange juice, fresh orange, white bread, butter and jam).[1] However, a 4-hour study is too short to assess the extent of the total absorption. Another study, in 16 children given methotrexate 8 to 22.7 mg/m^2, found that the peak levels and AUC were not significantly affected if methotrexate was given before a meal.[2] A further study in 12 healthy subjects found that a high fat-content breakfast delayed the absorption of methotrexate 7.5 mg orally by about 30 minutes but the extent of the absorption was unchanged.[3] It would therefore appear that methotrexate may be taken without regard to meals.

Methotrexate + Isoniazid

It is possible that the risk of liver function abnormalities seen with either methotrexate or isoniazid is increased when the two drugs are given together. One small review suggested this may be the case, but other larger reviews have not confirmed these findings.

Clinical evidence

In a review of clinical studies of tumour necrosis factor (TNF) antagonists given to patients already taking methotrexate or **sulfasalazine** for rheumatoid arthritis, 8 patients were identified who were also given prophylactic isoniazid 300 mg daily for inactive (latent) tuberculosis (positive PPD skin test). Of these, 4 patients (50%) developed mild to severe hepatic impairment within 7 to 16 weeks, and in three cases this resolved on discon-

tinuation of isoniazid. In one case, excessive alcohol consumption might have been a contributory factor. Two cases (one mild, one severe) occurred in 5 patients taking methotrexate, and 2 cases (one moderate and one severe) occurred in 3 patients taking **sulfasalazine**.[1]

In contrast, when 77 patients with rheumatoid arthritis were given methotrexate with isoniazid prophylaxis for 3 years, two patients stopped treatment due to increases in AST and ALT, but the incidence of hepatotoxic effects was no different to that found in the control group.[2] In a retrospective review of the records of 44 patients taking methotrexate for rheumatoid arthritis and given prophylactic isoniazid for inactive tuberculosis (38 patients) or isoniazid, **pyrazinamide**, rifampicin and ethambutol for a history of active tuberculosis (6 patients), just 5 patients (11.3%) had elevated liver function tests. None of these were more than twice the upper limit of normal, and all abnormalities resolved without intervention. None of the patients included in this study had experienced liver function abnormalities while taking methotrexate alone.[3] For comparison, the authors of this study[3] mention that in one large study, raised liver function tests (three times the upper limit of normal), occurred in 7.5% of patients treated with methotrexate for rheumatoid arthritis.

Mechanism

Both isoniazid and methotrexate are known to be hepatotoxic, and it has been suggested that the risk might be increased by combined use. Sulfasalazine is also hepatotoxic, as is rifampicin and, particularly, pyrazinamide.

Importance and management

An increased risk of hepatotoxicity during the concurrent use of methotrexate and isoniazid is not established, and this possible risk is not a reason to avoid the combination. Monitoring of liver function is recommended during long-term methotrexate use, and is also recommended for isoniazid. This would appear to be sufficient to identify any adverse hepatic effects.

Methotrexate + Miscellaneous

***Animal* studies suggested that the toxicity of methotrexate might be increased by the use of chloramphenicol, aminosalicylic acid, sodium salicylate, sulfamethoxypyridazine, tetracycline or tolbutamide, but confirmation of this in man has only been seen with the salicylates, sulphonamides, and possibly tetracycline.**

Clinical evidence, mechanism, importance and management

Some lists, reviews and books on interactions say that **chloramphenicol**, aminosalicylic acid, sodium salicylate, sulfamethoxypyridazine, tetracycline or **tolbutamide** interact with methotrexate, apparently based largely on the preliminary findings of a study in which male *mice* were treated for 5 days with each of 4 doses of methotrexate (1.53 to 12.25 mg/kg intravenously) and immediately afterwards with non-toxic intraperitoneal doses of the drugs listed. These drugs were said to decrease the lethal dose and/or decrease the survival time of the *mice*.[1] That is to say, the toxicity of the methotrexate was increased. The reasons are not understood, but it is suggested that displacement of the methotrexate from its plasma protein binding sites could result in a rise in the levels of unbound and active methotrexate, and in the case of sodium salicylate to a decrease in renal clearance.

These *animal* studies were done in 1968. Since then the clinical importance of the interaction with salicylates has been confirmed (see 'Methotrexate + NSAIDs, Aspirin or other Salicylates', below); there are a few cases involving sulfonamides (see 'Methotrexate + Antibacterials; Co-trimoxazole or Trimethoprim', p.745); and there are two isolated case reports of an interaction with tetracyclines (see 'Methotrexate + Antibacterials; Tetracyclines', p.748), but there appears to be no direct clinical evidence of interactions between methotrexate and **chloramphenicol** or **tolbutamide**. The results of *animal* experiments cannot be applied directly and uncritically to man and it now seems probable that some of these suggested or alleged interactions are more theoretical than real.

1. Dixon RL. The interaction between various drugs and methotrexate. *Toxicol Appl Pharmacol* (1968) 12, 308.

Methotrexate + Nitrous oxide

Methotrexate-induced stomatitis and other toxic effects may be increased by the use of nitrous oxide.

Clinical evidence, mechanism, importance and management

A study in which intravenous methotrexate, cyclophosphamide and fluorouracil (CMF) were used within 36 hours of mastectomy suggested that stomatitis may be caused by a toxic interaction between methotrexate and nitrous oxide used during anaesthesia. Stomatitis was much more common in those receiving CMF within 6 hours of surgery.[1-3] A possible reason is that the effects of methotrexate on tetrahydrofolate metabolism are increased by nitrous oxide, and this has been confirmed in *animals*.[4] It was found that the incidence of stomatitis, severe leucopenia, thrombocytopenia, and of severe systemic and local infections could be reduced by giving calcium folinate (leucovorin) and intravenous hydration.[2,3] Alternatively, the use of nitrous oxide shortly before methotrexate administration should be avoided.[4]

Methotrexate + NSAIDs, Aspirin or other Salicylates

Increased methotrexate toxicity, sometimes life-threatening, has been seen in a few patients also taking NSAIDs, whereas other patients have taken an NSAID and methotrexate uneventfully. The pharmacokinetics of methotrexate can also be changed by some NSAIDs, aspirin or other salicylates. The development of toxicity may be dose related: the risk appears to be lowest in those taking low-dose methotrexate for psoriasis or rheumatoid arthritis who have normal renal function.

Clinical evidence

(a) Aminophenazone

Megaloblastic pancytopenia occurred in a woman with rheumatoid arthritis who took methotrexate 15 mg weekly with aminophenazone 1 to 1.5 g daily.[1]

(b) Aspirin and other salicylates

A study in 15 patients with rheumatoid arthritis given a single 10-mg bolus dose of methotrexate, either with or without aspirin 975 mg four times daily, found that the methotrexate clearance was reduced by aspirin (systemic clearance about 16%, renal clearance of unbound methotrexate about 30%). Also, the unbound fraction of methotrexate was higher during aspirin use. Despite these changes no acute toxicity was seen.[2] Another study found that aspirin did not affect the pharmacokinetics of methotrexate.[3] A further study found that, although aspirin did not alter the pharmacokinetics of methotrexate, it did increase the AUC of the metabolite 7-hydroxymethotrexate.[4]

A study in 4 patients found that the renal clearance of methotrexate was reduced by 35% by an infusion of **sodium salicylate** (2 g initially, then 33 mg/minute).[5] A further study found that **choline magnesium trisalicylate** reduced methotrexate clearance by 24 to 41%, and increased the

unbound fraction by 28%, when compared with paracetamol (acetaminophen).[6]

Lethal pancytopenia in 2 patients given methotrexate and aspirin prompted a retrospective survey of the records of other patients given intra-arterial infusions of methotrexate 50 mg daily for 10 days, for epidermoid carcinoma of the oral cavity. Six out of 7 who developed rapid and serious pancytopenia were found to have taken aspirin or other salicylates.[7] There are other case reports[8,9] of methotrexate toxicity in patients taking salicylates but whether a causal relationship exists is uncertain. It has been suggested that pneumonitis in patients receiving low-dose methotrexate may have resulted from the concurrent use of aspirin 4 to 5 g daily.[10]

See also the report about the comparative use of aspirin and other NSAIDs in the section *NSAIDs in general*, below.

(c) Azapropazone

A woman who had been taking methotrexate 25 mg weekly for 4 years for psoriasis had acute toxicity (oral and genital ulceration, bone marrow failure) shortly after starting to take azapropazone (reducing from a dose of 2.4 g on the first day, 1.8 g on the second day to 1.2 g daily for a week). She was also taking aspirin 300 mg daily.[11,12]

(d) Bromfenac

In a short-term study, 10 patients taking methotrexate weekly were given bromfenac 50 mg three times daily for 6 days. No significant changes were seen in either the pharmacokinetics of bromfenac or methotrexate. However, the AUC of the major metabolite of methotrexate, 7-hydroxymethotrexate, was increased by 30% and its renal clearance was reduced by 16%. Eight of the patients had mild to moderate adverse effects and one patient had to withdraw because of moderate hypertension. No patient had any clinically important abnormal laboratory test results.[13] Note that systemic bromfenac has been withdrawn from the market because of reports of hepatic toxicity.

(e) Celecoxib

Fourteen female patients with rheumatoid arthritis taking methotrexate 5 to 20 mg weekly for at least 3 months were also given celecoxib 200 mg or a placebo twice daily for a week. It was found that the maximum serum levels of the methotrexate, its AUC, renal clearance, and other pharmacokinetic parameters were unchanged by celecoxib.[14] The authors note that, in clinical studies, celecoxib was taken in combination with low-dose methotrexate for up to 12 weeks by over 450 patients, and the incidence of adverse effects was similar to that in patients taking methotrexate with placebo.[14]

(f) Diclofenac

A study found that diclofenac 100 mg daily did not affect the pharmacokinetics of methotrexate.[3] Five patients taking low-dose methotrexate 7.5 to 12.5 mg weekly for psoriasis or rheumatoid arthritis developed serious/fatal neutropenias. These cases probably involved other drug interactions, but diclofenac may have been an additional factor in two of them.[15] Methotrexate pneumonitis occurred in a patient who had taken methotrexate 10 mg weekly for 4 weeks. He was also taking diclofenac 75 mg twice daily, although the relevance of this to the adverse reaction is uncertain.[16] Other cases involving diclofenac are mentioned in the sections on *indometacin* and *ketoprofen*, below.

(g) Dipyrone (Metamizole sodium)

A study in a patient with osteosarcoma found that dipyrone 4 g daily more than doubled the methotrexate AUC during the first cycle of high-dose methotrexate treatment.[17]

(h) Etodolac

A pharmacokinetic study in patients with rheumatoid arthritis found that etodolac 600 mg daily did not affect the AUC of methotrexate, but the duration of exposure was lengthened (mean residence time increased from 8.5 hours to 11.4 hours). No clinical toxicity was seen.[18]

(i) Etoricoxib

A study in patients taking methotrexate 7.5 to 20 mg weekly for rheumatoid arthritis found that the addition of etoricoxib 60, 90 or 120 mg daily had no effect on the methotrexate AUC or on its renal clearance. However, another similar study found that etoricoxib 120 mg daily increased the methotrexate AUC by 28% and reduced its clearance by 13%.[19]

(j) Flurbiprofen

A study in 6 patients taking methotrexate 10 to 25 mg weekly found no important changes in methotrexate levels when they were also given flurbiprofen 100 mg three times daily.[20] In another study in 10 patients with rheumatoid arthritis taking methotrexate 7.5 to 17.5 mg weekly and flurbiprofen 3 mg/kg daily, methotrexate oral and renal clearance were similarly unaffected by flurbiprofen.[21]

A case report describes an elderly woman who had been taking methotrexate 2.5 mg three times a week for 3 years for rheumatoid arthritis, who developed haematemesis, neutropenia and thrombocytopenia (diagnosed as methotrexate toxicity) within 1 to 2 weeks of starting to take flurbiprofen 100 mg daily.[22]

(k) Ibuprofen

A study in 7 patients found that the clearance of oral methotrexate 7.5 to 15 mg was halved by ibuprofen 40 mg/kg daily, when compared with paracetamol (acetaminophen).[23] In a related study the clearance of methotrexate was reduced by 40% by ibuprofen.[6] Another study in 6 patients with rheumatoid arthritis taking methotrexate 10 to 25 mg weekly found that ibuprofen 800 mg three times daily had no effect on the pharmacokinetics of methotrexate.[20] Similar findings have been reported by other workers.[3]

A patient taking methotrexate who was given ibuprofen required prolonged folinic acid rescue because the clearance of methotrexate had fallen by two-thirds.[24] Another patient receiving high-dose methotrexate (7.5 g/m^2) had severe methotrexate-induced nephrotoxicity and delayed excretion of methotrexate while taking ibuprofen 400 mg every 4 hours.[25] A report attributes pancytopenia and resulting pneumocystis pneumonia in a 16-year-old patient taking methotrexate 5 to 10 mg weekly to the concurrent use of ibuprofen 600 mg twice daily (and also prednisolone 1 mg daily).[26]

(l) Indometacin

In a child taking methotrexate 7.5 mg/m^2 weekly for 9 months, the AUC of methotrexate was increased by 140% when indometacin and aspirin were also given.[27] Another study found that indometacin did not affect the pharmacokinetics of methotrexate.[3]

Two patients given sequential intermediate-dose methotrexate and fluorouracil, who were also taking indometacin 75 to 100 mg daily, died from acute drug toxicity, which the authors of the report attributed to indometacin-associated renal failure.[28] Another case of acute renal failure has been described,[29] but there were no cases of toxicity in 4 other patients taking methotrexate with either paracetamol (acetaminophen) or indometacin.[9] An elderly woman taking indometacin 50 mg daily rectally and **diclofenac** 100 mg daily intravenously died after being given a single 10-mg intramuscular dose of methotrexate.[30]

(m) Ketoprofen

In a study in 10 patients with rheumatoid arthritis taking methotrexate 7.5 to 17.5 mg weekly and ketoprofen 3 mg/kg daily, the methotrexate oral and renal clearance and the fraction of methotrexate unbound were unaffected by ketoprofen.[21] Similarly, in another study in 18 patients with rheumatoid arthritis who were given intravenous methotrexate 15 mg weekly, ketoprofen had no significant effect on the AUC, half-life, or clearance of methotrexate and its major metabolite, 7-hydroxymethotrexate.[31] However, a retrospective study of 118 cycles of *high-dose* methotrexate (800 to 8300 mg/m^2; mean 3200 mg/m^2) in 36 patients found that 4 out of the 9 patients who developed severe methotrexate toxicity had also taken ketoprofen 150 to 200 mg daily for 2 to 15 days. Three of them died. A marked and prolonged rise in serum methotrexate levels was observed. Another patient who had methotrexate toxicity had also been given **diclofenac** 150 mg (in one day).[32] The authors of this report state that ketoprofen should not be given at the same time as high-dose methotrexate, but it may be safe to give it 12 to 24 hours after the methotrexate because 50% of the methotrexate is excreted by the kidneys within 6 to 12 hours. This was tried in two patients without adverse effects.[32]

(n) Lumiracoxib

In a double-blind, placebo-controlled study in patients with rheumatoid arthritis given methotrexate 7.5 to 15 mg weekly, lumiracoxib 400 mg daily for 7 days had no significant effects on the pharmacokinetics of methotrexate.[33]

(o) Meloxicam

Thirteen patients with rheumatoid arthritis were given intravenous methotrexate 15 mg before and after taking meloxicam 15 mg daily for a week.

The pharmacokinetics of methotrexate were unaffected by meloxicam and no increase in toxicity was seen.[34]

(p) Naproxen

Naproxen had no significant effect on the AUC, half-life, or clearance of methotrexate and its major metabolite 7-hydroxymethotrexate in 18 patients with rheumatoid arthritis given intravenous methotrexate 15 mg weekly.[31] Other studies have found that naproxen did not affect the pharmacokinetics of methotrexate and/or 7-hydroxymethotrexate.[3,35,36]

In contrast, a study found that the clearance of methotrexate was decreased by 22% by naproxen.[6,23] A further study in 9 children taking methotrexate 0.22 to 1.02 mg/kg weekly found that the clearance of methotrexate was increased in 4 children by more than 30% when they were given naproxen 14.6 to 18.8 mg/kg daily. There was also a 30% or more change in the pharmacokinetics of naproxen in 6 of the patients, but as both increases and decreases in clearance occurred, the significance of these findings are uncertain.[37] In addition, two children taking methotrexate for 1 and 2 years had increases in the AUC of methotrexate of 22% and 71% when given naproxen with aspirin or indometacin, respectively.[27] A woman died of gross methotrexate toxicity apparently exacerbated by the concurrent use of naproxen,[38] and a report attributes pneumonitis in a patient taking methotrexate 7.5 to 10 mg weekly to the concurrent use of naproxen (initially 1 g then 500 mg) daily.[39] A further report describes an infant who developed severe hepatitis while taking methotrexate and naproxen for juvenile idiopathic arthritis. Following intravenous folinic acid and cessation of methotrexate and naproxen her liver function normalised. The role of naproxen is unclear, but the authors consider that the toxicity of methotrexate may have been synergistic with naproxen.[40]

(q) Parecoxib

Studies in patients with rheumatoid arthritis found that oral valdecoxib 40 mg twice daily had no clinically significant effect on the plasma levels of methotrexate given weekly by the intramuscular route [dose not stated].[41] Note that valdecoxib is the main metabolite of parecoxib.

(r) Phenylbutazone

Two patients taking methotrexate for psoriasis developed methotrexate toxicity and skin ulceration shortly after starting to take phenylbutazone 200 to 600 mg daily. One of them died from septicaemia following bone marrow depression.[42]

(s) Piroxicam

No effect on the pharmacokinetics of either free or bound methotrexate was seen in 20 patients with rheumatoid arthritis taking methotrexate 10 mg weekly when they were given piroxicam 20 mg daily for at least 15 days.[43] In another study in 10 patients with rheumatoid arthritis taking methotrexate 7.5 to 17.5 mg weekly, methotrexate oral and renal clearance were unaffected by piroxicam 20 mg daily.[21]

(t) Rofecoxib

Rofecoxib 12.5 to 50 mg daily had no effect on the AUC and renal clearance of methotrexate or 7-hydroxymethotrexate in 19 patients taking methotrexate 7.5 to 20 mg weekly.[44] However, the authors note that in previous evaluations (data on file), higher than therapeutic doses of rofecoxib (75 mg and 250 mg) were associated with a 23% and 40% increase in the AUC of methotrexate, and an 11% and 40% decrease in its renal clearance, respectively.[44]

(u) Sulindac

Sulindac (mean dose 400 mg daily) had no effect on the pharmacokinetics of a single 10-mg/m^2 intravenous dose of methotrexate, but it slightly increased the AUC of the 7-hydroxymethotrexate metabolite.[4]

(v) Tolmetin

Three children taking methotrexate for between 6 months and 1 year had increases in the AUC of methotrexate of 42% when given tolmetin, and of 18% and 25% when given tolmetin with aspirin.[27]

(w) NSAIDs in general

In a study of 34 patients with rheumatoid arthritis taking methotrexate 5 or 10 mg/m^2 (to nearest 2.5 mg) weekly, 12 patients also took **aspirin** (average 4.5 g daily) and 22 took other NSAIDs. Twenty-one of the 34 also took prednisone. Toxicity, sometimes serious (5 patients withdrawn), was common, but no clinical differences between **aspirin** or other NSAIDs with respect to this toxicity was seen during 12 months of concurrent use.[45]

A preliminary report of a study in 87 patients receiving long-term treatment with methotrexate (mean weekly dose 8.19 mg), most of whom were also taking unspecified NSAIDs, found that the majority (72%) experienced no untoward effects and in the rest adverse effects were only relatively mild.[46] The concurrent use of methotrexate and NSAIDs in more than 450 patients with psoriatic arthritis or rheumatoid arthritis was said to be without clinical interaction problems.[47]

In a review of the records of 315 patients with rheumatoid arthritis taking low-dose methotrexate, 13 patients had low platelet counts. The thrombocytopenia was believed to have resulted from an interaction with an NSAID, or in some patients, a multiple drug interaction. If multiple drug interactions were not involved, the authors found that if the NSAID was given on a separate day, or doses spaced according to the NSAID half-life, treatment could be re-introduced avoiding the problems of thrombocytopenia.[48]

Mechanism

Methotrexate is largely cleared unchanged from the body by renal excretion. The NSAIDs as a group inhibit the synthesis of the prostaglandins (PGE_2) resulting in a fall in renal perfusion, which could lead to a rise in serum methotrexate levels, accompanied by increased toxicity. In addition, salicylates competitively inhibit the tubular secretion of methotrexate, which would further reduce its clearance.[5] NSAIDs can also cause renal impairment, which would allow the methotrexate to accumulate. The pyrazolone derivatives and related drugs (e.g. azapropazone, metamizole sodium, phenylbutazone, aminophenazone), in particular, can cause bone marrow depression, which could be additive with that of methotrexate. Protein binding displacement of methotrexate or its metabolite (7-hydroxymethotrexate) have also been suggested as possible additional mechanisms.[49,50] There is also some evidence that 7-hydroxymethotrexate is cleared more slowly in the presence of NSAIDs.[4]

Importance and management

The evidence presented here clearly shows that a few patients taking methotrexate have developed very serious toxicity, apparently due to the concurrent use of NSAIDs, whereas many other patients have experienced no problems at all. There is also other evidence that the pharmacokinetics of the methotrexate are changed (in particular reduced clearance) by some NSAIDs (aspirin, choline magnesium trisalicylate, etodolac, ibuprofen, metamizole sodium, rofecoxib (at higher than therapeutic doses), sodium salicylate, tolmetin), which might be expected to increase its toxicity.

The consensus of opinion seems to be that the risks are greatest with high-dose methotrexate (150 mg or more daily to treat neoplastic diseases) and in patients with impaired renal function, but less in those given low doses (5 to 25 mg weekly) for psoriasis or rheumatoid arthritis and with normal renal function. The manufacturers of methotrexate and the CSM in the UK do not advise the avoidance of NSAIDs (except azapropazone and non-prescription aspirin and ibuprofen), even though their use is a recognised additional risk factor for toxicity. Instead their advice is that the methotrexate dose should be well monitored, which implies that the precautions for methotrexate use should be stepped up. The advice of the CSM is that any patient given methotrexate alone should have a full blood count, renal and liver function tests before starting treatment. These should be repeated weekly until therapy is stabilised, and thereafter every 2 to 3 months. Patients should be told to report any sign or symptom suggestive of infection, particularly sore throat (which might possibly indicate that white cell counts have fallen) or dyspnoea or cough (suggestive of pulmonary toxicity).[51] Aminophenazone or metamizole sodium can cause agranulocytosis on their own (and they consequently have limited use) so their use with methotrexate should be avoided.

Some of the NSAIDs cited here have not been reported to interact (celecoxib, lumiracoxib, meloxicam, piroxicam), and information about some other NSAIDs seems to be lacking, but the same general precautions indicated above should be followed with all NSAIDs just to be on the safe side.

Methotrexate + Paracetamol (Acetaminophen)

Paracetamol appears not to interact with methotrexate.

Clinical evidence, mechanism, importance and management

A study in patients with rheumatoid arthritis found that the clearance of oral methotrexate 7.5 to 15 mg was unaffected by the concurrent use of paracetamol.[1] In a study of patients with psoriasis taking methotrexate in doses of up to 25 mg weekly, no cases of toxicity occurred in 4 patients also taking paracetamol or indometacin.[2] In one study, methotrexate clearance was reduced by NSAIDs but not by paracetamol, which was included in the study as a control.[3]

Methotrexate + Probenecid

Probenecid markedly increases serum methotrexate levels.

Clinical evidence

The concurrent use of oral or intravenous probenecid 500 mg to 1 g and methotrexate 200 mg/m^2 as an intravenous bolus resulted in serum methotrexate levels in 4 patients that were more than four times higher than in 4 other patients who had not been given probenecid (methotrexate levels 400 micrograms/L compared with 90 micrograms/L, measured 24-hours post-dose).[1] A three to fourfold increase in serum methotrexate levels at 24 hours was also seen in 4 patients given probenecid.[2] In another 4 patients, pretreatment with probenecid (500 mg every 6 hours for 5 doses) doubled serum methotrexate levels.[3] Severe and life-threatening pancytopenia occurred when a woman taking low-dose methotrexate 7.5 mg weekly for rheumatoid arthritis was given probenecid. She also had renal impairment, hypoalbuminaemia and was taking salsalate (a salicylic acid derivative).[4]

Mechanism

Probenecid inhibits the renal excretion of methotrexate in both *monkeys* and *rats*[5,6] and this probably also happens in man. Changes in the protein binding of methotrexate may also have some part to play.[7] The increased methotrexate levels increase the risk of serious bone marrow depression.

Importance and management

An established and clinically important interaction. A marked increase in both the therapeutic and toxic effects of methotrexate can occur, apparently even with low doses if other risk factors are present.[4] Anticipate the need to reduce the dose of methotrexate and monitor the effects well if probenecid is used concurrently. If this is not possible, avoid the combination.

Methotrexate + Proton pump inhibitors

The excretion of methotrexate is reported to have been reduced in several patients given omeprazole and a few patients given lansoprazole. However, similar elevations in methotrexate levels in another patient were independent of omeprazole use. One patient had myalgia and elevated 7-hydroxymethotrexate levels when given methotrexate with pantoprazole.

Clinical evidence

(a) Lansoprazole

In a study in 76 patients with solid tumours treated with high-dose methotrexate infusions (300 mg/m^2 to 12 g/m^2 over 1 to 24 hours), the clearance of methotrexate and its metabolite 7-hydroxymethotrexate was significantly decreased and its plasma levels significantly increased in the 3 patients who were also given lansoprazole 30 mg daily.[1]

(b) Omeprazole

In a study in 76 patients with solid tumours, receiving high-dose methotrexate infusions (300 mg/m^2 to 12 g/m^2 over 1 to 24 hours), the clearance of methotrexate and its metabolite 7-hydroxymethotrexate was significantly decreased and the plasma levels significantly increased in the 10 patients who had also been given omeprazole 20 to 40 mg daily.[1] A number of case reports support this finding. In one, a man with Hodgkin's disease developed osteosarcoma and was given cyclophosphamide, bleomycin, dactinomycin and methotrexate, followed by folinic acid rescue. He was also taking a number of other drugs, including omeprazole. During the first cycle of treatment his serum methotrexate levels remained elevated for several days, and suspicion fell on the omeprazole, which was stopped. The patient's serum methotrexate levels then fell rapidly, and during the following three cycles the methotrexate pharmacokinetics were normal.[2] In another case, an 11-year-old boy with osteoblastic osteosarcoma was given high-dose methotrexate 15 g as a 4-hour infusion. He was also given omeprazole 20 mg twice daily (for about one week before the methotrexate), megestrol acetate, sucralfate and folinic acid rescue. Methotrexate elimination was delayed and so further folinic acid was given. When later cycles of methotrexate were given, with ranitidine instead of omeprazole, the elimination of methotrexate was normal. The elimination half-life of the initial phase after the first dose given with omeprazole was 65% longer, when compared with that of the second dose without omeprazole.[3] In a third report, a 15-year-old boy experienced methotrexate toxicity, and elevated levels of methotrexate despite being given folinic acid, when he was also taking omeprazole. His symptoms of methotrexate resolved rapidly once omeprazole was stopped. He had experienced no toxicity in a previous cycle when he had taken ranitidine.[4]

In contrast to these findings, a case report describes a man with chondroblastic osteosarcoma, who had been taking omeprazole, and who was given high-dose methotrexate 20 g over 6 hours with hydration, urinary alkalinisation and, after 24 hours, folinic acid rescue. The folinic acid dose was adjusted in response to elevated methotrexate levels and omeprazole was stopped. A second dose of methotrexate 2 weeks later, this time without omeprazole, resulted in similar elevated methotrexate levels. Thus the elevated methotrexate levels in this patient could not be attributed to the concurrent use of omeprazole.[5]

(c) Pantoprazole

Severe generalised myalgia occurred in a man taking pantoprazole 20 mg daily after he received intramuscular methotrexate 15 mg weekly. The symptoms subsided and eventually disappeared when the pantoprazole was replaced with ranitidine. The symptoms reappeared in response to rechallenge with pantoprazole, and the AUC of 7-hydroxymethotrexate was found to be increased by about 70%, although the AUC of methotrexate was unchanged.[6]

Mechanism

Proton pump inhibitors may affect renal, and possibly hepatic, clearance of methotrexate by inhibition of methotrexate transporter proteins.[1,7] It has been suggested that omeprazole may inhibit the activity of a hydrogen-ion dependent mechanism in the kidney, on which methotrexate depends for its excretion, so that its renal clearance is reduced.[2] It has also been suggested that the situation with lansoprazole may be similar, but that pantoprazole may differ because at about the pH found in the renal tubules (pH 5), pantoprazole is more slowly activated than omeprazole.[3] However, a case of an interaction with pantoprazole has also been reported.[6]

Importance and management

Information seems to be limited to these few reports and, with the exception of one case report, they all found that proton pump inhibitors reduced the clearance of methotrexate. Any changes in methotrexate kinetics are important in terms of the potential for increased toxicity. The authors of one study in which the levels of methotrexate and its active metabolite were increased during the concurrent use of omeprazole or lansoprazole advise against concurrent use.[1] Further, the authors of one report recommend that if omeprazole is necessary for a patient about to receive methotrexate, then omeprazole should be discontinued 4 to 5 days before methotrexate administration.[3] The situation with other proton pump inhibitors may be similar. Ranitidine was found to be a suitable alternative in two of the cases.[3,6] Note that the risks would appear to be most significant with high-dose methotrexate, but the case report involving a 15 mg weekly dose of methotrexate introduces a note of caution in all patients.

Methotrexate + Retinoids

The levels of methotrexate may be increased by etretinate, and cases of severe liver toxicity have been reported.

Clinical evidence

(a) Acitretin

In a review of the medical records of 18 patients who had taken methotrexate and acitretin for psoriasis, two patients (both of whom had consumed alcohol during their treatment) developed mildly raised liver function tests, four patients experienced at least one elevated gamma-glutamyl transferase level, and no patient discontinued treatment due to abnormal laboratory results.[1]

(b) Etretinate

A man was given a 48-hour infusion of methotrexate 10 mg every week, for chronic discoid psoriasis but when he was also given etretinate 30 mg daily his serum methotrexate levels almost doubled. Concentrations at 12 and 24 hours during the infusion were 0.11 mmol/L, compared with 0.07 mmol/L and 0.05 mmol/L before the etretinate.[2] A later study[3] in patients with psoriasis found that those receiving etretinate had 38% higher maximum plasma levels of methotrexate, but no difference in the clearance or elimination half-life of methotrexate (i.e. no methotrexate accumulation).

Severe toxic hepatitis has been reported in a number of cases when both etretinate and methotrexate were given.[4-6] It may take several months to develop.[6] The author of two of these cases stated that these occurred in a total of just 10 patients given both drugs, whereas they not seen any cases of severe toxic hepatitis in 531 patients given methotrexate alone or in 110 patients given etretinate alone.[4]

Mechanism

Not understood. Both etretinate and methotrexate can cause hepatotoxicity. The increased incidence of toxic hepatitis seen with etretinate and methotrexate may possibly be related to the increased maximum methotrexate plasma levels.

Importance and management

Although methotrexate and etretinate have been used together with success for psoriasis,[7-9] the risk of severe drug-induced hepatitis seems to be increased. One author says that he has decided not to use this combination in future.[4] Concurrent use should clearly be undertaken with great care. Etretinate has been largely superseded by acitretin (a metabolite of etretinate, which has a shorter half-life), but some, including the manufacturers, consider that the concurrent use of methotrexate and acitretin should also be avoided.[10-12] However, some do use this combination.[1] If the combination is used, it would be prudent to increase the frequency of monitoring of liver function tests.

Methotrexate + Sulfasalazine

The pharmacokinetics of methotrexate are unaffected by sulfasalazine. Clinical studies in patients with rheumatoid arthritis suggest that the combination of methotrexate and sulfasalazine may result in folate-deficiency anaemias.

Clinical evidence, mechanism, importance and management

A study in 15 patients with rheumatoid arthritis found that when sulfasalazine 2 g was given with methotrexate 7.5 mg weekly, the pharmacokinetics of methotrexate remained unchanged. Similarly, methotrexate did not alter the trough levels of sulfasalazine.[1] Although this study suggests that there is no reason to avoid the concurrent use of sulfasalazine and methotrexate, clinical studies in patients with rheumatoid arthritis have found that concurrent use does not significantly increase therapeutic efficacy and seems to increase the development of folate-deficiency anaemias.[2] The results of an *in vitro* study suggest this may be because sulfasalazine is a potent inhibitor of the reduced folate carrier-mediated cellular uptake of methotrexate and folinate.[3] An alternative explanation is that both sulfasalazine and methotrexate promote enhanced adenosine release, which may suppress inflammation, and the combination of two drugs with the same mechanism of action may not improve the therapeutic response of either.[4]

Methotrexate + Tacrolimus

Limited evidence suggests that tacrolimus does not affect methotrexate levels.

Clinical evidence, mechanism, importance and management

In a study in 3 bone marrow transplant patients given tacrolimus 30 micrograms/kg daily from the day before transplantation and low-dose methotrexate 15 mg/m^2 on day one, and 10 mg/m^2 on days 3, 6 and 11, methotrexate levels at 24 hours post-dose remained below the range requiring folinic acid, suggesting that no interaction of clinical significance had occurred.[1] In a later, similar report from this research group, in a total of 40 patients, tacrolimus did not appear to affect methotrexate levels.[2]

Methotrexate + Taxanes

Docetaxel does not alter methotrexate pharmacokinetics. Methotrexate does not appear to alter paclitaxel pharmacokinetics.

Clinical evidence, mechanism, importance and management

(a) Docetaxel

In a study in 6 patients, the pharmacokinetics of methotrexate and its metabolite, 7-hydroxymethotrexate, were unaltered when methotrexate 30 mg/m^2 was given immediately before or 24 hours before an infusion of docetaxel 75 mg/m^2, compared with methotrexate 30 mg/m^2 given alone.[1]

(b) Paclitaxel

The pharmacokinetics of paclitaxel did not appear to be changed when a 24-hour infusion of paclitaxel was started 24 hours after a bolus of methotrexate, when compared with historical data of paclitaxel alone. Myelosuppression was severe in this study.[2]

Methotrexate + Theophylline

Methotrexate causes a modest reduction in theophylline clearance. Theophylline may reduce methotrexate-induced neurotoxicity, but there is the possibility that it may also reduce methotrexate efficacy.

Clinical evidence

(a) Effects on theophylline

In 8 patients with severe, steroid-dependent asthma, the apparent clearance of theophylline (given as oral aminophylline, choline theophyllinate or theophylline) was reduced by 19% after 6 weeks of treatment with intramuscular methotrexate 15 mg weekly. Three patients complained of nausea and the theophylline dose was reduced in one of them as the theophylline level was more than 20 micrograms/mL.[1]

(b) Effects on methotrexate

Four of 6 patients aged 3 to 16 years with acute lymphoblastic leukaemia and high-dose methotrexate-induced neurotoxicity had a complete resolution of their symptoms when they were given a 2.5-mg/kg aminophylline infusion over one hour. The other 2 patients had some improvement in symptoms. One patient also had symptom relief with rapid-release theophylline.[2] Similar results were reported in another child who developed

neurotoxicity after receiving high-dose methotrexate. In this case, aminophylline was reported not to alter methotrexate levels.[3] A patient with methotrexate-induced leukoencephalopathy recovered after being given a combination of intravenous folinic acid with intravenous aminophylline 145 mg daily for 7 days.[4]

Mechanism

It is not known why theophylline clearance is altered by methotrexate. Methotrexate neurotoxicity may be linked with increased levels of adenosine. Theophylline is a competitive antagonist for adenosine receptors at serum concentrations within the therapeutic range used in respiratory disease.[2]

Importance and management

The clinical importance of the small reduction in theophylline clearance is uncertain, although it may be worth bearing this in mind in patients maintained at the higher end of the therapeutic levels for theophylline, as they may be more likely to develop toxicity. One UK manufacturer of methotrexate (licensed for rheumatoid arthritis) recommends monitoring theophylline levels with concurrent use, and avoiding excessive consumption of theophylline-containing drinks; however, this recommendation appears to be based on studies and surveys that looked at the effects of caffeine intake in patients taking low-dose, weekly methotrexate for rheumatoid arthritis or psoriasis.[5,6] Consider also, 'Methotrexate + Caffeine', p.749.

Aminophylline may reduce methotrexate-induced neurotoxicity, and, although there is some evidence that theophylline does not alter the cytotoxic effects of methotrexate, this requires confirmation.[2]

Methotrexate + Urinary alkalinisers

Alkalinisation of the urine increases the urinary excretion of methotrexate.

Clinical evidence, mechanism, importance and management

Methotrexate is much more soluble in alkaline than in acidic fluids, therefore urinary alkalinisers such as **sodium bicarbonate** and **acetazolamide** (and ample fluids) are often given to patients receiving high-dose methotrexate to prevent the precipitation of methotrexate in the renal tubules, which would cause damage. However alkalinisation also increases the loss of methotrexate in the urine because at high pH values more of the drug exists in the ionised form, which is not readily reabsorbed by the tubules. This increased clearance was clearly shown in about 70 patients in whom alkalinisation of the urine (to pH greater than 7) with **sodium bicarbonate** and hydration reduced the serum methotrexate levels at 48 hours and 72 hours by 73% and 76%, respectively.[1] In this instance the interaction was being exploited therapeutically to avoid toxicity. This interaction has also been shown by others.[2,3] However, the possible consequences should be recognised if concurrent use is undertaken in other situations (e.g. if sodium bicarbonate is given as an antacid).

For the effects of acidic urine on methotrexate excretion see 'Methotrexate + Ascorbic acid (Vitamin C)', p.749.

Mitomycin + Doxorubicin

An increased incidence of cardiotoxicity has been seen in patients receiving mitomycin who were previously or simultaneously given doxorubicin.

Clinical evidence, mechanism, importance and management

Fourteen out of 91 patients (15.3%) with advanced breast cancer who had previously not responded to doxorubicin developed congestive heart failure when they were later given a combination of intravenous mitomycin 20 mg/m^2 every 4 to 6 weeks and megestrol acetate 160 mg daily. None of them had any pre-existing heart disease. This compares with only 3 out of 89 patients (3.5%) from another group who had received doxorubicin but no mitomycin. The maximum cumulative dose of doxorubicin was 450 mg/m^2 and all of the patients had also been given cyclophosphamide. Some of them also received other drugs during the doxorubicin phase. These included fluorouracil, methotrexate, tegafur and vincristine. The heart failure developed slowly (mean time of 8.5 months) compared with those in the control group (1.5 months).[1]

Other studies have also suggested that the combination of mitomycin and doxorubicin may increase cardiotoxicity.[2,3] In a randomised study, 2 of 39 patients given doxorubicin 45 mg/m^2 every 3 weeks and mitomycin 10 mg/m^2 every 6 weeks developed cardiomyopathy, compared with none of 42 patients given doxorubicin 75 mg/m^2 every 3 weeks alone.[4]

The reasons for this apparent synergistic cardiotoxicity are not understood, but it may be related to free radical generation. This interaction is not established with certainty. The authors of one report suggest that its incidence is probably less than 10%, and that it does not occur until a cumulative mitomycin dose of 30 mg/m^2 or more.[3] It may be prudent to monitor patients given mitomycin more closely if they have previously received anthracyclines.[1] Note that the combination (FAM, fluorouracil, doxorubicin and mitomycin) has been widely used for gastric cancer.

Mitomycin + Fluorouracil

Rarely, serious and potentially life-threatening intravascular haemolysis and renal failure may develop after the long-term use of mitomycin and fluorouracil.

Clinical evidence, mechanism, importance and management

Two patients developed chronic haemolysis and progressive renal impairment after the long-term use of mitomycin and fluorouracil following partial or total gastrectomy for gastric cancer. The haemolysis was exacerbated by blood transfusions. The authors of the report[1] suggested that these two cases were extreme examples of a syndrome that was becoming increasingly apparent in their pretransfusion patients, after the maintenance use of these drugs for 6 months or more. A similar syndrome occurred in 2 other patients, one with gastric carcinoma and one without, when given these two drugs.[2,3] This severe and potentially fatal syndrome has also been seen with mitomycin alone.[4,5] Its incidence is not known, but note that a regimen of fluorouracil, doxorubicin and mitomycin (FAM) has been widely used in gastric cancer and there are only a few reports of this syndrome. The authors of one report suggest that the drugs should be stopped at the first sign of intravascular haemolysis, persistent proteinuria and rising urea levels (two consecutive values above 8 mmol/L).[1] The syndrome has also occurred when tamoxifen was given to patients who had been treated with mitomycin, see 'Mitomycin + Tamoxifen', p.759.

Mitomycin + Furosemide

A study in 5 patients with advanced solid tumours receiving mitomycin C 10 mg/m^2 found that furosemide given as a 40 mg intravenous bolus either 120 minutes or 200 minutes after the mitomycin had no effect on its pharmacokinetics.[1]

1. Verweij J, Kerpel-Fronius S, Stuurman M, de Vries J, Pinedo HM. Absence of interaction between furosemide and mitomycin C. *Cancer Chemother Pharmacol* (1987) 19, 84–6.

Mitomycin + Tamoxifen

Haemolytic anaemia, thrombocytopenia and renal impairment, leading to potentially fatal haemolytic uraemic syndrome, has occurred in a few patients given tamoxifen with, or shortly after, mitomycin.

Clinical evidence, mechanism, importance and management

After a woman with metastatic breast cancer who had previously been given mitomycin, mitoxantrone and methotrexate, developed rapidly fatal acute renal failure 21 days after starting tamoxifen, a retrospective survey was undertaken of other patients who had also received all four of these drugs.[1] Nine out of 94 patients (9.6%) developed anaemia, thrombocytopenia and renal impairment, compared with none in another group of 45 patients not given tamoxifen. One of the 9 died from renal failure. The doses used were mitomycin 7 mg/m^2 intravenously every 42 days for four courses; mitoxantrone 7 mg/m^2 and methotrexate 35 mg/m^2 intravenously every 21 days for eight courses; and tamoxifen 20 mg orally daily.[1] A few other reports describe cases of haemolytic uraemic syndrome in patients given mitomycin and tamoxifen.[2-4]

The authors of the first study suggested that this haemolytic uraemic syndrome was due to a combination of subclinical endothelial damage induced by mitomycin, and a thrombotic effect on platelets caused by tamoxifen.[1] They advise the avoidance of tamoxifen with or shortly after mitomycin unless concurrent use can be carefully monitored. Erythropoietin may be useful in managing the syndrome.[4] This syndrome has also occurred rarely with mitomycin alone, and when mitomycin was given with fluorouracil, see 'Mitomycin + Fluorouracil', p.758.

Mitotane + Miscellaneous

The manufacturer advises that mitotane might reduce the plasma levels of drugs that are cytochrome P450 substrates. The absorption of mitotane may be increased when taken with food.

Clinical evidence, mechanism, importance and management

(a) Cytochrome P450 substrates

The manufacturer advises that mitotane may induce the activity of cytochrome P450 isoenzymes.[1,2] This appears to be based on a case report of decreased efficacy of warfarin (see 'Coumarins + Antineoplastics; Miscellaneous cytotoxics', p.432), and on studies in *rats*.[3] On this basis, the manufacturers give a general caution about the concurrent use of drugs influenced by hepatic enzyme induction.[1,2] However, if mitotane were an important enzyme inducer it might have been expected to have come to light by now, but there do not appear to be any case reports supporting this effect, other than the one case already mentioned with warfarin. On the basis of this proposed interaction, the UK manufacturer specifically recommends caution with **antiepileptics**, **griseofulvin**, **rifabutin**, **rifampicin**, and **St John's wort** (*Hypericum perforatum*).[1] However, most of these drugs are also enzyme inducers, with some being potent (e.g. rifampicin), and the effect of adding another modest enzyme-inducer is probably unlikely to be clinically relevant.

In summary, there is too little information available to warrant a general caution for the use of mitotane with all cytochrome P450 substrates that have a narrow therapeutic index. Further study is needed.

(b) Food

The UK manufacturer notes that the absorption of mitotane was increased when it was given with food (although they say the relative bioavailability was not calculated), and they say that mitotane should be preferably taken with meals.[1] The US information does not mention this effect, nor give any advice about administration in relation to meals.[2]

Mitotane + Spironolactone

In an isolated report, the effects of mitotane appeared to be inhibited by spironolactone in a patient with Cushing's disease.

Clinical evidence, mechanism, importance and management

A woman with Cushing's disease taking chlorpropamide, digoxin and furosemide was given spironolactone 50 mg four times daily to control hypokalaemia. She was also given mitotane 3 g daily for 5 months to control the elevated cortisol levels, but this had no effect.[1] When an interaction was suspected (on the basis of *animal* studies[1]) it was decided to withdraw the spironolactone, whereupon severe nausea and profuse diarrhoea developed within 24 to 48 hours, suggesting mitotane toxicity. This subsided, and then redeveloped when the mitotane was stopped, and then restarted a week later. The mechanism of this apparent interaction is not understood. It would seem that mitotane can become ineffective in the management of Cushing's syndrome in the presence of spironolactone. The UK manufacturer of mitotane contraindicates its use with spironolactone,[2] while the US manufacturer does not mention this interaction.[3]

Nilotinib + Miscellaneous

Rifampicin (rifampin), a CYP3A4 inducer, decreases nilotinib levels and ketoconazole, a CYP3A4 inhibitor, increases nilotinib levels. Other inducers and inhibitors of CYP3A4 are predicted to interact similarly. Additive QT prolongation may occur on the concurrent use of nilotinib and drugs that prolong the QT interval. Nilotinib increases midazolam levels, and is predicted to increase the levels of other CYP3A4 substrates. Food increases the absorption of nilotinib. No clinically relevant interaction appears to occur between nilotinib and esomeprazole, and no interaction is expected with other proton pump inhibitors.

Clinical evidence, mechanism, importance and management

(a) CYP2C9 substrates

In a single-dose study in healthy subjects, nilotinib had no effect on the pharmacokinetics or anticoagulant response to **warfarin** (a known substrate of CYP2C9).[1] Nevertheless, as **warfarin** is also (in part) metabolised by CYP3A4, which nilotinib modestly inhibits, the manufacturers of nilotinib advise caution on concurrent use and suggest that alternative anticoagulant drugs should be used.[1,2] Note that, from a disease perspective,

when treating venous thromboembolic disease in patients with cancer, **warfarin** is generally inferior (higher risk of major bleeds and recurrent thrombosis) to low-molecular-weight heparins.

The manufacturers of nilotinib[1,2] also advise caution if it is given with other drugs that are substrates of CYP2C9, particularly those with narrow therapeutic margins, although given the study with warfarin, this seems unlikely to be necessary.

(b) CYP2D6 substrates

In vitro studies have suggested that nilotinib is an inhibitor of the cytochrome P450 isoenzyme CYP2D6 and it may therefore increase the plasma levels of drugs that are substrates of this enzyme. The manufacturers advise caution when giving nilotinib with drugs that are substrates of CYP2D6, particularly those with narrow therapeutic margins.[1] For a list of drugs that are substrates of CYP2D6, see 'Table 1.3', (p.6).

(c) CYP3A4 inducers

In a study in healthy subjects, **rifampicin** (**rifampin**) 600 mg daily for 12 days reduced the AUC and peak levels of nilotinib by about 80% and 64%, respectively.[1,2] Nilotinib is metabolised by the cytochrome P450 isoenzyme CYP3A4, and therefore its levels may be reduced by drugs that induce this isoenzyme, such as **rifampicin**. The manufacturers of nilotinib advise against the concurrent use of drugs that are potent inducers of CYP3A4, and they specifically name **carbamazepine**, **dexamethasone**, **phenytoin**, **rifampicin** (**rifampin**), **rifabutin**, **rifapentine**, **phenobarbital**, and **St John's wort**.[1,2] Note however that clinically relevant interactions occurring as a result of **dexamethasone** inducing CYP3A4 are rare. The US manufacturer of nilotinib states that if it the concurrent use of a potent CYP3A4 inducer is necessary, the dose of nilotinib may need to be increased. The nilotinib dose should be readjusted when the CYP3A4 inducer is stopped.[1] For a list of drugs that are inducers of CYP3A4, see 'Table 1.4', (p.6).

(d) CYP3A4 inhibitors

In a study in healthy subjects, **ketoconazole** 400 mg daily for 6 days increased the AUC of nilotinib threefold.[1,2] Nilotinib is metabolised by the cytochrome P450 isoenzyme CYP3A4 and its levels may be increased by drugs that inhibit this isoenzyme, such as **ketoconazole**. The manufacturers of nilotinib advise against the concurrent use of drugs that are potent inhibitors of CYP3A4, and they specifically name **atazanavir**, **clarithromycin**, **grapefruit products**, **itraconazole**, **indinavir**, **ketoconazole**, **nefazodone**, **nelfinavir**, **ritonavir**, **saquinavir**, **telithromycin**, and **voriconazole**.[1,2] If treatment with a potent CYP3A4 inhibitor is cannot be avoided, nilotinib should be withheld, or, if this is not possible, both manufacturers advise close monitoring for QT prolongation: nilotinib prolongs the QT interval, and this effect may be greater at higher nilotinib levels. The US manufacturers also state that the dose of nilotinib should be reduced to 400 mg daily, half of the normal daily dose.[1,2] The US manufacturer further advises that a washout period should be allowed when the potent CYP3A4 inhibitor is stopped before the dose of nilotinib is readjusted.[1] Increased exposure to nilotinib may also occur with moderate inhibitors of CYP3A4, and the UK manufacturer advises that an alternative drug with no or only minimal CYP3A4 inhibition should be considered.[2] For a list of drugs that are inhibitors of CYP3A4, see 'Table 1.4', (p.6).

(e) CYP3A4 substrates

In a single-dose study in healthy subjects, nilotinib increased the exposure to oral **midazolam** by 30%.[1,2]. Nilotinib is an inhibitor of the cytochrome P450 isoenzyme CYP3A4, by which **midazolam** is metabolised; however, the study with **midazolam** suggests that its effects are modest. The manufacturers therefore caution the concurrent use of nilotinib with drugs that are substrates of CYP3A4, particularly those with narrow therapeutic margins. The UK manufacturer names **astemizole**, **terfenadine**, **cisapride**, **pimozide**, **quinidine**, and **ergot alkaloids** (e.g. **ergotamine**, **dihydroergotamine**).[2] For a list of drugs that are substrates of CYP3A4, see 'Table 1.4', (p.6).

(f) Cytochrome P450 substrates; Miscellaneous

In vitro studies have shown that nilotinib is an inhibitor and inducer of the cytochrome P450 isoenzyme CYP2C8,[1,2] and an inducer of CYP2B6.[1] In the absence of any specific information, the manufacturers advise that nilotinib has the potential to alter the pharmacokinetics of drugs that are metabolised by these isoenzymes.[1] For a list of drugs that are substrates of CYP2B6 and CYP2C8, see 'Table 1.3', (p.6).

(g) Drugs that affect gastric pH

It is suggested that drugs that suppress gastric acid may lead to lower exposure to nilotinib as the solubility of nilotinib is pH-dependent, with lower solubility at higher pH. In a study in healthy subjects, **esomeprazole** 40 mg daily for 5 days modestly reduced the AUC and maximum plasma levels of nilotinib by 34% and 27%, respectively, despite a marked increase in gastric pH. The manufacturers advise that nilotinib may be given with **esomeprazole** or other **proton pump inhibitors** as needed.[2]

(h) Drugs that prolong the QT interval

In an analysis of ECG recordings from 119 patients given nilotinib, it was found that the Fridericia-corrected QTc (QTcF) interval increased by 5 to 15 milliseconds.[3] In a study in patients with chronic myeloid leukaemia, nilotinib increased the QTcF by 6 to 8 milliseconds and no episodes of torsade de pointes were reported.[2] The US manufacturer advises avoiding the concurrent use of drugs that prolong the QT interval, whereas the UK manufacturer advises caution on concurrent use.[1,2] They specifically name **amiodarone**, **chloroquine**, **clarithromycin**, **disopyramide**, **halofantrine**, **haloperidol**, **methadone**, **moxifloxacin**, **pimozide**, **procainamide**, **quinidine** and **sotalol**. If concurrent use is necessary, nilotinib should be stopped,[1] or, if this is not possible, the manufacturers advise close monitoring for QT prolongation.[1,2] Consider also, 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290.

(i) Food

In a study in healthy subjects, a high-fat meal increased the AUC of nilotinib by 82%, when the dose was given 30 minutes after the meal, when compared with the fasting state. The bioavailability of nilotinib is reported to be increased by 29% and 15%, respectively, when it is taken 30 minutes or 2 hours after food.[2] The manufacturers therefore recommend that nilotinib is taken on an empty stomach, at least one hour before and 2 hours after food.[1,2]

(j) P-glycoprotein inhibitors and substrates

Nilotinib is an inhibitor and substrate of P-glycoprotein. The US manufacturer therefore predicts that the concurrent use of nilotinib with drugs that are substrates of P-glycoprotein may lead to an increase in their levels, and that inhibitors of P-glycoprotein will increase nilotinib levels, and they caution concurrent use;[1] however, the clinical relevance of this prediction needs confirming. For a list of drugs that inhibit and are substrates of P-glycoprotein, see 'Table 1.6', (p.8).

Nitrosoureas + Cimetidine

The bone marrow depressant effects of carmustine and lomustine are possibly increased by cimetidine.

Clinical evidence

Nine patients given **carmustine** 80 mg/m^2 daily for 3 days, cimetidine 300 mg four times daily for one to 4 weeks, steroids, and cranial irradiation over 6 weeks, had marked leucopenia during the first cycle. Bone marrow aspirates confirmed the marked decrease in granulocytic elements in 2 patients. In comparison, 31 patients similarly treated, but without cimetidine, had no significant white cell depression.[1,2]

Neutropenia was found in a man taking regular cimetidine, phenytoin, phenobarbital, and dexamethasone, 53 days after he was given **lomustine** 120 mg, and 16 days after he was given **lomustine** 160 mg. The cimetidine was discontinued and the neutropenia rapidly reversed within 14 days. The neutrophil nadir from the **lomustine** 160 mg dose occurred after a further 16 to 19 days and was much less severe than the first episode.[3]

Mechanism

Studies in *animals* suggest that cimetidine impairs the clearance of carmustine.[4]

Importance and management

Information appears to be limited to the reports cited, but it seems to be an established reaction. Patients given both lomustine or carmustine and cimetidine should be closely monitored for changes in blood cell counts. Because of its immunomodulatory effects, cimetidine has been used as an adjunct to carmustine in the treatment of malignant melanoma, but this did not improve outcomes.[5]

Nitrosoureas; Lomustine + Phenobarbital

***Animal* studies have shown that the antitumour effects and the toxicity of lomustine are markedly reduced by phenobarbital. It is suggested that the metabolism of lomustine is accelerated by the enzyme-inducing effects of phenobarbital.[1] There appears to be no clinical data confirming this; nevertheless, it would be prudent to bear the possibility of an interaction in mind if both drugs are given.**

1. Siemann DW. Effect of pretreatment with phenobarbital or SKF 525A on the toxicity and antitumor activity of lomustine. *Cancer Treat Rep* (1983) 67, 259–65.

Nitrosoureas; Lomustine + Theophylline

A single case report describes thrombocytopenia and bleeding, which was attributed to the concurrent use of lomustine and theophylline.

Clinical evidence, mechanism, importance and management

An woman with asthma taking theophylline and given lomustine, prednisone and vincristine for medulloblastoma, developed severe nose bleeding and thrombocytopenia 3 weeks after the third cycle of chemotherapy.[1] This was attributed to the concurrent use of lomustine and theophylline. The suggested explanation for this effect is that theophylline inhibited the activity of phosphodiesterase within the platelets, thereby increasing cyclic AMP levels and disrupting normal platelet function (which seems to be supported by an experimental study[2]) while lomustine causes thrombocytopenia. What is known is far too limited to act as more than a warning of the possibility of increased thrombocytopenia during the concurrent use of theophylline and lomustine.

Panitumumab + Antineoplastics

The efficacy of panitumumab was reduced and the toxicity increased when it was given with bevacizumab-containing chemotherapy regimens. When panitumumab was given with irinotecan, bolus fluorouracil plus folinic acid (IFL) there was a high incidence of severe diarrhoea.

Clinical evidence

(a) Bevacizumab with chemotherapy

In an interim analysis of a study of 823 patients randomised to receive bevacizumab plus **oxaliplatin**-based regimens, with or without panitumumab, there was an increased incidence of adverse effects (skin toxicity, diarrhoea, infections, pulmonary embolism), a shortened progression-free survival time (10 months versus 11.4 months) and increased deaths (from pulmonary embolism) in those receiving panitumumab.[1] In a smaller cohort receiving panitumumab with bevacizumab plus **irinotecan**-based regimens similar increased toxicity without improved efficacy was seen. Patients receiving panitumumab received a lower dose-intensity of the cytotoxics (**oxaliplatin**, **irinotecan**, **fluorouracil**) because of the toxicities experienced.[2]

(b) IFL and FOLFIRI

A high incidence of severe (grade 3 to 4) diarrhoea (58%) was noted when panitumumab was given to 19 patients who also received the IFL regimen (irinotecan, bolus fluorouracil and folinic acid): the concurrent use of these drugs was considered to be poorly tolerated.[3] In another arm of this study a 25% incidence of grade 3 diarrhoea was seen when panitumumab was added to the FOLFIRI regimen (irinotecan, folinic acid and infusional fluorouracil).[3]

Mechanism

Unknown. A pharmacokinetic interaction would not be anticipated.

Importance and management

Panitumumab is currently indicated for use only as monotherapy after the failure of chemotherapy.[2,4] One study shows that the effect of combining it with another monoclonal antibody, bevacizumab, plus chemotherapy is detrimental, and this combination should not be used. A high incidence of severe diarrhoea was also seen in the study with IFL, and the UK manufacturer advises against using this combination.[4]

Pemetrexed + Aspirin or NSAIDs

NSAIDs are predicted to decrease the renal excretion of pemetrexed. However, aspirin and ibuprofen had little effect on pemetrexed clearance in patients with normal renal function.

Clinical evidence

In a study in 27 patients with advanced cancer, aspirin 325 mg every 6 hours for 9 doses, starting 2 days before pemetrexed, and with the last dose one hour before an infusion of pemetrexed 500 mg/m^2, had no effect on the pharmacokinetics of pemetrexed.[1] In a similar study, **ibuprofen** 400 mg four times daily caused a slight 16% decrease in the clearance of pemetrexed, and increased its AUC by 20%.[1]

Mechanism

Pemetrexed is largely cleared unchanged from the body by renal excretion. The NSAIDs as a group inhibit the synthesis of the prostaglandins (PGE_2) resulting in a fall in renal perfusion, which could lead to a rise in serum pemetrexed levels, accompanied by increased toxicity.

Importance and management

The modest increase in pemetrexed exposure seen with ibuprofen 1.6 g daily or aspirin 1.3 g daily is unlikely to be clinically relevant in patients with *normal renal function*, and they may be used in these patients. However, the effects of higher doses of aspirin or ibuprofen are not known, and they could be greater. Because of this, in patients with normal renal function, the manufacturer recommends caution when pemetrexed is used with high doses of NSAIDs (e.g. ibuprofen greater than 1.6 g daily) or high-dose aspirin (greater than 1.3 g daily).[2] Moreover, in patients with *mild to moderate renal impairment*, the manufacturer recommends that NSAIDs with short half-lives such as ibuprofen and higher dose aspirin should be completely avoided from 2 days before to 2 days after pemetrexed use.[2,3]

Because of the lack of data on pemetrexed clearance with NSAIDs with

longer half-lives (e.g. **piroxicam**), the manufacturer recommends that all patients taking these NSAIDs should stop them from 5 days before to 2 days after pemetrexed.[2,3]

Pemetrexed + Gemcitabine

The concurrent use of pemetrexed and gemcitabine does not affect the pharmacokinetics of either drug.

Clinical evidence, mechanism, importance and management

In one study in 4 patients, the pharmacokinetics of pemetrexed were not affected when pemetrexed was given 90 minutes after gemcitabine on day one, when compared with its use alone on day 8.[1] Similarly, another report describes a study in 14 patients in which there was no pharmacokinetic interaction between pemetrexed and gemcitabine when a single dose of pemetrexed was given immediately after gemcitabine (gemcitabine 1.25 g/m^2 was given on days 1 and 8 of a 21-day cycle, with pemetrexed 500 mg/m^2 on day 8, for 84 cycles).[2]

Phase I and pharmacologic study of sequences of gemcitabine and the multitargeted antifolate agent in patients with advanced solid tumors. *J Clin Oncol* (2000) 18, 1748–57.
2. Adjei AA. Clinical studies of pemetrexed and gemcitabine combinations. *Ann Oncol* (2006) 17, v29–v32.

Pemetrexed + Irinotecan

The concurrent use of pemetrexed and irinotecan does not appear to affect the pharmacokinetics of either drug.

Clinical evidence, mechanism, importance and management

In a dose-finding study in 51 patients, when irinotecan 175 mg/m^2 to 350 mg/m^2 was given after pemetrexed 300 mg/m^2 to 500 mg/m^2, there did not appear to be any change in the pharmacokinetics of either drug, when compared with historical data for either drug alone.[1]

1. Rowinsky EK, Beeram M, Hammond LA, Schwartz G, De Bono J, Forouzesh B, Chu Q, Latz JE, Hong S, John W, Nguyen B. A phase I and pharmacokinetic study of pemetrexed plus irinotecan in patients with advanced solid malignancies. *Clin Cancer Res* (2007) 13, 532–9.

Pemetrexed + Miscellaneous

Caution is recommended if pemetrexed is given with nephrotoxic drugs such as the aminoglycosides, cisplatin, loop diuretics, and ciclosporin, and drugs that are secreted by the renal tubules, such as probenecid and penicillin. No pharmacokinetic interaction occurs between pemetrexed and cisplatin.

Clinical evidence, mechanism, importance and management

(a) Cisplatin

The US manufacturer states that there is no pharmacokinetic interaction between pemetrexed and cisplatin,[1] but there is the possibility that cisplatin-induced nephrotoxicity could decrease pemetrexed clearance and increase its toxicity.[1,2] However, it should be noted that the use of pemetrexed with cisplatin is indicated for mesothelioma.[1,2]

(b) Folic acid and Vitamin B_{12}

Oral folic acid and intramuscular vitamin B_{12} do not alter the pharmacokinetics of pemetrexed[1] and because these vitamins were found to decrease pemetrexed toxicity, it is recommended that all patients receiving pemetrexed should receive folic acid and B_{12} supplements.[1,2]

(c) Nephrotoxic drugs

The manufacturers consider that the concurrent use of nephrotoxic drugs could potentially decrease the clearance of pemetrexed and therefore increase its toxicity.[1,2] In the UK, the manufacturer specifically mentions **aminoglycosides**, **loop diuretics**, **platinum compounds** (see also *Cisplatin*, above) and **ciclosporin**, and recommends caution on concurrent use, and, if necessary, close monitoring of creatinine clearance.[2]

(d) Probenecid and other drugs secreted by the renal tubules

It is possible that drugs that are secreted by the renal tubules (e.g. probenecid, **penicillin**) could decrease the clearance of pemetrexed, which is also secreted by this mechanism. For this reason, the manufacturer recommends caution on concurrent use, and, if necessary, close monitoring of creatinine clearance.[2]

2. Alimta (Pemetrexed disodium). Eli Lilly and Company Ltd. UK Summary of product characteristics, September 2009.

Procarbazine + Antiepileptics; Enzyme-inducing

The use of phenytoin, phenobarbital or carbamazepine might increase the risk of procarbazine hypersensitivity reactions, and at high doses of procarbazine, a few cases of severe hepatotoxicity were seen with phenytoin and carbamazepine plus zolpidem. The pharmacokinetics of procarbazine did not appear to differ when given with phenytoin, phenobarbital or carbamazepine.

Clinical evidence

A retrospective study of the records of 83 patients with primary brain tumours who were given procarbazine between 1981 and 1996 found that 20 of them had experienced procarbazine hypersensitivity reactions. Of these 20, 95% had also taken antiepileptics, compared with 71% of those not developing hypersensitivity. In addition, there was a significant dose-response association between the development of hypersensitivity reactions and the serum levels of the antiepileptics used (**phenytoin**, **phenobarbital**, or **carbamazepine**, with or without valproate).[1]

In a prospective study, the pharmacokinetics of procarbazine did not differ between 31 patients taking enzyme-inducing antiepileptics (**carbamazepine**, **oxcarbazepine**, **phenobarbital** or **phenytoin**) and 18 patients taking non-enzyme-inducing antiepileptics or no antiepileptics. Procarbazine was given daily for 5 days every 4 weeks at a starting dose of 200 mg/m^2 escalated to the maximum tolerated dose. At procarbazine doses of 393 mg/m^2 and 429 mg/m^2, there were two cases of severe hepatic dysfunction in patients taking **phenytoin** (one of which was fatal), and one in a patient taking **carbamazepine** and **zolpidem** (this resolved on stopping the **zolpidem**). In addition, at a dose of procarbazine 343 mg/m^2, there was one case of liver dysfunction in a patient not taking enzyme-inducing antiepileptics, at which point the study was halted. In this study, the concurrent use of **dexamethasone** with or without enzyme-inducing antiepileptics also did not affect procarbazine pharmacokinetics.[2]

Mechanism

It was suggested that the enzyme-inducing antiepileptics may increase the metabolism of procarbazine to metabolites causing hypersensitivity.[1] However, no change in the pharmacokinetics of procarbazine itself was seen; suggesting this is unlikely.[2] Procarbazine clearly inhibited its own metabolism, which suggests that it might also inhibit the metabolism of the antiepileptics and this might have increased the risk of hepatotoxicity. However, hepatotoxicity may have also been a result of the high dose of procarbazine. Further study is needed.[2]

Importance and management

Enzyme-inducing antiepileptics do not appear to alter the pharmacokinetics of procarbazine, and, in clinical practice, the dose of procarbazine is not modified in patients taking these drugs.[2] There is some evidence that the incidence of procarbazine-induced hypersensitivity is higher in patients receiving enzyme-inducing antiepileptics. In one dose-finding study, an unexpectedly high incidence of hepatotoxicity was seen with

high-dose procarbazine, and a possible interaction with enzyme-inducing antiepileptics could not be ruled out.

Procarbazine + Chlormethine (Mechlorethamine)

A report suggests that, in two patients, the use of high doses of procarbazine with chlormethine may result in neurological toxicity.

Clinical evidence, mechanism, importance and management

Two patients with acute myelogenous leukaemia admitted to hospital for bone marrow transplantation and who were given *high doses* of procarbazine 12.5 mg/kg and 15 mg/kg with chlormethine 0.75 mg/kg and 1 mg/kg on the same day became lethargic, somnolent and disorientated for about a week. Two other patients who received the same drugs, but not on the same day, had no neurological complications. In addition, only one of 45 patients given high-dose procarbazine alone had similar persistent lethargy. Although no interaction has been proved, the authors suggest that the chlormethine may have enhanced the neurotoxic effects of the procarbazine, and advise that it would be prudent to avoid high-doses of these drugs on the same day.[1] Note that lower doses of the combination have been widely used in the MOPP regimen (mechlorethamine, vincristine, procarbazine, and prednisone) without problems.

Procarbazine + Miscellaneous

The effects of drugs that can cause CNS depression or lower blood pressure may possibly be increased by the presence of procarbazine. Some caution might be appropriate with tricyclics, as procarbazine is a weak MAOI.

Clinical evidence, mechanism, importance and management

(a) Antihypertensives

In one early clinical study, 4 of 48 patients developed postural hypotension when given procarbazine. In addition, another patient with hypertension (180/110 mmHg) had a progressive fall in blood pressure (to 110/80 mmHg) while taking procarbazine.[1] Additive hypotensive effects may therefore be expected if procarbazine is given to patients taking antihypertensives.

(b) CNS depressants

Procarbazine can cause CNS depression ranging from mild drowsiness to profound stupor. In early clinical studies, the incidence was variously reported as 8%, 14%, and 31% (when combined with prochlorperazine).[1-3] Additive CNS depression may therefore be expected if other drugs possessing CNS-depressant activity are given with procarbazine. The US manufacturer names **barbiturates**, **antihistamines**, **narcotics** and **phenothiazines**.[4]

(c) Prochlorperazine

An isolated report describes an acute dystonic reaction (difficulty in speaking or moving, intermittent contractions of muscles on the left side of the neck) in a patient taking procarbazine with prochlorperazine.[5] Prochlorperazine was thought to have contributed to the sedative effects of procarbazine in one early clinical study.[3]

(d) Tricyclics

Procarbazine is a weak inhibitor of MAO (see 'Procarbazine + Sympathomimetics', p.763), and it could therefore theoretically interact with tricyclics, in a similar way to the conventional 'MAOIs', (p.1391). On this basis, the US manufacturer specifically advises avoiding the concurrent use of tricyclics such as amitriptyline and imipramine,[4] whereas the UK manufacturer advises caution.[6]

Procarbazine + Sympathomimetics

Despite warnings, it seems doubtful that the weak MAO-inhibitory properties of procarbazine can, under normal circumstances, cause a hypertensive reaction with tyramine-rich foods or sympathomimetic drugs.

Clinical evidence, mechanism, importance and management

The manufacturers say that procarbazine is a weak inhibitor of MAO and therefore predict that interactions with certain foods and drugs may occur in rare cases.[1,2] This is apparently based on the results of *animal* studies, which show that the monoamine oxidase inhibitory properties of procarbazine are weaker than pheniprazine.[3] There seem to be no formal reports of hypertensive reactions in patients taking procarbazine who have eaten tyramine-containing foods (e.g. cheese) or after using indirectly-acting sympathomimetic amines (e.g. **phenylpropanolamine**, **amfetamines**, etc.). The only account traced is purely anecdotal and unconfirmed: one author states that he can recall one patient who had a vivid reaction to wine and chicken livers when taking MOPP (mechlorethamine, vincristine, procarbazine, and prednisone) several years earlier.[4] A practical way to deal with this interaction problem has been suggested by a practitioner in an oncology unit:[4] patients taking procarbazine should ideally be given a list of the potentially interacting foodstuffs (see 'MAOIs or RIMAs + Tyramine-rich foods', p.1395), with a warning about the nature of the possible reaction but also with the advice that it very rarely occurs. The foods may continue to be eaten, but patients should start with small quantities to ensure that they still agree with them. Those taking MOPP should also be told that any reaction is most likely to occur during the second week of a 14-day course of treatment with procarbazine, and during the week after it has been stopped.

4. Maxwell MB. Reexamining the dietary restrictions with procarbazine (an MAOI). *Cancer Nurs* (1980) 3, 451–7.

Raltitrexed + Miscellaneous

On theoretical grounds the manufacturers say that folinic acid and folic acid may possibly interfere with the action of raltitrexed. Warfarin and NSAIDs do not appear to interact with raltitrexed.

Clinical evidence, mechanism, importance and management

(a) Folinates

The antimetabolite, raltitrexed, is a folate analogue and is a potent and specific inhibitor of the enzyme thymidylate synthase. Inhibition of this enzyme ultimately interferes with the synthesis of deoxyribonucleic acid (DNA) leading to cell death. The intracellular polyglutamation of raltitrexed leads to the formation of even more potent inhibitors of thymidylate synthase. Folate (methylene tetrahydrofolate) is a co-factor required by thymidylate synthase and therefore theoretically folinic acid or folic acid

may interfere with the action of raltitrexed. Clinical interaction studies have not yet been undertaken to confirm these predicted interactions.[1]

(b) Warfarin and NSAIDs

The manufacturers say that no specific clinical interaction studies have been conducted, but a review of the clinical study database did not reveal any evidence of interactions between raltitrexed and warfarin, NSAIDs or other drugs.[1]

1. Tomudex (Raltitrexed). AstraZeneca UK Ltd. UK Summary of product characteristics, August 2008.

Sorafenib + Antineoplastics

Sorafenib may increase docetaxel and doxorubicin levels. Unexpectedly severe toxicity was seen when sorafenib was given with bevacizumab, which limited the dose of both drugs. Variable effects on the pharmacokinetics of fluorouracil have been seen. Sorafenib does not alter the pharmacokinetics of gemcitabine or oxaliplatin, or of paclitaxel when stopped for three days around its administration.

Clinical evidence, mechanism, importance and management

(a) Bevacizumab

In a dose-finding study, the maximum tolerated doses of sorafenib and bevacizumab were lower when they were given together compared with either drug alone. Unexpectedly severe toxicity was seen, in particular hypertension, proteinuria and thrombocytopenia. Three-quarters of patients required a further reduction in their sorafenib dose to 200 mg daily.[1]

(b) Docetaxel

Sorafenib 200 mg or 400 mg twice daily on days 2 to 19 of a 21-day cycle increased the AUC and maximum concentration of docetaxel 75 or 100 mg/m^2 given on day one every 21 days, by 36 to 80%, and by 16 to 32%, respectively.[2,3] The manufacturer therefore recommends caution on the concurrent use of these drugs.[2,3]

(c) Doxorubicin

A modest 21% increase in the AUC of doxorubicin occurred when it was given with sorafenib. The manufacturers therefore recommend caution on the concurrent use of these drugs.[2,3]

(d) Fluorouracil

The AUC of fluorouracil has been reported both to increase by up to 47% and to decrease by 10% when given with sorafenib. The manufacturer therefore advises caution on the concurrent use of these drugs.[3]

(e) Gemcitabine

In a phase I study The pharmacokinetics of gemcitabine and sorafenib were not significantly altered in 27 patients who received gemcitabine weekly and sorafenib daily from day 2.[4]

(f) Oxaliplatin

In clinical studies sorafenib did not affect the pharmacokinetics of oxaliplatin.[2,3]

(g) Paclitaxel

Sorafenib is predicted to inhibit the metabolism of paclitaxel by the cytochrome P450 isoenzyme CYP2C8. In one clinical study, there was no change in the pharmacokinetics of paclitaxel when sorafenib was stopped for 3 days around the administration of paclitaxel.[3]

2. Nexavar (Sorafenib tosylate). Bayer plc. UK Summary of product characteristics, July 2009.
3. Nexavar (Sorafenib tosylate). Bayer Pharmaceuticals Corp. US Prescribing information, February 2009.
4. Siu LL, Awada A, Takimoto CH, Piccart M, Schwartz B, Giannaris T, Lathia C, Petrenciuc O, Moore MJ. Phase I trial of sorafenib and gemcitabine in advanced solid tumors with an expanded cohort in advanced pancreatic cancer. *Clin Cancer Res* (2006) 12, 144–51.

Sorafenib + Miscellaneous

Sorafenib levels were modestly reduced by rifampicin (a potent enzyme inducer) and might be similarly affected by other inducers of cytochrome P450 isoenzymes. Ketoconazole (a CYP3A4 inhibitor) had no clinically relevant effect on sorafenib pharmacokinetics, suggesting that other CYP3A4 inhibitors are unlikely to interact. Sorafenib did not alter the pharmacokinetics of midazolam, dextromethorphan or omeprazole, but is predicted to inhibit the metabolism of CYP2B6 and CYP2C8 substrates.
Isolated cases of raised INRs and bleeding have been reported in patients taking warfarin with sorafenib, but no INR changes were seen in a study in patients.

Clinical evidence, mechanism, importance and management

(a) Cytochrome P450 inducers

A 5-day course of **rifampicin** (**rifampin**) reduced the AUC of a single dose of sorafenib by an average of 37%. Other inducers of cytochrome P450 isoenzymes and/or glucuronidation, such as **St John's wort**, **carbamazepine**, **phenytoin**, **phenobarbital** and **dexamethasone**, may also reduce sorafenib levels.[1,2] Sorafenib is given as a standard dose, and is not titrated to effect. The clinical relevance of this reduction is unknown, but the US manufacturer recommends avoiding strong enzyme inducers.[2] They say that, if an enzyme inducer is required, consideration can be given to increasing the dose of sorafenib with close monitoring for adverse effects.[2]

(b) CYP3A4 inhibitors

In a study in 15 healthy subjects, **ketoconazole** 400 mg daily for 7 days had no effect on the AUC or maximum level of a low 50-mg dose of sorafenib given on day 4. However, ketoconazole markedly inhibited the formation of the metabolite, sorafenib *N*-oxide. **Ketoconazole** is a known inhibitor of the cytochrome P450 isoenzyme CYP3A4, by which sorafenib is metabolised to its *N*-oxide metabolite. Nevertheless, because the exposure to sorafenib did not increase, it is likely the glucuronidation metabolic pathway compensated.[3] The pharmacokinetics of sorafenib are linear at clinical doses, therefore higher doses of sorafenib are also unlikely to be affected by ketoconazole.[3] The findings of this study suggest that no pharmacokinetic interaction is likely with other CYP3A4 inhibitors as a result of this mechanism.

(c) Cytochrome P450 substrates

Sorafenib did not alter the pharmacokinetics of **dextromethorphan**, **midazolam**, and **omeprazole**, used as substrates for the cytochrome P450 isoenzymes CYP2D6, CYP3A4 and CYP2C19, respectively. Pharmacokinetic interactions with drugs that are substrates of these isoenzymes are therefore not anticipated.[1]

In vitro studies have shown that sorafenib inhibits CYP2B6 and CYP2C8, but the clinical relevance of this is unclear. The manufacturers warn that the plasma levels of substrates of CYP2B6 (the UK manufacturer names **bupropion**, **cyclophosphamide**, **efavirenz**, **ifosfamide** and **methadone**) and of CYP2C8 (the UK manufacturer names **amodiaquine** and **repaglinide**) may be increased by sorafenib.[1,2] Until more is known, this warning seems prudent. Be alert for any increase in the adverse effects of these drugs in patients also given sorafenib. For a list of substrates of CYP2B6 and CYP2C8 see 'Table 1.3', (p.6).

(d) Warfarin

A study in patients given sorafenib and taking warfarin found that the INR did not differ between those patients taking sorafenib and those not taking sorafenib, despite previous *in vitro* evidence that sorafenib inhibits the cytochrome P450 isoenzyme CYP2C9, the main isoenzyme involved in the metabolism of warfarin.[1,2]

However, raised INRs and infrequent bleeding have been reported in patients taking warfarin with sorafenib. The manufacturers therefore advise that the INR should be closely monitored in patients taking these drugs together.[1,2] Note that, from a disease perspective, when treating venous thromboembolic disease in patients with cancer, warfarin is generally inferior (higher risk of major bleeds and recurrent thrombosis) to low-molecular-weight heparins.[4]

Streptozocin + Phenytoin

A single case report indicates that phenytoin can reduce or abolish the effects of streptozocin.

Clinical evidence, mechanism, importance and management

A patient with an organic hypoglycaemic syndrome, due to a metastatic apud cell carcinoma of the pancreas, who was taking streptozocin 2 g daily with phenytoin 400 mg daily for 4 days, did not have the expected response to streptozocin until phenytoin was withdrawn.[1] It would seem that the phenytoin inhibited the effects of the streptozocin by some mechanism as yet unknown. Although this is an isolated case report its authors recommend that concurrent use should be avoided.

1. Koranyi L, Gero L. Influence of diphenylhydantoin on the effect of streptozotocin. *BMJ* (1979) 1, 127.

Sunitinib + Food

Food does not affect the pharmacokinetics of sunitinib.

Clinical evidence, mechanism, importance and management

In a randomised study, 16 healthy subjects were given a single 50-mg dose of sunitinib following a 10 hour fast, or within 30 minutes of a high-fat, high-calorie breakfast. The rate of formation of the active metabolite, SU12662, was decreased resulting in a 23% reduction in its maximum concentration. However as the overall bioavailability of both sunitinib and the active metabolite were unaffected by food, the reduction in the maximum levels of the active metabolite is not thought to be clinically relevant. No difference in adverse effects was reported between the two groups.[1] Sunitinib may therefore be taken with or without food.[2]

2. Sutent (Sunitinib malate). Pfizer Ltd. UK Summary of product characteristics, October 2009.

Sunitinib + Miscellaneous

Ketoconazole increases sunitinib levels, and rifampicin reduces sunitinib levels. Other potent CYP3A4 inhibitors and inducers are expected to interact similarly. Sunitinib may have additive QT prolonging effects if it is given with other drugs that prolong the QT interval.

Clinical evidence, mechanism, importance and management

(a) CYP3A4 inducers

A study in healthy subjects found that **rifampicin** (**rifampin**) reduced the total AUC and maximum plasma concentration of sunitinib and its primary metabolite by 46% and 23%, respectively. Therefore, the manufacturers advise that the concurrent use of sunitinib and CYP3A4 inducers should be avoided.[1,2] They specifically mention **carbamazepine**,[1,2] **dexamethasone**,[1,2] **phenobarbital**,[1,2] **phenytoin**,[1,2] **rifabutin**,[2] **rifapentine**,[2] and **St John's wort**.[1] If concurrent use is necessary, the manufacturers advise increasing the dose of sunitinib in 12.5 mg increments to a maximum of 87.5 mg daily;[1,2] however, the US manufacturer advises that patients should not take **St John's wort** with sunitinib due to the unpredictable nature of the interaction.[2] Note that clinically relevant interactions occurring as a result of dexamethasone inducing CYP3A4 appear rare.

(b) CYP3A4 inhibitors

A study in healthy subjects found that **ketoconazole** increased the total AUC and maximum plasma concentration of sunitinib and its primary metabolite by 51% and 49%, respectively. Sunitinib was given as a single dose (amount not stated). Sunitinib is metabolised by the cytochrome P450 isoenzyme CYP3A4, and its metabolite is further metabolised by CYP3A4. Based on the results seen with ketoconazole, the manufacturers of sunitinib advise avoiding the concurrent use of potent CYP3A4 inhibitors. They specifically mention **atazanavir**,[2] **clarithromycin**,[1,2] **erythromycin**,[1] **grapefruit juice**,[1] **indinavir**,[2] **itraconazole**,[1,2] **nelfinavir**,[2] **ritonavir**,[1,2], **saquinavir**,[2] **telithromycin**,[2] and **voriconazole**.[2]. If concurrent use is necessary, the dose of sunitinib should be reduced to a minimum of 37.5 mg daily, based on tolerability.[1,2]

(c) Drugs that prolong the QT interval

Sunitinib has been shown to prolong the QTc interval in 24 patients, using Fridericia's correction, at twice the usual therapeutic concentrations, but none of these patients were noted to experience a cardiac arrhythmia.[1] Torsades de pointes has been reported in less than 0.1% of patients taking sunitinib.[1,2] The manufacturers advise caution in patients taking sunitinib with antiarrhythmic drugs (presumably class Ia and class III antiarrhythmics). This caution should probably also be extended to other drugs known to prolong the QT interval, see 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290.

Tamoxifen + Acitretin

A patient taking tamoxifen developed bradycardia and a prolonged QT interval when also taking acitretin.

Clinical evidence, mechanism, importance and management

A case report describes a woman taking tamoxifen 20 mg daily who experienced symptomatic bradycardia and QT prolongation 3 weeks after starting acitretin 50 mg daily for 14 days then 30 mg daily during radiation therapy. On stopping the acitretin and later the tamoxifen, her ECG returned to normal and her symptoms resolved.[1] It was suggested that the acitretin might have inhibited the metabolism of tamoxifen, thus increasing the plasma levels of tamoxifen to a level at which QT prolongation became symptomatic. However, this seems unlikely.

The clinical relevance of this isolated report is uncertain. Bear it in mind in the event of an unexpected response to treatment.

Tamoxifen + Aromatase inhibitors

Aminoglutethimide markedly increases tamoxifen clearance and reduces its serum levels. Anastrozole, exemestane and letrozole do not appear to affect tamoxifen levels. Tamoxifen modestly reduces anastrozole and letrozole levels, but it does not alter aminoglutethimide or exemestane levels, or anastrozole, exemestane or letrozole effects.

Clinical evidence

(a) Aminoglutethimide

In 6 menopausal women with breast cancer, aminoglutethimide 250 mg four times daily for 6 weeks markedly reduced the serum levels of tamoxifen 20 to 80 mg daily and most of its metabolites. The clearance of the tamoxifen was increased 3.2-fold and the tamoxifen AUC was reduced by 73% (range 56 to 80%). Tamoxifen did not alter the pharmacokinetics of aminoglutethimide.[1]

(b) Anastrozole

In a double-blind, placebo-controlled study in 34 women with breast cancer, who had been taking tamoxifen 20 mg daily for at least 10 weeks, the addition of anastrozole 1 mg daily for 28 days did not affect the pharmacokinetics of tamoxifen.[2] Although the estradiol suppressant effects of anastrozole 1 mg daily did not appear to be affected by tamoxifen 20 mg daily in two studies,[2,3] in one of these studies, anastrozole levels were decreased by 27% by tamoxifen.[3]

(c) Exemestane

In a study in 32 women who had been taking tamoxifen 20 mg daily for at least 4 months, exemestane 25 mg daily for 8 weeks had no effect on the pharmacokinetics of tamoxifen or the formation of tamoxifen metabolites.[4]

Tamoxifen did not affect the plasma levels of exemestane in a pilot study

in 18 postmenopausal women given exemestane 25 mg daily for 14 days, then exemestane and tamoxifen 20 mg daily for 4 weeks. In addition, tamoxifen did not affect the pharmacodynamics (estrone, estrone sulfate and estradiol suppression) of exemestane.[5]

(d) Letrozole

In 12 women, letrozole levels were reduced by 38% (range 0 to 70%) 6 weeks after tamoxifen 20 mg daily was added to letrozole 2.5 mg daily. This reduction persisted after 4 to 8 months; however, the estradiol suppressant effects of letrozole did not appear to be affected.[6] In 18 women, the pharmacokinetics of tamoxifen 20 mg daily were not affected by letrozole 2.5 mg daily.[7]

Mechanism

It is likely that aminoglutethimide, an enzyme inducer, increases the metabolism of the tamoxifen by the liver, thereby increasing its loss from the body. It is not known how tamoxifen reduces anastrozole and letrozole levels, although it may also be by enzyme induction.[6]

Importance and mechanism

Theoretically, the combination of an oestrogen antagonist such as tamoxifen and an aromatase inhibitor should provide additional benefit in the treatment of hormone-dependent cancers; however, no clinical studies have yet found this to be so. The pharmacokinetic interactions described above may partly explain this. It may be preferable to use these drugs sequentially rather than concurrently.[6]

Tamoxifen and other anti-oestrogens + HRT

In one cohort study, HRT did not increase the risk of recurrent breast cancer in women taking tamoxifen. HRT is reported to oppose the lipid-lowering effects of tamoxifen.

Clinical evidence, mechanism, importance and management

(a) Anti-oestrogenic effects

In a cohort study of the use of HRT in the management of menopausal symptoms in women treated for breast cancer, the use of continuous combined HRT (an oestrogen plus a progestogen) was not associated with an increased risk of breast cancer recurrence in women taking tamoxifen.[1] This is of interest because HRT increases the risk of oestrogen receptor-positive breast cancer and might therefore be expected to oppose the effects of anti-oestrogens such as tamoxifen in the treatment and prevention of breast cancer. For this reason, HRT and other oestrogens are often considered to be contraindicated in women taking anti-oestrogens such as **anastrozole**,[2] **exemestane**,[3,4] **letrozole**, tamoxifen and **toremifene**. The cohort study described[1] suggests that there need not be a complete restriction on their concurrent use, but ideally randomised prospective studies are required to confirm this. Note that adding low-dose tamoxifen to HRT is being tried as a way of reducing the risks of HRT. In one study in 210 healthy postmenopausal women taking HRT for menopausal symptoms, the addition of tamoxifen 5 mg daily appeared to have a favourable effect on markers of breast cancer risk without appreciably increasing menopausal symptoms.[5]

(b) Cardiovascular effects

A large-scale comparative study was undertaken over a 12-month period in groups of women taking tamoxifen alone, HRT alone, or tamoxifen with transdermal HRT to see whether the cardiovascular risk factors (low-density lipoprotein cholesterol, high-density lipoprotein-cholesterol levels, platelet counts) were changed by concurrent use. It was found that the decrease in total and LDL-cholesterol levels due to the tamoxifen was unchanged in current HRT users, but reduced by two-thirds in women taking tamoxifen who then started HRT.[6] In another study in 210 healthy postmenopausal women taking HRT for menopausal symptoms, the addition of low-dose tamoxifen 5 mg daily for 12 months appeared to have a beneficial effect on some markers of cardiovascular disease (C-reactive protein and antithrombin) but not others (lipids and fibrinogen).[5]

Tamoxifen + Medroxyprogesterone

Medroxyprogesterone reduces the levels of tamoxifen and its desmethyl metabolite.

Clinical evidence, mechanism, importance and management

In 20 women with breast cancer taking tamoxifen 20 mg twice daily, the addition of medroxyprogesterone acetate 500 mg twice daily only slightly reduced the tamoxifen serum levels over a 6-month period, but considerably reduced the levels of the desmethyl metabolite of tamoxifen, presumably because of some effect on the metabolism of the tamoxifen by the liver.[1] The clinical importance of this interaction is unclear.

1. Reid AD, Horobin JM, Newman EL, Preece PE. Tamoxifen metabolism is altered by simultaneous administration of medroxyprogesterone acetate in breast cancer patients. *Breast Cancer Res Treat* (1992) 22, 153–6.

Tamoxifen + Rifampicin (Rifampin)

Rifampicin increases the metabolism of tamoxifen.

Clinical evidence, mechanism, importance and management

In 10 healthy *men* rifampicin 600 mg daily for 5 days reduced the AUC of a single 80-mg dose of tamoxifen by 86%, reduced its peak plasma levels by 55%, and reduced its half-life by 44%. Similarly, the AUC of *N*-demethyltamoxifen was reduced by 62%.[1]

It is likely that rifampicin induces the metabolism of tamoxifen by the cytochrome P450 isoenzyme CYP3A4, thereby reducing its levels. These findings suggest that the efficacy of tamoxifen may be reduced by rifampicin. However, there is some *in vitro* evidence that suggests that tamoxifen and rifampicin have additive antineoplastic effects in pancreatic carcinoma cell lines.[2] Also, tamoxifen induces its own metabolism on long-term use.[3] Thus, further study is needed to assess the clinical impact of the long-term concurrent use of these drugs.

Tamoxifen + SSRIs

Paroxetine reduces the metabolism of tamoxifen to one of its active metabolites. One small case-control study found that inhibitors of CYP2D6 such as some SSRIs did not increase the recurrence of breast cancer in tamoxifen users, and another reported the same finding for citalopram or escitalopram.

Clinical evidence

Twelve women taking tamoxifen 20 mg daily were also given **paroxetine** 10 mg daily for 4 weeks, and plasma levels of tamoxifen and its metabolites were measured.[1] Before **paroxetine**, the plasma levels of the 4-hydroxy-*N*-desmethyl-tamoxifen metabolite (endoxifen) were about 12 times higher than those of the 4-hydroxy-tamoxifen metabolite. **Paroxetine** reduced endoxifen levels by 56%, but those of *N*-desmethyl-tamoxifen, and 4-hydroxy-tamoxifen were unchanged. The reduction in endoxifen levels was greatest in those who were CYP2D6 extensive metabolisers (that is, those with normal levels of this isoenzyme). In a further study by the same research group, 80 women starting tamoxifen 20 mg daily had plasma levels of tamoxifen measured after one and 4 months.[2] These were then correlated with CYP2D6 metaboliser phenotype and the concurrent use of CYP2D6 inhibitors (taken by 24 women). In women who were CYP2D6 extensive metabolisers, the use of CYP2D6 inhibitors was associated with a 58% lower endoxifen level, which was substantially lower in those taking **paroxetine** (a moderate CYP2D6 inhibitor), but only slightly reduced by venlafaxine, and intermediate in those taking **sertraline** (a weak CYP2D6 inhibitor).[2]

However, a case-control study of 28 women taking tamoxifen with recurrences of oestrogen receptor positive breast cancer found that there was no difference in the number of women taking CYP2D6 inhibitors (said to be **fluoxetine**, **paroxetine**, **sertraline**) between cases and controls (women taking tamoxifen with no recurrence). Similarly, there were no differences for CYP2C9 inhibitors (said to include **paroxetine** and **sertraline**).[3] Moreover, in another similar case-control study, there was no difference in incidence of use of **citalopram** or its isomer **escitalopram** between 184 women with breast cancer recurrence and 184 matched controls.[4]

Mechanism

Endoxifen and 4-hydroxy-tamoxifen are more active anti-oestrogens than tamoxifen.[1] Tamoxifen is metabolised to 4-hydroxy-tamoxifen and *N*-desmethyl-tamoxifen principally by the cytochrome P450 subfamily CYP3A,[1] although others have found that other isoenzymes are involved,[5] and to endoxifen by CYP2D6.[1] Of the SSRIs, paroxetine and fluoxetine are moderate inhibitors of CYP2D6, whereas citalopram and sertraline only weakly inhibit CYP2D6. However, tamoxifen resistance may be more to do with altered oestrogen receptor sensitivity than reduced levels of tamoxifen metabolites.[3] Further it has been suggested that the plasma levels of tamoxifen and metabolites found in one study[1] would be sufficient to block oestrogen binding to oestrogen receptors so that a decrease in endoxifen levels would not substantially affect anti-oestrogen activity.[6]

Importance and management

Although information is limited, it is established that moderate inhibitors of CYP2D6 such as paroxetine can alter the metabolism of tamoxifen to its active metabolites. However, the effect this has on the clinical efficacy of tamoxifen remains to be established. The case-control studies suggest the effect is not great for SSRIs as a whole or for citalopram or escitalopram (although it should be noted that these are weak inhibitors of CYP2D6). At present, there is insufficient evidence to recommend caution when giving SSRIs with tamoxifen, but further study is clearly needed.

Taxanes + Amifostine

Amifostine had no effect on docetaxel and paclitaxel pharmacokinetics, except in one study which found that amifostine extended paclitaxel plasma circulation time. Amifostine appears not to reduce the toxicity of these taxanes.

Clinical evidence, mechanism, importance and management

In a randomised study, amifostine did not alter the response to, or the pharmacokinetics of, **paclitaxel**, neither did it protect against **paclitaxel**-related neurotoxicity or myelotoxicity.[1] Another study in 8 patients has confirmed that amifostine (750 mg/m^2 as a 15-minute infusion 30 minutes before **paclitaxel**) had no effect on the pharmacokinetics of **paclitaxel** 135 to 200 mg/m^2. Six of the patients were also taking epirubicin and cisplatin.[2] Although the preliminary findings of an earlier study had suggested that pre-treatment with amifostine reduced the AUC of **paclitaxel** by 29%,[3] the full report of this study concluded that amifostine had no clinically relevant effect on **paclitaxel** pharmacokinetics.[4] In a study in which patients were given amifostine 500 mg as an infusion over 15 minutes just before low-dose **paclitaxel** 80 mg/m^2 as a one-hour infusion, amifostine reduced maximum plasma levels by about 20%. The AUC of paclitaxel was not affected, but the paclitaxel plasma circulation time was prolonged.[5]

Amifostine had no effect on the pharmacokinetics of **docetaxel**, and it did not reduce **docetaxel**-induced myelotoxicity.[6]

The finding in two of these studies[1,6] that the toxicity of taxanes was not reduced by amifostine does not support earlier *in vitro* data where amifostine protected normal tissue from **paclitaxel** toxicity.[7]

Most studies show no beneficial or adverse consequences from giving amifostine with the taxanes. Further study is needed to evaluate the possible effects of amifostine on taxane plasma circulation time.

Taxanes + Ciclosporin

Ciclosporin increases the levels of docetaxel and paclitaxel after *oral* administration.

Clinical evidence

(a) Docetaxel

One study found that the bioavailability of docetaxel after oral administration of the intravenous formulation was increased from 8% to 90% by oral ciclosporin 15 mg/kg.[1] In this study, the AUC of ciclosporin was about 50% higher than expected from previously published data, when it was given with oral docetaxel.[2]

(b) Paclitaxel

In 5 patients the plasma levels of paclitaxel were below therapeutic concentrations when they were given an oral dose (intravenous formulation) of paclitaxel 60 mg/m^2 followed by intravenous doses of 175 mg/m^2 for subsequent courses. However, therapeutic levels above 100 micromol/mL (a ninefold increase) were achieved in 9 patients who received the same regimen with ciclosporin 15 mg/kg.[3]

Mechanism

Oral paclitaxel and docetaxel have poor oral bioavailability because of a high affinity for P-glycoprotein in the gastrointestinal tract, and possibly also pre-systemic metabolism by the cytochrome P450 isoenzyme CYP3A4. Ciclosporin is a known P-glycoprotein inhibitor, and thereby increases their oral absorption, and might also interact via CYP3A4. It was suggested that docetaxel might increase ciclosporin levels because they are both substrates for CYP3A4, but this sort of competition for metabolism does not usually result in clinically relevant interactions.

Importance and management

The use of oral docetaxel or paclitaxel is not established, therefore the pharmacokinetic interaction with ciclosporin has little general relevance. The suggestion that oral docetaxel might increase ciclosporin levels requires confirmation in a prospective study.

Taxanes + Cisplatin and other platinum compounds

The toxicity of paclitaxel given with cisplatin appears to be dependent on the order of administration, with more severe myelosuppression occurring if cisplatin is given first. There does not appear to be any sequence dependent interaction for the combination of docetaxel with carboplatin or docetaxel with cisplatin. Paclitaxel may reduce the thrombocytopenia associated with carboplatin. The combination of carboplatin with paclitaxel appears to be more neurotoxic than carboplatin with docetaxel.

Clinical evidence, mechanism, importance and management

(a) Carboplatin

Several clinical studies have found that the severity of thrombocytopenia with the combination of **paclitaxel** and carboplatin was less than that expected with carboplatin alone.[1-5] This does not appear to be due to any changes in carboplatin pharmacokinetics. In one study, patients were given carboplatin as a 30-minute infusion, either alone or immediately after **paclitaxel** 175 mg/m^2 as a 3-hour infusion. It was found that the pharmacokinetics of carboplatin were not significantly affected by **paclitaxel**.[6] Similarly, a pharmacokinetic interaction was not noted when **paclitaxel** and carboplatin were given in either order in another study.[1] Other studies found the AUC of carboplatin to be similar to that predicted, despite the presence of paclitaxel.[2,5] Although one study found the AUC of carboplatin to be about 12% lower in the presence of **paclitaxel**,[4] the same researchers also found that the AUC associated with a 50% decrease in platelet count increased by 68% (i.e. more carboplatin is needed to cause the same degree of thrombocytopenia), which suggests a pharmacodynamic basis for the attenuated toxicity of the combination.[7] Other researchers also reported that the AUC of carboplatin causing a 50% reduction in platelets was about 6.3 mg/mL per minute when given with **paclitaxel** compared with historical data of 4 mg/mL per minute when given alone.[8] Although thrombocytopenia may be lower than expected, myelosuppression (in the form of neutropenia) is a dose-limiting toxicity of the combination of carboplatin and **paclitaxel**.[1-4] In one study, patients given **paclitaxel** with carboplatin experienced significantly greater neurotoxicity than those given **docetaxel** with carboplatin, but the regimens were similar in efficacy.[9] Further, there appear to be no pharmacokinetic interactions between carboplatin and **docetaxel**.[10,11]

(b) Cisplatin

Early studies of the combination of cisplatin and **paclitaxel** found that the degree of myelosuppression was sequence dependent. When cisplatin was given first, a greater degree of myelosuppression was seen.[12] Pharmacokinetic studies suggest that sequence-dependent differences in myelosuppression may be due to a 25% reduction in **paclitaxel** clearance when cisplatin is given first.[12] For this reason, the manufacturers recommend that **paclitaxel** is given before cisplatin.[13,14] There is also some evidence that *myelosuppression* is greater for the combination when **paclitaxel** is given over 24 hours as opposed to 3 hours.[13] When **paclitaxel** is given with cisplatin, *neurotoxicity* (peripheral neuropathy) is common,[13] and there is some evidence that this is more severe if the **paclitaxel** is given over 3 hours as opposed to over 24 hours.[15] In one study,[16] neurotoxicity was unexpectedly severe when **paclitaxel** alone was used in patients who had relapsed after treatment with cisplatin; however, this was not the case in another similar study.[17] There is also some retrospective evidence that the use of paclitaxel with cisplatin may increase *nephrotoxicity* when compared with cisplatin alone.[18]

In contrast to **paclitaxel**, early studies did not reveal any obvious sequence dependent toxicity for the combination of **docetaxel** and cisplatin.[19] In addition, cisplatin did not cause any significant changes in **docetaxel** pharmacokinetics.[19,20] A more recent analysis confirmed that cisplatin was not associated with any changes in docetaxel clearance.[21]

Taxanes + Protease inhibitors

Life-threatening haematological toxicities have been reported in a few patients taking protease inhibitors when given paclitaxel, and a couple of cases have been reported for docetaxel. Nelfinavir and ritonavir appear to inhibit the clearance of paclitaxel, although one case report did not find this. Protease inhibitors are also predicted to inhibit the metabolism of docetaxel.

Clinical evidence

(a) Docetaxel

An HIV-positive 64-year-old woman taking **nelfinavir** was given trastuzumab and docetaxel 36 mg/m^2 for breast cancer. Three days later she was hospitalised with early, severe myelosuppression, which was attributed to an interaction between the nelfinavir and docetaxel, and she died from sepsis.[1]

A 40-year-old HIV-positive man taking **ritonavir**-boosted **lopinavir** developed febrile neutropenia 8 days after a single 25-mg/m^{2}dose of docetaxel; microbiological tests were negative.[2]

(b) Paclitaxel

In a study of paclitaxel 100 mg/m^2 given every 2 weeks for the treatment of HIV-related Kaposi's sarcoma, there was no difference in haematological toxicity (including severe or life-threatening haematological toxicity) or other toxicities between patients taking protease inhibitors (mostly **indinavir**, but also **saquinavir**, **ritonavir**, or **nelfinavir**) and those not taking a protease inhibitor in each of the first 10 cycles. Grade 4 neutropenia was reported in 35% of patients. In this study, of 107 patients, 82 received protease inhibitor-based antiretroviral regimens, and protease inhibitor use had a favourable impact on survival. Nevertheless, paclitaxel-related adverse effects contributed to the deaths of 4 patients, all of whom were receiving multiple other drugs including protease inhibitor-based antiretroviral regimens and co-trimoxazole.[3]

A number of case reports describe unexpected paclitaxel-related toxicity with protease inhibitors. A 39-year-old woman taking **lopinavir** was given carboplatin and paclitaxel 175 mg/m^2 for adenocarcinoma. Five days later she was hospitalised with early, severe myelosuppression, which was attributed to an interaction between lopinavir and paclitaxel, and she later died.[1] In another report, an HIV-positive patient who was taking **ritonavir**-boosted **lopinavir**, delavirdine and didanosine was also given paclitaxel 100 mg/m^2 for Kaposi's sarcoma. Within 3 days he developed myalgia and arthralgia, and 8 days after treatment developed fever, tachycardia and a productive cough. He was treated with antibacterials and G-CSF, but later died. Findings at post mortem included severe oesophageal mucositis, *Streptococcus viridans* pneumonia and a massive saddle embolism (an embolism that sits across two vessels).[4] A second patient taking **indinavir**, **ritonavir**, lamivudine and stavudine developed severe leucopenia and thrombocytopenia within 7 days of being given paclitaxel 100 mg/m^2 for Kaposi's sarcoma, and again after a second course of paclitaxel. Further courses of paclitaxel were tolerated by giving a reduced dose of 60 mg/m^2 of paclitaxel with G-CSF.[4] Similar cases have been reported in 2 patients receiving paclitaxel 100 mg/m^2 every other week for Kaposi's sarcoma when their antiretroviral regimens were changed from **indinavir** or **nelfinavir** with NRTIs to **saquinavir**, delavirdine and didanosine. One of these patients also received intermittent fluconazole.[5]

The UK manufacturer of paclitaxel briefly mentions that studies in patients with Kaposi's sarcoma, who were taking multiple other drugs, suggest that the systemic clearance of paclitaxel was significantly lower in the presence of **nelfinavir** and **ritonavir**, but not with **indinavir**.[6] In one published study, the pharmacokinetics of paclitaxel did not differ in 4 patients receiving **indinavir**, compared with 5 patients not taking protease inhibitors.[7] In contrast, in one case, the clearance of paclitaxel was modestly *increased* and its AUC slightly reduced when it was given with protease inhibitors or nevirapine. This patient, over a number of cycles of paclitaxel, variously received paclitaxel alone, with **ritonavir**, **indinavir**, and two NRTIs, with **ritonavir**, **saquinavir**, and two NRTIs, or with **nevirapine** and two NRTIs. However, the pharmacokinetics of paclitaxel during any of these regimens did not differ from each other and were not significantly different from historical data from HIV-negative patients, and the pharmacokinetics of saquinavir, ritonavir, indinavir or nevirapine also did not differ from historical data.[8]

Mechanism

Uncertain. Paclitaxel is metabolised by the cytochrome P450 isoenzymes CYP2C8 and CYP3A4, whereas docetaxel is principally metabolised by CYP3A4. Protease inhibitors such as ritonavir and indinavir are known to inhibit CYP3A4, which might result in increased taxane levels and toxicity, but, docetaxel is more likely to be affected by this mechanism than paclitaxel. Nevertheless, additional use of a CYP2C8 inhibitor (such as trimethoprim as part of co-trimoxazole, as is common in HIV infection) could result in an interaction with paclitaxel.

Importance and management

Evidence is limited, nevertheless the UK manufacturers advise caution when docetaxel or paclitaxel is given to patients also receiving protease inhibitors.[6] Monitor patients receiving protease inhibitors closely for severe myelosuppression, peripheral neuropathy and mucositis. The interaction may be modified by the presence of other drugs: the NNRTI delavirdine is a known inhibitor of CYP3A4, but nevirapine (and also efavirenz) is usually an *inducer* of CYP3A4 and might therefore *decrease* taxane levels.

Taxanes; Docetaxel + Cannabis

The pharmacokinetics of docetaxel are not altered by a herbal tea containing cannabis.

Clinical evidence

In a study investigating the effects of cannabis on docetaxel pharmacokinetics, 12 patients were given 200 mL of a herbal tea containing cannabis 1 g/L each day for 15 days. The tea was prepared from medicinal-grade cannabis (*Cannabis sativa* L. Flos, Bedrocan®) containing the cannabinoids Δ^9-tetrahydrocannabinol 18% and cannabidiol 0.8%. The clearance and the AUC of docetaxel given on day 12 of the cannabis tea were not significantly altered, when compared with docetaxel given before the cannabis tea. The dose of docetaxel used was 180 mg, reduced to 135 mg in 3 patients who experienced dose-related docetaxel toxicity.

Mechanism

Docetaxel is metabolised by the cytochrome P450 isoenzyme CYP3A4, and this does not appear to be affected by oral cannabis.

Importance and management

This study suggests that cannabis taken orally will not affect the pharmacokinetics of docetaxel. No dose adjustments are likely to be needed if docetaxel is given with cannabis tea.[1] It is not known if this applies to other

drugs metabolised by CYP3A4, or to other preparations and routes of administration of cannabis.

Taxanes; Docetaxel + CYP3A4 inhibitors, inducers or substrates

Ketoconazole (a CYP3A4 inhibitor) halved the clearance of docetaxel, and would be expected to increase the risk of neutropenia. Other CYP3A4 inhibitors would also be expected to raise docetaxel levels, whereas potent CYP3A4 inducers (such as rifampicin (rifampin) and the barbiturates) would be expected to reduce docetaxel levels Prednisone did not alter docetaxel pharmacokinetics.

Clinical evidence, mechanism, importance and management

(a) CYP3A4 inducers

Docetaxel is known to be principally metabolised by CYP3A4. An *in vitro* study found that hyperforin, a constituent of **St John's wort** induced docetaxel metabolism in a dose-dependent manner by 2.6- to 7-fold when compared with controls. In the same study, **rifampicin** (**rifampin**) increased docetaxel metabolism by 6.8- to 32-fold when compared with controls.[1] Similarly, microsomes prepared from the livers of 3 patients taking **pentobarbital** and/or **phenobarbital** are reported to have strikingly induced docetaxel metabolism *in vitro*.[2]

Although there are no clinical data to back up these findings, the fact that the CYP3A4 inhibitor ketoconazole markedly reduced the clearance of docetaxel in patients (see *CYP3A4 inhibitors*, below) suggests that clinically relevant increases in docetaxel clearance are likely with potent inducers of CYP3A4. If potent inducers of CYP3A4 have to be used with docetaxel, it might be prudent to increase the dose of docetaxel, carefully monitoring for toxicity. For a list of CYP3A4 inducers, see 'Table 1.4', (p.6).

(b) CYP3A4 inhibitors

In a study in 7 patients, **ketoconazole**, 200 mg daily for 3 days, started one hour before an infusion of docetaxel 10 mg/m^2, reduced the clearance of docetaxel by 49%, which could increase the risk of neutropenia.[3] This interaction was expected, because, the metabolism of docetaxel is mainly mediated by the cytochrome P450 isoenzyme CYP3A subfamily, which is inhibited by ketoconazole.

The pharmacokinetic interaction with ketoconazole is clinically important. The manufacturers[4,5] advise caution with any potent CYP3A4 inhibitors: the UK manufacturer notes that reduced tolerance may occur even at lower doses of docetaxel.[4] In addition to ketoconazole, the manufacturers specifically name **itraconazole**, **erythromycin**, and **troleandomycin**,[4,5] For a list of CYP3A4 inhibitors, see 'Table 1.4', (p.6).

(c) CYP3A4 substrates

The manufacturers state that *in vitro* studies have shown that the metabolism of docetaxel can be modified by drugs that are metabolised by CYP3A4, and they name **terfenadine**.[4,5] However, pharmacokinetic drug interactions do not usually occur clinically between drugs that just share the same metabolic route.

(d) Prednisone

The manufacturers note that, in a study in patients with metastatic prostatic cancer, **prednisone** did not significantly affect the pharmacokinetics of docetaxel.[4,5] Microsomes prepared from the liver of a single patient who had been taking **prednisone** for a year did not inhibit docetaxel metabolism *in vitro*.[2] It was suggested that prednisone might induce the metabolism of docetaxel by CYP3A4, but this effect was not seen. No clinically relevant pharmacokinetic interaction therefore occurs, and no docetaxel dose adjustment would be expected to be needed on concurrent use.

Taxanes; Docetaxel + Tipifarnib

There was no pharmacokinetic interaction between tipifarnib and docetaxel in one study.

Clinical evidence, mechanism, importance and management

In a dose-finding study, docetaxel was given intravenously on day one of a 21-day cycle and oral tipifarnib 200 or 300 mg twice daily was given for 7 or 14 days starting one hour before docetaxel. There was no change in the pharmacokinetics of docetaxel or tipifarnib when compared with docetaxel given alone on day one or tipifarnib given alone on day 3.[1]

1. Awada A, Zhang S, Gil T, de Valeriola D, Lalami Y, De Porre P, Piccart-Gebhart MJ. A phase I clinical and pharmacokinetic study of tipifarnib in combination with docetaxel in patients with advanced solid malignancies. *Curr Med Res Opin* (2007) 23, 991–1003.

Taxanes; Paclitaxel + Clindamycin

Clindamycin does not appear to alter the pharmacokinetics of paclitaxel to a clinically significant extent.

Clinical evidence, mechanism, importance and management

In a study in 16 patients given intravenous paclitaxel 175 mg/m^2 over 3 hours, intravenous clindamycin 600 mg or 1.2 g over 30 minutes started 2.5 hours after the paclitaxel slightly reduced the $AUC_{0–4}$ and maximum plasma level of paclitaxel by about 11% when compared with placebo.[1]

Paclitaxel is highly bound to alpha-1-acid glycoprotein (AGP), and levels of this protein are increased in some cancers, which might contribute to reduced efficacy. Clindamycin was predicted to displace the AGP binding of paclitaxel, and might therefore alter paclitaxel pharmacokinetics.[1] However, the slight pharmacokinetic interaction seen in this study is not likely to be clinically relevant.

1. Fruscio R, Lissoni AA, Frapolli R, Corso S, Mangioni C, D'Incalci M, Zucchetti M. Clindamycin-paclitaxel pharmacokinetic interaction in ovarian cancer patients. *Cancer Chemother Pharmacol* (2006) 58, 319–25.

Taxanes; Paclitaxel + CYP3A4 inducers

Phenytoin, carbamazepine, and phenobarbital increase the clearance of paclitaxel and increase its maximum tolerated dose. Other CYP3A4 inducers are also predicted to decrease paclitaxel levels.

Clinical evidence, mechanism, importance and management

In a study in patients with glioblastoma multiforme the maximum tolerated dose of paclitaxel was 43% higher in patients receiving enzyme-inducing antiepileptics (**phenytoin**, **carbamazepine**, and **phenobarbital**) than in those not receiving them.[1] Another study in patients with recurrent malignant gliomas reported the same finding: a 50% increase in the maximum tolerated dose coupled with a 104% increase in the plasma clearance of paclitaxel in those taking enzyme-inducing antiepileptics. In addition, this study reported that the dose-limiting toxicity differed: central neurotoxicity in those taking enzyme-inducing antiepileptics and myelosuppression and/or gastrointestinal toxicity in those not taking these antiepileptics.[2]

It is probable that enzyme-inducing antiepileptics increase the metabolism of paclitaxel, and therefore it is likely that patients taking these antiepileptics will require an increase in their paclitaxel dose. The manufacturers suggest caution with all inducers of CYP3A4, and they specifically name the enzyme-inducing antiepileptics **carbamazepine**, **phenobarbital**, and **phenytoin**, and also the NNRTIs, **efavirenz** and **nevirapine**, and **rifampicin** (**rifampin**).[3,4] Close monitoring would be appropriate. Similar caution is probably warranted with **primidone**, which is metabolised to phenobarbital, and **fosphenytoin**, which is metabolised to phenytoin. For a list of inducers of CYP3A4, see 'Table 1.4', (p.6).

Taxanes; Paclitaxel + CYP3A4 inhibitors

In one patient fluconazole reduced the clearance of paclitaxel, whereas in two patients ketoconazole did not affect the pharmacokinetics of paclitaxel. CYP3A4 inhibitors are predicted to increase paclitaxel levels.

Clinical evidence

(a) Fluconazole

The clearance of paclitaxel was assessed in one patient who had taken fluconazole (dose not stated) for 2 weeks up until one day before his first cycle of paclitaxel and then 3 weeks later during his second cycle of paclitaxel. The clearance of paclitaxel was 44% lower after the use of fluconazole, and levels of the metabolites of paclitaxel formed by the action of CYP3A4 were lower.[1]

(b) Ketoconazole

Five women with ovarian cancer were given 3-hour infusions of paclitaxel 175 mg/m^2 every 21 days. In two of them, it was found that when single 200-mg oral doses of ketoconazole were given 3 hours before or 3 hours after the paclitaxel, the serum levels of the paclitaxel and its principal metabolite (6-alpha-hydroxypaclitaxel) remained unchanged.[2]

Mechanism

Paclitaxel is principally metabolised by the cytochrome P450 isoenzyme CYP2C8, and to a lesser extent by CYP3A4. Ketoconazole is a potent inhibitor of CYP3A4, and the findings of the study with this drug suggest that CYP3A4 inhibition alone might not affect paclitaxel levels. However, this study used a single low-dose of ketoconazole given just 3 hours before or after the paclitaxel, and it is possible that a longer course with a higher dose might have interacted. The data from the single case with fluconazole, which is a modest inhibitor of CYP3A4, suggest that CYP3A4 might be important, at least in some individuals.

Importance and management

Information is limited and not conclusive. Based on the study with ketoconazole, the UK manufacturer states that ketoconazole can be given without any paclitaxel dose adjustments.[3] However, they still continue to advise caution with other drugs that are inhibitors of CYP3A4, as does the US manufacturer.[4] They specifically name **erythromycin** and **fluoxetine** (but note that fluoxetine is usually considered a weak inhibitor of CYP3A4). Until more is known, some caution would appear to be appropriate with all moderate to potent CYP3A4 inhibitors. Note that interactions have, on occasion, been seen with the protease inhibitors (see 'Taxanes + Protease inhibitors', p.769), which are known potent CYP3A4 inhibitors. For a list of CYP3A4 inhibitors, see 'Table 1.4', (p.6).

Taxanes; Paclitaxel + Miscellaneous

***In vitro* studies with human liver tissue suggest that no metabolic interactions are likely to occur between paclitaxel and cimetidine, dexamethasone or diphenhydramine. *In vitro* data also suggest that *Cremophor* may inhibit the intracellular uptake and metabolism of paclitaxel. CYP2C8 inhibitors (e.g. gemfibrozil) are predicted to raise paclitaxel levels.**

Clinical evidence, mechanism, importance and management

(a) Cimetidine, Dexamethasone, Diphenhydramine

On the basis of an *in vitro* study using human liver slices and human liver microsomes,[1] it has been concluded that the metabolism of paclitaxel is unlikely to be altered by cimetidine, dexamethasone or diphenhydramine, all of which are frequently given to prevent the hypersensitivity reactions associated with paclitaxel or its vehicle, see *Cremophor*, below. The UK manufacturers say that paclitaxel clearance in patients is not affected by cimetidine premedication.[2] Nevertheless, some authors[3] have advised caution when using cimetidine with paclitaxel, because they have found profound neutropenia, which they attributed to a possible pharmacokinetic interaction. Cimetidine is known to inhibit the cytochrome P450 isoenzyme CYP3A4, which is responsible, in part, for the metabolism of paclitaxel. However, cimetidine is a weak inhibitor of CYP3A4 (and some other isoenzymes not involved in paclitaxel metabolism), and an interaction with CYP3A4 inhibitors is not established (see 'Taxanes; Paclitaxel + CYP3A4 inhibitors', p.771. A pharmacokinetic interaction between cimetidine and paclitaxel is therefore seems unlikely.

(b) Cremophor

In vitro, *Cremophor* was found to inhibit the metabolism of paclitaxel in human liver microsomes,[1] which might be expected to increase its toxicity. The concentration used in the *in vitro* study may be achieved clinically in patients given paclitaxel with *Cremophor* as the vehicle.[4] This may be worth bearing in mind if other drugs formulated with *Cremophor* are given with paclitaxel.

(c) CYP2C8 inhibitors

Although there do not appear to be any clinical pharmacokinetic data on the use of paclitaxel with CYP2C8 inhibitors, the manufacturers advise caution,[2,5] presumably because of the possibility of raised paclitaxel levels. They specifically name **gemfibrozil**. Note that **trimethoprim** is also a clinically relevant CYP2C8 inhibitor.

Taxanes; Paclitaxel + Quinine

One study found that quinine markedly reduced the plasma levels of paclitaxel.

Clinical evidence, mechanism, importance and management

In a study in 12 patients, paclitaxel levels at the end of a 20 to 24-hour infusion of paclitaxel 120 mg/m^2 given on day 2 were 40% lower when given with oral quinine 400 mg three times daily for 4 days started on day one. In one patient the paclitaxel levels were undetectable at this time point. Paclitaxel clearance was estimated to have increased twofold, but the reasons for this are unclear. Quinine was used as a chemosensitiser in this study, on the basis of *in vitro* findings, but was not very effective.[1] The pharmacokinetic interaction was unexpected, and its clinical relevance is unclear. Bear the possibility of an interaction in mind in the unlikely event that quinine is used with paclitaxel.

Taxanes; Paclitaxel + Verapamil

High-dose *R*-verapamil reduced the clearance of paclitaxel and increased the incidence of haematological toxicity.

Clinical evidence

In a crossover study in which 24 patients were given paclitaxel up to 200 mg/m^2 over 3 hours every 21 days alone, or with high-dose oral

R-verapamil (up to 250 mg/m^2 every 4 hours for 12 doses starting 24 hours before the paclitaxel), haematological toxicity was greater in those cycles when *R*-verapamil had also been given. In a subset of 6 patients, the pharmacokinetics of paclitaxel were assessed: the AUC and maximum plasma level of paclitaxel were increased by 90% and 122%, respectively, when *R*-verapamil was also given.[1]

Mechanism

Paclitaxel is a substrate of P-glycoprotein. It seems likely that *R*-verapamil inhibits the efflux of paclitaxel by this transporter protein.[1]

Importance and management

The clinical significance of this finding is unclear as the use of just the *R*-isomer of verapamil in such high doses is generally limited to investigational use only. However, bear in mind the possibility that verapamil might modestly increase paclitaxel levels.

Temozolomide + Miscellaneous

Valproic acid may slightly reduce the clearance of temozolomide. Carbamazepine, H_2-receptor antagonists, dexamethasone, phenobarbital, phenytoin, prochlorperazine and ondansetron did not affect the clearance of temozolomide. Food, but not ranitidine, slightly reduces the extent of absorption of temozolomide.

Clinical evidence, mechanism, importance and management

(a) Antiepileptics

The manufacturer notes that the concurrent use of **carbamazepine**, **dexamethasone**, **H_2-receptor antagonists**, **ondansetron**, **phenobarbital**, **phenytoin** or **prochlorperazine** did not affect the clearance of temozolomide, based on an analysis of population pharmacokinetics from phase II studies.[1,2] **Valproic acid** modestly reduces the oral clearance of temozolomide by 5%, however, the manufacturer states that clinical relevance of this small reduction is unclear.[2]

(b) Food

The manufacturer notes that food slightly reduces the temozolomide AUC by 9% and maximum plasma concentration by 33%. They recommend that it should be given without food.[1,2]

(c) Ranitidine

In a study in 12 patients given temozolomide 150 mg/m^2 daily, ranitidine 150 mg twice daily had no effect on the absorption or plasma pharmacokinetics of temozolomide, or that of its active metabolite.[3]

Teniposide + Antiepileptics; Enzyme-inducing

Carbamazepine, phenytoin and phenobarbital markedly increase the clearance of teniposide. A reduction in its effects has been noted in B-lineage leukaemia.

Clinical evidence, mechanism, importance and management

In 6 children with acute lymphocytic leukaemia the clearance of teniposide was increased two- to threefold (from 13 to 32 mL/minute per m^1) when they also took **phenytoin** or **phenobarbital**.[1] Another patient had a twofold increase in teniposide clearance when **carbamazepine** was given.[1] In a retrospective survey, long-term antiepileptic use (**phenytoin**, **phenobarbital**, **carbamazepine**, or a combination) was associated with worse event-free survival, and greater haematological relapse and CNS relapse in children receiving chemotherapy for B-lineage acute lymphoblastic leukaemia. In this study, faster clearance of teniposide was found in those receiving the antiepileptics.[2]

These effects probably occur because these antiepileptics are potent liver enzyme inducers, which may increase the metabolism of teniposide by the liver and thereby reduce its levels. The authors of these reports therefore conclude that an increased dose of teniposide will be needed in the presence of these antiepileptics to achieve systemic exposure to the drug comparable to that achievable in their absence.[1] It may be preferable to use alternative antiepileptics (that are not enzyme inducers) in patients requiring teniposide.[2] Note that **primidone** is metabolised to phenobarbital, and **fosphenytoin** is metabolised to phenytoin, and therefore these drugs may be expected to interact similarly.

Thalidomide + Doxorubicin

The concurrent use of thalidomide and chemotherapy regimens containing doxorubicin appears to be associated with an increased risk of deep-vein thrombosis in patients with multiple myeloma.

Clinical evidence, mechanism, importance and management

In a randomised study in 100 patients with newly diagnosed multiple myeloma given induction chemotherapy (dexamethasone, vincristine, doxorubicin, cyclophosphamide, etoposide and cisplatin) with or without thalidomide, deep-vein thrombosis developed in 14 of the 50 patients (28%) given thalidomide compared with 2 of 50 patients (4%) not given thalidomide.[1] In a further study by the same authors, 232 patients with multiple myeloma were given DT-PACE (dexamethasone, thalidomide, cisplatin, doxorubicin, cyclophosphamide, etoposide) if they had preceding standard dose therapy but no previous autotransplantation, or with DCEP-T (dexamethasone, cyclophosphamide, etoposide, cisplatin, thalidomide) for relapse after transplantation. Deep-vein thrombosis developed in 31 of 192 patients (16%) given the doxorubicin-containing regimen (DT-PACE) and only 1 of 40 (2.5%) given the regimen without doxorubicin (DCEP-T).[2]

In patients with multiple myeloma, the risk of deep-vein thrombosis appears to be increased when thalidomide is given with combination chemotherapy containing doxorubicin. Various strategies are recommended to reduce this risk of thrombosis including low-molecular-weight heparin, warfarin, and low-dose aspirin.[3]

Thalidomide + Epoetins

A higher than expected incidence of thromboembolic events occurred in one study in patients with myelodysplastic syndrome treated with thalidomide and darbepoetin alfa; however, this was not noted in a retrospective analysis of patients with multiple myeloma given thalidomide with epoetin, although cases of DVT have been reported with epoetin alfa and thalidomide.

Clinical evidence

A phase II study to investigate the efficacy and tolerability of the concurrent use of thalidomide 100 mg daily and subcutaneous **darbepoetin alfa** 2.25 micrograms/kg per week in patients with myelodysplastic syndrome was discontinued because of an unexpectedly high incidence of thromboembolic events. Of the first 7 patients enrolled in the study, two devel-

oped deep-vein thrombosis (DVT) and one died of pulmonary embolism.[1]

In contrast to these findings, in a retrospective analysis of patients with multiple myeloma who had been taking thalidomide, thromboses were reported in 4 of 49 patients (8.1%) also given **epoetin** and in 14 of 150 patients not given **epoetin** (9.3%). These results suggest that epoetin might not increase the risk of thrombosis in patients with multiple myeloma receiving thalidomide.[2] Nevertheless, two patients with myeloid cancers who had been taking thalidomide and dexamethasone for 5 to 6 months, developed DVTs 4 and 6 weeks, respectively, after starting treatment with **epoetin alfa** for anaemia.[3]

Mechanism

Both thalidomide and epoetins increase the risk of thromboembolism, and the risk might be increased with concurrent use. There seems to be a particular risk of thrombosis when using epoetins in patients with cancer.[4]

Importance and management

There is little information on the possible increased risk of thrombosis if epoetins are used with thalidomide in myeloid cancers. The authors of the first study recommended careful monitoring and possibly thromboprophylaxis (heparin or warfarin) in patients with myelodysplastic syndrome given both thalidomide and epoetin. This seems prudent.

Thalidomide + Interferon alfa

Severe bone marrow depression was reported in a patient given thalidomide with peginterferon alfa.

Clinical evidence, mechanism, importance and management

A patient with multiple myeloma in remission after an autologous stem cell transplantation was given thalidomide 200 mg daily. Five weeks after also being given **peginterferon alfa-2b**, severe reversible bone marrow hypoplasia developed. **Peginterferon** was probably responsible for the bone marrow depression. However, thalidomide may also cause bone marrow depression and it was suggested that the severe suppression in this patient may have been due to the combined effects of the **peginterferon** and thalidomide.[1] This should be considered in patients given both drugs.

Thalidomide + Miscellaneous

Rifampicin and phenobarbital did not appear to alter thalidomide clearance in one study. Thalidomide increases the sedative effect of other CNS depressants. Thalidomide does not alter the pharmacokinetics of digoxin, although additive bradycardia is expected with other drugs that slow heart rate. Peripheral neuropathy is common with thalidomide, and other drugs that have this effect might have an additive effect with thalidomide.

Clinical evidence, mechanism, importance and management

(a) CNS depressants

Animal studies have shown an increase in CNS depressant activity when thalidomide was given with **alcohol**, **barbiturates**, **chlorpromazine** and **reserpine**.[1] In clinical use, thalidomide frequently causes drowsiness, and the manufacturers advise caution with these drugs[2,3] and also with **anxiolytics**, **hypnotics**, **antipsychotics**, **antihistamines**, and **opioids**, because of the possibility of enhanced sedation.[3]

(b) Cytochrome P450 isoenzyme inducers

There was no clear relationship between thalidomide clearance and the concurrent use of enzyme inducers such as **rifampicin** (**rifampin**), or **phenobarbital** in a study in patients with glioma.[4] For the possible additive CNS depressant effect with barbiturates, see *CNS depressants*, above.

(c) Digoxin

In a study in 18 healthy subjects, multiple-doses of thalidomide 200 mg did not affect the pharmacokinetics of a single 500-microgram dose of digoxin, nor were the pharmacokinetics of thalidomide altered by this dose of digoxin.[3] However, see also *Other drugs*, below.

(d) Other drugs

Thalidomide can cause clinically relevant bradycardia, and patients should be monitored for this effect, which may require a dose reduction or discontinuation of thalidomide.[3] The UK manufacturer of thalidomide therefore cautions its use with other drugs that can cause bradycardia, and they name drugs that are known to induce torsade de pointes (unspecified), **beta blockers** and **anticholinesterases**.

Thalidomide very commonly causes peripheral neuropathy, which can be severe, and may require dose modification.[2,3] Because of this, the manufacturers recommend caution with other drugs that can cause peripheral neuropathy,[2,3] and the UK manufacturer specifically mentions **vincristine** and **bortezomib**.[3] However, in a review of 24 patients with multiple myeloma who had received **bortezomib** after relapse following allografting, the incidence of severe peripheral neuropathy was far higher than usually seen in non-transplant patients. Fourteen patients developed neurotoxicity; in 7 patients it was severe and 6 patients required treatment discontinuation as the neurotoxicity did not resolve following a **bortezomib** dose reduction. In an analysis of possible risk factors, previous treatment with thalidomide use (a drug with known potential to cause peripheral neuropathy) was not found to increase the risk of peripheral neuropathy.[5]

Thiopurines + Allopurinol

The haematological effects of azathioprine and mercaptopurine are markedly increased by allopurinol.

Clinical evidence

(a) Azathioprine

A patient taking allopurinol 300 mg daily for gout was also given azathioprine 100 mg daily to treat autoimmune haemolytic anaemia. Within 10 weeks his platelet count fell from 236×10^9/L to 45×10^9/L, his white cell count fell from 9.4×10^9/L to 0.8×10^9/L and his haemoglobin concentration fell from 11.5 g/dL to 5.3 g/dL.[1]

A number of other reports similarly describe reversible bone marrow toxicity associated with anaemia, pancytopenia, leucocytopenia and thrombocytopenia in patients given azathioprine with allopurinol,[1-9] and in one case a fatality occurred as a result of neutropenia and septicaemia.[8] In a retrospective analysis of 24 patients who had received both azathioprine and allopurinol, 11 developed leucopenia, 7 developed moderate anaemia, and 5 developed thrombocytopenia. Only 14 of the patients had received a greater than two-thirds reduction in their azathioprine dose when allopurinol was started, but despite this, some of these patients still developed haematological toxicity.[10]

(b) Mercaptopurine

In early studies, allopurinol 200 to 300 mg reduced the effective dose of mercaptopurine by about fourfold in 7 patients with chronic granulocytic leukaemia or variants.[11]

Profound pancytopenia developed in the first 3 of 13 children given mercaptopurine 2.5 mg/kg daily and allopurinol 10 mg/kg daily, but when the mercaptopurine dose was halved, toxicity was manageable in the remaining 9 children.[12] Severe leucopenia and thrombocytopenia occurred in another patient given allopurinol with standard-dose mercaptopurine.[13]

A pharmacokinetic study found that allopurinol caused a fivefold increase in the AUC and in peak plasma levels of mercaptopurine when the mercaptopurine was given *orally*. The bioavailability of mercaptopurine increased from 12% to 59%.[14] This did not occur when the mercaptopurine was given *intravenously*.[14,15]

Mechanism

Azathioprine is firstly metabolised in the liver to mercaptopurine and then enzymatically oxidised in the liver and intestinal wall by xanthine oxidase to an inactive compound (6-thiouric acid), which is excreted. Allopurinol inhibits first-pass metabolism by xanthine oxidase so that mercaptopurine accumulates, blood levels rise and its toxic effects develop (leucopenia, thrombocytopenia, etc.).

Importance and management

A well documented, well established, clinically important and potentially life-threatening interaction. The doses of azathioprine and mercaptopurine should be reduced by about two-thirds or three-quarters when given orally to reduce the development of toxicity. Despite taking these precautions toxicity may still be seen[10] and very close haematological monitoring is advisable if concurrent use is necessary. On the basis of two studies[14,15] it would seem that this precaution might not be necessary if mercaptopurine is given intravenously, but note that parenteral mercaptopurine is not routinely available.

Thiopurines + 5-Aminosalicylates

The haematological toxicity of azathioprine and mercaptopurine may be increased by mesalazine, olsalazine or sulfasalazine. Balsalazide may be less likely to interact but this requires confirmation.

Clinical evidence

(a) Balsalazide

The frequency of clinically important neutropenia did not increase in 10 patients with Crohn's disease receiving **azathioprine** or **mercaptopurine** when they were given balsalazide 6.75 g daily for 8 weeks, but increases in whole blood 6-thioguanine nucleotide concentrations were seen.[1]

(b) Mesalazine

A 13-year-old boy with severe ulcerative pancolitis and cholangitis was given prednisone 60 mg daily, ursodeoxycholic acid 15 mg/kg daily and mesalazine 25 mg/kg daily. When **azathioprine** 2 mg/kg daily was added in an attempt to reduce the prednisone dose, he developed marked and prolonged **azathioprine** toxicity (severe pancytopenia), which was attributed to an interaction resulting from abnormally high, persistent levels of an **azathioprine** metabolite.[2] In another study, there was a trend towards an increased rate of clinically important neutropenia in 10 patients with Crohn's disease receiving **azathioprine** or **mercaptopurine** when they were given mesalazine 4 g daily for 8 weeks. One patient was withdrawn from the study after 6 weeks because of leucopenia. Increases in whole blood 6-thioguanine nucleotide concentrations were also seen.[1]

(c) Olsalazine

A case report describes a patient with Crohn's disease who had two separate episodes of bone marrow suppression while receiving **mercaptopurine** 50 to 75 mg daily and olsalazine 1 to 1.75 g daily. It was found necessary to reduce the **mercaptopurine** dose on the first occasion and to withdraw both drugs on the second.[3]

(d) Sulfasalazine

A decrease in leucocyte counts was seen in 4 patients taking **azathioprine** (2.1 to 3.3 mg/kg daily) after the addition of sulfasalazine. This lasted several months in one patient, and was transitory in two. The fourth patient developed agranulocytosis after 4 days, which required treatment discontinuation. When the drugs were later resumed at a lower dose, no reduction in leucocyte counts occurred.[4] Another report describes 38 patients taking **azathioprine** (mean dose 92.8 mg) and sulfasalazine (mean dose 2.1 g) for rheumatoid or psoriatic arthritis. Some patients did well, but in general the combination was poorly tolerated, and only 45% continued treatment after 6 months. Reasons for withdrawal included rash (3 patients), gastrointestinal upset (7 patients), leucopenia (one patient) and nephrotic syndrome (one patient).[5] In another study, there was a trend towards an increased rate of clinically important neutropenia in 12 patients with Crohn's disease receiving **azathioprine** or **mercaptopurine** when they were given sulfasalazine 4 g daily for 8 weeks. One patient withdrew from the study after 6 weeks because of leucopenia. Increases in whole blood 6-thioguanine nucleotide concentrations were also found.[1]

Mechanism

The metabolism of azathioprine and mercaptopurine depends on *S*-methylation by thiopurine methyltransferase (TPMT) and oxidation by xanthine oxidase. An *in vitro* study using recombinant TPMT found that both sulfasalazine and its metabolites inhibit the activity of TPMT.[6] Therefore if these drugs are used together, the clearance of azathioprine and mercaptopurine may be reduced by the sulfasalazine, resulting in an increase in their toxicity (there is only a small margin between their therapeutic and toxic levels). About 11% of patients may be at particular risk because of genetic polymorphism whereby they have TPMT enzyme activity that is only half that of the rest of the population.[1,6] *In vitro* studies confirmed that mesalazine,[7] olsalazine and its metabolite olsalazine-*O*-sulfate[3,7] and balsalazide[7] are inhibitors of recombinant TPMT. In patients, increased levels of 6-thioguanine nucleotide are probably due to inhibition of TPMT.[1] It is suggested that the reported *in vitro* concentration (IC_{50}) of balsalazide required to halve the TPMT activity is about 1000 times higher than peak plasma levels after therapeutic doses and therefore an interaction is unlikely. Mesalazine and olsalazine peak levels may also be less than the IC_{50} concentrations, but peak plasma levels of sulfasalazine are close to IC_{50} concentrations.[8]

Importance and management

These reports underline the importance of taking particular care if azathioprine or mercaptopurine is used with balsalazide, mesalazine, olsalazine, or sulfasalazine. Balsalazide may be less likely to interact, but this requires confirmation.[1] Some have postulated that the interaction may actually benefit patients, as increased whole blood 6-thioguanine nucleotide or mild leucopenia is associated with a greater chance of remission in those taking azathioprine or mercaptopurine.[1,9] Additional monitoring of white blood cell counts is required when starting the combination.[9]

Thiopurines; Azathioprine + Co-trimoxazole or Trimethoprim

There is some evidence that the risk of haematological toxicity may be increased in renal transplant patients taking azathioprine if they are given co-trimoxazole or trimethoprim, particularly for extended periods. However, other evidence suggests that the drugs may be used together safely, and the combination is commonly used in practice.

Clinical evidence

The observation that haematological toxicity often seemed to occur in renal transplant patients given azathioprine and co-trimoxazole, prompted a retrospective survey of the records of 40 patients. It was found that there was no difference in the incidence of thrombocytopenia and neutropenia in those given azathioprine, either alone, or with co-trimoxazole, (trimethoprim 160 to 320 mg and sulfamethoxazole 800 mg to 1.6 g daily) for a short time (6 to 16 days), but a significant increase occurred in the incidence and duration of thrombocytopenia and neutropenia if both drugs were given together for 22 days or more.[1]

Another report describes a marked fall in white cell counts in renal transplant recipients during the concurrent use of azathioprine with either co-trimoxazole (described as frequent) or trimethoprim (3 cases).[2] In one case the fall occurred within 5 days and was managed by temporarily withdrawing the azathioprine and reducing the trimethoprim dose from 300 mg daily to 100 mg daily.[2]

Conversely, in an early study, there was no difference in the incidence of leucopenia when renal transplant recipients were given co-trimoxazole or other antibacterials.[3] Similarly, in 252 renal transplant patients given continuous prophylaxis with co-trimoxazole or **sulfafurazole** for 12 to 25 months, toxicity was minimal: leucopenia occurred only occasionally and was reversed by temporarily withholding azathioprine. This was needed in a similar number of patients with each antibacterial.[4] In another placebo-controlled study in heart transplant recipients taking triple therapy including azathioprine; co-trimoxazole prophylaxis for 4 months did not alter total white blood cell counts: leucopenia did not occur and no change in the dose of azathioprine was required.[5]

Mechanism

Not understood. It seems possible that the bone marrow depressant effects of azathioprine, trimethoprim and sulfamethoxazole may be additive. In addition, in some patients impaired renal function may allow co-trimoxazole levels to become elevated, and haemodialysis may deplete folate levels, which could exacerbate the anti-folate effects of the co-trimoxazole. Trimethoprim has been shown to inhibit renal tubular creatinine secretion.[6]

Importance and management

Information appears to be limited and the interaction is not established. Although there is some evidence of an increased risk of haematological toxicity in renal transplant patients taking azathioprine if they are given co-trimoxazole or trimethoprim, this has not been shown in all studies. Two of the early studies suggested that the incidence of leucopenia with co-trimoxazole was related to the time after transplantation, and it improved if the dose of azathioprine was decreased or temporarily suspended.[3,7] Prophylaxis with co-trimoxazole post-transplant is commonly used in some centres.

Thiopurines; Azathioprine + Myelosuppressive drugs

Azathioprine commonly causes myelosuppression and this effect might be enhanced by other myelosuppressive drugs.

Clinical evidence, mechanism, importance and management

Azathioprine commonly causes dose-related myelosuppression, and full blood counts should be regularly monitored when this drug is used. The manufacturers note that the concurrent use of other drugs that may have a myelosuppressive effect might lead to exaggerated leucopenia.[1,2] The UK manufacturer specifically states that, where possible such use should be avoided, and they name **penicillamine** as an example.[1] Note that the myelosuppressive effect of **penicillamine** mainly results in thrombocytopenia and less frequently neutropenia, and its use also requires monitoring of full blood counts. This advice therefore seems prudent.

The UK manufacturer also says that it has been suggested that **cimetidine** and **indometacin** may have myelosuppressive effects, which may be enhanced by azathioprine.[1] Leucopenia is a rare adverse effect of cimetidine and an infrequent adverse effect of indometacin. However, there appear to be no published clinical reports of any interactions of these drugs with azathioprine. In one *animal* study, cimetidine did *not* increase the haematopoietic toxicity of azathioprine or delay bone marrow recovery after cimetidine.[3] Whether there is a real additional risk from using drugs such as cimetidine and indometacin with azathioprine is unknown, but the likelihood seems small.

Thiopurines; Mercaptopurine + Doxorubicin

One study suggested that the hepatotoxicity of *intravenous* mercaptopurine can be increased by doxorubicin.

Clinical evidence, mechanism, importance and management

One report describes 11 patients who developed liver damage after being given *intravenous* mercaptopurine 500 mg/m^2 daily for 5 days, with doxorubicin 50 mg/m^2 on the first day. The frequency and severity of liver damage was greater than the authors had previously seen with mercaptopurine alone. They suggested that doxorubicin potentiated the hepatotoxicity of mercaptopurine.[1] Mercaptopurine is no longer commonly used *intravenously*, and the dose given in this study is much higher than that currently used *orally*. The general applicability of this study is therefore unknown.

Thiopurines; Mercaptopurine + Food

Some studies have shown that breakfast, usually including milk, may modestly reduce and delay the absorption of mercaptopurine, whereas others have not found this effect. A case report describes increased mercaptopurine dose requirements when it was taken with milk.

Clinical evidence

A study in 17 children with acute lymphoblastic leukaemia found that the absorption of mercaptopurine 5 mg/m^2 was reduced if it was given 15 minutes after a standard breakfast of 250 mL of **milk** and 50 g of biscuits, when compared with fasting. The AUC was reduced by 26%, the maximum plasma levels by 36%, and the time to maximum plasma levels delayed from 1.2 hours to 2.3 hours.[1] Some individuals had more marked effects than others; 11 subjects had a decrease in absorption, whereas 6 subjects had no change or a small increase.[1] Similarly, in another study in 7 children, peak plasma mercaptopurine levels were lower and were delayed when it was given with a standard breakfast (orange juice, cereal, toast) compared with those after an overnight fast.[2] Moreover, a case report describes a 4-year-old child who required a 60% increase in his calculated dose of mercaptopurine when he took it with **milk**, but no change when he took it with water lightly flavoured with fruit squash.[3]

In contrast, in a study in 10 children, mercaptopurine levels varied widely between individuals and there was no clear effect of food. The peak plasma levels were increased only 11% (range 67% decrease to 81% increase), and the AUC was increased by a mean of 3% (range 53% decrease to 86% increase) when given in the fasting state compared with after breakfast (not standardised, but consisting mainly of milk or yogurt plus cereal, or sandwiches).[4] Similarly, a further study in 15 children taking mercaptopurine found that there was a non-significant 20 to 22% decrease in the maximum plasma levels or AUC of mercaptopurine when it was taken after a standardised breakfast (milk, bread, ham, cheese) compared with after a 12 hour fast, and there was a delay in reaching the maximum plasma levels when mercaptopurine was taken after food. Again, there was wide inter-individual variation in these parameters.[5]

Mechanism

Not understood. Delayed gastric emptying is a suggested reason.[1] Alternatively, it has been suggested that xanthine oxidases in milk might inactivate mercaptopurine.[6]

Importance and management

Mercaptopurine levels vary widely, and it is not established whether food or milk is a clear factor in this variation. Some have suggested that mercaptopurine should be taken before food or without milk to optimise its absorption,[2,3,6] and the UK Acute Lymphoblastic Leukaemia (UK ALL) study requires doses to be taken at least one hour after the evening meal without milk products,[7] whereas others do not consider the evidence sufficient to make a recommendation.[4] Note that the manufacturers of mercaptopurine do not include any specific instructions regarding food or milk intake.[8,9]

Thiopurines; Mercaptopurine + Methotrexate

Methotrexate can increase the bioavailability of mercaptopurine, but the contribution this makes to their synergistic action in the maintenance of remission of leukaemia is unclear.

Clinical evidence

(a) Oral mercaptopurine

In 14 children receiving maintenance therapy for leukaemia, oral low-dose methotrexate 20 mg/m^2 increased the AUC and peak plasma levels of mercaptopurine 75 mg/m^2 by 31% and 26%, respectively.[1] In another study, 10 children with acute lymphoblastic leukaemia in remission were given mercaptopurine 25 mg/m^2 daily and intravenous infusions of high-dose methotrexate 2 or 5 g/m^2 every other week for consolidation therapy. It was found that methotrexate 2 or 5 g/m^2 increased the AUC of mercaptopurine by 69% and 93%, respectively, and raised the maximum serum levels of mercaptopurine by 108% and 121%, respectively.[2] Nevertheless, the risk of relapse of leukaemia did not appear to be related to the pharmacokinetics of methotrexate or mercaptopurine, which showed considerable inter- and intrapatient variability, in one study in children.[3]

(b) Intravenous mercaptopurine

One report suggests that, with high dose induction therapy, the combination of mercaptopurine and methotrexate may not be synergistic. In this study, children with newly diagnosed acute lymphoblastic leukaemia were given *intravenous* mercaptopurine 1 g/m^2 over 6 hours, either alone, or after low-dose oral methotrexate (6 doses of 30 mg/m^2), or high-dose intravenous methotrexate (1 g/m^2 over 24 hours). Methotrexate increased the plasma levels of mercaptopurine, but, unexpectedly, it was also found that thioguanine nucleotide levels in bone marrow leukaemic lymphoblasts were 13-fold lower during methotrexate use. It is not known whether methotrexate would reduce thiopurine metabolite levels in leukaemic lymphoblasts when mercaptopurine is given as continuation therapy where the leukaemic burden is less substantial than in newly diagnosed cases. In addition, the changes in leukocyte counts over 3 days suggested that mercaptopurine alone had little effect, and although methotrexate caused a reduction in intracellular thiopurine metabolite levels, it produced a greater decrease in leukocytes than mercaptopurine alone. It was concluded that, in this particular study, the antileukaemic effect was primarily due to methotrexate.[4]

Mechanism

The reasons for the pharmacokinetic interaction are not understood, although it is thought that methotrexate is a xanthine oxidase inhibitor, which may therefore inhibit the metabolism of mercaptopurine.[1,2,5]

Importance and management

The combination of methotrexate and mercaptopurine has an established place in the maintenance therapy of leukaemia once it is in remission after successful induction and consolidation therapy. The pharmacokinetic findings may be part of the explanation for the benefits of combined use, although biochemical mechanisms may be more important.[5]

Thiotepa + Phenytoin

The metabolism of thiotepa to its active metabolite, TEPA (triethylenephosphamide), was increased by phenytoin in one patient.

Clinical evidence

A 42-year-old man received two courses of CTC (high-dose cyclophosphamide, thiotepa and carboplatin), with phenytoin 150 mg twice daily started 5 days before the second course, for seizures. When compared with the first course, phenytoin caused a 115% increase in the AUC of TEPA (triethylenephosphamide), the active metabolite of thiotepa, and a 29% reduction in the AUC of thiotepa. On the basis of these data, the dose of thiotepa was reduced by about one-third for the remaining 2 days of the course, and this resulted in plasma levels within the therapeutic range.[1]

Mechanism

Phenytoin probably induces the cytochrome P450 isoenzyme CYP2B6, which is involved in the metabolism of thiotepa.

Importance and management

This appears to be the only case report of such an interaction, but it would seem prudent to monitor the effects of concurrent use, and reduce the dose of thiotepa if necessary.

1. de Jonge ME, Huitema ADR, van Dam SM, Beijnen JH, Rodenhuis S. Significant induction of cyclophosphamide and thiotepa metabolism by phenytoin. *Cancer Chemother Pharmacol* (2005) 55, 507–510.

Topotecan + Amifostine

In 10 women with ovarian cancer, amifostine, given daily for 5 days before topotecan, did not significantly affect the pharmacokinetics of topotecan.[1]

1. Zackrisson A-L, Malmström H, Peterson C. No evidence that amifostine influences the plasma pharmacokinetics of topotecan in ovarian cancer patients. *Eur J Clin Pharmacol* (2002) 58, 103–8.

Topotecan + Amrubicin

A study in which 9 patients were given topotecan as an infusion on days one to 5 of a 4-week cycle, with amrubicin on days 3 to 5 of each cycle, found that amrubicin did not affect the pharmacokinetics of topotecan.[1]

1. Shibayama T, Hotta K, Takigawa N, Tada A, Ueoka H, Harita S, Kiura K, Tabata M, Segawa Y, Nogami N, Kuyama S, Shinkai T, Tanimoto M. A phase I and pharmacological study of amrubicin and topotecan in patients of small-cell lung cancer with relapsed or extensive-disease small-cell lung cancer. *Lung Cancer* (2006) 53, 189–95.

Topotecan + Miscellaneous

Ciclosporin and elacridar markedly increase the AUC of oral topotecan, and other inhibitors of P-glycoprotein and BCRP transporters are predicted to interact similarly. Food did not alter the extent of absorption of oral topotecan. Corticosteroids, co-trimoxazole, granisetron, morphine, and ondansetron are not expected to significantly alter the pharmacokinetics of intravenous topotecan.

Clinical evidence, mechanism, importance and management

(a) Ciclosporin

The manufacturer reports that giving oral ciclosporin 15 mg/kg within 4 hours of oral topotecan increased the AUC of the metabolite topotecan lactone and total topotecan by 2- and 2.5-fold, respectively. This is likely to be because ciclosporin is an inhibitor of P-glycoprotein and the cytochrome P450 isoenzyme CYP3A4, which affect the transport and metabolism of topotecan, thereby increasing its oral bioavailability. Patients should be carefully monitored for topotecan adverse effects if inhibitors of P-glycoprotein are used with oral topotecan.[1]

(b) Elacridar

Studies have shown that elacridar (an investigational drug) markedly increased the oral bioavailability of topotecan from 40% to 100%, but had little effect on intravenous topotecan.[2,3] In these studies, a reduced dose of topotecan was used,[2,3] and elacridar use actually appeared to be associated with a reduced incidence of dose-limiting diarrhoea, when compared with historical data.[3] Elacridar is a P-glycoprotein inhibitor and also an inhibitor of the BCRP transporter protein, for which topotecan is a substrate. Patients should be carefully monitored for adverse reactions if inhibitors of BCRP are used with oral topotecan.[1]

(c) Food

The AUC of oral topotecan was found to be similar when it was taken either in the fasted state or after a high-fat meal, although the time to maximum plasma levels was delayed from 1.5 hours to 3 hours.[4] The manufacturer advises that oral topotecan can be taken with or without food.[1]

(d) Other drugs

The UK manufacturer reports that, in a population pharmacokinetic analysis, the pharmacokinetics of intravenous topotecan did not appear to be significantly affected by **granisetron**, **ondansetron**, **morphine** or **corticosteroids**.[1] Similarly, in a population pharmacokinetic analysis of intravenous topotecan in children, **dexamethasone** and **co-trimoxazole** (**sulfamethoxazole**/**trimethoprim**) did not appear to alter the clearance of topotecan.[5]

5. Schaiquevich P, Panetta JC, Iacono LC, Freeman BB 3rd, Santana VM, Gajjar A, Stewart CF. Population pharmacokinetic analysis of topotecan in pediatric cancer patients. *Clin Cancer Res* (2007) 13, 6703–11.

Topotecan + Phenytoin

Phenytoin may possibly increase topotecan clearance.

Clinical evidence, mechanism, importance and management

When a 5-year-old child with medulloblastoma received a course of topotecan, with phenytoin, the total clearance of topotecan was increased by 47%, when compared with a cycle of topotecan without phenytoin.[1] Similarly, in a population pharmacokinetic analysis of studies of intravenous topotecan in children, topotecan clearance was significantly higher in those receiving phenytoin (estimated mean increase of 80%).[2]

Evidence is limited, but the case report and the pharmacokinetic data suggest that an increased topotecan dose may possibly be needed in the presence of phenytoin. It would seem prudent to monitor topotecan efficacy more closely if phenytoin is given.

1. Zamboni WC, Gajjar AJ, Heideman RL, Beijnen JH, Rosing H, Houghton PJ, Stewart CF. Phenytoin alters the disposition of topotecan and *N*-desmethyl topotecan in a patient with medulloblastoma. *Clin Cancer Res* (1998) 4, 783–9.

Topotecan + Probenecid

In *mice*, probenecid markedly inhibited the renal tubular secretion of topotecan, which led to an increase in topotecan systemic exposure.[1] The clinical relevance of this finding is unknown, but it would seem prudent to monitor for topotecan adverse effects in patients also given probenecid. More study is needed to confirm a clinically relevant interaction.

1. Zamboni WC, Houghton PJ, Johnson RK, Hulstein JL, Crom WR, Cheshire PJ, Hanna SK, Richmond LB, Luo X, Stewart CL. Probenecid alters topotecan systemic and renal disposition by inhibiting renal tubular secretion. *J Pharmacol Exp Ther* (1998) 284, 89–94.

Topotecan + Ranitidine

Ranitidine does not alter the pharmacokinetics of topotecan.

Clinical evidence, mechanism, importance and management

In 18 patients with solid tumours, the pharmacokinetics of topotecan (given in initial doses of 2.3 mg/m^2 daily for 5 days, repeated every 3 weeks) and its active metabolite, topotecan lactone, were not affected by the previous use of ranitidine 150 mg twice daily for 4 days.[1] No special precautions would seem necessary if ranitidine or other drugs that increase gastric pH are given with oral topotecan.

1. Akhtar S, Beckman RA, Mould DR, Doyle E, Fields SZ, Wright J. Pretreatment with ranitidine does not reduce the bioavailability of orally administered topotecan. *Cancer Chemother Pharmacol* (2000) 46, 204–10.

Toremifene + Antiepileptics; Enzyme-inducing

Carbamazepine, phenobarbital and possibly phenytoin can reduce the serum levels of toremifene.

Clinical evidence, mechanism, importance and management

A pharmacokinetic study of toremifene in two groups of 10 patients (a control group and a group of patients taking antiepileptics) found that the AUC and half-life of a single 120-mg dose of toremifene were approximately halved in the antiepileptic group. The antiepileptics used were **carbamazepine** alone (3 patients) or with clonazepam (3 patients), or **phenobarbital** alone (3 patients) or with **phenytoin** (1 patient). This interaction is thought to occur because these antiepileptics induce the liver enzymes (almost certainly the cytochrome P450 isoenzyme CYP3A4) by which toremifene is metabolised, resulting in increased toremifene clearance.[1] The UK manufacturers of toremifene have therefore reasonably suggested that the toremifene dose may need to be doubled in the presence of these antiepileptics.[2] **Primidone** is metabolised to phenobarbital, and **fosphenytoin** is metabolised to phenytoin. Similar precautions may therefore be prudent in patients taking these drugs.

2. Fareston (Toremifene citrate). Orion Pharma UK Ltd. UK Summary of product characteristics, January 2009.

Toremifene + Miscellaneous

Based on theoretical considerations, the manufacturers advise care when toremifene is given with thiazides. CYP3A inhibitors such as erythromycin, ketoconazole, and troleandomycin would be expected to increase toremifene levels.

Clinical evidence, mechanism, importance and management

(a) CYP3A inhibitors

The manufacturers of toremifene note that it is mainly metabolised by the cytochrome P450 isoenzymes CYP3A4, CYP3A5, and CYP3A6 so it is suggested that drugs that can inhibit these enzymes (such as **erythromycin**, **troleandomycin**, and **ketoconazole**) may possibly increase its effects.[1,2] Although the clinical relevance of these interactions has not been established, note that CYP3A4 *inducers* (see 'Toremifene + Antiepileptics; Enzyme-inducing', above, and 'Toremifene + Rifampicin (Rifampin)', below) have been found to interact, so a pharmacokinetic interaction with CYP3A inhibitors would be expected. For a list of CYP3A4 inhibitors, see 'Table 1.4', (p.6).

(b) Thiazides

Hypercalcaemia is a recognised adverse effect of toremifene, and it is suggested that drugs such as the **thiazides**, which decrease renal calcium excretion, may increase the risk of hypercalcaemia.[1,2] This warning is based on indirect evidence and theoretical considerations so its clinical importance awaits confirmation.

Toremifene + Rifampicin (Rifampin)

Rifampicin increases the metabolism of toremifene, and might be expected to reduce its efficacy.

Clinical evidence, mechanism, importance and management

A study in 9 healthy men found that rifampicin 600 mg daily for 5 days reduced the AUC, peak plasma levels, and half-life of a single 120-mg dose of toremifene by 87%, 55%, and 44%, respectively. Similarly, the AUC of the metabolite *N*-demethyltoremifene was reduced by 80%.[1] Rifampicin may therefore reduce the efficacy of toremifene.[1] It would therefore seem prudent to monitor concurrent use for toremifene efficacy.

Trabectedin + Miscellaneous

Trabectedin is mainly metabolised by CYP3A4 and therefore inhibitors of this isoenzyme are predicted to raise its levels, whereas inducers of this isoenzyme are predicted to reduce its levels. Trabectedin is also a substrate for P-glycoprotein, and therefore inhibitors of this transporter are expected to raise trabectedin levels. The concurrent use of trabectedin with statins is expected to increase the risks of rhabdomyolysis, and the concurrent use of hepatotoxic drugs is expected to increase the risks of hepatotoxicity. Trabectedin may reduce the absorption of phenytoin. The use of live vaccines should be avoided.

Clinical evidence, mechanism, importance and management

(a) Alcohol

The manufacturer warns that because of the risk of additive hepatotoxicity, the use of trabectedin with hepatotoxic drugs is not recommended. They specifically advise that alcohol consumption must be avoided during treatment with trabectedin.[1]

(b) CYP3A4 inducers and inhibitors

Trabectedin is mainly metabolised by the cytochrome P450 isoenzyme CYP3A4. The manufacturer therefore predicts that inducers of this enzyme (they name **phenobarbital**, **rifampicin** (**rifampin**) and **St John's wort**) may decrease trabectedin levels, and that inhibitors of this isoenzyme (they name **ketoconazole**, **fluconazole**, **ritonavir**, **aprepitant** and **clarithromycin**) may increase trabectedin levels.[1]

Patients should be monitored to ensure that the trabectedin is effective if inducers of CYP3A4 are taken concurrently (see also *Phenytoin*, below). The manufacturers advise that potent CYP3A4 inhibitors should be avoided, but suggest that, if concurrent use cannot be avoided, patients should be closely monitored for trabectedin toxicity and consideration should be given to reducing its dose.[1]

(c) P-glycoprotein inhibitors

Trabectedin is a substrate of P-glycoprotein. The manufacturer therefore advises caution when inhibitors of P-glycoprotein are given to patients taking trabectedin. They specifically name **ciclosporin** and **verapamil**.[1]

(d) Phenytoin

The manufacturer warns that trabectedin may reduce the absorption of phenytoin and therefore increase the risk of seizures. This is predicted on the basis that trabectedin is a cytotoxic and can damage the gastric mucosa and may therefore reduce phenytoin absorption.[2] They therefore do not recommend the combination.[1] There are a few cases of this having occurred with other cytotoxics, see 'Antiepileptics + Antineoplastics; Cytotoxic', p.593; however, it is by no means an established interaction mechanism, and therefore the advice seems over cautious. Note that phenytoin would also be predicted to decrease trabectedin levels, see *CYP3A4 inducers*, above. If both drugs are required, it would seem prudent to monitor phenytoin levels more closely and monitor for trabectedin efficacy.

(e) Statins

In rare cases trabectedin has been associated with rhabdomyolysis. The manufacturers therefore advise caution if other drugs that cause rhabdomyolysis are also given, and they specifically name the statins.[1]

(f) Vaccines

The manufacturer warns that patients receiving trabectedin should not also receive live attenuated vaccines, presumably because of the risks of a generalised infection developing. They specifically contraindicate **yellow fever vaccine**.[1]

Tretinoin + Antifibrinolytics

In acute promyelocytic leukaemia the combination of tretinoin and antifibrinolytics such as tranexamic acid and aprotinin has been associated with fatal thrombotic complications.

Clinical evidence, mechanism, importance and management

In an analysis of 31 patients with acute promyelocytic leukaemia (APL) treated over a 7-year period, **tranexamic acid** 1 to 2 g daily for 6 days was given for prophylaxis of haemorrhage to 15 of 24 patients receiving tretinoin and chemotherapy, 4 of 4 receiving tretinoin only and 2 of 3 receiving chemotherapy only. Seven of the patients receiving tretinoin died during the study period and 4 of them, who had received the combination of tretinoin and **tranexamic acid**, died within 42 days (early deaths). Three of the early deaths were attributed to thrombotic complications.[1] Another earlier report describes a similar fatal case of thromboembolism in a patient given tretinoin and **tranexamic acid**,[2] and another in a patient given tretinoin and **aprotinin**.[3] A further report describes acute renal cortex necrosis as a result of arterial thrombosis in a patient given tretinoin and **tranexamic acid**.[4] Tretinoin alone causes a procoagulant tendency in APL, and this may be exacerbated by use of antifibrinolytics. Although antifibrinolytics and chemotherapy may be safely used concurrently in APL, the combination of tretinoin and antifibrinolytics can cause fatal thrombotic complications and should be used with caution. The use of blood, platelets and plasma rather than **tranexamic acid** for prophylaxis of haemorrhage has been advocated for APL patients.[1]

Tretinoin + Azoles

The metabolism of tretinoin can be inhibited by fluconazole and ketoconazole, and a case report describes tretinoin toxicity as a result of this interaction.

Clinical evidence

(a) Fluconazole

In 2 patients taking tretinoin, a loading dose of fluconazole 400 mg then 200 mg daily thereafter, increased the tretinoin AUC about two- to four-fold, after the second fluconazole dose, when compared with the AUC 8 days after starting tretinoin, but tretinoin levels were similar to those on the first day of use.[1] A 4-year-old boy with acute promyelocytic leukaemia was given induction chemotherapy consisting of cytarabine, daunorubicin and tretinoin 45 mg/m^2 daily in two divided doses. Febrile neutropenia was treated with meropenem and amphotericin B for periods up to day 20. On day 20 he started antifungal prophylaxis with fluconazole 100 mg daily. The next day he complained of headache and a week later he had headache, vomiting and papilloedema. His CT scan was normal. Pseudotumor cerebri was diagnosed and symptoms of increased intracranial pressure resolved within a day of stopping tretinoin. Restarting tretinoin on day 30 at 75% of the previous dose resulted in headache and vomiting, and the treatment was continued from day 35 with an even lower dose (30%), which caused headache but only one episode of vomiting. Fluconazole was stopped on day 41 and within 24 hours the patient had improved clinically with the headache and vomiting fully resolved. He was then able to tolerate the full dose of tretinoin without adverse effects.[2]

(b) Ketoconazole

In 6 patients with lung cancer,[3] a single 400-mg dose of ketoconazole given one hour before tretinoin on day 29 increased the AUC of tretinoin by 115% (compared with day 28 when tretinoin was given alone), but a 200 mg dose of ketoconazole had little effect on the AUC of tretinoin. Ketoconazole had no effect on the AUC of tretinoin when given on day 2 (compared with tretinoin alone on day one).

Mechanism

Fluconazole inhibits the cytochrome P450 isoenzymes CYP3A4 and CYP2C9, and ketoconazole inhibits CYP3A4. *In vitro* both these azoles inhibited the oxidative metabolism of tretinoin, with ketoconazole being more potent.[1] Tretinoin induces its own metabolism over time, and the effect of these azoles is not as great on the first day of tretinoin administration as after a week or more of use.[1,3]

Importance and management

Although it has been suggested that drugs such as fluconazole and ketoconazole may be useful in overcoming clinical resistance to tretinoin,[1,3] it has also been suggested that the concurrent use of tretinoin with drugs that affect its metabolism should be avoided if possible, or patients should be carefully monitored.[2] Given the reaction described in the case report of the child, this seems advisable.

Vinca alkaloids + Antiepileptics; Enzyme-inducing

Carbamazepine and phenytoin appear to reduce the plasma levels of vincristine, and may reduce its efficacy. Other vinca alkaloids may interact similarly.

Clinical evidence, mechanism, importance and management

The systemic clearance of vincristine 2 mg was 63% higher and the AUC was 43% lower in 9 patients receiving **carbamazepine** or **phenytoin** than in 6 patients not taking antiepileptics. In this study, patients were being treated with procarbazine, lomustine and vincristine for brain tumours.[1] In a retrospective survey, long-term antiepileptic use (**phenytoin**, **phenobarbital**, **carbamazepine**, or a combination) was associated with worse event-free survival, and greater haematological relapse and CNS relapse in children receiving chemotherapy for B-lineage acute lymphoblastic leukaemia. The authors considered that the increased clearance of vincristine induced by the antiepileptics was a likely factor in these findings.[2]

These enzyme-inducing antiepileptics increase the metabolism of vincristine by the cytochrome P450 isoenzyme CYP3A4. Other vinca alkaloids are also metabolised by this route. However, *in vitro* studies have shown that **phenytoin** may potentiate the antineoplastic (antimitotic) effects of the vinca alkaloids.[3,4] Thus, further study is required to determine the overall effect of **phenytoin** on the efficacy and toxicity of vincristine and other vinca alkaloids. **Carbamazepine** and **phenobarbital** would be expected to reduce the efficacy of vincristine. Therefore it would seem prudent to monitor concurrent use for efficacy. Also note that **primidone** is metabolised to phenobarbital and **fosphenytoin** is metabolised to phenytoin, and these drugs may therefore be expected interact with the vinca alkaloids.

Note that a number of case reports have described reduced phenytoin

levels in patients receiving chemotherapy including vinca alkaloids, see 'Table 14.1', (p.594).

Vinca alkaloids + Azoles

Itraconazole can increase the toxicity of vincristine, and there is some limited evidence that this is particularly likely with the oral liquid formulation and at higher doses. There are case reports of itraconazole increasing the toxicity of vinblastine, vindesine, and vinorelbine. One case report describes a similar interaction between posaconazole and vincristine. Voriconazole is expected to interact similarly, although this was not seen in one study with vincristine.

Clinical evidence

(a) Vinblastine

Acute neurotoxicity and myelotoxicity occurred in a boy with Hodgkin's lymphoma receiving vinblastine, doxorubicin and methotrexate when he was also given **itraconazole**. The toxicity did not occur when he was given the same chemotherapy without **itraconazole**.[1]

(b) Vincristine

1. Itraconazole. Four out of 14 adults with acute lymphoblastic leukaemia (ALL) given induction chemotherapy with weekly injections of vincristine (with prednisone, daunorubicin and asparaginase) and antifungal prophylaxis with oral itraconazole capsules 400 mg daily, developed severe and early vincristine-induced neurotoxicity (paraesthesia and muscle weakness of the hands and feet, paralytic ileus, mild laryngeal nerve paralysis). The degree and early onset of these neurotoxic reactions were unusual, and were all reversible except for mild paraesthesia in one patient. The complications were more serious than in a previous series of 46 patients given vincristine without itraconazole (29% compared with 6%).[2] Similarly, five consecutive children with ALL enrolled in an open study of prophylactic oral itraconazole 2.5 mg/kg daily (presumably as a liquid formulation) developed severe vincristine toxicity (constipation, abdominal pain, hypertension, ileus, hyponatraemia, seizures) attributed to the concurrent use of itraconazole. They were also receiving nifedipine, which is known to reduce the clearance of vincristine (see 'Vinca alkaloids; Vincristine + Nifedipine', p.782), and which may have made things worse.[3] Since these two reports, cases of severe vincristine neurotoxicity have been reported in five other children[4-8] and two adults[9] with ALL when they were given oral (liquid formulation where stated[8,9]) or intravenous[6] itraconazole. In a further series of 9 children given weekly vincristine and oral itraconazole 5 mg/kg (liquid formulation), all developed increased vincristine toxicity, with 4 patients experiencing seizures.[10] Similarly, in yet another study, 5 of 7 adults given vincristine as part of CHOP (cyclophosphamide, doxorubicin, vincristine and prednisolone) for lymphoma developed vincristine neurotoxicity when receiving oral itraconazole 200 mg daily as a solution. Of note, none of the patients who received vincristine and itraconazole 200 mg daily as capsules developed neurotoxicity.[11]

2. Posaconazole. A patient given posaconazole 400 mg twice daily who also received four doses of vincristine 2 mg at weekly intervals developed bilateral foot paraesthesias and was unable to walk unassisted. Treatment with posaconazole and any vinca alkaloids was stopped, but the patient showed little signs of improvement 5 months later.[12]

3. Voriconazole. None of eight patients who received antifungal prophylaxis with voriconazole 200 mg twice daily during the initial phase of treatment for acute lymphoblastic leukaemia with vincristine and other chemotherapy developed neurotoxicity.[13]

(c) Vindesine

Two cases of vindesine-associated neuropathy were reported in two adult patients. In the first case, paralytic ileus developed 9 days after the patient started to take **itraconazole** solution; vindesine was given 2 and 9 days after **itraconazole** was started. On stopping the **itraconazole**, his symptoms improved rapidly. The second case was that of a 37-year-old woman who received vindesine on days one, 8 and 15. Intravenous **itraconazole** was given from day 9, and 5 days after this she developed symptoms of neurotoxicity, which resolved rapidly on stopping **itraconazole** and vindesine.[14]

(d) Vinorelbine

A 72-year-old man with fungal pneumonia and lung cancer received **itraconazole** (dose not stated) and vinorelbine with cisplatin. After chemotherapy he developed constipation, oral mucositis, leucopenia, progressively deteriorated and died 12 days later.[15]

Mechanism

The reasons for these interactions are not understood, but it has been suggested that itraconazole inhibits the metabolism of vincristine by the cytochrome P450 isoenzyme CYP3A subfamily.[2] Another possible explanation is that itraconazole inhibits P-glycoprotein,[2] and increased vincristine neurotoxicity may be the result of the inhibition of this pump in endothelial cells of the blood-brain barrier.[16] All of the other clinically used vinca alkaloids (vinblastine, vindesine and vinorelbine) are known to be metabolised by CYP3A4, and vinblastine is also a substrate for P-glycoprotein.

Of the other azoles, ketoconazole is also a potent inhibitor of CYP3A4, whereas fluconazole is a moderate inhibitor of CYP3A4 and a potent inhibitor of CYP2C9 (which is not involved in the metabolism of vinca alkaloids). Both of the newer azoles, posaconazole and voriconazole, inhibit CYP3A4.

Importance and management

The interaction of **itraconazole** with vincristine appears to be well documented. The authors of many of the reports[2,4,8-10] suggest that itraconazole should be avoided in patients taking vincristine, or that it should be interrupted when vincristine is given.[6,7] There is some evidence that the liquid oral formulations may be more likely to interact (because of higher oral bioavailability for a given dose)[11] and that the interaction may be dose related (less likely with 200 mg daily than 400 mg daily as capsules[11] and less likely with monthly vincristine than weekly vincristine[4]). Although less well documented; itraconazole may interact similarly with vinblastine, vindesine and vinorelbine. Some UK[17] and US[18] manufacturers advise caution if vinorelbine, is given with itraconazole and **ketoconazole**. The manufacturers of vindesine also note that concurrent use of CYP3A inhibitors may result in early onset or increased severity of vindesine adverse effects.[19]

Data for other azoles is sparse. Some limited evidence indicates that fluconazole did not interact.[10,16] Of the newer azoles, the manufacturer of **posaconazole** advises avoidance of concurrent use with vinca alkaloids (vincristine and vinblastine are named), but if they are given, then dose adjustments of the vinca alkaloids should be considered.[20] Similarly, the manufacturers of **voriconazole** advise caution if it is given to patients receiving vinca alkaloids (vincristine and vinblastine are named) because of the risk of neurotoxicity.[21,22] The US manufacturer of voriconazole recommends that dose adjustments of the vinca alkaloids should be considered.[22]

Vinca alkaloids + Macrolides

Erythromycin increased the toxicity of vinblastine in three patients. Other macrolides are predicted to interact similarly with the vinca alkaloids, but limited evidence suggests that not all patients are affected.

Clinical evidence

Three patients with renal cell carcinoma given ciclosporin 10 or 13 mg/kg daily and **erythromycin** 1 g daily for 3 days developed severe toxicity when given **vinblastine** 7 to 10 mg/m^2 on the third day. Ciclosporin was used as a modifier of multidrug resistance and **erythromycin** was given to achieve higher ciclosporin levels at a lower dose (see 'Ciclosporin + Antibacterials; Macrolides', p.1218). To rule out increased ciclosporin toxicity, one patient was given **erythromycin** without ciclosporin but he still developed **vinblastine** toxicity (severe neutropenia, constipation, myositis, severe myalgia) typical of much higher doses of **vinblastine**. Of the other 2 patients, only negligible toxicity developed in one when he was later given **vinblastine** alone, and the other had received ciclosporin and **vinblastine** on two previous occasions without problems.[1] Other authors report that they have used **clarithromycin** with standard doses of vinca alkaloids in at least 6 patients without any evidence of increased toxicity.[2]

Mechanism

Uncertain, but erythromycin inhibits the cytochrome P450 isoenzyme CYP3A4, which is concerned with the metabolism of vinblastine and other vinca alkaloids. This would be expected to reduce their metabolism resulting in an increase in toxicity.

Importance and management

Information about an interaction between vinca alkaloids and macrolides seems to be limited to this report. On the basis of their findings the authors suggest that erythromycin should be avoided at the time of vinblastine infusion.[1] Use with clarithromycin may be safe,[2] although given that clarithromycin is known to inhibit CYP3A4, by which the vinca alkaloids are metabolised, this needs establishing. The UK manufacturers of **vincristine**, **vindesine** and **vinorelbine** have warned that caution should be exercised in patients taking any drugs known to inhibit the CYP3A subfamily[3-5] because of the risk of an earlier onset and/or increased severity of adverse effects.[3,4] This would be expected to include a number of macrolides (notably, clarithromycin, erythromycin and **telithromycin**). Note that itraconazole, another CYP3A4 inhibitor, is known to increase the toxicity of the vinca alkaloids, see 'Vinca alkaloids + Azoles', p.780.

Vinca alkaloids + Mitomycin

A syndrome of acute pulmonary toxicity, characterised by severe shortness of breath, can occur when vinblastine, vindesine or vinorelbine is given with mitomycin. Fatalities have occurred.

Clinical evidence, mechanism, importance and management

There are numerous reports describing acute lung disease in patients given mitomycin with vinca alkaloids, which appears to be different to the chronic pulmonary fibrosis seen with mitomycin alone. Sudden onset of acute shortness of breath has been described shortly after administration of the vinca alkaloid as part of a vinca alkaloid and mitomycin-containing regimen. Chest radiographs have shown diffuse lung damage characterised by interstitial infiltrates and pulmonary oedema. The acute syndrome has usually improved over 24 hours, although some patients have chronic respiratory impairment (60% in one case series[1]). Fatalities have occurred.[2-4] The syndrome has been reported with mitomycin and **vinblastine**,[1-9] **vindesine**[1,8,10-12] or intravenous **vinorelbine**.[12-15] The incidence is reported to be about 3 to 6%.[1,7,12]

The potential hazards of combining these drugs should be recognised, and in view of the unpredictability of the reaction, close observation of patients receiving this combination is recommended.[1,3] If the reaction occurs, supportive measures such as supplemental oxygen and mechanical ventilation may be needed. Corticosteroids are also often used in an attempt to treat the acute symptoms, and to possibly decrease the risk of chronic respiratory impairment.[1] In patients who have developed acute pulmonary toxicity, the use of both mitomycin and vinca alkaloids should subsequently be avoided.[1]

Vinca alkaloids + Protease inhibitors

Severe neutropenia has been seen in two patients given vinblastine and antiretroviral regimens including ritonavir-boosted lopinavir.

Clinical evidence, mechanism, importance and management

A 55-year-old HIV-positive man who was taking zidovudine, lamivudine, abacavir, nevirapine and **ritonavir**-boosted **lopinavir** experienced unexpected severe gastrointestinal and haematological toxicities and moderate renal failure after the second and third intravenous injections of vinblastine 10 mg given to treat multicentric Castleman's disease (MCD). Subsequently, the antiretrovirals were stopped and the patient did not experience these toxicities when vinblastine was given alone. When the MCD was under control, the antiretrovirals were restarted, and the vinblastine dose reduced to 3 mg every 3 weeks without problems.[1] A second HIV-positive patient who was taking a **lopinavir**/**ritonavir**-based antiretroviral regimen developed life-threatening neutropenia when given ABVD (doxorubicin, bleomycin, vinblastine and dacarbazine) for Hodgkin's lymphoma. Further vinblastine treatment was successfully given by interrupting the protease inhibitors around the time the chemotherapy was given.[2]

It was suggested that the metabolism of vinblastine by the cytochrome P450 isoenzyme CYP3A was inhibited by ritonavir, resulting in increased toxicity.

These appear to be the only cases so far of a possible interaction. Nevertheless, it would now be prudent to carefully monitor any patient taking a ritonavir-based antiretroviral regimen who receives vinblastine. Note that, many manufacturers of vinca alkaloids advise caution if these drugs are given with CYP3A4 inhibitors because of the risks of toxicity. This would be expected to include the protease inhibitors.

For mention that protease inhibitor regimens have been associated with an increased risk of infection when used with various antineoplastic regimens, including those containing vincristine, see 'Antineoplastics + Protease inhibitors', p.703.

Vinca alkaloids; Vinblastine + Bleomycin

The combination of vinblastine and bleomycin, with or without cisplatin, commonly causes Raynaud's phenomenon. Rarely, it also appears to cause serious life-threatening cardiovascular toxicity.

Clinical evidence, mechanism, importance and management

Five patients (aged 23 to 58 years) treated for germ cell tumours died from unexpected acute life-threatening vascular events (myocardial infarction, rectal infarction, cerebrovascular accident) after treatment with VBP (vinblastine, bleomycin, cisplatin). A survey of the literature by the authors of this paper revealed 14 other cases of both acute and long-term cardiovascular problems (myocardial infarction, coronary heart disease, cerebrovascular accident) in patients given VBP.[1]

Raynaud's phenomenon is common, occurring in one-third to one-half of those given vinblastine and bleomycin or VBP,[2,3] and there is evidence that blood vessels are pathologically altered.[2] Cisplatin may contribute to the effect.[3] Analysis of late vascular toxicity after chemotherapy for testicular cancer revealed that the use of VBP carried a higher risk of Raynaud's phenomenon than BEP (bleomycin with etoposide and cisplatin).[4]

The use of the VBP (PVB) regimen has largely been replaced by the BEP (PEB) regimen, because of its reduced toxicity.

Vinca alkaloids; Vincristine + Asparaginase

An isolated case report suggests that vincristine neurotoxicity may possibly have been increased by the subsequent use of asparaginase.[1,2] The UK manufacturer recommends that vincristine should be given 12 to 24 hours before asparaginase.[3] Regimens including both drugs are commonly used in treating leukaemia.

3. Vincristine sulphate. Hospira UK Ltd. UK Summary of product characteristics, January 2008.

Vinca alkaloids; Vincristine + Isoniazid

Some limited evidence suggests that vincristine neurotoxicity may possibly be increased by isoniazid.

Clinical evidence, mechanism, importance and management

An 85-year-old woman with Hodgkin's disease was given COPP and ABVD (doxorubicin, bleomycin, vinblastine and dacarbazine), alternating every 28 days. She started COPP (cyclophosphamide and 2 mg vincristine on day one, with procarbazine and prednisone days one to 14) and was also given isoniazid 300 mg daily as prophylaxis of tuberculosis. Five days after the start of this treatment she experienced tingling in her fingers and weakness in her legs, which was interpreted by the authors of this report as being vincristine toxicity (paraesthesia of the feet and/or hands being a recognised early sign of vincristine toxicity) brought about by the concurrent use of isoniazid. Their reasoning was that such a small dose of vincristine on its own was unlikely to cause severe neurotoxicity of this kind, but it is not clear why isoniazid should apparently interact like this. The authors suggest that the age of this patient and the fact that she had diabetes (well controlled) may have contributed to this increase in vincristine neurotoxicity.[1]

This report is consistent with another much earlier report of 2 patients who also developed peripheral neurotoxicity when they were given vincristine after starting to take isoniazid and pyridoxine, the cumulative doses of vincristine being 11 mg and 11.2 mg, respectively.[2,3] Similarly, another case describes severe neurotoxicity with an overdose of isoniazid and high-dose vincristine.[4]

These reports appear to be the only ones implicating isoniazid in an increase in vincristine toxicity, but they serve to emphasise the importance of very close neurological supervision in anyone given both drugs.

Vinca alkaloids; Vincristine + Nifedipine

Nifedipine reduces the clearance of vincristine.

Clinical evidence, mechanism, importance and management

In a study in 12 patients, nifedipine reduced the clearance of a single 2-mg intravenous dose of vincristine by 68%, and increased its AUC threefold, when compared with 14 patients receiving vincristine alone. Nifedipine was given at a dose of 10 mg three times daily for 3 days before and 7 days after vincristine was given. However, no important adverse effects were noted in either group of patients, suggesting that these pharmacokinetic changes did not markedly increase vincristine toxicity.[1] Further study is needed to establish any interaction.

1. Fedeli L, Colozza M, Boschetti E, Sabalich I, Aristei C, Guerciolini R, Del Favero A, Rossetti R, Tonato M, Rambotti P, Davis S. Pharmacokinetics of vincristine in cancer patients treated with nifedipine. *Cancer* (1989) 64, 1805–11.

Vinca alkaloids; Vinorelbine + Cisplatin

The pharmacokinetics of intravenous vinorelbine were not altered by cisplatin in one study. The incidence of granulocytopenia is reported to be higher when vinorelbine is given with cisplatin than when given alone.

Clinical evidence, mechanism, importance and management

The pharmacokinetics of vinorelbine did not differ between 4 patients who received a single 30-mg/m^2 infusion of vinorelbine given over 15 minutes and 4 patients who were also given a single 80-mg/m^2 dose of cisplatin given one hour after the start of the vinorelbine infusion.[1]

The incidence of granulocytopenia is reported to be higher when vinorelbine is given with cisplatin, than when given alone.[2,3] In one large clinical study, the incidence of grade 3 to 4 granulocytopenia was 79% in patients receiving intravenous vinorelbine 30 mg/m^2 weekly with cisplatin (120 mg/m^2 on days one and 29, and then every 6 weeks) compared with an incidence of 53% in patients receiving vinorelbine 30 mg/m^2 weekly alone.[3] However, the combination regimen improved survival.

The combination of vinorelbine and cisplatin is in established use. Note that close monitoring for granulocytopenia and appropriate dose adjustment or a delay in treatment is important if granulocytopenia develops with vinorelbine alone.

Vinca alkaloids; Vinorelbine + Rifampicin (Rifampin)

The manufacturers advise that the pharmacokinetics of vinorelbine may be altered if it is given with rifampicin.

Clinical evidence, mechanism, importance and management

In a small study in 4 *pigs*, there was no difference in the clearance of vinorelbine when a single intravenous dose of 500 micrograms/kg was given alone or on the day 7 of intravenous rifampicin 600 mg daily. The AUC and maximum level of vinorelbine were increased by about 66% by rifampicin, but this was not statistically significant,[1] possibly because of the small sample size. The pig was chosen for this study because porcine CYP3A is reportedly similar to that of humans.[1]

Vinorelbine is known to be metabolised by the cytochrome P450 isoenzyme CYP3A4, of which rifampicin is a known potent inducer, therefore rifampicin would be expected to increase the clearance of vinorelbine and reduce its levels. The manufacturers of vinorelbine advise caution with potent inducers of the CYP3A subfamily,[2,3] which would include rifampicin. Until more is known, this seems prudent.

Vorinostat + Antineoplastics

Use of paclitaxel and carboplatin with vorinostat modestly increased vorinostat levels in one study. Paclitaxel levels were unaffected.

Clinical evidence, mechanism, importance and management

In a study in 28 patients with solid tumours, the AUC and half-life of vorinostat were increased by 37% and 61%, respectively, when given with **carboplatin** and **paclitaxel**. In this study, patients received intravenous **paclitaxel** 175 mg/m^2 increased to 200 mg/m^2 over 3 hours then **carboplatin** (dose adjusted to reach a target exposure) as a 30-minute infusion every 3 weeks. Oral vorinostat 200 mg daily for 14 days was given, starting 4 days before chemotherapy in the first cycle, then in increasing doses of 300 mg daily then 400 mg daily for 14 days starting on day one for subsequent cycles. The pharmacokinetics of **paclitaxel** were unaffected by vorinostat when compared with historical data, but the pharmacokinetics of **carboplatin** were not assessed. The incidence of grade 4 neutropenia was higher in this study (50%) than historical data for **carboplatin** with **paclitaxel**.[1]

The reason for the apparent alteration in vorinostat pharmacokinetics is uncertain. There was no definite relationship between vorinostat dose and the incidence of neutropenia, but it is possible that the use of vorinostat with paclitaxel contributed to this. Further study is needed to establish the effects of concurrent use.

Phase I and pharmacokinetic study of vorinostat, a histone deacetylase inhibitor, in combination with carboplatin and paclitaxel for advanced solid malignancies. *Clin Cancer Res* (2007) 16, 3605–10.

Vorinostat + Food

The absorption of oral vorinostat is modestly increased by food.

Clinical evidence, mechanism, importance and management

The pharmacokinetics of vorinostat were investigated in 23 patients who received a single 400-mg oral dose of vorinostat in the fasted state, and again after a standardised high-fat meal. There was a 38% increase in the AUC of vorinostat when taken with food, and a delay of 2.5 hours in reaching the maximum plasma levels. This modest effect of food was not considered to be clinically relevant.[1] However, note that the manufacturer advises that the daily dose is taken with food, as this is how the clinical studies were conducted.[2]

1. Rubin EH, Agrawal NGB, Friedman EJ, Scott P, Mazina KE, Sun L, Du L, Ricker JL, Frankel SR, Gottesdiener KM, Wagner JA, Iwamoto M. A study to determine the effects of food and multiple dosing on the pharmacokinetics of vorinostat given orally to patients with advanced cancer. *Clin Cancer Res* (2006) 12, 7039–45.
2. Zolinza (Vorinostat). Merck & Co., Inc. US Prescribing information, September 2009.

Vorinostat + Miscellaneous

Severe thrombocytopenia and gastrointestinal bleeding have been reported in patients who took vorinostat and valproic acid. Increased INRs have occurred in patients taking vorinostat with coumarins.

Clinical evidence, mechanism, importance and management

(a) Valproate

The manufacturer notes that severe thrombocytopenia and gastrointestinal bleeding have been reported in patients who took vorinostat and other drugs that are histone deacetylase inhibitors. They specifically name **valproic acid**.[1] Note that thrombocytopenia is common with vorinostat alone.

(b) Warfarin and related drugs

The manufacturer notes that prolongation of the prothrombin time and raised INRs have been observed in patients receiving vorinostat with coumarin anticoagulants. They recommend close monitoring of the prothrombin time and INR in these patients.[1]

1. Zolinza (Vorinostat). Merck & Co., Inc. US Prescribing information, September 2009.

18

Antiparkinsonian and related drugs

The drugs in this section are considered together because their major therapeutic application is in the treatment of Parkinson's disease, although some of the related antimuscarinic (anticholinergic) drugs included here are also used for other conditions. Parkinson's disease is named after Dr James Parkinson who originally described the four main signs of the disease, namely rigidity, tremor, dystonias and dyskinesias (movement disorders). Similar symptoms may also be displayed as the unwanted adverse effects of certain drugs.

The basic cause of the disease lies in the basal ganglia of the brain, particularly the striatum and the substantia nigra, where the normal balance between dopaminergic nerve fibres (those that use dopamine as the chemical transmitter) and cholinergic nerve fibres (those that use acetylcholine as the transmitter) is lost, because the dopaminergic fibres degenerate. As a result the cholinergic fibres end up in relative excess. Much of the treatment of Parkinson's disease is based on an attempt to redress the balance, and there are several groups of drugs that can be used to this end. These are listed in 'Table 18.1', (below), and discussed below.

Levodopa

Levodopa can pass the blood-brain barrier (unlike dopamine), where it is converted into dopamine, and thus acts by 'topping up' the CNS dopaminergic system. Levodopa is most usually given with **carbidopa** or **benserazide** (dopa-decarboxylase inhibitors), which prevent the 'wasteful' peripheral metabolism of levodopa. This allows lower doses of levodopa to be given, which results in fewer adverse effects.

Amantadine

Amantadine may augment dopaminergic activity in the brain.

Dopamine agonists

Bromocriptine, cabergoline, pergolide, ropinirole and similar drugs act as dopamine agonists and so also have the effect of increasing dopaminergic activity in the brain.

Entacapone and Tolcapone

The catechol-*O*-methyltransferase (COMT) inhibitors work by inhibiting the peripheral metabolism of levodopa by COMT. Note that this enzyme is the major metabolising enzyme for levodopa when a decarboxylase inhibitor (e.g. benserazide) is being used.

Rasagiline and Selegiline

The selective irreversible MAO-B inhibitors enhance dopamine activity by preventing dopamine degradation. These drugs sometimes interact like non-selective MAOIs, and the reader is cross-referred to the information under MAOIs when appropriate. Selegiline undergoes rapid first-pass metabolism to produce amfetamine metabolites. A buccal tablet has been developed, which markedly reduces this first-pass metabolism, and is consequently given as a smaller dose.

Antimuscarinics

Benzhexol, orphenadrine, procyclidine and other antimuscarinic (anticholinergic) drugs work by correcting the relative cholinergic excess.

The interactions that affect the antimuscarinic effects of these drugs are discussed in this section. However, the antimuscarinics also affect the actions of other drugs (such as the centrally-acting anticholinesterases) and these are therefore discussed elsewhere in the publication.

Table 18.1 Antiparkinsonian drugs

Group	*Drugs*
Dopaminergic drugs	
Amino-acid precursor of dopamine	Levodopa
Levodopa combined with a peripheral dopa-decarboxylase inhibitor	Co-beneldopa (levodopa with benserazide) Co-careldopa (levodopa with carbidopa)
COMT-inhibitors	Entacapone, Tolcapone
Dopamine agonists	
Ergot derivatives	Bromocriptine, Cabergoline, Lisuride, Pergolide
Non-ergot dopamine agonists	Piribedil, Pramipexole, Quinagolide, Ropinirole, Rotigotine
Other dopamine agonists	Apomorphine
MAO-B inhibitors	Rasagiline, Selegiline
Other	Amantadine
Other	
Peripheral dopa-decarboxylase inhibitors	Benserazide, Carbidopa
Antimuscarinics	Benzatropine, Biperiden, Bornaprine, Dexetimide, Metixene, Orphenadrine, Procyclidine, Profenamine, Trihexyphenidyl, Tropatepine

Amantadine + Co-trimoxazole

An interaction between amantadine and co-trimoxazole is thought to have caused acute confusion in an elderly man, and amantadine toxicity in a patient with end-stage renal disease. However, in both cases other factors could have been responsible for the adverse reactions.

Clinical evidence, mechanism, importance and management

An 84-year-old man with parkinsonism, COPD and chronic atrial fibrillation, had been taking amantadine 100 mg twice daily and digoxin 125 micrograms daily for at least 2 years. Within 72 hours of starting co-trimoxazole twice daily for bronchitis he became mentally confused, incoherent and combative. He also had cogwheel rigidity and a resting tremor. Within 24 hours of stopping the amantadine and co-trimoxazole, the patient's mental status returned to normal.[1] The reasons for this reaction are not understood, but on the basis of *animal* studies, the authors suggest that the **trimethoprim** component of co-trimoxazole may have competed with amantadine for renal secretion. This resulted in an accumulation of amantadine and led to the adverse effects seen.[1] This interaction is more likely in the elderly because ageing results in a decreased clearance of these and many other drugs. However, it should be noted that both drugs can cause some mental confusion, and also that mental confusion is not an uncommon symptom of infection in the elderly. Another case of amantadine toxicity has been reported in a 27-year-old woman with end-stage renal disease who was also taking co-trimoxazole. As in the other case the authors suggest that the **trimethoprim** component of co-trimoxazole may have competed with amantadine for renal secretion. However, they also note that amantadine toxicity occurred 5 days after the amantadine dose was increased, and during an episode of acute renal failure, which could also account for the toxicity.[2]

These seem to be the only reports of a possible interaction, and therefore their general importance remains uncertain.

2. Michalski LS, Hantsch CE, Hou SH. Amantadine toxicity in a renal transplant patient. Abstracts of the 2003 North American Congress of Clinical Toxicology Annual Meeting, 93.

Amantadine + Diuretics

A patient has been described who developed amantadine toxicity when given hydrochlorothiazide with triamterene, and another patient taking amantadine developed myoclonic jerks after starting to take spironolactone and altizide.

Clinical evidence

Amantadine toxicity (ataxia, agitation, hallucinations) developed in a patient within a week of starting to take two tablets of *Dyazide* (**hydrochlorothiazide** with **triamterene**) daily. The symptoms rapidly disappeared when all the drugs were withdrawn. In a later study the amantadine plasma levels of this patient rose by about 50% (from 156 to 243 nanograms/mL) after taking the diuretic for 7 days.[1] A further case describes myoclonic jerks in a 64-year-old man after the addition of **spironolactone** and **altizide** to established treatment for Parkinson's disease, which included levodopa with benserazide, amantadine, orphenadrine, imipramine and diazepam. The diuretics were stopped, but the myoclonic jerks only resolved after the amantadine was also stopped.[2]

Mechanism

Uncertain. Amantadine is largely excreted unchanged in the urine and it seems probable that these diuretics reduce its renal clearance.[1]

Importance and management

Published information about an adverse interaction between amantadine and diuretics appears to be limited. There seems to be little reason for avoiding concurrent use, but bear these cases in mind in the event of an unexpected response to treatment.

2. Chevalier JF, Renier E, Brion S. Œdème et myoclonies chez un parkinsonien traité par Mantadix®. Problème des associations médicamenteuses. *Encephale* (1980) 6, 381–4.

Amantadine + MAOIs or MAO-B inhibitors

An isolated report describes a rise in blood pressure in a patient taking amantadine within 72 hours of taking phenelzine. The use of selegiline with amantadine may increase adverse effects.

Clinical evidence, mechanism, importance and management

A 49-year-old woman taking amantadine 200 mg daily, haloperidol 5 mg daily and flurazepam 30 mg at night was given **phenelzine** 15 mg twice daily for depression. Within 72 hours her blood pressure rose from 140/90 mmHg to 160/110 mmHg. The **phenelzine** was withdrawn, and 24 hours later, the amantadine and haloperidol were withdrawn. The blood pressure remained elevated for a further 72 hours.[1] In contrast, a woman is reported to have successfully and uneventfully taken amantadine 200 mg daily for Parkinson's disease and **phenelzine** 45 mg daily for depression.[2]

The first case appears to be the only reported interaction with amantadine. Its general importance is therefore uncertain, but bear it in mind in case of an unusual response to treatment.

One manufacturer of **selegiline** states that concurrent use of amantadine can lead to an increased occurrence of adverse effects,[3] but no further information is given.

3. Zelapar (Selegiline hydrochloride). Cephalon Ltd. UK summary of product characteristics, September 2008.

Amantadine + Miscellaneous

Amantadine has antimuscarinic adverse effects and therefore may interact in the same way as the antimuscarinics.

Clinical evidence, mechanism, importance and management

The adverse effects of amantadine resemble those of antimuscarinic drugs. The manufacturers of amantadine note[1,2] that it may interact with a number of drugs, presumably somewhat based on the way these antimuscarinics are known to interact. They name alcohol (consider 'Alcohol + Antimuscarinics', p.51), antimuscarinics (consider 'Antimuscarinics + Antimuscarinics', p.786), antipsychotics (consider 'Antipsychotics + Antimuscarinics', p.833), and levodopa (consider 'Levodopa + Antimuscarinics', p.796).

2. Symmetrel (Amantadine hydrochloride). Endo Pharmaceuticals Inc. US Prescribing information, May 2007.

Amantadine + Phenylpropanolamine

The use of amantadine in a patient also taking phenylpropanolamine resulted in psychosis, and concurrent use in another patient resulted in intense and recurrent déjà vu experiences.

Clinical evidence, mechanism, importance and management

A case report describes the development of severe psychosis in a woman within 7 to 8 days of starting amantadine 100 mg [frequency unclear but possibly twice daily] and phenylpropanolamine 80 mg daily. The reasons are not known, but both drugs alone, and in high doses sometimes cause psychosis, and concurrent use may enhance this effect.[1] Another report describes intense and recurrent déjà vu experiences in a 39-year-old man taking amantadine 100 mg twice daily and phenylpropanolamine 25 mg twice daily during a viral infection. These experiences stopped the day he discontinued the drugs. He had previously taken phenylpropanolamine

without this effect. The authors considered the déjà vu experiences to be related to increased dopamine activity caused by both drugs.[2]

Concurrent use need not be avoided, but remain aware of the potential for this interaction.

Amantadine + Quinidine or Quinine

In a single-dose study, quinidine and quinine modestly reduced the loss of amantadine in the urine in men, but not women.

Clinical evidence, mechanism, importance and management

Single-dose studies into the renal excretion of amantadine in healthy subjects found that quinine sulfate 200 mg and quinidine sulfate 200 mg reduced the renal clearance of oral amantadine 3 mg/kg by about 30%, but only in male subjects.[1] Whether the long-term use of these drugs would therefore cause a clinically relevant rise in serum amantadine levels is uncertain. However, the absence of any clinical reports suggests it is unlikely. Nevertheless, be aware that amantadine toxicity (e.g. headache, nausea, or dizziness) could possibly result from the concurrent use of quinine or quinidine.

1. Gaudry SE, Sitar DS, Smyth DD, McKenzie JK, Aoki FY. Gender and age as factors in the inhibition of renal clearance of amantadine by quinine and quinidine. *Clin Pharmacol Ther* (1993) 54, 23–7.

Amantadine + Tobacco

Amantadine clearance was not altered by tobacco smoking in one study.

Clinical evidence, mechanism, importance and management

The elimination of a single 3-mg/kg dose of amantadine was compared between heavy smokers (20 or more cigarettes daily) and non-smokers.

Although a higher apparent volume of distribution was noted in the heavy smokers, renal and plasma clearances were unchanged, suggesting that no interaction of note occurs.[1]

Antimuscarinics + Antimuscarinics

Additive antimuscarinic effects, both peripheral and central, can develop if two or more drugs with antimuscarinic effects are used together. The outcome may be harmful.

Clinical evidence, mechanism, importance and management

The antimuscarinic (sometimes called anticholinergic) effects of some drugs are exploited therapeutically. These include antimuscarinic bronchodilators, gastrointestinal antispasmodics, mydriatics, urological antimuscarinics, and drugs such as **trihexyphenidyl** and **benzatropine** (see 'Table 18.1', (p.784)), which are used for the control of parkinsonian symptoms. Other drugs, such as some antiemetics, sedating antihistamines, antipsychotics, and tricyclic antidepressants, (see 'Table 18.2', (below)), may also possess some antimuscarinic effects that are unwanted and troublesome, but usually not serious, unless they are worsened by the addition of another drug with similar properties.

The easily recognised and common peripheral antimuscarinic effects are blurred vision, dry mouth, constipation, difficulty in urination, reduced sweating and tachycardia. Central effects include confusion, disorientation, visual hallucinations, agitation, irritability, delirium, memory problems, belligerence and even aggressiveness. Problems are most likely to arise in patients with particular physical conditions such as glaucoma, prostatic hypertrophy or constipation, in whom antimuscarinic drugs should be used with caution, if at all. It has been pointed out that the antimuscarinic adverse effects can mimic the effects of normal ageing.

'Table 18.1', (p.784) and 'Table 18.2', (below) list many of the drugs with antimuscarinic effects, which may be expected to be additive if used together, but apart from some reports describing life-threatening reactions (see 'Antipsychotics + Antimuscarinics', p.833) there are very few reports describing this simple additive interaction, probably because the outcome is so obvious. Many of these interactions are therefore theoretical but their probability is high.

Some drugs with only minimal antimuscarinic properties sometimes cause difficulties if given with other antimuscarinics. A patient taking **isopropamide iodide** developed urinary retention needing catheterisation, only when **trazodone** 75 mg daily was also taken, but not when either drug was taken alone.[1] **Trazodone** is usually regarded as having minimal antimuscarinic effects. Another case describes acute psychosis in an elderly woman taking **hyoscine** and **meclozine**, both of which have antimuscarinic effects.[2]

If the central antimuscarinic effects caused by the use of antimuscarinic drugs are not clearly recognised for what they are, there is the risk that antipsychotics may be prescribed to treat them. Many antipsychotics also have antimuscarinic adverse effects so that matters are simply made worse. If the patient then demonstrates dystonias, akathisia, tremor and rigidity, even more antimuscarinics may be added to control the extrapyramidal effects, which merely adds to the continuing downward cycle of drug-induced problems.

In addition to the obvious and very well recognised drugs with antimuscarinic effects, a study of the 25 drugs most commonly prescribed for the elderly identified detectable antimuscarinic activity (using an antimuscarinic radioreceptor assay) in 14 of them, 9 of which (**codeine**, **digoxin**, **dipyridamole**, **isosorbide dinitrate**, **nifedipine**, **prednisolone**, **ranitidine**, **theophylline**, and **warfarin**) produced levels of antimuscarinic activity that have been shown to cause significant impairment in tests of memory and attention in the elderly.[3] Thus the problem may not necessar-

Table 18.2 Drugs with antimuscarinic effects (main or adverse effects)

Group	*Drugs*
Antiarrhythmics	Disopyramide, Propafenone
Antiemetics	Cyclizine, Dimenhydrinate, Hyoscine (Scopolamine), Meclozine
Antihistamines	Brompheniramine, Chlorphenamine, Cyproheptadine, Diphenhydramine, Hydroxyzine, Promethazine, Tripelennamine, Triprolidine
Antiparkinsonian drugs (Antimuscarinics)	see Table 18.1, p.784
Antipsychotics	Chlorpromazine, Chlorprothixene, Clozapine, Loxapine, Mesoridazine, Perphenazine, Pimozide, Thioridazine, Trifluoperazine
Antispasmodics	Anisotropine, Atropine, Belladonna alkaloids, Dicycloverine (Dicyclomine), Flavoxate, Hyoscine (Scopolamine), Hyoscyamine, Isopropamide, Propantheline
Antiulcer drugs	Clidinium, Hexocyclium, Isopropamide, Mepenzolate, Methanthelinium, Oxyphencyclimine, Pirenzepine, Tridihexethyl
Bronchodilators	Ipratropium, Tiotropium
Cycloplegic mydriatics	Atropine, Cyclopentolate, Homatropine, Hyoscine (Scopolamine), Tropicamide
Muscle relaxants	Baclofen, Cyclobenzaprine, Orphenadrine
Peripheral vasodilator	Papaverine
Tricyclic and related antidepressants	Amitriptyline, Amoxapine, Clomipramine, Desipramine, Doxepin, Imipramine, Maprotiline, Protriptyline, Nortriptyline, Trimipramine
Urinary antimuscarinics	Darifenacin, Oxybutynin, Solifenacin, Tolterodine, Trospium

After Barkin RL, Stein ZLG. *South Med J* (1989) 82, 1547, and others.
The categorization is not exclusive; some of these drugs are used for a range of effects. There are many other antimuscarinic drugs.

ily be confined to those drugs that have well recognised antimuscarinic properties.

Antimuscarinics + Areca (Betel nuts)

The control of the extrapyramidal (parkinsonian) adverse effects of fluphenazine and flupenthixol with procyclidine was lost in two patients when they began to chew areca.

Clinical evidence

An Indian patient receiving depot fluphenazine (50 mg every 3 weeks) for schizophrenia, and with mild parkinsonian tremor controlled with **procyclidine** 5 mg twice daily, developed marked rigidity, bradykinesia and jaw tremor when he began to chew areca. The symptoms were so severe he could barely speak. When he stopped chewing areca his stiffness and abnormal movements disappeared. Another patient receiving depot flupenthixol developed marked stiffness, tremor and akathisia when he began to chew areca, despite taking up to 20 mg of **procyclidine** daily. The symptoms vanished within 4 days of stopping the areca.[1]

Mechanism

Areca contains arecoline, an alkaloid with cholinergic activity, which could therefore oppose the antimuscarinic (anticholinergic) actions of procyclidine. As the procyclidine was being used to control the extrapyramidal adverse effects of the two antipsychotics, opposing its action allowed the adverse effects to re-emerge and worsen.

Importance and management

Direct information seems to be limited to this report but the interaction would seem to be established and clinically important. Patients taking antimuscarinic drugs for the control of drug-induced extrapyramidal (parkinsonian) adverse effects, or Parkinson's disease, should avoid areca (betel nuts). Betel is traditionally chewed by those from the continent of Asia, and the East Indies. The authors of this report suggest that a dental inspection for the characteristic red stains of the areca may possibly provide a simple explanation for the sudden and otherwise mysterious deterioration in the symptoms of patients. Symptoms seem to develop over a period of 2 weeks, and resolve fairly rapidly (within a week).

Antimuscarinics + SSRIs

Nine patients developed delirium when given fluoxetine, paroxetine or sertraline with benzatropine, in the presence of an antipsychotic (usually perphenazine or haloperidol).

Clinical evidence

Five patients became confused and developed delirium when given an antipsychotic, an SSRI (4 taking **fluoxetine** and one taking **paroxetine**) and **benzatropine**. No peripheral antimuscarinic toxicity was seen. The delirium developed within 2 days in two cases, but took several weeks to appear in another. The authors also very briefly mention two other patients who became delirious when given an unnamed antipsychotic and either **sertraline** or **paroxetine** with **benzatropine**.[1] Another case describes delirium in a 17-year-old boy, 8 days after **paroxetine** was added to his medication, which included **benzatropine** and haloperidol. Serum levels of **benzatropine** were markedly increased.[2] A further case report describes delirium in a 26-year-old woman taking **sertraline** 200 mg daily, haloperidol up to 9 mg daily, and lithium 900 mg daily after **benzatropine** 5 mg daily was added to her medication, to treat an episode of parkinsonism.[3] In contrast, another report describes 12 patients taking **fluoxetine** and perphenazine who also received **benzatropine** 1 mg daily without showing signs of delirium.[4,5]

The manufacturers note that **paroxetine** 30 mg daily increased the AUC, maximum and minimum plasma levels of **procyclidine** 5 mg daily by 35%, 37%, and 67%, respectively.[6]

Mechanism

The authors of the first report attributed these effects to an interaction between the SSRIs and benzatropine, speculating that the SSRIs may have inhibited the metabolism of the benzatropine thereby increasing its toxicity. Alternatively they suggest a possible additive central antimuscarinic effect. It is noteworthy that 4 of the first group of patients were given perphenazine and one haloperidol,[1] which have been involved in additive antimuscarinic interactions (see 'Antipsychotics + Antimuscarinics', p.833). Also note that adverse interactions have been reported with the use of haloperidol and SSRIs, see 'Haloperidol + SSRIs', p.887.

Importance and management

The general clinical importance of this interaction is uncertain, but it would seem prudent to be alert for evidence of confusion and possible delirium in patients given SSRIs with benzatropine, particularly if they are also taking other psychotropics that may have antimuscarinic actions. The authors of the first report say that they have not seen delirium with combinations of SSRIs (not named) and other antimuscarinic drugs such as **biperiden** and **diphenhydramine**.[1] If antimuscarinic effects are seen in patients taking paroxetine and procyclidine, the dose of procyclidine should be reduced.[6,7]

Apomorphine + Antihypertensives

The hypotensive adverse effects of apomorphine may possibly be increased by nitrates, calcium-channel blockers and alpha blockers. There is some evidence that ACE inhibitors, beta blockers and diuretics do not generally increase the risk of hypotension with apomorphine.

Clinical evidence

(a) ACE inhibitors

A single 5-mg sublingual dose of apomorphine produced no clinically relevant changes in heart rate or blood pressure in 25 patients taking ACE inhibitors [not specifically named]. One patient experienced symptomatic hypotension.[1]

(b) Alpha blockers

A single 5-mg sublingual dose of apomorphine caused a greater decrease in systolic blood pressure from supine to standing in 24 patients taking alpha blockers [not specifically named] when compared with placebo (decrease in systolic blood pressure of 23 mmHg versus 13 mmHg at 40 minutes post dose). One patient experienced symptomatic hypotension.[1]

(c) Beta blockers

A single 5-mg sublingual dose of apomorphine produced no clinically relevant changes in heart rate or blood pressure in 26 patients taking beta blockers [not specifically named]. One patient experienced syncope and one had symptomatic hypotension.[1]

(d) Calcium-channel blockers

A single 5-mg sublingual dose of apomorphine caused a greater decrease in systolic blood pressure from supine to standing in 26 patients taking calcium-channel blockers [not specifically named] when compared with pla-

cebo (decreased in systolic blood pressure of 17 mmHg versus 11 mmHg at 20 minutes post dose).[1]

(e) Diuretics

A single 5-mg sublingual dose of apomorphine produced no clinically relevant changes in heart rate or blood pressure in 21 patients taking diuretics [not specifically named]. One patient experienced symptomatic hypotension.[1]

(f) Nitrates

1. Short-acting. A single 5-mg sublingual dose of apomorphine produced no clinically relevant changes in heart rate or blood pressure in 20 patients taking short-acting nitrates. The apomorphine was given 30 minutes before the patient took their short-acting nitrate. Two patients experienced symptomatic hypotension after their sublingual glyceryl trinitrate.[1]

2. Long-acting. A single 5-mg sublingual dose of apomorphine caused a greater decrease in systolic blood pressure from supine to standing in 20 patients taking long-acting nitrates when compared with placebo (decrease in systolic blood pressure of 12 mmHg versus 6 mmHg at 50 minutes post dose). Two patients experienced symptomatic hypotension.[1]

Mechanism

Apomorphine alone may cause postural hypotension, and this is potentially additive with the effects of vasoactive antihypertensives and nitrates.

Importance and management

A potentially clinically relevant interaction resulting in orthostatic hypotension may occur when sublingual apomorphine is given to patients taking calcium-channel blockers or alpha blockers. Similarly, symptomatic hypotension on standing may be more common in patients taking nitrates. Note that the 5-mg dose used in the study was slightly higher than the recommended 2- to 3-mg sublingual dose commonly used for erectile dysfunction. All the patients who had symptomatic hypotension experienced a prodrome of symptoms such as nausea, dizziness, pallor, and/or sweating.[1] The manufacturer of apomorphine used subcutaneously for Parkinson's disease suggests caution in patients taking antihypertensives[2] and on the basis of the study mentioned above[1], particular caution should be taken with nitrates. In practice, this means telling patients what may possibly happen and what to do if adverse effects occur (i.e. do not attempt to stand up, but lie down and raise their legs until the symptoms resolve). Note that apomorphine should be given with caution to patients with cardiovascular disease.[2]

Apomorphine + COMT inhibitors

Entacapone had no effect on the pharmacokinetics or efficacy of apomorphine in a single-dose study. Similarly, tolcapone had no relevant effect on the pharmacokinetics of a single dose of apomorphine.

Clinical evidence

(a) Entacapone

In a placebo-controlled, crossover study in 24 patients with Parkinson's disease a single dose of entacapone 200 mg or 400 mg given 30 minutes before a subcutaneous injection of apomorphine had no effect on the pharmacokinetics of apomorphine. In addition, entacapone had no effect on measures of apomorphine efficacy (tapping test and incidence of dyskinesias).[1]

(b) Tolcapone

In 5 patients with Parkinson's disease, tolcapone 200 mg three times daily for 5 days then 200 mg one hour before sublingual apomorphine 40 mg caused a non-significant increase in the AUC of apomorphine of about 13%.[2]

Mechanism

In vitro and *animal* data suggested that the enzyme catechol-*O*-methyl transferase (COMT) is involved in the metabolism of apomorphine[3] and that COMT inhibitors might increase apomorphine bioavailability. However, the single dose studies above suggest that this metabolic pathway for apomorphine may not be important in humans.

Importance and management

The evidence from these single-dose studies suggest that there is no pharmacokinetic interaction between entacapone or tolcapone and apomorphine, and that the drugs can be used together without alteration of the apomorphine dose. However, further data are required from longer-term concurrent use to confirm this. Until more is known, increased monitoring during concurrent use of COMT inhibitors and apomorphine may be prudent, in order to detect any apomorphine adverse effects that may develop.

Apomorphine + Hormonal contraceptives

The sedative effects of apomorphine were decreased by an oral combined hormonal contraceptive in one study.

Clinical evidence, mechanism, importance and management

A study in a group of 9 women found that the sedative effects of a single 5-micrograms/kg subcutaneous dose of apomorphine were decreased when they were taking an oral combined hormonal contraceptive (**ethinylestradiol** 30 micrograms, **levonorgestrel** 150 or 250 micrograms).[1] The clinical importance of this is uncertain.

1. Chalmers JS, Fulli-Lemaire I, Cowen PJ. Effects of the contraceptive pill on sedative responses to clonidine and apomorphine in normal women. *Psychol Med* (1985) 15, 363–7.

Apomorphine + Miscellaneous

The concurrent use of apomorphine and other drugs used for erectile dysfunction or dopamine antagonists is not recommended. Domperidone and prochlorperazine are said not to interact when apomorphine is used for erectile dysfunction, and domperidone is the recommended antiemetic when apomorphine is used for Parkinson's disease. There have been reports of profound hypotension when ondansetron was used with apomorphine. There appears to be no evidence that antidepressants or antiepileptics interact adversely with apomorphine.

Clinical evidence, mechanism, importance and management

(a) Antidepressants

An analysis of phase II/III studies found no difference in the efficacy of sublingual apomorphine for erectile dysfunction in patients receiving antidepressants, nor was there any significant difference in the adverse effects reported, when compared with the general study population.[1] In a study in 7 patients with Parkinson's disease, **fluoxetine** 20 mg given twice daily for about 11 days did not alter the apomorphine-induced decrease in parkinsonian motor disability, but it did result in an improvement in the dyskinesias induced by apomorphine.[2]

(b) Antiemetics

The small doses of apomorphine used for erectile dysfunction (2 to 3 mg) do not normally cause vomiting, but nausea does occur in about 7% of patients and the manufacturer reported that interaction studies and/or clinical experience has shown that **domperidone**, **ondansetron** or **prochlorperazine** can safely be given as antiemetics in this patient group (but see below for use in Parkinson's disease).[3] Studies with other antiemetics have not been carried out, so concurrent use was not recommended.[3]

Note that **prochlorperazine** should not be given if apomorphine is used for Parkinson's disease, as its dopamine antagonist actions can worsen the disease. It is possible that the use of the dopamine antagonist, **metoclopramide**, may diminish the effects of apomorphine[4] (see also 'Levodopa + Antiemetics', p.796). Because apomorphine is highly emetogenic at the doses required for the treatment of Parkinson's disease (1 to 4 mg/hour by subcutaneous infusion), patients with Parkinson's disease requiring apomorphine should be pretreated with **domperidone** 20 mg three times daily for at least 2 days.[5] Rarely, extrapyramidal adverse effects have been reported with **ondansetron**,[6] which may be of relevance in patients with Parkinson's disease. However, the US manufacturer of apomorphine injection, indicated for the management of Parkinson's disease, contraindicates the concurrent use of 5-HT_3 receptor antagonists based on reports of profound hypotension and loss of consciousness when **ondansetron** was given with apomorphine; they name **alosetron**, **dolasetron**, **granisetron**, **ondansetron** and **palonosetron**.[4]

(c) Antiepileptics

The manufacturer of a preparation of apomorphine used for erectile dysfunction noted that no studies about interactions between apomorphine and antiepileptics have been undertaken, but clinical experience in erectile dysfunction suggests that no interaction occurs.[3]

(d) Antipsychotics

The manufacturer of a preparation of apomorphine used for erectile dysfunction, advised that apomorphine should not be given with centrally-acting dopamine antagonists[3] because potentially they may antagonise the effects of apomorphine. Such drugs would include some antipsychotics. Some manufacturers recommend that if neuroleptics are necessary in patients with Parkinson's disease receiving dopamine agonists, the dopamine agonist should be progressively reduced (and then stopped[7]), as sudden withdrawal may cause neuroleptic malignant syndrome.[5,7]

The manufacturer of *APO-go* specifically notes that there is a potential interaction between **clozapine** and apomorphine, although they say that **clozapine** may also be used to reduce the symptoms of neuropsychiatric complications of Parkinson's disease.[5]

(e) Other dopamine agonists

One manufacturer advised that apomorphine, used for erectile dysfunction, should not be given with other centrally-acting dopamine agonists.[3] See 'Table 18.1', (p.784) for a list of these drugs.

(f) Other drugs used for erectile dysfunction

One manufacturer reported that although no formal studies had been done with a combination of apomorphine and other drugs used for erectile dysfunction, there seemed to be no evidence of problems, nevertheless concurrent use was not recommended.[3] Other drugs used for this condition include **alprostadil**, **moxisylyte**, **papaverine**, **phentolamine**, and the **phosphodiesterase type-5 inhibitors** such as **sildenafil**. A study using a combination of up to three of apomorphine, **papaverine** and **phentolamine**, found that the lowest incidence of treatment-related adverse effects occurred with apomorphine and **phentolamine** (9.8%), a higher incidence with **papaverine** and **phentolamine** (16.7%) and the highest incidence with all three drugs (17.5%).[8]

Bromocriptine and other dopamine agonists + ACE inhibitors

A single report describes severe hypotension when a patient taking lisinopril was given pergolide. Dopamine agonists are well known to be associated with hypotensive reactions during the first few days of treatment.

Clinical evidence

A man successfully treated for hypertension with **lisinopril** 10 mg daily experienced a severe hypotensive reaction within 4 hours of taking a single 50-microgram dose of **pergolide** for periodic leg movements during sleep. He needed hospitalisation and treatment with intravenous fluids.[1]

Mechanism

All dopamine agonists can cause hypotensive reactions during the first few days of treatment. It is not clear whether this patient was extremely sensitive to pergolide or whether what occurred was due to an interaction. However, it is not unreasonable to assume that the hypotensive effects of dopamine agonists and ACE inhibitors might be additive.

Importance and management

Evidence for an interaction between the dopamine agonists and ACE inhibitors appears to be limited to this isolated case, but what happened is in line with the known effects of both classes of drug. Postural hypotension on starting dopamine agonists is a well recognised adverse effect, but this appears to be the only report that this might be of more concern in patients taking antihypertensives. The manufacturers of pergolide recommend caution when it is given with antihypertensives because of the risk of postural and/or sustained hypotension. The authors of the case report suggest that in patients taking antihypertensives the initial dose of pergolide should be 25 micrograms.[1] It would seem prudent to exercise extra caution with the initial use of pergolide and other dopamine agonists in patients taking ACE inhibitors.

1. Kando JC, Keck PE, Wood PA. Pergolide-induced hypotension. *Ann Pharmacother* (1990) 24, 543.

Bromocriptine and other dopamine agonists + Antiemetics

Domperidone and metoclopramide would be expected to reduce the prolactin-lowering effect of bromocriptine. The hypotensive effect of bromocriptine has also been reduced by metoclopramide and domperidone. Metoclopramide, but not domperidone, would be expected to reduce the antiparkinsonian effect of any dopamine agonist.

Metoclopramide does not affect the overall bioavailability of bromocriptine. The pharmacokinetics of ropinirole or rotigotine are not affected by domperidone.

Clinical evidence, mechanism, importance and management

(a) Effect on Parkinson's disease

Dopamine agonists frequently cause nausea and vomiting on starting treatment. The manufacturers of bromocriptine,[1] **lisuride**,[2] and **pergolide**[3] state that, if necessary, this may be reduced by taking a peripheral dopamine antagonist such as **domperidone**. **Metoclopramide** is not considered a suitable antiemetic for use in Parkinson's disease because it crosses the blood brain barrier and has central dopamine antagonist effects, and may therefore reduce the efficacy of dopamine agonists in this condition, see also 'Levodopa + Antiemetics', p.796. In a single-dose study in 10 patients with Parkinson's disease, giving **metoclopramide** before bromocriptine resulted in a slight reduction in clinical response to bromocriptine in some patients.[4] The manufacturers of **cabergoline**,[5] **ropinirole**,[6] and **rotigotine**[7] advise against the use of metoclopramide for this reason.

(b) Pharmacokinetic effects

In a study, 7 healthy subjects were given a single 7.5-mg dose of bromocriptine alone or with a single 500-microgram/kg intravenous dose of **metoclopramide**, after a standardised breakfast and after an overnight fast. The bioavailability of bromocriptine was unaffected by the concurrent use of **metoclopramide**, but the time to reach the maximum plasma level of bromocriptine, after fasting, was reduced by 30% by metoclopramide.[8]

In a study in 10 patients with Parkinson's disease, giving a single 60-mg dose of **metoclopramide** before single doses of up to 100 mg of bromocriptine caused a slight increase in peak plasma bromocriptine levels in some patients, which occurred a little earlier than when bromocriptine was given alone. However, these changes did not result in any change in clinical outcomes.[4]

In a single-dose study in 9 healthy subjects, giving **domperidone** 20 mg one hour before **ropinirole** 800 micrograms did not alter the pharmacokinetics of **ropinirole**.[9]

In a crossover study, 16 healthy subjects applied a **rotigotine** patch 2 mg/24 hours daily for 4 days with or without **domperidone** 10 mg three times daily for 5 days. The pharmacokinetics of rotigotine were not affected by concurrent domperidone, and no dose adjustment is likely to be required on concurrent use.[10]

(c) Prolactin-lowering effect

Both **domperidone** and **metoclopramide** are dopamine antagonists and can raise prolactin levels, sometimes causing galactorrhoea, gynaecomastia or mastalgia.[11,12] They would therefore be expected to reduce the prolactin-lowering effect of bromocriptine.[1] However, an early study in 10 patients with Parkinson's disease given single doses of bromocriptine 12.5 to 100 mg found that pretreatment with a single 60-mg dose of **metoclopramide** had no consistent effect on plasma bromocriptine levels or on the clinical or hormonal response,[4] although this does not seem to have been studied in a multiple dose study. Further, in a single-dose study in 9 healthy subjects, a single 20-mg dose of **domperidone** increased the plasma level of prolactin whereas a single 800-microgram dose of **ropinirole** given alone reduced it. Giving **ropinirole** one hour after **domperidone** tended to blunt the response of prolactin to domperidone, but the differences were small and not likely to be clinically significant.[9] Nevertheless, it would be prudent to monitor the efficacy of bromocriptine and other dopamine agonists used for their effect on prolactin if **domperidone** or **metoclopramide** are required.

(d) Other effects

In a placebo-controlled study, 9 patients with hypertension received a single 2.5-mg dose of bromocriptine after taking **metoclopramide** 30 mg daily for one week. Bromocriptine alone reduced blood pressure from 163/93 mmHg to 143/82 mmHg, three hours after administration, but this hypotensive effect was not seen after pretreatment with **metoclopramide**. Plasma renin activity and plasma aldosterone levels were reduced after taking bromocriptine alone, but after pretreatment with **metoclopramide**, bromocriptine did not cause any significant changes in these hormonal parameters.[13] Similar results were seen in a study in which a single 2.5-mg dose of bromocriptine was given after the subjects took **domperidone** 30 mg daily for a week.[14]

In a placebo-controlled, crossover study, 9 healthy subjects took a single 20-mg dose of **domperidone** followed, one hour later, by a single 800-microgram dose of **ropinirole**. There was no significant difference in the effects on supine blood pressure when each drug was taken alone or together, but pretreatment with **domperidone** prevented orthostatic reactions to **ropinirole** in all but one subject.[9]

Bromocriptine and other dopamine agonists + Antipsychotics

Many antipsychotics are dopamine antagonists. Therefore if they are given with dopamine agonists, such as bromocriptine, the effects of both drugs may be expected to be reduced. In particular the antipsychotics are associated with extrapyramidal adverse effects, which would be expected to oppose the effects of bromocriptine and related drugs in treating Parkinsonian symptoms. Case reports describe a reduction in prolactin-lowering effects and the emergence of schizophrenic symptoms in patients given an antipsychotic with a dopamine agonist.

Clinical evidence, mechanism, importance and management

(a) Effect on antipsychotic drug activity

A woman with schizoaffective schizophrenia, taking **molindone** 100 mg and imipramine 200 mg daily, relapsed within 5 days of starting to take bromocriptine 2.5 mg three times daily for amenorrhoea and galactorrhoea.[1] Within 3 days of stopping the bromocriptine the symptoms of relapse (agitation, delusions, and auditory hallucinations) vanished. The reason suggested by the authors of the report is that the bromocriptine (a dopamine agonist) opposed the actions of the antipsychotic medication (dopamine antagonists) thereby allowing the schizophrenia to re-emerge. Limited evidence suggests that levodopa may antagonise the effects of antipsychotics (see 'Levodopa + Antipsychotics', p.797), which adds weight to this theory.

(b) Effect on prolactin levels

A case of reduced prolactin levels has been reported in a man taking **fluphenazine** and **benzatropine** who was given bromocriptine to treat a pituitary tumour. His prolactin level became undetectable, and his psychiatric status was unchanged, although no reduction in tumour size was seen with the bromocriptine.[2] The prolactin levels of a patient with a prolactin-secreting pituitary adenoma fell from almost 8000 nanograms/mL to 400 nanograms/mL when bromocriptine was started, but increased again to 1000 nanograms/mL when he started to take **thioridazine** 25 mg twice daily. As the **thioridazine** dose was increased to 200 mg daily, his prolactin level increased further, to 2000 nanograms/mL, and his visual fields deteriorated. Normal vision returned within 5 days of stopping the **thioridazine**, and his prolactin levels fell to below 500 nanograms/mL.[3]

Other dopamine agonists used for their prolactin-lowering effects would be expected to be similarly affected.

(c) Extrapyramidal effects

Many antipsychotics have dopamine antagonist properties and can cause movement disorders (extrapyramidal effects). For this reason, these drugs can reduce the efficacy of dopamine agonists used in Parkinson's disease, and exacerbate the disorder. This interaction is well established for levodopa: see 'Levodopa + Antipsychotics', p.797, which discusses the relative tendency for various classical and atypical antipsychotics to cause this effect. It would equally well be anticipated for any dopamine agonist.

If an antipsychotic is required for psychosis in Parkinson's disease, the risk-benefit ratio should be carefully assessed, and an antipsychotic chosen that has a lower risk of extrapyramidal effects such as an atypical antipsychotic.

Bromocriptine and other dopamine agonists + Azoles

Two patients taking cabergoline had improvements in their Parkinson's disease symptoms while taking itraconazole. In one case a 300% increase in cabergoline levels occurred, and the other patient reduced the dose of her medications without adversely affecting disease control. All azoles may interact to a greater or

lesser extent. Bromocriptine is predicted to interact in the same way as cabergoline.

Clinical evidence

A man with Parkinson's disease taking cabergoline 4 mg daily and selegiline 5 mg twice daily was prescribed pulse itraconazole (200 mg twice daily for one week out of four) for a fungal nail infection. At the end of the first week the patient reported improvements in his parkinsonism, which was confirmed by clinical investigation. The improvement gradually decreased during the weeks without itraconazole, and re-emerged while taking the itraconazole. Analysis of cabergoline blood levels found a 300% increase in levels after he had taken itraconazole for a week.[1]

Another similar patient taking cabergoline 2 mg twice daily, selegiline, entacapone, and levodopa with carbidopa, experienced symptoms of overdose (hyperkinesia of the extremities) 3 days after starting itraconazole 200 mg twice daily. She reduced the dose of her Parkinson's medication, and had marked improvement in her usual Parkinson's symptoms, which then gradually reduced after stopping the itraconazole. This was repeated following two additional periods of itraconazole use.[1]

Mechanism

Cabergoline is metabolised by the cytochrome P450 isoenzyme CYP3A4. Itraconazole is a potent inhibitor of this isoenzyme, and would therefore be expected to increase cabergoline levels.

Importance and management

Although evidence is limited, this interaction would be predicted on the basis of the known pharmacokinetics of cabergoline and enzyme-inhibitory effects of itraconazole. It would be prudent to monitor toxicity and efficacy in any patient taking cabergoline requiring itraconazole, or similar potent inhibitors of CYP3A4, which include a number of the azole antifungals. Bromocriptine is metabolised in a similar way to cabergoline, and would be expected to interact similarly. The manufacturer of bromocriptine advises caution on the concurrent use of azole antifungals.[2]

2. Parlodel (Bromocriptine mesilate). Meda Pharmaceuticals. UK Summary of product characteristics, November 2007.

Bromocriptine and other dopamine agonists + Ergot derivatives

Because cabergoline is an ergot derivative, the manufacturers have looked at what happens if other ergot derivatives are used concurrently, but have so far found no evidence of changes in the efficacy or safety of cabergoline. Nevertheless they do not recommend their concurrent use during long-term treatment with cabergoline.[1] Similarly, the manufacturer of bromocriptine does not recommend concurrent use of other ergot derivatives during the puerperium.[2] It would seem prudent to use similar caution with other dopamine agonists that are ergot derivatives (e.g. lisuride, pergolide), although there appears to be no information available. See also 'Ergot derivatives + Ergot derivatives', p.682, for a description of a number of adverse effects that have occurred as a result of the concurrent use of two ergot derivatives.

Bromocriptine and other dopamine agonists + Food

Food does not alter the pharmacokinetics of bromocriptine, cabergoline or lisuride and has little effect on the extent of absorption of ropinirole.

Clinical evidence

(a) Bromocriptine

In a study in 7 healthy subjects, taking a single 7.5-mg dose of bromocriptine after breakfast did not alter the bromocriptine AUC, when compared with the fasted state, although it slightly reduced the maximum plasma level.[1]

(b) Cabergoline

In a study in healthy subjects, the pharmacokinetics of cabergoline did not change when a single 1-mg dose of cabergoline was taken after breakfast, when compared with the fasting state.[2]

(c) Lisuride

Thirty healthy subjects were given lisuride 200 micrograms orally while fasting or with food. It was found that food did not significantly modify either the pharmacokinetics or the pharmacodynamics of lisuride.[3]

(d) Ropinirole

In a study, 12 patients who had achieved ropinirole steady-state levels took a single 2-mg dose after an overnight fast, or after a high-fat breakfast. The mean maximum ropinirole plasma levels were reduced by about 25%, and the median time to reach maximum plasma levels was delayed from 1.25 hours to 4 hours, in the presence of food. The $AUC_{0\text{-}8}$ was reduced by 11% after a high-fat breakfast. The effect of these changes on the patients' Parkinson's disease was not monitored.[4] A study involving 20 patients with Parkinson's disease who received ropinirole 8 mg as a prolonged-release tablet, after fasting or after a high-fat breakfast, found that the AUC and maximum plasma levels of ropinirole were similar when given in the fed or fasted state. Reports of adverse effects were similar between the two groups.[5]

Mechanism

None.

Importance and management

Food had no effect on the pharmacokinetics of the dopamine agonists studied. Food decreased the rate of absorption of ropinirole, but had little effect on the extent of absorption. The manufacturers of bromocriptine, cabergoline, lisuride and ropinirole recommend that they are taken with food.[6-9] These drugs commonly cause nausea and vomiting, especially when they are newly started, and taking them with food may improve tolerability.[7-9] As **rotigotine** is given transdermally, food is not expected to affect its pharmacokinetics.[10]

Bromocriptine and other dopamine agonists + Macrolides

Erythromycin markedly increases bromocriptine levels, and a case of toxicity has been reported. Bromocriptine toxicity also occurred in a patient given josamycin. Clarithromycin increases cabergoline levels, and erythromycin would be expected to interact similarly. Erythromycin has no effect on lisuride levels.

Clinical evidence

(a) Bromocriptine

1. Erythromycin. In 5 healthy subjects, erythromycin estolate 250 mg four times daily for 4 days increased the peak plasma levels and the AUC of a single 5-mg oral dose of bromocriptine by about 360% and 268%, respectively.[1] Another report describes 2 women taking levodopa with carbidopa and bromocriptine for parkinsonism in whom the disease was better controlled when erythromycin was added. Bromocriptine plasma levels were found to be 40 to 50% higher while they were taking erythromycin.[2] An elderly woman taking levodopa and bromocriptine 15 mg developed psychotic symptoms when she took erythromycin, which were attributed to bromocriptine toxicity.[3]

2. Josamycin. An elderly man with Parkinson's disease, which was well-controlled for 10 months with levodopa with benserazide, bromocriptine 70 mg daily and domperidone, was given josamycin 2 g daily for a respiratory infection. Shortly after the first dose he became drowsy with visual hallucinations, and began to have involuntary movements of his limbs, similar to the dystonic and dyskinetic movements seen in choreoathetosis. These adverse effects (interpreted as bromocriptine toxicity) disappeared within a few days of withdrawing the josamycin.[4]

(b) Cabergoline

In a crossover study, 10 healthy subjects received cabergoline 1 mg daily with or without **clarithromycin** 200 mg twice daily for 6 days. The AUC of cabergoline was increased by 162% and its maximum plasma level increased by 176%. The study was repeated with 7 patients with Parkinson's disease already taking cabergoline, and this found that **clarithromycin** increased the average plasma level of cabergoline by about 70%. Three of the patients experienced an improvement in their Parkinson's disease symptoms; none of the patients had adverse effects.[5]

(c) Lisuride

Twelve healthy subjects were given lisuride 200 micrograms orally or 50 micrograms as a 30 minute intravenous infusion after taking **erythromycin** (dose unknown) twice daily for 4 days. Preliminary results showed that **erythromycin** did not significantly modify either the pharmacokinetics or the pharmacodynamics of the lisuride.[6]

Mechanism

The ergot dopamine agonists, bromocriptine and cabergoline, undergo extensive metabolism, most likely by the cytochrome P450 isoenzyme CYP3A4. Erythromycin and clarithromycin (and potentially other macrolides, see 'Ergot derivatives + Macrolides', p.683) inhibit this metabolism, thus significantly elevating bromocriptine and cabergoline plasma levels.[1] *In vitro* study has suggested that bromocriptine is also a substrate of OATP-C (organic anion transporting polypeptide C), which may be inhibited by erythromycin, resulting in reduced hepatic uptake and thus metabolism of bromocriptine.[7] It is also possible that P-glycoprotein may be involved in the transport of these ergot dopamine agonists and that inhibition of P-glycoprotein-mediated excretion by macrolides such as clarithromycin may result in increased plasma levels.[5]

Importance and management

Information seems to be limited to these reports, but the pharmacokinetic interaction would appear to be established. Concurrent use should be well monitored if any of these macrolides (clarithromycin, erythromycin, josamycin) is added to bromocriptine or cabergoline treatment. Note that **azithromycin** does not normally cause enzyme inhibition and so may not interact. Moderately increased levels may be therapeutically advantageous, but grossly elevated levels can be toxic. The authors of one report[1] suggest reducing the bromocriptine dose, while in another case the dose was reduced by 50% to avoid toxicity.[3] The manufacturer of cabergoline advises avoiding the concurrent use of macrolides, and specifically names erythromycin.[8] Preliminary data suggest that dose adjustments are not needed if lisuride is given with erythromycin.

Bromocriptine and other dopamine agonists + Proton pump inhibitors

A single case describes worsening mobility, which was attributed to an interaction between lansoprazole and bromocriptine. The same patient later received bromocriptine and omeprazole without problems. No pharmacokinetic interaction occurred when omeprazole was taken with rotigotine.

Clinical evidence, mechanism, importance and management

(a) Bromocriptine

A 73-year-old man taking levodopa with benserazide and bromocriptine for Parkinson's disease was given **lansoprazole** 15 mg daily to treat reflux oesophagitis. Two days later, the patient exhibited akinesia (more motor difficulties and slowness in movements) associated with frequent falls. **Lansoprazole** was discontinued, and the symptoms had resolved by the following day. About 3 months later the patient took **omeprazole** 20 mg daily, which caused no aggravation of Parkinson's disease over the following 6 months. The authors attribute this case to a possible interaction between **lansoprazole** and bromocriptine,[1] although any mechanism is unclear, especially as **omeprazole** was given without problems. This single unexplained case seems unlikely to be of general significance.

(b) Rotigotine

The pharmacokinetics of rotigotine were unaltered by **omeprazole** 40 mg daily, in healthy subjects.[2]

1. Anglès A, Bagheri H, Saivin S, Montastruc JL. Interaction between lansoprazole and bromocriptine in a patient with Parkinson's disease. *Therapie* (2002) 57, 408–10.
2. Neupro (Rotigotine). UCB Pharma Ltd. UK Summary of product characteristics, August 2009.

Bromocriptine + Griseofulvin

Evidence from a single patient, who was taking bromocriptine for acromegaly, suggests that the effects of bromocriptine can be opposed by griseofulvin.

Clinical evidence, mechanism, importance and management

In a study of the effects of bromocriptine used for the treatment of acromegaly, one patient who initially had a good response to bromocriptine developed resistance to the drug. After a number of months it was found that this patient had subsequently been given griseofulvin 500 mg daily for the treatment of a fungal nail infection. When the griseofulvin was stopped, the bromocriptine was again effective.[1] The mechanism of this interaction and its general importance are unknown.

1. Schwinn G, Dirks H, McIntosh C, Köbberling J. Metabolic and clinical studies on patients with acromegaly treated with bromocriptine over 22 months. *Eur J Clin Invest* (1977) 7, 101–7.

Bromocriptine + Nasal decongestants and related drugs

Adverse effects, including hypertension, severe headache, seizures and psychosis, have been seen in patients taking phenylpropanolamine, pseudoephedrine or isometheptene with or shortly after the use of bromocriptine.

Clinical evidence

Two healthy women who had given birth 3 to 4 days previously, developed severe headaches while taking bromocriptine 2.5 mg twice daily for

milk suppression. After additionally taking three 65-mg doses of **isometheptene mucate**, the headache of one of them markedly worsened, and hypertension with life-threatening ventricular tachycardia and cardiac dysfunction developed. The other woman took two 75-mg doses of **phenylpropanolamine**, and developed grand mal seizures and cerebral vasospasm.[1]

A 32-year-old woman took two 5-mg doses of bromocriptine for milk suppression without any adverse effects following the birth of a child. Within 2 hours of taking a third dose with **phenylpropanolamine** 50 mg she awoke with a very severe headache and was found to have a blood pressure of 240/140 mmHg. She was given 5 mg of intramuscular morphine and her blood pressure became normal within 24 hours. Another 5-mg dose of bromocriptine taken 48 hours after the original dose of **phenylpropanolamine** had the same effect, but the blood pressure rise was less severe (160/120 mmHg).[2]

A case report describes a 37-year-old woman who took bromocriptine for 17 days. Nine days later, she took *Rinurel*, a preparation for colds containing **phenylpropanolamine**, and 90 minutes later she developed a severe headache: cerebral haemorrhagic lesions were detected. It was thought that the phenylpropanolamine was mainly responsible for the vascular effects, but it was also suggested that the recent use of bromocriptine may have contributed to this effect.[3]

A woman who had recently given birth and who had taken bromocriptine 2.5 mg twice daily for 9 days without problems became psychotic shortly after starting to take **pseudoephedrine** 60 mg four times daily.[4]

Mechanism

Not understood. Severe hypertension occasionally occurs with either bromocriptine or phenylpropanolamine given alone. Shortly after giving birth some individuals show increased vascular reactivity, and it could be that all of these factors conspired together to cause the adverse effects seen.[2] Psychosis occasionally occurs after giving birth or with bromocriptine alone, so that in the latter case the addition of pseudoephedrine may have been coincidental.[4]

Importance and management

Direct information seems to be limited to these cases, but the severity of the reactions suggests that it might be prudent for postpartum patients to avoid indirectly-acting sympathomimetics like these (e.g. phenylpropanolamine, ephedrine, pseudoephedrine) while taking bromocriptine. Note that bromocriptine is not recommended for the routine suppression of lactation postpartum.

Bromocriptine + Octreotide

Octreotide modestly increases the bioavailability of bromocriptine, whereas bromocriptine does not appear to alter octreotide pharmacokinetics.

Clinical evidence, mechanism, importance and management

The concurrent use of bromocriptine 5 mg twice daily and subcutaneous octreotide 200 micrograms twice daily increased the bioavailability of bromocriptine by about 40%, without altering its clearance or half-life. The pharmacokinetics of octreotide were unchanged.[1] This effect may contribute to the increased efficacy of concurrent use in acromegaly, which has been seen in some studies. It seems unlikely that any particular precautions are necessary on concurrent use.

1. Fløgstad AK, Halse J, Grass P, Abisch E, Djøseland O, Kutz K, Bodd E, Jervell J. A comparison of octreotide, bromocriptine, or a combination of both drugs in acromegaly. *J Clin Endocrinol Metab* (1994) 79, 461–5.

Cabergoline + Grapefruit juice

Grapefruit juice increases cabergoline levels.

Clinical evidence, mechanism, importance and management

When 5 patients with Parkinson's disease were given grapefruit juice (quantity not specified) with cabergoline, the plasma levels of cabergoline were increased by about 70%. No adverse events were reported by the patients.[1]

Grapefruit juice is an inhibitor of the cytochrome P450 isoenzyme CYP3A4 in the gut, which is involved in the metabolism of cabergoline. Therefore the concurrent use of grapefruit reduces the metabolism of cabergoline in the gut, increasing its bioavailability.

Evidence for an interaction appears to be limited to this study, but the interaction is established. However, there appear to be no reports of adverse effects in patients receiving grapefruit juice and cabergoline, so its clinical relevance is not established. The authors suggest that, as cabergoline has a large therapeutic index, concurrent use need not be avoided, and may even be beneficial.[1]

1. Nagai M, Nakatsuka A, Yabe H, Moritoyo T, Nomoto M. Effect of grapefruit juice on cabergoline pharmacokinetics in patients with Parkinson's disease. *Clin Pharmacol Ther* (2005) 77, P84.

COMT inhibitors + Inotropes and Vasopressors

Entacapone potentiated the increase in heart rate and arrhythmogenic effects of isoprenaline (isoproterenol) and adrenaline (epinephrine) in a study in healthy subjects. Therefore, the manufacturers of entacapone and tolcapone issue a caution about the concurrent use of adrenaline, isoprenaline, and a number of other inotropes and vasopressors.

Clinical evidence

In a study in healthy subjects, the maximal increase in heart rate during an infusion of **adrenaline** (**epinephrine**) was about 80% greater (25 bpm versus 14 bpm) after pretreatment with a single 400-mg dose of **entacapone**. Similarly, the maximal increase in heart rate during **isoprenaline** (**isoproterenol**) infusion was about 50% greater (40 bpm versus 27 bpm) after pretreatment with the same dose of **entacapone**. Moreover, more subjects experienced palpitations when pretreated with **entacapone**, and this study was terminated early because of two cases of ventricular arrhythmias, one requiring treatment with propranolol. There was no change in blood pressure, nor any increase in plasma levels of the **adrenaline** or **isoprenaline**.[1]

Mechanism

Tolcapone and entacapone inhibit the enzyme catechol-*O*-methyl transferase (COMT), which is concerned with the metabolism of drugs such as adrenaline (epinephrine) and isoprenaline (isoproterenol). There is therefore a possibility of increased plasma levels and related adverse effects of these drugs.

Importance and management

The evidence from this single-dose study confirms the theoretical prediction that COMT inhibitors might potentiate the effects of adrenaline (epinephrine). Because of this, the manufacturers of entacapone and tolcapone suggest caution if drugs known to be metabolised by COMT are given to patients taking COMT inhibitors.[2-5] Adrenaline (epinephrine), **dobutamine**, **dopamine**, isoprenaline (isoproterenol) and **noradrenaline** (**norepinephrine**), are specifically named in one or more of the lists,[2-5] and one manufacturer of entacapone also lists **bitolterol** and **isoetarine** (**isoetharine**), which are usually used in asthma, and specifically includes the inhaled route of administration.[5]

COMT inhibitors + MAOIs

In a single-dose study, there was no adverse effect on heart rate or blood pressure when entacapone was given with moclobemide. The COMT inhibitors may be used with the MAO-B inhibitors (such as selegiline). However, the manufacturers of entacapone and tolcapone contraindicate concurrent use of non-selective MAOIs or a combination of both a RIMA and an MAO-B inhibitor.

Clinical evidence

In a single-dose, placebo-controlled study, **moclobemide** 150 mg did not change the heart rate or blood pressure at rest or during exercise, when given with **entacapone** 200 mg, compared with either drug alone or placebo. In addition, the plasma concentrations of endogenous noradrenaline (norepinephrine) and adrenaline (epinephrine) were not altered.[1] In 13 patients with Parkinson's disease, the addition of **selegiline** 10 mg daily to treatment with **entacapone** 200 mg three or four times daily, and levodopa with benserazide 200/50 mg three or four times daily, did not result in any clinically significant changes in haemodynamic parameters or adverse effects.[2]

Mechanism

Monoamine oxidase and COMT are the two major enzyme systems involved in the metabolism of catecholamines. Therefore it is theoretically possible that the combination of a COMT inhibitor and a non-selective MAOI would result in inhibition of the normal metabolism of catecholamines, with an increase in their effects (e.g. hypertension). Using an MAO-B inhibitor with a RIMA is similar to giving a non-selective MAOI and therefore using these two drugs with a COMT inhibitor would also be likely to inhibit the normal metabolism of catecholamines.

Importance and management

The results of the single-dose study with entacapone and moclobemide suggest that no adverse haemodynamic interaction occurs. Nevertheless, this finding needs confirmation in a clinical setting. Until further information is available, caution would be advisable on concurrent use. The manufacturers of entacapone and **tolcapone** contraindicate or advise against the use of non-selective MAOIs (e.g. **phenelzine**, **tranylcypromine**)[3-6] and combinations of both a RIMA [e.g. moclobemide] plus an MAO-B inhibitor (e.g. **selegiline**).[3,5] However, they state that **selegiline** alone is compatible with the COMT inhibitors provided not more than 10 mg daily is used.[3,5] At this dose, **selegiline** is likely to remain selective for MAO-B.

COMT inhibitors + Nasal decongestants

A single case report describes severe hypertension in a patient given entacapone and intravenous ephedrine. Tolcapone did not alter the effect of ephedrine in one study.

Clinical evidence

(a) Entacapone

A 76-year-old woman with Parkinson's disease taking levodopa with carbidopa and entacapone 200 mg five times daily, was given 3 mg of intravenous **ephedrine** during cataract surgery to correct a low blood pressure of 85/35 mmHg. Her blood pressure immediately rose to 225/125 mmHg. The patient needed several doses of hydralazine over the following 140 minutes before her blood pressure returned to normal.[1]

(b) Tolcapone

The manufacturer notes that tolcapone did not alter the effect of **ephedrine** (route of administration not stated) on haemodynamic parameters or plasma catecholamine levels, either at rest or during exercise.[2,3]

Mechanism

COMT inhibitors may inhibit the normal metabolism of ephedrine (and the catecholamines it releases at adrenergic nerve endings), which could result in a marked exaggeration of its normal effects.[1]

Importance and management

The single case report with entacapone and intravenous ephedrine appears to be the only evidence that COMT inhibitors could potentiate the effect of indirectly-acting sympathomimetics such as ephedrine. The manufacturer of tolcapone states that ephedrine and tolcapone can be used concurrently.[2,3] Nevertheless, some caution may be warranted with intravenous ephedrine.

3. Tasmar (Tolcapone). Valeant Pharmaceuticals North America. US Prescribing information, June 2009.

COMT inhibitors + Tricyclic and related antidepressants

Entacapone and imipramine did not interact adversely in a single-dose study. Similarly, in another study, tolcapone and desipramine did not interact adversely.

Clinical evidence

(a) Entacapone

In a single-dose, crossover study, 12 healthy women were given entacapone 200 mg with **imipramine** 75 mg, either drug alone, or placebo. Although both drugs can impair the inactivation of catecholamines the study found no evidence that concurrent use had any relevant effect on haemodynamics or on free adrenaline (epinephrine) or noradrenaline (norepinephrine) plasma levels. The combination was well tolerated in all subjects.[1]

(b) Tolcapone

In one study, healthy subjects were given **desipramine** 25 mg three times daily for 3 days then 50 mg three times daily for 10 days. For the last 5 days they were also given levodopa with carbidopa 100/25 mg three times daily and either a placebo or tolcapone 200 mg three times daily. The addition of tolcapone to the use of levodopa with carbidopa and **desipramine** did not lead to any changes in haemodynamics or catecholamine levels, or to any changes in **desipramine** pharmacokinetics.[2]

Mechanism

Both COMT inhibitors and drugs with noradrenaline re-uptake inhibitory activity (e.g. the tricyclics) can impair the inactivation of catecholamines, so in theory the effects of catecholamines may be increased by concurrent use. However, this did not appear to occur in the above studies.

Importance and management

In these pharmacological studies, no important interaction between entacapone and imipramine or between tolcapone and desipramine was detected. Nevertheless, the manufacturer of entacapone says there is limited clinical experience of the use of entacapone with tricyclic antidepressants, and they therefore recommend caution.[3] Similarly, the manufacturers of tolcapone suggest that caution should be exercised with desipramine[4,5] and any drugs that are potent noradrenaline uptake inhibitors such as **maprotiline** and **venlafaxine**.[4]

COMT inhibitors; Entacapone + Iron compounds

Entacapone formed chelates with iron *in vitro*.

Clinical evidence, mechanism, importance and management

An *in vitro* study[1] found that entacapone formed chelates with iron. Although the clinical relevance of this does not appear to have been assessed, the UK manufacturer recommends that entacapone and iron compounds should be taken at least 2 to 3 hours apart.[2]

COMT inhibitors; Tolcapone + Clozapine

A case report describes neuroleptic malignant-like syndrome and acute hepatitis in a patient who took tolcapone and clozapine.

Clinical evidence, mechanism, importance and management

A case report describes a 70-year-old woman taking levodopa with benserazide who developed a neuroleptic malignant-like syndrome, with a temperature of 40.5°C, coma, and muscular rigidity, and fulminant hepatitis about 2 weeks after starting to take tolcapone, and about 10 days after also starting to take clozapine. Twelve hours after stopping tolcapone and clozapine her temperature normalised, and within 2 days she had regained consciousness. Clozapine was restarted with no recurrence of these symptoms.[1] Tolcapone alone can cause increases in liver transaminases, hepatocellular injury, and a neuroleptic malignant-like syndrome, and therefore an interaction is not established.

Levodopa + Antacids

Antacids do not appear to interact significantly with immediate-release levodopa, but they may reduce the bioavailability of modified-release preparations of levodopa.

Clinical evidence

(a) Immediate-release levodopa

One study found that 15 mL of an **aluminium/magnesium hydroxide** antacid, given 30 minutes before levodopa, to a patient with a prolonged gastric emptying time, caused a threefold increase in levodopa serum levels, which was associated with a marked improvement in symptoms.[1] Another patient was able to reduce his levodopa dose when taking antacids, without affecting symptom control.[1] A further study found that the maximum plasma concentration of levodopa was raised by 20% when 20 mL of an antacid was given before the levodopa.[2]

However, when 8 patients (only 3 with Parkinson's disease) were given *Mylanta* (containing **aluminium/magnesium hydroxide** and simeticone), 30 minutes before, and/or with levodopa, only occasional increases in bioavailability were seen. One of the 3 patients with Parkinson's disease who had shown improved bioavailability while taking antacids had his levodopa dose lowered and continued to take *Mylanta*, but the parkinsonian symptoms worsened and the levodopa was increased back to the original dose.[3] Another study, in 15 patients taking dopamine agonists (e.g. bromocriptine) and levodopa with carbidopa who were given six 30-mL doses of **aluminium hydroxide** daily, inferred that the antacid had no significant effect on levodopa bioavailability, because of the lack of clinical fluctuations in effect.[4]

(b) Sustained-release levodopa

In a study in healthy subjects, using *Madopar HBS*, a sustained-release preparation of levodopa with benserazide, the concurrent use of an unnamed antacid reduced the levodopa bioavailability by about one-third.[5] The manufacturer of *Madopar CR* states that antacids reduce the bioavailability of levodopa from the controlled-release preparation in comparison with conventional *Madopar*.[6]

Mechanism

The small intestine is the major site of absorption for levodopa, and delayed gastric emptying appears to result in low plasma levodopa levels, probably because levodopa can be metabolised in the stomach. In theory, antacids may reduce gastric emptying time, and increase levodopa absorption.[1] It is not known why antacids reduced absorption from the slow-release preparation.[5]

Importance and management

The overall picture is that the concurrent use of antacids need not be avoided with standard preparations of levodopa (with a dopa-decarboxylase inhibitor), although some individuals may be affected so the outcome should be monitored. With modified-release preparations it would seem advisable to avoid concurrent administration (one to 2 hours is usually enough in other similar cases of interactions with antacids). Again, the outcome should be monitored.

Levodopa + Anticholinesterases; Centrally acting

Reports describe cases of a worsening of Parkinson's disease in a few patients given donepezil, rivastigmine or tacrine. Other centrally acting anticholinesterases may exacerbate or induce extrapyramidal symptoms, including worsening of Parkinson's disease. In contrast, one study found that donepezil did not affect the control of Parkinson's disease.

Clinical evidence

(a) Donepezil

In a placebo-controlled study in 23 patients with Parkinson's disease taking levodopa with carbidopa, donepezil 5 mg daily for 15 days caused a modest 30% increase in the $AUC_{0\text{-}4}$ of levodopa. There was no change in carbidopa pharmacokinetics, and the pharmacokinetics of donepezil did not differ between the patients with Parkinson's disease and a control group of healthy subjects. There was no obvious difference in adverse effects between patients with Parkinson's disease and the control subjects, and no evidence that donepezil significantly altered motor activity in patients taking levodopa with carbidopa.[1] This latter finding is in contrast to a report that found a worsening of Parkinson's disease, which responded to levodopa with carbidopa, in 3 of 9 patients who had taken donepezil for 24 weeks.[2]

(b) Rivastigmine

A case report describes a 71-year-old woman taking levodopa with carbidopa and tolcapone, who experienced a worsening of her Parkinson's disease after taking a single 3-mg dose of rivastigmine. She became anxious and dysphoric, had severe bradykinesia and rigidity, and felt nauseous. Note that this dose is higher than the usual starting dose of rivastigmine, and this may have contributed to the effects seen.[3]

(c) Tacrine

The mild parkinsonism of an elderly woman with Alzheimer's disease worsened, leading to severe tremor, stiffness and gait dysfunction within 2 weeks of doubling her tacrine dose from 10 mg to 20 mg four times daily. This improved when levodopa with carbidopa was started, but the tremor returned when tacrine was increased to 30 mg four times daily. The symptoms disappeared when the tacrine dose was reduced to 20 mg four times daily.[4]

Mechanism

Parkinsonism is due to an imbalance between two neurotransmitters, dopamine and acetylcholine, in the basal ganglia of the brain. Centrally acting anticholinesterases increase the amount of acetylcholine in the brain, which could lead to an exacerbation of parkinsonian symptoms. Levodopa improves the situation by increasing the levels of dopamine. It is not known why donepezil modestly increased the levels of levodopa.

Importance and management

Direct information seems to be limited, but the reports of worsening Parkinson's disease are consistent with the known pharmacology of these drugs and the biochemical pathology of Parkinson's disease. Be aware that if centrally acting anticholinesterases are given to any patient with parkinsonism, whether taking levodopa or any other anti-parkinson drug, the disease may possibly worsen. The antiparkinson drug dose may need increasing and/or the dose of the anticholinesterase may need reducing.

Levodopa + Antiemetics

Although metoclopramide can increase the rate of levodopa absorption, it may also antagonise its effects by aggravating symptoms of Parkinson's disease, although some studies have found no evidence of this effect. Phenothiazine antiemetics such as prochlorperazine are also generally considered to be contraindicated in Parkinson's disease. In one small study, promethazine did not affect the control of Parkinson's disease in patients taking levodopa. Domperidone is the antiemetic of choice to prevent and treat nausea and vomiting caused by levodopa. Other antiemetics that are generally considered useful include cyclizine and 5-HT_3 receptor antagonists.

Clinical evidence, mechanism, importance and management

(a) Domperidone

Domperidone is a dopamine antagonist similar to metoclopramide.[1] However, as it acts on the dopamine receptors in the stomach wall, and unlike metoclopramide, it does not readily cross the blood-brain barrier, it does not appear to oppose the effects of levodopa within the brain, although some extrapyramidal symptoms have been observed. It may even slightly increase the bioavailability and effects of levodopa (by stimulating gastric emptying).[2] Domperidone can therefore be used to control the nausea and vomiting associated with levodopa treatment of Parkinson's disease.

(b) Metoclopramide

Metoclopramide is a dopamine antagonist that can cause extrapyramidal disturbances (parkinsonian symptoms), especially in children and young adults, and possibly also in the elderly, where the effects may be misdiagnosed as Parkinson's disease.[3] On the other hand, metoclopramide stimulates gastric emptying, which can result in an increase in the bioavailability of levodopa.[4,5] The outcome of these two effects (possible antagonism resulting in aggravation of Parkinson's disease, or potentiation resulting in increased bioavailability) is uncertain, and it is generally considered that metoclopramide should be avoided in Parkinson's disease. However, in one open study, metoclopramide 30 to 60 mg daily in divided doses for a range of 4 to 16 weeks caused no change in mean total disability scores in 10 patients with Parkinson's disease taking levodopa.[6] Similarly, in a controlled study in 7 patients, the incidence and severity of levodopa-induced involuntary movements were unchanged and additional acute dyskinesias did not appear when metoclopramide was also given.[6] Furthermore, in a retrospective analysis, by the same authors, there was no worsening of parkinsonian symptoms in 40 patients with Parkinson's disease taking levodopa who were also given metoclopramide up to 80 mg daily.[7] Nevertheless, if alternative antiemetics are unsuitable for a patient with Parkinson's disease and consequently metoclopramide is given, it would seem prudent to monitor the outcome closely.

(c) Phenothiazine antiemetics

Phenothiazines block the dopamine receptors in the brain and can therefore upset the balance between cholinergic and dopaminergic components within the striatum and substantia nigra. As a consequence they may not only induce the development of extrapyramidal (parkinsonian) symptoms, but they can aggravate parkinsonism and antagonise the effects of levodopa used in its treatment. See 'Levodopa + Antipsychotics', p.797. Phenothiazines, used in smaller doses as antiemetics, such as **prochlorperazine**,[8,9] can also behave in this way. For this reason, drugs of this kind are generally regarded as contraindicated in patients with Parkinson's disease, and there are other more suitable alternatives, see *Non-interacting antiemetics*, below. However, one small controlled study found that **promethazine** (a phenothiazine derivative with few extrapyramidal effects) did not change the total disability score or alter the incidence or severity of levodopa-induced involuntary movements in 6 patients with Parkinson's disease taking levodopa.[6]

(d) Non-interacting antiemetics

Antiemetics that are generally considered useful in patients with Parkinson's disease include **cyclizine** and 5-HT_3 antagonists such as **granisetron** and **ondansetron**,[3] which do not affect dopamine, and **domperidone** as discussed above. However, note that rare cases of extrapyramidal adverse effects have been reported with **ondansetron**, which may be of relevance in patients with Parkinson's disease.[10]

Levodopa + Antimuscarinics

Antimuscarinics and other drugs with antimuscarinic effects, such as the tricyclics, may modestly reduce the rate, and possibly the extent, of absorption of levodopa. One case describes levodopa toxicity, which occurred after the withdrawal of an antimuscarinic.

Clinical evidence

A study in 6 healthy subjects and 6 patients with Parkinson's disease found that **trihexyphenidyl** 2 mg twice daily for 3 days lowered the peak plasma levels of a 500-mg dose of levodopa by 42% in the healthy subjects and by 17% in the patients, although the interaction was present in only about half of the subjects. The AUC was reduced in both groups by less than 20%.[1] Similarly, a study in 10 healthy subjects found that the initial levodopa plasma levels were lowered when a single 250-mg dose of levodopa was taken 90 minutes after a single 5-mg dose of **trihexyphenidyl**. The absorption of levodopa was slower, but the overall bioavailability was not significantly altered. Carbidopa 100 mg was given one hour before the levodopa, and a 50-mg dose was given 5 hours after the levodopa.[2]

A study in 6 patients with Parkinson's disease taking levodopa with car-

bidopa or benserazide found that **orphenadrine** caused either a delay, a reduction, or an increase in levodopa absorption in 3 patients.[3] A patient who needed 7 g of levodopa daily while taking **homatropine** developed levodopa toxicity when the **homatropine** was withdrawn, and he was subsequently restabilised on only 4 g of levodopa daily.[4]

A study in 4 healthy subjects[5] found that **imipramine** 25 mg four times daily for 3 days reduced the peak plasma concentration of a single 500-mg dose of levodopa by about 50%, but did not appear to alter the extent of absorption. See also 'Levodopa + Tricyclic antidepressants', p.806, for other non-antimuscarinic interactions of the tricyclics.

Mechanism

The small intestine is the major site of absorption for levodopa. Delayed gastric emptying, which can be caused by antimuscarinics, appears to result in lower plasma levodopa levels and thus lower brain levodopa levels. This is because the gastric mucosa has more time to metabolise the levodopa to dopamine and therefore less is available for absorption.[6]

Importance and management

Antimuscarinics are commonly given with levodopa, and they are of established benefit. However, limited evidence suggests they might sometimes reduce levodopa efficacy. Levodopa preparations are now more usually given in conjunction with a dopa decarboxylase inhibitor to minimise metabolism in the gastric mucosa. This would be expected to minimise the effects of any interaction. However, note that two of the above studies included a dopa-decarboxylase inhibitor, yet still found an effect on levodopa absorption. There is certainly no need to avoid concurrent use, but it would be prudent to be alert for any evidence of a reduced levodopa response if antimuscarinics are added, or for levodopa toxicity if they are withdrawn.

Levodopa + Antipsychotics

Phenothiazines, butyrophenones, thioxanthenes and pimozide can oppose the effects of levodopa because of their dopamine antagonist properties, causing deterioration of motor function in Parkinson's disease. The antipsychotic effects and extrapyramidal adverse effects of these drugs can be opposed by levodopa. Of the atypical antipsychotics, risperidone and olanzapine cause deterioration in motor function in Parkinson's disease. Ziprasidone and paliperidone may act similarly, and there have been reports of mild motor deterioration with quetiapine. Clozapine does not have this effect.

Clinical evidence, mechanism, importance and management

(a) Classical antipsychotics

Phenothiazines (e.g. fluphenazine, perphenazine, prochlorperazine, and trifluoperazine), **butyrophenones** (e.g. droperidol and haloperidol), **thioxanthenes** (e.g. flupentixol and zuclopenthixol) and pimozide block the dopamine receptors in the brain and can therefore upset the balance between cholinergic and dopaminergic components within the striatum and substantia nigra. As a consequence they may not only induce the development of extrapyramidal (parkinsonian) symptoms, but they can aggravate parkinsonism and antagonise the effects of levodopa used in its treatment.[1-5] For this reason drugs of this kind are generally regarded as contraindicated in patients being treated for Parkinson's disease, or only used with great caution in carefully controlled conditions. The extrapyramidal symptoms that frequently occur with the **phenothiazines** have in the past been treated without much success with levodopa. However, the levodopa may also antagonise the antipsychotic effects of the **phenothiazines**,[6] and other dopamine-antagonist antipsychotics. Phenothiazines used as antiemetics may also act in this way. Consider also 'Levodopa + Antiemetics', p.796.

(b) Atypical antipsychotics

Of the atypical antipsychotics, both **risperidone** and **olanzapine** have caused deterioration of motor function in patients with Parkinson's disease.[7,8] **Paliperidone**, the active metabolite of risperidone, is expected to have similar effects.[9,10] There have also been reports of deterioration in motor function with **quetiapine**, but in general this effect seems to be mild[7] and, in patients with Parkinson's disease, quetiapine appears to be better tolerated than risperidone or olanzapine.[8] There is far less experience with **ziprasidone**, but it may have a propensity to cause extrapyramidal adverse effects that is similar to **olanzapine**.

Low-dose **clozapine** appears to cause little deterioration in motor function, and may improve tremor. It is therefore a preferred antipsychotic for patients with Parkinson's disease and levodopa-induced psychosis. Note that individual reports and studies of the use of these antipsychotics in patients with Parkinson's disease are numerous. Reviews on the topic have been published.[7,8]

Levodopa + Ascorbic acid (Vitamin C)

Ascorbic acid does not appear to alter the pharmacokinetics of levodopa.

Clinical evidence, mechanism, importance and management

In a study, 67 elderly patients with Parkinson's disease took a single dose of levodopa 100 mg with carbidopa 10 mg alone, and with a single 200-mg dose of ascorbic acid. The AUC, maximum plasma levels, and time to reach maximum levodopa plasma levels were increased when ascorbic acid was also given, but these increases were not statistically significant. However, there was a trend towards a larger effect in those patients with lower baseline levodopa bioavailability.[1] Based on the available evidence, there would appear to be no reason for patients taking levodopa to avoid modest doses of ascorbic acid.

Levodopa + Baclofen

Unpleasant adverse effects (hallucinations, confusion, headache, nausea) and worsening of the symptoms of parkinsonism have occurred in patients taking levodopa who were given baclofen.

Clinical evidence

Twelve patients with parkinsonism taking levodopa with a dopa-decarboxylase inhibitor were also given baclofen. The eventual baclofen dose was intended to be 90 mg daily, but the adverse effects were considerable (visual hallucinations, a toxic confusional state, headaches, nausea) so that only 2 patients reached this dose, and 2 patients withdrew because they

could not tolerate these adverse effects. The mean dose for those who continued was 45 mg daily. Rigidity was aggravated by an average of 46% and functional capacity deteriorated by 21%.[1]

A patient with Parkinson's disease taking levodopa with carbidopa, orphenadrine and diazepam became acutely confused, agitated, incontinent and hallucinated when given a third dose of baclofen (in all 15 mg). The baclofen was stopped, but on the following night she again hallucinated and became confused. The next day she was given two 2.5-mg doses of baclofen but she became anxious and hallucinated with paranoid ideas.[2]

Mechanism

Not understood. The toxicity seen appears to be an exaggeration of the known adverse effects of baclofen.

Importance and management

Information appears to be limited to these reports, but they suggest that baclofen should be used very cautiously in patients taking levodopa.

Levodopa + Benzodiazepines and related drugs

On rare occasions it seems that the therapeutic effects of levodopa can be reduced by chlordiazepoxide, diazepam or nitrazepam.

Clinical evidence

Various benzodiazepines (dose unstated) were given to 8 patients with Parkinson's disease taking levodopa. In 5 of the patients (3 taking **chlordiazepoxide**, one taking **nitrazepam**, one taking **oxazepam**) no interactions were seen. However, the other 3 patients (one taking **diazepam**, 2 taking **nitrazepam**) experienced transient disturbances in the control of their Parkinson's disease, which lasted up to 3 weeks in the case of the patient taking **diazepam**.[1] Other cases of a reversible loss of control of Parkinson's disease have been seen in 3 patients taking **diazepam**[2] and 4 patients taking **chlordiazepoxide**.[3,4] In one further case, a patient taking **chlordiazepoxide** experienced falls associated with a worsening of parkinsonian symptoms while taking **chlordiazepoxide**. She recovered 5 days after the **chlordiazepoxide** was withdrawn.[5]

In contrast, a case-control study of patients with Parkinson's disease taking levodopa did not find a statistically significant increase in the required dose of antiparkinsonian drug treatment in the 180 days after starting a benzodiazepine.[6]

Mechanism

Not understood, although *animal* studies have shown that benzodiazepines can decrease the levels of dopamine in the striatum.[6]

Importance and management

Not established. Given the widespread use of benzodiazepines in patients taking levodopa,[7] any major or common interaction would be expected to have come to light by now. It would therefore seem that any interaction is fairly rare, and on the basis of one of the reports cited above, possibly only transient. There is no need to avoid concurrent use, but bear these reports in mind in the case of an unexpected response to treatment.

Levodopa + Beta blockers

The concurrent use of levodopa and beta blockers normally appears to be favourable, but be aware that, as with all antihypertensives, additive hypotensive effects can occur.

Clinical evidence, mechanism, importance and management

Most of the effects of the concurrent use of levodopa and beta blockers seem to be favourable, although additive hypotension can be a problem. Dopamine derived from levodopa stimulates beta-receptors in the heart, which can cause arrhythmias.[1] These receptors are blocked by **propranolol** and other beta blockers. An enhancement of the effects of levodopa and a reduction in tremor has been described in 23 out of 25 patients taking **propranolol**,[2] but not in 9 patients taking **oxprenolol**,[3] or in another placebo-controlled study in 18 patients taking **propranolol**.[4] Early evidence found that growth hormone levels were substantially raised by **propranolol**[5,6] or **practolol**[6] [now withdrawn due to fatal reactions] in conjunction with levodopa, but no clinical relevance for this has been demonstrated.

Levodopa + Bromocriptine and other dopamine agonists

The concurrent use of levodopa and dopamine agonists can increase efficacy and adverse effects in Parkinson's disease. Bromocriptine may sometimes alter levodopa levels and levodopa may lower bromocriptine levels. There appears to be no pharmacokinetic interaction between levodopa and cabergoline, pramipexole or ropinirole. An isolated report describes the development of serotonin syndrome when levodopa with carbidopa was added to treatment with bromocriptine.

Clinical evidence

(a) Bromocriptine

A study in 20 patients with Parkinson's disease taking levodopa with carbidopa found that overall there was no difference in plasma levodopa levels after bromocriptine was also taken, although some patients had either significant elevations or significant reductions in levels. However, the only adverse clinical change found was an increase in dyskinesias in the patients with elevated levodopa levels.[1] An earlier study found no pharmacokinetic interaction between levodopa with carbidopa and bromocriptine, but it should be noted that this was a single-dose study and may not reflect long-term concurrent use.[2] A further study in 7 patients with Parkinson's disease taking long-term levodopa with benserazide found that the addition of bromocriptine, 15 mg daily in three divided doses for 6 months, had no effect on the pharmacokinetics of levodopa.[3] Steady-state bromocriptine plasma levels were found to be reduced by levodopa in a study in 10 patients with Parkinson's disease. The patients normally took levodopa, but this was withheld to give baseline bromocriptine pharmacokinetics.[4]

A patient with parkinsonism, who had been taking bromocriptine 60 mg daily for nearly 3 years, was also given levodopa with carbidopa (250/25 mg daily increasing over a week to 750/75 mg) while the bromocriptine dose was reduced to 20 mg daily. On the seventh day he started shivering, and developed myoclonus of the trunk and limbs, hyperreflexia, patellar clonus, tremor, diaphoresis, anxiety, diarrhoea, tachycardia and had a temperature of 37.9°C with a blood pressure of 180/100 mmHg. Serotonin syndrome was suspected. The patient responded to treatment with the 5-HT antagonist methysergide.[5]

A case of pathological gambling in a 54-year-old woman was attributed to the concurrent use of bromocriptine and levodopa with carbidopa.[6]

(b) Cabergoline

Levodopa with carbidopa 250/25 mg daily did not cause a clinically significant change in the pharmacokinetics of cabergoline 2 mg daily when the combination was given to patients newly diagnosed with Parkinson's disease. Similarly, cabergoline (in increasing doses up to 4 mg daily) for 8 weeks had no effect on the absorption, AUC or elimination half-life of levodopa in another group of patients with fluctuating Parkinson's disease who were taking levodopa with carbidopa.[7]

(c) Pergolide

The manufacturer notes that the use of pergolide in patients taking levodopa may cause and/or exacerbate pre-existing states of dyskinesia, confusion, and hallucinations. Also, they say that stopping pergolide abruptly in patients taking levodopa may precipitate the onset of hallucinations and confusion.[8]

(d) Pramipexole

Patients taking a stable dose of levodopa with carbidopa were given increasing doses of pramipexole or placebo for 7 weeks. Pramipexole 1.5 mg daily and 4.5 mg daily had no effect on levodopa bioavailability.[9] Several cases of pathological gambling have been reported in patients taking pramipexole, usually in association with levodopa.[10]

(e) Ropinirole

In patients taking a stable dose of levodopa with a dopa-decarboxylase inhibitor, ropinirole had no effect on the pharmacokinetics of levodopa, except for a small clinically irrelevant 16% increase in its maximum level. Levodopa also had no effect on the pharmacokinetics of ropinirole in another group of patients.[11] Similarly, in a single-dose study in healthy subjects, levodopa with benserazide had no significant effect on the pharmacokinetics of ropinirole.[12]

(f) Rotigotine

The manufacturer of rotigotine reports that levodopa and carbidopa had no effect on the pharmacokinetics of rotigotine and similarly, rotigotine had no effect on the pharmacokinetics of either levodopa or carbidopa. However, as with other dopamine agonists, rotigotine may cause and/or exacerbate dyskinesia in patients taking levodopa and may potentiate the dopaminergic adverse reactions of levodopa.[13]

Mechanism

Additive dopaminergic effects would be expected. Serotonin syndrome is thought to occur because of increased stimulation of the 5-HT receptors in the brainstem and spinal cord. A syndrome resembling neuroleptic malignant syndrome (which has similar symptoms to serotonin syndrome) can occur when a dopamine agonist like bromocriptine is withdrawn abruptly. It is therefore possible that the effects of reducing the bromocriptine dose were additive with those of levodopa, which can displace serotonin from the nerve endings.[5]

Importance and management

The concurrent use of levodopa and dopamine agonists can increase efficacy in Parkinson's disease, but adverse effects such as hallucinations and dyskinesias may also be increased, and the dose of both drugs should be gradually adjusted to optimise therapy. The manufacturer of ropinirole suggests a total reduction in the levodopa dose of about 20%.[14] If the decision is made to withdraw the dopamine agonist, this should be done slowly, over several days.

Serotonin syndrome described with levodopa and bromocriptine appears to be an isolated incident and not of general importance. A number of cases of pathological gambling have been reported in patients taking dopamine agonists with levodopa. It has been suggested that pathological gambling may be a class effect of dopamine agonists, although levodopa may have contributed in patients receiving both drugs.[10]

Levodopa + Caffeine

Caffeine increased the rate of absorption of levodopa, but not its overall bioavailability.

Clinical evidence, mechanism, importance and management

In a crossover study, 12 patients with Parkinson's disease were given a single 200-mg dose of caffeine or placebo 15 minutes before receiving levodopa 250 mg with carbidopa 25 mg. The rate of absorption of levodopa was increased by caffeine, with maximum levodopa plasma levels being achieved at one hour, compared with 1.5 hours when taken with placebo. There was also a shortening of the time to detect a motor response to levodopa when caffeine was taken. However, the maximum plasma levels and the $AUC_{0\text{-}3}$ of levodopa were not significantly altered by caffeine.[1]

A study in 4 patients with Parkinson's disease investigated the therapeutic benefit of adding caffeine to levodopa with carbidopa. Doses of up to 1.4 g of caffeine daily did not potentiate the antiparkinsonian action of levodopa, but there was an increase in the duration of involuntary movements during the use of high doses of caffeine, and signs or symptoms of caffeine toxicity appeared in all 6 patients.[2]

These studies suggest that caffeine need not be avoided in patients taking levodopa, but high doses may increase movement disorders in response to levodopa. If this becomes troublesome, it may be prudent to try to decrease caffeine intake.

Levodopa + Clonidine

Limited evidence suggests that clonidine may oppose the effects of levodopa. Be aware that, as with the use of all antihypertensives with levodopa, additive hypotensive effects may occur.

Clinical evidence

A study in 2 patients taking levodopa with carbidopa found that the concurrent use of clonidine (up to 1.5 mg daily for 10 to 24 days) caused a worsening of parkinsonism (an exacerbation of rigidity and akinesia). The concurrent use of antimuscarinic drugs reduced the effects of this interaction.[1]

Another report on 10 hypertensive and 3 normotensive patients with Parkinson's disease, 9 of them taking levodopa and 4 of them not, suggested that the concurrent use of clonidine did not affect the control of the parkinsonism. However, 2 patients stopped taking clonidine because of an increase in tremor and gait disturbances.[2]

Mechanism

Not understood. One suggestion is that clonidine opposes the antiparkinson effects by stimulating alpha-receptors in the brain. Another idea is that clonidine directly stimulates post-synaptic dopaminergic receptors.

Importance and management

Information seems to be limited to these reports. Be alert for a reduction in the control of the Parkinson's disease during the concurrent use of levodopa and clonidine. The effects of this interaction appear to be reduced if antimuscarinic drugs are also being used.[1] Also note, that as with all antihypertensives, additive hypotensive effects may occur.

Levodopa + COMT inhibitors

Entacapone and tolcapone increase the AUC of levodopa given with benserazide or carbidopa. This may require a reduction in the levodopa dose to avoid symptoms of dopamine excess when first starting the COMT inhibitor. Tolcapone increases the levels of benserazide, but neither entacapone nor tolcapone alters carbidopa pharmacokinetics.

Clinical evidence

(a) Levodopa

Entacapone[1-3] and **tolcapone**[4,5] have been shown to increase the AUC and/or prolong the elimination half-life of levodopa (given with benserazide or carbidopa) without significantly altering the maximum levodopa level. However, in some studies, the maximum levodopa plasma levels have also been increased by **entacapone** or **tolcapone**.[6,7]

COMT inhibitors can therefore improve the clinical condition of patients with Parkinson's disease, which is mainly seen as a decrease in 'off' time.[8] However, as levodopa levels are raised, there may be an accompanying increase in the adverse effects of levodopa (e.g. dyskinesias, nausea, vomiting, orthostatic hypotension, hallucinations).[9-11]

(b) Benserazide or Carbidopa

The effects of COMT inhibitors on the pharmacokinetics of dopa-decarboxylase inhibitors have also been studied. Neither **entacapone**[2] nor **tolcapone**[12] altered the pharmacokinetics of carbidopa. However, **tolcapone** increased the plasma levels of benserazide in patients with Parkinson's disease.[13] The benserazide levels remained within the usual range in patients taking levodopa with benserazide 25 mg and **tolcapone** 200 mg three times daily. However, with a 50-mg dose of benserazide the AUC of benserazide was increased 4.8-fold with standard-release preparation and 2.3-fold with a controlled-release preparation.[13]

Mechanism

When levodopa is given with a dopa-decarboxylase inhibitor such as carbidopa or benserazide, COMT becomes the major enzyme for metabolising levodopa, so inhibiting COMT delays the breakdown of levodopa.

Importance and management

When starting a COMT inhibitor, all patients should be informed of the symptoms of excess levodopa, and what to do if they occur. The manufacturers of entacapone suggest that if entacapone is started, the daily dose of levodopa should be reduced by about 10 to 30% (within the first few days or weeks) to accommodate these potential adverse effects.[10,14] This can be done by either extending the dosing intervals and/or by reducing the amount of levodopa per dose. Patients taking levodopa with benserazide may require a greater dose reduction than those taking levodopa with carbidopa because entacapone increases the bioavailability of standard levodopa with benserazide preparations by 5 to 10% more than standard levodopa with carbidopa.[10] The manufacturers of tolcapone say that the average reduction in the daily dose of levodopa required on starting tolcapone was 30%, and that greater than 70% of patients taking levodopa doses above 600 mg daily required such a reduction.[11,15] The clinical significance of the increase in benserazide levels is unknown, but the manufacturers advise good monitoring for benserazide adverse effects.[15]

Levodopa + Dacarbazine

An isolated report describes a reduction in the effects of levodopa caused by dacarbazine.

Clinical evidence, mechanism, importance and management

A patient who had been treated surgically for melanoma, continued to receive dacarbazine 200 mg intravenously daily, intermittently, for sporadic positive melanuria. He later developed Parkinson's disease, and was given levodopa, which had no effect on his melanoma. However, each time he was given dacarbazine he complained that the effects of the levodopa with benserazide were reduced and his Schwab and England score (measures of activities of daily living) fell by as much as 25%. A subsequent double-blind study in this patient, using a modified Columbia Score, confirmed this.[1] The reasons are not understood, but as the serum dopamine levels remained unchanged it is suggested that competition between the two drugs at the blood-brain barrier may be the explanation.[1] Be alert for the need to modify levodopa treatment if dacarbazine is used concurrently. However, note also that the manufacturers contraindicate levodopa in those with a history of malignant melanoma because there is some suggestion that levodopa may activate this malignancy,[2] although some consider that, from the available evidence, this is unlikely.[3]

Levodopa + Food

The fluctuations in response to levodopa experienced by some patients may be due to the timing of meals and the type of diet, particularly the protein content, both of which can reduce the effects of levodopa. The effects of levodopa can be reduced by the amino acid methionine, and the blood levels of levodopa can be reduced by the amino acid tryptophan.

Clinical evidence

(a) Effects of meals

A study in patients with Parkinson's disease taking levodopa found that if taken with a meal, the mean absorption of levodopa from the gut and its peak plasma levels were reduced by 27% and 29%, respectively, and the peak plasma level was delayed by 34 minutes.[1] Other studies have found that the absorption of levodopa is delayed and peak plasma levels are reduced if the levodopa is taken with food rather than when fasting.[2-4]

(b) Effects of protein

1. Levodopa levels. A study in healthy subjects found that a low-protein meal (protein 10.5 g) caused a small reduction in levodopa absorption when compared with the fasting state, but also found that a high-protein meal (protein 30.5 g) was no different to the fasting state.[5] In another study, the protein content of the diet appeared to have little effect on levodopa pharmacokinetics.[6]

In contrast, other studies have found that a high daily intake of protein reduces the effects of levodopa (with or without a dopa-decarboxylase inhibitor), compared with a lower intake of protein.[7-9]

2. Subjective or clinical response. A study in 20 patients with Parkinson's disease who took levodopa with carbidopa four times daily with no-, low-, or high-protein snacks, each for one day, found no difference in markers of their Parkinson's disease (such as functional activity, dyskinesias, mental status).[10]

In a study, 11 patients with Parkinson's disease followed a restricted-protein diet in which they ingested up to about 10 g of protein during the day, but their intake was unrestricted during the evening. After following this diet for 6 weeks, 7 patients reported an improvement in their daytime mobility, and 6 patients indicated that they would continue with such a diet.[11]

A case report describes a patient with Parkinson's disease, receiving levodopa with carbidopa, who was admitted to an intensive care unit and developed severe rigidity after he was given continuous **enteral nutrition** with 1.4 g/kg of protein daily, despite continuing with his antiparkinsonian medication via the gastric tube. The protein content of the feed was reduced to 900 mg/kg per day, and given as bolus doses, with the levodopa given between the boluses. His parkinsonian symptoms improved with this feeding regime.[12]

(c) Effects of specific amino acids

A study found that the clinical response to a constant intravenous infusion of levodopa in 4 patients was unchanged by **glycine** and **lysine** but was reduced by **phenylalanine**, **leucine** and **isoleucine**, although the plasma levodopa levels remained unchanged.[1]

Fourteen patients taking levodopa for Parkinson's disease were given a **low-methionine** diet (0.5 g daily) for a period of 8 days. Seven patients were given additional **methionine** (4.5 g daily), while the other 7 were given placebo. Five out of the 7 given **methionine** 4.5 g daily had a definite worsening of their symptoms (gait, tremor, rigidity, etc.). The symptoms subsided when the **methionine** was withdrawn, although this took 7 to 10 days in one patient. Three out of the 7 given placebo (while following the low-methionine diet) had some subjective improvement.[13]

The blood levels of levodopa were markedly reduced in healthy subjects when levodopa 500 mg was taken with 1 g of **tryptophan**.[14] The clinical importance of this was not assessed.

(d) Broad bean pods (Vicia faba)

In a study, patients who took levodopa with carbidopa or benserazide additionally ate a portion (approximately 250 g) of cooked broad beans at least twice a day for up to 3 months. Three patients completed diary cards, and it was found that their 'on' periods were prolonged. One patient experienced an improvement in his 'on' periods each day even when he ate the broad beans on alternate days, and another patient reduced his dose of levodopa with carbidopa, from 500/50 mg to 375/37.5 mg each day.[15]

(e) Dietary fibre

In a study, 16 patients with Parkinson's disease and severe constipation took dietary fibre, to achieve a diet high in insoluble fibre (mean 28 g daily), with their usual medications. Plasma levodopa levels were increased significantly after increasing the fibre content of the diet, and there was improvement in constipation and motor function.[16]

Mechanism

Meals that delay gastric emptying increase the potential for peripheral metabolism of levodopa in the gut, which reduces the amount available for absorption. Conversely, a diet high in insoluble fibre may possibly increase levodopa absorption due to improved gastrointestinal motility. In addition some large neutral amino acids arising from the digestion of proteins can compete with levodopa for transport into the brain so that the therapeutic response may be reduced, whereas other amino acids do not have this effect.[1,5,8,17] Broad bean pods have been shown to contain a significant amount of levodopa, which may have contributed to the beneficial effect.

Importance and management

An established interaction, but unpredictable. As the fluctuations in the response of patients to levodopa may be influenced by what is eaten and when, a change in the pattern of drug and food administration on a trial-and-error basis may be helpful. Note that the manufacturer of *Madopar* recommends taking this preparation with food or slowly increasing the dose in the early stages of treatment to control anorexia, nausea, vomiting, and diarrhoea.[18] Multiple small doses of levodopa and distributing the intake of proteins may also diminish the effects of these interactions. Diets that conform to the recommended daily allowance of protein (said to be 800 mg/kg in this report) are reported to reduce this adverse drug-food interaction.[8]

The amino acid methionine is used therapeutically, and although information about its interaction with levodopa is very limited, the available data indicate that large doses of methionine should be avoided in patients taking levodopa.

Levodopa + Indinavir

An isolated report describes a man taking levodopa who developed severe dyskinesias when given indinavir.

Clinical evidence, mechanism, importance and management

A 66-year-old man with idiopathic Parkinson's disease and AIDS was free of dyskinesias when taking levodopa with a dopa-decarboxylase inhibitor, although he had unpredictable fluctuations. One month after starting indinavir 2.4 g daily, lamivudine and zidovudine, he developed severe peak-dose dyskinesias, and the 'on' periods lasted all day, with no fluctuations. The antivirals were stopped and the dyskinesias improved within 5 days. Each antiviral was then given separately for 2 weeks. Only indinavir induced dyskinesias, which started after 3 days of concurrent use.[1]

The mechanism of this interaction is uncertain, but may be related to the

inhibition of cytochrome P450 by protease inhibitors such as indinavir.[1]

This appears to be the only report of this possible interaction. Bear in mind the possibility that the levodopa dose may need to be decreased if a protease inhibitor such as indinavir is required.

Levodopa + Iron compounds

Ferrous sulfate can reduce the bioavailability of levodopa and carbidopa, and may possibly reduce the control of Parkinson's disease.

Clinical evidence

A study in 9 patients with Parkinson's disease found that a single 325-mg dose of **ferrous sulfate** reduced the AUC of levodopa by 30% and reduced the AUC of carbidopa by more than 75%. There was a trend towards an increase in disability, suggesting a worsening of disease, but this did not reach statistical significance. Some, but not all of the patients had some deterioration in the control of their disease.[1]

In another study, 8 healthy subjects were given a single 250-mg dose of levodopa, with and without a single 325-mg dose of **ferrous sulfate**, and the plasma levodopa levels were measured for the following 6 hours. Peak plasma levodopa levels and the levodopa AUC were reduced by 55% and 51%, respectively. Those subjects who had the highest peak levels and greatest absorption when given levodopa alone, had the greatest reductions when they were also given **ferrous sulfate**.[2]

Mechanism

Ferrous iron rapidly oxidises to ferric iron at the pH values found in the gastrointestinal tract. Ferric iron binds strongly to carbidopa and levodopa to form chelation complexes that are poorly absorbed.[2-4]

Importance and management

Information appears to be limited to these single-dose and *in vitro* studies. The importance of this interaction in patients taking both drugs long-term does not appear to have been studied, but the extent of the reductions in absorption (30 to 50%), and the hint of worsening control,[1] suggests that this interaction may be of clinical importance in some patients. Be alert for any evidence of this. Separating the administration of the iron and levodopa as much as possible is likely to prove effective, as this appears to be an absorption interaction.

Levodopa + Isoniazid

There is evidence that isoniazid can reduce the control of Parkinson's disease in patients taking levodopa. An isolated case report describes hypertension, tachycardia, flushing and tremor in a patient, which was attributed to the use of levodopa with isoniazid.

Clinical evidence

Following the observation that levodopa-induced dyskinesias were reduced by isoniazid in one patient, a further study was undertaken in 20 other patients taking levodopa with a dopa-decarboxylase inhibitor. It was found that isoniazid (average dose 290 mg daily, range 100 to 800 mg daily) reduced the dyskinesias of 18 of the 20 patients. However, the reduction in dyskinesias was accompanied by an intolerable worsening of parkinsonism, shown by decreased mobility and greater 'off' periods. The reduction in mobility was so severe that the isoniazid had to be stopped immediately in several cases and was discontinued after an average of 5.2 weeks in all the patients. Control of parkinsonism was then restored.[1] Another patient taking levodopa with carbidopa similarly had a deterioration in the control of parkinsonism within one to 2 weeks of starting isoniazid with rifampicin (*Rifinah*). When the antitubercular drugs were stopped, the patient's motor performance improved ('on' period lengthened by 75%), the levodopa AUC rose by 37%, its half-life doubled, and its maximum plasma levels fell by 33%.[2]

An isolated report describes a patient taking levodopa who developed hypertension, agitation, tachycardia, flushing and severe non-parkinsonian tremor after starting to take isoniazid. He recovered when the isoniazid was stopped.[3]

Mechanism

Not understood. Metabolic studies in one patient suggest that isoniazid inhibits dopa-decarboxylase,[2] although other mechanisms have been proposed.[1,2] The isolated case of hypertension and tachycardia is also not understood, but it has been suggested that it may have been due to a weak monoamine oxidase inhibitory effect of the isoniazid metabolites. See 'MAOIs or RIMAs + Levodopa', p.1377, for further explanation.

Importance and management

Information seems to be limited to the reports cited. If concurrent use is thought to be necessary, be alert for any evidence of a reduction in the control of the parkinsonism, and be aware that drug treatment may need to be modified. One of the reports suggests that it may take 15 to 20 days or more for the deterioration in parkinsonian symptoms to occur.[1] The isolated case seems not to be of general importance.

Levodopa + MAO-B inhibitors

No serious interaction usually occurs between levodopa and selegiline, although the dose of levodopa may need to be reduced when selegiline is added. Levodopa does not affect rasagiline clearance.

Clinical evidence

(a) Rasagiline

The manufacturer notes that levodopa had no effect on rasagiline clearance.[1]

(b) Selegiline

The combination of levodopa and selegiline has been very extensively used. No serious hypertensive reactions of the kind seen with non-selective MAOIs (see 'MAOIs or RIMAs + Levodopa', p.1377) seem to occur. No adverse pharmacokinetic interactions have been reported,[2,3] and serious adverse interactions are said to be lacking.[4,5] Many studies have reported the beneficial effects of this combination,[6-11] but one has suggested that it may result in increased mortality in patients with early, mild Parkinson's disease.[12] Although no clear reason for this increase in mortality could be found, it appeared that patients receiving selegiline with levodopa were more likely to have possible dementia and have had recent falls, postural dizziness, and shortness of breath.[13] Urinary retention has also been suggested as being associated with this drug combination.[14] Selegiline potentiates the effects of levodopa, so the usual adverse effects (dyskinesias, nausea, agitation, confusion, hallucinations, headache, postural hypotension, cardiac arrhythmias, and vertigo) may be increased, particularly if the levodopa dose is too high.[15]

Mechanism

MAO-B inhibitors prevent the metabolism of dopamine, therefore additive dopaminergic effects occur with levodopa.

Importance and management

No adverse interactions usually occur if levodopa and selegiline are given concurrently. However, the manufacturers say that after adding selegiline a reduction in the dose of levodopa is usually required to avoid symptoms

of levodopa excess (about 10 to 30% is suggested).[15-17] Reduction of the levodopa dose should be gradual, in steps of 10% every 3 to 4 days.[16] It has been suggested that the concurrent use is probably best avoided in patients with postural hypotension, frequent falls, confusion and dementia.[13]

Levodopa + Methyldopa

Methyldopa can increase the effects of levodopa and permit a reduction in the dose in some patients taking levodopa alone, but the benefit may only be temporary and dyskinesias may be worsened in some patients. This interaction would not be expected to be significant in a patient taking levodopa with benserazide or carbidopa but this does not appear to have been studied. A small increase in the hypotensive actions of methyldopa may also occur.

Clinical evidence

(a) Effects on the response to levodopa

A double-blind, crossover study in 10 patients with Parkinson's disease who had been taking levodopa alone for 12 to 40 months, found that the optimum daily dose of levodopa fell by 68% with methyldopa 1.92 g daily, and by 50% with methyldopa 800 mg daily.[1]

Other reports in patients taking levodopa alone describe reductions in the levodopa dose of up to 30%[2] and 70%[3] during the concurrent use of methyldopa. Another report states that the control of Parkinson's disease improved during the concurrent use of methyldopa in some patients taking levodopa alone, but the dyskinesias were worsened in others.[4] Similar findings have been reported elsewhere: in some cases an initial improvement was followed by a loss of benefit.[5] Methyldopa on its own can cause a reversible parkinsonian-like syndrome.[6-8]

(b) Effects on the response to methyldopa

A study in 18 patients with Parkinson's disease taking levodopa alone found that the concurrent use of levodopa and methyldopa lowered the blood pressure. The doses used did not affect the systolic blood pressure when given alone, whereas daily doses of 1 to 2.5 g of levodopa with methyldopa 500 mg caused a 12/6 mmHg fall in blood pressure. No change in the control of the Parkinson's disease was seen, but the study lasted only a few days.[9] In a study of 41 patients who took methyldopa in daily doses of 125 mg to 1.25 g with levodopa 1 g to 7 g daily, two patients experienced a significant drop in blood pressure.[5]

Mechanism

Methyldopa inhibits the breakdown of levodopa outside the brain (by dopa decarboxylase) so that more is available to exert its therapeutic effects.

The increased hypotension may simply be due to the additive effects of the two drugs.

Importance and management

Well documented. Concurrent use need not be avoided but the outcome should be well monitored. In patients taking levodopa alone, the use of methyldopa may allow a reduction in the dose of the levodopa (the reports cited[1-3] give figures of 30 to 70%) and may enhance the control of Parkinson's disease, but it should also be borne in mind that in some patients dyskinesias may be worsened. However, in the presence of carbidopa or benserazide the dopa decarboxylase effects of methyldopa would be expected to be less significant and so it seems unlikely that a dose reduction of levodopa would be required. The increased hypotensive effects seem to be small, but they too should be checked.

Levodopa + Methylphenidate

Methyldopa does not appear to affect the levels of levodopa or the response to levodopa.

Clinical evidence, mechanism, importance and management

A study in 12 patients with Parkinson's disease who took methylphenidate 400 micrograms/kg three times daily in addition to their normal antiparkinsonian medicines which included levodopa, found that methylphenidate had no clinically significant effect on the response to levodopa as measured by tapping speed, a walking test or the presence of dyskinesia. Methylphenidate did not significantly alter the plasma levels of levodopa.[1]

1. Nutt JG, Carter JH, Carlson NE. Effects of methylphenidate on response to oral levodopa. A double-blind clinical trial. *Arch Neurol* (2007) 64, 319–23.

Levodopa + Mirtazapine

An isolated report describes the development of serious psychosis, which was attributed to an interaction between levodopa and mirtazapine.

Clinical evidence, mechanism, importance and management

A 44-year-old woman taking levodopa with carbidopa, pergolide, selegiline and memantine for Parkinson's disease, started taking mirtazapine, in increasing doses rising from 15 to 60 mg daily over 24 days, for depression, labile mood, anxiety, social withdrawal and sleep disturbance. She initially improved, but then major depression and psychosis developed, and on day 26 she attempted self-strangulation. She recovered when the mirtazapine, memantine and selegiline were stopped and low-dose clozapine started. The authors concluded that the reaction was attributable to dopamine-induced psychosis triggered by the addition of mirtazapine to levodopa.[1] This appears to be an isolated case, and as such, no general conclusions can be drawn.

1. Normann C, Hesslinger B, Frauenknecht S, Berger M, Walden J. Psychosis during chronic levodopa therapy triggered by the new antidepressive drug mirtazapine. *Pharmacopsychiatry* (1997) 30, 263–5.

Levodopa + Papaverine

Case reports describe a deterioration in the control of parkinsonism when patients taking levodopa were given papaverine, but a controlled study did not find an interaction.

Clinical evidence

(a) Levodopa effects reduced

A woman with long-standing parkinsonism, well controlled with levodopa (and the later addition of carbidopa), began to have a steady worsening of her parkinsonism within a week of starting papaverine 100 mg daily for cerebral vascular insufficiency. The deterioration continued until the papaverine was withdrawn. The normal response to levodopa returned within a week. Four other patients had a similar response.[1] Two other similar cases have been described in another report.[2]

(b) Levodopa effects unchanged

A double-blind, crossover study in 9 patients with parkinsonism, taking levodopa (range 100 to 750 mg daily) with a dopa-decarboxylase inhibitor, did not find any changes in disease control when they also took papaverine hydrochloride 150 mg daily for 3 weeks. Two patients were also taking bromocriptine 40 mg daily and two patients were also taking trihexyphenidyl 15 mg daily.[3]

A study in 6 healthy subjects, who took a single 500-mg dose of levodopa before and after taking papaverine 150 mg twice daily for 2 weeks, found that papaverine did not affect the increase in serum growth hormone and the decrease in prolactin levels caused by levodopa.[4]

Mechanism

Not understood. One suggestion is that papaverine blocks the dopamine receptors in the striatum of the brain, thereby inhibiting the effects of the levodopa.[1,5] Another is that papaverine may have a reserpine-like action on the vesicles of adrenergic neurones[1,6] (i.e. it can deplete dopamine stores).

Importance and management

Direct information seems to be limited to the reports cited. Concurrent use can apparently be uneventful. However, in the light of the reports of adverse interactions it would be prudent to monitor the outcome closely. Carefully controlled studies can provide a good picture of the general situation, but may not necessarily identify the occasional patient who may be affected by an interaction.

Levodopa + Penicillamine

Penicillamine can raise levodopa levels in a few patients. This may improve the control of the parkinsonism but the adverse effects of levodopa may also be increased.

Clinical evidence, mechanism, importance and management

A patient with Parkinson's disease taking levodopa with a dopa-decarboxylase inhibitor [probably carbidopa] had a 60% increase in his levodopa plasma levels after taking penicillamine 600 mg daily. This resulted in improved control of symptoms but with an increase in dyskinesia. It was noted that this patient had slightly low serum copper and ceruloplasmin levels.[1] In another study 2 patients with Parkinson's disease taking levodopa also improved when they also took penicillamine, but levodopa levels were apparently not measured. Again it was noted that the patients had slightly low copper and ceruloplasmin levels. In another 4 similar patients the effects of penicillamine on levodopa seemed absent in the presence of normal copper and ceruloplasmin levels.[2] The authors of this report[2] attribute the improvement in parkinsonism to the copper chelating properties of penicillamine. However, the authors of the other report[1] suggest that the effect of penicillamine would not be this rapid, and suggested that penicillamine must be affecting levodopa pharmacokinetics.

This limited evidence suggests that the concurrent use of levodopa and penicillamine need not be avoided, and in some patients parkinsonian symptoms may be improved. However, if both drugs are given, monitor the effects as an increase in the adverse effects of levodopa is also possible.

Levodopa + Phenylbutazone

A single case report describes antagonism of the effects of levodopa by phenylbutazone.

Clinical evidence, mechanism, importance and management

A patient (who was very sensitive to levodopa) found that he was only able to prevent the involuntary movements of his tongue, jaw, neck and limbs caused by levodopa, by taking frequent small doses (125 mg) of levodopa. He was able to suppress the levodopa adverse effects with phenylbutazone. However, the phenylbutazone also lessened the therapeutic effect of the levodopa.[1] The reason is not understood. This interaction has not been confirmed, and its general importance is not known.

Levodopa + Phenytoin

The therapeutic effects of levodopa can be reduced or abolished by phenytoin.

Clinical evidence, mechanism, importance and management

A study in 5 patients taking levodopa 630 to 4600 mg (four also taking carbidopa 150 to 225 mg daily) for Parkinson's disease, found that when they also took phenytoin in doses of up to 500 mg daily for 5 to 19 days the levodopa-induced dyskinesias were relieved, but the beneficial effects of the levodopa on parkinsonism were reduced or abolished. The patients became slow, rigidity re-emerged, and some of them became unable to get out of a chair. Within 2 weeks of stopping the phenytoin, their parkinsonism was again well controlled by the levodopa.[1] Despite many suggestions, the mechanism of this interaction is not understood. Information relating to a reduction in efficacy of levodopa seems to be limited to this study, nevertheless it would seem prudent to monitor concurrent use for any evidence of reduced levodopa efficacy.

Levodopa + Pyridoxine (Vitamin B_6)

The effects of levodopa are reduced or abolished by pyridoxine, but this interaction does not occur when levodopa is given with the dopa-decarboxylase inhibitors carbidopa or benserazide, as is usual clinical practice.

Clinical evidence

A study in 25 patients taking levodopa alone found that if they were given high doses of pyridoxine (750 mg to 1 g daily), the effects of the levodopa were reduced within 24 hours, and were completely abolished within 3 to 4 days. Daily doses of pyridoxine 50 to 100 mg also reduced or abolished the effects of levodopa, and an increase in the signs and symptoms of parkinsonism occurred in 8 out of 10 patients taking only 5 to 10 mg of pyridoxine daily.[1]

The antagonism of the effects of levodopa (given without a dopa-decar-

boxylase inhibitor) by pyridoxine has been described in numerous other reports.[1-6]

In contrast, a study in 15 patients with Parkinson's disease taking long-term levodopa found that a single 250-mg oral dose of levodopa produced a peak dopa level of 600 nanograms/mL. When pyridoxine 50 mg was also given, the peak plasma levels of dopa fell by almost 70%. When the levodopa was given with carbidopa 50 mg the peak plasma dopa levels were 1300 nanograms/mL, and were not significantly affected by pyridoxine.[6] The results from a subset of these patients have been reported elsewhere.[7] The absence of an interaction in the presence of a dopa-decarboxylase inhibitor is confirmed in another report.[8]

Mechanism

The conversion of levodopa to dopamine within the body requires the presence of pyridoxal-5-phosphate (derived from pyridoxine) as a co-factor. When dietary amounts of pyridoxine are high, the peripheral metabolism of levodopa by dopa-decarboxylase is increased so that less is available for entry into the CNS, and its effects are reduced accordingly. Pyridoxine may also alter levodopa metabolism by Schiff-base formation. However, in the presence of dopa-decarboxylase inhibitors such as carbidopa or benserazide, this peripheral metabolism of levodopa is reduced and much larger amounts are available for entry into the CNS, even if quite small doses are given. Therefore, even in the presence of large amounts of pyridoxine, the peripheral metabolism remains unaffected and the serum levels of levodopa are virtually unaltered.

Importance and management

A clinically important, well documented and well established interaction, but principally of historical interest now as levodopa is rarely used alone. The problem of this interaction can be totally solved by giving levodopa with a dopa-decarboxylase inhibitor such as carbidopa or benserazide. In the rare cases that levodopa is used alone, pyridoxine in doses as low as 5 mg daily can reduce the effects of levodopa and should therefore be avoided. Warn patients about proprietary pyridoxine-containing preparations such as multivitamins and supplements. Some breakfast cereals are fortified with pyridoxine and other vitamins, but the amounts are usually too small to matter (e.g. a 30 g serving of Kellogg's Corn Flakes or Rice Krispies (UK products) contains only about 0.5 mg of pyridoxine). There is no good clinical evidence to suggest that a low-pyridoxine diet is desirable, and indeed it may be harmful as the normal dietary requirements are about 2 mg daily.

Levodopa + Rauwolfia alkaloids

The effects of levodopa are opposed by rauwolfia alkaloids such as reserpine.

Clinical evidence, mechanism, importance and management

Reserpine and other rauwolfia alkaloids deplete the brain of monoamines, including dopamine, thereby reducing their effects.[1] This can lead to parkinsonian-like symptoms, and may oppose the actions of levodopa. There are not only sound pharmacological reasons for believing this to be an interaction of clinical importance, but a reduction in the antiparkinsonian activity of levodopa has been observed in patients given **reserpine**.[2] The rauwolfia alkaloids should be avoided in patients with Parkinson's disease, whether or not they are taking levodopa.

2. Yahr MD. Personal communication, February 1977.

Levodopa + Spiramycin

The plasma levels of levodopa (given with carbidopa) are reduced by spiramycin, thereby reducing its therapeutic effects.

Clinical evidence

The observation of a patient with Parkinson's disease taking levodopa with carbidopa whose condition became less well-controlled when spiramycin was taken, prompted further study. Levodopa 250 mg with carbidopa 25 mg was given to 7 healthy subjects after they had taken spiramycin 1 g twice daily for 3 days. The spiramycin reduced the AUC of levodopa by 57%, and its maximum plasma levels fell by about 20%, which was not statistically significant. The relative bioavailability of levodopa was only 43%. The plasma levels of the carbidopa were barely detectable.[1]

Mechanism

Not fully established. In some way spiramycin markedly reduces the absorption of carbidopa, possibly by forming a non-absorbable complex in the gut or by accelerating its transit through the gut. As a result, not enough carbidopa is absorbed to inhibit the peripheral metabolism of the levodopa by dopa-decarboxylase, so that the effects of the levodopa are reduced.[1]

Importance and management

Information is very limited, but the interaction appears to be established and of clinical importance. The management of this interaction is unclear, but as it appears to be due to an effect on absorption it would seem prudent to try to separate the dosing of these two drugs by as much as possible, although this may be difficult with some levodopa regimens. Monitor the outcome of concurrent use on the control of Parkinson's disease. It is not known whether other macrolide antibacterials behave in a similar way, or whether spiramycin affects levodopa with benserazide. More study is needed.

Levodopa + SSRIs and related antidepressants

The use of an SSRI is often beneficial in parkinsonian patients taking levodopa, to treat the depression associated with the disease. However, sometimes parkinsonian symptoms are worsened.

Clinical evidence

A number of reviews have been published about the extrapyramidal effects of SSRIs.[1,2] A retrospective study of patients taking levodopa, found that 15 patients taking an SSRI (**fluoxetine**, **fluvoxamine**, **paroxetine**) required faster increases in their antiparkinsonian drugs than 31 patients taking a tricyclic antidepressant, or 304 patients taking antiparkinsonian drugs only.[3] However, a retrospective study of the effect of SSRIs or serotonergic antidepressants, in patients taking levodopa, found that the change in antiparkinsonian medication in 90 patients taking SSRIs was similar to that in 99 patients taking tricyclic antidepressants. Furthermore, initiation of antidepressants with a high inhibition of serotonin reuptake was not associated with a change in antiparkinsonian drug treatment compared with antidepressants with a low inhibition of serotonin reuptake.[4] Other cases and studies outlined below have shown conflicting outcomes.

(a) Citalopram

A case report describes an 81-year-old woman who experienced an increase in the duration of her tremor and 'off' periods 2 days after starting to take citalopram 20 mg daily. She was also taking levodopa with benserazide 1 g daily and alprazolam 1.5 mg daily. One month after stopping citalopram, her parkinsonian symptoms had improved.[5]

A study in 44 patients with Parkinson's disease taking levodopa with carbidopa, 30 of whom received citalopram 10 mg daily increasing to 20 mg daily, found an improvement in bradykinesia in those patients taking citalopram.[6]

(b) Fluoxetine

Four patients taking levodopa 375 to 990 mg daily, a dopa-decarboxylase inhibitor (drug and dose not stated) and amantadine (dose not stated), had a deterioration in the control of their parkinsonism when they were also given fluoxetine 20 mg daily for 8 to 11 weeks. The fluoxetine was withdrawn and their motor performance was restored. The antidepressant efficacy of fluoxetine was not found to be substantial in any of the 4 patients.[7] A case report describes a 34-year-old woman whose dystonia was well controlled by levodopa with carbidopa 100/25 mg three times daily. Five days after starting to take fluoxetine 20 mg daily her dystonia and torticollis returned. Two days after stopping the fluoxetine her symptoms started to improve, and had resolved in about a week.[8] Another patient taking levodopa developed frequent hallucinations after the addition of fluoxetine. They resolved when the fluoxetine was withdrawn.[9]

In a retrospective study of 23 parkinsonian patients who were given fluoxetine up to 40 mg daily, 20 patients had no change in the control of their parkinsonism but 3 others experienced a worsening in their Parkinson's disease signs.[10]

However, in a study, 14 patients with Parkinson's disease whose treatment included levodopa, started to take fluoxetine 20 mg daily for one month. One patient dropped out because of intolerable asthenia. Of the remaining 13 patients there was no change in rigidity or bradykinesia, but tremor was significantly reduced.[11]

(c) Nefazodone

A case report describes a 70-year-old man whose Parkinson's disease was well controlled by levodopa with benserazide and bromocriptine, but when he started to take nefazodone, he developed severe bradykinesia, rigidity, gait instability and akathisia. He stopped taking nefazodone, and the dose of levodopa with benserazide was increased to 500 mg daily with improvement in his condition.[12] However, in a small study, nefazodone was found to be of benefit in treating depression in 9 patients taking levodopa for Parkinson's disease, and motor symptoms also improved.[13]

(d) Paroxetine

In a placebo-controlled study in 14 patients with Parkinson's disease, paroxetine 10 mg daily for 5 days and then 20 mg daily for 9 days did not significantly alter the response to an infusion of levodopa 1 mg/kg per hour given for 2 hours. Several patients reported a reduction in their sense of balance, and one patient fell, resulting in a pelvic fracture.[14]

A case report describes visual hallucinations in a 79-year-old woman taking levodopa with carbidopa when she started to take paroxetine 20 mg daily. The hallucinations stopped when paroxetine was withdrawn.[15] It has been suggested that the hallucinations may have been related to the Parkinson's disease and use of levodopa, rather than an interaction with paroxetine.[16]

(e) Sertraline

A review of 101 patients receiving treatment for Parkinson's disease and who also took an antidepressant, identified 5 patients who experienced a worsening of their Parkinson's disease, possibly attributed to the use of an SSRI. Three of these patients were taking sertraline, one **fluoxetine**, and one took **fluoxetine** followed by sertraline. Four of the 5 patients who experienced a worsening of their symptoms were also taking selegiline.[17] See also 'MAO-B inhibitors + SSRIs or SNRIs', p.808 for details of possible interactions between selegiline and the SSRIs.

(f) Venlafaxine

A case report describes a 32-year-old woman who took levodopa with carbidopa 50/1.25 mg twice daily to treat tremor, dystonia and rigidity. She started to take venlafaxine, and within 4 days her dystonia and trembling returned. Two days after stopping the venlafaxine her symptoms started to improve, and had resolved in about a week.[8]

Mechanism

Not understood. The mechanism is likely to involve a complex interaction between various neurotransmitters.[2] Extrapyramidal effects are rare but recognised adverse effects of SSRIs.[1,2]

Importance and management

Although the information is conflicting, it seems that in some cases parkinsonism can be worsened by SSRIs, venlafaxine or nefazodone. Concurrent use is valuable and need not be avoided, but monitor the outcome and withdraw the antidepressant if necessary.

Levodopa + Tetrabenazine

Tetrabenazine may interfere with the effects of levodopa.

Clinical evidence, mechanism, importance and management

Caution is advised when tetrabenazine is given with levodopa, because it can deplete dopamine and can cause parkinsonian adverse effects. Tetrabenazine may therefore be expected to diminish the effects of levodopa and interfere with its use in the management of Parkinson's disease. One manufacturer of levodopa states that concurrent use should be avoided where possible, but if both drugs are considered essential, extreme care should be exercised and patients should be monitored for any signs of potentiation, antagonism or other unusual adverse effects.[1]

1. Madopar Capsules (Levodopa and Benserazide hydrochloride). Roche Products Ltd. UK Summary of product characteristics, April 2009.

Levodopa + Tricyclic antidepressants

The concurrent use of levodopa and the tricyclics is usually uneventful although two unexplained hypertensive crises have occurred when imipramine or amitriptyline was given with levodopa and carbidopa.

Clinical evidence

A hypertensive crisis (blood pressure 210/110 mmHg) associated with agitation, tremor and generalised rigidity developed in a woman taking 6 tablets of levodopa 100 mg with carbidopa 10 mg daily the day after she started to take **imipramine** 25 mg three times daily. The **imipramine** was stopped and she recovered over the following 24 hours. The same reaction occurred again when she was later accidentally given **amitriptyline** 25 mg three times daily.[1] A similar hypertensive reaction (a rise in blood pressure from 190/110 mmHg to 270/140 mmHg) occurred over 34 hours in another woman taking **amitriptyline** 20 mg at night when she was given levodopa 50 mg with carbidopa 5 mg and metoclopramide 10 mg, both three times daily. This resolved when all the drugs were stopped.[2]

Mechanism

Not understood.

Importance and management

Information seems to be limited to these reports. Concurrent use is normally successful and uneventful.[3-5] However, be alert for the possibility of a hypertensive reaction, which resolves if the tricyclic antidepressant is withdrawn. See also 'Levodopa + Antimuscarinics', p.796 for interactions due to the antimuscarinic adverse effects of tricyclic antidepressants.

MAO-B inhibitors + Dextromethorphan

The manufacturer of rasagiline[1] suggests that its use with dextromethorphan should be avoided. Similarly, some consider that patients taking selegiline should try to avoid dextromethorphan.[2] These warnings are based on the serious adverse reactions (serotonin syndrome or similar) that have rarely occurred when dextromethorphan has been used with non-selective MAOIs, see 'MAOIs or RIMAs + Dextromethorphan', p.1375. The likelihood of any interaction with MAO-B inhibitors would appear to be very small, but because of the potential severity, some caution would appear to be prudent.

1. Azilect (Rasagiline mesilate). Teva Pharmaceuticals Ltd. UK Summary of product characteristics, November 2009.
2. Jacob JE, Wagner ML, Sage JI. Safety of selegiline with cold medications. *Ann Pharmacother* (2003) 37, 438–41.

MAO-B inhibitors + MAOIs or RIMAs

Marked orthostatic hypotension has been seen in two patients taking iproniazid or tranylcypromine with trifluoperazine when they were given selegiline. When moclobemide is given with selegiline, restriction of dietary tyramine is necessary, and there may be an increased risk of hypotensive reactions. Some manufacturers of MAO-B inhibitors contraindicate the concurrent use of MAOIs or RIMAs.

Clinical evidence, mechanism, importance and management

(a) MAOIs

In a pilot study, one patient taking **iproniazid** 150 mg daily developed severe orthostatic hypotension on two occasions within an hour of taking **selegiline** 5 mg. Two other patients (one taking **tranylcypromine** with trifluoperazine and one taking **tranylcypromine** with trifluoperazine and **isocarboxazid**) did not have this reaction to **selegiline** 5 mg twice daily. The authors mention another patient who similarly developed postural hypotension on two occasions within 2 hours of taking **selegiline** 5 mg. He had stopped taking **tranylcypromine** with trifluoperazine, 4 weeks previously.[1] This evidence suggests that **selegiline** should be given with caution to patients taking, or who have recently stopped, non-selective MAOIs. One UK manufacturer of **selegiline**[2] and the manufacturer of **rasagiline**[3] contraindicate the concurrent use of non-selective MAOIs. The manufacturer of rasagiline includes **St John's wort** (*Hypericum perforatum*) in this contraindication, because they state that it has MAO inhibitory properties.[3] At least 14 days should elapse between stopping **rasagiline** or **selegiline** and starting an MAOI.[2,3]

(b) RIMAs

A study in 24 healthy subjects, designed to assess the safety and tolerability of giving **moclobemide** 100 to 400 mg and **selegiline** 5 mg twice daily, sequentially or concurrently, found that the adverse effects were no greater under steady-state conditions than with either drug alone, but the sensitivity to tyramine was considerably increased. The mean tyramine sensitivity factor for **moclobemide** alone was 2 to 3, for **selegiline** alone was 1.4, and for **moclobemide** with **selegiline** was 8 to 9 (and even 18 in one subject).[4,5] The reason for this effect is, that when taken together, the **moclobemide** inhibits MAO-A while **selegiline** inhibits MAO-B, so that little or no MAO activity remains available to metabolise the tyramine. However, unexpectedly, the combined effect was more than additive.[5] **Selegiline** had no effect on the pharmacokinetics of **moclobemide**.[6] In a clinical study using tyramine restriction, one of 5 subjects taking **selegiline** and one of 5 subjects taking **selegiline** with **moclobemide** reported symptomatic hypotension, and there was no increase in blood pressure in any patient.[7]

In practical terms this means that patients taking **moclobemide** with **selegiline** should be given the same dietary restrictions for tyramine-rich foods and drinks (see 'MAOIs or RIMAs + Tyramine-rich drinks', p.1393, and 'MAOIs or RIMAs + Tyramine-rich foods', p.1395), that relate to the non-selective MAOIs such as phenelzine and tranylcypromine.[5] However, because of the potential risks the manufacturer of **moclobemide**[8] contraindicates the concurrent use of **selegiline**. It has been suggested that if **selegiline** is replaced by **moclobemide**, the dietary restrictions can be relaxed after a wash-out period of about 2 weeks. If switching from **moclobemide** to **selegiline**, a wash-out period of one to 2 days is sufficient.[4]

MAO-B inhibitors + Nasal decongestants

An isolated report describes a hypertensive crisis, which was attributed to an interaction between selegiline, ephedrine, and maprotiline. Selegiline does not appear to affect the pharmacokinetics of pseudoephedrine or phenylpropanolamine.

Clinical evidence

An isolated case report describes a man taking **selegiline** 10 mg daily, levodopa with carbidopa, lisuride, maprotiline 75 mg daily, and theophylline with **ephedrine** 180/32 mg daily who developed hypertensive crises (blood pressure up to 300/150 mmHg), intense vasoconstriction, confusion, abdominal pain, sweating, and tachycardia (110 bpm) within 2 days of raising the dose of theophylline with **ephedrine** to 270/48 mg daily. All of the drugs were stopped, and the patient was treated with intravenous nicardipine. He recovered uneventfully.[1]

In a study, 10 healthy subjects received **selegiline** via a transdermal patch delivering 6 mg/24 hours, applied daily, and **pseudoephedrine** 60 mg up to three times daily, for 3 days. **Selegiline** did not cause any significant changes in the cardiovascular pharmacodynamics or the pharmacokinetics of **pseudoephedrine**. In a separate part of this study, 11 healthy subjects received **selegiline** via a transdermal patch delivering 6 mg/24 hours and **phenylpropanolamine** 25 mg up to six times daily. Selegiline did not cause any clinically significant changes in the pharmacodynamics or pharmacokinetics of **phenylpropanolamine**.[2]

Mechanism

It is thought that this reaction described in the case report occurred as a result of excess sympathomimetic amines: ephedrine is an indirectly-acting sympathomimetic that causes increased release of noradrenaline; selegiline has some MAO-A inhibitory activity and may therefore inhibit noradrenaline metabolism; and maprotiline inhibits reuptake of noradrenaline.[1] Compare also 'MAOIs or RIMAs + Sympathomimetics; Indirectly-acting', p.1388 and 'MAOIs or RIMAs + Tricyclic and related antidepressants', p.1391.

Importance and management

This appears to be the only report of a hypertensive reaction in a patient taking selegiline and ephedrine, and the concurrent maprotiline was also implicated in this reaction. In general, if selegiline is used at recommended doses it is selective for MAO-B and no restrictions are required in the use of nasal decongestants with indirect sympathomimetic actions, such as ephedrine and pseudoephedrine. Nevertheless, this report suggests that, rarely, interactions are still possible, and some consider that patients taking selegiline should try to avoid pseudoephedrine or other related drugs.[2,3] The manufacturers of both **rasagiline**[4] and selegiline[5] suggest avoiding the concurrent use of sympathomimetics such as those present in decongestants or cold medications containing ephedrine or pseudoephedrine.[4]

MAO-B inhibitors + Pethidine (Meperidine)

A case of fluctuating stupor and agitation, with muscle rigidity, sweating and a raised temperature has been reported when pethidine was used with selegiline. Rasagiline is expected to interact similarly.

Clinical evidence, mechanism, importance and management

A patient taking **selegiline** 5 mg twice daily, pergolide, levodopa with carbidopa, imipramine and desipramine was given pethidine beginning on postoperative day one for 4 days in doses of 75 to 150 mg daily. On the second day he became increasingly restless and irritable, progressing to delirium on the fourth day, with fluctuations between stupor and severe agitation associated with muscular rigidity, sweating and a raised temperature. The patient remained normotensive. Both pethidine and then **selegiline** were stopped, with full recovery.[1] This case is similar to various cases described with non-selective MAOIs and pethidine, see 'MAOIs or RIMAs + Opioids; Pethidine (Meperidine)', p.1381. The US manufacturer of selegiline states that other serious reactions including death have occurred when **selegiline** was given with pethidine.[2]

On the basis of this evidence the manufacturers of **selegiline**[2,3] and **rasagiline**[4] contraindicate the concurrent use of **pethidine**, which is a prudent precaution. Some manufacturers of **rasagiline** additionally say that pethidine should not be given until 14 days after stopping **rasagiline**,[4] which makes sense because they are irreversible inhibitors of MAO-B. One UK manufacturer of **selegiline** also contraindicates concurrent use with all opioids,[3] which is probably unnecessary, based on the evidence with non-selective MAOIs, see 'MAOIs or RIMAs + Opioids; Pethidine (Meperidine)', p.1381. Another UK manufacturer of **selegiline** cautions that **tramadol** may potentially interact,[5] which seems a possibility based on evidence of an interaction between tramadol and non-selective MAOIs, see 'MAOIs or RIMAs + Opioids; Tramadol', p.1382.

MAO-B inhibitors + SSRIs or SNRIs

A few cases of serotonin syndrome and other serious CNS disturbances have been seen when selegiline was given with fluoxetine or venlafaxine. Other SSRIs and SNRIs are expected to interact similarly. Rasagiline is expected to interact in the same way as selegiline.

Clinical evidence

(a) Citalopram

In a double-blind, randomised study, 18 healthy subjects were given citalopram 20 mg or placebo daily for 10 days, with **selegiline** 10 mg daily added for a further 4 days. There was no evidence of changes in vital signs or in the frequency of adverse events, but the bioavailability of **selegiline** was slightly reduced by about 30% by citalopram. The authors of this report concluded that no clinically relevant interaction occurred between **selegiline** and citalopram.[1]

(b) Fluoxetine

A woman with Parkinson's disease taking **selegiline**, bromocriptine and levodopa with carbidopa was also given fluoxetine 20 mg. Several days later she developed episodes of shivering and sweating in the mid-afternoon, which lasted several hours. Her hands became blue, cold and mottled and her blood pressure was elevated (200/120 mmHg). These episodes disappeared when both fluoxetine and **selegiline** were stopped, and did not reappear when the fluoxetine alone was restarted.[2] A case of mild serotonin syndrome has been described in a woman taking levodopa and **selegiline**, which developed a few days after she started fluoxetine,[3] and a possible case of serotonin syndrome has been described in another patient taking selegiline and fluoxetine.[4] A further case of serotonin syndrome, which was fatal, developed in a patient taking levodopa with carbidopa and fluoxetine when **selegiline** was added and the dose of levodopa increased.[5] Other patients have become hyperactive and apparently manic,[2,6] have developed ataxia,[7] or developed a tonic-clonic seizure and headache, flushes, palpitations, and a blood pressure of 250/130 mmHg (a pseudophaeochromocytoma syndrome),[8] all after the concurrent use of fluoxetine and **selegiline**.

These reports contrast with a retrospective study of 23 patients with parkinsonism, who received both **selegiline** and fluoxetine without any serious adverse effects occurring, although worsening confusion was noted in 5 patients.[9]

(c) Fluvoxamine

The manufacturer of **selegiline** notes that serious reactions similar to those seen with fluoxetine have occurred in patients receiving **selegiline** and fluvoxamine.[10] Fluvoxamine may be expected to inhibit the metabolism of **rasagiline**, see 'MAO-B inhibitors; Rasagiline + Miscellaneous', p.810.

(d) Paroxetine

A retrospective study of patients with Parkinson's disease taking **selegiline** 5 to 10 mg daily (and other antiparkinsonian drugs such as levodopa with carbidopa, bromocriptine, amantadine, pergolide, and antimuscarinics) noted that the addition of paroxetine 10 to 40 mg daily caused no adverse effects and the patients appeared to obtain overall benefit, including some improvement in parkinsonian symptoms.[11] However, the manufacturers of **selegiline** note that serious reactions similar to those seen with fluoxetine have occurred in patients receiving **selegiline** and paroxetine.[10,12]

(e) Sertraline

A retrospective study of patients with Parkinson's disease taking **selegiline** 5 to 10 mg daily (and other antiparkinsonian drugs such as levodopa with carbidopa, bromocriptine, amantadine, pergolide, and antimuscarinics) noted that the addition of sertraline 25 to 100 mg daily caused no adverse effects and the patients appeared to obtain overall benefit, including some improvement in parkinsonian symptoms.[11] However, the manufacturers of **selegiline** note that serious reactions similar to those seen with concurrent fluoxetine have occurred in patients receiving **selegiline** and sertraline.[10,12]

108 (f) Venlafaxine

A man developed serotonin syndrome 15 days after stopping **selegiline** 50 mg [daily] and within 30 minutes of starting venlafaxine 37.5 mg.[13]

Mechanism

Not fully understood. In some cases the symptoms seen appear to be consistent with serotonin syndrome, which is typified by CNS irritability, increased muscle tone, shivering, altered consciousness and myoclonus, and appears to be associated with the use of more than one serotonergic drug, see *Serotonin syndrome*, under 'Additive or synergistic interac-

tions', (p.9). This syndrome has also occurred when non-selective MAOIs were given with SSRIs or venlafaxine (see 'MAOIs or RIMAs + SSRIs', p.1384, and 'MAOIs or RIMAs + SNRIs', p.1383). Note that selegiline may have some non-selective MAOI activity, especially at higher doses.

Importance and management

The possibility of serotonin syndrome or similar occurring with selegiline and SSRIs or venlafaxine would appear to be established, although the incidence is very rare. Nevertheless, the manufacturers of selegiline recommend that these drug combinations should be avoided.[10,12,14] In addition, selegiline should not be started for 5 weeks after stopping fluoxetine, 2 weeks after stopping sertraline, and one week after stopping other SSRIs, and SSRIs should not be started for 2 weeks after stopping selegiline.[10,14]

Similarly, the manufacturers of **rasagiline** recommend avoiding the concurrent use of fluoxetine and fluvoxamine. Rasagiline should not be started for 5 weeks after stopping fluoxetine, and fluoxetine or fluvoxamine should not be started for 2 weeks after stopping rasagiline.[15]

For more information about serotonin syndrome, including signs and symptoms, and management, see under 'Additive or synergistic interactions', (p.9).

MAO-B inhibitors + Tricyclic and related antidepressants

The concurrent use of selegiline and tricyclics may lead to adverse effects such as serotonin syndrome. Trazodone may interact similarly, although evidence for this is lacking. Rasagiline is expected to interact in the same way as selegiline.

Clinical evidence

(a) Trazodone

A retrospective study of patients with Parkinson's disease taking **selegiline** 5 to 10 mg daily (and other antiparkinson drugs such as levodopa with carbidopa, bromocriptine, amantadine, pergolide, and antimuscarinics) noted that the addition of trazodone 25 to 150 mg daily caused no adverse effects and the patients appeared to obtain overall benefit, including some improvement in parkinsonian symptoms.[1]

(b) Tricyclic antidepressants

Between 1989 and 1994 the FDA in the US received 16 reports of adverse interactions between **selegiline** and tricyclic antidepressants, which were attributed to serotonin syndrome.[2] The manufacturers of **selegiline** very briefly describe severe CNS toxicity in one patient given **selegiline** and **amitriptyline** (hyperpyrexia and death), and in another given **selegiline** and **protriptyline** (tremor, agitation, restlessness, followed by unresponsiveness and death).[3-5] They state that related adverse events including hypertension, syncope, asystole, diaphoresis, seizures, changes in behavioural and mental status, and muscular rigidity have also been reported in some patients receiving **selegiline** and various tricyclics.[3,4] A further report describes serotonin syndrome in a woman given **nortriptyline** with **selegiline**.[6] Another report describes hypomania occurring in a woman taking **selegiline** and **nortriptyline**;[7] the contribution of a drug interaction is unclear in this case. However, these warnings need to be balanced by other reports indicating that these reactions are uncommon. One study based on the findings of 47 investigators treating 4 568 patients with **selegiline** and antidepressants [not specifically named but possibly including the tricyclics and related antidepressants] found that only 11 patients (0.24%) experienced symptoms considered to represent serotonin syndrome, and only 2 patients (0.04%) experienced symptoms considered to be serious.[8] Another small retrospective study designed to evaluate the tolerability and efficacy of combining **selegiline** and tricyclic antidepressants (not specifically named) identified 28 patients who had taken both drugs.[2] In total, 17 patients definitely benefited and 6 patients possibly benefited from taking the combination. Another retrospective study of 25 occasions of the use of a tricyclic with **selegiline** found no cases of serotonin syndrome.[9]

Mechanism

Not fully understood. In some cases the symptoms seen appear to be consistent with serotonin syndrome, which is typified by CNS irritability, increased muscle tone, shivering, altered consciousness and myoclonus, and appears to be associated with the use of more than one serotonergic drug, see *Serotonin syndrome*, under 'Additive or synergistic interactions', (p.9). This syndrome has also occurred with non-selective MAOIs and tricyclics or trazodone (see 'MAOIs or RIMAs + Tricyclic and related antidepressants', p.1391, and 'MAOIs + Trazodone', p.1390). Note that selegiline may have some non-selective MAOI activity, especially at high doses.

Importance and management

Evidence for an interaction between the tricyclic and related antidepressants and selegiline is sparse, and needs to be balanced by the reports of safe and uneventful concurrent use. If the decision is made to use selegiline with any of the tricyclic antidepressants, the outcome should be well monitored, but the likelihood of problems seems to be small. Nevertheless, some manufacturers of selegiline advise avoiding tricyclic antidepressants.[4,5] Similarly, the manufacturers of **rasagiline** advise caution if it is given with antidepressants.[10] This caution should also apply to the use of trazodone, as studies will not always identify rare adverse effects.

MAO-B inhibitors + Tyramine-rich foods

No dietary restrictions are required with the doses of rasagiline and selegiline recommended for use in Parkinson's disease. An isolated report describes a hypertensive reaction in a patient taking selegiline 20 mg daily. Thus, at higher doses of selegiline, restriction of the amount of tyramine in the diet may be necessary.

Clinical evidence

(a) Rasagiline

In a study in which 72 patients with Parkinson's disease were given rasagiline, there was no statistically significant change in the cardiovascular response to a single 50-mg or 75-mg dose of tyramine when compared with 38 patients not taking rasagiline. Three patients taking rasagiline and one taking placebo experienced an asymptomatic increase in systolic blood pressure of 30 mmHg or more, after the tyramine challenge.[1]

The manufacturer notes that the results of four tyramine challenge studies, together with the results of home monitoring of blood pressure after meals (from 464 patients taking rasagiline 0.5 or 1 mg daily or placebo without tyramine restrictions), and the lack of reported problems in clinical studies without tyramine restriction, indicate that no dietary restrictions are necessary with rasagiline.[2]

(b) Selegiline

1. Oral selegiline. The pressor response to oral tyramine was not altered by pretreatment with selegiline 10 mg daily in healthy subjects and patients with Parkinson's disease.[3] However, another study[4] found that selegiline 5 mg daily for at least 14 days reduced the dose of oral tyramine required to achieve the cardiovascular threshold (increase in systolic blood pressure of greater than 30 mmHg, a diastolic blood pressure greater than 100 mmHg or a fall in heart rate of greater than 20%) by a factor of 2.8. Nevertheless, this reduction was less than that found with the RIMA moclobemide (4.3) and the MAOI phenelzine (10.3).[4] In other studies, higher doses of selegiline (20 or 30 mg daily) increased the sensitivity to oral tyramine by 2- to 4.5-fold.[5,6] A patient taking selegiline 20 mg daily was reported to have had a hypertensive reaction (severe headache and rise in blood pressure) after eating macaroni and cheese,[7] but this appears to be the only published report of this type of hypertensive reaction with selegiline.

2. Buccal and transdermal selegiline. The dose of tyramine required to elicit a pressor effect was not altered by pretreatment with buccal selegiline 1.25 mg in healthy subjects.[8] Similarly, the pressor response to tyramine up to 200 mg was not significantly altered by pretreatment with a single 24-hour application of transdermal selegiline 7.8 mg/24 hour in healthy subjects.[9] Another study in 12 healthy subjects who applied selegiline transdermal patches 6 mg/24 hours daily for 13 days, in order to achieve steady-state levels, similarly found no clinically significant blood pressure response to meals containing up to 400 mg of tyramine.[10] A study by the same authors, in which the use of selegiline was extended to 33 days also found no clinically meaningful change in the pressor sensitivity to tyramine.[11]

Mechanism

Rasagiline and selegiline specifically inhibit MAO-B, which leaves MAO-A still available to metabolise any tyramine in foodstuffs. However, at higher doses the selectivity of selegiline diminishes, and inhibition of the metabolism of tyramine is more likely. Nevertheless, the 2- to 4.5-fold increase in effect of tyramine seen with selegiline 5 to 30 mg daily is still less than that seen with the non-selective MAOIs, see 'MAOIs or RIMAs + Tyramine-rich foods', p.1395.

Importance and management

The absence of an interaction between rasagiline or selegiline and tyramine is well established, and the manufacturer of rasagiline states that no dietary tyramine restrictions are necessary.[2] Similarly, at the recommended doses of conventional or buccal selegiline used in Parkinson's disease the manufacturers say that no dietary restrictions are necessary,[12-14] and this is supported by the scarcity of any published reports of reactions. If higher doses of selegiline are used, MAO-B selectivity may be lost, and patients should be advised to avoid large amounts of tyramine-rich foods. This is reflected by the advice given by one manufacturer of a transdermal selegiline patch who suggests that restrictions on tyramine ingestion are only necessary with a daily dose of 9 mg/24 hours or more.[15] For a list of the possible tyramine-content of some foods, see 'Table 32.3', (p.1396).

MAO-B inhibitors; Rasagiline + Miscellaneous

Ciprofloxacin increases the AUC of rasagiline by inhibiting CYP1A2. Other inhibitors of CYP1A2 are predicted to interact similarly. There is a theoretical possibility that tobacco smoke, may reduce the plasma levels of rasagiline. Rasagiline does not affect the pharmacokinetics of theophylline.

Clinical evidence, mechanism, importance and management

(a) CYP1A2 inhibitors

The manufacturer notes that concurrent use of rasagiline and **ciprofloxacin** increased the AUC of rasagiline by 83%.[1] **Ciprofloxacin** inhibits the cytochrome P450 isoenzyme CYP1A2, which is the major enzyme responsible for the metabolism of rasagiline. The clinical relevance of this increase has not been assessed, but until more is known caution is warranted. Be alert for rasagiline adverse effects (e.g. headache, dyspepsia). This caution should be extended to other potent inhibitors of CYP1A2, such as **enoxacin**. Note that fluvoxamine is also a CYP1A2 inhibitor, but concurrent use with, and for 2 weeks after, rasagiline should be avoided, see 'MAO-B inhibitors + SSRIs or SNRIs', p.808.

(b) Theophylline

The manufacturer reports that the pharmacokinetics of neither rasagiline nor theophylline, a substrate of cytochrome P450 isoenzyme CYP1A2, were altered when the two drugs were given together.[1] Rasagiline would not be expected to affect the metabolism of other drugs by this route.

(c) Tobacco

Rasagiline is a substrate of the cytochrome P450 isoenzyme CYP1A2, and the manufacturer advises that the plasma levels of rasagiline may be lowered in patients who smoke, due to the inducing effect of tobacco smoke on CYP1A2.[1] Bear this theoretical interaction in mind if rasagiline seems less effective than anticipated.

MAO-B inhibitors; Selegiline + Alprazolam

In a study in 12 healthy subjects, the concurrent use of transdermal selegiline patches 6 mg/24 hours and alprazolam

500 micrograms three times daily did not affect the steady-state pharmacokinetics of either drug.[1]

1. Azzaro AJ, Ziemniak J, Kemper E, Campbell BJ, VanDenBerg C. Selegiline transdermal system: an examination of the potential for CYP450-dependent pharmacokinetic interactions with 3 psychotropic medications. *J Clin Pharmacol* (2007) 47, 146–58.

MAO-B inhibitors; Selegiline + Antipsychotics

When healthy subjects were given selegiline transdermal patches 6 mg/24 hours either alone, or with olanzapine 5 mg daily or risperidone 1 mg twice daily, the steady-state pharmacokinetics of olanzapine, risperidone and selegiline were not affected.[1]

1. Azzaro AJ, Ziemniak J, Kemper E, Campbell BJ, VanDenBerg C. Selegiline transdermal system: an examination of the potential for CYP450-dependent pharmacokinetic interactions with 3 psychotropic medications. *J Clin Pharmacol* (2007) 47, 146–58.

MAO-B inhibitors; Selegiline + Cocaine

Cocaine and selegiline appear not to interact adversely.

Clinical evidence, mechanism, importance and management

In a study to establish the safety of using selegiline to prevent relapse in cocaine addiction, 5 otherwise healthy intravenous cocaine users were given 0, 20 and 40 mg intravenous doses of cocaine one hour apart after receiving selegiline 10 mg or placebo orally. The cocaine increased the heart rate, blood pressure, pupil diameter and subjective indices of euphoria as expected. However, the presence of selegiline reduced pupillary diameter, but did not alter the pupil dilation or other effects normally caused by cocaine.[1] In another study, transdermal selegiline did not alter the pharmacokinetics of intravenous cocaine in cocaine-dependent subjects. Some physiological effects (blood pressure and heart rate) and subjective effects of cocaine were attenuated by selegiline.[2]

The authors of the first study[1] concluded that concurrent use is safe and unlikely to increase the reinforcing effects of cocaine.

MAO-B inhibitors; Selegiline + Dopamine agonists

No pharmacokinetic interaction occurs between selegiline and cabergoline, pramipexole or ropinirole.

Clinical evidence, mechanism, importance and management

(a) Cabergoline

In a study in 6 subjects with Parkinson's disease, no pharmacokinetic interaction was found to occur between cabergoline 1 mg daily and selegiline 10 mg daily after 22 days of concurrent use.[1]

(b) Pramipexole

The manufacturer of pramipexole says that no pharmacokinetic interaction occurs with selegiline.[2]

(c) Ropinirole

The manufacturer of ropinirole notes that a population pharmacokinetic analysis showed a lack of relevant effects of selegiline on ropinirole.[3]

3. SmithKline Beecham. Personal Communication, September 1996.

MAO-B inhibitors; Selegiline + Hormonal contraceptives or HRT

In a small study, the bioavailability of selegiline was markedly higher (mean of about 20-fold) in women taking oral combined hormonal contraceptives than in those not taking contraceptives. A controlled study found that the effect of HRT was more modest.

Clinical evidence

(a) Combined oral contraceptives

The AUCs of single doses of selegiline 5 to 40 mg were 16- to 45-fold higher in 4 women taking oral combined hormonal contraceptives than in 4 women who were not taking contraceptives. Three subjects were taking **ethinylestradiol/gestodene** 30/75 micrograms, and one was taking a triphasic preparation of **ethinylestradiol/levonorgestrel**.[1]

(b) HRT

In a crossover study in 12 young healthy women, the AUC of a single 10-mg dose of selegiline was increased by 60% (which was not statistically significant) following 10 days of HRT (containing **estradiol valerate/levonorgestrel** 2 mg/250 micrograms). There was marked variability in selegiline levels with two women having a threefold increase in AUC, and 3 having a decrease. Other changes in pharmacokinetics of selegiline or its metabolites were small.[2]

Mechanism

It was suggested that the combined hormonal contraceptive inhibited the first pass metabolism of selegiline and so markedly increased its bioavailability.[1] However, this was not found for HRT containing a different estrogenic hormone.

Importance and management

Although data are limited, it appears that combined hormonal contraceptives may markedly increase the bioavailability of selegiline. One UK manufacturer advises caution with concurrent use,[3] and the other suggests the combination should be avoided.[4] Although the short-term use of HRT also increased the AUC of selegiline, the changes were modest and were not considered clinically relevant. Nevertheless, the results perhaps need confirming with longer term concurrent use. One UK manufacturer of selegiline also advises the avoidance of concurrent HRT.[4]

3. Eldepryl (Selegiline hydrochloride). Orion Pharma (UK) Ltd. UK Summary of product characteristics, June 2009.
4. Zelapar (Selegiline hydrochloride). Cephalon Ltd. UK Summary of product characteristics, September 2008.

MAO-B inhibitors; Selegiline + Itraconazole

The concurrent use of selegiline and itraconazole does not appear to alter the pharmacokinetics of either drug.

Clinical evidence, mechanism, importance and management

In a randomised, placebo-controlled, crossover study, 12 healthy subjects were given selegiline 10 mg after taking itraconazole 200 mg daily for 4 days. Itraconazole did not have any significant effects on the pharmacokinetics of selegiline, although the AUC of desmethylselegiline, a primary metabolite, was increased by 11%. The pharmacokinetics of

itraconazole were also unaffected. There would appear to be no reason for avoiding concurrent use.[1]

1. Kivistö KT, Wang J-S, Backman JT, Nyman L, Taavitsainen P, Anttila M, Neuvonen PJ. Selegiline pharmacokinetics are unaffected by the CYP3A4 inhibitor itraconazole. *Eur J Clin Pharmacol* (2001) 57, 37–42.

MAO-B inhibitors; Selegiline + Metamfetamine

Selegiline does not alter the pharmacokinetics of metamfetamine.

Clinical evidence, mechanism, importance and management

In a study, 5 subjects who used metamfetamine at least twice a week, took selegiline 5 mg twice daily for 12 days, and 4 subjects took placebo. During this time they received intravenous metamfetamine 15 mg and 30 mg given 2 days apart. When compared with placebo, selegiline did not affect either the pharmacokinetics of metamfetamine and its metabolite, d-amfetamine or the cardiovascular effects of metamfetamine. Subjects reported greater metamfetamine-associated "bad effects" while taking selegiline than while taking placebo, but other subjective effects were not altered.[1]

Piribedil + Clonidine

Clonidine is reported to oppose the effects of piribedil.

Clinical evidence, mechanism, importance and management

A study in 5 patients taking piribedil found that the concurrent use of clonidine (up to 1.5 mg daily for 10 to 24 days) caused a worsening of parkinsonism (an exacerbation of rigidity and akinesia). The concurrent use of antimuscarinic drugs reduced the effects of this interaction.[1] The reason is uncertain, and the general relevance of this small study is unclear.

1. Shoulson I, Chase TN. Clonidine and the anti-parkinsonian response to L-dopa or piribedil. *Neuropharmacology* (1976) 15, 25–7.

Pramipexole + Drugs that alter its renal clearance

Cimetidine, and possibly amantadine modestly reduce the clearance of pramipexole. Probenecid had a minor effect on pramipexole clearance in one study.

Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects found that multiple doses of **cimetidine** reduced the total oral clearance of a single 250-microgram dose of pramipexole by about 35% and increased its half-life by 40%. A similar reduction in the renal clearance of pramipexole was noted. The authors suggest that **cimetidine** reduces the renal excretion of pramipexole by inhibiting the active renal organic cation transport system.[1] The manufacturers say that **cimetidine** and other drugs that are eliminated by this route such as **amantadine** may interact with pramipexole to reduce excretion of either or both drugs.[2] The clinical significance of these interactions is uncertain, and as yet there appear to be no reports of any adverse interactions. Nevertheless, the manufacturers suggest a reduction of the pramipexole dose should be considered when **amantadine** or **cimetidine** are given with pramipexole.[2]

In a study in 12 healthy subjects, multiple doses of **probenecid** reduced the clearance of a single 250-microgram dose of pramipexole by 10%.[1] This change is not clinically relevant.

Ropinirole + CYP1A2 inhibitors

Ciprofloxacin increased the AUC of ropinirole by 84%, by inhibiting CYP1A2: other CYP1A2 inhibitors are predicted to interact similarly.

Clinical evidence

In a study in 12 patients **ciprofloxacin** 500 mg twice daily increased the AUC of ropinirole 2 mg three times daily by 84% and increased the maximum plasma level by 60%.[1]

Mechanism

Ropinirole is principally metabolised by the cytochrome P450 isoenzyme CYP1A2, of which ciprofloxacin is a known inhibitor.

Importance and management

Although the clinical relevance of this pharmacokinetic interaction has not been assessed, it would seem possible that the effects of ropinirole may be increased. The manufacturers suggest that if a known potent inhibitor of CYP1A2 is stopped or started in a patient taking ropinirole, adjustment of the ropinirole dose may be required.[1,2] The UK manufacturer specifically mentions **cimetidine** (which is not usually considered a potent CYP1A2 inhibitor) and **fluvoxamine** in addition to ciprofloxacin.[2] Note that enoxacin is usually also considered to be a potent CYP1A2 inhibitor.

1. Requip (Ropinirole hydrochloride). GlaxoSmithKline. US Prescribing information, May 2009.
2. Requip (Ropinirole hydrochloride). GlaxoSmithKline UK. UK Summary of product characteristics, September 2009.

Ropinirole + Miscellaneous

Estrogens (HRT) may reduce the clearance and tobacco smoking may increase the clearance of ropinirole.

Clinical evidence, mechanism, importance and management

(a) Oestrogens

Population pharmacokinetic analysis of clinical study data showed that estrogens (mainly ethinylestradiol[1]) used in HRT reduced ropinirole clearance by one-third.[1-4] In another analysis it was found that women taking HRT received a slightly lower daily dose of ropinirole than those not taking HRT, with no difference in adverse effects.[4] Therefore, in women already receiving HRT, ropinirole treatment may be started using the usual dose titration.[1,3] However, it is suggested that an adjustment [reduction] in the ropinirole dose may be needed if HRT is started.[1,3]

(b) Tobacco

The manufacturer notes that, in a study in patients with restless leg syndrome, 7 tobacco smokers were found to have a 38% lower ropinirole AUC and a 30% lower maximum level than 11 non-smokers.[1] Tobacco induces the cytochrome P450 isoenzyme CYP1A2, by which ropinirole is extensively metabolised. Because the dose of ropinirole is titrated to effect, this interaction is unlikely to be clinically relevant, except perhaps if patients stop or start smoking while taking ropinirole, when further dose titration may be necessary.

(c) Other drugs

The manufacturer notes that population analysis revealed that **amantadine**, **antimuscarinics**, **antihistamines**, **benzodiazepines**, **ibuprofen**, **thiazides**, **tricyclic antidepressants**, and **trihexyphenidyl** did not have any relevant effects on the pharmacokinetics and/or clearance of ropinirole.[1,2,5]

19

Antiplatelet drugs and Thrombolytics

Platelets usually circulate in the plasma in an inactive form, but following injury to blood vessels they become activated and adhere to the site of injury. Platelet aggregation then occurs, which contributes to the haemostatic plug. Platelet aggregation involves the binding of fibrinogen with a glycoprotein IIb/IIIa receptor on the platelet surface. The activated platelets secrete substances such as adenosine diphosphate (ADP) and thromboxane A_2 that result in additional platelet aggregation and also cause vasoconstriction. Finally a number of platelet-derived factors stimulate production of thrombin and hence fibrin through the coagulation cascade (see 'The blood clotting process', (p.405)). Opposing this process is the fibrinolysis pathway, which is initiated during clot formation by a number of mediators such as tissue plasminogen activator (tPA) and urokinase. These proteins convert plasminogen to plasmin, which in turn degrades fibrin, the main component of the clot.

Antiplatelet drugs (see 'Table 19.1', (below)) reduce platelet aggregation and are used to prevent thromboembolic events. They act through a wide range of mechanisms including:

- prevention of thromboxane A_2 synthesis or inhibition of thromboxane receptors e.g. aspirin inhibits platelet cyclo-oxygenase, preventing the synthesis of thromboxane A_2
- interference with adenosine diphosphate mediated platelet activation e.g. thienopyridines; inhibition of adenosine reuptake e.g. dipyridamole; interference with adenosine metabolism by inhibiting cyclic adenosine monophosphate (cAMP) phosphodiesterase e.g. cilostazol
- interference in the final step in platelet aggregation by stopping fibrinogen binding with the glycoprotein IIb/IIIa receptor on the platelet surface e.g. abciximab

Therefore some antiplatelet drugs can have beneficial additive effects with other antiplatelet drugs that act via different mechanisms. Furthermore, other drugs such as dextrans, heparin, some prostaglandins and sulfinpyrazone also have some antiplatelet activity. It should be noted that the additive bleeding effects of using two drugs with antiplatelet and/or thrombolytic properties should always be considered, and patients monitored appropriately. Consideration should also be given when using these types of drugs with other drugs that may cause bleeding such as 'NSAIDs', (p.158) or 'SSRIs', (p.817).

Thrombolytics (see 'Table 19.1', (below)) are used in the treatment of thromboembolic disorders. Thrombolytics activate plasminogen to form plasmin, which is a proteolytic enzyme that degrades fibrin and therefore produces clot dissolution.

This section is primarily concerned with those interactions where the activities of antiplatelet drugs or thrombolytics are changed by the presence of another drug. Note that the interactions of high-dose aspirin are covered under analgesics.

Table 19.1 Antiplatelet drugs and thrombolytics

Group	*Drugs*
Antiplatelet drugs	
Adenosine reuptake inhibitors/Phosphodiesterase inhibitors	Cilostazol, Dipyridamole
Cyclo-oxygenase inhibitors	Aspirin, Indobufen, Triflusal
Glycoprotein IIb/IIIa-receptor antagonists	Abciximab, Eptifibatide, Tirofiban
Thienopyridines (inhibitors of adenosine diphosphate mediated platelet aggregation)	Clopidogrel, Prasugrel, Ticlopidine
Thromboxane receptor antagonists	Picotamide
Miscellaneous	Ditazole, Trapidil
Thrombolytics	
Thrombolytics	Alteplase, Anistreplase, Defibrotide, Reteplase, Streptokinase, Tenecteplase, Urokinase

Anagrelide + Miscellaneous

Anagrelide should not be used with other phosphodiesterase III inhibitors (e.g. milrinone) because of the potential for increased inotropic effects. Inhibitors of CYP1A2 (e.g. fluvoxamine) are predicted to increase anagrelide levels, and substrates of CYP1A2 (e.g. theophylline) are predicted to be affected by anagrelide. Some caution might be required with concurrent aspirin. Food delays the absorption of anagrelide, but does not affect the systemic exposure. Isolated reports suggested that sucralfate and hydroxycarbamide may interact with anagrelide. Allopurinol, digoxin, furosemide, iron, paracetamol (acetaminophen), ranitidine and warfarin are not expected to interact with anagrelide.

Clinical evidence, mechanism, importance and management

(a) Aspirin

A study found that the concurrent use of single doses of anagrelide 1 mg and aspirin 900 mg were generally well tolerated and no clinically significant pharmacokinetic interaction occurred. No changes in the bleeding time, aPTT or PT were seen.[1] Nevertheless, anagrelide was found to have additive antiplatelet effects with aspirin *in vitro*, and the manufacturer recommends that the risk/benefit ratio should be assessed before aspirin is used with anagrelide in patients with a high platelet count (greater than 1500 x 10^9/L) and/or a history of haemorrhage.[2]

(b) CYP1A2 inhibitors and substrates

Anagrelide is principally metabolised by the cytochrome P450 isoenzyme CYP1A2. Drugs that are inhibitors of this isoenzyme are therefore predicted to reduce the clearance of anagrelide, and the manufacturers specifically name **fluvoxamine**[1,2] and **omeprazole**.[2] Be aware that increased effects, both beneficial and adverse, might occur. However, note that **omeprazole** is only a weak CYP1A2 inhibitor, and would not be expected to have much effect on anagrelide. **Grapefruit juice** has also been predicted to interact via this mechanism,[2] but again, it appears to have little clinically relevant effect on CYP1A2. For a list of CYP1A2 inhibitors, see 'Table 1.2', (p.4).

Anagrelide is a weak inhibitor of CYP1A2, and therefore the manufacturers suggest that it might interact with CYP1A2 substrates, such as **theophylline**.[1,2] The clinical significance of this is unknown, but it seems likely to be small.

(c) Hydroxycarbamide

In a preclinical study in *dogs*, there was no pharmacokinetic interaction between hydroxycarbamide and anagrelide, therefore no clinical pharmacokinetic interaction is expected.[2] A patient taking hydroxycarbamide for 7 years developed severe hypersensitivity pneumonitis soon after anagrelide was started.[3] The clinical significance of this isolated case is unknown, although there has been another case report of hypersensitivity pneumonitis with anagrelide alone.[4]

(d) Phosphodiesterase inhibitors

Anagrelide is a cyclic AMP phosphodiesterase III inhibitor, and consequently has positive inotropic effects. The manufacturer recommends against its concurrent use with other phosphodiesterase III inhibitors, because of the potential increased inotropic effects, and they specifically mention **amrinone**, **cilostazol**, **enoximone**, **milrinone**, and **olprinone**.[2]

(e) Sucralfate

An isolated case report suggested that sucralfate may interfere with the absorption of anagrelide,[1] however the clinical significance of this is unclear. If an interaction is suspected, it is usual practice to separate administration by 2 hours.

(f) Other medications

The US manufacturer notes that although no formal drug interaction studies have been performed, **allopurinol**, **furosemide**, **iron**, **paracetamol** (acetaminophen), and **ranitidine** did not appear to interact with anagrelide in clinical studies.[1] The manufacturer briefly mentions that there was no pharmacokinetic interaction between **digoxin** or **warfarin** and anagrelide.[1,2] Food delays the absorption of anagrelide, but does not alter the overall amount absorbed.[2] The interaction is not clinically relevant.[1,2]

Antiplatelet drugs + Antacids

***Maalox* causes a moderate decrease in the absorption of ticlopidine. An aluminium/magnesium-containing antacid did not affect the absorption of clopidogrel in one study.**

Clinical evidence, mechanism, importance and management

(a) Clopidogrel

In a randomised study, 12 healthy subjects were given two 400-mg tablets of *Maalox* (**aluminium**/**magnesium hydroxide**) followed, one hour later, by a single 75-mg dose of clopidogrel. The maximum levels and AUC (only 9 subjects assessed) of the major carboxylic acid metabolite of clopidogrel were not significantly affected, suggesting that clopidogrel absorption was not altered by the antacid.[1]

(b) Dipyridamole

See 'Dipyridamole + Drugs that affect gastric pH', p.825, for the suggestion that antacids can affect the absorption of dipyridamole from some dosage forms.

(c) Ticlopidine

In a study in 12 healthy subjects the extent of absorption of a single 250-mg dose of ticlopidine was decreased by about 20% by 30 mL of *Maalox* [**aluminium**/**magnesium hydroxide**].[2] These modest changes are unlikely to be of much clinical importance.

1. McEwen J, Strauch G, Perles P, Pritchard G, Moreland TE, Necciari J, Dickinson JP. Clopidogrel bioavailability: absence of influence of food or antacids. *Semin Thromb Hemost* (1999) 25 (Suppl 2), 47–50.
2. Shah J, Fratis A, Ellis D, Murakami S, Teitelbaum P. Effect of food and antacid on absorption of orally administered ticlopidine hydrochloride. *J Clin Pharmacol* (1990) 30, 733–6.

Antiplatelet drugs + Aspirin

There is an increased risk of bleeding if clopidogrel is given with aspirin, but their concurrent use can be beneficial. Ticlopidine increases the antiaggregant effects of aspirin and there is an increased risk of bleeding on concurrent use. Cilostazol appears not to interact to a clinically relevant extent with low-dose aspirin, and the addition of dipyridamole to aspirin does not appear to increase the incidence of bleeding.

Clinical evidence, mechanism, importance and management

(a) Cilostazol

In a randomised, placebo-controlled study in 11 healthy subjects, giving aspirin 325 mg daily for 5 days with cilostazol 100 mg twice daily increased the inhibition of ADP-induced platelet aggregation by 23 to 35%, when compared with the use of cilostazol alone. Aspirin also appeared to cause a minor 22% increase in the AUC of cilostazol. However, there were no statistically significant additive effects on arachidonic acid-induced platelet aggregation, and no clinically relevant effects on prothrombin times, aPTT or bleeding times.[1] The US manufacturer reports that in 8 randomised, placebo-controlled studies, in a total of 201 patients receiving cilostazol and aspirin, the incidence of bleeding was no greater than that seen with aspirin and placebo. The most frequent doses and mean duration of aspirin therapy were 75 to 81 mg daily for 137 days (107 patients) and 325 mg daily for 54 days (85 patients).[2]

These studies suggest that no special precautions are needed if cilostazol is used concurrently with low-dose aspirin, although note that the UK manufacturer of cilostazol recommends that, when given with cilostazol, the daily dose of aspirin should not exceed 80 mg.[3]

(b) Clopidogrel

A variety of studies have investigated the beneficial effects of using the combination of aspirin with clopidogrel. Although these studies were pri-

marily designed to assess the benefits of concurrent use they did also report on bleeding events. The key findings were:

- In patients with recent acute coronary syndrome (CURE): an increase in major bleeding events following the use of clopidogrel 75 mg daily with aspirin 75 to 325 mg daily compared with aspirin alone (3.7% versus 2.7%, respectively).[4]
- In patients with recent stroke or transient ischaemic attack (MATCH): an increase in life-threatening bleeding events following the use of clopidogrel 75 mg daily with aspirin 75 mg daily, when compared with aspirin alone (2.6% versus 1.3%, respectively).[5]
- In patients with clinically evident cardiovascular disease or multiple atherosclerotic risk factors (CHARISMA): an increase in the risk of moderate and severe bleeding following the use of clopidogrel 75 mg daily with aspirin 75 to 162 mg daily, when compared with aspirin alone (moderate 2.1% and 1.3%, respectively, severe 1.7% and 1.3%, respectively).[6]

Other studies designed to assess the risk of bleeding when aspirin was given with clopidogrel found the following results:

- A retrospective, population based, case-control study identified 1443 cases of significant upper gastrointestinal bleeding; 380 of these patients were taking antiplatelet and/or anticoagulant drugs. The study found that the adjusted odds ratio for serious upper gastrointestinal bleeding with clopidogrel alone was 1.1 but that this rose to 7.4 in patients taking clopidogrel with aspirin.[7]
- Another study in 3335 patients with atrial fibrillation found that the rates of major bleeding were similar to that of oral anticoagulation, but a higher rate of minor bleeds occurred with clopidogrel and aspirin combined (relative risk of 1.23).[8]
- A study in 7 healthy subjects found that clopidogrel 75 mg and aspirin 150 mg daily for 2 days caused a significant 3.4-fold increase in bleeding time relative to baseline, and when the clopidogrel dose was increased to 300 mg there was a 5-fold increase in bleeding time.[9]

Furthermore, a number of case reports describe adverse effects when using the combination:

- Spontaneous haemarthrosis of the knee has been associated with the concurrent use of aspirin and clopidogrel in one patient.[10]
- A report describes two surgical cases, which were complicated by bleeding associated with the combination of aspirin and clopidogrel. In both cases the bleeding was delayed, in that it was not obvious until the end of surgery, causing unanticipated surgical re-exploration.[11]
- Further reports describe increased perioperative bleeding in patients taking both aspirin and clopidogrel.[12,13]

The manufacturer of clopidogrel warns that the concurrent use of clopidogrel and aspirin should be undertaken with caution because of the increased risk of bleeding, although this combination is recommended for use in patients with acute coronary syndromes for up to one year. They recommend that, in patients taking clopidogrel, the dose of aspirin should not exceed 100 mg daily as higher doses are associated with higher bleeding risks.[14] For patients undergoing surgery, it has been suggested that, if possible, the combined use of clopidogrel and aspirin should be discontinued about 5 days before the surgery to minimise the risks of bleeding.[4,12,15] The manufacturers say that if an antiplatelet effect is not necessary, clopidogrel should be discontinued 5 to 7 days before surgery,[14,16] although note that this needs to be balanced against the possible adverse effects of stopping such treatment, such as recurrent myocardial infarction or in-stent stenosis.

(c) Dipyridamole

A study in 10 healthy subjects found that dipyridamole 50 mg three times daily given with a single 180-mg dose of aspirin, or dipyridamole 75 mg three times daily given with aspirin 120 mg maximally inhibited platelet functions but did not prolong the bleeding time.[17] Two major studies in stroke patients (ESPRIT and ESPS-2) reported no significant increase in bleeding with combined use of aspirin and dipyridamole, when compared with aspirin alone, and the combination was beneficial in reducing the risk of further stroke.[18,19] The manufacturer of dipyridamole states that the addition of dipyridamole to aspirin does not increase the incidence of bleeding events.[20] However, be aware that the manufacturer of *Asasantin* (dipyridamole 200 mg with aspirin 25 mg) recommends caution when taking this product with other antiplatelet drugs because of the possible risk of increased bleeding.[21]

(d) Ticlopidine

Aspirin combined with ticlopidine appears to inhibit platelet aggregation more than either drug alone.[22,23] The rate of haemorrhagic complications at 30 days in the STARS study for ticlopidine 250 mg twice daily with low-dose aspirin was 5.5% compared with 1.8% for aspirin alone.[24] The US manufacturer of ticlopidine warns that its use with aspirin increases the risk of bleeding and that the safety of combined use beyond 30 days has not been established. They recommend that clinical monitoring is advisable.[24]

Antiplatelet drugs + Food

Food increases the bioavailability of cilostazol, which may increase the incidence of adverse effects. Food increases the absorption of clopidogrel and ticlopidine.

Clinical evidence, mechanism, importance and management

(a) Cilostazol

A randomised, crossover study in 15 healthy subjects found that giving a single 100-mg dose of cilostazol within 10 minutes of a high-fat meal caused an increase in the rate and extent of cilostazol absorption. The maximum plasma level of cilostazol was increased by about 95%, the AUC was increased by 25%, and the half-life decreased from 15.1 to 5.4 hours, when compared with the fasted state.[1] The manufacturers recommend that cilostazol should be taken 30 minutes before or 2 hours after food, because the increase in maximum plasma levels of cilostazol when taken with food may be associated with an increased incidence of adverse effects.[2,3]

(b) Clopidogrel

Two studies in 12 healthy subjects, one group with an average age of 67 years and the other with an average age of 23 years, found that the bioavailability of the carboxylic acid metabolite of clopidogrel (a major metabolite used as a marker of absorption) remained unchanged when a single 75-mg dose of clopidogrel was taken in the fasting state or with food.[4] In another small study in 12 healthy subjects, food delayed the absorption of a single dose of clopidogrel, and increased its maximum concentration and AUC by about sixfold and ninefold, respectively.[5] The clinical significance of this increase is unclear as clopidogrel and its carboxylic acid metabolite are not active. Furthermore, neither study measured levels of the *active* thiol metabolite. The UK manufacturers currently recommend that clopidogrel may be taken without regard to food intake.[6]

(c) Ticlopidine

In a study in 12 healthy subjects the extent of absorption of a single 250-mg dose of ticlopidine was increased by 20% and occurred more rapidly when ticlopidine was taken after food, when compared with the fasting state.[7] These modest changes are unlikely to be of much clinical importance, and, although it is suggested that ticlopidine is taken with food, this is to minimise gastric intolerance.[7,8]

Antiplatelet drugs + Ginkgo (*Ginkgo biloba*)

Ginkgo has been associated with platelet, bleeding, and clotting disorders, and there are isolated reports of serious adverse reactions after its concurrent use with antiplatelet drugs such as aspirin, clopidogrel, and ticlopidine.

Clinical evidence

A study in 10 healthy subjects found no significant increase in the antiplatelet effects of single doses of **clopidogrel** 75 mg or **cilostazol** 100 mg when a single dose of ginkgo 120 mg was added. However, the bleeding time was significantly increased when **cilostazol** was combined with ginkgo, although none of the subjects developed any significant adverse effects.[1] Another study[2] in 8 healthy subjects found that ginkgo 40 mg three times daily had no significant effect on the pharmacokinetics of a single dose of **ticlopidine** 250-mg taken on day 4.

A randomised, double-blind study in 55 patients with established peripheral artery disease (PAD) or with risk factors for developing PAD, found that the addition of ginkgo extract 300 mg (EGb 761) in divided doses to **aspirin** 325 mg daily did not have a significant effect on platelet aggregation. Five of the patients taking combined therapy reported nosebleeds or minor bleeding; however, 4 patients from the **aspirin**-only group also reported minor bleeding.[3] Similarly, a study in 41 healthy subjects found that 120-mg ginkgo coated-tablets (EGb 761) twice daily had no effect on the antiplatelet activity of **aspirin** 500 mg daily given for seven days. Minor bleeding was seen in a few subjects but this was attributed to the use of **aspirin**.[4] In an analysis of supplement use, 23% of 123 patients were currently taking supplements, and 4 patients were found to be taking ginkgo and **aspirin**. However, no problems from this use were found on review of the patients' notes.[5]

Nevertheless, a number of cases of clinically significant bleeding have been reported. A 70-year-old man developed spontaneous bleeding from the iris into the anterior chamber of his eye within one week of starting to take a ginkgo supplement (*Ginkoba*) tablet twice daily. He experienced recurrent episodes of blurred vision in one eye lasting about 15 minutes, during which he could see a red discoloration through his cornea. Each tablet contained 40 mg of concentrated (50:1) extract of ginkgo. He was also taking **aspirin** 325 mg daily, which he had taken uneventfully for 3 years since having coronary bypass surgery. He stopped taking the ginkgo but continued with the **aspirin**, and 3 months later had experienced no recurrence of the bleeding.[6] Another case reports persistent postoperative bleeding from a hip arthroplasty wound, which continued despite stopping **aspirin**. On closer questioning, the patient had continued to take ginkgo extract 120 mg daily postoperatively. The oozing from the wound gradually reduced when the ginkgo was stopped.

A search of Health Canada's database of spontaneous adverse reactions for the period January 1999 to June 2003 found 21 reports of suspected adverse reactions associated with ginkgo. Most of these involved platelet, bleeding, and clotting disorders. One report of a fatal gastrointestinal haemorrhage was associated with **ticlopidine** and ginkgo, both taken over 2 years along with other medications. Another report was of a stroke in a patient taking multiple drugs, including **clopidogrel**, **aspirin**, and a herbal product containing ginkgo.[7]

Mechanism

The reason for the bleeding is not known, but ginkgo extract contains ginkgolide B, which is a potent inhibitor of platelet-activating factor *in vitro*, which is needed for arachidonate-independent platelet aggregation. However, in one controlled study in healthy subjects, taking a ginkgo preparation alone for two weeks had no effect on platelet function.[8] Nevertheless, there are case reports of ginkgo supplements, on their own, being associated with prolonged bleeding times,[9-11] left and bilateral subdural haematomas,[9,12] a right parietal haematoma,[13] a retrobulbar haemorrhage,[14] post-laparoscopic cholecystectomy bleeding,[15] and subarachnoid haemorrhage.[10] Therefore it seems that the effects of ginkgo and conventional antiplatelet drugs can be additive, leading to bleeding complications on rare occasions.

Importance and management

The evidence from these case reports is too slim to advise patients taking aspirin, clopidogrel, or ticlopidine to avoid ginkgo, but some do recommend caution,[7] which seems prudent, especially as this is generally advised with most combinations of conventional antiplatelet drugs. There may also be a theoretical risk of increased bleeding if ginkgo is taken with other antiplatelet drugs; interactions have been reported with NSAIDs, some of which have antiplatelet effects (see 'NSAIDs + Ginkgo (*Ginkgo biloba*)', p.164).

Antiplatelet drugs + NSAIDs

The manufacturers of clopidogrel warn about possible gastrointestinal bleeding if it is used with naproxen or other NSAIDs. There is also an increased risk of bleeding if ticlopidine is given with NSAIDs.

Clinical evidence, mechanism, importance and management

(a) Clopidogrel

A double-blind, placebo-controlled study in 30 healthy subjects given **naproxen** 250 mg twice daily, found that the addition of clopidogrel 75 mg daily increased faecal blood loss, when compared with **naproxen** alone. Six subjects receiving both drugs had their bleeding time prolonged by a factor of more than 5, which was greater than expected (clopidogrel alone prolongs bleeding by a factor of about 2) and one subject had subcutaneous haemorrhages of moderate intensity after taking clopidogrel with **naproxen**.[1] A retrospective study of patient records in the UK found that the adjusted rate ratio for the risk of gastrointestinal bleeding in patients taking clopidogrel with an NSAID increased from 1.67 for clopidogrel alone to 2.9 when clopidogrel was taken with an NSAID or 2.6 when clopidogrel was taken with a coxib.[2]

A case report describes intracerebral haemorrhage in an 86-year-old woman who had been taking **celecoxib** 200 mg daily with clopidogrel 75 mg daily for 3 weeks. The authors comment that there may possibly have been a pharmacokinetic interaction between clopidogrel and **celecoxib** [a metabolite of clopidogrel may inhibit CYP2C9, by which **celecoxib** is metabolised, although interaction have not been found between clopidogrel and other CYP2C9 substrates], although the haemorrhage could have been secondary to other factors, such as age, or the individual drugs.[3]

The manufacturers advise caution if NSAIDs, including coxibs, and clopidogrel are given together.[4,5] Note that, due to an increased thrombotic risk, the use of a coxib is contraindicated in those with ischaemic heart disease, cerebrovascular disease, and peripheral artery disease; and some evidence suggests that **diclofenac**, and high doses of **ibuprofen**, may similarly be associated with an increased risk of thrombotic events.[6] The use of an antiplatelet drug may indicate the presence of one of these conditions, and therefore the concurrent use of an NSAID should be considered carefully.

(b) Ticlopidine

The US manufacturer of ticlopidine states that drugs which might induce lesions with a propensity to bleed (such as ulcers) should be used with caution and also that ticlopidine potentiates the effect of NSAIDs on platelet aggregation. The safety of concurrent use of ticlopidine with NSAIDs has not been established,[7] and therefore caution should be used when prescribing an NSAID in patients taking ticlopidine. See above under clopidogrel, for comment on the use of NSAIDs in patients with coronary or cerebrovascular disease.

Antiplatelet drugs + Policosanol

Policosanol has antiplatelet effects, which may be additive with those of other antiplatelet drugs.

Clinical evidence

In a randomised study, four groups, each containing 10 or 11 subjects, were given placebo, policosanol 20 mg daily, **aspirin** 100 mg daily, or both drugs together, for 7 days. Adrenaline-induced platelet aggregation was reduced in the group given **aspirin** and policosanol by about 35% more than in the group given **aspirin** alone: the effects of **aspirin** and policosanol were approximately additive. Furthermore, collagen-induced platelet aggregation was reduced in the group given **aspirin** and policosanol by about 10% more than in the group given **aspirin** alone. One patient taking both drugs suffered from bleeding gums. There was no significant effect on coagulation time.[1] A 3-year study, primarily designed to assess the safety and efficacy of policosanol in patients taking beta blockers, included 32 patients taking antiplatelet drugs (mainly **aspirin**). No adverse effects related to bleeding were reported.[2]

Mechanism

Additive antiplatelet effects.

Importance and management

The concurrent use of two conventional antiplatelet drugs is not uncommon, and so concurrent use of policosanol and aspirin need not be avoided. However, because platelet aggregation was reduced significantly, and a bleeding event was experienced, caution is perhaps warranted when taking policosanol supplements with aspirin or any other antiplatelet drug.

Antiplatelet drugs + SSRIs

The bleeding risk associated with antiplatelet drugs such as aspirin, clopidogrel, dipyridamole, and ticlopidine may be further increased by concurrent use of an SSRI, although the data appears to be conflicting.

Clinical evidence

A retrospective study[1] of the UK general practice research database identified 1651 cases of upper gastrointestinal bleeding diagnosed between 1993 and 1997. The concurrent use of an SSRI significantly increased the risk of bleeding threefold, when compared with 10 000 control patients. In addition, the concurrent use of an SSRI with **aspirin** was associated with a relative excess risk of upper gastrointestinal bleeding of 3.5.

Another retrospective study found that the observed-expected ratio of an upper gastrointestinal bleed was 3.6 in patients taking an SSRI (17 320 patients), 2.5 in patients taking low-dose **aspirin** (26,762 patients), but increased to 5.2 in patients taking both an SSRI and low-dose **aspirin** (2 640 patients).[2] A retrospective case-control study in 579 patients diagnosed with gastrointestinal bleeding (upper and lower) found that the concurrent use of SSRIs with low-dose **aspirin** increased the risk of gastrointestinal bleeding above the risk found with each drug separately (odds ratio 2.1 for the combination, compared with 1.8 and 1.5 for **aspirin** and an SSRI, respectively).[3]

In contrast, a case-control study of hospital admissions for gastrointestinal bleeding reported no substantial increase in the risk of a gastrointestinal bleed in patients taking an SSRI. Furthermore, an interaction with low-dose **aspirin** was not seen.[4] Some workers have agreed with these results and found no evidence to suggest that SSRIs are more likely to cause gastrointestinal bleeding than other drugs.[5] In the SADHART study, which looked at the efficacy and cardiac safety of **sertraline** in the treatment of depression in patients with acute coronary syndromes, bleeding was not reported as an adverse effect of concurrent treatment, even though 170 of the 186 patients randomised to treatment with sertraline were also taking **aspirin**. Thirty-five (19%) of the **sertraline** group were taking other antiplatelet drugs such as **clopidogrel** and **ticlopidine**.[6] A substudy of SADHART, which included 25 patients taking **sertraline**, found that the use of **sertraline** was associated with a decrease in platelet/endothelial activation, suggesting that **sertraline** did not have an additional antiplatelet effect.[7] Similarly, a randomised, placebo-controlled study in patients with

coronary artery disease found no increased risk in reported bleeding in those taking **citalopram** 20 to 40 mg daily, when compared with placebo. Of the patients taking **citalopram**, 80% were also taking **aspirin** and 25% were taking other antiplatelet drugs (not specified).[8] A study in 20 healthy male smokers found that **paroxetine** 20 mg daily for 21 days did not produce an increase in the platelet inhibition produced by **aspirin** 100 mg daily from days 18 to 21.[9]

Mechanism

Serotonin is not synthesised by platelets but is taken up into platelets from the bloodstream. At therapeutic doses SSRIs can block this uptake, leading to serotonin depletion within the platelet. Serotonin released from platelets has an important role in regulating the haemostatic response to injury as it potentiates platelet aggregation. Therefore SSRIs may impair the haemostatic function of the platelets, which may increase the risk of bleeding,[10] especially in the presence of other antiplatelet drugs.

Importance and management

There appears to be an association between the use of antidepressant drugs that interfere with serotonin reuptake and the occurrence of bleeding, including gastrointestinal bleeding. **Citalopram**, **fluoxetine**, **fluvoxamine**, paroxetine, and sertraline have all been reported to cause bleeding.[10] It therefore seems reasonable to anticipate that the risks of bleeding with an antiplatelet drug may be increased by an SSRI. However, the overall evidence for an increased risk of bleeding when giving an SSRI with an antiplatelet drug, such as aspirin or clopidogrel, is conflicting, with some studies demonstrating an increased risk and others suggesting no additional antiplatelet effect occurs.

The manufacturers advise caution in patients taking SSRIs with aspirin or other drugs that affect coagulation or platelet function,[11] and this would seem prudent. This is especially important in patients taking combinations of antiplatelet drugs, such as aspirin and clopidogrel for acute coronary syndromes or coronary stents, where the risk of bleeding from this combination alone appears to be significant, see 'Antiplatelet drugs + Aspirin', p.814. Consideration should be given to the prescribing of gastroprotective drugs in those at high risk of gastrointestinal bleeding, such as elderly patients or those with a history of gastrointestinal bleeding. Note that this advice would also apply to those patients taking analgesic-dose aspirin with an SSRI.

For a discussion on the theoretical pharmacokinetic interaction of fluoxetine and fluvoxamine with clopidogrel, see 'Clopidogrel + Proton pump inhibitors and other CYP2C19 inhibitors', p.821.

Aspirin + Fish oils

The concurrent use of aspirin and fish oil caused at least additive effects on bleeding time in healthy subjects, but in one clinical study there was no increase in incidence of bleeding episodes.

Clinical evidence

In a study in 8 healthy subjects, aspirin (325 mg on day one followed by 80 mg daily on days 2 and 3) prolonged the bleeding time by a mean of 2.2 minutes, whereas fish oil 4.5 g daily for 14 days had a non-significant effect (bleeding times increased by a mean of just 0.6 minutes). The combination prolonged bleeding time by a mean of 5 minutes, although this was stated to be not significantly different from a purely additive (43%) effect.[1] In this and a later study by the same researchers, fish oil did not increase the antiplatelet effect of aspirin.[1,2]

In a large placebo-controlled, randomised study of the effect of fish oils taken with either aspirin or warfarin over 9 months, there was no difference in the frequency of bleeding episodes between 119 patients taking aspirin 300 mg daily and fish oil 4 g daily and 106 taking aspirin alone (10 episodes versus 8 episodes, respectively).[3]

For a case of life-threatening bleed after a minor fall in a patient who had been taking omega-3 fatty acids 6 g daily, together with aspirin and warfarin for a year, see 'Coumarins + Fish oils', p.459.

Mechanism

Fish oils contain omega-3 fatty acids particularly **eicosapentaenoic acid** and **docosahexaenoic acid**. These are considered to have some antiplatelet activity, and may prolong the bleeding time. Theoretically, this effect might be additive with other antiplatelet drugs such as aspirin.

Importance and management

It appears that the concurrent use of aspirin and fish oils might increase bleeding times, particularly at high doses of fish oils, but one moderately large study found no evidence of increased incidence of bleeding episodes in clinical use. The manufacturer[4] of one product, *Omacor* (omega-3-acid ethyl esters), notes that at high doses of 4 g daily it may increase bleeding time, and advises caution in patients at a high risk of bleeding, but the only example they give is with anticoagulants. Some caution might be appropriate.

Note that this product is also licensed to be used with other standard therapies including antiplatelets as adjuvant treatment after myocardial infarction, but at a lower dose of just 1 g daily.[2]

Cilostazol + Clopidogrel

Clopidogrel slightly increases the levels of cilostazol, without altering platelet count, aPTT, or prothrombin time. The addition of cilostazol to clopidogrel (with aspirin) does not appear to increase the risk of major or minor bleeding in some patient groups.

Clinical evidence, mechanism, importance and management

The concurrent use of cilostazol 150 mg twice daily and clopidogrel 75 mg daily for 5 days increased the AUC of cilostazol by only 9%, but increased the AUC of the dehydro metabolite of cilostazol by 24% (this metabolite has 3 to 4 times the potency of cilostazol in inhibiting platelet aggregation). No changes in platelet count, prothrombin time or aPTT were seen. However, clopidogrel alone prolonged bleeding time, and it was not possible to determine whether there was an additive effect with cilostazol.[1]

The DECLARE-Long study evaluated the efficacy of cilostazol 100 mg twice daily with clopidogrel 75 mg and aspirin 200 mg daily (triple thera-

py), in 250 patients with drug-eluting stents by comparing treatment with 250 similar patients taking just aspirin and clopidogrel (dual therapy). No major bleeding requiring transfusion occurred in either the triple or dual therapy group. Only 2 patients in the triple therapy group developed minor bleeding (ecchymoses) compared with 4 in the dual therapy group. However, the incidence of rash and gastrointestinal adverse effects was more common in the group that also took cilostazol (24 compared with 5 patients). There was also a higher discontinuation rate in the triple therapy patients.[2]

The CREST study also found no significant difference in bleeding rates (major or minor) between 354 patients taking aspirin, clopidogrel and cilostazol after percutaneous coronary intervention compared with those taking aspirin and clopidogrel (351 patients). Compliance with the triple therapy was similar to dual therapy and the only increased adverse effect reported in the triple therapy group was headache.[3]

A study found that the addition of cilostazol to aspirin and clopidogrel significantly increased the inhibition of ADP-induced platelet aggregation in patients undergoing primary percutaneous coronary intervention, although cilostazol had no significant additive effect on aspirin-induced antiplatelet activity. There was no major bleeding and no discontinuation of cilostazol because of adverse drug reactions.[4] Similar findings were reported in another study.[5]

Although it appears that the addition of cilostazol to clopidogrel therapy may not increase the risk of bleeding, the UK manufacturer suggests caution if cilostazol is given with any drug that inhibits platelet aggregation, and says that consideration should be given to monitoring the bleeding time at intervals.[1] This would seem prudent until more data, particularly in those patient groups at higher risk of bleeding, are available.

Cilostazol + Miscellaneous

Erythromycin, diltiazem and ketoconazole, all inhibitors of the cytochrome P450 isoenzyme CYP3A4, increase the plasma levels of cilostazol. Other inhibitors of CYP3A4 are predicted to interact similarly, but grapefruit juice does not appear to significantly interact. Inducers of CYP3A4 (such as rifampicin (rifampin)) may also, in theory, alter cilostazol pharmacokinetics. Cilostazol is predicted to increase the levels of substrates of CYP3A4 (e.g. cisapride). Quinidine, an inhibitor of CYP2D6, does not appear to affect the pharmacokinetics of cilostazol and it is therefore suggested that other CYP2D6 inhibitors or substrates will not interact. Cilostazol appears not to interact to a clinically relevant extent with tobacco smoke.

Clinical evidence, mechanism, importance and management

(a) CYP3A4 and CYP2C19 inducers

The manufacturers of cilostazol state that the effect of inducers of the cytochrome P450 isoenzymes CYP3A4 and CYP2C19 (they name **carbamazepine**, **phenytoin**, **rifampicin** (**rifampin**) and **St John's wort**) on the pharmacokinetics of cilostazol has not been evaluated. In view of the effects of CYP3A4 inhibitors (see below) the manufacturers advice, to monitor concurrent use for an alteration in the antiplatelet effects of cilostazol, appears prudent.[1]

(b) CYP3A4 inhibitors

A study in 16 healthy subjects found that **erythromycin** 500 mg three times daily increased the maximum plasma level and the AUC of a single 100-mg oral dose of cilostazol by 47% and 73%, respectively. **Erythromycin** inhibits the cytochrome P450 isoenzyme CYP3A4, by which cilostazol is metabolised, thereby raising its plasma levels.[2] Other macrolide antibacterials e.g. **clarithromycin** (but not **azithromycin**) would be expected to have a similar effect.[3]

Diltiazem is also a moderate inhibitor of CYP3A4. When **diltiazem** 180 mg daily was given with cilostazol 100 mg twice daily, the AUC of cilostazol was increased by about 40%.[1,3]

In a single-dose study, **ketoconazole** 400 mg caused a greater than twofold increase in the AUC of cilostazol.[1] Other potent CYP3A4 inhibitors such as **itraconazole** are expected to interact similarly.[3]

In view of these effects the manufacturers suggest reducing the dose of cilostazol to 50 mg twice daily in the presence of CYP3A4 inhibitors such as the **macrolides** (e.g. **erythromycin**), **diltiazem**, some **azoles** (**itraconazole**, **ketoconazole**, **fluconazole**, **miconazole**) and the **protease inhibitors**.[1,3] The US manufacturer suggests that other CYP3A4 inhibitors, such as **SSRIs** (**fluoxetine**, **fluvoxamine**, **sertraline**) and **nefazodone**, may also interact.[3] Note that the SSRIs are, at worst, weak inhibitors of this isoenzyme, and therefore a clinically relevant interaction seems unlikely.

(c) CYP3A4 substrates

The UK manufacturer advises caution when cilostazol is given with drugs that are substrates of CYP3A4, especially those with a narrow therapeutic index. They specifically mention **cisapride**, **halofantrine**, **pimozide** and **ergot alkaloids** [**ergot derivatives**].[1] Further study is needed to establish these predicted interactions, although note that cilostazol has been seen to increase the levels of the CYP3A4 substrate lovastatin, see 'Statins + Cilostazol', p.1328.

(d) Grapefruit juice

The US manufacturer reports that grapefruit juice (a moderate inhibitor of CYP3A4) increased the maximum levels of cilostazol by approximately 50%, but had no clinically significant effect on the AUC.[3] However, the UK manufacturer says that 240 mL of grapefruit juice did not have a notable effect on the pharmacokinetics of a single 100-mg dose of cilostazol.[1] There has been a single, published case report of an interaction between grapefruit juice and cilostazol. A patient taking aspirin 100 mg daily and cilostazol 100 mg twice daily developed purpura, which resolved when the patient stopped drinking grapefruit juice. Neither aspirin nor cilostazol were stopped, and no dosage adjustments of either drug were made.[4] The general significance of this case is unclear, particularly as no pharmacokinetic data were reported confirming an increase in cilostazol levels. At present there appears to be no good evidence for avoiding the concurrent intake of grapefruit juice with cilostazol. However, bear the case report in mind, particularly in patients taking combinations of antiplatelet drugs who develop signs of bleeding.

(e) Quinidine

A crossover study in 22 healthy subjects found that the pharmacokinetics of a single 100-mg dose of cilostazol were unaffected by pretreatment with two 200-mg doses of quinidine sulfate, one taken 25 hours previously and the other taken one hour previously. Quinidine inhibits the activity of the cytochrome P450 isoenzyme CYP2D6, and it appears that this enzyme does not play a significant role in the metabolism of cilostazol or its primary metabolites.[5]

(f) Tobacco smoking

The manufacturer reports that population pharmacokinetic analysis suggests that tobacco smoking reduces the exposure to cilostazol by about 20%,[1,3] but this is unlikely to have much, if any, clinical relevance.

Cilostazol + Proton pump inhibitors

Omeprazole, a CYP2C19 inhibitor, increases the bioavailability of cilostazol and its active metabolite. Other CYP2C19 inhibitors (such as esomeprazole) are predicted to interact similarly.

Clinical evidence

In a crossover study in 20 healthy subjects, **omeprazole** 40 mg daily for one week increased the AUC of a single 100-mg dose of cilostazol by a modest 26%.[1] More importantly, the AUC of 3,4-dehydro-cilostazol (a metabolite with 4 to 7 times the activity of cilostazol) was increased by 69%.[1-3] The AUC of the other active cilostazol metabolite (with low activity) was reduced by 31%.[1,3] The manufacturer notes this results in an overall increase in pharmacological activity of 42% when compared with cilostazol alone.[3]

Mechanism

Cilostazol is partially metabolised by the cytochrome P450 isoenzyme CYP2C19, and therefore omeprazole, an inhibitor of this isoenzyme, may inhibit the metabolism of cilostazol, and may possibly also affect the elimination of its active metabolites.

Importance and management

The clinical relevance of the pharmacokinetic interaction between cilostazol and omeprazole is uncertain, but some caution would seem prudent. The manufacturer suggests that the interaction could have the potential to increase cilostazol adverse effects, and they say that the dose of cilostazol could be reduced to 50 mg twice daily in patients also taking omeprazole or other CYP2C19 inhibitors (such as **esomeprazole**), based on individual assessment of efficacy and tolerability.[2,3] For a list of CYP2C19 inhibitors, see 'Table 1.3', (p.6).

3. Pletal (Cilostazol). Otsuka Pharmaceuticals (UK) Ltd. UK Summary of product characteristics, November 2008.

Clopidogrel + Azoles

In one study, ketoconazole modestly reduced the formation of the active metabolite of clopidogrel, and reduced its antiplatelet effect. Fluconazole and voriconazole are predicted to have a similar effect. In one study itraconazole reduced the antiplatelet effect of clopidogrel, but only in a subgroup of patients.

Clinical evidence

(a) Itraconazole

In a study to determine the effect of itraconazole on clopidogrel inhibition of platelet aggregation, 32 healthy subjects took itraconazole 200 mg daily, starting 4 days before clopidogrel was given (300 mg as a loading dose followed by 75 mg daily for 6 days). The antiplatelet effect of clopidogrel was also determined when subjects took clopidogrel alone. Platelet aggregation was significantly reduced by itraconazole, but only in the 16 subjects who were CYP3A5 non-expressor genotypes (that is, those lacking this isoenzyme), and not in the 16 subjects who were CYP3A5 expressors.[1]

(b) Ketoconazole

In a controlled study, 18 healthy subjects received clopidogrel (300 mg on day one followed by 75 mg daily for 5 days) alone and then with ketoconazole 400 mg daily, which was started 3 days before the clopidogrel. Ketoconazole reduced the AUC of the active metabolite of clopidogrel by 22% and 29%, after the loading and maintenance doses of clopidogrel, respectively. Inhibition of platelet aggregation (IPA) was also significantly reduced with ketoconazole, from 43% to 15% at 4 hours after the loading dose, and from 50% to 17% at 24 hours after the last maintenance dose. Of the 19 subjects, 14 had an IPA of less than 20% following the loading dose, a level seen in non-responders to clopidogrel.[2]

Mechanism

Formation of the active metabolite of clopidogrel is dependent on metabolism by the cytochrome P450 isoenzyme CYP2C19 and possibly also CYP3A4, and is therefore likely to be reduced by azoles that inhibit these isoenzymes. Ketoconazole is an inhibitor of CYP3A4 and CYP3A5,[2] and itraconazole is principally a CYP3A4 inhibitor. The interaction with itraconazole appeared to occur only in those without CYP3A5 activity, which suggests that CYP3A5 may be involved in the formation of the active metabolite of clopidogrel in the presence of CYP3A4 inhibition.[1] This appeared to be confirmed by a further study in patients given clopidogrel after stent implantation, which found a greater risk of atherothrombotic events in those without CYP3A5 activity.[1] Azoles that are inhibitors of CYP2C19 are also predicted to interact.

Importance and management

Evidence for an interaction between clopidogrel and the azoles appears to be limited to these two studies. The clinical relevance of the pharmacokinetic interaction with ketoconazole is unclear, but the level of inhibition of platelet aggregation in about three-quarters of healthy subjects taking ketoconazole with clopidogrel was below the level at which patients are classed as non-responders to clopidogrel, suggesting it may be important. The data with itraconazole suggest that the interaction with CYP3A4 inhibitors might be important in those lacking CYP3A5. Until more is known, some caution may be appropriate with azoles that are potent inhibitors of CYP3A4. Note that the US manufacturer advises the avoidance of ketoconazole with clopidogrel[3] (but on the basis that it is a CYP2C19 inhibitor; however, studies with CYP2C19 substrates suggests that it is not an inhibitor of this isoenzyme, see 'Azoles + Proton pump inhibitors', p.246).

The interaction of clopidogrel with CYP2C19 inhibitors is more extensively investigated than that with CYP3A4 inhibitors (see 'Clopidogrel + Proton pump inhibitors and other CYP2C19 inhibitors', p.821), and the manufacturers advise that the concurrent use of CYP2C19 inhibitors should be discouraged, and, of the azoles, they specifically name **fluconazole** and **voriconazole**.[3,4]

Clopidogrel + Miscellaneous

No adverse interactions appear to occur with clopidogrel and atenolol, cimetidine, digoxin, insulin, nifedipine, oestrogens, phenobarbital, phenytoin or tolbutamide.

Clinical evidence, mechanism, importance and management

No clinically significant pharmacodynamic interactions were seen when clopidogrel was given with **atenolol**, **nifedipine** or a combination of **atenolol** and **nifedipine**,[1] and the activity of clopidogrel was not altered by the concurrent use of **oestrogen**[2] or **phenobarbital**.[2] Another study found that clopidogrel does not alter the plasma levels of **digoxin** and that the pharmacodynamics of clopidogrel do not appear to be affected by **digoxin**.[3] One study found that the inhibition of platelet aggregation by clopidogrel was not reduced by **acetylcysteine**.[4]

Data from CAPRIE and other clinical studies showed that **ACE inhibitors**, **antidiabetics** (**insulin** and **tolbutamide** named),[2] **antiepileptics** (**phenytoin** named),[2] **beta blockers**, **calcium-channel blockers**, **coronary or peripheral vasodilators**, **diuretics** and **HRT** have been safely given with clopidogrel.[5]

No special precautions would therefore seem necessary when clopidogrel is given with any of these drugs.

Clopidogrel + Proton pump inhibitors and other CYP2C19 inhibitors

Information from controlled studies suggests that high-dose omeprazole almost halves exposure to the active metabolite of clopidogrel and reduces the antiplatelet action of clopidogrel by 30%. However, preliminary findings from one large clinical study found no reduction in clopidogrel efficacy with omeprazole 20 mg daily. Nevertheless, reduced efficacy has been seen in some, but not all, retrospective analyses.

In one controlled study, lansoprazole showed a trend towards a reduction in the antiplatelet action of clopidogrel, and some, but not all, retrospective analyses also show reduced efficacy. There is no information from *controlled* studies on the effect of other proton pump inhibitors. In one study, esomeprazole and pantoprazole did not appear to alter clopidogrel antiplatelet effects; however, some, but not all, retrospective analyses have shown poorer cardiovascular outcomes with both these proton pump inhibitors and also rabeprazole.

Clopidogrel slightly increases omeprazole exposure in CYP2C19 extensive metabolisers.

Clinical evidence

A. Pharmacokinetics and antiplatelet effects

(a) Controlled studies

1. Lansoprazole. In a randomised study, 24 healthy subjects were given lansoprazole 30 mg daily with a single 300-mg dose of clopidogrel on day 7. Lansoprazole had no effect on the AUC and maximum levels of the *inactive* carboxylic acid metabolite of clopidogrel, a major metabolite formed by esterases and used as a marker of absorption. The authors state that this study did not look at the effect of lansoprazole on the pharmacokinetics of the *active* metabolite of clopidogrel, because an assay was not available at the time. Lansoprazole tended to slightly reduce the effects of clopidogrel on platelet aggregation, but the effect was only statistically significant at 24 hours after the single dose of clopidogrel (39% versus 49%). A post-hoc analysis suggested that this effect was more pronounced in the subjects that had the greatest antiplatelet response to clopidogrel.[1]

2. Omeprazole. The manufacturer notes that, in a crossover study in 72 healthy subjects given a 300-mg loading dose of clopidogrel then clopidogrel 75 mg daily for 5 days, high-dose omeprazole 80 mg daily for 5 days, taken at the same time as clopidogrel, reduced the exposure to the active metabolite of clopidogrel by about 45%. In addition, the mean inhibition of platelet aggregation was reduced by 47% at 24 hours and reduced by 30% on day 5, when compared with clopidogrel alone. Similar results were seen in a further study when the daily dose of omeprazole and clopidogrel were taken 12 hours apart.[2]

In a randomised, placebo-controlled study in 124 patients undergoing elective coronary stent insertion and taking aspirin 75 mg daily and clopidogrel (300 mg loading dose followed by 75 mg daily), 64 patients were also given omeprazole 20 mg daily for 7 days. On day 7, the group given omeprazole were found to have a higher platelet reactivity index when compared with placebo recipients (51% compared with 40%, respectively), indicating a reduced antiplatelet effect.[3] The authors note that a platelet reactivity index of greater than 50% indicates a poor response to clopidogrel. On this basis, 61% of omeprazole recipients were considered to have had a poor response to clopidogrel, compared with 27% in the placebo group.[3] Note that, in this study, CYP2C19 metaboliser status was unknown,[4] although given that it was a large randomised study in a specific population, a difference between the groups would not usually be expected.

In a pharmacokinetic study in healthy subjects, clopidogrel (a 300-mg loading dose and then 75 mg daily for 3 days) modestly increased the AUC of a single 40-mg dose of omeprazole given on day 4 by 30% and decreased its clearance by 22% in CYP2C19 extensive metabolisers (that is, those with normal levels of this isoenzyme), but had no effect in CYP2C19 poor metabolisers (that is, those lacking or totally deficient in this isoenzyme). The degree of inhibition was modest, and omeprazole exposure in CYP2C19 extensive metabolisers given clopidogrel was still lower than in CYP2C19 poor metabolisers (with or without clopidogrel). The effect of omeprazole on clopidogrel was not assessed.[5]

(b) Non-randomised studies

1. Esomeprazole. A study in patients taking aspirin 100 mg daily with clopidogrel 75 mg daily for at least 5 days (average 3 months) included 74 patients taking esomeprazole. The study found no difference in the platelet reactivity index or ADP-induced platelet aggregation when these patients were compared with 74 patients not taking a proton pump inhibitor.[6] Similarly, in a study of patients with coronary artery disease taking both aspirin and clopidogrel, the proportion of patients having a poor antiplatelet response to clopidogrel was similar in 42 patients taking esomeprazole and in patients not taking a proton pump inhibitor (about 20% in both groups).[7]

2. Omeprazole. In a study in patients with coronary artery disease taking both aspirin and clopidogrel, the proportion of patients having a poor antiplatelet response to clopidogrel was about 13% higher in the 64 patients taking omeprazole, when compared with patients taking esomeprazole or pantoprazole, or not taking a proton pump inhibitor (about 33% versus 20%).[7]

3. Pantoprazole. In a study in patients taking aspirin 100 mg daily with clopidogrel 75 mg daily for at least 5 days (average 3 months) included 152 patients taking pantoprazole. This study found that there was no difference in the platelet reactivity index or ADP-induced platelet aggregation in the patients taking pantoprazole when compared with 74 patients not taking a proton pump inhibitor.[6] Similarly, in a study of patients with coronary artery disease taking both aspirin and clopidogrel, the proportion of patients having a poor antiplatelet response to clopidogrel was similar in 162 patients taking pantoprazole and those patients not taking a proton pump inhibitor (about 20% in both groups).[7]

4. Unspecified proton pump inhibitors. In a study, the platelet reactivity index was measured in 105 consecutive patients taking aspirin and clopidogrel to investigate its relationship with various other concurrent drugs. A higher platelet reactivity index (indicating a poor response to aspirin and clopidogrel) was found in the 24 patients taking proton pump inhibitors, when compared with the 81 patients not taking proton pump inhibitors (about 61% versus 50%).[8] Similarly, in a post-hoc analysis of a clinical study in patients given a 600-mg loading dose of clopidogrel then clopidogrel 150 mg daily (PRINCIPLE-TIMI 44), mean inhibition of platelet aggregation was lower in those patients also taking a proton pump inhibitor. The proportion of patients with reduced platelet responsiveness to clopidogrel was twofold higher in patients taking a proton pump inhibitor than in patients not taking a proton pump inhibitor, when assessed at 24 hours after the 600-mg loading dose of clopidogrel.[9]

B. Clinical outcomes

Note that, at present, there are no data from placebo-controlled, randomised studies on the effect of any proton pump inhibitors on the long-term cardiovascular efficacy of clopidogrel, apart from preliminary data from the halted Cogent study, see *Prospective studies*, below. All other data available are retrospective analyses, and, as it is impossible to control for all possible confounders, definitive conclusions cannot be drawn from these studies. Note that there is also some information showing that the clinical benefit of clopidogrel depends on CYP2C19 genotype,[2] which partly supports the proposed mechanism of the interaction by CYP2C19 inhibition.

(a) Prospective studies

A preliminary analysis of data from the COGENT-1 study found that, of the 3 627 patients enrolled, there appeared to be no clinically significant difference in the incidence of all cardiovascular events as well as myocardial infarction or in the need for revascularisation between the patients taking clopidogrel and omeprazole 20 mg daily and those patients taking clopidogrel but not omeprazole, for a mean follow-up of 133 days.[10] However, note that this large, phase III clinical study was unfinished due to bankruptcy, and was primarily designed to investigate the gastrointestinal benefits of a combined preparation of omeprazole and clopidogrel, rather than to investigate a drug interaction between omeprazole and clopidogrel and its possible effects on cardiovascular outcomes.

(b) Retrospective studies

1. Poorer outcomes with all proton pump inhibitors. A large, retrospective, cohort study in patients taking clopidogrel who were hospitalised with acute coronary syndrome, investigated the use of proton pump inhibitors to establish if concurrent use was associated with an increase in adverse cardiovascular outcomes. In this study, the 5 244 patients taking a proton pump inhibitor with clopidogrel were reported to have a 9% additional increase in the rate of death or rehospitalisation for acute coronary syndrome compared with the 2 961 patients not taking a proton pump inhibitor (29.8% versus 20.8%), although the patients in the proton pump inhibitor group were older and had more co-morbid conditions. After adjusting for these confounding factors, the odds ratio was 1.25. Further analysis on the secondary outcomes reported that the rate of rehospitalisation for acute coronary syndrome was 14.6% in those taking a proton pump inhibitor with clopidogrel, compared with 6.9% for those patients not taking a proton pump inhibitor with clopidogrel, with an adjusted odds ratio of 1.86. The proton pump inhibitors given included **omeprazole** (59.7%), **rabeprazole** (2.9%), **lansoprazole** (0.4%) and **pantoprazole** (0.2%), and 36.7% of patients took more than one proton pump inhibitor during follow-up (that is, they switched between different proton pump inhibitors). Individual data for **lansoprazole** and **pantoprazole** were not analysed as the patient numbers were too small, but **omeprazole** and **rabeprazole** use were reported to have an increased risk of adverse outcomes (odds ratio 1.24 and 2.83, respectively). In patients discharged after an episode of acute coronary syndrome who were not given clopidogrel, the use of proton pump inhibitors was not associated with an increased risk of death or re-admission to hospital, suggesting that any effect was the result of an interaction, rather than a factor of proton pump inhibitor use.[11] Similarly, in a cohort study of 18 565 patients who were given clopidogrel, there was a slight increased risk of hospitalisation for myocardial infarction, or death (adjusted risk ratio of 1.26) in those taking a proton pump inhibitor (**omeprazole**, **esomeprazole**, **lansoprazole**, **pantoprazole**, **rabeprazole**) compared with patients not taking a proton pump inhibitor. This suggests that if an effect exists, it is unlikely to be greater than a 20% increased risk.[12] In an unpublished retrospective cohort study, there was an increased risk of hospitalisation for a major adverse cardiovascular event for all proton pump inhibitors compared with clopidogrel alone (25% versus 18%, hazard ratio 1.51). The most common proton pump inhibitors taken were **esomeprazole** (3 257 patients), **omeprazole** (2 307 patients) and **pantoprazole** (1 653 patients), with fewer patients taking **lansoprazole** (785 patients) or **rabeprazole** (298 patients). When the data was analysed by individual proton pump inhibitor, a similar increased risk was seen for **lansoprazole** (24%), **esomeprazole** (25%), **omeprazole** (25%), and **pantoprazole** (29%): the patient group taking **rabeprazole** was too small for individual statistical evaluation. No increased risk was found with in 472 patients taking an **H_2-receptor antagonist** (not specified), when compared with a control group not taking an **H_2-receptor antagonist** (9390 patients).[13]

2. Poorer outcomes with some proton pump inhibitors. In a retrospective case-control study in 734 patients taking clopidogrel post myocardial infarction and readmitted within 90 days with a further myocardial infarction, the concurrent use of a proton pump inhibitor (**lansoprazole**, **omeprazole**, **pantoprazole**, or **rabeprazole**; 194 cases) was associated with a 27% increased risk of re-infarction. When the data was analysed for **pantoprazole** separately (46 cases), there was no additional risk of myocardial infarction.[14] The remaining proton pump inhibitors as a group were associated with a 40% increased risk and the data for them were not analysed separately. However, the difference between the risk for pantoprazole and the other drugs was not statistically significant. The proton pump inhibitors were grouped like this on the basis of *in vitro* CYP2C19 inhibition data; however, see under *Mechanism*, below, for further discussion of the potential relevance of this. In this study, use of the **H_2-receptor antagonists**, **ranitidine**, **famotidine** and **nizatidine**, were not associated with an increased risk of re-infarction.

3. No effect of proton pump inhibitors. In a retrospective analysis of a large clinical study in patients taking clopidogrel (TRITON-TIMI 38), no association was found between proton pump inhibitor use and an increased incidence of cardiovascular death, myocardial infarction, stroke or coronary stent thrombosis. The most common proton pump inhibitors taken were **pantoprazole** (1 844 patients) and **omeprazole** (1 675 patients), with fewer patients taking **esomeprazole** (613 patients), **lansoprazole** (441 patients) and **rabeprazole** (66 patients).[9]

Mechanism

The mechanism for the interaction between the proton pump inhibitors and clopidogrel is unclear. At present, the most plausible mechanism is that omeprazole inhibits the conversion of clopidogrel to its active metabolite by the cytochrome P450 isoenzyme CYP2C19. *In vitro* data indicate that lansoprazole, esomeprazole and a metabolite of rabeprazole can all inhibit CYP2C19, but that pantoprazole does not significantly affect this isoenzyme.[15] However, *in vitro* inhibitory activity does not always translate to a clinically relevant effect *in vivo*: inhibition of CYP2C19 appears to occur between the known CYP2C19 substrate diazepam, and omeprazole and esomeprazole, but a significant interaction does not occur with rabeprazole, lansoprazole or pantoprazole (see 'Benzodiazepines + Proton pump inhibitors', p.860). Furthermore, CYP2C19 inhibition by the proton pump inhibitors is not entirely consistent with the available data for their suggested interaction with clopidogrel. For example, there are data suggesting that esomeprazole does not alter the antiplatelet effects of clopidogrel, and some evidence from retrospective studies that all proton pump inhibitors are associated with a similar risk of poorer outcomes in patients taking clopidogrel. However, if the proton pump inhibitors completely inhibited the activity of CYP2C19, this would effectively make CYP2C19 extensive metabolisers into poor metabolisers, who have been reported to have a reduced antiplatelet response to clopidogrel and a higher than expected rate of cardiovascular events.[2,16]

Others have suggested that P-glycoprotein may also possibly be involved;[4] *in vitro* data suggest that clopidogrel absorption may be reduced by P-glycoprotein inhibition,[17] and based on their interaction with digoxin, a key P-glycoprotein substrate (see 'Digoxin and related drugs + Proton pump inhibitors', p.1111), most proton pump inhibitors appear to affect this drug transporter protein, although the effect is mild.

Clopidogrel is a minor inhibitor of CYP2C19, by which omeprazole and many other proton pump inhibitors are partly metabolised. In this study, the metabolism of omeprazole to 5-hydroxyomeprazole by CYP2C19 was decreased, whereas its metabolism to omeprazole sulfone by CYP3A4 was unchanged.[5]

Importance and management

A pharmacokinetic interaction between high-dose **omeprazole** (80 mg daily) and clopidogrel appears to be established, roughly halving the levels of the active metabolite of clopidogrel and reducing its antiplatelet effects by 30%. Separating the dose of clopidogrel and omeprazole by 12 hours did not reduce or abolish the pharmacokinetic interaction in one study. However, what is not clearly established is to what degree this might reduce the clinical efficacy of clopidogrel, and to what extent it applies to more commonly used doses of omeprazole (20 mg daily). Limited evidence from one unfinished prospective, randomised controlled study suggests that omeprazole 20 mg daily has no effect on clopidogrel efficacy,[10] and data from retrospective analyses have varied from no effect to an increased risk of adverse cardiac outcomes, with the greatest effect being a 1.86-fold increased risk in the rate of rehospitalisation for acute coronary syndrome. This, coupled with the data showing a reduced clinical response to clopidogrel alone in patients who are CYP2C19 poor metabolisers, suggests that it is not unreasonable to suppose that omeprazole causes some reduction in the efficacy of clopidogrel.

Evidence for a class interaction between clopidogrel and the **proton pump inhibitors** is mostly based on retrospective data, some of which is contradictory, and does not appear to fit with the known CYP2C19 inhibitory activity of these proton pump inhibitors. On reviewing the available evidence, in November 2009 the FDA in the US recommended that omeprazole should be avoided in patients taking clopidogrel. A similar recommendation is made for **esomeprazole** on the basis that it is the *S*-isomer of omeprazole, and also inhibits CYP2C19.[18] At present, the FDA states that there is insufficient evidence to make specific recommendations about the concurrent use of clopidogrel with other proton pump inhibitors.[18] The EMEA and MHRA guidance[19-21] does not distinguish between the proton pump inhibitors. These bodies advise that proton pump inhibitors [as a class] should only be given with clopidogrel if it is considered essential (such as, where the risk of gastric disease is greater than the risk of a cardiac event). If a proton pump inhibitor is considered essential, based on the lack of a pharmacokinetic interaction with the known CYP2C19 substrate diazepam (consider 'Benzodiazepines + Proton pump inhibitors', p.860), **rabeprazole**, and possibly also **pantoprazole** or **lansoprazole**, would seem to be the most appropriate options. However, the effects or lack of effect of these individual proton pump inhibitors on clopidogrel efficacy

is not established, and more prospective studies are needed to investigate this.

H_2-receptor antagonists would seem to offer an alternative to the proton pump inhibitors, with **ranitidine**, **famotidine** or **nizatidine** not having been implicated in causing an interaction in a number of the retrospective analyses. Although the UK manufacturer of clopidogrel briefly reports that **cimetidine** has no significant effects on the antiplatelet activity of clopidogrel;[16] cimetidine is a known weak inhibitor of various cytochrome P450 isoenzymes, and is known to inhibit the metabolism of diazepam, a substrate of CYP2C19 (see 'Benzodiazepines and related drugs + H_2-receptor antagonists', p.849). Therefore, it may be prudent to avoid the use of cimetidine.

On the basis of the interaction with omeprazole, the FDA say that other drugs that inhibit CYP2C19 would also be expected to interact similarly, and concurrent use should be avoided. The US and UK manufacturers[2,16] list a number of drugs, including **cimetidine**, **etravirine**, **felbamate**, **fluoxetine**, **fluvoxamine**, **ticlopidine**, **moclobemide**, **ciprofloxacin**, **carbamazepine**, **oxcarbazepine** and **chloramphenicol**. However, not all of these drugs are proven, clinically relevant CYP2C19 inhibitors. Note that, **ticlopidine**, like clopidogrel, is a thienopyridine antiplatelet drug, and it is not usually used with clopidogrel because it has the same mechanism of action.

Clopidogrel + Statins

Atorvastatin had no clinically relevant effect on the pharmacokinetics or antiplatelet effect of clopidogrel in controlled studies. Similarly, pravastatin, and possibly lovastatin and rosuvastatin, do not to alter the antiplatelet effect of clopidogrel. The data for simvastatin and fluvastatin are limited, with one study showing some reduction in antiplatelet effect. Nevertheless, clinical outcome data from retrospective analysis of large studies does not support an interaction with any of these other statins.
Isolated cases of rhabdomyolysis have been reported in patients taking statins (atorvastatin, lovastatin, simvastatin) and given clopidogrel.

Clinical evidence

A. Clopidogrel effects

(a) Atorvastatin

In 2003, a small non-randomised study reported that 19 patients taking atorvastatin 10 to 40 mg daily had lower antiplatelet activity of clopidogrel after undergoing coronary artery stenting when compared with 16 patients not receiving statins or 9 receiving **pravastatin**, and the effect appeared to be dose related.[1] Note that non-randomised comparisons like this cannot account for all differences between patients (e.g. genetic differences resulting in non-response to clopidogrel), and the smaller they are, the more likely that differences could bias the results. Since this original publication suggesting an interaction, numerous non-randomised and retrospective analyses have been conducted. Of studies looking at antiplatelet effects, one other non-randomised study found that the antiplatelet effects of clopidogrel were lower in those receiving atorvastatin,[2] whereas other non-randomised studies[3-5] and, more importantly, three randomised studies,[6-8] have not found any effect. However, of these randomised studies, one used a high dose of clopidogrel (600 mg)[6] and one used a low dose of atorvastatin (10 mg),[7] both factors that might minimise any interaction.

Platelet reactivity studies may not be directly relevant to clinical outcomes, so the efficacy of clopidogrel in relation to statin type has been retrospectively analysed from a number of studies and patient cohorts. Interpretation of this sort of study is complicated by the presence of unknown confounders. In one retrospective, observational review of prescribing data, a 1.49-fold higher rate of cardiovascular events at day 30 post-procedure was noted in patients taking atorvastatin with clopidogrel, when compared with control patients, about 55% of whom were taking other statins (mostly **pravastatin** or **simvastatin**).[9] However, note that simvastatin might also be anticipated to interact, based on the original proposed mechanism. Conversely, in all other analyses, use of atorvastatin, or any other statin studied, has not been associated with reduced efficacy in patients receiving clopidogrel.[10-15] For example, a retrospective examination of data from the CREDO study found no difference in one-year outcomes in patients given atorvastatin or **pravastatin**,[10] although there appeared to be a slightly better outcome in those given a statin that is not a CYP3A4 substrate (**fluvastatin**, **pravastatin**) compared with statins that are (**atorvastatin**, **cerivastatin**, **lovastatin**, **simvastatin**).[16,17] Furthermore, a prospective, cohort study in 1651 patients with acute coronary syndromes found that the use of clopidogrel with a statin was associated with *lower* 6-month mortality and morbidity compared with the use of clopidogrel in the absence of a statin. There was no significant difference in clinical benefit between a statin predominantly metabolised by the cytochrome P450 isoenzyme CYP3A4 or a statin not predominantly metabolised by CYP3A4.[12] Similarly, retrospective analysis of data from the CHARISMA study, which involved 15 603 patients and had a median duration of 28 months, also found no difference in terms of clinical outcomes between patients who received statins primarily metabolised by CYP3A4 and those who took statins not predominantly affected by CYP3A4. Also, those who took a statin had a lower risk of myocardial infarction, stroke or cardiovascular death, when compared with those who did not take a statin.[13] Similarly, there was no difference in clinical outcomes between those patients randomised to receive **atorvastatin** 80 mg daily or **pravastatin** 40 mg daily and also receiving clopidogrel in a retrospective analysis of the PROVE IT–TIMI 22 study.[14] In addition, one-year outcomes did not differ between statins (**atorvastatin**, **simvastatin**, **fluvastatin** and **pravastatin**) in the EXCELSIOR study.[15]

In 2008, a key randomised, crossover study was published, which conclusively demonstrates, that, if anything high-dose atorvastatin actually modestly *increases* the levels of the active metabolite of clopidogrel and slightly *increased* its antiplatelet effect. In this study, 31 healthy subjects received clopidogrel alone (300 mg loading dose then 75 mg daily for 10 days) with atorvastatin 80 mg daily started 6 days before the clopidogrel. Atorvastatin did not change the exposure (AUC) to the active metabolite of clopidogrel after the 300 mg dose, but, on day 10, there was a modest 28% increase in AUC of the active metabolite. The antiplatelet effect of clopidogrel was unchanged after the 300 mg dose, but tended to be increased on the final day. There was an increase of about 6 to 16%; differences which were statistically significant at some, but not all, time points.[18]

(b) Other statins metabolised by CYP3A4

In one crossover study in 20 healthy subjects given clopidogrel 75 mg daily, **simvastatin** 20 mg daily for 7 days reduced the antiplatelet response by about 31%, with just one subject then classified as a clopidogrel non-responder.[8] However, in a randomised study in patients, **simvastatin** (20 mg given 24 hours before the clopidogrel) did not alter the antiplatelet effects of clopidogrel after a 600 mg dose, when compared with placebo.[6] This study also found no effect of **lovastatin**.[6] Of non-randomised studies looking at antiplatelet effects, one found a lower antiplatelet response to clopidogrel after coronary artery stenting in those receiving simvastatin,[2] whereas, in another very similar study, no effect of **simvastatin** was detected.[5] Moreover, retrospective clinical outcome studies have shown no detrimental effect of simvastatin or lovastatin, see *Atorvastatin*, above. There are no studies on the effect of **simvastatin** or **lovastatin** on clopidogrel pharmacokinetics.

(c) Statins not principally metabolised by CYP3A4

There do not appear to be any studies suggesting that an interaction between clopidogrel and **pravastatin** occurs, and a number of studies showing no interaction. In one crossover study in 20 healthy subjects given clopidogrel 75 mg daily, neither **pravastatin** 40 mg daily nor **rosuvastatin** 10 mg daily for 7 days reduced the antiplatelet response of clopidogrel.[8] Similarly, in two randomised studies in patients, **pravastatin** (20 mg or 40 mg started 24 hours before the clopidogrel) did not alter the antiplatelet effects of clopidogrel after a 600 mg or 375 mg dose.[6,7] Similarly, in non-randomised studies, pravastatin did not affect the antiplatelet activity of clopidogrel.[1,5] Retrospective clinical outcome studies have shown no detrimental effect of **pravastatin**, see *Atorvastatin*, above. There are no studies on the effect of **pravastatin** on clopidogrel pharmacokinetics

In one crossover study in 20 healthy subjects given clopidogrel 75 mg daily, **fluvastatin** 80 mg daily for 7 days reduced the antiplatelet response by about 29%, with just two subjects then classified as clopidogrel non-responders.[8] However, in a randomised study in patients, **fluvastatin** (20 mg given 24 hours before the clopidogrel) did not alter the antiplatelet effects of clopidogrel after a 600 mg dose, when compared with placebo.[6] Similarly, one retrospective analysis found that **fluvastatin** did not affect the platelet activity of clopidogrel.[3] Clopidogrel had no effect on the pharmacokinetics of **fluvastatin** 80 mg daily in a controlled study in healthy subjects, and the antiplatelet effect of clopidogrel was similar to that expected for clopidogrel alone.[19] Moreover, retrospective clinical outcome studies have shown no detrimental effect of **fluvastatin**, see *Atorvastatin*, above.

B. Rhabdomyolysis

Isolated cases of rhabdomyolysis precipitated by clopidogrel have been reported. Two heart transplant patients taking **simvastatin** or **lovastatin**, together with ciclosporin for several years with no reported problems, developed rhabdomyolysis within 2 weeks of starting clopidogrel.[20] Another similar report describes a patient who was stable taking ciclosporin and **atorvastatin** who developed rhabdomyolysis when a 4-week course of clopidogrel was started.[21]

Mechanism

Clopidogrel is an inactive prodrug that is metabolised to its active metabolite by the cytochrome P450 isoenzyme system, with CYP2C19 known to be important, and possibly also CYP3A4 (see 'Clopidogrel + Azoles', p.820). Several statins (lovastatin, simvastatin, atorvastatin), are principally metabolised by CYP3A4 and it has been suggested that these statins may competitively inhibit the activation of clopidogrel,[1] and this was shown *in vitro* for atorvastatin lactone.[22] However, note that this is not an established mechanism for pharmacokinetic drug interactions, and substrates of CYP3A4 do not cause clinically relevant interactions unless they are also CYP3A4 inhibitors, which none of the statins are known to be. The well-designed pharmacokinetic study with atorvastatin conclusively shows that it does not inhibit the formation of the active metabolite of clopidogrel. In fact, it actually resulted in a modest increase in active metabolite levels, the mechanism for which is unknown.

One controlled study showed a reduction in antiplatelet effects of clopidogrel with simvastatin and fluvastatin. The mechanism for this is unknown.

Clopidogrel (a possible CYP2C9 inhibitor) does not alter the metabolism of fluvastatin (a CYP2C9 substrate).[19]

Importance and management

The possible interaction between clopidogrel and the statins has been the subject of much study and debate. The few studies showing a reduced antiplatelet effect of atorvastatin are all limited by their non-randomised design and small number of patients, and the findings could therefore easily be due to confounding by unknown factors. These sorts of studies are useful in generating hypotheses, but should not be used to guide clinical decisions.[23] A subsequent well-designed study has shown that atorvastatin 80 mg daily has no inhibitory effect on the pharmacokinetics and antiplatelet effects of clopidogrel, and, in fact, slightly increased the levels and activity of clopidogrel, although probably not to a clinically relevant extent. Therefore, no interaction would be expected in clinical use. This is supported by all of the retrospective analyses of clinical outcome data except one.

Apart from pravastatin, which also appears to have no effect on the antiplatelet action of clopidogrel, data for other statins are limited. Of some concern, in one controlled crossover study, the antiplatelet effect of clopidogrel was reduced with both simvastatin and fluvastatin (but not with atorvastatin, pravastatin or rosuvastatin), and further study into this is therefore needed. Nevertheless, all the available retrospective outcome data show no adverse effect of either simvastatin or fluvastatin.

The general significance of the case reports describing rhabdomyolysis, when clopidogrel was given to transplant patients who were stable taking a statin with ciclosporin, is unclear.

Dipyridamole + Beta blockers

No adverse reactions normally occur in patients taking beta blockers who undergo dipyridamole–thallium-201 scintigraphy and echocardiography, but case reports suggest that very rarely bradycardia and asystole can occur.

Clinical evidence

A 71-year-old woman taking **nadolol** 120 mg daily and bendroflumethiazide, with a 3-week history of chest pain, was given a 300-mg dose of oral dipyridamole as part of a diagnostic dipyridamole-thallium imaging test for coronary artery disease. She was given thallium-201 intravenously, 50 minutes after the dipyridamole, but 3 minutes later, while exercising, she complained of chest pain and then had a cardiac arrest. She was given cardiopulmonary resuscitation and a normal cardiac rhythm was obtained after she was given intravenous aminophylline.[1]

Adverse interactions have been reported in another 3 patients taking beta blockers during diagnostic dipyridamole-thallium stress testing. One patient, who was taking **atenolol**, developed bradycardia and then asystole, another patient who was taking **metoprolol** developed bradycardia,[2] and a third patient, also taking **metoprolol**, developed sinus bradycardia and then asystole.[3] All three patients recovered when treated with aminophylline.[2,3]

These reports need to be set in a broad context. A very extensive study of high-dose dipyridamole echocardiography (10 451 tests in 9 122 patients) noted significant adverse effects in only 96 patients, with major adverse reactions occurring in just 7 patients. Three of the 7 developed asystole and two of these patients were taking unnamed beta blockers.[4] However, a further three case reports describe the development of asystole or symptomatic bradycardia during dipyridamole infusion in patients *not* taking beta blockers.[5,6]

Mechanism

Not established. One possible explanation is that both drugs have negative chronotropic effects on the heart.

Importance and management

The value and safety of dipyridamole perfusion scintigraphy and echocardiography have been very extensively studied in very large numbers of patients, and reports of bradycardia and asystole, attributed to an interaction between dipyridamole and beta blockers, are sparse. It would therefore appear to be a relatively rare interaction (if such it is).

Dipyridamole + Drugs that affect gastric pH

The effective disintegration, dissolution and eventual absorption of dipyridamole formulated as a tablet or suspension depends upon having a low pH in the stomach. Drugs that raise the gastric pH significantly are expected to reduce the bioavailability of dipyridamole. Modified-release preparations of dipyridamole (that are buffered) do not appear to be affected.

Clinical evidence, mechanism, importance and management

The solubility of dipyridamole depends very much on pH. It is very soluble at low pH values and almost insoluble at neutral pH.[1] This indicates that dipyridamole needs a low pH in the stomach if solid formulations of the drug are to disintegrate and dissolve adequately. A study in 11 healthy elderly subjects (6 control subjects with a low fasting gastric pH and 5 achlorhydric subjects with fasting gastric pH greater than 5) found that elevated gastric pH reduced the absorption of a single 50-mg oral dose of dipyridamole. In addition, pretreatment with **famotidine** 40 mg increased the gastric pH to above 5 for at least 3 hours, which resulted in reduced dipyridamole absorption. The dipyridamole AUC was reduced by 37% (not statistically significant) and the maximum serum levels were significantly delayed and reduced.[2] In another study, 20 healthy subjects were given **lansoprazole** 30 mg daily for 5 days and then either:

- a single dose of an extended-release preparation of dipyridamole 200 mg with aspirin 25 mg (formulated with tartaric acid to improve bioavailability of dipyridamole if the gastric pH is elevated)
- or a conventional dipyridamole formulation (100 mg given with 81 mg of aspirin, followed 6 hours later by another dose of dipyridamole).

In the presence of **lansoprazole** (gastric pH greater than 4) the relative bioavailability of conventional dipyridamole tablets was about 50% of that with the buffered extended-release tablets.[3]

A consequential conclusion is that any drug that raises the stomach pH significantly would be likely to reduce the dissolution and absorption of dipyridamole *tablets* and *suspension*. It would therefore be reasonable to expect that proton pump inhibitors, H_2-receptor antagonists and antacids, which can raise the gastric pH, could interact to reduce the bioavailability of dipyridamole tablets and *suspension*. Further study is needed to find out whether this is a clinically relevant interaction or not, but note that the manufacturers advise that **antacids** may reduce the efficacy of dipyridamole tablets and suspension.[4,5]

Modified-release dipyridamole capsules (*Persantin Retard*, and the formulation containing aspirin, *Asasantin Retard*) do not appear to be affected[6] and may therefore be a suitable alternative in some patients.

Dipyridamole + Irbesartan

A study in 13 patients with coronary artery disease found that irbesartan 150 mg daily reduced the extent and severity of perfusion defects after dipyridamole-induced stress.[1] The authors of this study suggest that irbesartan and other angiotensin II receptor antagonists should be stopped before dipyridamole-stress testing, as they may mask the true extent of the problems with myocardial blood flow. Note that it is generally recommended that the initial risk study be performed with patients off cardiac active medications,[2] and this study would seem to suggest that angiotensin II receptor antagonists should be included in this.

Dipyridamole + Xanthines

Caffeine (in tea, coffee, cola, etc.) may interfere with dipyridamole–thallium-201 scintigraphy tests. Similarly, theophylline and aminophylline can also reduce some of the effects of dipyridamole.

Clinical evidence, mechanism, importance and management

In one patient, **caffeine** 4 mg/kg intravenously (roughly equivalent to 2 to 3 cups of coffee), given before dipyridamole–thallium-201 myocardial scintigraphy, caused a false-negative test result.[1] A further study in 8 healthy subjects confirmed that **caffeine** inhibits the haemodynamic response to an infusion of dipyridamole,[2] and another study similarly found that **caffeine** reduced myocardial blood flow in response to dipyridamole.[3]

Other xanthines appear to interact like **caffeine**. In one study oral **theophylline** markedly reduced the diagnostic accuracy of myocardial imaging using dipyridamole,[4] and intravenous **aminophylline** has been found to accelerate the myocardial washout rate of thallium-201 after a dipyridamole infusion.[5]

It appears that xanthine derivatives such as **caffeine** and **theophylline** might antagonise some of the haemodynamic effects of dipyridamole because they act as competitive antagonists of adenosine (an endogenous vasodilator involved in the action of dipyridamole).[1,2] Due to these opposing effects, parenteral **aminophylline** has been used to treat adverse events associated with intravenous dipyridamole,[6,7] and it is recommended that **aminophylline** should be made available before beginning dipyridamole myocardial imaging.[7,8]

Patients should therefore abstain from **caffeine** (tea, coffee, chocolate, cocoa, cola, caffeine-containing analgesics etc.)[1,2,8] and other xanthine derivatives, such as **theophylline**,[4] for 24 hours[2,7] before dipyridamole testing, and if during the test the haemodynamic response is low (e.g. no increase in heart rate) the presence of **caffeine** should be suspected.[2]

Adenosine, also used in cardiac radionuclide scans, may interact with caffeine in a similar way, see 'Adenosine + Xanthines', p.274.

Glycoprotein IIb/IIIa antagonists + Miscellaneous

The risk of bleeding with glycoprotein IIb/IIIa antagonists may be increased by heparin and thrombolytics, but low-dose thrombolytic therapy appears less likely to cause a problem. Increased bleeding may occur with other drugs that affect coagulation.

Clinical evidence, mechanism, importance and management

(a) Abciximab

Although the manufacturers of abciximab recommend the concurrent use of **heparin**, they also report that there is an increase in the incidence of bleeding.[1,2] In one study in patients with acute coronary syndrome without early revascularisation, the concurrent use of **low-molecular-weight heparin** was considered to be one of the factors that increased the risk of bleeding events with abciximab.[3] A study in patients receiving a single intravenous dose of **enoxaparin** 750 micrograms/kg with abciximab (250 micrograms/kg bolus followed by 125 nanograms/kg per minute as an infusion over 12 hours) found that abciximab had no significant effect on plasma antifactor Xa pharmacokinetics and antithrombin activity, suggesting that the pharmacokinetics of enoxaparin were not affected.[4]

Limited experience of abciximab in patients who have received **thrombolytics** suggests an increase in the risk of bleeding.[1,2] A retrospective analysis of 103 patients who presented with acute myocardial infarction and underwent angioplasty with adjunctive abciximab, found that there was a significant increase in major bleeding complications when abciximab was used with full-dose **alteplase**. A major bleed occurred in 5 of 22 (23%) patients who underwent angioplasty within 15 hours of receiving a thrombolytic, compared with 0 of 36 patients who underwent elective angioplasty more than 15 hours after fibrinolysis, and 1 of 45 (2%) without prior fibrinolysis.[5] However, the combination of abciximab with low-dose **reteplase** appeared not to result in the haemorrhagic complications associated with full-dose fibrinolytic therapy,[6] and no increase in bleeding complications were reported in studies using a reduced-dose of a thrombolytic with full-dose abciximab.[6,7]

The manufacturer of abciximab recommends caution when it is used with other drugs that affect haemostasis, such as **heparin**, **oral anticoagulants** such as **warfarin**, **thrombolytics**, antiplatelet drugs such as **dipyridamole**, **ticlopidine**, or **dextrans**, and **NSAIDs**.[1,2]

No adverse drug reactions were reported in clinical studies in patients given abciximab and also taking commonly used cardiovascular medications such as **ACE inhibitors**, **beta blockers**, **calcium-channel blockers** and **nitrates** (oral and intravenous).[1]

(b) Eptifibatide

In an acute myocardial infarction study involving 181 patients, eptifibatide at the highest infusion rates studied (1.3 and 2 micrograms/kg per minute) appeared to increase the risk of bleeding when given with **streptokinase** 1.5 million units over 60 minutes. In a percutaneous coronary intervention study and an acute myocardial infarction study there was no consistent evidence that eptifibatide increased the risk of major or minor bleeding associated with **alteplase**.[8,9] However, the manufacturers state that data on the use of eptifibatide in patients receiving thrombolytics are limited.

The UK manufacturer of eptifibatide reports that its concurrent use with **warfarin** and **dipyridamole** did not appear to increase the risk of major and minor bleeding. The use of **heparin** is recommended, but they warn that if eptifibatide is given with **heparin**, there must be careful monitoring, including the aPTT.

Caution must be employed when eptifibatide is used with drugs that affect haemostasis, including **clopidogrel**, **dipyridamole**, **ticlopidine**, **oral anticoagulants** or **thrombolytics**, **dextrans**, **adenosine**, **epoprostenol**, **NSAIDs**, and **sulfinpyrazone**.[8] Concurrent or planned use of another **glycoprotein IIb/IIIa inhibitor** is contraindicated.[8,9]

(c) Tirofiban

The manufacturers of tirofiban state that the safety of using tirofiban with **thrombolytic** therapy has not been established, although an increased risk of bleeding would be expected, and therefore they do not recommend concurrent use.[10]

The concurrent use of tirofiban with **enoxaparin** has been shown to have a similar efficacy as unfractionated **heparin** but a slightly higher bleeding risk.[11,12] Tirofiban is recommended for concurrent use with **heparin**; however there is an increased risk of bleeding with this combination, when compared with either drug alone.[10,13]

The following drugs had no clinically significant effects on the plasma clearance of tirofiban in the PRISM study: **ACE inhibitors** (**captopril**, **enalapril**), **aspirin**, **beta blockers** (including **acebutolol**, **atenolol**, **metoprolol**, **propranolol**), **benzodiazepines** (including **alprazolam**, **bromazepam**, **diazepam**, **lorazepam**, **oxazepam**, **temazepam**), **calcium-channel blockers** (**amlodipine**, **diltiazem**, **nifedipine**), **digoxin**, **docusate sodium**, **furosemide**, **glibenclamide** (**glyburide**), **heparin**, **insulin**,

metoclopramide, **morphine**, **nitrate** preparations, **paracetamol** (acetaminophen), **potassium chloride**, **ranitidine**, **statins** (**lovastatin**, **simvastatin**), and **sucralfate**.[13]

Tirofiban clearance appeared to be increased in patients taking **levothyroxine** or **omeprazole**, however the clinical significance of this is unknown.[13]

Caution should be used when tirofiban is used with other drugs that affect haemostasis, including **clopidogrel**, **ticlopidine**, **dipyridamole**, **oral anticoagulants** (e.g. **warfarin**), **epoprostenol** (prostacyclin), and **sulfinpyrazone**.[10]

Prasugrel + Miscellaneous

The use of prasugrel with other drugs that affect bleeding (e.g. antiplatelet drugs, anticoagulants, NSAIDs) may increase the risk of bleeding.
The manufacturer suggests that prasugrel may alter the pharmacokinetics of cyclophosphamide and efavirenz.
Ketoconazole and rifampicin do not affect the pharmacokinetics of prasugrel. Other CYP3A4 inhibitors and inducers are therefore not expected to interact. Prasugrel does not have a clinically relevant effect on the pharmacokinetics of bupropion, digoxin, or warfarin; and atorvastatin, lansoprazole and ranitidine do not alter the pharmacokinetics and/or antiplatelet effects of prasugrel.

Clinical evidence, mechanism, importance and management

(a) Antiplatelet drugs

The concurrent use of low-dose **aspirin** and prasugrel is licensed for treating acute coronary syndromes. However, the manufacturer of prasugrel advises caution as there is a possible increased risk of bleeding in the presence of aspirin. Patients should be warned that they may bleed for longer than expected when taking prasugrel with aspirin and should be advised to report any unusual bleeding.[1]

The concurrent use of **clopidogrel** and prasugrel has not been specifically studied; however, the manufacturer logically advises that this combination may increase the risk of bleeding. As both drugs have the same mechanism of action, concurrent use is unlikely to be desirable, but if concurrent use is necessary, the patient should be monitored for signs of increased bleeding, and told to report any unexplained bruising or bleeding.[1] Similar advice would apply to **ticlopidine**.

The manufacturer of prasugrel notes that in phase III studies, no clinically significant interaction was reported when **glycoprotein IIb/IIIa-receptor antagonists** (unspecified) were given with prasugrel.[1] However, due to the actions of both drugs there is a possible increased risk of bleeding with combined use. Be aware of the potential for this interaction if bleeding occurs.

(b) Bivalirudin

The manufacturer of prasugrel notes that in phase III studies, no clinically significant interaction was reported when bivalirudin was given with prasugrel.[1] However, due to the actions of both drugs there is a possible increased risk of bleeding with combined use. Be aware of the potential for this interaction if bleeding occurs.

(c) Coumarins and related drugs

The manufacturer reports that prasugrel has no effect on the metabolism of ***S*-warfarin** by the cytochrome P450 isoenzyme CYP2C9. They advise that the use of prasugrel in patients also taking other **coumarins** has not been studied, and recommend caution on concurrent use due to the theoretical possibility of an increased risk of bleeding.[1] If concurrent use is necessary, the patient should be monitored for signs of increased bleeding, and told to report any unexplained bruising or bleeding.[1]

Due to the actions of both drugs there is a possible increased risk of bleeding with combined use of prasugrel and the **indanediones**. If prasugrel is given with an indanedione it would seem prudent to follow the same precautions advised for the coumarins.

(d) Digoxin

The manufacturer reports that prasugrel has no significant effect on the pharmacokinetics of digoxin.[1] Therefore no digoxin dosage adjustments are likely to be needed on concurrent use.

(e) Drugs that affect gastric pH

In a randomised study, 24 healthy subjects were given **lansoprazole** 30 mg daily for 7 days with a single 60-mg dose of prasugrel on day 7. **Lansoprazole** slightly reduced the AUC of the active metabolite of prasugrel by 12% (not clinically significant), and reduced its maximum concentration by 29%; however, the antiplatelet effect of prasugrel was unaffected.[2]

In a study in 23 healthy subjects, **ranitidine** had no statistically significant effect on the AUC or the maximum concentration of the active metabolite of prasugrel, and did not have a clinically relevant effect on platelet inhibition in response to prasugrel. In this study prasugrel was given as a single 60-mg loading dose, followed by 10 mg daily for 7 days, started on the second day of treatment with **ranitidine** 150 mg twice daily.[3]

These minor pharmacokinetic changes are not expected to be of clinical significance, and the manufacturer of prasugrel advises that it may be taken with **proton pump inhibitors** or **H_2-receptor antagonists**. However, they do suggest that a quicker onset of action may occur if the loading dose of prasugrel is taken without the use of a proton pump inhibitor.

(f) Drugs that are substrates of CYP2B6

In a study in 30 healthy subjects, prasugrel, given as a 60-mg loading dose, then 10 mg daily for 10 days, increased the AUC and maximum concentration of a single 150-mg dose of **bupropion** given on day 7 by a modest 18% and 14%, respectively. Prasugrel reduced the AUC and maximum concentration of the active hydroxyl metabolite of bupropion by 23% and 32%, respectively.[4] Bupropion and its hydroxyl metabolite are substrates of the cytochrome P450 isoenzyme CYP2B6. The authors of this paper and the manufacturer of prasugrel state that this weak inhibition of CYP2B6 is unlikely to be of clinical significance. However, they advise that caution may be needed in patients taking high doses of drugs with a narrow therapeutic margin and that are solely metabolised by CYP2B6, such as **cyclophosphamide** and **efavirenz**.[1] However, given the slight effects seen with bupropion a clinically relevant interaction seems unlikely, even with narrow therapeutic index drugs.

(g) Drugs that induce CYP3A4

The manufacturer of prasugrel reports that **rifampicin** 600 mg daily had no significant effect on the pharmacokinetics of prasugrel. Rifampicin is a potent inducer of the cytochrome P450 isoenzyme CYP3A4, which converts prasugrel to its active metabolite, and so it seemed possible that it may increase this metabolic conversion and therefore alter the efficacy of prasugrel. As no significant interaction appears to occur with rifampicin, the manufacturer advises that no significant interaction would be expected with other inducers of CYP3A4 (they name **carbamazepine**).[1] For a list of other known inducers of CYP3A4, see 'Table 1.4', (p.6). No prasugrel dosage adjustments are therefore likely to be needed if prasugrel is given with any CYP3A4 inducer.

(h) Drugs that inhibit CYP3A4

In a randomised study[5] in 18 healthy subjects given prasugrel 60 mg as a loading dose followed by 15 mg daily for 6 days, **ketoconazole** 400 mg daily for 10 days reduced the maximum concentration of the active metabolite of prasugrel by 34% to 46% but had no significant effect on the $AUC_{0\text{-}24}$. Ketoconazole is a potent inhibitor of the cytochrome P450 isoenzyme CYP3A4, which converts prasugrel to its active metabolite, and it seemed possible that it may reduce this metabolic conversion and therefore reduce the efficacy of prasugrel. However, no significant change in the antiplatelet effect of prasugrel was seen in this study,[5] and the manufacturer advises that other CYP3A4 inhibitors, they name the **azoles**, **ciprofloxacin**, **clarithromycin**, **diltiazem**, **grapefruit juice**, **protease inhibitors**, **telithromycin**, and **verapamil** are unlikely to have a significant pharmacokinetic effect on the active metabolite of prasugrel.[1] Therefore, no prasugrel dosage adjustments appear to be necessary when prasugrel is taken with ketoconazole or other inhibitors of CYP3A4.

Note that, despite its inclusion in the manufacturer's list, ciprofloxacin is not usually considered to be an inhibitor of CYP3A4.

(i) Heparin and Low-molecular-weight heparins

The manufacturer reports that a single 100-unit/kg bolus of intravenous heparin had no effect on the antiplatelet effect of prasugrel, and prasugrel did not affect the anticoagulant effect of heparin. In phase III studies, no clinically significant interaction was reported when low-molecular-weight heparins were given with prasugrel. However, the manufacturer advises that although prasugrel may be given with heparin, there is a possible increased risk of bleeding on concurrent use.[1] Be aware of the potential for this interaction if bleeding occurs.

(j) NSAIDs

The manufacturer notes that the use of prasugrel in patients taking long-term NSAIDs, including coxibs, has not been studied, and they therefore advise caution due to the potential increased risk of bleeding.[1]

(k) Statins

In a randomised study, 31 healthy subjects were given **atorvastatin** 80 mg daily for 16 days with prasugrel 60 mg as a loading dose on day 7 followed by 10 mg daily for 10 days. **Atorvastatin** had no effect on the AUC of the loading dose of prasugrel, and the AUC of the active metabolite of prasugrel was only slightly increased (by 17%) by day 16. The rate of bleeding associated with the use of prasugrel was not affected by the concurrent use of **atorvastatin**, and its effects on platelet inhibition were also unchanged.[6] No clinically relevant interaction would therefore be expected if **atorvastatin** is given with prasugrel.

Note that, although there appear to be no other drug interaction studies, the manufacturer of prasugrel states that it may be given with statins.

Ticlopidine + Codergocrine mesilate (Ergoloid mesylates)

Codergocrine mesilate reduces the bioavailability of a single dose of ticlopidine.

Clinical evidence, mechanism, importance and management

A study in 8 healthy subjects found that codergocrine mesilate 1.5 mg three times daily for 4 days decreased both the AUC and maximum level of a single 250-mg dose of ticlopidine by about 30%. It was suggested that codergocrine mesilate inhibits the human organic anion transporting polypeptide B (OATP-B)-mediated absorption of ticlopidine from the intestine.[1] However, *in vitro* data from the same study suggested that *Ginkgo biloba* also inhibits OATP-B, but *Ginkgo biloba* did not alter ticlopidine levels in an *in vivo* study, see 'Antiplatelet drugs + Ginkgo (*Ginkgo biloba*)', p.816.

The general significance of this study in patients is unclear; however, bear the potential for an interaction in mind, particularly in patients where reductions in the levels of ticlopidine may be critical, such as those with drug-eluting stents.

Ticlopidine + Miscellaneous

Ticlopidine-induced increases in bleeding times are opposed by methylprednisolone and prednisolone but its effects on platelet function are not affected. Ticlopidine decreases the clearance of phenazone (antipyrine), which suggests that it has mild enzyme-inhibiting effects. Beta blockers, calcium-channel blockers and diuretics are reported not to interact with ticlopidine.

Clinical evidence, mechanism, importance and management

(a) Corticosteroids

A study involving 14 healthy subjects found that a single 20-mg intravenous injection of **methylprednisolone**, or oral **prednisolone** 15 mg twice daily for 7 days, decreased the prolongation of bleeding times caused by ticlopidine 250 to 500 mg twice daily for 7 days. However, the antiplatelet effects of ticlopidine were not affected.[1] The clinical importance of this interaction is therefore uncertain.

(b) Phenazone (Antipyrine)

A study in 10 healthy subjects found that ticlopidine 250 mg twice daily for 3 weeks decreased the clearance of phenazone (a marker of enzyme inhibition or induction). The AUC increased by 14% and the half-life increased by 27%, suggesting that ticlopidine has some mild enzyme-inhibiting effects.[2] This is consistent with the way ticlopidine appears to inhibit the metabolism of 'theophylline', (p.1436).

(c) Non-interacting drugs

The manufacturer of ticlopidine reports that, in clinical studies in which ticlopidine was given with **beta blockers**, **calcium-channel blockers** and **diuretics** [none of the individual drugs named], no clinically significant adverse interactions were reported.[3]

Thrombolytics + Aspirin

Patients with acute ischaemic stroke treated with streptokinase have an increased risk of early death due to cerebral haemorrhage if they are also given aspirin.

Clinical evidence, mechanism, importance and management

A post hoc analysis of 313 patients with acute ischaemic stroke given intravenous **streptokinase** 1.5 million units found that the addition of oral aspirin 300 mg daily, started at the same time as **streptokinase**, increased the risk of early death. The combined regimen significantly increased early fatalities (from day 3 to 10) with 53 deaths occurring out of 156 patients (34%), compared with 30 of 157 (19%) who received **streptokinase** alone. This was mainly due to cerebral causes (42 versus 24) and associated with intracranial haemorrhage (25 versus 11).[1] Other studies have also reported less favourable results, and therefore **streptokinase** is not recommended in the management of acute stroke.[2,3]

Alteplase has been shown to improve the outcome in acute ischaemic stroke and is now recommended management for selected patients, as is aspirin.[2-4] This combination is still associated with an increased risk of

bleeding, therefore treatment with aspirin should not be initiated within the first 24 hours after treatment with **alteplase** in acute stroke patients.[5]

Thrombolytics; Alteplase + Glyceryl trinitrate (Nitroglycerin)

Glyceryl trinitrate may reduce the thrombolytic efficacy of alteplase, but this is not thought to be clinically relevant.

Clinical evidence, mechanism, importance and management

In a randomised study, 60 patients with acute anterior myocardial infarction were given intravenous alteplase 100 mg over 3 hours, as well as heparin and aspirin. In addition, 27 of the patients were also given intravenous glyceryl trinitrate 100 micrograms/minute for 8 hours. Patients receiving both alteplase and glyceryl trinitrate had signs of reperfusion less often (56%) than the patients who received alteplase alone (76%). In the combined treatment group time to reperfusion was also longer (37.8 versus 19.6 minutes) and the incidence of coronary artery re-occlusion was higher (53% versus 24%). Giving alteplase with glyceryl trinitrate produced plasma levels of tissue plasminogen activator (tPA) antigen that were about two-thirds lower than when alteplase was given alone.[1] Impaired thrombolysis has been found in another study[2] and also in an earlier study in *dogs*.[3]

It was postulated that glyceryl trinitrate increased hepatic blood flow and therefore increased the metabolism of alteplase, which resulted in reduced plasma tPA levels.[1] However, an *in vitro* study found that glyceryl trinitrate enhanced the degradation of alteplase, and therefore a mechanism other than increased hepatic blood flow seems likely to be involved.[4] Given the results of subsequent major studies on thrombolytics in patients with myocardial infarction, where most patients also received intravenous or sublingual nitrates it seems unlikely that this interaction is generally significant.

Thrombolytics; Streptokinase + Other thrombolytics

The thrombolytic effects of streptokinase and anistreplase are likely to be reduced or abolished if either drug is given some time after a dose of streptokinase, because of persistently high levels of streptokinase antibodies. There is also an increased risk of hypersensitivity reactions. This may also be true for urokinase.

Clinical evidence

A study in 25 patients who had been given streptokinase for acute myocardial infarction, found that 12 weeks later, 24 patients had enough anti-streptokinase antibodies in circulation to neutralise an entire 1.5 million unit dose of streptokinase. After 4 to 8 months, 18 out of 20 patients still had enough antibodies to neutralise half of a 1.5 million unit dose of streptokinase.[1] Further study has suggested that, after streptokinase use, anti-streptokinase antibodies fall within 24 hours, but then increase gradually and are significantly raised by 4 days after treatment. The antibody titres reach a peak (approximately 200 times that of pretreatment levels) after 2 weeks and then subsequently decline, but remain above baseline values for at least one year.[2] Studies in patients given streptokinase[3-7] or **anistreplase**[7] have variously found that:

- antibody levels return to their pretreatment range in 92% of patients approximately 12 months after treatment,[7]
- neutralising antibody titres return to control levels by 2 years,[6]
- antibody titres may remain high enough to neutralise the effects of streptokinase for several years after a dose,[3,4]
- high titres may persist for up to 7.5 years.[5]

Increased titres of streptokinase antibodies have also been seen in patients receiving topical streptokinase for wound care,[8] intrapleural streptokinase for pleural effusions,[9] and following streptococcal infections.[10] Apart from the reduced thrombolytic effect, repeated dosing[11] or high pretreatment anti-streptokinase antibody titres[12] may increase the risk of allergic reactions.

Anistreplase, like its parent drug streptokinase, has been shown to be neutralised by anti-streptokinase antibodies.[13,14]

Of 6 patients given **urokinase** 1.5 million units infused over 30 minutes for recurrent myocardial infarction, rigors occurred in 4 patients and 2 of these also had bronchospasm; they had all previously received streptokinase.[15]

Mechanism

Streptokinase use causes the production of anti-streptokinase antibodies. These persist in the circulation so that the clot-dissolving effects of another dose of streptokinase given many months later may be ineffective, or less effective, because it becomes bound and neutralised by the antibodies. Many people already have a very low titre of antibodies resulting from previous streptococcal infections, yet this does not usually appear to influence thrombolysis.[16]

Importance and management

The interaction that results in neutralisation of the thrombolytics is established and clinically important. One author[17] suggests that therapy should not be repeated within one year as it would not be effective. Given that it has been suggested that the neutralising effects may be very persistent, it would seem prudent, if subsequent treatment is needed, to use a thrombolytic with less antigenic effects, such as alteplase. The BNF in the UK states that streptokinase should not be used again beyond 4 days of the first use of either streptokinase or anistreplase.[18] The American College of Cardiology/American Heart Association guidelines recommend avoiding the readministration of streptokinase,[19] and the European Society of Cardiology specifically contraindicates the use of streptokinase or anistreplase in patients who have previously been treated with either drug.[20] In addition, the manufacturer recommends avoidance of streptokinase in patients who have had recent streptococcal infections that have produced high anti-streptokinase titres, such as acute rheumatic fever or acute glomerulonephritis.[10]

Little is known about the increased risk of hypersensitivity reactions.

Antipsychotics, Anxiolytics and Hypnotics

The interactions where the effects of antipsychotic, anxiolytic and hypnotic drugs are affected are covered in this section but there are other monographs elsewhere in this publication where the effects of other drugs are altered by benzodiazepines or related drugs, or antipsychotics.

Antipsychotics

The antipsychotics are represented by chlorpromazine (and other phenothiazines), haloperidol (and other butyrophenones), thioxanthenes, and the atypical, or newer, antipsychotic drugs, such as clozapine, olanzapine, risperidone and its main metabolite, paliperidone (9-hydroxyrisperidone), and ziprasidone. Their major use is in the treatment of psychoses such as schizophrenia and mania; a list of these drugs is given in 'Table 20.1', (below). Some of the antipsychotics are also used as antiemetics, and for motor tics and hiccups.

Many of the interactions of the older antipsychotics are pharmacodynamic, relating to their effect on dopamine, whilst several of the newer atypical antipsychotics are metabolised to a significant extent by cytochrome P450 isoenzymes. The concurrent use of other drugs that are inhibitors or inducers of these isoenzymes may result in large changes in plasma levels. Furthermore, lifestyle factors, such as tobacco smoking and caffeine intake can have an effect on the pharmacokinetics of some of these drugs, leading to adverse effects or lack of therapeutic effect following lifestyle changes.

Anxiolytics and Hypnotics

Anxiolytics include the benzodiazepines (e.g. diazepam, alprazolam, lorazepam), buspirone and other drugs used to treat psychoneuroses such as anxiety and tension, and are intended to induce calm without causing drowsiness and sleep. Hypnotics include benzodiazepines such as nitrazepam or temazepam and non-benzodiazepines such as zaleplon, zolpidem or zopiclone; however, the difference in action between anxiolytics and hypnotics is mainly one of degree and, in general, the same drug or group of drugs can have both effects.

Anxiolytics and hypnotics may impair judgement and increase reaction time and they can interact with other drugs, such as 'alcohol', (p.56), that affect the CNS, see 'CNS depressants + CNS depressants', p.1553. Some of the benzodiazepines and related drugs are also used as antiepileptics. 'Table 20.1', (below) contains a list of the benzodiazepines and other anxiolytics and hypnotics.

Table 20.1 Antipsychotics, anxiolytics, and hypnotics

Group	*Drugs*
Antipsychotics	
Atypical antipsychotics	Amisulpride, Aripiprazole, Clozapine, Olanzapine, Paliperidone, Quetiapine, Risperidone, Sertindole, Ziprasidone, Zotepine
Phenothiazines	Butaperazine, Chlorpromazine, Cyamemazine, Fluphenazine, Levomepromazine, Mesoridazine, Metopimazine, Pericyazine, Perphenazine, Prochlorperazine, Promazine, Thioridazine, Trifluoperazine
Butyrophenones	Benperidol, Bromperidol, Droperidol, Haloperidol, Melperone, Pipamperone
Thioxanthenes	Chlorprothixene, Flupentixol, Tiotixene, Zuclopenthixol
Miscellaneous	Loxapine, Molindone, Pimozide, Ritanserin, Sulpiride
Anxiolytics and hypnotics	
Benzodiazepines	Alprazolam, Bromazepam, Brotizolam, Chlordiazepoxide, Clobazam, Clonazepam, Clorazepate, Clotiazepam, Diazepam, Estazolam, Etizolam, Flunitrazepam, Flurazepam, Ketazolam, Loprazolam, Lorazepam, Lormetazepam, Medazepam, Midazolam, Nitrazepam, Oxazepam, Oxazolam, Quazepam, Temazepam, Triazolam
Miscellaneous	Buspirone, Clomethiazole, Cloral betaine, Cloral hydrate, Eszopiclone, Glutethimide, Hydroxyzine, Meprobamate, Promethazine, Ramelteon, Tandospirone, Triclofos, Zaleplon, Zolpidem, Zopiclone

(a) Benzodiazepines

Many benzodiazepines undergo phase I metabolism by *N*-dealkylation and hydroxylation and many of the metabolites are active. They may then undergo phase II conjugation, mainly to form glucuronides before being excreted. For example, diazepam is metabolised to nordazepam (desmethyldiazepam), temazepam and oxazepam. The metabolism of diazepam in the liver is also mediated by cytochrome P450 isoenzymes, particularly CYP2C19 and to a lesser extent CYP3A4, and diazepam is excreted mainly as free or conjugated metabolites.

The triazolo- and related benzodiazepines, such as alprazolam, midazolam and triazolam, are mainly metabolised by hydroxylation, mediated by CYP3A4, to active compounds, which then rapidly undergo glucuronide conjugation.

Therefore, drugs that affect CYP2C19 may interact with benzodiazepines such as diazepam and those that affect CYP3A4 may interact with midazolam or triazolam.

Benzodiazepines such as lorazepam, oxazepam and temazepam, which are mainly conjugated without prior phase I metabolism, are less likely to be involved in interactions with inhibitors or inducers of cytochrome P450. Benzodiazepines themselves do not significantly induce cytochrome P450 isoenzymes, so interactions involving enhanced metabolism of other drugs are not usual.

(b) Non-benzodiazepine hypnotics

Zaleplon, zolpidem and zopiclone are non-benzodiazepine hypnotics, but they act at the benzodiazepine receptor. They are metabolised by several cytochrome CYP450 isoenzymes and it has been suggested that because of this, other drugs that affect a particular isoenzyme such as CYP3A4, may have less effect on their metabolism. However, their pharmacokinet-

ics are affected by potent CYP3A4 inducers such as rifampicin (rifampin) and by potent CYP3A4 inhibitors such as the azole antifungals.

(c) Miscellaneous anxiolytics and hypnotics

Buspirone is an azapirone anxiolytic that does not act on benzodiazepine receptor sites and lacks sedative, antiepileptic and muscle relaxant properties. It enhances the activity of specific dopaminergic and noradrenergic pathways, and also affects serotonin and acetylcholine systems of the brain. Buspirone is metabolised by hepatic CYP3A4.

Clomethiazole is a hypnotic and sedative with anticonvulsant effects. It is extensively metabolised in the liver.

Ramelteon is a melatonin receptor agonist, but has no appreciable affinity for the GABA-receptor complex, or for dopamine, noradrenaline, serotonin or acetylcholine receptors. Ramelteon is metabolised primarily by oxidation and then by glucuronidation. Ramelteon is primarily metabolised by CYP1A2 in the liver.

Antipsychotics + Antimuscarinics

Antipsychotics and antimuscarinics are very often given together advantageously and uneventfully, but occasionally serious and even life-threatening interactions occur. These include heat stroke in hot and humid conditions, severe constipation and adynamic ileus, and atropine-like psychoses. Antimuscarinics used to counteract the extrapyramidal adverse effects of antipsychotics may also reduce or abolish their therapeutic effects.

Clinical evidence

The use of antipsychotics with antimuscarinics can result in a generalised, low grade, but not usually serious, additive increase in the antimuscarinic effects of these drugs (blurred vision, dry mouth, constipation, difficulty in urination, see 'Antimuscarinics + Antimuscarinics', p.786). However, sometimes serious intensification takes place. For the sake of clarity these effects have been subdivided here into (a) heat stroke, (b) constipation and adynamic ileus, (c) atropine-like psychoses, (d) antagonism of antipsychotic effects and (e) miscellaneous effects.

(a) Heat stroke

Three patients were admitted to hospital in Philadelphia for drug-induced hyperpyrexia during a hot and humid period. In each case their skin and mucous membranes were dry and they were tachycardic (120 bpm). There was no evidence of infection.[1]

Drug combinations implicated in reports of heat stroke, some of them fatal, include:[1-5]

- **chlorpromazine** and **benzatropine**
- **chlorpromazine** and **trifluoperazine**
- **chlorpromazine**, **amitriptyline** and **benzatropine**
- **chlorpromazine**, **chlorprothixene** and **benzatropine**
- **chlorpromazine**, **fluphenazine**, **trihexyphenidyl** and **benzatropine**
- **chlorpromazine**, **trifluoperazine** and **benzatropine**
- **haloperidol** and **benzatropine**
- **promazine** and **benzatropine**.

The danger of heat stroke in patients taking **atropine** or **atropine-like compounds** was recognised in the 1920s, and the warning has been repeated many times.[6,7]

(b) Constipation and adynamic ileus

Paralytic ileus with faecal impaction (fatal in 6 cases) has been reported in a number of patients taking:

- **chlorpromazine** and **amitriptyline**,[8] **imipramine**,[9] **nortriptyline**,[10] or **trihexyphenidyl**[9]
- **haloperidol** and **benzatropine**[11]
- **levomepromazine** and **imipramine** with **benzatropine**[9]
- **levomepromazine** and **trihexyphenidyl**[9]
- **mesoridazine** and **benzatropine**[12]
- **thioridazine** and **imipramine** with **trihexyphenidyl**[9]
- **trifluoperazine** and **benzatropine**[13] or **trihexyphenidyl**[9]
- **trifluoperazine** and **benzatropine** with **methylphenidate**.[14]

Severe constipation also occurred in a woman given **thioridazine**, **biperiden** and **doxepin**.[15]

(c) Atropine-like psychoses

In a double-blind study 3 patients given a **phenothiazine** and **benzatropine** for the parkinsonian adverse effects, developed an intermittent toxic confusional state (marked disturbance of short-term memory, impaired attention, disorientation, anxiety, visual and auditory hallucinations) with peripheral antimuscarinics signs.[16] Similar reactions occurred in 3 elderly patients given **imipramine** or **desipramine**, with **trihexyphenidyl**,[17] and in another man given **chlorpromazine**, **benzatropine** and **doxepin**.[15]

(d) Antagonism of antipsychotic effects

A study in psychiatric patients given **chlorpromazine** 300 to 800 mg daily found that when **trihexyphenidyl** 6 to 10 mg daily was added, the plasma **chlorpromazine** levels were reduced from a range of 100 to 300 nanograms/mL to less than 30 nanograms/mL. When the **trihexyphenidyl** was withdrawn the plasma **chlorpromazine** levels rose again and clinical improvement was seen.[18,19]

Other studies confirm that **trihexyphenidyl**[20,21] and **orphenadrine**[22] reduce the plasma levels and effects of **chlorpromazine**. In another study, patients with schizophrenia taking **chlorpromazine**, **levomepromazine**, **thioridazine**, or **haloperidol** and in some cases also taking small doses of **trifluoperazine**, **fluphenazine**, **thioproperazine**, **perphenazine** or **tiotixene** were all taking either **benzatropine**, **trihexyphenidyl** or **procyclidine** for extrapyramidal symptoms. These antimuscarinic antiparkinsonian drugs were gradually withdrawn in the fifth study week. Plasma levels of the antipsychotics increased during the next 12 weeks after which a plateau was reached, suggesting that the antimuscarinic drugs reduced plasma levels of the antipsychotics.[23] In contrast to these reports, another found that **trihexyphenidyl** increased **chlorpromazine** levels by 41% in 20 young schizophrenics, but no clinical change was seen. The levels dropped again over the first 4 weeks of treatment.[24] Some of the beneficial actions of **haloperidol** on social avoidance behaviour are lost during concurrent treatment with **benzatropine**, but cognitive integrative function is unaffected.[25] Other studies found that the effects of **chlorpromazine** on social, affective and cognitive dysfunctions in patients with schizophrenia were reversed by **benzatropine**[26]and that **benzatropine**[27] and **trihexyphenidyl**[28] diminished the effects of **chlorpromazine** to a greater extent than those of **haloperidol**.

A study to investigate any possible interaction between **procyclidine** 5 to 15 mg daily and **chlorpromazine**, **fluphenazine** or **haloperidol** found that the addition of **procyclidine** caused a transient fall in the serum levels of **chlorpromazine**, whilst the fall in levels of **fluphenazine** and **haloperidol** was maintained for the 4-week treatment period with **procyclidine**. Two patients in the **haloperidol** group experienced a worsening of symptoms whilst taking **procyclidine**.[29]

(e) Miscellaneous effects

A study in psychotic patients found that the addition of **biperiden** 2 mg three times daily or **orphenadrine** 50 mg three times daily for 3 weeks had no effect on the steady-state levels of **perphenazine** 24 to 48 mg daily.[30] A study in patients with schizophrenia found that **biperiden** 6 mg daily or **trihexyphenidyl** 8 mg daily had no effect on steady-state plasma levels of **bromperidol** or its reduced metabolite.[31]

An isolated report describes the development of a hypoglycaemic coma in a non-diabetic patient given **chlorpromazine** and **orphenadrine**.[32]

Mechanism

Antimuscarinic (anticholinergic) drugs inhibit the parasympathetic nervous system, which innervates the sweat glands, so that when the ambient temperature rises the major heat-losing mechanism of the body can be partially or wholly lost.[33] Phenothiazines, thioxanthenes and butyrophenones may also have some antimuscarinic effects, but additionally they impair (to a varying extent) the hypothalamic thermoregulatory mechanisms that control the body's ability to keep a constant temperature when exposed to heat or cold. Thus, when the ambient temperature rises, the body temperature also rises. The tricyclics can similarly disrupt temperature control. Therefore in very hot and humid conditions, when the need to reduce the temperature is great, the additive effects of these drugs can make patients unable to control their temperature,[4] which can be fatal.

Antimuscarinic drugs also reduce peristalsis, which in the extreme can result in total gut stasis. Additive effects can occur if two or more antimuscarinic drugs are taken.

The toxic psychoses described resemble the CNS effects of atropine or belladonna poisoning and appear to result from the additive effects of the drugs used.

The mechanism for antipsychotic antagonism is not understood. *Animal* studies suggest that the site of interaction is in the gut.[19]

Importance and management

Established and well-documented interactions. While antipsychotics and antimuscarinics (including **tricyclics**, which have antimuscarinic adverse effects) have been widely used together with apparent advantage and without problems, prescribers should be aware that low-grade antimuscarinic toxicity can easily go undetected, particularly in the elderly because the symptoms can be so similar to the general complaints of this group. Also be aware of the serious problems that can sometimes develop, particularly if high doses are used.

- Warn patients to minimise outdoor exposure and/or exercise in hot and humid climates, particularly if they are taking high doses of antipsychotic/antimuscarinic drugs.
- Be alert for severe constipation and for the development of complete gut stasis, which can be fatal.

- Be aware that the symptoms of central antimuscarinic psychosis can be confused with the basic psychotic symptoms of the patient. Withdrawal of one or more of the drugs, or a dosage reduction and/or appropriate symptomatic treatment can be used to control these interactions.
- Ensure that the concurrent use of antimuscarinics to control the extrapyramidal adverse effects of neuroleptics is necessary[34,35] and be aware that the therapeutic effects may possibly be reduced as a result.

Antipsychotics + Coffee or Tea

Tea and coffee can cause some drugs to precipitate out of solution *in vitro*, but so far there is no clinical evidence to show that this normally affects the bioavailability of these drugs nor that it has a detrimental effect on treatment.

Clinical evidence, mechanism, importance and management

A single report describes 2 patients whose schizophrenia was said to have been exacerbated by an increased consumption of tea and coffee.[1] Subsequent *in vitro* studies[2-6] found that a number of drugs (**chlorpromazine**, **promethazine**, **fluphenazine**, orphenadrine, **promazine**, **prochlorperazine**, **trifluoperazine**, **thioridazine**, **loxapine**, **haloperidol**, **droperidol**) form a precipitate with tea or coffee due to the formation of a drug-tannin complex, which was thought might possibly lower the absorption of these drugs in the gut. Studies with *rats* also found that tea abolished the cataleptic effects of **chlorpromazine**, which did not appear to be related to the presence of caffeine.[7] However, the drug-tannin complex gives up the drug into solution if it becomes acidified, as in the stomach.[6] Moreover, a clinical study of this interaction in 16 patients found that the plasma levels of **chlorpromazine**, **fluphenazine**, **trifluoperazine** and **haloperidol** were unaffected by the consumption of tea or coffee. Their behaviour also remained unchanged.[8] Similarly, a study in 12 healthy subjects concluded that there was no significant decrease in the plasma levels of a single 5-mg dose of **fluphenazine** given with either tea, coffee, or water.[9] Therefore there appears to be little or no direct evidence that this physicochemical interaction is normally of any clinical importance.

Antipsychotics + Lithium

Chlorpromazine levels can be reduced to subtherapeutic concentrations by lithium. The development of severe extrapyramidal adverse effects or severe neurotoxicity has been seen in one or more patients given lithium with various antipsychotics. Sleepwalking has been described in some patients taking chlorpromazine-like drugs and lithium.

Clinical evidence

(a) Chlorpromazine

In a double-blind study in psychiatric patients it was found that chlorpromazine 400 to 800 mg daily, a dose that normally produced plasma levels of 100 to 300 nanograms/mL, only produced levels of 0 to 70 nanograms/mL when lithium carbonate was also given.[1] Other studies confirm that normal therapeutic levels of lithium carbonate reduce plasma chlorpromazine levels.[2,3] The peak serum levels and AUC of chlorpromazine were reduced by 40% and 26%, respectively, in healthy subjects given lithium carbonate.[2]

A paranoid schizophrenic taking chlorpromazine 200 to 600 mg daily for 5 years with no extrapyramidal symptoms developed stiffness of his face, arms and legs, and parkinsonian tremor of both hands within one day of starting to take lithium 900 mg daily. His lithium blood level after 3 days was 0.5 mmol/L. He was later given lithium 1.8 g daily (blood level 1.17 mmol/L), chlorpromazine 200 mg daily and benzatropine 2 mg daily, which improved his condition, but he still complained of stiffness and had a persistent hand tremor.[4]

A number of other reports describe the emergence of severe extrapyramidal adverse effects when chlorpromazine was given with lithium.[5-7] Ventricular fibrillation, thought to be caused by chlorpromazine toxicity, occurred in a patient taking lithium when both drugs were suddenly withdrawn.[8] Severe neurotoxicity has also been seen in a handful of other patients taking lithium and chlorpromazine.[9,10]

(b) Haloperidol

A large-scale retrospective study of the literature over the period 1966 to 1996 using the Medline database identified 41 cases of neurotoxic adverse effects in 41 patients with low therapeutic concentrations of lithium. Of these patients, 10 were taking haloperidol.[9]

Another retrospective study using both Medline and the spontaneous reporting system of the FDA in the US, over the period 1969 to 1994, identified 237 cases of severe neurotoxicity involving lithium, of which 59 also involved the concurrent use of haloperidol.[11,12]

Other reports describe encephalopathic syndromes (lethargy, fever, tremulousness, confusion, extrapyramidal and cerebellar dysfunction),[13] neuromuscular symptoms, impaired consciousness and hyperthermia,[14] delirium, severe extrapyramidal symptoms and organic brain damage in patients taking haloperidol with lithium.[15-26] In one study it was found that of the 13 patients who were taking haloperidol, 5 developed neurotoxic reactions, and they were receiving higher doses of haloperidol (average dose was 59 mg) than the 8 patients who did not develop such symptoms (average dose was 34.9 mg).[27] The sudden emergence of extrapyramidal or other adverse effects with lithium and haloperidol has also been described in other studies.[9,15,28]

In contrast to the reports cited above, there are others describing successful and uneventful use.[13,29-32] A retrospective search of Danish hospital records found that 425 patients had taken both drugs and none of them had developed serious adverse reactions.[33]

A small rise in serum lithium levels occurs in the presence of haloperidol, but it is almost certainly of little or no clinical significance.[34]

(c) Other antipsychotics

A large-scale retrospective study of the literature over the period 1966 to 1996 using the Medline database identified 41 cases of neurotoxic adverse effects in 41 patients with low, therapeutic concentrations of lithium. Of these patients, 51.2% were also taking at least one antipsychotic drug.[9] Another retrospective study using both Medline and the spontaneous reporting system of the FDA in the US, over the period 1969 to 1994, identified 237 cases of severe neurotoxicity involving lithium, with 188 involving lithium with antipsychotics.[11,12] The sudden emergence of extrapyramidal or other adverse effects has also been described in other studies. The antipsychotics implicated in this interaction with lithium are **bromperidol**,[11,12] **chlorprothixene**,[11,12] **clopenthixol**,[9] **flupentixol**,[15,28,35] **fluphenazine**,[9,11,12,15,28,36] **levomepromazine**,[9,11,12] **loxapine**,[11,12,37,38] **mesoridazine**,[11,12] **molindone**,[11,12] **perphenazine**,[11,12,28] **pipotiazine**,[39] **prochlorperazine**,[11,12] **sulpiride**,[40] **thioridazine**,[9,11,12,28,41,42] **tiotixene**,[9,11,12,16,28] **trifluoperazine**,[11,12] and **zuclopenthixol**.[9] Examples of some cases are cited in a little more detail below.

A study in 10 patients taking **fluphenazine**, **haloperidol** or **tiotixene** found that the addition of lithium worsened their extrapyramidal symptoms.[43] Neurotoxicity (tremor, rigidity, ataxia, tiredness, vomiting, confusion) attributed to an interaction between lithium and **fluphenazine** has been described in another patient. He previously took **haloperidol** and later took **chlorpromazine** with lithium, without problem.[44] Irreversible brain damage has been reported in a patient taking **fluphenazine decanoate** and lithium.[45] Severe neurotoxic complications (seizures, encephalopathy, delirium, abnormal EEGs) developed in 4 patients taking **thioridazine** 400 mg daily or more and lithium. Serum lithium levels remained below 1 mmol/L. Lithium and other phenothiazines had been taken by 3 of the patients for extended periods without problems, and the fourth subsequently took lithium and **fluphenazine** without problems.[46] In one study the concurrent use of lithium and **chlorpromazine**, **perphenazine**, or **thioridazine** was associated with sleep-walking episodes in 9% of patients.[47] A retrospective review of 39 patients with a diagnosis of neurotoxicity caused by treatment with lithium and an antipsychotic, found that the onset of symptoms varied from 24 hours to 3 months after taking the two drugs together, with an average delay of 12.7 days.[28]

A study in 8 patients found a fourfold increase in the half-life of **molindone** when lithium was also given.[48]

Mechanism

Not understood. One suggestion to account for the reduced serum levels of chlorpromazine, which is based on *animal* studies,[49,50] is that chlorpromazine can be metabolised in the gut. Therefore, if lithium delays gastric emptying, more chlorpromazine will be metabolised before it reaches the circulation. Just why severe neurotoxicity and other adverse effects sometimes develop in patients taking lithium and antipsychotics is not understood. It is the subject of considerable discussion and debate.[9,11,12,51,52]

Importance and management

Information about the reduction in chlorpromazine levels caused by lithium is limited, but it would seem to be an established interaction of clinical importance. Serum chlorpromazine levels below 30 nanograms/mL have been shown to be ineffective, whereas clinical improvement is usually associated with levels within the 150 to 300 nanogram/mL range.[53] Thus a fall in levels to below 70 nanograms/mL, as described in one study, would be expected to result in a reduced therapeutic response to chlorpromazine. Therefore the effects of concurrent use should be closely monitored and the chlorpromazine dosage increased if necessary.

The development of severe neurotoxic or severe extrapyramidal adverse effects with combinations of antipsychotics and lithium appears to be uncommon and unexplained but be alert for any evidence of toxicity if lithium is given with any of these drugs. One recommendation is that the onset of neurological manifestations, such as excessive drowsiness or movement disorders, warrants electroencephalography without delay and withdrawal of the drugs, especially as irreversible effects have been seen. A review[54] suggests that the concurrent use of haloperidol seems to be safe if lithium levels are below 1 mmol/L. It is not known whether this also applies to other antipsychotics.

At the moment there seems to be no way of identifying the apparently small number of patients who are particularly at risk, but possible likely factors include a previous history of extrapyramidal reactions with antipsychotics and the use of large doses of the antipsychotic.

Note that the interactions of **atypical antipsychotics** with lithium are covered elsewhere.

Antipsychotics + Orlistat

No changes in the plasma levels of haloperidol or clozapine were seen when orlistat was also given.

Clinical evidence, mechanism, importance and management

In a study, 8 patients who had experienced weight gain as a result of treatment with **haloperidol** (2), **clozapine** (2), clomipramine (3), desipramine (1), or carbamazepine (2), were given orlistat 120 mg three times daily for 8 weeks. There were no significant changes in the plasma levels of the antipsychotic drugs, and steatorrhoea, which occurred in three patients, had no effect on their bioavailability.[1] Although an interaction appears to be unlikely, due to the small numbers involved in the study, this needs confirmation.

Aripiprazole + Miscellaneous

Aripiprazole plasma levels are increased by inhibitors of CYP3A4 and decreased by inducers of CYP3A4. Quinidine increases aripiprazole levels. The manufacturers advise caution with drugs that can prolong the QT interval. Food, famotidine, and lorazepam do not have a clinically relevant effect on the pharmacokinetics of aripiprazole, and aripiprazole does not affect the pharmacokinetics of dextromethorphan, lamotrigine, lorazepam, omeprazole, and warfarin.

Clinical evidence, mechanism, importance and management

(a) CYP3A4 inducers

In a study, 6 patients were given aripiprazole 30 mg daily and **carbamazepine** in doses to produce trough serum levels of 8 to 12 mg/L. After 4 to 6 weeks of concurrent use, the peak plasma levels and AUC of aripiprazole were reduced by 66% and 71%, respectively. The apparent oral clearance of aripiprazole was increased about fourfold.[1] Analysis of results from a routine therapeutic monitoring service found **carbamazepine** lowered the dose-adjusted serum level of aripiprazole by 88% in one patient.[2]

It is recommended that the dose of aripiprazole is doubled when it is taken with **carbamazepine**.[1,3,4] Other potent inducers of CYP3A4 (the UK manufacturers name **efavirenz**, **nevirapine**, **phenytoin**, **phenobarbital**, **primidone**, **rifabutin**, **rifampicin** and **St John's wort**) are expected to have similar effects and an increase in the dose of aripiprazole may also be necessary if these drugs are given.[3]

(b) CYP3A4 inhibitors

In a study in 24 healthy subjects, **itraconazole**, an inhibitor of CYP3A4, given in a dose of 100 mg daily for 7 days increased the peak levels, AUC and half-life of a single 3-mg dose of aripiprazole by 19%, 48% and 19%, respectively.[5]

Similarly, **ketoconazole**, another inhibitor of CYP3A4, given in a dose of 200 mg daily for 14 days increased the AUC and maximum plasma concentration of a single 15-mg dose of aripiprazole by 63% and 37%, respectively.[3,4] The UK manufacturers note that other potent inhibitors of CYP3A4, such as the **protease inhibitors** would be expected to produce similar or greater increases in aripiprazole levels to those seen with ketoconazole, and they recommend that the dose of aripiprazole should be halved with these drugs.[3] The dose of aripiprazole should also be increased again if the drug is stopped. Moderate inhibitors of CYP3A4, such as **diltiazem**, may produce more modest increases in aripiprazole levels,[3] and patients should be closely monitored for signs of aripiprazole toxicity, although an initial dose reduction of aripiprazole may not be required.

(c) Drugs that prolong the QT interval

The manufacturers report that in clinical studies the incidence of QT prolongation with aripiprazole was comparable to placebo. Nevertheless, they recommend caution when prescribing aripiprazole with other drugs that may prolong the QT interval or cause electrolyte disturbances.[3] See 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290, for a list.

(d) Famotidine

In a single-dose study, famotidine 40 mg reduced the rate of absorption of aripiprazole 15 mg, and reduced the peak level and AUC of aripiprazole by 37% and 13% respectively,[4] but these effects are not clinically significant.[3,4]

(e) Food

A study in 39 healthy subjects who took aripiprazole 15 mg either after fasting, or 5 minutes after a high-fat breakfast, found no significant changes in the pharmacokinetics of aripiprazole.[6]

(f) Haloperidol

A case report describes a 30-year-old man with schizophrenia who developed worsening psychotic symptoms while taking aripiprazole 10 mg daily and haloperidol 5 mg twice daily. The symptoms worsened when the aripiprazole dose was increased to 30 mg daily, and a doubling of the haloperidol dose only achieved a marginal improvement. His psychotic symptoms and agitation improved within 4 days of stopping aripiprazole. He was later discharged taking haloperidol, and had some extrapyramidal adverse effects and a raised prolactin level, which had been absent when taking the aripiprazole. It was suggested that aripiprazole, a partial D_2 agonist had interfered with the effects of haloperidol, a D_2 antagonist.[7]

(g) Lamotrigine

The manufacturers report that giving aripiprazole 10 to 30 mg daily to patients with bipolar disorder had no effect on the steady-state pharmacokinetics of lamotrigine 100 to 400 mg daily. The dose of lamotrigine does not need to be adjusted when aripiprazole is also given.[3,4]

(h) Lorazepam

A study in healthy subjects given lorazepam 2 mg and aripiprazole 15 mg, both by injection, found there were no clinically important changes in the pharmacokinetics of either drug. No dosage adjustment is required on combined use. However, the intensity of sedation with the combination was greater than that observed with aripiprazole alone and orthostatic hypotension was greater with the combination than with lorazepam alone.[4]

(i) Quinidine

Quinidine, an inhibitor of CYP2D6, has been found to increase the AUC of aripiprazole by 107%, although the maximum concentration was unchanged. It is recommended that the dose of aripiprazole is halved if quinidine is also given.[3,4]

(j) Other drugs

Aripiprazole 10 to 30 mg daily had no significant effects on the metabolism of **dextromethorphan** (CYP2D6 substrate), **warfarin** (CYP2C9 substrate) and **omeprazole** (CYP2C19 substrate). The manufacturers

therefore conclude that aripiprazole is unlikely to have clinically significant interactions with drugs that are substrates for these isoenzymes.[3,4]

Aripiprazole + Oxcarbazepine

An isolated case describes priapism in a patient taking oxcarbazepine, aripiprazole and lithium.

Clinical evidence, mechanism, importance and management

A case report describes a 16-year old patient who developed painless priapism after oxcarbazepine (total daily dose of 600 mg increased to 900 mg) was added to his established treatment with lithium and aripiprazole. On discontinuing the oxcarbazepine, the patient experienced no further episodes of priapism. Priapism is a known adverse effect of aripiprazole, and it is not known if priapism occurred as an adverse reaction to this drug, or whether an interaction with oxcarbazepine or lithium was responsible.[1] This is an isolated case, and as such no general recommendations can be made.

1. Negin B, Murphy TK. Priapism associated with oxcarbazepine, aripiprazole, and lithium. *J Am Acad Child Adolesc Psychiatry* (2005) 44, 1223–4.

Aripiprazole + SSRIs or SNRIs

Fluoxetine and probably paroxetine may cause clinically significant increases in aripiprazole levels. The concurrent use of aripiprazole with SSRIs or venlafaxine has led to adverse effects such as neuroleptic malignant syndrome and extrapyramidal symptoms.

Clinical evidence, mechanism, importance and management

A study analysing routine samples sent for aripiprazole monitoring noted that the plasma levels of aripiprazole were 44% higher in 5 patients taking inhibitors of the cytochrome P450 isoenzyme CYP2D6, which included 2 patients taking **fluoxetine**. However, note that they also included levomepromazine in this group, which is not known to be a potent CYP2D6 inhibitor, and may therefore have reduced the true increase seen with **fluoxetine**. Further, in 6 patients taking **escitalopram** or **citalopram** (also CYP2D6 inhibitors, but generally considered to be weaker than **fluoxetine**) the plasma levels of aripiprazole were found to be 39% and 34% higher, respectively, when compared with patients taking aripiprazole alone.[1]

The manufacturers recommend that the dose of aripiprazole should be halved if CYP2D6 inhibitors are given.[2,3] The UK manufacturer suggests that weaker inhibitors of this isoenzyme would only be expected to cause modest increases in aripiprazole levels, and therefore no dose adjustment would expected to be required.[2]

Two case reports describing extrapyramidal effects in association with aripiprazole attribute this effect to an interaction with antidepressants. In the first case, a patient taking **venlafaxine**, trazodone and clonazepam developed parkinsonian symptoms a few days after starting to take aripiprazole 15 mg daily. Her symptoms resolved on stopping the aripiprazole. In the second case, a patient taking **sertraline** 200 mg daily developed akathisia after starting to take aripiprazole 10 mg daily. This did not respond to a reduction of aripiprazole dose, but gradually resolved when the aripiprazole was withdrawn. The authors attributed these effects to an interaction due to the low incidence of extrapyramidal adverse effects with aripiprazole alone.[4]

Neuroleptic malignant syndrome developed in a patient within 2 weeks of starting aripiprazole 30 mg daily and **fluoxetine** 20 mg daily. The patient had stopped taking the aripiprazole 2 days before admission, **fluoxetine** was stopped on admission, and he recovered within one week with symptomatic treatment. The authors suggested that **fluoxetine** may have increased the risk of this syndrome developing by raising aripiprazole levels.[5]

The concurrent use of aripiprazole and an SSRI can be useful, but it would be prudent to be alert for adverse effects (e.g. constipation, anxiety, insomnia). With **paroxetine** and **fluoxetine**, dose reductions should be considered. An interaction resulting in adverse effects, such as extrapyramidal symptoms, is not established.

Aripiprazole + Valproate

Valproate can modestly reduce aripiprazole levels.

Clinical evidence, mechanism, importance and management

Analysis of results from a routine therapeutic monitoring service found that valproate lowered the dose-adjusted serum level of aripiprazole by 24% in 9 patients.[1] Similarly, in a study in 6 healthy subjects, aripiprazole 30 mg daily for 5 weeks, with **valproate semisodium** (**divalproex sodium**) daily in doses to achieve a serum valproate levels of 50 to 125 mg/L, for weeks 3 to 5 of the study, decreased the maximum plasma concentrations of aripiprazole by 26%.[2] Aripiprazole and valproate share the same protein binding sites, and it was therefore considered likely that the valproate displaced bound aripiprazole leading to increased oral clearance. However, this change in valproate levels is not considered to be clinically significant, and aripiprazole dose adjustments are not expected to be necessary on concurrent use.

Barbiturates + Miscellaneous

Miconazole increases pentobarbital levels. The hypnotic effects of pentobarbital are reduced or abolished by the concurrent use of caffeine.

Clinical evidence, mechanism, importance and management

(a) Caffeine

In a placebo-controlled study in 34 patients, caffeine 250 mg and **pentobarbital** 100 mg were given together and alone. It was found that the hypnotic effects of **pentobarbital** were reduced in the presence of caffeine, and indistinguishable from those of placebo.[1] Caffeine stimulates the cerebral cortex and impairs sleep, whereas **pentobarbital** depresses the cortex and promotes sleep. These mutually opposing actions would seem to explain this interaction. This seems to be only direct study of this interaction, but it is well supported by common experience and the numerous studies of the properties of each of these compounds. Patients given barbiturate hypnotics should avoid caffeine-containing drinks (tea, coffee, cola drinks, etc.) or analgesics at or near bedtime if the hypnotic is to be effective.

(b) Miconazole

High-dose intravenous pentobarbital was given to 5 patients in intensive care to decrease intracranial pressure. When miconazole was also given, all patients had marked rises in plasma **pentobarbital** levels, and a 50 to 90% reduction in its total plasma clearance. This is thought to occur because miconazole inhibits the liver enzymes concerned with the metabolism of the barbiturate, thereby reducing its clearance from the body.[2] It would be prudent to monitor the effects of concurrent use to ensure that plasma barbiturate levels do not rise too high. Note that miconazole oral

gel can be absorbed in sufficient amounts to potentially interact and therefore some caution is also warranted with this product.

Benzodiazepines + Acetazolamide

Although acetazolamide can be used to treat acute mountain sickness at very high altitudes, a case report suggests that it may potentiate the respiratory depressant effects of benzodiazepines such as triazolam. Acetazolamide did not improve symptoms of sleep apnoea worsened by flurazepam.

Clinical evidence, mechanism, importance and management

A study in elderly subjects found that sleep apnoea worsened in 4 of 10 subjects given a single 30-mg dose of **flurazepam** at night. These 4 subjects were then pretreated with acetazolamide 500 mg twice daily for 3 days, as acetazolamide has been found to improve sleep apnoea. A further dose of **flurazepam** 30 mg was given on the fourth night.[1] Treatment with acetazolamide did not block the benzodiazepine-associated increase in sleep apnoea in these subjects, possibly because the acetazolamide treatment period was not long enough.[1]

Acetazolamide is sometimes used by climbers at very high altitudes as a prophylactic against acute mountain sickness. Benzodiazepines are used in this situation to treat insomnia, which is common at high altitude. Benzodiazepines are believed to depress breathing because they reduce the normal respiratory response to hypoxia. This was demonstrated by a Japanese climber in the Himalayas who took acetazolamide 500 mg daily and **triazolam** 500 micrograms, and then needed to be reminded to hyperventilate in order to relieve his hypoxia while returning from a climb. The acetazolamide did not prevent, and may possibly have increased, the central ventilatory depression of the **triazolam**, possibly by increasing its delivery to the brain. The authors of the report advise against taking these two drugs together at high altitudes,[2] thus confirming a previous warning about the risks of taking benzodiazepines at high altitude.[3]

1. Guilleminault C, Silvestri R, Mondini S, Coburn S. Aging and sleep apnea: action of benzodiazepine, acetazolamide, alcohol, and sleep deprivation in a healthy elderly group. *J Gerontol* (1984) 39, 655–61.

Benzodiazepines + Alosetron

In a study in 12 healthy subjects, alosetron 1 mg twice daily for 2 days had no significant effect on the pharmacokinetics of a single 1-mg dose of alprazolam. No increase in adverse effects was noted with the combination.[1] No alprazolam dose adjustment therefore seems necessary on concurrent use. Note that this study suggests that alosetron is unlikely to affect the pharmacokinetics of similarly metabolised benzodiazepines (e.g. midazolam, triazolam), but this needs confirmation.

1. D'Souza DL, Levasseur LM, Nezamis J, Robbins DK, Simms L, Koch KM. Effect of alosetron on the pharmacokinetics of alprazolam. *J Clin Pharmacol* (2001) 41, 452–4.

Benzodiazepines + Amiodarone

An isolated report describes clonazepam toxicity, which was attributed to the concurrent use of amiodarone. Amiodarone is predicted to inhibit the metabolism of midazolam, triazolam, and possibly alprazolam.

Clinical evidence, mechanism, importance and management

A 78-year-old man with congestive heart failure and coronary artery disease was taking furosemide, potassium, and calcium supplements, a multivitamin preparation, and amiodarone 200 mg daily for sustained ventricular tachycardia. Two months after **clonazepam** 500 micrograms at night was added to treat restless leg syndrome he developed slurred speech, confusion, difficulty in walking, dry mouth and urinary incontinence. This was interpreted as **clonazepam** toxicity. The problems cleared when the **clonazepam** was stopped. The authors of the report suggest that the amiodarone may have inhibited the oxidative metabolism of the **clonazepam** by the liver, thereby allowing it to accumulate. They also point out that this patient may have been more sensitive to these effects because of a degree of hypothyroidism caused by the amiodarone. Hypothyroidism is known to decrease the metabolism of drugs that undergo oxidative metabolism by the liver.[1] This is an unconfirmed and isolated case and therefore its general importance is unknown.

Amiodarone is a known inhibitor of the cytochrome P450 isoenzyme, by which a number of benzodiazepines are metabolised. The UK manufacturer of amiodarone reasonably predicts that it may raise the levels of **midazolam** and **triazolam**.[2] **Alprazolam** may be similarly affected. It would therefore seem prudent to be alert for evidence of increased and/or prolonged sedation if patients taking amiodarone are given these benzodiazepines.

2. Cordarone X (Amiodarone hydrochloride). Sanofi-Aventis. UK Summary of product characteristics, March 2009.

Benzodiazepines + Antacids

Although antacids can moderately change the rate of absorption of chlordiazepoxide, clorazepate and diazepam, no adverse interaction of clinical importance has been reported.

Clinical evidence

In a three-period study, 10 healthy subjects were given **clorazepate** 7.5 mg at night, with either water, with *Maalox* (**aluminium/magnesium hydroxide** mixture) 30 mL, or with *Maalox* 30 mL three times daily before meals. The mean steady-state plasma levels of the active metabolite of clorazepate, desmethyldiazepam, were not affected by *Maalox*, although they varied widely between individuals.[1] This is in line with another report,[2] but contrasts with a single-dose study, in which the peak plasma concentration of desmethyldiazepam was delayed and reduced by about one-third by the use of *Maalox*. The $AUC_{0\text{-}48}$ was reduced by about 10%.[3]

In another study the absorption of a single dose of **chlordiazepoxide** was delayed by *Maalox*, but the total amount of drug absorbed was not significantly affected.[4] Similar results have been found with **diazepam** and **aluminium hydroxide**-containing antacids (*Maalox* and *Gelusil*).[5] Another study found that 40 mL of **Aluminium Hydroxide Gel BP** and 30 mL of **sodium citrate** (0.3 mmol/L) marginally hastened the sedative effect of **diazepam** 10 mg when used as an oral premedication before minor surgery. **Magnesium Trisilicate Mixture BPC** 30 mL tended to delay sedation with **diazepam**.[6]

Mechanism

The delay in the absorption of chlordiazepoxide and diazepam is attributed to the effect of the antacid on gastric emptying. Clorazepate on the other hand is a prodrug, which needs acid conditions in the stomach for conversion by hydrolysis and decarboxylation to its active form. Antacids are presumed to inhibit this conversion by raising the pH of the stomach contents.[7]

Importance and management

Most of the reports describe single-dose studies, but what is known suggests that no adverse interaction of any clinical importance is likely if antacids are given with chlordiazepoxide, clorazepate or diazepam. Whether the delay in absorption has an undesirable effect in those who only take benzodiazepines during acute episodes of anxiety, and who need rapid relief is uncertain. Information about other benzodiazepines is lacking. However, no special precautions would be expected to be necessary.

Benzodiazepines + Antiepileptics; Miscellaneous

The use of benzodiazepines with antiepileptics is common and possibly accompanied by some changes in plasma levels, which are normally of limited clinical importance. Pharmacokinetic interactions have been reported between clobazam and felbamate, and clonazepam and lamotrigine.

Clinical evidence

(a) Felbamate

A retrospective study compared *N*-desmethylclobazam plasma level to dose ratios in patients taking **clobazam** and enzyme-inducing antiepileptics, without felbamate (group B, 28 patients) or with felbamate (group C, 16 patients). When compared with 22 patients (group A) receiving **clobazam** alone or with non-enzyme-inducing antiepileptics, the *N*-desmethylclobazam level to dose ratio of group B was increased twofold and the *N*-desmethylclobazam level to dose ratio of group C was increased fivefold,[1] suggesting that felbamate further increased the effect of enzyme-inducing antiepileptics on **clobazam** metabolism.

In a study in 18 healthy subjects, the pharmacokinetics of **clonazepam** 1 mg every 12 hours were not significantly altered by felbamate 1.2 g every 12 hours for 10 days.[2] No serious adverse reactions were reported.

(b) Lamotrigine

The plasma **clonazepam** levels in 4 of 8 patients fell by about 38% when they were also given lamotrigine.[3]

(c) Tiagabine

A single-dose study in healthy subjects did not find any clinically important pharmacodynamic or pharmacokinetic interactions between tiagabine and **triazolam**.[4]

Mechanism

Uncertain. It has been suggested that felbamate inhibits the clearance of *N*-desmethylclobazam.[1]

Importance and management

None of the interactions between the benzodiazepines and antiepileptics described here appear to be of major clinical importance, with the possible exception of the interaction between clobazam and felbamate. If these drugs are given be aware that additive sedative or other adverse effects may occur. There may also be a potential interaction between clonazepam and lamotrigine in some patients, but the clinical significance is not known.

Benzodiazepines and related drugs + Antimuscarinics

Atropine and hyoscine do not affect the absorption or the sedative effects of diazepam but atropine may slow the absorption of zopiclone.

Clinical evidence, mechanism, importance and management

(a) Diazepam

A study in 8 healthy subjects given a single 10-mg oral dose of diazepam found that serum diazepam levels were not significantly changed by the concurrent use of **atropine** 1 mg or **hyoscine hydrobromide** 1 mg. Furthermore, the sedative effects of diazepam were not altered.[1]

(b) Zopiclone

In 12 healthy subjects the absorption of a single 7.5-mg dose of zopiclone was reduced by intravenous **atropine** 600 micrograms. Mean plasma zopiclone levels at one hour were reduced from 22.7 nanograms/mL to 6.5 nanograms/mL and at 2 hours from 49.3 nanograms/mL to 31.9 nanograms/mL by **atropine**. This was presumably to be due to altered gut motility.[2] The clinical importance of these findings is not known.

Benzodiazepines and related drugs + Antipsychotics

Additive CNS depressant effects might be expected between antipsychotics and benzodiazepines or related drugs: sedation, respiratory depression and airways obstruction has been reported. In addition, hypotension, and rare cases of neuroleptic malignant syndrome have been reported in patients taking benzodiazepines and antipsychotics. The effects vary with different pairs, but the parenteral use of these drugs is frequent in the more severe cases. In one study the effect of lorazepam on psychomotor tests and memory was not affected by amisulpride.

Clinical evidence, mechanism, importance and management

A. Benzodiazepines

(a) Lorazepam

1. Amisulpride. A single-dose study in 18 healthy subjects found that amisulpride 50 mg or 200 mg did not potentiate or antagonise the effects of a single 2-mg dose of lorazepam on psychomotor performance or memory.[1]

2. Loxapine. A woman with a manic bipolar affective disorder was admitted to hospital and given lorazepam 2 mg with loxapine 25 mg. After 2 hours she was found to be lethargic with sonorous respirations, occasional episodes of apnoea and an irregular respiration as low as 4 breaths per minute. She was given oxygen and recovered spontaneously within 12 hours. She had experienced no previous problems with lorazepam, and had none when it was later given while she was taking perphenazine.[2] Two other cases have been reported where patients given intramuscular lorazepam 1 to 2 mg and oral loxapine 50 mg developed prolonged stupor, a significantly lowered respiration rate (8 breaths per minute), and in one case hypotension. Both showed signs of recovery within 3 to 5 hours and both had taken each of these drugs alone without problems.[3]

3. Promethazine. A case report describes a patient who developed neuroleptic malignant syndrome after treatment with promethazine and lorazepam. He had recently stopped taking haloperidol, trihexyphenidyl and chlorpromazine due to the development of extrapyramidal symptoms. The role of promethazine and lorazepam is unclear, but it was suggested that they had both reduced dopaminergic activity, and the lorazepam had additionally reduced cholinergic activity.[4]

4. Other antipsychotics. Hypotension, respiratory depression and/or sedation have been reported in patients given lorazepam and ‘clozapine’, (p.873) or ‘olanzapine’, (p.889).

(b) Other benzodiazepines

1. Alzheimer's disease deterioration. A study involving 224 patients diagnosed with probable Alzheimer's disease examined the effects of all prescribed drugs on the progression of the disease over a 12-month period. Overall, the 34 patients taking antipsychotic drugs and the 30 patients taking benzodiazepines or benzodiazepine-related drugs were more likely to have a faster rate of deterioration than those who were not taking these drugs (odds ratio 2.74 and 2.77, respectively). However, a higher risk of deterioration was observed in those who were taking both antipsychotic and benzodiazepines or benzodiazepine-related drugs (odds ratio 3.86). The decline in patients treated with antipsychotics and benzodiazepines appeared to be additive.[5]

2. Neuroleptic malignant syndrome. Three cases of neuroleptic malignant syndrome have been reported following the use of **diazepam** with **risperidone**; **clorazepate** with **zuclopenthixol**; and **clonazepam** with **tiapride**. In 2 cases this followed the abrupt withdrawal of long-term benzodiazepines. All 3 patients recovered, one without any treatment.[6] These reports are isolated and unexplained.

3. Obstruction of airways. A patient with catatonic schizophrenia was given intravenous **diazepam** 20 mg followed by intramuscular haloperidol 10 mg and **levomepromazine** 50 mg. Because of combative behaviour about 50 minutes later, he was given intravenous **flunitrazepam** 2 mg, and about 2 hours later another dose of both intravenous haloperidol 12 mg and **flunitrazepam** 5 mg. An hour after the last injection he became mildly cyanotic due to collapse of glossopharyngeal structures and excessive oral and nasal secretions, causing airways obstruction. Four other cases of airways obstruction associated with the combination of intramuscular **levomepromazine** in doses of 0.52 mg/kg or more and intravenous **flunitrazepam** or **diazepam** are also described. A subsequent review of all cases found that there were no cases of airways obstruction in patients who received haloperidol with either **levomepromazine** or a benzodiazepine. The interaction occurred immediately after the last intravenous injection in one patient and about 25 minutes after intramuscular **levomepromazine** but onset may be delayed up to 2 hours or more.[7]

B. Non-benzodiazepine hypnotics

(a) Zaleplon

A single 50-mg dose of **thioridazine** had no effect on the pharmacokinetics of zaleplon 20 mg, and the psychomotor tests showed only short-term additive effects lasting 1 to 4 hours.[8] These short-term CNS additive effects are small and unlikely to be clinically relevant, and so there would seem to be no reason for avoiding concurrent use.

(b) Zolpidem

Single-dose studies found that the pharmacokinetics of 20-mg doses of zolpidem were unaffected by 50 mg of **chlorpromazine**[9,10] or 2 mg of **haloperidol**.[9] The pharmacokinetics of both of these antipsychotics were unaffected by zolpidem, except that in one study the elimination half-life of **chlorpromazine** was increased from about 5 hours to 8 hours.[10] **Chlorpromazine** increased the sedative effects of zolpidem (as indicated by impaired performances of manual dexterity and Stroop's tests).[9,10] It seems likely that additive sedation will be seen with other sedative drugs.

(c) Zopiclone

No pharmacokinetic interaction was found when 12 healthy subjects were given a single 7.5-mg oral dose of zopiclone with **chlorpromazine** 50 mg. However, the overall performance in a number of psychomotor tests (including digit symbol substitution and simulated driving) was definitely impaired more by the combination of the drugs than by **chlorpromazine** alone. Zopiclone with **chlorpromazine** impaired memory and learning, and caused a marked impairment of the performance of the tests.[11] In practical terms this means that patients given **chlorpromazine** with zopiclone should be warned that drowsiness may persist the next day and they may be less able to drive or handle potentially hazardous machinery safely.

Benzodiazepines + Aprepitant

Aprepitant inhibits the metabolism of oral midazolam resulting in increased levels. Aprepitant appears to have less effect on intravenous midazolam. A few days after aprepitant treatment is stopped a transient slight reduction in midazolam plasma levels may occur due to induction of its metabolism. Alprazolam and triazolam are expected to be affected similarly. Fosaprepitant is a prodrug of aprepitant, and may therefore be expected to share its interactions.

Clinical evidence

In a randomised study, 16 healthy subjects took either aprepitant 125 mg on day one followed by 80 mg daily for 4 days, or 40 mg on day one followed by 25 mg daily for 4 days, with a single 2-mg oral dose of midazolam on days one and 5. The aprepitant 40/25 mg dosing schedule had no significant effect on the pharmacokinetics of midazolam. However, the aprepitant 125/80 mg dosing schedule increased the AUC of oral midazolam by 126% and 229% on days one and 5, respectively, and increased the maximum plasma levels of midazolam by 46% and 94% on days one and 5, respectively.[1]

In a randomised, placebo-controlled study, 24 healthy subjects were given aprepitant 125 mg on day one then 80 mg daily for a further 2 days. A single 2-mg intravenous dose of midazolam was given on days 4, 8 and 15. The 3-day aprepitant regimen increased midazolam levels slightly on day 4 (AUC increased by 25% and clearance reduced by 20%), decreased midazolam levels slightly on day 8 (AUC decreased by 19% and clearance increased by 24%) and had almost no effect by day 15.[2] Another study also found that a single 125-mg oral dose of aprepitant modestly increased the AUC of intravenous midazolam by 47%.[3]

Mechanism

Aprepitant is a moderate (dose-dependent) inhibitor of the cytochrome P450 isoenzyme CYP3A4 by which midazolam is metabolised; concurrent use therefore results in increased midazolam levels. There appears to be a greater pharmacokinetic effect on oral midazolam than on intravenous midazolam indicating that aprepitant affects intestinal as well as hepatic CYP3A4 activity. Aprepitant is also a mild inducer of CYP3A4;[2,4] however, the induction is transient, with a maximal effect 3 to 5 days after the end of the usual prescribed 3 days of treatment.

Importance and management

Based on the way midazolam interacts with similarly potent inhibitors of CYP3A4, aprepitant may be expected to increase the drowsiness and length of sedation and amnesia in patients given midazolam. Consider reducing the midazolam dose in patients given aprepitant and monitor the outcome of concurrent use carefully. The manufacturers note that the potential effects of increased levels of other benzodiazepines metabolised via CYP3A4, such as **alprazolam** and **triazolam**, should be considered if they are given with aprepitant. They also state that the effects of aprepitant on plasma levels of intravenously administered CYP3A4 substrates are expected to be less than the effects on orally administered substrates.[4,5] Fosaprepitant is a prodrug of aprepitant, and may therefore be expected to share its interactions; similar precautions are therefore warranted.

Benzodiazepines + Aspirin

The induction of anaesthesia with midazolam is more rapid in patients who have been pretreated with aspirin.

Clinical evidence

A study in patients about to undergo surgery found that pretreatment with aspirin 1 g (given as intravenous **lysine acetylsalicylate**) one minute before induction shortened the induction time with intravenous midazolam 300 micrograms/kg. Only 60% were 'asleep' within 3 minutes of receiving midazolam alone, but about 80% were 'asleep' within 3 minutes of receiving midazolam given after the aspirin pretreatment.[1]

Mechanism

Not understood. It has been suggested that aspirin increases the amount of free (and active) midazolam in the plasma because both drugs compete for the binding sites on the plasma albumins.[1,2]

Importance and management

Information is limited but what is known shows that the effects of midazolam are increased by aspirin, but the effects seem relatively modest, and, if the mechanism is correct, no greater effect would be expected on long-term concurrent use. Note also that regular aspirin use may increase the risk of bleeding during surgery, and in some situations this may justify avoidance of aspirin in the week before surgery.[3]

Benzodiazepines and related drugs + Azoles

Fluconazole, itraconazole and ketoconazole very markedly increase the plasma levels of midazolam and triazolam, thereby increasing and prolonging their sedative and amnesic effects. Voriconazole and posaconazole also markedly increase midazolam levels. Similar but smaller effects are seen with itraconazole or ketoconazole and alprazolam and with itraconazole and brotizolam. Even less effect is seen with itraconazole and etizolam. Fluconazole and voriconazole increase the levels of diazepam, but itraconazole has only a minor effect.
Ketoconazole or itraconazole cause modest increases in the levels of the non-benzodiazepine hypnotics, zolpidem, eszopiclone, and zopiclone.
No important interaction appears to occur between fluconazole and bromazepam or zolpidem; between itraconazole and estazolam, quazepam or temazepam; and probably between ketoconazole and chlordiazepoxide.

Clinical evidence

A. Benzodiazepines

(a) Alprazolam

1. Itraconazole. In a study, 10 healthy subjects were given a single 800-microgram dose of alprazolam before and after itraconazole 200 mg daily for 6 days. The itraconazole increased the AUC and the half-life of alprazolam nearly threefold, and psychomotor function was impaired.[1]

2. Ketoconazole. A study in healthy subjects found that ketoconazole 200 mg twice daily decreased the clearance of alprazolam 1 mg by about two-thirds, and prolonged its half-life fourfold; the maximum plasma levels only slightly increased, but the AUC increased almost fourfold.[2]

(b) Bromazepam

In a study in 12 healthy subjects, **fluconazole** 100 mg daily for 4 days had no effect on the pharmacokinetics or pharmacodynamics of oral or rectal bromazepam.[3]

(c) Brotizolam

In a placebo-controlled study, 10 healthy subjects were given **itraconazole** 200 mg daily for 4 days with a single 500-microgram dose of brotizolam given on day 4. **Itraconazole** increased the $AUC_{0\text{-}24}$ and maximum plasma levels of brotizolam by about 2.5-fold and 25%, respectively. The elimination half-life of brotizolam was also increased, from 4.51 hours to 23.27 hours, and sedation was increased.[4]

(d) Chlordiazepoxide

In 12 healthy subjects, **ketoconazole** 400 mg daily for 5 days decreased the clearance of chlordiazepoxide 600 micrograms/kg by 38%.[5]

(e) Diazepam

1. Fluconazole. A study in healthy subjects found that fluconazole 400 mg on the first day and 200 mg on the second day increased the AUC of a single 5-mg oral dose of diazepam 2.5-fold and prolonged the half-life from 31 hours to 73 hours.[6]

2. Itraconazole. In a study in 10 healthy subjects, itraconazole 200 mg daily for 4 days slightly increased the AUC of a single 5-mg oral dose of diazepam by about 15%, but there was no clinically significant interaction as determined by psychomotor performance tests.[7]

3. Voriconazole. A study in healthy subjects found that voriconazole 400 mg twice daily on the first day and 200 mg twice daily on the second day increased the AUC of a single 5-mg oral dose of diazepam 2.2-fold and prolonged the half-life from 31 hours to 61 hours.[6]

(f) Estazolam

A placebo-controlled study in 10 healthy subjects[8] found that **itraconazole** 100 mg daily for 7 days did not affect the pharmacokinetics or pharmacodynamics of a single 4-mg dose of estazolam given on day 4.

(g) Etizolam

A placebo-controlled study in healthy subjects found that **itraconazole** 100 mg twice daily for 7 days increased the AUC of a single 1-mg dose of etizolam given on day 6 by about 50%. The elimination half-life of etizolam was also increased, from 12 hours to 17.3 hours.[9]

(h) Midazolam

1. Fluconazole. A study in 12 healthy subjects found that fluconazole 400 mg on the first day and then 200 mg daily for 5 days reduced the clearance of a single 7.5-mg oral dose of midazolam by 51%, and increased the AUC of midazolam approximately 3.5-fold. It was found that the subjects could hardly be wakened during the first hour after taking the midazolam.[10] Another study found that a single 150-mg dose of fluconazole increased the plasma levels of a single 10-mg dose of midazolam by about 40%.[11] Yet another study found that the route of administration of fluconazole (i.e. whether oral or intravenous) made little or no difference to the pharmacodynamic effects of midazolam.[12] Fluconazole 400 mg initially and then 200 mg daily given by infusion over 30 minutes caused a fourfold increase in the plasma levels of midazolam in intensive care unit patients receiving midazolam infusions. The interaction was most marked in patients with renal failure.[13] These reports contrast with another, which found that a single 150-mg dose of fluconazole only slightly increased the effects of a single 10-mg dose of midazolam.[14]

2. Itraconazole. When 9 healthy subjects were given oral midazolam 7.5 mg, before and after taking itraconazole 200 mg daily for 4 days, the AUC of midazolam was increased about tenfold, the peak plasma levels were increased about threefold, and the half-life was prolonged, from 2.8 hours to 7.9 hours. The subjects could hardly be wakened during the first hour after taking the midazolam and most of them experienced amnesia lasting several hours.[15] A later study found that itraconazole 100 mg daily for 4 days increased the AUC of oral midazolam sixfold and increased its peak plasma levels 2.5-fold.[16] A further study found that itraconazole 200 mg daily for 4 days increased the AUC of midazolam 7.5 mg eightfold when the midazolam was taken on day 4, and 2.6-fold when the midazolam was taken on day 8.[17]

Another study confirmed the marked effect of itraconazole on oral midazolam, but found that the effects of bolus doses of intravenous midazolam were not increased to a clinically significant extent, although their results suggested that long-term, high-dose infusions of midazolam need to be titrated according to effect to avoid overdose.[10] The manufacturer of midazolam reports that itraconazole increased the plasma levels of intravenous midazolam two- to threefold and its terminal half-life was increased 2.4-fold.[18]

3. Ketoconazole. When 9 healthy subjects were given oral midazolam 7.5 mg before and after taking ketoconazole 400 mg daily for 4 days, the AUC of midazolam was increased almost 17-fold, its peak plasma levels were increased about fourfold, and its half-life was prolonged, from 2.8 hours to 8.7 hours. The subjects could hardly be wakened during the first hour after taking the midazolam and most of them experienced amnesia lasting several hours.[15] A study in healthy subjects found that 3 doses of oral ketoconazole 200 mg increased the AUC of a single 6-mg dose of oral midazolam 16-fold, but only increased the AUC of a single 2-mg dose of intravenous midazolam fivefold.[19] Another study found that the increase in the AUC of oral and intravenous midazolam was significantly greater after ketoconazole 400 mg for 7 days (15-fold and 4.2-fold, respectively) than after ketoconazole 200 mg daily for 7 days (11-fold and 3.4-fold, respectively).[20] Ketoconazole has been shown to reduce the metabolism of midazolam and greatly prolong its effects in further studies.[21,22]

4. Posaconazole. In a study in healthy subjects, posaconazole 200 mg daily for 10 days increased the AUC of intravenous midazolam 50 micrograms/kg by 83%.[23] In another study, oral posaconazole 200 mg or 400 mg twice daily for 7 days increased the AUC of intravenous midazolam 4.6-fold and 6.2-fold, respectively. Similarly, both doses of posaconazole increased the AUC of a single 2-mg oral dose of midazolam 4.5-fold. In addition, posaconazole 200 mg or 400 mg prolonged the mean terminal half-life of midazolam from about 3 to 4 hours to 8 to 10 hours.[23]

5. Voriconazole. A study in 10 healthy subjects found that voriconazole 400 mg twice daily on the first day and 200 mg twice daily on the second day affected the pharmacokinetics of both intravenous and oral midazolam. Voriconazole reduced the clearance of intravenous midazolam 50 micrograms/kg by 72% and increased its half-life from 2.8 hours to 8.3 hours. Voriconazole increased the maximum plasma level and AUC of a single 7.5-mg oral dose of midazolam by 3.8-fold and 10.3-fold, respectively. The psychomotor effects of oral midazolam were profoundly increased by voriconazole, but the effects of small intravenous doses of midazolam were only weakly increased. However, the authors suggested that high intravenous doses or long-term infusions might result in long-lasting hypnotic effects.[24]

(i) Quazepam

Ten healthy subjects were given **itraconazole** 50 mg twice daily or placebo for 14 days, with a single 20-mg dose of quazepam on day 4. **Itraconazole** did not affect the pharmacokinetics of quazepam, but the maximum plasma level and AUC of its two active metabolites, 2-oxoquazepam and N-desalkyl-2-oxoquazepam were decreased. However, psychomotor tests were not affected by **itraconazole**.[25]

(j) Temazepam

In a study, 10 healthy subjects were given **itraconazole** 200 mg daily for 4 days, with a single 20-mg dose of temazepam on day 4. A very small increase in the temazepam AUC was seen, but the psychomotor tests carried out were unchanged.[26]

(k) Triazolam

1. Fluconazole. Eight healthy subjects were given fluconazole or a placebo daily for 4 days, with a single 250-microgram dose of oral triazolam on day 4. The AUC of triazolam was increased 1.6-fold, 2.1-fold, and 4.4-fold by 50 mg, 100 mg, and 200 mg fluconazole, respectively, and the maximum plasma triazolam levels were more than doubled by the 200-mg dose of fluconazole. The 100- and 200-mg doses of fluconazole both produced significant changes in the psychomotor tests of triazolam, but the 50-mg dose did not.[27]

2. Itraconazole. In a study in 9 healthy subjects, the AUC of a single 250-microgram dose of triazolam was increased about 28-fold by itraconazole 200 mg daily for 4 days. Peak plasma levels were increased threefold. Marked changes in psychomotor and other responses were also seen. The subjects had amnesia and were still very tired and confused as long as 17 hours after taking the triazolam.[28] Another study found that the interaction persists for several days after taking the itraconazole.[29]

3. Ketoconazole. A study in healthy subjects found that when they were given triazolam 125 micrograms, after ketoconazole 200 mg taken 17 hours and 1 hour earlier, the triazolam half-life was prolonged (from 4 hours to almost 18 hours in one subject) and the clearance was increased ninefold. Pharmacodynamic testing found an increase in the impairment of a digit-symbol substitution test, and there were increased effects on EEG beta activity.[30] In another study, the AUC of a single 250-microgram dose of triazolam was increased about 23-fold by ketoconazole 400 mg daily for 4 days. Peak plasma levels were increased threefold. Marked changes in psychomotor and other responses were seen. The subjects had amnesia and were still very tired and confused as long as 17 hours after taking the triazolam.[28] A further study similarly found that ketoconazole inhibited the metabolism of triazolam leading to an increase in its sedative effects.[31]

B. Non-benzodiazepine hypnotics

(a) Zolpidem

1. Fluconazole. In a placebo-controlled study in healthy subjects fluconazole 100 mg twice daily for 2 days had no significant effect on the pharmacokinetics of a single 5-mg dose of zolpidem given after the third dose of fluconazole.[32]

2. Itraconazole. In a placebo-controlled study, 10 healthy subjects were given itraconazole 200 mg daily for 4 days with a single 10-mg oral dose of zolpidem on day 4. The mean peak plasma levels of the zolpidem were increased by 10.5% and the AUC was increased by 34%, but the performance of a number of psychomotor tests (digit symbol substitution, critical flicker fusion, subjective drowsiness, postural sway) remained unaltered.[33] Another study similarly found that itraconazole did not interact with zolpidem to a clinically significant extent.[32]

3. Ketoconazole. A study in 12 healthy subjects found that ketoconazole 200 mg twice daily for 2 days increased the AUC of a single 5-mg oral dose of zolpidem by 70% and the subjects were more sedated, as shown by the digit symbol substitution test.[32]

4. Voriconazole. In a study in 10 healthy subjects, pretreatment with voriconazole 400 mg twice daily for one day and then 200 mg twice daily for the second day increased the AUC of a single 10-mg oral dose of zolpidem by 50%: its half-life was prolonged from 3.2 hours to 4.1 hours. Voriconazole appeared to increase drowsiness in the immediate period following administration of zolpidem, but no statistically significant differences in pharmacodynamic variables were seen.[34]

(b) Zopiclone or Eszopiclone

1. Itraconazole. In a placebo-controlled study, 10 healthy subjects were given itraconazole 200 mg daily for 4 days with a single 7.5-mg oral dose of zopiclone on day 4. Itraconazole increased the maximum plasma levels of zopiclone by 29% (from 49 to 63 nanograms/mL), increased its AUC by 73%, and prolonged its half-life from 5 hours to 7 hours. Despite these increases, there were no statistical or clinical differences between the performance of the psychomotor tests carried out during the placebo and itraconazole phases of the study.[35]

2. Ketoconazole. In a multiple-dose, crossover study in 18 healthy subjects ketoconazole 400 mg increased the AUC of eszopiclone 3 mg 2.2-fold and increased its maximum plasma level by 40%. The AUC of ketoconazole was decreased by 12% with concurrent eszopiclone, but this was not considered to be clinically significant.[36]

Mechanism

Itraconazole, ketoconazole, voriconazole and to a lesser extent fluconazole and posaconazole are inhibitors of the cytochrome P450 isoenzyme CYP3A4. The benzodiazepines and zopiclone and zolpidem are, to varying degrees, metabolised by CYP3A4, with the extent of the interaction related to how significant CYP3A4 is in their metabolism and how potent a CYP3A4 inhibitor the azole is. So, for example midazolam, which is predominantly metabolised by CYP3A4 is greatly affected by potent inhibitors (e.g. itraconazole), whereas CYP3A4 is not a significant route in the metabolism of temazepam, so it is only slightly affected. Other isoenzymes are also involved in the metabolism of zolpidem, and to some extent zopiclone, so they are only moderately affected by CYP3A4 inhibitors. Similarly, diazepam is extensively metabolised by CYP2C19 and also CYP3A4, and so itraconazole has only a minor effect; whereas

fluconazole and voriconazole, which inhibit both CYP2C19 and CYP3A4, can significantly decrease the elimination of diazepam.

The azoles inhibit CYP3A4 in the liver (hence intravenous benzodiazepines can be affected) but studies have also suggested that ketoconazole inhibits the metabolism of midazolam[19,21] and triazolam[31] by CYP3A4 in the gut wall, which explains why oral benzodiazepines are more affected than intravenous benzodiazepines.

Ketoconazole appears to partially inhibit the oxidation of chlordiazepoxide by the liver.[5]

Importance and management

The interactions between midazolam or triazolam and itraconazole or ketoconazole are established and clinically important. In very broad terms the dose of midazolam would need to be reduced by about 75% or more in the presence of these antifungals to avoid excessive sedation, and even then the effects would still be expected to be prolonged. Unless appropriate precautions are taken (very reduced doses with careful monitoring and management) these interactions can be dangerous; most manufacturers contraindicate the concurrent use of oral midazolam or triazolam with itraconazole or ketoconazole. Patients taking these azoles should be warned about the likelihood of increased and prolonged sedation and advised not to drive (for example) after receiving midazolam until completely recovered; one study found that patients are not likely to be capable of tasks such as driving for at least 6 hours after the dose of the benzodiazepine,[10] but it could be substantially longer especially after multiple doses of these azoles. There is some evidence that bolus doses of intravenous midazolam given in the presence of itraconazole or fluconazole are not increased to a clinically significant extent, and normal doses can be used.[16] However, where high doses of intravenous midazolam are used long term (e.g. during intensive care treatment) it has been suggested that the dose will need to be titrated to avoid long-lasting hypnotic effects.[10] These precautions appear to be equally applicable to voriconazole. The manufacturer of **miconazole** oral gel also contraindicates triazolam and oral midazolam.[37] This is probably because a large proportion of miconazole oral gel (both prescription and non-prescription doses) may be swallowed and therefore adequate systemic absorption may occur to produce an interaction.

Fluconazole interacts less significantly but even so, the midazolam or triazolam dose probably needs to be reduced, possibly by as much as half. Similarly, posaconazole may also increase midazolam levels and dose adjustments may be required.

The effects of alprazolam and brotizolam are increased and prolonged by ketoconazole and itraconazole, but the extent of this is less than that seen with midazolam or triazolam. However, dose reductions may still be necessary; most manufacturers suggest caution, but a few have contraindicated the concurrent use of these azoles and benzodiazepines. Alprazolam and brotizolam should also be used with caution with oral miconazole.[37]

Diazepam, in single doses, is not significantly affected by itraconazole, however, both fluconazole and voriconazole considerably increase exposure to diazepam and a dose reduction may be required. Zopiclone or eszopiclone are moderately affected by itraconazole and ketoconazole and it may be necessary to reduce the dose.

The effects of itraconazole on etizolam, quazepam, temazepam or zolpidem, ketoconazole on chlordiazepoxide or zolpidem, and voriconazole on zolpidem are small and seem unlikely to be clinically significant in most patients.

Benzodiazepines + Beta blockers

Only small and clinically unimportant pharmacokinetic interactions occur between most benzodiazepines and beta blockers, but there is limited evidence that some psychomotor tests may possibly be impaired in patients taking benzodiazepines combined with beta blockers.

Clinical evidence, mechanism, importance and management

No significant *pharmacokinetic* interactions were reported to occur between:

- **alprazolam** and **propranolol**[1]
- **clorazepate** and **propranolol**[2]
- **diazepam** and **atenolol**[3] or **propranolol**[3]
- **lorazepam** and **metoprolol**[4] or **propranolol**[1]
- **oxazepam** and **labetalol**[5] or **propranolol**.[5]

Moderate changes, which seem unlikely to be clinically significant, were found between:

- **diazepam** and **propranolol** (diazepam clearance reduced by 17%)[1] or **metoprolol** (diazepam clearance reduced by 18%,[6] AUC increased by 25%[3])
- **bromazepam** and **metoprolol** (bromazepam AUC increased by 35%)[4] or **propranolol** (bromazepam half-life increased by 22%).[7]

However, studies of psychomotor performance have shown that simple reaction times with **oxazepam** given with either **propranolol** or **labetalol** are increased,[5] and those taking **diazepam** and **metoprolol** have a reduced kinetic visual acuity,[3,8] which is related to driving ability.[9] Moreover, choice reaction times at 2 hours were also found to be lengthened when taking **diazepam** and **metoprolol**, **propranolol** or **atenolol**, but at 8 hours they only persisted with **diazepam** and **metoprolol**.[8]

Information about interactions between the benzodiazepines and beta blockers is very limited indeed. The current evidence does not seem to justify any additional caution, but bear the possibility of an interaction in mind in case of an unexpected response to treatment.

Benzodiazepines + Buspirone

No adverse interaction appears to occur if buspirone is given with alprazolam, flurazepam or triazolam. When buspirone is given with diazepam the adverse effects appear to be mild and short-lived.

Clinical evidence, mechanism, importance and management

In 12 healthy subjects, buspirone 10 mg every 8 hours increased the maximum plasma levels and AUC of **alprazolam** 1 mg every 8 hours by 7% and 8%, respectively. The maximum plasma levels of buspirone were not altered, but the AUC of buspirone was increased by 29%. However, these changes were within the normal pharmacokinetic variability of these drugs, and no unexpected adverse effects were seen.[1]

In 12 healthy subjects given **diazepam** 5 mg daily for 22 days, buspirone 15 mg every 8 hours for 12 days had no effect on the plasma levels of **diazepam**, but the levels of the metabolite nordiazepam were raised by about 20%. Concurrent use resulted in some mild adverse effects (headache, nausea, dizziness) in all subjects, and in two cases muscle twitching was seen. These symptoms subsided after a few days.[2]

The concurrent use of buspirone with either **flurazepam** or **triazolam** did not appear to prolong or intensify the sedative effects of either benzodiazepine.[3]

There would seem to be no reason for avoiding the concurrent use of these benzodiazepines and buspirone.

Benzodiazepines and related drugs + Caffeine

Caffeine appears to antagonise the effects of the benzodiazepines (mainly sedative effects, but possibly also anxiolytic effects). The effects of zopiclone may be similarly antagonised.

Clinical evidence

(a) Benzodiazepines

In a study in healthy subjects, a single 250-mg or 500-mg dose of caffeine (added to decaffeinated coffee) counteracted the drowsiness and mental slowness induced by a single 10- to 20-mg dose of **diazepam**.[1] The same or a similar study has been reported elsewhere.[2] Conversely, in a study in 6 healthy subjects, the concurrent use of caffeine 6 mg/kg and **diazepam** 300 micrograms/kg did not antagonise the effects of either drug; however, caffeine caused a minor 22% reduction in **diazepam** levels.[3] In one study the sedative effects of **midazolam**[4] were moderately antagonised by caffeine 250 mg but not 125 mg, and there is also some evidence to suggest that caffeine and **clonazepam**[5] or **triazolam**[6] have mutually opposing effects.

No pharmacokinetic interaction appears to occur between caffeine and **midazolam**[7] or **alprazolam**.[8]

(b) Non-benzodiazepine hypnotics

Zopiclone 7.5 mg appears to counter the stimulant effects of **caffeine** 300 mg more easily than **caffeine** counters the sedative effects of **zopiclone**.[6] In one study, no pharmacokinetic interaction occurred between **zolpidem** 10 mg and **caffeine** 300 mg (added to decaffeinated coffee), and the hypnotic effects of **zolpidem** were unchanged.[9] However, a placebo-controlled, crossover study in 12 healthy subjects found that **caffeine** 250 mg and 500 mg reversed the pharmacodynamic effects (such as sedation, reduced tapping speed, reaction time) caused by **zolpidem** 7.5 mg. Even though the pharmacodynamic effects of **zolpidem** were reduced by **caffeine**, the AUC of **zolpidem** was *increased* by 41% by **caffeine** 500 mg, when compared with placebo.[10]

Mechanism

Uncertain. One suggestion is that caffeine can block adenosine receptors, leading to CNS stimulation, which would antagonise the CNS depressant effects of the benzodiazepines.[11] Another suggestion is that the stimulant effects of caffeine and the sedative effects of benzodiazepines are simply antagonistic.

Importance and management

The evidence suggests that caffeine, particularly at higher doses, at least partially reduces the sedative and performance-impairing effects of benzodiazepines and related hypnotics. This would appear to be a disadvantage at night, but may possibly be useful the next morning, although caffeine should not be considered an antidote to the residual effects of these hypnotics. The extent to which caffeine reduces the anxiolytic effects of the benzodiazepines remains uncertain (it needs assessment), but be alert for reduced benzodiazepine effects if both are used.

Benzodiazepines + Calcium-channel blockers

Of the calcium-channel blockers, diltiazem and verapamil are known to inhibit CYP3A4, the route by which benzodiazepines such as midazolam and triazolam are metabolised. Increased effects, such as sedation, which have been marked in some cases, have been seen in patients given these drugs. Alprazolam would be expected to interact similarly. There appear to be no clinically significant interactions between other calcium-channel blockers and benzodiazepines.

Clinical evidence

(a) Diazepam

1. Diltiazem. In 6 healthy subjects, the concurrent use of single doses of diazepam 5 mg and diltiazem 60 mg did not significantly affect the plasma levels of either drug.[1] In another study, poor and extensive metabolisers of the cytochrome P450 isoenzyme CYP2C19 (that is, those lacking or deficient in this isoenzyme, and those with normal levels of this isoenzyme, respectively) were given diltiazem 200 mg daily for 3 days before and 7 days after a single 2-mg dose of diazepam. Diltiazem increased the AUC of diazepam by 25% in both poor and extensive metabolisers, when compared with placebo; however, the half-life of diazepam increased from 46 hours to 65 hours in extensive metabolisers and from 77 hours to 104 hours in poor metabolisers. The clinical effects of these pharmacokinetic changes were not assessed.[2]

2. Felodipine. In 12 healthy subjects, felodipine 10 mg daily for 12 days did not affect the pharmacokinetics of a 10-mg intravenous dose of diazepam, but the AUC and peak plasma levels of the diazepam metabolite, desmethyldiazepam, were raised by 14% and 16%, respectively.[3]

3. Nimodipine. In 24 healthy, elderly subjects the plasma levels of diazepam 10 mg daily and nimodipine 30 mg three times daily were unaffected by concurrent use, and no clinically relevant changes in haemodynamics, ECG recordings, clinical chemistry or haematology occurred.[4]

(b) Midazolam

1. Diltiazem. After taking diltiazem 60 mg three times daily for 2 days, 9 healthy female subjects were given midazolam 15 mg orally. The AUC of midazolam was increased fourfold, the maximum plasma levels doubled, and the half-life increased by 49%. It was almost impossible for the subjects to stay awake for 90 minutes after taking the midazolam. They suffered several hours of amnesia and there was a marked decrease in the performance of pharmacodynamic tests (digit symbol substitution, Maddox wing test).[5] Diltiazem 60 mg, given to 15 patients 2 hours before induction of anaesthesia with midazolam and alfentanil, increased the AUC and half-life of midazolam by 15% and 43%, respectively. Tracheal extubation was performed on average 2.5 hours later, when compared with placebo.[6]

2. Lercanidipine. Midazolam appears to increase the absorption of lercanidipine by 40%.[7] The clinical relevance of this interaction is as yet unclear.

3. Nitrendipine. A study in 9 healthy subjects found that the pharmacokinetics and pharmacodynamics of midazolam were unaffected by a single 20-mg dose of nitrendipine.[8]

4. Verapamil. After taking verapamil 80 mg three times daily for 2 days, 9 healthy female subjects were given midazolam 15 mg orally. The AUC of the midazolam was increased threefold, the maximum plasma levels were doubled, and the half-life increased by 41%. It was almost impossible for the subjects to stay awake for 90 minutes after taking the midazolam. They suffered several hours of amnesia and there was a marked decrease in the performance of pharmacodynamic tests (digit symbol substitution, Maddox wing test).[5] Another study found that verapamil 240 mg daily for 7 days decreased the oral clearance of midazolam fourfold and the systemic clearance was decreased by about 60%.[9]

(c) Temazepam

In 16 healthy insomniacs, **diltiazem** 40 mg had little or no effect on the hypnotic effects of temazepam.[10]

(d) Triazolam

1. Diltiazem. A study in 7 healthy subjects found that diltiazem 60 mg three times daily for 3 days increased the AUC of a single 250-microgram dose of triazolam 2.3-fold and almost doubled its peak plasma levels. Pharmacodynamic tests showed an increase in the sedative effects of triazolam.[11] Another study in 10 healthy subjects found that diltiazem 60 mg three times daily for 2 days increased the AUC of a single 250-microgram dose of triazolam 3.4-fold, and approximately doubled its maximum plasma level and half-life. The pharmacodynamic changes were briefly described as profound and prolonged.[12] In contrast, in another study, diltiazem 40 mg was found to have little or no effect on the hypnotic effects of triazolam in 16 healthy insomniacs.[10]

2. Isradipine. In 9 healthy subjects, isradipine 5 mg daily reduced the AUC of a single 250-microgram dose of triazolam by 20%, but no difference in the pharmacodynamic effects of triazolam were seen.[13]

Mechanism

The evidence suggests that diltiazem and verapamil inhibit the metabolism of midazolam and triazolam, by the cytochrome P450 isoenzyme CYP3A4, leading to increased plasma levels and increased effects. It appears that the intestine is the major site of the interaction between midazolam and verapamil.[9]

Importance and management

The interactions between midazolam and diltiazem or verapamil are established and clinically important. The authors of one report say that patients taking either diltiazem or verapamil are probably incapable of doing skilled tasks (e.g. car driving) for up to 6 hours after taking midazolam 15 mg, and possibly even after 8 to 10 hours. They suggest that the usual dose of midazolam should be reduced by at least 50% to avoid unnecessarily deep sleep and prolonged hypnosis, and they also point out that as the half-life of the midazolam is prolonged, the effects will persist regardless of the dose.[5] The effects are not so marked with intravenous midazolam, but the elimination of midazolam is still reduced and postoperative recovery may be delayed.[6] Similar precautions are likely to be needed for triazolam with diltiazem, and the interaction is also predicted to occur with triazolam and verapamil.[12] As **alprazolam** is also metabolised by CYP3A4, diltiazem and verapamil would also be expected to increase its levels; however, there do not appear to be any clinical reports of an interaction.

No special precautions appear to be necessary when other calcium-channel blockers are given with a benzodiazepine.

Benzodiazepines and related drugs + Carbamazepine

The use of benzodiazepines with carbamazepine is common, and some evidence suggests that the effects of the benzodiazepines are sometimes reduced. Levels of alprazolam were reduced and levels of midazolam were markedly reduced and its effects almost abolished by carbamazepine. Single-dose studies have shown that the sedative effects of zopiclone and carbamazepine are additive; however it has been predicted that, when taken long-term, carbamazepine might reduce the effects of zopiclone.

Clinical evidence

A. Benzodiazepines

(a) Alprazolam

In a placebo-controlled, crossover study in 7 healthy subjects, carbamazepine 100 mg three times daily for 10 days increased the apparent oral clearance of a single 800-microgram dose of alprazolam 2.4-fold and reduced the elimination half-life from about 17 hours to 8 hours.[1] The plasma alprazolam levels of a patient with atypical bipolar disorder and panic attacks, taking alprazolam 7.5 mg daily, were reduced by more than 50% (from 43 to 19.3 nanograms/mL) when carbamazepine was given. This was accompanied by a deterioration in his clinical condition, which was managed with haloperidol.[2]

(b) Clobazam

A study in patients with epilepsy found that carbamazepine reduces the plasma levels of clobazam and increases the levels of *N*-desmethylclobazam (the principal metabolite).[3] Similar results are described in other studies in healthy subjects and patients with epilepsy taking clobazam and carbamazepine.[4,5]

A 66-year-old man taking carbamazepine and topiramate experienced fatigue, ataxia, impairment of gait and clumsiness while taking clobazam 10 mg daily. His symptoms resolved when the clobazam was stopped. When he was later given carbamazepine, topiramate, and clobazam 20 mg daily his carbamazepine level rose from 36.8 micromol/L to 41.9 micromol/L. Five days after the clobazam was stopped the carbamazepine level had returned to approximately the pre-clobazam level (35.5 micromol/L).[6] However, another study in 15 patients with epilepsy taking carbamazepine alone and another 7 patients taking carbamazepine with clobazam, found that carbamazepine levels were similar in both groups, despite patients receiving monotherapy taking a significantly lower dose of carbamazepine, but levels of carbamazepine metabolites, including the active carbamazepine-10,11-epoxide, were higher in those also taking clobazam. It was suggested that clobazam increased the metabolism of carbamazepine by about 50%.[7]

(c) Clonazepam

Clonazepam, in slowly increasing doses up to a maximum of 4 to 6 mg/day given over a 6-week period, had no effect on carbamazepine serum levels. Some patients were also taking phenobarbital.[8] A study in 7 healthy subjects found that carbamazepine 200 mg daily given over a 3-week period reduced the plasma levels of clonazepam 1 mg daily from a range of 4 to 7 nanograms/mL down to 2.5 to 4 nanograms/mL, and reduced the half-life of clonazepam by about one-third.[9] A retrospective analysis of this interaction in 183 patients found that clonazepam clearance was increased by 22% and carbamazepine clearance was decreased by 21% during concurrent use.[10]

(d) Diazepam

A study found that the plasma clearance of a single 10-mg intravenous dose of diazepam was threefold greater, and the half-life shorter in a group of 9 patients with epilepsy when compared with 6 healthy subjects. Seven of the patients with epilepsy were taking carbamazepine.[11]

(e) Etizolam

In healthy subjects, carbamazepine 200 mg daily for 6 days decreased the maximum plasma level and AUC of a single 1-mg dose of etizolam by about 20% and 42%, respectively. The elimination half-life was reduced from 11 hours to about 7 hours.[12]

(f) Midazolam

The pharmacokinetics and pharmacodynamics of a single 15-mg oral dose of midazolam were studied in 6 patients with epilepsy taking either carbamazepine, phenytoin or both drugs together, and in 7 control subjects not taking either antiepileptic. The AUC of midazolam in the patients with epilepsy was reduced to 6%, and the peak plasma levels to 7% of the value in the control subjects. The pharmacodynamic effects of the midazolam (subjective drowsiness, body sway with eyes closed and open, as well as more formal tests) were also reduced. Most of the patients did not notice any effects from taking midazolam, while the control subjects were clearly sedated for 2 to 4 hours, and also experienced amnesia after taking the midazolam.[13]

B. Non-benzodiazepine hypnotics

A crossover study in 12 healthy subjects given single oral doses of **zopiclone** 7.5 mg and carbamazepine 600 mg found only minor changes in the plasma levels of both drugs. **Zopiclone** levels were higher and carbamazepine levels slightly lower. Psychomotor tests confirmed that both drugs had sedative effects, which were additive, and in a simulated driving test it was found that co-ordination was impaired and reaction times prolonged.[14]

Mechanism

Alprazolam and midazolam are both metabolised by the cytochrome P450 isoenzyme CYP3A4, of which carbamazepine is a known inducer. Concurrent use therefore increases the metabolism of these benzodiazepines and decreases their levels.

Importance and management

The interaction between carbamazepine and midazolam appears to be of greatest clinical significance. Much larger doses of midazolam are likely to be required in the presence of carbamazepine, or an alternative sedative may be needed. **Triazolam** is predicted to interact like midazolam.[13] Alprazolam and etizolam interact similarly, but to a lesser extent. The dose of these drugs may also need to be increased to ensure adequate serum levels.

One small study[11] suggests that enzyme-inducing antiepileptic drugs including carbamazepine may increase the clearance of diazepam; however, the clinical relevance of this does not appear to have been assessed. Nevertheless, it would seem prudent to monitor concurrent use for reduced efficacy.

As *N*-desmethylclobazam retains some of the activity of clobazam the effects of carbamazepine on clobazam metabolism probably have little clinical significance. In addition, the case of carbamazepine toxicity appears to be isolated and is therefore probably of limited importance.

The pharmacokinetic changes seen with clonazepam seem likely to be too small to be clinically significant, but this needs confirmation.

Note that carbamazepine is also metabolised via CYP3A4 and it appears that some benzodiazepines such as clonazepam, which share the same metabolic pathway, may interfere with the metabolism of carbamazepine. However, the effects are small, and unlikely to be of clinical relevance in most patients.

The evidence for an interaction between zopiclone and carbamazepine is slim, and the effects of long-term use are unclear. Carbamazepine is a strong inducer of CYP3A4 (by which zopiclone is metabolised) and it has been predicted that the effect of long-term carbamazepine treatment might be a reduction in zopiclone plasma levels and hypnotic effects.[15] It would seem prudent to be alert for the need to increase the zopiclone dose in patients taking carbamazepine. More study of this potential interaction is needed.

Benzodiazepines + Ciclosporin

No pharmacokinetic interaction appears to occur between intravenous midazolam and ciclosporin.

Clinical evidence, mechanism, importance and management

In a study in 9 transplant patients taking ciclosporin, the pharmacokinetics of a single 75-microgram/kg dose of intravenous midazolam did not differ from those of historical values in healthy subjects. In addition, the length of time of midazolam sedation did not differ from that expected. Midazolam did not appear to alter ciclosporin levels in these patients.[1] These findings suggest that there is no pharmacokinetic interaction between intravenous midazolam and oral ciclosporin. However, it might be prudent to confirm this with oral midazolam.

1. Li G, Treiber G, Meinshausen J, Wolf J, Werringloer J, Klotz U. Is cyclosporin A an inhibitor of drug metabolism? *Br J Clin Pharmacol* (1990) 30, 71–7.

Benzodiazepines + Corticosteroids

The metabolism of midazolam may possibly be increased in patients receiving long-term treatment with corticosteroids.

Clinical evidence, mechanism, importance and management

Intravenous **midazolam** 200 micrograms/kg was given to 8 patients receiving long-term treatment with corticosteroids (6 taking **prednisolone** 2.5 mg to 15 mg daily; 1 taking **betamethasone** 0.5 mg daily; one taking **methylprednisolone** 48 mg daily) and to 10 other patients not taking corticosteroids. In the patients taking corticosteroids the AUC of **midazolam** was decreased and the clearance increased, when compared with the patients not taking corticosteroids; however the differences were not statistically significant. The onset of anaesthesia between the two groups was also not notably different. It was suggested that the trend towards increased **midazolam** metabolism might be due to induction of the cytochrome P450 isoenzyme CYP3A4 and/or UDP-glucuronosyltransferase. Although the results with intravenous midazolam appeared not to be clinically significant, the authors suggested that the metabolism of oral **midazolam** might possibly be more markedly affected.[1] Other benzodiazepines metabolised in a similar way to midazolam (e.g. **alprazolam**, **triazolam**) may be similarly affected. However, further study is needed to establish if any effect is clinically relevant.

Benzodiazepines + Dexamfetamine

Dexamfetamine reverses the sedative effects and some of the memory-impairing effects of triazolam. Alprazolam attenuates the behavioural effects of dexamfetamine, but oxazepam appears to have no effect on dexamfetamine pharmacodynamics.

Clinical evidence, mechanism, importance and management

A placebo-controlled study in 20 healthy subjects found that a single 20-mg/70 kg dose of dexamfetamine sulfate reversed the sedative effects of a single 250-microgram/70 kg dose of **triazolam**. The study also found that dexamfetamine selectively reversed some of the memory-impairing effects of **triazolam**.[1] Similar results were reported in a related study.[2]

In a study, 6 healthy subjects were trained to discriminate between placebo and dexamfetamine 15 mg. Pretreatment with single 500-microgram doses of **alprazolam** significantly attenuated the discriminative-stimulus effects of dexamfetamine, and some of the self-reported drug effects.[3] A further study in 6 healthy subjects found that **oxazepam** 20 mg was ineffective at modulating the discriminative-stimulus or subject-rated effects of dexamfetamine.[4]

It is thought that the behavioural effects of dexamfetamine are due to increased synaptic dopamine levels, which are under the inhibitory control of GABA systems, whereas benzodiazepines are $GABA_A$ receptor positive modulators. However, it appears that benzodiazepines differ in their ability to affect the behavioural effects of dexamfetamine.[3,4]

Benzodiazepines + Disulfiram

The plasma levels of chlordiazepoxide, diazepam and possibly temazepam are increased by the use of disulfiram and some patients may experience increased drowsiness. Alprazolam, oxazepam and lorazepam appear to be either not affected, or only minimally affected, by disulfiram. The intensity of the disulfiram-alcohol reaction may possibly be decreased by diazepam.

Clinical evidence

A man taking disulfiram 200 mg daily developed confusion, drowsiness, slurred speech and an unsteady gait within a few days of starting to take **temazepam** 20 mg at night. This was interpreted as **temazepam** toxicity. The symptoms disappeared when both drugs were stopped.[1]

After taking disulfiram 500 mg daily for 14 to 16 days, the median plasma clearance of single doses of **chlordiazepoxide** and **diazepam** were reduced by 54% and 41%, respectively, and the half-lives were increased by 84% and 37%, respectively, although there was considerable interindividual variation. The plasma levels of **chlordiazepoxide** were approximately doubled. **Oxazepam** was also given after the use of disulfiram, but changes in **oxazepam** pharmacokinetics were minimal. There was no difference in the interaction between alcoholic subjects (without hepatic cirrhosis) and healthy subjects.[2] Other studies have found that the pharmacokinetics of **lorazepam**[3] and **alprazolam**[4] were unaffected by disulfiram.

It has been reported that the intensity of the disulfiram-alcohol reaction may be decreased by **diazepam**.[5]

Mechanism

Disulfiram inhibits the initial metabolism (*N*-demethylation and oxidation) of chlordiazepoxide and diazepam by the liver so that an alternative but slower metabolic pathway is used. This results in the accumulation of these benzodiazepines in the body. However, alprazolam is metabolised by hepatic microsomal oxidation, but does not appear to interact with disulfiram.[4]

The metabolism (glucuronidation) of oxazepam and lorazepam is minimally affected by disulfiram so that their clearance from the body remains largely unaffected.[2,3] The possible interaction between disulfiram and

temazepam is not understood, as temazepam is also mainly eliminated in the urine as the inactive glucuronide metabolite, and so its metabolism would not generally be expected to be affected by disulfiram.

Importance and management

There seems to be only one report (with temazepam) of a clinically significant interaction between disulfiram and the benzodiazepines, and this report is unconfirmed, as the patient did not take temazepam alone. The other reports only describe potential interactions that have been identified by single-dose studies. These do not necessarily reliably predict what will happen in practice. However, it seems possible that some patients will experience increased drowsiness, maybe due to this interaction or because drowsiness is a very common adverse effect of disulfiram. Reduce the dose of the benzodiazepine if necessary. Benzodiazepines that are metabolised by similar pathways to diazepam and chlordiazepoxide, may possibly interact in the same way, but this needs confirmation. Alprazolam, oxazepam and lorazepam appear to be non-interacting alternatives.

Benzodiazepines + Ethambutol

Ethambutol appears not to affect the pharmacokinetics of diazepam.

Clinical evidence, mechanism, importance and management

A study in 6 patients, newly diagnosed with tuberculosis and taking ethambutol 25 mg/kg, found that although some of the pharmacokinetic parameters of **diazepam** were different to those obtained in healthy control subjects not taking ethambutol, the differences were not significant.[1] There seems to be nothing in the literature to suggest that ethambutol interacts with other benzodiazepines.

Benzodiazepines + Food

Food can delay and reduce the hypnotic effects of flunitrazepam and loprazolam. Food can markedly enhance the absorption of quazepam. Food does not appear to have a clinically relevant effect on the overall bioavailability of alprazolam, diazepam or nitrazepam.

Clinical evidence, mechanism, importance and management

(a) Alprazolam

When compared with the fasting state, food had no effect on the extent of absorption of alprazolam 1 mg, formulated as an immediate-release orally disintegrating tablet. However, the maximum plasma level decreased by 23% and the time to maximum level increased from 2.5 to 4 hours. The clinical significance of this was thought to be minimal.[1]

(b) Diazepam

In a single-dose, crossover study, light food delayed the time to maximum plasma levels of diazepam by about one hour, but had no effect on its maximum plasma level or AUC, when compared with the fasting state. Light food did not appear to affect the CNS-depressant effects of diazepam.[2]

(c) Flunitrazepam

A study in 8 healthy subjects found that when they took a single 2-mg dose of flunitrazepam 2 hours after an evening meal (spaghetti, meat, salad, an apple and wine) and one hour before going to bed, the peak plasma levels of flunitrazepam were reduced by 63%. The time to reach these levels was delayed by 2.5 hours, and the absorption half-life was considerably prolonged.[3] It seems probable therefore that the onset of sleep with flunitrazepam may be delayed by food.

(d) Loprazolam

A study in 8 healthy subjects found that when they took a single 2-mg dose of loprazolam 2 hours after an evening meal (spaghetti, meat, salad, an apple and wine) and one hour before going to bed, the peak plasma levels of loprazolam were reduced by 41%. The time to reach these levels was delayed by 3.6 hours, and the absorption half-life was considerably prolonged.[3] It seems probable therefore that the onset of sleep with loprazolam may be delayed by food.

(e) Nitrazepam

In a single-dose, crossover study, light food delayed the time to maximum plasma levels of nitrazepam by about one hour, but had no effect on its maximum plasma level or AUC, when compared with the fasting state. Light food did not appear to affect the CNS-depressant effects of nitrazepam.[2]

(f) Quazepam

In a crossover study, 9 healthy subjects were given single 20-mg doses of quazepam immediately after a standard meal, and 3 hours after a standard meal. When compared with the fasting state, the peak plasma levels and $AUC_{0\text{-}8}$ for quazepam were increased 3-fold and 2.4-fold, respectively, when given 30 minutes after food, and by 2.5-fold and 2.1-fold, respectively, when given 3 hours after food. The CNS-depressant effects of quazepam were enhanced to a similar extent by administration 30 minutes or 3 hours after food.[4] In another study by the same authors, it was found that both low-fat and high-fat meals increased the absorption of quazepam.[5] A further study found that a light snack increased the bioavailability of quazepam and prolonged the reaction time at 4 and 6 hours after dosing.[2] However, another study found increases in the bioavailability when quazepam was taken 2 hours after food, but did not find any significant difference in the subjective effects of quazepam, such as drowsiness, malaise, and calmness, when compared with fasting.[6] It appears that food affects the absorption of quazepam and this effect may continue for at least 3 hours after food intake.[4] Some authorities have contraindicated the administration of quazepam with food;[4-6] however, it has also been suggested that, because of the good tolerability of quazepam, it may not be necessary to adjust the dose with meal content.[5] The US manufacturer does not suggest any restrictions concerning administration with food.[7]

Benzodiazepines + Grapefruit and other fruit juices

Grapefruit juice can increase the bioavailability of oral diazepam, midazolam and triazolam. Quazepam levels are also raised by grapefruit juice.

Clinical evidence

(a) Diazepam

A study in 8 healthy subjects found that simultaneous administration of 250 mL of grapefruit juice increased the AUC and maximum plasma levels of a single 5-mg oral dose of diazepam 3.2-fold and 1.5-fold, respectively.[1]

(b) Midazolam

Grapefruit juice 200 mL was given to 8 healthy subjects followed 15 minutes later by 5 mg of intravenous midazolam or 60 minutes later by

15 mg of oral midazolam. The pharmacokinetics of intravenous midazolam remained unchanged, but the AUC of oral midazolam was increased by 52%, and its maximum plasma levels rose by 56%. These changes were also reflected in the psychometric measurements made.[2] Grapefruit juice resulted in a similar increase in the AUC of oral midazolam in another study.[3] A further study found that the AUC of oral midazolam increased by 65% when midazolam was given 2 hours after grapefruit juice, but when the midazolam was given 26 hours, 50 hours and 74 hours after grapefruit juice, its AUC was increased by 21%, 22% and 6%, respectively. Midazolam elimination half-life was not altered by grapefruit juice.[4]

A large-scale placebo-controlled study involving a total of 120 healthy young medical students used psychomotor tests to measure the effect of benzodiazepines with and without grapefruit juice. Subjects were given midazolam 10 mg or **triazolam** 250 micrograms with 300 mL of grapefruit juice or water. Only a minor increase in the benzodiazepine effects occurred with grapefruit juice, and these effects were of little or no practical importance.[5]

(c) Quazepam

A study in 9 healthy subjects found that 250 mL of grapefruit juice three times daily for 3 days increased the AUC of a single 15-mg oral dose of quazepam and its active metabolite, 2-oxoquazepam, by 38% and 28%, respectively, although these increases were not statistically significant. The pharmacodynamic effects of quazepam, such as sedation, were not enhanced by grapefruit juice.[6]

(d) Triazolam

A single oral 250-microgram dose of triazolam was given to 10 healthy subjects with either 250 mL of grapefruit juice or water. The mean AUC of the triazolam was increased by 50% by the grapefruit juice, the peak plasma levels were increased by 30%, and the time to peak plasma levels was prolonged from 1.5 hours to 2.5 hours. A slight decrease in psychomotor performance occurred (more drowsiness and tiredness).[7]

Another study of the interaction between triazolam and grapefruit juice found that the effects of grapefruit juice were much more pronounced when multiple doses of grapefruit juice were given. The triazolam AUC and half-life were increased by about 50% and 6 to 9%, respectively, when single doses of normal or double-strength grapefruit juice were given, and by about 150% and 50%, respectively, by multiple doses (3 times daily) of double-strength grapefruit juice. The effect of grapefruit juice on psychomotor tests was also greater after multiple dosing.[8] Similar increases in the AUC of triazolam were found in a study using normal-strength grapefruit juice three times daily for 3 days, and although grapefruit juice was not found to enhance the sedative effects of triazolam, it did result in deterioration of performance in the digit symbol substitution test.[6] However, in another study, 300 mL of grapefruit juice once daily for 10 days only increased the AUC of a single dose of oral triazolam by 60%, which was similar to the effects of exposure to a single dose of grapefruit juice.[9]

For another study in which grapefruit juice had little effect on the response to triazolam, see under *Midazolam*, above.

Mechanism

The evidence suggests that grapefruit juice inhibits the metabolism of these benzodiazepines by the cytochrome P450 isoenzyme CYP3A4, so that more is left to enter the circulation.[2] Single exposure to grapefruit juice appears to mainly impair enteric, but not hepatic, metabolism and recovery of enteric CYP3A function seems to be largely complete within 3 days.[4] In one study grapefruit juice was found to have a greater effect on the bioavailability and pharmacodynamics of triazolam than on quazepam. This was considered to be because triazolam is metabolised by CYP3A4, while quazepam is metabolised by CYP2C9 as well as by CYP3A4.[6]

Importance and management

Established interactions. These increases in bioavailability might be expected to increase the extent of the sedation and amnesia due to these benzodiazepines, but in young healthy adults this is apparently of little importance, although multiple doses of grapefruit juice may increase the risk of adverse effects. The clinical effects of the interaction with diazepam appear not to have been investigated. The effects of midazolam and triazolam may be more enhanced than those of other benzodiazepines, because these drugs are more dependent on CYP3A4 for their metabolism (see *Mechanism*, above).

Other fruit juices have been reported to affect CYP3A4 *in vitro*, but studies in healthy subjects have not found any clinically relevant pharmacokinetic interactions with midazolam and **cranberry juice**,[10] **pomegranate juice**[3] or **tangerine juice**.[11]

Benzodiazepines and related drugs + H_2-receptor antagonists

The levels of many of the benzodiazepines and related drugs are raised by cimetidine, but normally this appears to be of little or no clinical importance and only the occasional patient may experience an increase in effects (sedation). The interactions with midazolam, and possibly zaleplon may be more significant, but this is not established. Famotidine, nizatidine and ranitidine do not normally appear to interact with most benzodiazepines.

Clinical evidence

A. Benzodiazepines

(a) Cimetidine

In 10 patients who took cimetidine 300 mg four times daily for 2 weeks the combined plasma level of **diazepam** and its active metabolite, desmethyldiazepam, was found to be increased by 57%, but reaction times and other motor and intellectual tests remained unaffected.[1] Other reports describe a rise in the plasma levels and/or AUC of **diazepam** (associated with increased sedation in one report[2]) due to cimetidine,[3-9] and generalised incoordination has also been described in one individual.[10]

Cimetidine also raises the plasma levels of **adinazolam**,[11] **alprazolam**,[12,13] **bromazepam**,[14] **chlordiazepoxide**,[15] **clobazam**[16,17] (this interaction was considered to be both clinically significant[16] and clinically irrelevant due to large interpatient variation in clobazam plasma levels[17]), **clorazepate**,[18] **flurazepam**,[19] **nitrazepam**,[20] and **triazolam**.[12,13,21,22] Liver cirrhosis increases the effects of cimetidine on the loss of **chlordiazepoxide**.[23]

Confusion has been reported in a 50-year-old man taking **clorazepate** when he was given cimetidine,[24] and increased sedation has been seen in some patients taking **adinazolam** and cimetidine.[11] Prolonged hypnosis in an elderly woman[25] and CNS toxicity (including lethargy and hallucinations) in a 49-year-old woman[26] have been attributed to an interaction between **triazolam** and cimetidine but this remains unconfirmed.

In contrast, cimetidine does not normally interact with **clotiazepam**,[27] **lormetazepam**,[28] **oxazepam**[19,29,30] or **temazepam**,[31,32] although prolonged post-operative sedation was seen in one patient given **oxazepam** and cimetidine.[33] Similarly, some studies suggest that no interaction occurs between **lorazepam** and cimetidine,[19,29] although one study found an increase in **lorazepam** levels, but this was only statistically significant with a 400-mg intravenous dose of cimetidine and not with a 200-mg dose.[3]

There is some controversy about whether or not **midazolam** is affected by cimetidine. An increase in sedation,[34,35] an increase in **midazolam**

levels[35-37] and no pharmacokinetic interaction[38] have been reported with the combination.

(b) Famotidine

Famotidine does not interact with **bromazepam**,[39] **clorazepate**,[39] **chlordiazepoxide**,[39] **diazepam**[9,40] or **triazolam**.[39]

(c) Nizatidine

Nizatidine does not interact significantly with **diazepam**.[41-43]

(d) Ranitidine

Ranitidine does not interact to a clinically significant extent with **adinazolam**,[44] **diazepam**[41,45] (although diminished absorption of diazepam may possibly occur),[46] **lorazepam**,[45] or **temazepam**,[32,47] but it can modestly increase the bioavailability (by about 10 to 30%) of oral **triazolam**:[48,49] this is unlikely to be clinically relevant.

There is some controversy about whether or not **midazolam** is affected by ranitidine. Increases in **midazolam** levels[36] and sedation[47,50] have been reported on a few occasions, but a lack of effect has also been documented.[34,37,38]

(e) Roxatidine

Roxatidine does not interact with **diazepam** or its active metabolite, desmethyldiazepam.[51]

B. Non-benzodiazepine hypnotics

(a) Cimetidine

Cimetidine increased plasma levels of a single dose of **zaleplon** by 85%.[52] There appeared to be no significant pharmacokinetic interaction between cimetidine and **zolpidem** in healthy subjects, although sleep duration tended to be prolonged.[53]

(b) Ranitidine

There appeared to be no significant pharmacokinetic interaction between ranitidine and **zolpidem**.[53] Ranitidine did not affect the hypnotic action of **zopiclone**.[47]

Mechanism

Cimetidine inhibits the liver enzymes concerned with the metabolism of diazepam, alprazolam, chlordiazepoxide, clorazepate, flurazepam, nitrazepam, triazolam, and zaleplon. As a result their clearance from the body is reduced and their plasma levels rise.

Lorazepam, oxazepam and temazepam are metabolised by a different metabolic pathway involving glucuronidation, which is not affected by cimetidine, and so they do not usually interact.

Ranitidine, famotidine and nizatidine appear not to inhibit liver microsomal enzymes. There is some evidence that ranitidine increases the absorption of triazolam, and possibly other benzodiazepines, due to changes in gastric pH,[49] although it has been suggested that this effect is negligible.[22] Cimetidine has been said to similarly affect the absorption of diazepam and lorazepam.[3]

Importance and management

The interactions between the benzodiazepines or related drugs and cimetidine are well documented (not all the references are listed here) but normally they appear to be of little clinical importance. However, a few patients may be adversely affected (increased effects, drowsiness, etc.) and this may possibly be more common with midazolam and the non-benzodiazepine hypnotic, zaleplon. If symptoms occur in any patient taking a benzodiazepine or related drug and cimetidine, reduce the benzodiazepine dose: a dose reduction of one-third or increased dosing intervals (twice daily instead of three times daily) have been suggested for alprazolam.[12] Alternatively, use a non-interacting benzodiazepine, such as lorazepam, lormetazepam, oxazepam or temazepam, or a non-interacting H_2-receptor antagonist such as ranitidine, famotidine, nizatidine or roxatidine.

Benzodiazepines and related drugs + Hormonal contraceptives

Hormonal contraceptives can increase the effects of alprazolam, chlordiazepoxide, diazepam, nitrazepam and triazolam, and reduce the effects of oxazepam, lorazepam and temazepam. Chlordiazepoxide, diazepam, nitrazepam and meprobamate can possibly increase the incidence of break-through bleeding in patients taking hormonal contraceptives.

Clinical evidence

(a) Effects on benzodiazepines and related drugs

A controlled study found that the mean half-life of intravenous **chlordiazepoxide** 600 micrograms/kg was virtually doubled (20.6 hours compared with 11.6 hours) and the total clearance was almost two-thirds lower in 6 women taking oral hormonal contraceptives when compared with 6 women not taking oral hormonal contraceptives.[1]

Similar but less marked effects were found in other studies in women taking oral hormonal contraceptives given **chlordiazepoxide**,[2] **diazepam**,[3,4] and to an even lesser extent with **nitrazepam**[5] and **triazolam**.[6] Oral hormonal contraceptives have also been reported to inhibit[6] or to have no significant influence[7] on the metabolism of **alprazolam**. No clinically significant pharmacokinetic changes were seen when **bromazepam**,[8] **clotiazepam**,[9] **midazolam** (given orally,[10,11] intramuscularly,[12] or intravenously[10]) or **zolpidem**[13] were given with hormonal contraceptives.

A controlled study, comparing 7 women taking an oral hormonal contraceptive with 8 women not taking oral hormonal contraceptives found that the mean half-life of intravenous **lorazepam** 2 mg was over 50% shorter in the contraceptive group (6 hours compared with 14 hours) and the total clearance was over threefold greater.[1]

A smaller increase in the elimination rate was seen in other controlled studies in women taking oral hormonal contraceptives and **lorazepam**,[6,14] or **temazepam**,[6] and in two other studies small decreases in the half-life of **oxazepam** were observed.[1,14]

(b) Effects on contraceptives

A study in 72 patients taking oral combined hormonal contraceptives (*Rigevidon*, *Anteovin*) found that breakthrough bleeding occurred in 36% of patients while taking **chlordiazepoxide** 10 to 20 mg daily, **diazepam** 5 to 15 mg daily, **nitrazepam** 5 to 10 mg daily or **meprobamate** 200 to 600 mg daily, but no pregnancies occurred. Only three cases of bleeding occurred with **diazepam** or **nitrazepam**.[15] The average values for breakthrough bleeding with these two oral contraceptives were 9.1% for *Rigevidon* and 3.3% for *Anteovin* in the absence of other drugs. It was possible to establish a causal relationship between the bleeding and the use of the anxiolytic/hypnotic in 77% of the cases either by stopping the drug or by changing it for another.[15]

Mechanism

Hormonal contraceptives affect the metabolism of the benzodiazepines by the liver in different ways: oxidative metabolism is reduced (alprazolam, chlordiazepoxide, diazepam, etc.), whereas metabolism by glucuronide conjugation is increased (lorazepam, oxazepam, temazepam, etc.). Just why these hypnotics should cause breakthrough bleeding is not understood.

Importance and management

Established interactions, but of uncertain clinical importance. Long-term use of benzodiazepines that are highly oxidised (alprazolam, chlordiazepoxide, diazepam, nitrazepam, etc.) in women taking oral hormonal contraceptives should be monitored to ensure that the dose is not too high. Those taking benzodiazepines that are metabolised to glucuronides (lorazepam, oxazepam, temazepam, etc.) may possibly need a dose increase but this is not proven. Bromazepam, clotiazepam, midazolam and zolpidem appear not to interact. No firm conclusions could be drawn from the results of one study, which set out to evaluate the importance of this interaction.[16]

The increased incidence of breakthrough bleeding (more than one-third) due to these anxiolytics/hypnotics, is an unpleasant reaction, but no contraceptive failures have been reported.[15] Limited evidence from the study suggests that changing the anxiolytic/hypnotic or the contraceptive might avoid breakthrough bleeding. Note that the UK Family Planning Association[17] did not consider that additional contraceptive precautions were necessary with **clonazepam** or **clobazam** and it seems unlikely that they will be necessary with most benzodiazepines.

Benzodiazepines + 5-HT_3-receptor antagonists

Granisetron does not appear to interact with lorazepam, and ondansetron does not appear to interact with temazepam.

Clinical evidence, mechanism, importance and management

Lorazepam 2.5 mg, given to 12 healthy subjects, clearly affected the performance of a number of psychometric tests. Statistically significant increases occurred in drowsiness, feebleness, muzziness, clumsiness, lethargy, mental slowness, relaxation, dreaminess, incompetence, sadness, and withdrawal. However, there was very little evidence that **granisetron** 160 micrograms/kg alone had any effect on the performance of these tests except that clumsiness and inattentiveness were increased, nor was there evidence that granisetron added to the effects of **lorazepam** when both drugs were taken concurrently.[1]

In a placebo-controlled, crossover study in 24 healthy subjects, **ondansetron** 8 mg did not affect the pharmacokinetics of **temazepam** 20 mg. The psychomotor performances of the subjects (subjective and ob-

jective sedation, memory and other measurements) were not influenced by the presence of the **ondansetron**.[2]

No additional special precautions would seem to be necessary if either of these pairs of drugs are given.

Benzodiazepines + Influenza vaccines

The pharmacokinetics of alprazolam, chlordiazepoxide and lorazepam are not affected by influenza vaccination.

Clinical evidence, mechanism, importance and management

The pharmacokinetics of single doses of oral **alprazolam** 1 mg, or intravenous **lorazepam** 2 mg remained unaffected in healthy subjects when the benzodiazepines were given 7 and 21 days after 0.5 mL of an intramuscular trivalent influenza vaccine.[1] Similarly, in another study, neither **lorazepam** nor **chlordiazepoxide** metabolism was altered when they were given one and 7 days after a trivalent influenza vaccine.[2] There would seem to be no reason for avoiding the concurrent use of these drugs.

Benzodiazepines + Isoniazid

Isoniazid reduces the clearance of both diazepam and triazolam. Some increase in their effects would be expected. No interaction occurs between isoniazid and oxazepam or clotiazepam.

Clinical evidence

A study in 9 healthy subjects found that isoniazid 90 mg twice daily for 3 days increased the half-life of a single 5- or 7.5-mg dose of **diazepam** from about 34 hours to 45 hours, and reduced its total clearance by 26%.[1] A study in 6 healthy subjects found that isoniazid 90 mg twice daily for 3 days, increased the half-life of a single 500-microgram dose of **triazolam** from 2.5 hours to 3.3 hours, increased its AUC by 46% and reduced its clearance by 42%.[2]

A study in 9 healthy subjects found that isoniazid 90 mg twice daily for 3 days had no effect on the pharmacokinetics of a single 30-mg oral dose of **oxazepam**.[2] Similarly, in another study, the pharmacokinetics of **clotiazepam** were not altered by isoniazid.[3]

Mechanism

What is known suggests that isoniazid acts as an enzyme inhibitor, decreasing the metabolism and loss of diazepam and triazolam from the body, thereby increasing and prolonging their effects. Oxazepam, which is metabolised by glucuronidation, would be unlikely to interact.

Importance and management

Information is limited but the interactions appear to be established. Their clinical importance is uncertain but be alert for the need to decrease the doses of diazepam and triazolam if isoniazid is started. There seems to be no direct information about other benzodiazepines, but those undergoing high first-pass extraction and/or liver microsomal metabolism (e.g. **alprazolam** or **triazolam**) may interact similarly. Oxazepam and clotiazepam appear not to interact.

Benzodiazepines + Kava

A man taking alprazolam became semicomatose a few days after starting to take kava, which was suggested to be due to additive sedation. The pharmacokinetics of midazolam are not affected by kava.

Clinical evidence, mechanism, importance and management

(a) Alprazolam

A 54-year-old man taking alprazolam, cimetidine and terazosin was hospitalised in a lethargic and disorientated state 3 days after starting to take kava, which he had bought from a local health food store. He denied having overdosed with any of these drugs. The patient became alert again after several hours.[1] The reason for what happened is not known, but the suggested explanation is that the kava α-pyrones might have had additive sedative effects with those of the alprazolam.[1,2] This is an isolated case and its general importance is not known.

(b) Midazolam

In a study in 6 subjects, who regularly took 7 to 27 g of kavalactones weekly as an aqueous kava extract, there was no change in the metabolism of a single 8-mg oral dose of midazolam before or after they *stopped* kava for 30 days.[3] Similar results were found in a study in 12 healthy subjects given kava kava root extract 1 g twice daily for 28 days before receiving a single 8-mg dose of oral midazolam.[4] A pharmacokinetic interaction requiring a midazolam dose alteration therefore seems unlikely.

Benzodiazepines and related drugs + Macrolides

The plasma levels and effects of midazolam, triazolam and zopiclone are increased and prolonged by erythromycin. The same interaction has been seen with clarithromycin, telithromycin and troleandomycin, and to a limited extent with josamycin and roxithromycin, but not with azithromycin. Alprazolam and brotizolam would be expected to be similarly affected by these macrolides. Other benzodiazepines such as diazepam, flunitrazepam, nitrazepam, and the related hypnotic, zaleplon, only appear to interact with erythromycin to a fairly modest extent, and temazepam and zolpidem appear not to interact.

Clinical evidence

A. Benzodiazepines

(a) Alprazolam

In a randomised study, 12 healthy subjects were given **erythromycin** 400 mg three times daily for 10 days with a single 800-microgram dose of alprazolam on day 8. The alprazolam AUC was increased 2.5-fold and the half-life increased from 16 hours to 40.3 hours. However, no increase in sedation was seen.[1]

(b) Brotizolam

A randomised study in healthy subjects found that **erythromycin** 400 mg three times daily for 7 days increased AUC of a single 500-microgram dose of brotizolam 2.5-fold. The elimination half-life was also increased from 9.4 hours to 20.7 hours. However, **erythromycin** did not affect the changes in psychomotor function associated with brotizolam.[2]

(c) Diazepam

In a crossover study, 6 healthy subjects were given a single 5-mg oral dose of diazepam after taking **erythromycin** 500 mg three times daily for one week. The diazepam $AUC_{0\text{-}42}$ was increased by a modest 15% and its pharmacodynamic effects were unchanged.[3]

(d) Flunitrazepam

In a crossover study, 5 healthy subjects were given a single 1-mg oral dose of flunitrazepam after taking **erythromycin** 500 mg three times daily for one week. The flunitrazepam AUC_{0-42} was increased by a modest 25%, and its pharmacodynamic effects were unchanged.[3]

(e) Midazolam

1. Azithromycin. A study in 64 healthy medical students found that azithromycin 750 mg had no effect on the metabolism of a 10- or 15-mg dose of midazolam, and did not alter the performance of a number of psychomotor tests.[4] A study in 10 healthy subjects given azithromycin 250 mg daily found that some small changes in the pharmacokinetics of midazolam 15 mg occurred (a possible small delay in its onset of action), but its pharmacodynamic effects were unaltered.[5] Other studies confirm that azithromycin does not interact with midazolam.[6,7]

2. Clarithromycin. In a study, 16 healthy subjects were given a concurrent oral 4 mg and intravenous 50 microgram/kg dose of midazolam, before and after they took clarithromycin 500 mg twice daily for 7 days. It was found that clarithromycin reduced the systemic clearance of midazolam by about 64%, which resulted in a doubling of the midazolam-induced sleeping time.[8] Similarly, a study in elderly subjects, aged 66 to 80 years, found that clarithromycin 500 mg twice daily for 7 days increased the AUC of intravenous midazolam about threefold and increased the AUC of oral midazolam eightfold.[9] Another study reported a similar interaction.[7]

3. Erythromycin. A study in 12 healthy subjects found that erythromycin 500 mg three times daily for 6 days almost tripled the peak plasma levels of a single 15-mg oral dose of midazolam, more than doubled its half-life and increased its AUC more than fourfold. The subjects could hardly be wakened during the first hour after being given the midazolam, and most experienced amnesia lasting several hours.[10] Another study found that the increase in dose-corrected AUCs for oral midazolam in subjects that had taken erythromycin 200 mg four times daily for 2, 4, or 7 days were 2.3-, 3.4- and 3.4-fold, respectively. It appeared that a plateau level of CYP3A4 inhibition could be achieved by 4 days or more of erythromycin treatment.[11] The manufacturer reports that erythromycin causes a twofold increase in the plasma levels and half-life of intravenous midazolam.[12]
The plasma levels of a 500-microgram/kg oral dose of midazolam, given to an 8-year-old boy as premedication before surgery, were approximately doubled when he was given intravenous erythromycin. He developed nausea and tachycardia, and after 40 minutes (by which point he had received 200 mg of erythromycin) he lost consciousness.[13] A patient in a coronary care unit given 300 mg of intravenous midazolam over 14 hours slept for about 6 days (apart from brief wakening when given flumazenil). The midazolam half-life was increased about tenfold. This was attributed to an interaction due to the combined effects of erythromycin 4 g daily and amiodarone 1.7 g over 3 days.[14,15] Other studies and reports have also described this interaction.[4,6,16,17]

4. Roxithromycin. In 10 healthy subjects roxithromycin 300 mg daily for 6 days increased the AUC of a single 15-mg dose of midazolam by about 47%, and lengthened the half-life from 1.7 hours to 2.2 hours. Only minor psychomotor changes were seen.[18] A modest increase in the effects of midazolam were seen in another study in subjects given roxithromycin 300 mg, but the effects were very much weaker than those seen with erythromycin.[17]

5. Telithromycin. When intravenous and oral midazolam were given with telithromycin, the AUC of midazolam was increased 2.2-fold and 6.1-fold, respectively. The midazolam half-life was increased about 2.5-fold.[19]

(f) Nitrazepam

When 10 healthy subjects were given **erythromycin** 500 mg three times daily for 4 days, the AUC of a single 5-mg dose of nitrazepam was increased by 25%, its peak plasma levels were increased by 30% and the time to peak concentration was reduced by over 50%. However, hardly any changes were seen in the psychomotor tests undertaken.[20]

(g) Temazepam

A randomised, study in 10 healthy subjects found that **erythromycin** 500 mg three times daily for 6 days had no significant effect on the pharmacokinetics or psychomotor effects of a single 20-mg dose of temazepam.[21]

(h) Triazolam

1. Azithromycin. A clinical study in 12 healthy subjects found that azithromycin did not affect the pharmacokinetics of a single 125-microgram dose of triazolam.[22] These results were supported by an *in vitro* study, which suggested that azithromycin was only a weak inhibitor of triazolam metabolism.[22]

2. Clarithromycin. An *in vitro* study found clarithromycin to be a relatively potent inhibitor of triazolam metabolism. These results were confirmed in practice with 12 healthy subjects, who were given both drugs. The oral clearance of triazolam was reduced by 77% by clarithromycin and the AUC was increased about fivefold, when compared with placebo.[22]

3. Erythromycin. A study in 16 healthy subjects found that erythromycin 333 mg three times daily for 3 days, reduced the clearance of a single 500-microgram dose of triazolam by about 50%, doubled its AUC, and increased its maximum plasma levels by about one-third (from 2.8 to 4.1 nanograms/mL).[23] Other reports confirm the marked decrease in triazolam clearance and an increase in its peak levels in the presence of erythromycin.[22,24] A patient with acute pneumonia and chronic renal failure taking erythromycin 600 mg daily developed visual hallucinations and abnormal body sensations each time a dose of triazolam and **nitrazepam** were taken. These symptoms had not occurred before the addition of erythromycin.[25]

4. Josamycin. A patient taking josamycin experienced confusion lasting about 24 hours after taking a single dose of triazolam.[26]

5. Roxithromycin. A single-dose study found that the psychomotor effects of triazolam were only slightly affected by roxithromycin 300 mg.[17]

6. Troleandomycin. Troleandomycin 2 g daily given to 7 healthy subjects for 7 days increased the peak triazolam levels by 107%, increased its AUC by 275% and prolonged its half-life from 1.81 hours to 6.48 hours. Apparent oral clearance was reduced by 74%. Marked psychomotor impairment and amnesia was seen.[27] Troleandomycin has been reported to interact similarly in a patient taking triazolam, causing an increase in its effects.[26] An *in vitro* study has shown troleandomycin to be a potent inhibitor of triazolam metabolism.[22]

B. Non-benzodiazepine hypnotics

(a) Zaleplon

The manufacturers of zaleplon note that a single 800-mg dose of **erythromycin** increased the maximum plasma levels of zaleplon by 34% and increased its AUC by 20%.[28,29]

(b) Zolpidem

In a study in 10 healthy subjects 4 doses of **clarithromycin** 500 mg had no effect on the pharmacokinetics of a single 5-mg dose of zolpidem or on its sedative effects. Clarithromycin pharmacokinetics were unaffected by zolpidem.[30]

(c) Zopiclone

Zopiclone 7.5 mg was given to 10 healthy subjects before and after they took **erythromycin** 500 mg three times daily for 6 days. **Erythromycin** increased the plasma levels of zopiclone fivefold at 30 minutes and twofold at one hour. Peak plasma levels rose by about 40% and occurred at 1 hour instead of 2 hours. The 1-hour and 2-hour AUCs were increased threefold and twofold, respectively, while the total AUC was increased by nearly 80%.[31] These pharmacokinetic changes were reflected in some small changes in a number of psychomotor tests.[31]

Mechanism

Some of the macrolides (notably clarithromycin, erythromycin and telithromycin) are moderate to potent inhibitors of the cytochrome P450 isoenzyme CYP3A4. They therefore inhibit the metabolism of some benzodiazepines by this route, causing an increase in their levels, and increasing and prolonging their effects. Benzodiazepines, such as midazolam, that are predominantly metabolised by CYP3A4 are affected more than those such as diazepam, where CYP3A4 plays only a minor part in the metabolism. Further, CYP3A4-mediated metabolism occurs in the liver and also in the intestines. Midazolam and triazolam undergo extensive first-pass metabolism (low bioavailability of about 40%) but alprazolam and brotizolam undergo less first-pass metabolism (bioavailabilities of about 90% and 70%, respectively). Erythromycin causes greater increases in the levels and AUCs of midazolam and triazolam than in those of alprazolam and brotizolam, and this may be related to the extent of first-pass metabolism.[2] The non-benzodiazepine hypnotics, zaleplon and zopiclone are, to

varying degrees, also metabolised by CYP3A4: they are therefore similarly affected by the macrolides.

Importance and management

The interactions of midazolam with clarithromycin, erythromycin and telithromycin appear to be established, and of clinical importance. Troleandomycin would be expected to interact similarly. The dose of midazolam should be reduced 50 to 75% when these antibacterials are used if excessive effects (marked drowsiness, memory loss) are to be avoided. Remember too that the hypnotic effects are also prolonged so that patients should be warned about hangover effects the following morning if they intend to drive. There is some evidence that the effects of single bolus doses of intravenous midazolam given in the presence of erythromycin are not increased to a clinically significant degree, and normal doses can be used, although the duration of effect may be prolonged. However, where high doses of intravenous midazolam are used long term (e.g. during intensive care treatment) one manufacturer of midazolam suggests[32] that the initial dose may need to be reduced by up to 50% and the dose will then need to be titrated to avoid long-lasting hypnotic effects. Triazolam appears to interact similarly, and similar precautions would seem advisable.

Limited information from single-dose studies suggests that erythromycin may increase the levels of alprazolam, brotizolam and zopiclone but only small pharmacodynamic changes were reported. Nevertheless, the extent of the pharmacokinetic effect is reasonably large, and a degree of caution is warranted as some patients may be affected. Clarithromycin, telithromycin and troleandomycin would be expected to interact similarly.

The manufacturers of zaleplon say that patients should be advised that increased sedation is possible with erythromycin,[28] although a dose adjustment is usually not required;[28,29] however the extent of the effect is small, and would not generally be expected to lead to a clinically relevant interaction.

Other macrolides appear not to interact (azithromycin) or only interact to a modest extent (roxithromycin) with midazolam and/or triazolam. Similarly modest effects would be expected with other benzodiazepines or related hypnotics partly metabolised by CYP3A4 (e.g. alprazolam, brotizolam).

Other benzodiazepines and related hypnotics not significantly metabolised by CYP3A4 (diazepam, flunitrazepam, nitrazepam, temazepam and zolpidem) have only minor or insignificant interactions with any of the macrolides, suggesting that no special precautions are necessary on their concurrent use.

Benzodiazepines and related drugs + Melatonin

The CNS effects of benzodiazepines and related hypnotics, such as zolpidem, may be additive with those of melatonin.

Clinical evidence

In a well-controlled, single-dose study in 16 healthy subjects aged 55 years and older, giving prolonged-release melatonin 2 mg with **zolpidem** 10 mg at bedtime enhanced the impairment of cognitive function seen with **zolpidem** alone at one hour and 4 hours post-dose, but not the next morning. Melatonin alone had no effect on cognitive function. No pharmacokinetic interaction was found.[1]

Mechanism

The activity of melatonin is thought to involve similar interactions at the GABA receptors in the brain to benzodiazepines. It may therefore enhance the activity of benzodiazepines and related drugs.

Importance and management

The evidence available suggests that melatonin might enhance the sedative properties of benzodiazepines and related hypnotics such as zolpidem. Although in the study of zolpidem, the enhanced effect was not apparent the morning after dosing, it would be wise to be aware that increased drowsiness is a possibility if melatonin is also given, especially with longer-acting hypnotics.

Benzodiazepines and related drugs + Metoclopramide

Intravenous, but not oral, metoclopramide increases the rate of absorption of diazepam and raises its maximum plasma levels. Intravenous metoclopramide increases the rate of absorption of zopiclone.

Clinical evidence, mechanism, importance and management

(a) Diazepam

Intravenous metoclopramide increased the peak plasma levels of diazepam by 38% and increased the rate of absorption (peak levels occurred at 30 minutes instead of 60 minutes),[1] but in another study in 6 healthy

subjects oral metoclopramide 10 mg did not increase the rate of absorption of oral diazepam 0.2 mg/kg.[2] The reason is not understood. The clinical importance of this interaction is not known, but it is probably small.

(b) Zopiclone

In a study in 12 healthy subjects, intravenous metoclopramide 10 mg increased the rate of absorption of a single 7.5-mg dose of oral zopiclone. This was presumably because metoclopramide alters gut motility. Metoclopramide almost doubled the mean plasma levels of zopiclone (from 22.7 to 44.4 nanograms/mL) at 1 hour, but the increase in zopiclone levels was only about 20% (from 49.3 to 59.6 nanograms/mL) at 2 hours.[3] The clinical importance of these findings is not known.

Benzodiazepines + Metronidazole

Metronidazole does not affect the pharmacokinetics of alprazolam, diazepam, lorazepam, or midazolam.

Clinical evidence, mechanism, importance and management

A study in healthy subjects found that metronidazole 400 mg twice daily for 5 days had no effect on the pharmacokinetics of a single 100-microgram/kg intravenous dose of **diazepam**.[1] Another study in healthy subjects found that metronidazole 750 mg had no effect on the pharmacokinetics of **alprazolam** or **lorazepam**.[2] *In vivo* and *in vitro* studies have shown that metronidazole has no effect on the pharmacokinetics or pharmacodynamics of **midazolam**.[3] Although they do not appear to have been studied, interactions with other benzodiazepines seem unlikely.

Benzodiazepines + Modafinil

Modafinil reduces triazolam levels. It may therefore also affect the metabolism of other similarly metabolised benzodiazepines such as midazolam and possibly alprazolam. Conversely, modafinil might increase diazepam levels.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study, 34 healthy women (all taking an oral hormonal contraceptive containing ethinylestradiol and norgestimate) were given a single 125-microgram dose of **triazolam**, both before and on the last day of taking modafinil 200 mg daily for 7 days then 400 mg daily for 21 days. The AUC of **triazolam** was reduced by almost 60%, its maximum plasma level was reduced by 42%, and its elimination half-life was reduced by about one hour by modafinil.[1]

Modafinil is known to induce the cytochrome P450 isoenzyme CYP3A4, by which **triazolam** is metabolised, and it is therefore likely to reduce **triazolam** levels by this mechanism, particularly in the gastrointestinal tract.[1] It seems possible that other benzodiazepines metabolised by CYP3A4 (e.g. **midazolam** and possibly **alprazolam**) may be similarly affected. It would therefore seem prudent to monitor for a reduction in the sedative effects and a reduced duration of action of these benzodiazepines in patients taking modafinil: increase the dose if necessary.

Conversely, modafinil inhibits the cytochrome P450 isoenzyme CYP2C19. The manufacturers therefore predict that the elimination of **diazepam**, which is metabolised by this isoenzyme, may be reduced. They suggest that a dose reduction of **diazepam** may be necessary on concurrent use.[2,3]

3. Provigil (Modafinil). Cephalon (UK) Ltd. UK Summary of product characteristics, November 2009.

Benzodiazepines and related drugs + Nefazodone

Nefazodone increases the plasma levels and effects of alprazolam, midazolam, triazolam and zopiclone, but not lorazepam.

Clinical evidence

A. Benzodiazepines

(a) Alprazolam

A placebo-controlled study in 12 healthy subjects found that nefazodone 200 mg twice daily caused an almost twofold increase in the plasma levels of alprazolam 1 mg twice daily taken for 7 days.[1] Another study found that nefazodone increased the mean AUC of alprazolam by 47%.[2] A further study reported impairment of psychomotor performance and increased sedation when nefazodone was given with alprazolam.[3] A case report describes a woman taking alprazolam who developed benzodiazepine withdrawal symptoms after nefazodone was withdrawn following several years of concurrent use. She needed an alprazolam dose increase from 500 micrograms daily to 4 mg daily to control her symptoms.[4]

(b) Lorazepam

A placebo-controlled study in healthy subjects given nefazodone 200 mg twice daily found no changes in the pharmacokinetics of lorazepam 2 mg twice daily.[5] Another study found that psychomotor performance was not further impaired and no additional sedation occurred when nefazodone was given with lorazepam.[3]

(c) Midazolam

A study in 10 healthy subjects found that both the AUC and the maximum plasma level of a single 10-mg oral dose of midazolam were increased about fivefold and twofold, respectively, when they took nefazodone 200 mg twice daily.[6]

(d) Triazolam

A study in 12 healthy subjects found that the maximum plasma levels, the half-life and the AUC of a single 250-microgram dose of triazolam were increased 1.7-fold, 4.6-fold, and 4-fold, respectively, by nefazodone 200 mg twice daily.[7] Another study found that impairment of psychomotor performance and increased sedation occurred when nefazodone was given with triazolam.[3]

B. Non-benzodiazepine hypnotics

An 86-year-old woman taking diltiazem, irbesartan, lorazepam, and pravastatin started taking nefazodone 50 mg twice daily, increasing to 500 mg daily in divided doses, for the treatment of a major depressive episode. Because of associated insomnia, **zopiclone** was added, starting at 15 mg each night, but this was reduced after 5 days to 7.5 mg because of morning drowsiness. Plasma levels of *S*-zopiclone and *R*-zopiclone were 107 nanograms/mL and 20.6 nanograms/mL, respectively, at this time. After several months, nefazodone was replaced by venlafaxine. The *S*-zopiclone and *R*-zopiclone levels were again measured and found to be only 16.9 nanograms/mL and 1.45 nanograms/mL, respectively.[8]

Mechanism

Nefazodone appears to inhibit the oxidative metabolism of alprazolam, midazolam, triazolam and zopiclone by the cytochrome P450 isoenzyme CYP3A4 so that they accumulate in the body. Lorazepam is unaffected because it is primarily excreted as a conjugate.

Importance and management

The interactions of nefazodone with alprazolam, midazolam, triazolam and zopiclone are established and clinically important; the practical consequences are that the effects of these drugs are expected to be increased to varying extents. Be alert for any evidence of any psychomotor impairment, drowsiness etc. and reduce the benzodiazepine dose if necessary. A substantial reduction (approximately 50%) in the initial dose of alprazolam might be required, and an even greater reduction might be needed for midazolam and triazolam; however, the manufacturer of triazolam[9]

contraindicates its concurrent use with nefazodone. Lorazepam does not interact with nefazodone. There seems to be no direct information about other benzodiazepines and related drugs.

Benzodiazepines + NNRTIs

Delavirdine is predicted to increase the levels of alprazolam, midazolam and triazolam. Etravirine is predicted to increase the levels of diazepam, and modestly decreases the levels of midazolam. Efavirenz and nevirapine may increase the metabolism of midazolam by induction of CYP3A4. However, efavirenz may also compete for metabolism by CYP3A4 and potentially *decrease* the metabolism of midazolam and triazolam.

Clinical evidence, mechanism, importance and management

(a) Delavirdine

Delavirdine is an inhibitor of the cytochrome P450 isoenzyme CYP3A4 and may increase the plasma levels of drugs that are metabolised by this route. Delavirdine is contraindicated with drugs that are highly dependent on CYP3A4 for clearance including **alprazolam**, **midazolam** and **triazolam**.[1]

(b) Efavirenz or Nevirapine

In a study, 90 HIV-positive patients not taking antiretrovirals (control group) and 56 similar patients already taking antiretrovirals, were given a 75-microgram dose of oral **midazolam**. When compared with the control group, the 1-hydroxymidazolam to **midazolam** ratio was fivefold higher in 28 patients receiving efavirenz, but 17-fold lower in 3 patients receiving efavirenz together with ritonavir (the ratio for ritonavir alone was 50-fold lower). Similarly, the 1-hydroxymidazolam to **midazolam** ratio was sevenfold lower in 3 patients receiving nevirapine together with ritonavir or nelfinavir or grapefruit juice. It appears that efavirenz and nevirapine *induce* the metabolism of midazolam by the cytochrome P450 isoenzyme CYP3A4, but the inhibition of CYP3A4 by ritonavir or nelfinavir offsets the inductive effects of efavirenz or nevirapine given concurrently.[2] Note that the manufacturers of efavirenz contraindicate its use with **midazolam** or **triazolam** as they suggest that competition for CYP3A4 by efavirenz could also result in *inhibition* of metabolism and the potential for prolonged sedation or respiratory depression.[3,4] However, note that competition for metabolism rarely results in clinically relevant increases in the levels of either of the two drugs involved.

A study in 12 subjects found that efavirenz 600 mg daily for 10 days increased the maximum plasma level of a single 2-mg dose of **lorazepam** by 16%[4] and the AUC by 7%.[3] These changes are not considered to be clinically significant and no dose adjustment is considered necessary for either efavirenz or **lorazepam**.[3]

(c) Etravirine

Etravirine is a weak inhibitor of the cytochrome P450 isoenzyme CYP2C19, by which **diazepam** is metabolised. The manufacturers of etravirine therefore predict that concurrent use will raise **diazepam** levels[5,6] (which would increase the risk of prolonged and/or excessive sedation). The UK manufacturer suggests that alternatives to **diazepam** should be considered,[5] whereas the US manufacturer suggests that a decrease in the dose of **diazepam** may be necessary.[6]

In a study, 12 healthy subjects were given a single dose of intravenous **midazolam** 250 micrograms/kg on day one and day 14 of a 14-day course of etravirine 200 mg twice daily. Etravirine modestly reduced the ratio of the AUC of **midazolam** to its metabolite, 1-hydroxymidazolam, by 37%.[7] However, this modest reduction in **midazolam** levels would not be expected to be of clinical significance in most patients.

Benzodiazepines and related drugs + NSAIDs

The interactions of the NSAIDs with the benzodiazepines are usually minor and of little clinical relevance; however, diclofenac appears to reduce the dose of midazolam needed to produce sedation and hypnosis, and in some cases feelings of dizziness may be increased.

Clinical evidence, mechanism, importance and management

(a) Diazepam

1. Diclofenac. In a study in 8 healthy subjects, diazepam increased the AUC of diclofenac by 60% and reduced its clearance by 36%.[1] The effects of diazepam on diclofenac appeared to depend on the time of administration and may reflect time-dependent effects of diazepam on gastrointestinal function. More study is needed to establish the mechanism and clinical relevance of this interaction.

2. Ibuprofen. A study in 8 healthy subjects investigating the effects of diazepam on ibuprofen pharmacokinetics found that the ibuprofen half-life was increased from 2.39 hours to 3.59 hours and its clearance was reduced by about one-third when diazepam and ibuprofen were given at 10 pm, but no effect was seen with morning dosing.[2] The clinical importance of this is uncertain.

3. Indometacin. Diazepam 10 to 15 mg impaired the performance of a number of psychomotor tests (digit symbol substitution, letter cancellation, tracking and flicker fusion) in 119 healthy medical students. It also caused subjective drowsiness, mental slowness and clumsiness. When indometacin 50 or 100 mg was given the effects were little different from diazepam alone, except that feelings of dizziness (common to both drugs) were increased and caused subjective clumsiness.[3]

4. Naproxen. A double-blind, crossover study did not find any clinically important changes in mood or attention in healthy subjects given naproxen and diazepam.[4] A single-dose study in 10 healthy subjects found that peak serum concentrations of naproxen 500 mg were reduced by 23%, the time to peak concentration was increased (from 1.36 hours to 2 hours) and the absorption rate constant was decreased by 40% by diazepam 10 mg. Other pharmacokinetic parameters were not affected.[5] No special precautions appear to be necessary on concurrent use.

5. Parecoxib. Valdecoxib, the active metabolite of parecoxib is an inhibitor of CYP2C19 and may possibly increase the serum levels of diazepam, see 'NSAIDs; Parecoxib + Miscellaneous', p.177.

(b) Midazolam

A clinical study found that **diclofenac** 75 mg given intravenously to 10 patients reduced the dose of intravenous midazolam needed to produce sedation and hypnosis by 35%, when compared with 10 control subjects not given **diclofenac**.[6] The clinical importance of this is uncertain.

A randomised, crossover study in 32 patients undergoing two surgical procedures for bilateral symmetrically impacted third molars, found that midazolam, in doses used for conscious sedation, had no effect on the potency or duration of action of **diflunisal** for postoperative pain relief.[7]

A study in 12 healthy adults found no significant changes in the pharmacokinetics of midazolam 70 micrograms/kg given an hour after a single 40-mg dose of intravenous **parecoxib**.[8] Valdecoxib, the active metabolite

of **parecoxib** is a substrate for the cytochrome P450 isoenzyme CYP3A4, but does not appear to affect the pharmacokinetics of midazolam, which is metabolised by CYP3A4.

(c) Oxazepam

In a study in 6 healthy subjects, **diflunisal** 500 mg twice daily decreased the peak plasma concentration and AUC of a single 30-mg dose of oxazepam by 38% and 16%, respectively; the AUC of oxazepam glucuronide increased by 70%. It was suggested that **diflunisal** displaced oxazepam from its plasma protein binding sites leading to a slightly increased presystemic hepatic extraction and a slightly decreased systemic availability. In addition, there appeared to be competition between the glucuronides of oxazepam and **diflunisal** for tubular secretion. The overall clinical significance was thought to be small.[9]

(d) Zaleplon

A randomised, single-dose study in 17 healthy subjects found that **ibuprofen** 600 mg had no effect on the pharmacokinetics of zaleplon 10 mg.[10]

Benzodiazepines + Paracetamol (Acetaminophen)

Paracetamol reduces the urinary excretion of diazepam but diazepam plasma levels are little affected. Oxazepam does not affect the pharmacokinetics of paracetamol.

Clinical evidence, mechanism, importance and management

The 96-hour urinary excretion of a single 10-mg oral dose of **diazepam** and its metabolite, nordiazepam, were reduced from 44% to 12% and from 27% to 8%, respectively, in 2 female subjects, and from 11% to 4.5%, respectively, in a male subject, by a single 500-mg dose of paracetamol. The reasons for these changes are not understood. The plasma levels of **diazepam** and its metabolite were not significantly affected,[1] which suggests that these changes are of limited clinical relevance.

In a study, 7 healthy subjects received a single 500-mg intravenous dose of paracetamol alone, and with a single 30-mg dose of oral **oxazepam**. The pharmacokinetics of paracetamol and its metabolites were unaffected by **oxazepam**, and no adverse effects were observed.[2]

There would seem to be no reason for avoiding the concurrent use of these benzodiazepines and paracetamol. There seems to be no information about other benzodiazepines.

Benzodiazepines and related drugs + Phenobarbital or Primidone

The use of benzodiazepines with phenobarbital or primidone may possibly be accompanied by some changes in plasma levels, which are normally of limited clinical importance. However, additive adverse effects such as sedation may occur during initial use. More serious effects (hallucinations, violent behaviour) have been reported, but appear rare.

Clinical evidence

(a) Chlordiazepoxide

A single case report describes a man given phenobarbital, secobarbital and chlordiazepoxide who became drowsy, unsteady, and developed slurred speech, nystagmus, poor memory and hallucinations, all of which disappeared once the phenobarbital was withdrawn and the chlordiazepoxide dose reduced from 80 to 60 mg daily.[1]

(b) Clobazam

A study in patients with epilepsy receiving long-term clobazam, alone or with other antiepileptic drugs, found that phenobarbital slightly reduced the plasma levels of both clobazam and its active metabolite, *N*-desmethylclobazam.[2] Similarly, another study reported that phenobarbital reduced the plasma levels of clobazam by 63% and reduced *N*-desmethylclobazam by 31%, although the effect on *N*-desmethylclobazam was not statistically significant. The plasma levels of phenobarbital were not affected by clobazam.[3] A further study also found that clobazam plasma levels were decreased by phenobarbital, and that the ratio between *N*-desmethylclobazam and clobazam levels increased. Clobazam significantly reduced the apparent clearance of primidone.[4]

(c) Clonazepam

Clonazepam, in slowly increasing doses up to a maximum of 4 to 6 mg daily, given over a 6-week period to patients taking phenobarbital with or without carbamazepine, had no effect on phenobarbital levels.[5] A study in patients receiving various combinations of phenytoin, phenobarbital and primidone, found that their plasma levels were not significantly altered by the addition of clonazepam 3 mg daily for 4 weeks, but the levels of clonazepam were reduced in the presence of the other antiepileptics, particularly phenobarbital and primidone. Drowsiness occurred in 44 of 66 patients in the first week after clonazepam was added to their antiepileptic treatment, but this improved in most patients; after 2 to 3 weeks only 6 patients still reported drowsiness, together with ataxia and hypotonicity. Depression was reported in one patient and personality changes with irritability and violent behaviour was reported in another.[6] A study found that phenobarbital caused some small changes in the pharmacokinetics of a single dose of clonazepam but only the small increase in clearance was statistically significant.[7] In contrast, an analysis of the serum levels of antiepileptics in children found that those taking clonazepam had markedly higher levels of primidone, and toxicity was seen.[8]

(d) Clorazepate

A report suggested that the concurrent use of primidone and clorazepate may have been responsible for the development of irritability, aggression and depression in 6 of 8 patients.[9]

(e) Diazepam

Phenobarbital 100 mg daily for 8 days had no effect on the metabolism of diazepam in a group of healthy subjects.[10] Some modest additive CNS depression may possibly be expected, but the authors of this report make no comment about this.

(f) Nitrazepam

An analysis of the serum levels of antiepileptics in children found that those taking nitrazepam had lower levels of primidone.[8]

Mechanism

Uncertain. Simple additive effects in some cases or changes in the drug metabolism in others seem likely. Phenobarbital may increase the rate of metabolism of some benzodiazepines through induction of liver enzymes.

Importance and management

Phenobarbital may increase the clearance of benzodiazepines and related drugs, although none of the interactions described here appear to be of major clinical importance. However, caution might be necessary with benzodiazepines, such as **midazolam**, that are primarily metabolised by CYP3A4. Similarly, the manufacturer of **zopiclone** notes that the concurrent use of phenobarbital may decrease the plasma levels of **zopiclone** and a dose increase may be required.[11] Primidone levels may be affected by clobazam and clonazepam and one study reported increased toxicity in children. It may be prudent to be alert for primidone adverse effects

such as drowsiness, ataxia or dysarthria, and monitor levels should these develop.

Adverse effects such as sedation may be more evident when benzodiazepines are combined with barbiturates, particularly in the initial stages of treatment, and careful dose adjustment may be required.

Benzodiazepines and related drugs + Phenytoin

Reports are inconsistent: benzodiazepines can cause phenytoin levels to increase (toxicity has been seen), decrease, or remain unaltered. In addition phenytoin may reduce clonazepam, diazepam, midazolam and oxazepam levels.

Clinical evidence

(a) Phenytoin levels increased

The observation that toxicity developed in patients taking phenytoin when they were given **chlordiazepoxide** or **diazepam** prompted a more detailed study. The plasma phenytoin levels of 25 patients taking phenytoin 300 or 400 mg daily and **chlordiazepoxide** or **diazepam** were 80 to 90% higher than those of 99 subjects taking phenytoin without a benzodiazepine.[1]

Further reports attribute increased phenytoin plasma levels and phenytoin toxicity to **chlordiazepoxide**,[2] **clobazam**,[3] **clonazepam**,[4-6] and **diazepam**.[7-9]

(b) Phenytoin levels decreased

The plasma phenytoin levels of 12 patients fell by about 30% over a 2-month period while they were taking **clonazepam** 1.5 to 12 mg daily. When data from another 12 patients were combined, the mean fall was only 18%.[10] Other studies describe similar findings with **clonazepam**[11] and **diazepam**.[12,13]

(c) Phenytoin levels unchanged

In one study, **alprazolam** did not affect the serum phenytoin levels in healthy subjects.[14] **Clonazepam** did not alter serum phenytoin levels in one study,[15] and another study concluded that **clonazepam** produced no predictable change in phenytoin levels, as phenytoin levels were increased in 9 patients, decreased in one patient, and unchanged in 3 patients.[16] A single-dose study in healthy subjects found no significant pharmacokinetic interaction between intravenous **diazepam** 10 mg and intravenous **fosphenytoin** 1.125 g (or the phenytoin formed by the hydrolysis of fosphenytoin).[17]

(d) Benzodiazepine levels reduced

A study in 5 patients given phenytoin 250 to 400 mg daily found that plasma **clonazepam** levels were reduced by more than 50%,[18] and another study found that phenytoin increased the clearance of **clonazepam** by about 50%.[19] In further studies, phenytoin reduced the plasma levels of **clobazam** and increased the levels of *N*-desmethylclobazam (the principal metabolite).[20,21] **Diazepam**[22] and **oxazepam**[23] may be similarly affected in patients with epilepsy given phenytoin.

The pharmacokinetics and pharmacodynamics of a single 15-mg oral dose of **midazolam** were studied in 6 patients with epilepsy taking carbamazepine, phenytoin, or both drugs together, and in 7 control subjects not taking either of these antiepileptics. The AUC of **midazolam** in the patients with epilepsy was reduced to 5.7%, and the peak plasma levels to 7.4%, of their value in the control subjects. The pharmacodynamic effects (subjective drowsiness, body sway with eyes closed and open, as well as more formal tests) were also reduced. Most of the patients did not notice any effects of the **midazolam**, while the control subjects were clearly sedated for 2 to 4 hours after taking the **midazolam**, and also experienced amnesia.[24]

Mechanism

The inconsistency of these reports is not understood. Benzodiazepine-induced changes in the metabolism of phenytoin[2,7,9,13] as well as alterations in the apparent volume of distribution have been suggested as possible mechanisms. Enzyme induction by phenytoin may possibly account for the reduction in plasma benzodiazepine levels.

Importance and management

A confusing picture. Concurrent use certainly need not be avoided (it has proved to be valuable in many cases) but monitor the outcome of concurrent use and consider monitoring plasma phenytoin levels so that undesirable changes can be detected. Only diazepam, chlordiazepoxide, clobazam and clonazepam have been implicated, but it seems possible that other benzodiazepines could also interact. One manufacturer of **temazepam** suggests that plasma phenytoin levels may be increased or decreased by temazepam and that phenytoin levels may need to be monitored during temazepam withdrawal. In addition, adverse effects may be more evident.[25]

Phenytoin may induce the metabolism of some benzodiazepines including clonazepam, diazepam, and midazolam causing a decrease in benzodiazepine levels. Similarly, the manufacturer of the non-benzodiazepine hypnotic, **zopiclone**,[26] suggests that its plasma levels may be decreased by phenytoin. If necessary, dose adjustments should be considered. Phenytoin may also cause an increase in the metabolic conversion of clobazam to the active metabolite *N*-desmethylclobazam.

Benzodiazepines + Probenecid

Probenecid reduces the clearance of adinazolam, lorazepam and nitrazepam. Increased effects (e.g. sedation) may be expected. Probenecid does not appear to interact with temazepam.

Clinical evidence

(a) Adinazolam

In a single-dose study in 16 healthy subjects, probenecid 2 g increased the psychomotor effects of sustained-release adinazolam 60 mg. The tests used were symbol-digit substitution, digit span forwards and continuous performance tasks.[1] The peak plasma levels of adinazolam and its active metabolite, *N*-desmethyladinazolam, were increased by 37% and 49%, respectively, and the clearances were reduced by 16% and 53%, respectively, by probenecid. Both drugs have uricosuric actions, but when used together the effects appear not to be additive.[1]

(b) Lorazepam

In 9 healthy subjects, probenecid 500 mg every 6 hours approximately halved the clearance of a single 2-mg intravenous dose of lorazepam. The elimination half-life was more than doubled, from 14.3 hours to 33 hours.[2]

(c) Nitrazepam

In healthy subjects, probenecid 500 mg daily for 7 days reduced the clearance of nitrazepam by 25%.[3]

(d) Temazepam

In healthy subjects, probenecid 500 mg daily for 7 days did not significantly affect the clearance of temazepam.[3]

Mechanism

Probenecid inhibits the renal tubular clearance of many drugs and their metabolites, including some of the benzodiazepines. It also inhibits the glucuronidation of nitrazepam and lorazepam by the liver.[2,3] The overall result is that these benzodiazepines accumulate and their effects are increased. Temazepam, which also undergoes glucuronidation, was not affected, possibly as increased sulfation compensated.[3]

Importance and management

Established interactions but of uncertain clinical importance. Be alert for increases in the effects (sedation, antegrade amnesia) of adinazolam, lorazepam and possibly nitrazepam. Reduce the dose as necessary. Note that adinazolam is no longer available. There seems to be no direct information about other benzodiazepines, but those that are metabolised like lorazepam or nitrazepam may possibly interact. Temazepam does not appear to interact with probenecid.

Benzodiazepines and related drugs + Protease inhibitors

Ritonavir, nelfinavir, saquinavir and ritonavir-boosted saquinavir, lopinavir and tipranavir reduce the metabolism and/or increase the bioavailability of midazolam. Ritonavir affects triazolam and, to a lesser extent, alprazolam and zolpidem. Increased sedative effects are predicted with several different pairs of protease inhibitors and benzodiazepines.

Clinical evidence

A. Benzodiazepines

(a) Alprazolam

A crossover study in 10 healthy subjects found that **ritonavir** 200 mg for 4 doses decreased the clearance of a single 1-mg dose of alprazolam by 59% and increased its AUC approximately 2.5-fold. The half-life of alprazolam was increased from 13.3 hours to 29.6 hours and the subjects experienced increased and prolonged sedation.[1] However, in another study when **ritonavir** 500 mg was given every 12 hours for 10 days, the AUC of a single dose of alprazolam *decreased* by 12%.[2,3]

(b) Midazolam

In a study, 90 HIV-positive patients not taking antiretrovirals (control group) and 56 similar patients taking antiretrovirals were given a 75-microgram oral dose of midazolam. The ratio of 1-hydroxymidazolam to midazolam, assessed 30 minutes after the midazolam dose, was found to be 13-fold lower in 18 patients taking **nelfinavir**, when compared with the control group. Similarly, the 1-hydroxymidazolam to midazolam ratio was 50-fold lower in 4 patients taking **ritonavir**, but less reduced in other patients who were also taking efavirenz or nevirapine.[4]

A randomised study in 12 healthy subjects found that **saquinavir** (soft-gel formulation) 1.2 g three times daily increased the bioavailability of oral midazolam from 41% to 90% and increased its AUC more than fivefold. Psychomotor tests showed impaired skills and greater sedation in the presence of **saquinavir**.[5] When intravenous midazolam was given with **saquinavir**, its sedative effects were only marginally altered.[5] However, a 32-year-old man with advanced HIV, taking zidovudine, lamivudine, co-trimoxazole and **saquinavir** 600 mg three times daily, did not wake spontaneously from a 5-mg intravenous dose of midazolam. He was given 300 micrograms of intravenous flumazenil to revert the prolonged sedation, but he was not free from sedation until 5 hours later. On a previous occasion, in the absence of **saquinavir**, he woke spontaneously 2 hours after the dose of midazolam.[6] The manufacturers of saquinavir note that in 16 healthy subjects, ritonavir-boosted **saquinavir** 100/1000 mg twice daily for 2 weeks increased the maximum levels and AUC of a single 7.5-mg oral dose of midazolam 4.3-fold and 12.4-fold, respectively.[7,8]

The manufacturer of **tipranavir** notes that ritonavir-boosted **tipranavir** increased the AUCs of intravenous and oral midazolam 2.8-fold and tenfold, respectively.[9] Similarly, the manufacturer of ritonavir-boosted **lopinavir** notes that, in a study in 14 healthy subjects, ritonavir-boosted **lopinavir** raised the AUC of intravenous and oral midazolam fourfold and 13-fold, respectively.[10]

(c) Triazolam

In a crossover study in 6 healthy subjects, **ritonavir** 200 mg for 4 doses reduced the clearance of triazolam 125 micrograms to less than 4% of control values, increased its AUC about 20-fold and increased its half-life from 3 hours to 41 hours, which resulted in increased and prolonged sedation.[11] A very brief case report also describes prolonged sedation in a patient given **ritonavir** and triazolam.[12]

B. Non-benzodiazepine hypnotics

A crossover study in 6 healthy subjects found that **ritonavir** 200 mg twice daily for 4 doses resulted in a 28% increase in the AUC of a single 5-mg dose of **zolpidem**. The reduction in the clearance of **zolpidem** was considered to be clinically unimportant.[11]

Mechanism

Alprazolam, midazolam and triazolam are metabolised by the cytochrome P450 isoenzyme CYP3A4, which is inhibited, to varying degrees, by the protease inhibitors. Benzodiazepine levels and effects are therefore

increased by the protease inhibitors. However, ritonavir may also induce CYP3A and although metabolism may be inhibited following the introduction of ritonavir, it appears that for some drugs, such as alprazolam, the inhibitory effects of ritonavir on CYP3A4 may decrease over time,[2,3] possibly reflecting the effect of induction from chronic exposure overcoming the inhibition due to acute exposure.[13] One study suggested that the enzyme-inducing effects of the protease inhibitors is diminished by efavirenz and nevirapine, which are known enzyme inducers.[4]

Zolpidem metabolism depends on several isoenzymes so inhibition of CYP3A4 alone may not produce clinically significant changes in its clearance.

Interactions between the protease inhibitors and the benzodiazepines that are metabolised mainly by glucuronidation, such as **lorazepam**, **oxazepam** or **temazepam**, are less likely, and reports are lacking. However, some protease inhibitors, such as ritonavir, also induce glucuronidation, and so in theory they may also affect the metabolism of these benzodiazepines.[2,14]

Importance and management

The interaction between the protease inhibitors and **midazolam** is established and of clinical importance. The UK manufacturers of the protease inhibitors contraindicate the concurrent use of *oral* midazolam, but advise that *intravenous* midazolam may be used with close monitoring within an intensive care unit or similar setting so that the appropriate management of respiratory depression is available. They also suggest that dose reductions should be considered. The authors of the study[5] suggest that continuous intravenous midazolam doses should be reduced by 50%, but do not consider dose adjustments for single intravenous doses necessary. **Triazolam** would be expected to interact in the same way as midazolam, and therefore the UK manufacturers generally contraindicate its use. The US manufacturers similarly contraindicate the concurrent use of midazolam and triazolam with protease inhibitors; however, they do not always differentiate between oral or intravenous midazolam. **Alprazolam** is contraindicated by the UK and US manufacturers of indinavir,[15,16] but cautioned by the manufacturers of saquinavir.[7,8] The manufacturer of ritonavir also suggests caution during the first several days when alprazolam is given with ritonavir, before induction of alprazolam metabolism develops.[2] Careful monitoring and dose adjustment will be required. It would seem prudent to apply some caution on the concurrent use of any protease inhibitor, as alprazolam is, in part, metabolised by the same route as midazolam.

Recommendations regarding other benzodiazepines vary slightly. **Clorazepate**, **diazepam**, **estazolam**, and **flurazepam** are contraindicated by the UK manufacturer of ritonavir[2] and indinavir,[15] but cautioned by the US manufacturer of ritonavir.[3] The US manufacturer of fosamprenavir and the UK and US manufacturers of saquinavir also suggest the possibility of an interaction with clorazepate, diazepam and flurazepam, and suggest that careful monitoring is needed, with dose adjustments as required.[7,8,17]

The manufacturers of ritonavir note that **zolpidem** may be given concurrently with careful monitoring for excessive sedative effects[2] and consideration of reducing the dose of zolpidem.[3] Similarly, the manufacturer of **zopiclone** warns that, as zopiclone is metabolised by CYP3A4, plasma levels of zopiclone may be increased when it is given with CYP3A4 inhibitors such as ritonavir, and a dose reduction of zopiclone may be required.[18]

Benzodiazepines + Proton pump inhibitors

Gait disturbances (attributed to benzodiazepine toxicity) occurred in two patients given triazolam and lorazepam or flurazepam with omeprazole, and another patient taking diazepam and omeprazole became wobbly and sedated. Lansoprazole, pantoprazole, or rabeprazole appear not to interact to a clinically relevant extent with diazepam. Diazepam plasma levels are increased by esomeprazole.

Clinical evidence

(a) Esomeprazole

In a placebo-controlled study 10 healthy subjects took esomeprazole 30 mg daily for 9 days, with a single 100-microgram/kg intravenous infusion of **diazepam** on day 5. The AUC of **diazepam** was increased by 81%, its clearance was decreased by 45%, and the half-life was extended from 43 hours to 86 hours. However, increased plasma levels of **diazepam** were only observed 12 hours or more after dosing, at which point they were subtherapeutic, and thus the interaction was thought unlikely to be of clinical relevance. **Diazepam** did not appear to change the pharmacokinetics of esomeprazole.[1]

(b) Lansoprazole

Lansoprazole 60 mg daily for 10 days was found to have no effect on the pharmacokinetics of a single 100-microgram/kg intravenous dose of **diazepam**.[2]

(c) Omeprazole

Two elderly patients, both smokers, taking **triazolam** with **lorazepam**, or **flurazepam**, developed gait disturbances when they were given omeprazole 20 mg daily. They rapidly recovered when either the benzodiazepines or the omeprazole were stopped.[3] A brief report describes a patient taking omeprazole who became wobbly and sedated by small, unspecified doses of **diazepam**,[4] and another report describes a patient who developed toxic levels of nordiazepam and remained unconscious for 13 days after receiving a high dose of **clorazepate** (1.5 g over about 29 hours) and omeprazole 80 mg daily.[5]

One study in 8 healthy subjects found that omeprazole 40 mg daily for one week reduced the clearance of a single 100-microgram/kg intravenous dose of **diazepam** by 54%,[6] while another study found that omeprazole 20 mg reduced **diazepam** clearance by 27%.[7]

A further study found that omeprazole 40 mg reduced the oral clearance of **diazepam** by 38% in white American subjects but only by 21% in Chinese subjects.[8] Metaboliser status (see 'Genetic factors', (p.4)) was also found to be important in other studies of this interaction: only extensive metabolisers of CYP2C19 showed a significant decrease in **diazepam** clearance when given omeprazole.[9,10]

(d) Pantoprazole

In a placebo-controlled study in 12 healthy subjects, intravenous pantoprazole 240 mg for 7 days did not change the half-life, clearance and AUC of a 100-microgram/kg intravenous bolus dose of **diazepam**.[11]

(e) Rabeprazole

In a crossover study, rabeprazole 20 mg daily or placebo was given to 20 subjects for 35 days with a single 100-microgram/kg intravenous dose of **diazepam** on day 8. The subjects were also assessed for mephenytoin hydroxylator status [a measure of CYP2C19 activity, see 'Genetic factors', (p.4)] and 2 subjects were found to be poor metabolisers. No signif-

icant changes in the pharmacokinetics of the **diazepam** were seen with rabeprazole, either when analyses were conducted including all the subjects or when excluding the poor metabolisers.[12] Another study similarly found that rabeprazole does not affect the pharmacokinetics of **diazepam** in both poor and extensive metabolisers of CYP2C19.[9]

Mechanism

In vitro studies with human liver microsomes suggest that omeprazole inhibits diazepam metabolism because it inhibits the cytochrome P450 isoenzymes CYP3A and CYP2C19.[13] Studies in humans suggest that CYP2C19 may be the most important isoenzyme in this interaction.[8] Esomeprazole also inhibits CYP2C19.[1]

Omeprazole is not expected to interact with benzodiazepines that are mainly metabolised by glucuronide conjugation such as lorazepam.[3] The reaction involving lorazepam[3] may possibly not be an interaction (so it is suggested) but an adverse effect of giving sedating medications to markedly anaemic patients.[4]

Importance and management

Information is limited, but what is currently known suggests that patients given omeprazole, and possibly esomeprazole, with diazepam may experience increased benzodiazepine effects (sedation, unstable gait etc.). If this occurs the benzodiazepine dose should be reduced. Lansoprazole, pantoprazole and rabeprazole do not appear to interact with diazepam. There seems to be no information regarding other benzodiazepines.

Benzodiazepines + Quinolones

Ciprofloxacin causes a marked reduction in the clearance of diazepam, but this does not appear to be clinically important in healthy subjects. Ciprofloxacin appears not to affect the pharmacokinetics of temazepam, and gatifloxacin appears not to interact with midazolam. Patients who are dependent on or withdrawing from long-term benzodiazepine use may possibly be more susceptible to CNS adverse effects of quinolones.

Clinical evidence and mechanism

(a) Ciprofloxacin

In a study in 10 healthy subjects, ciprofloxacin 500 mg twice daily for 3 days was found to have no effect on the pharmacokinetics of **diazepam**.[1] However, a later study in 12 healthy subjects found that ciprofloxacin 500 mg twice daily for 5 days increased the AUC of a single 5-mg intravenous dose of **diazepam** by 50%, reduced its clearance by 37% and doubled its half-life. These changes caused no significant alteration in the performance of a number of psychometric tests. It was suggested that the clearance of **diazepam** was reduced because ciprofloxacin inhibited the cytochrome P450-mediated metabolism of **diazepam**.[2] Another study by the same group found that ciprofloxacin 500 mg twice daily for 4 days does not interact with a single 10-mg oral dose of **temazepam**.[3]

(b) Gatifloxacin

In 14 healthy subjects gatifloxacin 400 mg daily for 5 days had no effect on the pharmacokinetics of **midazolam**. The pharmacokinetics of gatifloxacin were also unaffected by concurrent use.[4]

(c) Norfloxacin

A 44-year-old woman, who had undergone withdrawal from high doses of benzodiazepines 3 months previously, experienced an acute psychotic reaction within one hour of starting norfloxacin, and attempted suicide. Her condition quickly deteriorated and she developed repeated seizures progressing to status epilepticus. Her seizures were only controlled after norfloxacin was stopped.[5] Note that quinolones alone are known to cause psychiatric reactions and trigger seizures or lower the seizure threshold.

(d) Unnamed quinolones

Results from a survey of patients dependent on and withdrawing from benzodiazepines suggested an abnormally high incidence of adverse reactions to fluoroquinolones. Eleven participants reported severe or very severe adverse reactions, one participant reported a moderate adverse reaction and a further participant reported no reaction to fluoroquinolone treatment. All participants reported adverse effects similar to those of acute benzodiazepine withdrawal, which included depression, anxiety, psychosis, paranoia, severe insomnia, paraesthesia, tinnitus, hypersensitivity to light and sound, and tremors; four patients became acutely suicidal.[5] See also *Norfloxacin*, above

Importance and management

Ciprofloxacin may cause a reduction in the clearance of diazepam, but it seems unlikely that any marked increases in diazepam effects (drowsiness etc.) will occur in most patients. However, it may possibly be significant in those who have reduced renal or hepatic clearance (e.g. the elderly).[2] This needs confirmation.

Patients who are dependent on or withdrawing from chronic benzodiazepines may be more susceptible to adverse reactions to fluoroquinolones.[5]

5. McConnell JG. Benzodiazepine tolerance, dependency, and withdrawal syndromes and interactions with fluoroquinolone antimicrobials. Br J Gen Pract (2008) 58, 365–6.

Benzodiazepines + Ramelteon

A study in 28 healthy subjects found that ramelteon 32 mg daily for 9 days had no effect on the pharmacokinetics of a single 10-mg oral dose of midazolam. No midazolam dose adjustments are therefore expected to be necessary on concurrent use.[1]

1. Karim A, Tolbert D, Cao C, Zhao Z, Sainati SM. The effect of multiple doses of ramelteon (TAK-375) on the single-dose pharmacokinetic profile of midazolam in healthy adult subjects. *Sleep* (2004) 27 (Abstract Suppl), A47.

Benzodiazepines + Reboxetine

There is no pharmacokinetic interaction between lorazepam and reboxetine, and reboxetine does not alter the pharmacokinetics of alprazolam.

Clinical evidence

(a) Alprazolam

In a study in 12 healthy subjects, reboxetine 4 mg twice daily had no effect on the clearance of a single 1-mg dose of alprazolam given on day 12. This study was summarised in a review paper.[1]

(b) Lorazepam

In a study in 6 healthy subjects, the AUC of lorazepam did not differ when a single 2.5-mg dose of lorazepam was given alone or with reboxetine 2 mg twice daily. There was a less than 10% change in the lorazepam maximum level and half-life.[2] In a further study in 6 healthy subjects, the pharmacokinetics of a single 4-mg dose of reboxetine were not altered by lorazepam 1 mg twice daily for 7 days.[3]

Mechanism

These studies suggest that reboxetine does not alter the glucuronidation of lorazepam or the metabolism of alprazolam by the cytochrome P450 isoenzyme CYP3A4.

Importance and management

These studies show that no pharmacokinetic interactions are anticipated between lorazepam or alprazolam and reboxetine. Nevertheless, the manufacturer notes that during the concurrent use of reboxetine and lorazepam, mild to moderate drowsiness and an orthostatic increase in heart rate was observed in healthy subjects,[4] but they do not say how frequently these occurred with either drug alone, and, specifically, whether the effects were actually increased on combined use.

Benzodiazepines and related drugs + Rifampicin (Rifampin)

Rifampicin causes a very marked increase in the metabolism and/or clearance of diazepam, lorazepam, midazolam, nitrazepam, triazolam, zaleplon, zolpidem and zopiclone. Benzodiazepines and related drugs that are metabolised similarly are expected to interact in the same way. Temazepam pharmacokinetics are unchanged by rifampicin.

Clinical evidence

A. Benzodiazepines

(a) Diazepam

In 7 patients with tuberculosis who were given daily doses of isoniazid 500 mg to 2.2 g, rifampicin 450 to 600 mg and ethambutol 25 mg/kg, the mean half-life of diazepam was reduced from 58 hours to 14 hours and the clearance was increased fourfold, when compared with healthy control subjects.[1] In 21 healthy subjects rifampicin 600 mg or 1.2 g daily for 7 days increased the clearance of diazepam by about fourfold.[2]

(b) Lorazepam

In a study in healthy subjects, rifampicin increased the mean systemic clearance of intravenous lorazepam by approximately 140%, but interindividual variability occurred and clearance values were also affected by genetic variations in uridine diphosphate glucuronosyltransferase (UGT).[3]

(c) Midazolam

A pharmacokinetic study in 10 healthy subjects found that rifampicin 600 mg daily for 5 days reduced the AUC of a single 15-mg oral dose of midazolam by 96%, and reduced its half-life by almost two-thirds. The psychomotor effects of the midazolam (as measured by the digit symbol substitution test, Maddox wing test, postural sway and drowsiness) were almost totally lost.[4] The manufacturers note that rifampicin 600 mg daily for 7 days decreased the plasma concentrations of intravenous midazolam by about 60% and decreased its half-life by about 50 to 60%.[5]

(d) Nitrazepam

A study in healthy subjects found that rifampicin 600 mg daily for 7 days increased the total body clearance of nitrazepam by 83%.[6]

(e) Temazepam

A study found that the pharmacokinetics of temazepam were unchanged by rifampicin.[6]

(f) Triazolam

In a placebo-controlled study, 10 healthy subjects were given oral triazolam 500 micrograms before and after rifampicin 600 mg daily for 5 days. Rifampicin reduced the triazolam AUC by 95% and decreased its maximum plasma levels by 88%, when compared with placebo. The elimination half-life was reduced from 2.8 hours to 1.3 hours. Pharmacodynamic tests (drowsiness, sway, Maddox wing, etc.) showed that rifampicin abolished the effects of triazolam.[7]

B. Non-benzodiazepine hypnotics

(a) Zaleplon

A non-randomised, crossover study in healthy subjects found that rifampicin 600 mg daily for 14 days increased the clearance of a 10-mg dose of zaleplon 5.4-fold, decreasing its maximum plasma levels and AUC by 80%.[8]

(b) Zolpidem

In a randomised, placebo-controlled study, 8 healthy subjects were given rifampicin 600 mg daily for 5 days with a single 20-mg oral dose of zolpidem on day 6. It was found that the rifampicin reduced the zolpidem AUC by 73%, reduced its maximum plasma level by about 60% and reduced its half-life from 2.5 hours to 1.6 hours. A significant reduction in the effects of zolpidem was also seen, as measured by a number of psychomotor tests (digital symbol substitution, critical flicker fusion, subjective drowsiness, etc.).[9]

(c) Zopiclone

In a placebo-controlled study, 8 healthy subjects were given rifampicin 600 mg for 5 days, with a single 10-mg oral dose of zopiclone on day 6. The rifampicin reduced the AUC of zopiclone by 81%, decreased its peak plasma levels by 71% and reduced its half-life from 3.8 hours to 2.3 hours. A significant reduction in the effects of zopiclone was also seen, as measured by the performance of psychomotor tests.[10]

Mechanism

Rifampicin is a potent liver enzyme inducer, which increases the metabolism of several benzodiazepines and the non-benzodiazepine hypnotics, zaleplon, zolpidem and zopiclone, thereby decreasing their levels. The metabolism of midazolam by the cytochrome P450 isoenzyme CYP3A4 in both liver and gut is affected.[4] The enzyme-inducing effects of rifampicin seem to predominate if isoniazid (an enzyme inhibitor) is also present. Temazepam undergoes glucuronidation and seems to be unaffected by rifampicin. However, lorazepam glucuronidation appears to be induced by rifampicin, although lorazepam pharmacokinetics may also be influenced by drug transporter activity.[3]

Importance and management

The documentation of these interactions is limited but what has been reported is consistent with the way rifampicin interacts with many other drugs. The clinical importance of some of these interactions between the benzodiazepines and related drugs and rifampicin has not yet been assessed, but what is known suggests that the dose of diazepam and nitrazepam may need to be increased if rifampicin is given. Be alert for a reduction in the effects of other similarly metabolised benzodiazepines (e.g. **chlordiazepoxide**, **flurazepam**).

The effect of rifampicin on oral midazolam and triazolam is so large that they are likely to become ineffective and an alternative should be used instead. **Alprazolam** is also predicted to interact because CYP3A is involved with its metabolism.[11] The plasma levels and/or the pharmacodynamic effects of the non-benzodiazepine hypnotics, zaleplon, zolpidem and zopiclone, are also substantially reduced and a dose increase may be required.

Those benzodiazepines that, like temazepam, undergo glucuronidation (e.g. lorazepam, **oxazepam**) are not expected to be affected by rifampicin to such an extent as those metabolised primarily by hepatic microsomal oxidation, and may be useful alternatives; however, note that lorazepam has been seen to interact and so, until more is known, some caution may be warranted.

Benzodiazepines + Rifaximin

In a study in healthy subjects, rifaximin 200 mg three times daily did not affect the pharmacokinetics of single oral or intravenous doses of midazolam.[1] Therefore, rifaximin does not appear to affect intestinal or hepatic CYP3A4 activity, and would therefore not be expected to affect the pharmacokinetics of other benzodiazepines metabolised in this way (e.g. alprazolam, triazolam). No dose adjustments of these benzodiazepines would therefore be necessary if rifaximin is also given.

1. Pentikis HS, Connolly M, Trapnell CB, Forbes WP, Bettenhausen DK. The effect of multiple-dose, oral rifaximin on the pharmacokinetics of intravenous and oral midazolam in healthy volunteers. *Pharmacotherapy* (2007) 27, 1361–9.

Benzodiazepines + Roflumilast

Roflumilast did not affect the pharmacokinetics of midazolam in one study.

Clinical evidence, mechanism, importance and management

In a study, 18 healthy subjects were given a single 2-mg oral dose of midazolam, and a single 1-mg intravenous dose of midazolam before and after taking roflumilast 500 micrograms daily for 14 days. Roflumilast did not affect the pharmacokinetics of midazolam.[1] Midazolam is used as a probe drug for the activity of the cytochrome P450 isoenzyme CYP3A4. These findings therefore suggest that roflumilast will not affect the metabolism of other benzodiazepines metabolised by this route (e.g. alprazolam and triazolam). No dose adjustments would therefore appear necessary if roflumilast is given with any of these benzodiazepines.

1. Nassr N, Lahu G, von Richter O, Reutter F, Knoerzer D, Zech K, Erb KA, Schug B, Blume H, Hermann R. Lack of a pharmacokinetic interaction between steady-state roflumilast and single-dose midazolam in healthy subjects. *Br J Clin Pharmacol* (2007) 63, 365–70.

Benzodiazepines and related drugs + SNRIs

Visual hallucinations have been seen in one patient given zolpidem and venlafaxine. No important interaction normally appears to occur between venlafaxine and alprazolam, diazepam or zaleplon. The pharmacokinetics of duloxetine are not affected by lorazepam or temazepam. However, there is limited evidence to suggest that sedation might initially be increased by the concurrent use of duloxetine and lorazepam.

Clinical evidence

(a) Duloxetine

In a placebo-controlled study, the pharmacokinetics of duloxetine 60 mg twice daily and **lorazepam** 2 mg twice daily were not affected by concurrent use. However, compared with **lorazepam** alone, the addition of duloxetine led to decreased vigilance on various psychomotor tests (such as digit symbol substitution test) during the first day of concurrent use, although this effect tended to lessen over the 4 days of the study.[1] The steady-state pharmacokinetics of duloxetine 20 mg at bedtime were not affected by **temazepam** 30 mg at bedtime.[2]

(b) Venlafaxine

A 27-year-old woman who had been taking venlafaxine 37.5 mg at night for a week and terfenadine for a few years started taking **zolpidem** 10 mg daily. After 2 days, and within 45 minutes of the **zolpidem** dose, she developed visual hallucinations, which lasted for 2 to 4 hours. A similar episode occurred 2 weeks later when she had discontinued the terfenadine.[3]

A study in 16 healthy subjects found that venlafaxine 75 mg twice daily reduced the AUC of a single 2-mg oral dose of **alprazolam** by 29% and reduced its half-life by 21%, and the performance of psychometric tests were only minimally changed.[4] A double-blind study in 18 healthy subjects taking venlafaxine 50 mg every 8 hours found that the concurrent use of **diazepam** 10 mg did not have a clinically significant effect on the pharmacokinetics of either drug, or their major active metabolites (*O*-desmethylvenlafaxine and desmethyldiazepam). **Diazepam** affected the performance of a series of pharmacodynamic tests, but the addition of venlafaxine had no further effects.[5]

The manufacturers of **zaleplon** describe a study in which a single dose of **zaleplon** 10 mg and extended-release venlafaxine 150 mg did not result in any significant changes in the pharmacokinetics of either **zaleplon** or venlafaxine.[6,7] Additionally, there was no pharmacodynamic interaction[7] with tests for memory and psychomotor performance being unaffected.[6]

Mechanism

Uncertain. Zolpidem alone is associated with hallucinations, and it has been suggested that a pharmacodynamic interaction between serotonin reuptake inhibition and zolpidem may lead to a prolongation of this effect in susceptible individuals.[3]

Importance and management

The studies suggest that no special precautions are necessary during the concurrent use of venlafaxine and alprazolam or diazepam, or between duloxetine and lorazepam or temazepam. However, a pharmacodynamic interaction may possibly occur and caution has been advised due to the potential for increased sedation.[1] Hallucinations have been seen with zolpidem alone, and they have also occurred, rarely, when zolpidem was given with some 'SSRIs', (below), which are related to venlafaxine. Reports of adverse effects such as these seem rare and the concurrent use of these drugs need not be avoided, but bear these possible interactions in mind if hallucinations or increased sedation occur.

Benzodiazepines and related drugs + SSRIs

The metabolism of some benzodiazepines such as alprazolam, bromazepam and diazepam (and also possibly midazolam and triazolam) may be reduced by fluvoxamine. There is some evidence to suggest that fluoxetine may have some effect on the pharmacokinetics and psychomotor impairment caused by alprazolam and diazepam. On the whole, no clinically significant interaction appears to occur between other SSRIs and the benzodiazepines or related drugs such as cloral hydrate or zaleplon. However, there is limited evidence to support the suggestion that sedation may be increased by the concurrent use of SSRIs and benzodiazepines. Rare cases of hallucinations have been seen with zolpidem and some SSRIs. Symptoms of the serotonin syndrome have been reported in two patients taking paroxetine and benzodiazepines.

Clinical evidence

(a) Citalopram

1. Alprazolam. A general study in psychiatric patients found that when data on benzodiazepines was pooled, they caused a modest 23% increase in serum citalopram levels, which is almost certainly too small to be clinically relevant. Alprazolam was the only benzodiazepine to cause an elevation of citalopram levels (by 13%) when analysed alone.[1] In another study, citalopram was found to have no effect on alprazolam plasma levels, although the time to peak alprazolam levels was increased by 30 minutes.[2]

2. Triazolam. A study in 17 healthy subjects found no pharmacokinetic interaction between triazolam and citalopram.[3]

(b) Fluoxetine

1. Alprazolam. The concurrent use of fluoxetine 60 mg daily has been found to reduce the clearance of alprazolam 1 mg four times daily by about 21% and to increase its plasma levels by about 30%. These changes were accompanied by increased psychomotor impairment.[4] Another study also reported impaired alprazolam metabolism, although no significant changes in alprazolam pharmacodynamics were found.[2]

2. Diazepam. Fluoxetine 30 mg, given either as s single dose, or daily for 8 days, had no effect on the pharmacokinetics of diazepam 10 mg.[5] A later study by the same group, using 60 mg of fluoxetine suggested that the diazepam half-life and AUC were increased, possibly because the fluoxetine decreased the metabolism of diazepam. However, they concluded that this was not of any clinical significance.[6] Another study found that fluoxetine 60 mg alone did not affect psychomotor performance but fluoxetine 60 mg plus diazepam 5 mg significantly impaired the divided attention tracking test and vigilance test more than with diazepam 5 mg alone.[7]

3. Other benzodiazepines and related drugs. Other studies found that the pharmacokinetics of **clonazepam**,[8] **estazolam**,[9] **midazolam**,[10,11] **triazolam**,[12] and **zolpidem**[13,14] were not significantly affected by fluoxetine. Isolated cases of visual hallucinations lasting up to 7 hours have been reported in patients taking **zolpidem** who were also taking fluoxetine.[15] Marked drowsiness occurred for a whole day in a patient taking fluoxetine 20 mg daily after being given **cloral hydrate** 500 mg the night before. She later tolerated **cloral hydrate** 1 g in the absence of fluoxetine without adverse effects.[16]

(c) Fluvoxamine

1. Alprazolam. In 60 healthy subjects, fluvoxamine 50 mg daily for 3 days then 100 mg daily for 7 days, doubled the plasma levels of alprazolam 1 mg four times daily given on days 7 to 10. The alprazolam clearance was more than halved. Psychomotor performance and memory were found to be significantly worsened, even after only one day.[17] A study in 23 Japanese patients found that fluvoxamine increased the plasma levels of alprazolam by 58%. There was wide interpatient variability, possibly associated with differences in the cytochrome P450 isoenzyme CYP2C19 levels in these patients although it is unclear exactly what impact this isoenzyme has on the interaction.[18]

2. Bromazepam. In 12 healthy subjects, fluvoxamine 50 mg twice daily increased the plasma levels of a single 12-mg dose of bromazepam by 36% and increased the AUC almost 2.5-fold. Some increased impairment in cognitive function was seen.[19]

3. Cloral hydrate. Fluvoxamine has been found not to interact adversely with cloral hydrate.[20]

4. Diazepam. In 8 healthy subjects, fluvoxamine (50 mg on day one, 100 mg on day 2, then 150 mg daily thereafter) for 16 days decreased the clearance of a single 10-mg dose of diazepam given on day 4 by about 65%. The half-life was increased from 51 hours to 118 hours, and the AUC was increased threefold.[21]

5. Lorazepam. In 12 healthy subjects, fluvoxamine 50 mg twice daily caused a very small, non-significant, increase in the plasma levels and AUC of a single 4-mg dose of lorazepam.[19]

6. Midazolam. A study in 10 healthy subjects[11] found that fluvoxamine 50 mg twice daily for 8 days then 100 mg twice daily for 6 days had minimal effects on the pharmacokinetics of a single 10-mg dose of midazolam given on day 12.

7. Quazepam. A placebo-controlled study in 12 healthy subjects found that fluvoxamine 25 mg twice daily for 14 days had no effect on the pharmacokinetics of a single 20-mg dose of quazepam. However, formation of the metabolite, 2-oxoquazepam, was decreased, and there was a minor decrease in the sedative effects of quazepam at 4 hours, although these changes were considered to be of little clinical significance.[22]

(d) Paroxetine

1. Alprazolam. A randomised, placebo-controlled study in 22 healthy subjects reported no evidence for a pharmacokinetic or pharmacological interaction between paroxetine and alprazolam.[23]

2. Clonazepam. An isolated report describes worsening anxiety, agitation, mild abdominal cramps and diaphoresis in a woman taking paroxetine, shortly after starting clonazepam (dose stated as one tablet). This toxic response was suggested as being serotonin syndrome, although in fact many of the usual signs were absent and moreover, clonazepam has actually been used to treat the myoclonus that occurs in serotonin syndrome. The patient was effectively treated with **lorazepam**.[24]

3. Diazepam. No important changes in the pharmacokinetics of paroxetine were seen when 12 healthy subjects given paroxetine 30 mg daily were also given diazepam 5 mg three times a day. Adverse events were not increased by the combination.[25]

4. Etizolam. Another report describes a patient who was admitted to hospital with symptoms of serotonin syndrome within 6 days of starting daily treatment with paroxetine 20 mg, etizolam 1 mg and **brotizolam** 250 micrograms. Paroxetine was discontinued on day 6. Serotonin syndrome usually resolves within 24 hours of discontinuing the causative medication but symptoms in this patient continued for a total of 10 days.[26]

5. Oxazepam. One study found that paroxetine did not increase the impairment of a number of psychomotor tests caused by oxazepam.[27]

6. Zaleplon. In a double-blind study in healthy subjects it was found that paroxetine 20 mg for 9 days had no effect on the pharmacokinetics of zaleplon 20 mg, and psychomotor performance was unaffected by concurrent use.[28]

7. Zolpidem. An isolated report describes a healthy 16-year-old girl with depression who took paroxetine 20 mg daily for 3 days, and then on the evening of the third night a single 10-mg dose of zolpidem. Within one hour she began to hallucinate, then became disorientated and was unable to recognise members of her family. She recovered spontaneously within 4 hours.[29]

(e) Sertraline

1. Alprazolam. A pharmacokinetic study in 10 healthy subjects found that sertraline 50 to 150 mg daily had no effect on the pharmacokinetics of alprazolam 1 mg and did not potentiate the psychomotor impairment produced by alprazolam alone, although there was a decrease in peak performance in the manual tracking test.[30] Similarly, in 12 healthy subjects, sertraline 50 mg daily had no effect on the pharmacokinetics of alprazolam 1 mg daily after 2 weeks of concurrent use.[31]

2. Clonazepam. A study in 13 subjects given clonazepam 1 mg daily with sertraline 100 mg daily for 10 days found that sertraline did not significantly affect the pharmacokinetics of clonazepam. There was also no evidence that the addition of sertraline to clonazepam made the subjects more sedated or less able to carry out simple psychometric tests.[32]

3. Diazepam. In a placebo-controlled study, the systemic clearance of a single intravenous dose of diazepam was reduced by 13% after 21 days of sertraline treatment. This small effect was thought unlikely to be of clinical significance, although the effect of sertraline on repeated oral doses of diazepam was not studied.[33,34]

4. Zolpidem. Sertraline appears to have no clinically significant effects on the pharmacokinetics of zolpidem,[35] but isolated cases of visual hallucinations lasting up to 7 hours have been reported in patients taking zolpidem and sertraline.[15]

Mechanism

The evidence suggests that fluvoxamine inhibits the metabolism of benzodiazepines that undergo oxidation (e.g. alprazolam, bromazepam, diazepam) thereby increasing and prolonging their effects, but not those that are metabolised by glucuronidation (e.g. lorazepam). Fluoxetine is a weak inhibitor of CYP3A4, and it appears to inhibit the metabolism of alprazolam by this route.[2]

Importance and management

A well studied interaction, although the evidence regarding individual pairs of benzodiazepines and SSRIs is generally limited. The available data suggests that the doses of alprazolam, bromazepam and diazepam should be reduced, probably by half, in the presence of fluvoxamine to avoid adverse effects (drowsiness, reduced psychomotor performance and memory). Furthermore, some US manufacturers recommend avoiding the use of fluvoxamine with diazepam as substantial diazepam accumulation could occur. They also note that fluvoxamine has non-linear kinetics, and therefore the effects of higher doses of fluvoxamine such as 300 mg daily could be even more pronounced, particularly with long-term diazepam use.[36] Some manufacturers warn that the clearance of other oxidatively metabolised benzodiazepines (e.g. midazolam and **triazolam**) is likely to be decreased by fluvoxamine[36,37] and the dose of these benzodiazepines may need to be reduced;[37] however, one study with midazolam and fluvoxamine found only a minimal interaction. Fluvoxamine is unlikely to affect lorazepam and other benzodiazepines metabolised by glucuronidation (e.g. oxazepam, **temazepam**).[36]

Fluoxetine also appears to have some effect on the pharmacokinetics and pharmacodynamics of alprazolam and diazepam and so some caution would be prudent.

It seems unlikely that citalopram, paroxetine or sertraline will affect the pharmacokinetics of the benzodiazepines and they may therefore be a useful alternative to fluvoxamine. However, it should be noted that some of the studies found pharmacodynamic effects (that is, increased sedation or clumsiness) in the absence of a pharmacokinetic interaction. Patients should be advised to be alert for the possibility of these effects when first starting treatment.

The hallucinations seen with the SSRIs and zolpidem appear rare, and reactions of this kind have been seen with zolpidem alone. The concurrent use of these drugs need not be avoided, but bear this possible interaction in mind if hallucinations occur.

Benzodiazepines and related drugs + St John's wort (*Hypericum perforatum*)

Long-term use of St John's wort decreases the plasma levels of alprazolam, midazolam and quazepam. Zopiclone is predicted to be similarly affected. St John's wort preparations taken as a single dose, or containing low-hyperforin levels, appear to have less of an effect.

Clinical evidence, mechanism, importance and management

(a) Alprazolam

In a study in 12 healthy subjects, St John's wort (*LI 160, Lichtwer Pharma*, 0.12 to 0.3% hypericin) 300 mg three times daily for 16 days with a single 2-mg dose of alprazolam on day 14. The AUC of alprazolam was halved by St John's wort and the clearance was increased by about twofold.[1]

In another study, alprazolam 1 or 2 mg was given to 7 healthy subjects on the third day of a 3-day treatment period with St John's wort (*Solaray*; hypericin content standardised at 0.3%) 300 mg three times daily. The pharmacokinetics of alprazolam were unchanged by St John's wort, but the authors note that 3 days may have been an insufficient time for St John's wort to fully induce cytochrome P450 isoenzymes.[2] In another study, 16 healthy subjects were given St John's wort extract 120 mg (*Esbericum* capsules; corresponding to 0.5 mg total hypericins and 1.76 mg hyperforin) twice daily for 10 days. A single 1-mg dose of alprazolam was given on the day before treatment with St John's wort and on the last day of treatment. St John's wort extract at this low dosage and low hyperforin content had no clinically relevant effects on the pharmacokinetics of alprazolam, when compared with 12 subjects given placebo.[3]

(b) Midazolam

An open-label study in 12 healthy subjects found that a single 900-mg dose of St John's wort had no significant effect on the pharmacokinetics of single doses of either *oral* midazolam 5 mg or *intravenous* midazolam 0.05 mg/kg, although there was a trend for increased oral clearance. However, St John's wort 300 mg three times daily for 14 or 15 days decreased the AUC and maximum plasma concentration of *oral* midazolam by about 50% and 40%, respectively. Intravenous midazolam was not significantly affected. Similar results were found in another six studies.[4-9] In one of the studies, although no serious adverse events occurred, 3 subjects reported that the sedative effects of midazolam were less noticeable when St John's wort was taken at the same time.[6]

(c) Quazepam

In a placebo-controlled study, 13 healthy subjects were given St John's wort (*TruNature*; hypericin content standardised at 0.3%) 300 mg three

times daily for 14 days with a single 15-mg dose of quazepam on day 14. St John's wort modestly decreased the AUC and maximum plasma levels of quazepam by 26% and 29%, respectively, but the pharmacodynamic effects of quazepam were not affected.[10]

Mechanism

Alprazolam, midazolam and quazepam are substrates of the cytochrome P450 isoenzyme CYP3A4. St John's wort appears to induce CYP3A4 thus increasing the metabolism of *oral* midazolam,[5-9,11] alprazolam,[1] and quazepam,[10] and reducing the bioavailability of these benzodiazepines.

Hyperforin appears to be the main active constituent that induces CYP3A4, because high-hyperforin extracts have more of an inducing effect than low-hyperforin extracts.[6-9]

Importance and management

Although not all the studies found an interaction between St John's wort and alprazolam or midazolam, those that did found a reduction in levels, which is in line with the known CYP3A4 inducing effects of St John's wort. The variable findings reported in the studies (some found no interaction) could be due to the preparation of St John's wort used and the duration of treatment.[2,9] Until more is known about the interacting constituents of St John's wort, and the amount necessary to provoke an interaction it would seem prudent to monitor patients receiving alprazolam and oral midazolam concurrently for any signs of reduced efficacy. Single doses of *intravenous* midazolam do not appear to be significantly affected. Note that triazolam is also a substrate of CYP3A4 and is likely to be affected in the same way as alprazolam and midazolam.

The non-benzodiazepine hypnotic, **zopiclone**, is also metabolised by CYP3A4 and the manufacturer of zopiclone suggests that the dose may need to be increased if St John's wort is also given.[12]

The modest reduction in quazepam levels did not reduce its efficacy; however, it may be prudent to bear the potential for an interaction in mind should a patient taking St John's wort have a reduced response to quazepam.

Those benzodiazepines that undergo glucuronidation, such as lorazepam, oxazepam and temazepam, would not be expected to be affected by St John's wort, and may be useful alternatives.

Benzodiazepines + Statins

The long-term use of atorvastatin appears to decrease the clearance of intravenous midazolam.

Clinical evidence, mechanism, importance and management

In a study in 14 patients given intravenous **midazolam** during elective surgery, long-term **atorvastatin** therapy in 7 of the patients was found to decrease the plasma clearance of midazolam by one-third and increase the AUC of midazolam by about 40%. It was therefore suggested that, in patients receiving **atorvastatin** long-term, the potential for respiratory depression or prolonged sedation should be considered if high-dose **midazolam** is used.[1]

The reason for this effect is unclear. The effect of other statins and benzodiazepines does not appear to have been studied. Nevertheless, some caution would seem warranted with benzodiazepines that are metabolised in the same way as midazolam (e.g. **alprazolam**, **triazolam**).

Benzodiazepines + Sucrose polyesters

Sucrose polyesters (e.g. *Olestra*) do not appear to interact with diazepam.

Clinical evidence, mechanism, importance and management

In a study in 8 healthy subjects, a single 5-mg dose of **diazepam** was given with 18 g of sucrose polyester (*Olestra*). Sucrose polyester had no effect on the pharmacokinetics of **diazepam**.[1] Sucrose polyesters are non-absorbable, non-calorific fat replacements. It has been concluded that sucrose polyesters are unlikely to reduce the absorption of oral drugs in general.[2]

2. Goldman P. Olestra: assessing its potential to interact with drugs in the gastrointestinal tract. *Clin Pharmacol Ther* (1997) 61, 613–18.

Benzodiazepines + Tadalafil

Tadalafil does not alter the pharmacokinetics of midazolam.

Clinical evidence, mechanism, importance and management

An open label study in 12 healthy subjects found that while taking tadalafil 10 mg daily for 14 consecutive days, the pharmacokinetics of a single 15-mg oral dose of **midazolam** were unchanged.[1] **Midazolam** is metabolised by the cytochrome P450 isoenzyme CYP3A4, and it was therefore concluded that the absence of any interaction shows that tadalafil does not inhibit or induce the activity of this isoenzyme.[1] No special precautions are therefore needed if **midazolam** is given with tadalafil.

1. Ring BJ, Patterson BE, Mitchell MI, Vandenbranden M, Gillespie J, Bedding AW, Jewell H, Payne CD, Forgue ST, Eckstein J, Wrighton SA, Phillips DL. Effect of tadalafil on cytochrome P450 3A4-mediated clearance: studies in vitro and in vivo. *Clin Pharmacol Ther* (2005) 77, 63–75.

Benzodiazepines + Terbinafine

Terbinafine does not interact with midazolam or triazolam to a clinically relevant extent.

Clinical evidence, mechanism, importance and management

In studies in healthy subjects, terbinafine 250 mg daily for 4 days had no effect on the pharmacokinetics of a single 7.5-mg oral dose of **midazolam**[1] or a single 250-microgram oral dose of **triazolam**.[2] The performance of a number of psychomotor tests was unaffected by concurrent use. No special precautions would seem to be necessary if terbinafine is given with either of these drugs.

2. Varhe A, Olkkola KT, Neuvonen PJ. Fluconazole, but not terbinafine, enhances the effects of triazolam by inhibiting its metabolism. *Br J Clin Pharmacol* (1996) 41, 319–23.

Benzodiazepines and related drugs + Theophylline

Aminophylline and theophylline appear to antagonise the effects of the benzodiazepines (mainly sedative effects, but possibly also anxiolytic effects). Theophylline appears to reduce the levels of alprazolam.

Clinical evidence

In a comparative study, two groups of patients were given **alprazolam** 500 micrograms twice daily for 7 days. In one group there were 6 patients who had chronic obstructive pulmonary disease (COPD) and were taking theophylline; and in the other group there were 7 patients with chronic heart failure or atherosclerotic disease (one patient also with COPD) who were not taking theophylline. On day 7, those taking the theophylline were found to have trough serum **alprazolam** levels of 13.25 nanograms/mL, whereas in the group not taking theophylline, **alprazolam** trough levels were 43.92 nanograms/mL.[1] Note that the groups were not randomised, or equivalent in terms of disease state, and other medications taken, so other factors may have had a part to play in this finding.

A patient who was unrousable and unresponsive having been given **diazepam** 60 mg over 10 minutes and nitrous oxide/oxygen anaesthesia, rapidly returned to consciousness when given aminophylline 56 mg intravenously.[2] Other reports confirm this antagonism of **diazepam**-induced sedation, by low doses of aminophylline (60 mg to 4.5 mg/kg intravenously).[3-5] Further studies report that aminophylline and theophylline counteract the drowsiness and mental slowness induced by a single 10- to 20-mg dose of **diazepam**.[6-8] **Flunitrazepam**,[9] **lorazepam**,[10] and **midazolam**[11,12] also appear to be affected; however, there is some controversy about whether or not aminophylline antagonises the effects of **midazolam**.[13]

Mechanism

Uncertain. One suggestion is that the xanthines can block adenosine receptors,[3] which regulate the release of neurotransmitters, and may therefore lead to stimulant effects, which oppose the sedative effects of the benzodiazepines.

Importance and management

The documentation is somewhat sparse and there is a need for more study over the range of benzodiazepines, but the overall picture is that these interactions are established. The extent to which theophylline and aminophylline actually reduce the anxiolytic effects of the benzodiazepines remains uncertain (it needs assessment) but be alert for reduced benzodiazepine effects if either xanthine is used.

Benzodiazepines and related drugs + Tobacco

Smokers may possibly need larger doses of some benzodiazepines or zolpidem than non-smokers.

Clinical evidence, mechanism, importance and management

Some studies have suggested that smoking does not affect the pharmacokinetics of **chlordiazepoxide**,[1] **clorazepate**,[2] **diazepam**,[3,4] **estazolam**,[5] **lorazepam**,[4] **midazolam**,[4] **quazepam**,[6] or **triazolam**,[7] but others have found that the clearance of **alprazolam**,[8] **clorazepate**,[9] **diazepam**,[10] **lorazepam**,[4,11] **oxazepam**[12,13] or **zolpidem**[14] is increased by smoking, although not all the changes were statistically significant,[4,8,10-12,14] often due to the small numbers of smokers involved in the studies. The Boston Collaborative Drug Surveillance Program reported a decreased frequency of drowsiness in smokers who took **diazepam** or **chlordiazepoxide**,[15] which confirmed the findings of a previous study.[16] It has also been noted that two heavy smokers had a very high clearance and did not experience any sedative effects following the use of **zolpidem**.[17]

The probable reason for the reduction in sedative effects with these drugs is that some of the components of tobacco smoke are enzyme inducers, which increase the rate at which the liver metabolises these benzodiazepines, thereby reducing their effects. The inference to be drawn is that smokers may possibly need larger doses than non-smokers to achieve the same therapeutic effects. Smoking also possibly reduces the drowsiness that the benzodiazepines and non-benzodiazepine hypnotics, such as **zolpidem**, can cause. However, one study suggested that caffeine intake,[16] and others have suggested age, may affect the response to benzodiazepines, so the picture is not altogether clear. Whether any of these interactions has much clinical relevance awaits assessment.

Benzodiazepines + Ursodeoxycholic acid (Ursodiol)

Ursodeoxycholic acid does not appear to affect the pharmacokinetics of midazolam.

Clinical evidence, mechanism, importance and management

A placebo-controlled, crossover study in 14 healthy subjects found that ursodeoxycholic acid 100 mg three times daily for 9 days did not affect the pharmacokinetics or the pharmacodynamics of single doses of intravenous **midazolam** 5 micrograms/kg or oral midazolam 15 micrograms/kg. This suggests that ursodeoxycholic acid has no effect on both intestinal and hepatic CYP3A activities in healthy subjects.[1] Another study also reported

that ursodeoxycholic acid had no effect on the pharmacokinetics of a single 7.5-mg oral dose of **midazolam**.[2]

Other benzodiazepines do not appear to have been studied, but as **alprazolam** and **triazolam** are metabolised in a similar way to **midazolam**, they would also not be expected to interact with ursodeoxycholic acid.

1. Yan D, Yang Y, Uchida S, Misaka S, Luo J, Takeuchi K, Inui N, Yamada S, Ohashi K, Watanabe H. Effects of ursodeoxycholic acid on the pharmacokinetics and pharmacodynamics of intravenous and oral midazolam in healthy volunteers. Naunyn-Schmiedebergs Arch Pharmacol (2008) 377, 629–36.

Benzodiazepines and related drugs + Valproate

Valproate appears to increase the plasma levels of diazepam, lorazepam and possibly midazolam, while clobazam appears to raise valproate levels. Clonazepam clearance may increase and valproate clearance decrease during concurrent use, and increased adverse effects have been seen. An isolated case describes sleepwalking in a patient taking valproate and zolpidem.

Clinical evidence

A. Benzodiazepines

(a) Clobazam

In a study in patients with epilepsy, the plasma levels of clobazam appeared lower in the presence of antiepileptics including sodium valproate than when patients were given monotherapy, but sodium valproate did not affect the levels of the main metabolite of clobazam, *N*-desmethylclobazam.[1] A study in children found that clobazam caused an 11% increase in the serum levels of valproate, despite a reduction of at least 10% in the valproate dose.[2]

(b) Clonazepam

The addition of clonazepam to sodium valproate increased the unwanted effects (drowsiness, absence status) in 9 out of 12 paediatric and adolescent patients.[3] An analysis of the interaction between clonazepam and valproate in 317 patients with epilepsy found that concurrent use increased clonazepam clearance by 14% and decreased valproate clearance by 18%.[4]

(c) Diazepam

In 6 healthy subjects sodium valproate increased the serum levels of free diazepam twofold.[5] Valproate may slightly increase the sedative effects of diazepam.[6]

(d) Lorazepam

In healthy subjects, lorazepam 1 mg every 12 hours for 3 days had no effect on the pharmacokinetics of valproate semisodium 500 mg every 12 hours. Valproate semisodium increased the AUC and maximum plasma levels of lorazepam by 20% and 8%, respectively. Sedation scores were slightly increased by concurrent use, although this was not statistically significant.[7]

The clearance of a 2-mg intravenous bolus dose of lorazepam was decreased by 40% in 6 out of 8 healthy subjects while they were taking valproate 250 mg twice daily.[8] Similarly, in another study, valproate decreased the mean systemic clearance of intravenous lorazepam by 20%, but interindividual variability occurred and clearance values were also affected by variations in uridine diphosphate glucuronosyltransferase (UGT) genotype.[9] A woman taking valproate, phenytoin, and carbamazepine went into a coma after she received a total of 6 mg of intravenous lorazepam. She promptly recovered on stopping the valproate.[10] Valproate may slightly increase the sedative effects of lorazepam.[7]

B. Non-benzodiazepine hypnotics

A report describes a patient taking **zolpidem** 5 mg at night and citalopram 30 mg daily, who started sleepwalking when valproate 250 mg twice daily was started. The patient stopped the valproate and the sleepwalking episodes resolved. Later, the valproate was restarted causing the sleepwalking to recur. This time the symptoms resolved when the **zolpidem** was stopped.[11]

Mechanism

It seems that valproate reduces the glucuronidation of lorazepam,[7,8] thereby decreasing its clearance. Other benzodiazepines that are mainly metabolised by glucuronide conjugation, such as **oxazepam** and **temazepam** would be expected to be similarly affected. However, lorazepam pharmacokinetics may additionally be influenced by other factors including genetic polymorphism.[9] It is also thought that valproate may displace diazepam from plasma binding sites.[5] However, this mechanism alone rarely results in clinically significant interactions.

Importance and management

Evidence of an adverse interaction between valproate and the benzodiazepines and related hypnotics is sparse, and concurrent use is generally beneficial. Although potentially clinically significant effects (sedation, absence seizures) have been seen only rarely, it has been suggested that the combination of clonazepam and sodium valproate should be avoided.[3] However, a very brief letter points out that clonazepam and valproate can be given together in patients with absence seizures and some patients have an excellent response to the combination.[12] Nevertheless, the potential hazard should be borne in mind when concurrent use is considered.

It has been recommended that if clobazam is given with valproate it would be prudent to monitor for any increases in valproate serum levels.[2]

The increased levels of lorazepam seen with valproate are relatively modest; however the case report describing coma introduces a note of caution. The manufacturer of lorazepam advises that the dose of lorazepam should be halved in patients taking valproate.[13] Enhanced sedation has been briefly described during the concurrent use of valproate and unnamed benzodiazepines,[14] and diazepam. Be aware of this potential adverse effect when valproate is given with any benzodiazepine.

Benzodiazepines + Vinpocetine

Vinpocetine does not appear to interact adversely with oxazepam. Vinpocetine did not appear to affect the ability to sleep, or the short-term memory impairment, induced by flunitrazepam.

Clinical evidence, mechanism, importance and management

In a study in 16 healthy subjects, vinpocetine 10 mg three times daily for 7 days did not affect the steady-state plasma levels of **oxazepam** 10 mg three times daily.[1] There would therefore seem to be no reason for taking special precautions if these two drugs are given together.

A crossover study in 8 healthy subjects found that although vinpocetine 40 mg three times daily for 2 days improved short-term memory processes, it did not significantly affect **flunitrazepam**-induced impairment of

memory. **Flunitrazepam** either alone or in combination with vinpocetine appeared to improve patients' ability to sleep.[2]

2. Bhatti JZ, Hindmarch I. Vinpocetine effects on cognitive impairments produced by flunitrazepam. *Int Clin Psychopharmacol* (1987) 2, 325–31.

Benzodiazepines; Diazepam + Misoprostol

A study in 12 subjects found that misoprostol 200 micrograms four times daily for 7 days had no effect on the steady-state plasma levels of diazepam 10 mg daily or on the plasma levels of the metabolite, nordiazepam.[1] Similar results were found in another study.[2] No dose adjustments of diazepam would therefore seem to be necessary if misoprostol is also given.

1. Lima DR, Santos RM, Werneck E, Andrade GN. Effect of orally administered misoprostol and cimetidine on the steady state pharmacokinetics of diazepam and nordiazepam in human volunteers. *Eur J Drug Metab Pharmacokinet* (1991) 16, 161–70.

Benzodiazepines; Lorazepam + Colestyramine and Neomycin

The clearance of lorazepam is increased by colestyramine with neomycin.

Clinical evidence, mechanism, importance and management

A study in 7 healthy subjects found that neomycin 1 g every 6 hours, given with colestyramine 4 g every 4 hours, reduced the half-life of oral **lorazepam** from 15.8 hours to 11.7 hours, and increased the clearance of free **lorazepam** by 34%.[1] The reasons for these changes are not clear but parallel studies using intravenous **lorazepam**[1] suggested that neomycin and colestyramine may interfere with the enterohepatic circulation of **lorazepam**.

The clinical importance of this interaction is uncertain but probably small. Other benzodiazepines do not appear to have been studied.

1. Herman RJ, Duc Van Pham J, Szakacs CBN. Disposition of lorazepam in human beings: enterohepatic recirculation and first-pass effect. *Clin Pharmacol Ther* (1989) 46, 18–25.

Buspirone + Azoles

The plasma levels of buspirone are markedly increased by itraconazole. Ketoconazole is predicted to interact similarly.

Clinical evidence

In a placebo-controlled study, 8 healthy subjects were given buspirone 10 mg, before and after taking **itraconazole** 100 mg twice daily for 4 days. It was found that the buspirone maximum plasma levels and its AUC were increased 13-fold and 19-fold, respectively, by **itraconazole**. These increased buspirone levels caused a moderate impairment of psychomotor performance (digital symbol substitution, body sway, drowsiness, etc.) and an increase in adverse effects.[1]

Mechanism

Itraconazole is a potent inhibitor of the cytochrome P450 isoenzyme CYP3A4, by which buspirone is metabolised. Itraconazole therefore increases buspirone levels and effects.

Importance and management

Direct information appears to be limited to this study but the interaction would seem to be established. The dose of buspirone should be greatly reduced if itraconazole is given concurrently. The manufacturers recommend 2.5 mg daily[2] or twice daily.[3] **Ketoconazole** is predicted to interact similarly because it is also a potent CYP3A4 inhibitor.[1,2]

2. BuSpar (Buspirone hydrochloride). Bristol-Myers Squibb Company. US Prescribing information, March 2007.
3. Buspar (Buspirone hydrochloride). Bristol-Myers Pharmaceuticals. UK Summary of product characteristics, May 2008.

Buspirone + Calcium-channel blockers

Diltiazem and verapamil can markedly raise the plasma levels of buspirone, increasing the likelihood of adverse effects.

Clinical evidence, mechanism, importance and management

In a randomised study in 9 healthy subjects, **diltiazem** 60 mg three times daily for 5 doses increased the AUC of a single 10-mg dose of buspirone 5.5-fold and increased its maximum plasma level 4.1-fold.

When **verapamil** 80 mg three times daily was similarly given with buspirone, the buspirone AUC and maximum plasma level were both increased 3.4-fold.

The increased buspirone levels are thought to occur because both **diltiazem** and **verapamil** inhibit the cytochrome P450 isoenzyme CYP3A4, which is concerned with the metabolism of buspirone.[1]

The practical consequences of this interaction are that the effects of buspirone are likely to be increased by **diltiazem** and **verapamil**. Concurrent use need not be avoided but be alert for the need to reduce the buspirone dose. The US manufacturer suggests adjusting the dose according to response,[2] while the UK manufacturer suggests using a lower dose of buspirone e.g. 2.5 mg twice daily.[3] Information about other calcium-channel blockers appears to be lacking, but they do not usually appear to interact by inhibiting CYP3A4 (see 'Calcium-channel blockers', (p.1025)).

Buspirone + Disulfiram

An isolated report describes mania in an alcoholic patient taking buspirone 20 mg daily, possibly due to an interaction with disulfiram 400 mg daily;[1] however, buspirone on its own has also apparently caused mania.[2,3] Therefore an interaction is not established and no general recommendations can be made.

Buspirone + Grapefruit juice

Grapefruit juice can markedly increases the plasma levels of buspirone.

Clinical evidence, mechanism, importance and management

In a randomised, crossover study, 10 healthy subjects were given either double-strength grapefruit juice 200 mL or water 200 mL three times daily for 2 days. On the third day, a single 10-mg dose of buspirone was given with the grapefruit juice or water, and additional grapefruit juice or water ingested 30 and 90 minutes later. Grapefruit juice increased the peak plasma level and AUC of buspirone 4.3-fold and 9.2-fold, respectively. The time to peak buspirone level was also increased from 45 minutes to 3 hours. However, an increase in the pharmacodynamic effects of buspirone was seen only in the subjective overall drug effect. Grapefruit juice probably inhibited the metabolism of buspirone by the cytochrome P450 isoenzyme CYP3A4 in the gut. The authors of this study recommended that the concurrent use of buspirone and grapefruit juice should be avoided.[1] However, the UK manufacturer recommends that a lower dose of bus-

pirone e.g. 2.5 mg twice daily should be used with potent inhibitors of CYP3A4 such as grapefruit juice:[2] the US manufacturer suggests that patients should avoid drinking large quantities of grapefruit juice.[3]

3. BuSpar (Buspirone hydrochloride). Bristol-Myers Squibb Company. US Prescribing information, March 2007.

Buspirone + Macrolides

The plasma levels of buspirone are markedly increased by erythromycin.

Clinical evidence

In a placebo-controlled study buspirone 10 mg was given to 8 healthy subjects before and after they took **erythromycin** 500 mg three times daily for 4 days. It was found that the buspirone maximum plasma level and AUC were increased fivefold and sixfold, respectively, by **erythromycin**. The increased buspirone levels caused a moderate impairment of psychomotor performance (digital symbol substitution, body sway, drowsiness, etc.) and an increase in adverse effects.[1]

Mechanism

Erythromycin is an inhibitor of the cytochrome P450 isoenzyme CYP3A4, by which buspirone is metabolised. Erythromycin therefore increases buspirone levels and hence its effects.

Importance and management

Direct information appears to be limited to this study, but the interaction would seem to be established. The dose of buspirone should be reduced if erythromycin is given concurrently. The manufacturers suggest using a low dose of buspirone e.g. 2.5 mg twice daily,[2,3] adjusted according to response.[3]

Other macrolides (most notably **clarithromycin** and **telithromycin**) are also inhibitors of CYP3A4 and may therefore interact similarly.

Buspirone + Miscellaneous

Buspirone does not appear to interact with amitriptyline, cimetidine or terfenadine. Nefazodone greatly increases buspirone levels.

Clinical evidence, mechanism, importance and management

(a) Amitriptyline

In a study in healthy subjects, buspirone 15 mg every 8 hours, given with amitriptyline 25 mg every 8 hours for 10 days, had no significant effect on the steady-state plasma levels of amitriptyline or its metabolite, nortriptyline. No evidence of a pharmacodynamic interaction was seen.[1] There would seem to be no reason for avoiding concurrent use.

(b) Cimetidine

In 10 healthy subjects, cimetidine 1 g daily for 7 days had no effect on the plasma levels of buspirone 15 mg three times daily. Some small pharmacokinetic changes were seen, but the performance of three psychomotor function tests remained unaltered.[2] There would seem to be no reason for avoiding concurrent use.

(c) Nefazodone

Nefazodone 250 mg twice daily caused a 20-fold increase in the maximum plasma levels of buspirone 2.5 or 5 mg twice daily and a 50-fold increase in its AUC. Buspirone 5 mg twice daily raised the AUC of nefazodone by 23%, which is unlikely to be clinically significant. The manufacturers of buspirone have recommended that a lower dose of buspirone e.g. 2.5 mg daily[3] or twice daily[4] should be used if nefazodone is given.

(d) Terfenadine

A single 10-mg dose of buspirone was given to 10 healthy subjects after they had taken terfenadine 120 mg daily for 3 days. There were no significant effects on the pharmacokinetics or pharmacodynamics of buspirone.[5]

5. Lamberg TS, Kivistö KT, Neuvonen PJ. Lack of effect of terfenadine on the pharmacokinetics of the CYP3A4 substrate buspirone. *Pharmacol Toxicol* (1999) 84, 165–9.

Buspirone + Protease inhibitors

Ritonavir, and possibly indinavir, are predicted to reduce the metabolism of buspirone. This resulted in Parkinson-like symptoms in one case.

Clinical evidence, mechanism, importance and management

A 54-year-old man who had been taking high-dose buspirone (40 mg every morning and 30 mg every evening) developed Parkinson-like symptoms about 6 weeks after starting to take **ritonavir** 400 mg and **indinavir** 400 mg, both twice daily. The dose of buspirone was reduced to 15 mg three times daily, **ritonavir** and **indinavir** were discontinued, and amprenavir 1.2 g twice daily was started. The Parkinson-like symptoms were reduced after about one week and completely resolved after 2 weeks.[1]

Buspirone is metabolised by the cytochrome P450 isoenzyme CYP3A4, and it is probable that **ritonavir** and **indinavir** inhibited the metabolism of buspirone resulting in toxic levels.

This appears to be an isolated case report,but it is in line with the way buspirone is known to interact with other CYP3A4 inhibitors. The manufacturer of buspirone usually recommends that a lower dose of buspirone (e.g. 2.5 mg twice daily in the UK) should be used with potent inhibitors of CYP3A4,[2] such as **ritonavir**. All protease inhibitors inhibit CYP3A4 to a greater or lesser extent, and therefore some caution would be prudent if buspirone is given with any protease inhibitor.

2. Buspar (Buspirone hydrochloride). Bristol-Myers Pharmaceuticals. UK Summary of product characteristics, May 2008.

Buspirone + Rifampicin (Rifampin)

Rifampicin can cause a marked reduction in the plasma levels and effects of buspirone.

Clinical evidence

In a randomised study, a single 30-mg dose of buspirone was given to 10 healthy subjects, before and after they took rifampicin 600 mg daily for 5 days. It was found that rifampicin reduced the total AUC of buspirone by about 90% and reduced its peak plasma level by 84%. The pharmacodynamic effects of buspirone were reduced accordingly (as measured by digit symbol substitution, critical flicker fusion, body sway and visual analogue scales for subjective drowsiness).[1]

Mechanism

Not fully established, but it is almost certain that rifampicin induces the cytochrome P450 isoenzyme CYP3A4 in the gut and liver, which metabolises buspirone. Therefore the metabolism and clearance of buspirone are increased.

Importance and management

Direct information appears to be limited to this study, but it is consistent with the way rifampicin interacts with many other drugs. This interaction would appear to be clinically important. If both drugs are used in combi-

nation, the buspirone dose may need to be increased, although note that the extent of this interaction is so great that this may not be effective, and therefore it may be prudent to consider alternatives to buspirone, where possible.

1. Lamberg TS, Kivistö KT, Neuvonen PJ. Concentrations and effects of buspirone are considerably reduced by rifampicin. *Br J Clin Pharmacol* (1998) 45, 381–5.

Buspirone + SSRIs

Isolated reports describe symptoms of serotonin syndrome when buspirone was given with SSRIs, although in some cases there may have been other contributing factors. The combination of buspirone and fluoxetine can be effective, but seizures and worsening of symptoms have been reported. Fluvoxamine may increase the levels of buspirone, but may possibly reduce its effects.

Clinical evidence, mechanism, importance and management

(a) Citalopram

An isolated report describes the development of serotonin syndrome and hyponatraemia, thought to be caused by an interaction between citalopram and buspirone, which had been taken in higher doses than prescribed.[1] The general importance of this interaction when conventional doses are used is unknown.

(b) Fluoxetine

An isolated report describes serotonin syndrome in a 48-year-old man after his dose of clomipramine was increased to 250 mg daily and buspirone 5 mg three times daily and fluoxetine 20 mg daily were added to his treatment. As all three drugs can affect brain serotonin concentrations, buspirone was considered to be partially responsible.[2]

A 35-year-old man with a long history of depression, anxiety and panic started taking buspirone 60 mg daily. His anxiety abated, but because of worsening depression he was also given trazodone 200 mg daily for 3 weeks. This had little effect, so fluoxetine 20 mg daily was added. Within 48 hours his usual symptoms of anxiety had returned and persisted even when the dose of buspirone was raised to 80 mg daily. Stopping the buspirone did not increase his anxiety.[3] Another patient with obsessive-compulsive disorder taking fluoxetine experienced a marked worsening of his symptoms when buspirone 5 mg twice daily was added.[4] A patient taking fluoxetine 80 mg daily had a grand mal seizure 3 weeks after buspirone 30 mg daily was added. The drugs were stopped and an EEG showed no signs of epilepsy, so the seizure was attributed to a drug interaction.[5] Other reports describe the effective concurrent use of fluoxetine and buspirone in patients with treatment-resistant depression[6] and with obsessive-compulsive disorder.[7,8]

There would seem to be little reason for avoiding concurrent use, however bear these case reports of interactions in mind when both drugs are used.

(c) Fluvoxamine

Serotonin syndrome developed in a 48-year-old man taking fluvoxamine and haloperidol after buspirone and valproate semisodium were also given. The symptoms subsided within 24 to 36 hours after discontinuation of these medications. Buspirone affects 5-HT_{1A} receptors and so may contribute to the development of serotonin syndrome with fluvoxamine.[9]

A double-blind study in 9 healthy subjects found that after taking fluvoxamine (mean dose 127 mg daily, range 100 to 150 mg daily) for 3 weeks, the plasma levels of a single 30-mg dose of buspirone were increased almost threefold. Even so, the psychological responses to the buspirone were reduced.[10] However, a study in 10 healthy subjects given a single 10-mg dose of buspirone after taking fluvoxamine 100 mg daily for 5 days, found that although the pharmacokinetics of buspirone were altered (AUC increased 2.4-fold) the pharmacodynamic tests remained unchanged.[11]

It has been suggested that fluvoxamine inhibits the liver enzymes concerned with the metabolism of buspirone. Concurrent use need not be avoided but it would be wise to remain alert to the possibility of reduced buspirone effects until more is known.

(d) Paroxetine

A 52-year-old woman experienced symptoms of serotonin syndrome within a month of taking the combination of buspirone, paroxetine and paverine. The symptoms rapidly decreased after paroxetine was withdrawn.[12]

(e) Sertraline

Symptoms of serotonin syndrome occurred in a patient 11 days after buspirone, sertraline and loxapine were started for recurrent major depression. Buspirone was discontinued and the main symptoms resolved over the next day, although facial dyskinesias remained until the other two drugs were stopped. The patient had previously received buspirone together with **citalopram** or another serotonergic drug without any adverse effects. It was suggested that the concurrent use of drugs with serotonergic and antidopaminergic properties may have produced two different effects: serotonin syndrome and extrapyramidal adverse effects.[13]

Buspirone + St John's wort (*Hypericum perforatum*)

Two patients taking buspirone developed marked CNS effects after starting to take herbal medicines including St John's wort.

Clinical evidence

A 27-year-old woman who had been taking buspirone 30 mg daily for over one month started to take St John's wort (*Hypericum 2000 Plus*, Herb Valley, Australia) three tablets daily. After 2 months she complained of nervousness, aggression, hyperactivity, insomnia, confusion and disorientation, which was attributed to serotonin syndrome. The St John's wort was stopped, the buspirone was increased to 50 mg daily and her symptoms resolved over a week.[1] A 42-year-old woman who was taking fluoxetine 20 mg twice daily and buspirone 15 mg twice daily started to develop symptoms of anxiety, with episodes of over-sleeping and memory deficits. It was discovered that she had been self-medicating with St John's wort, **ginkgo biloba** and **melatonin**. She was asked to stop the non-prescribed medication and her symptoms resolved.[2]

Mechanism

The exact mechanism of these interactions are not clear, but it seems most likely they were due to the additive effects of the buspirone and the herbal medicines, either through their effects on elevating mood or through excess effects on serotonin. Fluoxetine may have had a part to play in one of the cases. See 'SSRIs + St John's wort (*Hypericum perforatum*)', p.1492.

Importance and management

The clinical significance of these cases is unclear, but they highlight the importance of considering adverse effects from herbal medicines when they are used with conventional medicines.

Buspirone + Trazodone

The concurrent use of buspirone and trazodone may result in serotonin syndrome, and may possibly affect liver enzymes.

Clinical evidence, mechanism, importance and management

A report describes serotonin syndrome in a patient receiving several drugs including buspirone and trazodone.[1] Mild serotonin syndrome occurred in another patient receiving **tandospirone** (which is structurally related to buspirone) and trazodone.[2]

It was suggested that synergistic effects on the 5-HT system might be responsible, and/or an increase in the plasma levels of the drugs might occur due to a shared metabolic pathway.[2] A further report suggested that the concurrent use of buspirone and trazodone may have caused three- to sixfold elevations of ALT in a few patients. However, in a similar study no interactive effect on hepatic transaminases was identified.[3]

For more information on serotonin syndrome, see under 'Additive or synergistic interactions', (p.9). The clinical relevance of the effect on liver enzymes is unclear; note that trazodone is, rarely, known to cause hepatocellular damage, sometimes severe, when given alone.

Clomethiazole + Diazoxide

Clomethiazole and diazoxide, given to pregnant women in labour, can cause marked respiratory depression in their infants for up to 36 hours after birth.

Clinical evidence

An infusion of 0.8% clomethiazole, in a dose of 4 to 24 g, was given during labour to 21 pregnant women of 28 to 40 weeks gestation for eclampsia or pre-eclamptic toxaemia. Diazoxide 75 to 150 mg was also given intravenously to 14 of the women for hypertension. All 21 babies were born alive but 13 suffered hypotonia, hypoventilation or apnoea for 24 to 36 hours after birth. All of the neonates affected, apart from one, came from the group of mothers who had been given diazoxide. Three of them died of respiratory distress syndrome; one was only 28 weeks' gestation.[1]

Mechanism

Clomethiazole has some respiratory depressant effects, and is contraindicated in patients with respiratory deficiency, but it is not clear why, having passed across the placenta into the foetus, its effects should apparently be so markedly increased by diazoxide.

Importance and management

Although use of this drug combination in eclampsia is historical, the interaction is included on account of its severity. The author of the report says that the respiratory depression was managed successfully with intermittent positive pressure ventilation, provided that respiratory distress syndrome was not also present.[1]

1. Johnson RA. Adverse neonatal reaction to maternal administration of intravenous chlormethiazole and diazoxide. *BMJ* (1976) 1, 943.

Clomethiazole + Furosemide

Ten female patients aged 66 to 90 years were given clomethiazole edisilate syrup 500 mg each evening and 250 mg each morning as a sedative, with furosemide 20 to 80 mg. No significant changes in the plasma levels or effects of clomethiazole or furosemide were detected, and no other significant adverse reactions were seen.[1] No particular precautions therefore seem necessary on concurrent use.

1. Reid J, Judge TG. Chlormethiazole night sedation in elderly subjects receiving other medications. *Practitioner* (1980) 224, 751–3.

Clomethiazole + H_2-receptor antagonists

Increased sedation appears to occur when clomethiazole is given with cimetidine. Ranitidine does not appear to affect the pharmacokinetics of clomethiazole.

Clinical evidence, mechanism, importance and management

In a study in 8 healthy subjects, cimetidine 1 g daily for one week reduced the clearance of a single 768-mg dose of clomethiazole by 31% and prolonged its elimination half-life from 2.33 hours to 3.63 hours. Furthermore, clomethiazole produced a sleep duration of 30 to 60 minutes, but this was prolonged in most subjects to at least 2 hours after cimetidine. It was suggested that cimetidine inhibits the metabolism of clomethiazole and increases the bioavailability of the drug resulting in increased pharmacodynamic effects.[1] The clinical relevance of these relatively modest effects is probably small.

In two studies, each in 7 healthy subjects, ranitidine 150 mg twice daily did not significantly affect the pharmacokinetics of a single 768-mg dose of oral clomethiazole, or a single 192-mg dose of intravenous clomethiazole, given over 5 minutes.[2]

2. Mashford ML, Harman PJ, Morphett BJ, Breen KJ, Desmond PV. Ranitidine does not affect chlormethiazole or indocyanine green disposition. *Clin Pharmacol Ther* (1983) 34, 231–3.

Clomethiazole + Miscellaneous

Carbamazepine increases the clearance of clomethiazole. Other enzyme inducers are expected to interact similarly.

Clinical evidence, mechanism, importance and management

The manufacturers of clomethiazole note that the clearance of intravenous clomethiazole was increased by 30% by **carbamazepine**, resulting in decreased plasma levels. Although this interaction has not been studied with oral clomethiazole, the concurrent use of **carbamazepine** would be expected to result in decreased clomethiazole bioavailability. Higher doses of clomethiazole may therefore be needed in the presence of **carbamazepine** or other potent inducers of the cytochrome P450 isoenzyme CYP3A4.[1] For a list of inducers of this isoenzyme see 'Table 1.4', (p.6).

1. Heminevrin Capsules (Clomethiazole). AstraZeneca UK Ltd. UK Summary of product characteristics, August 2009.

Clomethiazole + Propranolol

An isolated report describes marked bradycardia when an elderly woman taking propranolol started to take clomethiazole.

Clinical evidence, mechanism, importance and management

An 84-year-old woman taking propranolol 40 mg twice daily for hypertension underwent skin grafting. Her pulse was stable (54 to 64 bpm) until the thirteenth day after the operation when she took two oral doses of clomethiazole 192 mg, 9 hours apart. Three hours after taking the second dose, her heart rate fell to 43 bpm with a PR interval of 240 milliseconds, and by 5 hours after the dose her pulse rate was down to 36 bpm. Her pulse had risen to 70 bpm twelve hours after stopping both drugs, and had restabilised 2 days later at about 60 bpm with a PR interval of 200 milliseconds. At this time the propranolol was restarted, with haloperidol.[1] This interaction appears to be an isolated case and therefore probably of limited clinical significance.

1. Adverse Drug Reactions Advisory Committee. Chlormethiazole/propranolol interaction? *Med J Aust* (1979) 2, 553.

Clozapine + Antihypertensives

There are isolated cases of apparent hypotensive interactions in patients taking clozapine, and enalapril, lisinopril or propranolol. Additive hypotensive effects are possible with clozapine and any antihypertensive drug.

Clinical evidence, mechanism, importance and management

A patient taking **enalapril** 5 mg twice daily fainted within an hour of being given an initial 25-mg dose of clozapine. Later he was stabilised without problems taking **enalapril** 2.5 mg twice daily and clozapine, initially 12.5 mg daily, later rising to 800 mg daily. Another patient taking **enalapril** 5 mg daily fainted within 5 hours of being given clozapine 25 mg. He needed resuscitation, but was later treated with clozapine in doses up to 600 mg daily.[1] The clozapine blood levels of a 39-year-old man rose from 490 nanograms/mL to 966 nanograms/mL after the addition of **lisinopril** 5 mg daily. When the **lisinopril** dose was increased to 10 mg daily, the levels further rose to 1092 nanograms/mL. The dose of clozapine was reduced, and **lisinopril** replaced by diltiazem, after which his levels began to return to normal.[2]

Coma developed in a woman taking **propranolol** 40 mg daily 1.5 to 2 hours after she was given a single 150-mg dose of clozapine. She had stopped taking fluphenazine 24 hours earlier. The patient recovered, and was subsequently slowly titrated up to a daily clozapine dose of 100 mg in addition to the **propranolol**, without any problems. Although the authors state that an interaction between **propranolol** and clozapine was the likely cause of the coma, the effects of fluphenazine cannot be wholly ruled out.[3]

Clozapine has alpha-blocking effects and therefore may cause orthostatic hypotension. The manufacturers note that this is more likely in the presence of other antipsychotics or benzodiazepines and during initial titration with rapid dose increases. Because of the potential for additive effects they recommend caution when giving clozapine to patients taking any hypotensive drug.[4,5]

Clozapine + Antimuscarinics

The antimuscarinic effects of clozapine are additive with those of other antimuscarinic drugs, which has led to urinary retention and delirium.

Clinical evidence, mechanism, importance and management

The manufacturers of clozapine warn that the antimuscarinic effects of some drugs (such as those used to control hypersalivation[1]), may be additive with those of clozapine, which may lead to adverse effects such as dry mouth and constipation.[2,3] Confirmation of the clinical relevance of this proposed interaction was seen in a patient who developed severe urinary retention while taking clozapine and **meclozine**.[4]

Another case report describes a man with a schizoaffective disorder taking **nortriptyline**, **perphenazine** and propranolol was also given clozapine 150 mg daily. Some improvement was seen after 8 days, and over the next week the propranolol was gradually discontinued while the clozapine dosage was raised to 225 mg daily. The patient then began to complain of extreme fatigue and slurred speech, and by day 17 was delirious and confused. His serum **nortriptyline** levels were found to have doubled (from 93 to 185 nanograms/mL) from the time the clozapine was started. He recovered within 5 days of stopping all of the drugs, after which the clozapine was restarted.[5] The authors of the report interpreted the symptoms as an antimuscarinic delirium arising from the additive antimuscarinic effects of the clozapine, **nortriptyline** and **perphenazine**, made worse by the increased levels of **nortriptyline**.[5] Just why the **nortriptyline** levels rose is not clear, but one possible explanation is that the **nortriptyline** and clozapine compete for metabolism by the same liver enzymes, resulting in a reduction in the clearance of the **nortriptyline**.

However, **pirenzepine**, which has antimuscarinic activity, has been used to control clozapine-associated hypersalivation. In one study in 29 patients, there were no significant changes in the serum levels of clozapine or its metabolite desmethylclozapine (although levels were increased in 3 patients) when **pirenzepine** was also taken, and the risk of additional adverse effects was reportedly low.[6]

'Table 18.1', (p.784) and 'Table 18.2', (p.786) give lists of drugs that have antimuscarinic activity.

Clozapine + Azoles

Itraconazole and ketoconazole do not affect the pharmacokinetics of clozapine.

Clinical evidence, mechanism, importance and management

A double-blind study in 7 patients with schizophrenia taking clozapine found that giving **itraconazole** 200 mg daily for a week did not affect the serum levels of clozapine or its desmethylclozapine metabolite.[1]

In a study, 5 patients with schizophrenia were given a single 50-mg dose of clozapine before and after a 7-day course of **ketoconazole** 400 mg daily. **Ketoconazole** had no significant effect on the pharmacokinetics of clozapine.[2]

The authors of these reports conclude that the cytochrome P450 isoenzyme CYP3A4 is of only minor importance in clozapine metabolism, and that because no interaction takes place between clozapine and **itraconazole** or **ketoconazole**, these azoles and other inhibitors of CYP3A4 can be used with clozapine.[1,2] However, note that raised clozapine levels have been attributed to treatment with the CYP3A4 inhibitor, erythromycin, see 'Clozapine + Macrolides', p.876, and lowered clozapine levels have been seen with the CYP3A4 inducer phenytoin, see 'Clozapine + Phenytoin', p.878. This suggests that, in some circumstances at least, CYP3A4 may be important in clozapine metabolism, and so the potential for an interaction cannot entirely be dismissed.

Clozapine + Benzodiazepines

A handful of reports describe severe hypotension, respiratory depression, unconsciousness and respiratory arrest (fatal in one case) in patients taking benzodiazepines and clozapine. Dizziness and sedation are also increased.

Clinical evidence

A schizophrenic patient did not respond to treatment with fluphenazine, **diazepam**, **clobazam** and **lormetazepam** having taken the combination for several weeks. The fluphenazine was stopped and clozapine started at a dose of 25 mg at noon and 100 mg at night. Toxic delirium and severe hypersalivation developed 3 hours later. The patient collapsed (systolic blood pressure 50 mmHg, diastolic blood pressure unrecordable) and stopped breathing. Resuscitation was started, and the patient remained unconscious for 30 minutes. After a few drug-free days clozapine 12.5 mg was successfully re-introduced, and very slowly titrated upwards; a low benzodiazepine dosage was also given.[1]

Another patient taking clozapine died suddenly and unexpectedly during the night, apparently due to respiratory arrest, after being given three 2-mg intravenous doses of **lorazepam** the previous day.[2]

There are at least 6 other cases of severe hypotension, respiratory depres-

sion or loss of consciousness in patients taking clozapine and **flurazepam**, **lorazepam** or **diazepam**,[1,3-5] as well as other cases of marked sedation, hypersalivation, ataxia and delirium in patients taking **lorazepam** and clozapine.[6,7] Two of these reports[1,3] are from the same group of workers and it is not clear whether they are about the same or different patients.

Mechanism

Not understood. Clozapine on its own very occasionally causes respiratory arrest and hypotension.

Importance and management

Evidence for an interaction between benzodiazepine and clozapine appears to be limited to case reports. The authors of the first of these reports[1] say that the relative risk of a cardiovascular/respiratory reaction is only 2.1%. Another report[2] says that the death they reported is the only life-threatening event among 162 patients given clozapine and benzodiazepines between 1986 and 1991 so that the incidence of serious problems is quite low. Even so, concurrent use should be very well monitored for any evidence of CNS depression because of the severity of the reaction, even if it is rare.

Clozapine + Caffeine

Caffeine increases serum clozapine levels, which may increase the incidence of its adverse effects.

Clinical evidence

A study in 12 healthy subjects[1] found that caffeine 400 mg to 1 g daily, raised the AUC and decreased the clearance of a single 12.5-mg dose of clozapine by 19% and 14%, respectively. A previous study in 7 patients had found that clozapine levels *decreased* by 47% when the subjects *avoided* caffeine for 5 days, and increased again when caffeine consumption was resumed.[2] In a crossover study, 6 coffee-drinking patients taking clozapine were given decaffeinated or caffeine-containing instant coffee for 7 days. The plasma levels of clozapine were 26% higher while the patients were taking caffeine-containing coffee.[3]

A patient taking clozapine for schizophrenia had an exacerbation of his psychotic symptoms, which was attributed to caffeinated coffee (5 to 10 cups daily). The problem resolved when the patient stopped drinking caffeine-containing beverages. He had previously not had any problems with caffeine while taking haloperidol 30 mg and procyclidine 30 mg daily.[4]

A 31-year-old woman taking clozapine 550 mg daily developed increased daytime sleepiness, sialorrhoea and withdrawn behaviour after taking caffeine (about 1.2 g daily as drinks and tablets). Her plasma clozapine levels fell from 1500 nanograms/mL to 630 nanograms/mL when her caffeine intake was stopped.[5]

A 66-year-old woman taking clozapine 300 mg daily developed supraventricular tachycardia (180 bpm) when she was given 500 mg of intravenous caffeine sodium benzoate to increase seizure length during an ECT session. Verapamil was needed to revert the arrhythmia. Before taking clozapine she had received caffeine sodium benzoate in doses of up to 1 g during ECT sessions without problems.[6]

Mechanism

It has been suggested that caffeine and clozapine compete for the same metabolic pathway (the cytochrome P450 isoenzyme CYP1A2) resulting in a reduction in clozapine metabolism and its accumulation. Consequently clozapine serum levels and effects increase.[1,2,7] In most cases the effects appear to be modest.

Importance and management

The interaction between caffeine and clozapine would appear to be established and of clinical relevance to some patients. However, it seems unlikely to be a problem if clozapine serum levels are established and well monitored, and caffeine intake remains fairly stable and moderate. Possible exceptions are if large doses of caffeine are given during ECT treatment or if for some other reason the caffeine intake suddenly markedly increases or decreases. Patients taking clozapine should probably avoid taking large doses of caffeine-containing herbal preparations.

Clozapine + Carbamazepine or Oxcarbazepine

Clozapine serum levels are approximately halved by carbamazepine. An isolated case of fatal pancytopenia has been seen in one patient taking clozapine and carbamazepine, and neuroleptic malignant syndrome occurred in another.

Clinical evidence

A study by a therapeutic drug monitoring service for clozapine found that the concentration/dose ratio of 17 patients taking carbamazepine was 50% of that found in 124 other patients taking clozapine alone.[1] This suggests that clozapine levels are decreased by carbamazepine. In another 12 patients, the serum levels of clozapine decreased by 47% when they were given carbamazepine. Oxcarbazepine did not interact.[2] The plasma clozapine levels of 2 patients who had been taking clozapine 600 or 800 mg daily and carbamazepine 600 or 800 mg daily for several months were *increased* from 1.4 to 2.4 micromol/L and from 1.5 to 3 micromol/L, respectively, within 2 weeks of *stopping* the carbamazepine.[3] Similarly, a case report describes 2 schizophrenic patients taking clozapine whose treatment was changed from carbamazepine to oxcarbazepine. After 3 weeks their plasma clozapine levels had risen from 1.4 to 1.7 micromol/L and from 1.5 to 2.5 micromol/L, respectively.[4]

A man with mania taking carbamazepine 1.2 g daily and lithium developed muscle rigidity, mild hyperpyrexia, tachycardia, sweating and somnolence (diagnosed as neuroleptic malignant syndrome) 3 days after his lithium was stopped and clozapine 25 mg daily started. The symptoms immediately improved when the clozapine was stopped.[5]

A patient taking carbamazepine, lithium, benzatropine and clonazepam developed fatal pancytopenia about 10 weeks after starting clozapine 400 mg daily.[6] A retrospective study of the records of other patients given clozapine and carbamazepine found a significant increase in granulopenia.[7] A previous report had not found this, due to a statistical error.[8]

Mechanism

Not established, but it seems likely that carbamazepine (a recognised potent enzyme inducer) increases the metabolism of clozapine by the liver, thereby reducing its effects. It has been suggested that this is because carbamazepine induces the activity of the cytochrome P450 isoenzyme CYP1A2.[1] Carbamazepine may also have an effect via CYP3A4. The case of pancytopenia may possibly have been due to the additive bone marrow depressant effects of the clozapine and carbamazepine.

Importance and management

The interaction between clozapine and carbamazepine is established and clinically important: one small sub-group analysis appears to suggest that treatment with clozapine is less effective if antiepileptics (including carbamazepine) are also taken.[9] The manufacturers of clozapine advise that carbamazepine should not be given with clozapine, although this is be-

cause of the risk of bone marrow suppression.[10,11] If both drugs are necessary, monitor for clozapine efficacy and be alert for the need to increase the clozapine dosage. Furthermore, it would seem essential to increase the frequency of monitoring associated with the use of clozapine (e.g. white cell counts).

Clozapine + Drugs that cause bone marrow suppression

The manufacturers caution the use of clozapine with other drugs that can cause bone marrow suppression. Low white cells counts have been seen in patients taking clozapine and co-trimoxazole, methazolamide, nitrofurantoin, olanzapine, or thiamazole.

Clinical evidence, mechanism, importance and management

Clozapine can cause blood dyscrasias and potentially fatal agranulocytosis, therefore the manufacturers contraindicate its use with other drugs that have a well-known potential to cause agranulocytosis.[1,2] A systematic review of MEDLINE reports in English or German of non-chemotherapy, drug-induced agranulocytosis published between January 1996 and December 2006, identified 11 drugs including clozapine where there were more than 10 reports of definite or probable drug-associated agranulocytosis. The other drugs were **benzylpenicillin** (long-term, high dose), **carbimazole**, **dapsone**, **dipyrone**, **procainamide**, **propylthiouracil**, **rituximab**, **sulfasalazine**, **thiamazole**, and **ticlopidine**.[3] Comments on this review have suggested additional drugs.[4-7]

The UK manufacturer lists **chloramphenicol**, **cytotoxics**, **penicillamine**, pyrazolone analgesics (e.g. **phenylbutazone**), and **sulfonamides** (e.g. **co-trimoxazole**) as drugs that should not be given with clozapine. Furthermore, because they cannot be stopped if an adverse reaction occurs, they advise against the use of **depot antipsychotics**.[1] There are several cases that confirm the clinical significance of these predicted interactions.

A woman was taking **thiamazole** for Graves' disease, at times with various different antipsychotics including haloperidol, flupentixol, zuclopenthixol and perphenazine for schizophrenia. Because of the severe extrapyramidal reactions and failure to control the schizophrenia, clozapine, increased over 5 days to 250 mg daily, was started instead. Within 5 days her white cell count had fallen to 2.2×10^9/L, which rose to 4×10^9/L, one month after both drugs were stopped. Later, after the **thiamazole** was stopped, she was given the same dose of clozapine without these adverse effects.[8]

A patient who had been taking clozapine 500 mg daily for 8 months developed granulocytopenia within 8 days of starting to take **nitrofurantoin** 200 mg daily.[9]

An 86-year old woman taking clozapine developed neutropenia 2 weeks after **methazolamide** was added for glaucoma. Both drugs were stopped and her white cell count recovered. She later restarted clozapine without problem and so the toxic effect was attributed to the combined use of the two drugs.[10]

A 47-year-old woman who had been uneventfully taking clozapine for 5 years developed neutropenia 4 days after **co-trimoxazole** was started. **Co-trimoxazole** was stopped and the white cell counts returned to normal over the next 2 weeks.[11]

Three patients had a delay in their recovery from clozapine-induced agranulocytosis when they were given **olanzapine**, and it has been suggested that **olanzapine** should therefore be avoided until the patient's haematological status has normalised.[12]

The manufacturers also suggest that carbamazepine should not be given with clozapine, because of the risks of bone marrow depression; cases of this adverse effect have been reported. See 'Clozapine + Carbamazepine or Oxcarbazepine', p.874.

Clozapine + H_2-receptor antagonists

A case report describes increased serum clozapine levels and toxicity due to cimetidine. Another case report describes the use of cimetidine to increase levels of clozapine to the therapeutic range. Ranitidine does not appear to interact.

Clinical evidence

A man with chronic paranoid schizophrenia was taking atenolol and clozapine 900 mg daily. When **cimetidine** 400 mg twice daily was added for gastritis, his serum clozapine levels rose by almost 60% (from a range of 992 to 1081 nanograms/mL, up to a range of 1559 to 1701 nanograms/mL) but this did not result in any adverse effects. Within 3 days of raising the dosage of **cimetidine** to 400 mg three times daily he developed evidence of clozapine toxicity (marked diaphoresis, dizziness, vomiting, weakness, orthostatic hypotension), all of which resolved over 5 days when the clozapine dosage was lowered to 200 mg daily, and the **cimetidine** was stopped. The serum clozapine levels during this period were not reported. When **cimetidine** was replaced by **ranitidine** 150 mg twice daily his clozapine serum levels were not affected.[1]

Another patient with schizophrenia who was given clozapine, titrated to 400 mg daily, had clozapine and norclozapine levels of 120 nanograms/mL and 38 nanograms/mL, respectively. The patient refused to take a higher clozapine dose. **Cimetidine** 300 mg twice daily was started, both to treat gastro-oesophageal reflux and to increase clozapine levels. After one month of concurrent use, his clozapine and norclozapine levels had increased to 278 nanograms/mL and 122 nanograms/mL, respectively. Clozapine and norclozapine levels further increased to 502 nanograms/mL and 176 nanograms/mL when the dose of **cimetidine** was increased to 1.5 g daily. The symptoms of schizophrenia improved, but he also experienced increased salivation.[2]

Mechanism

The suggested reason for this interaction is that the cimetidine (a potent non-specific enzyme inhibitor) reduces the metabolism of clozapine by the liver so that it accumulates, causing toxicity. Ranitidine does not cause enzyme inhibition and therefore does not interact.

Importance and management

Information appears to be limited to these reports but it is consistent with the way that cimetidine interacts with many other drugs. If cimetidine is

given to a patient taking clozapine, it would seem prudent to monitor the outcome closely, being alert for clozapine adverse effects, and consider monitoring clozapine levels. Ranitidine, and possibly other H_2-receptor antagonists such as famotidine or nizatidine, which do not inhibit liver enzymes and therefore do not raise clozapine levels, would seem to be preferable and safer alternatives to cimetidine; however, this needs confirmation.

Clozapine + Hormonal contraceptives

Two case reports describe raised clozapine levels with associated adverse effects in patients who also took oral hormonal contraceptives.

Clinical evidence, mechanism, importance and management

A 47-year-old smoker with paranoid schizophrenia taking clozapine 550 mg daily had a good therapeutic response at this dose, but also reported drowsiness, weakness and dizziness. The patient was also taking an oral combined hormonal contraceptive containing **norethisterone** 500 micrograms and **ethinylestradiol** 35 micrograms. Clozapine plasma levels ranged from 736 to 792 nanograms/mL (reference range 300 to 700 nanograms/mL). After 2 months she stopped taking her contraceptive and noted that the adverse effects of clozapine resolved: her clozapine levels were found to be 378 to 401 nanograms/mL. The patient did not stop smoking during this time.[1]

A second report describes a 33-year-old woman who had taken clozapine 500 mg daily for several months. Within one week of starting to take an oral hormonal contraceptive containing **ethinylestradiol**, she experienced marked drowsiness, anergy, dizziness, and orthostasis. Her blood level of clozapine had increased from 448 nanograms/mL to 1281 nanograms/mL. The oral contraceptive was stopped and after 3 days the clozapine level fell to 577 nanograms/mL. Several weeks later, the dose of clozapine was reduced to 200 mg daily, and she restarted the contraceptive: her clozapine level was 531 nanograms/mL.[2]

It was suggested that the hormonal contraceptive inhibited the cytochrome P450 isoenzymes CYP1A2, CYP2C19 and CYP3A4 resulting in raised clozapine plasma levels.[1,2] The authors note that slower titration and smaller doses of clozapine may be needed in patients taking hormonal contraceptives.[1,2] Further study is needed as these reports appear to be the only published cases of this interaction.

Clozapine + Lamotrigine

An isolated case report suggests that lamotrigine may raise clozapine plasma levels. A study did not find an interaction.

Clinical evidence, mechanism, importance and management

A 35-year-old man, who had been taking clozapine for 3 years, became dizzy and sedated about one month after starting to take lamotrigine. His plasma clozapine levels were found to have increased to 1020 micrograms/L. When the lamotrigine was stopped his levels fell to 450 micrograms/L.[1]

In contrast, a study in 11 patients taking clozapine in doses of 200 mg to 500 mg daily, and who were also given lamotrigine in increasing doses over 8 weeks to 200 mg daily found no significant changes in the pharmacokinetics of clozapine.[2]

Evidence for an interaction between lamotrigine and clozapine appears to be limited to the isolated case report, the findings of which are in contrast to the study. Furthermore, there appears to be no pharmacokinetic mechanism for this interaction. The evidence is currently too slim to recommend any additional precautions if lamotrigine is given to a patient taking clozapine.

Clozapine + Macrolides

A study in healthy subjects found no evidence of an interaction between clozapine and erythromycin, but three case reports describe clozapine toxicity (e.g. seizures drowsiness, neutropenia) when the patients were given erythromycin.

Clinical evidence

A randomised, crossover study in 12 healthy subjects found that **erythromycin** 500 mg three times daily did not affect the pharmacokinetics of a single 12.5-mg dose of clozapine.[1]

In contrast, a man with schizophrenia taking clozapine 800 mg daily, was given **erythromycin** 250 mg four times daily for a fever and sore throat caused by pharyngitis. After a week he had a single tonic-clonic seizure and his serum clozapine levels were found to be 1300 micrograms/mL. Both drugs were stopped, and the clozapine restarted 2 days later, initially at only 400 mg daily, but then, after several weeks, the dose had increased to 800 mg daily, giving serum clozapine levels of 700 micrograms/mL.[2] Another man with schizophrenia taking clozapine 600 mg daily became drowsy, with slurred speech, incontinence, difficulty in walking and incoordination within 2 to 3 days of starting to take **erythromycin** 333 mg three times daily. His serum clozapine level was found to be 1150 micrograms/L and he had leucocytosis. He recovered when both drugs were stopped. When he later restarted treatment with the same clozapine dose, but without the **erythromycin**, his steady-state trough clozapine serum level was 385 micrograms/L.[3] Another case also describes a reduced white cell count when **erythromycin** was added to established treatment with clozapine, but no clozapine levels were available.[4]

Mechanism

Uncertain. One suggestion is that erythromycin might have inhibited the cytochrome P450 isoenzyme CYP3A4, which has a minor role in the metabolism of clozapine, leading to a reduced clearance, which resulted in increased serum clozapine levels and toxicity.[2,3] Clozapine is mainly metabolised by CYP1A2, which is not known to be affected by the macrolides.

Importance and management

Information appears to be limited to this study and the three case reports, but there are a number of case reports describing *reduced* clozapine levels with CYP3A4 *inducers*. This suggests that, in some circumstances at least, CYP3A4 may be important in clozapine metabolism, and so the potential for an interaction cannot entirely be dismissed. Some reports suggest that clozapine levels may be increased by bacterial infections and therefore it is possible that the effects seen were independent of erythromycin use. However, in one of these cases **roxithromycin** (which is known to interact similarly to erythromycin) was given,[5] and in the other, an effect of mirtazapine could not be ruled out.[6] Whatever the reason, cases of raised clozapine levels with erythromycin appear to be rare. Bear this interaction in mind if clozapine adverse effects (e.g. agitation, dizziness, sedation, hypersalivation) develop.

There does not appear to be any information about other macrolides. However, until the mechanism for this effect is established, it may be prudent to suspect an interaction if clozapine adverse effects develop in any patient taking a macrolide that inhibits CYP3A4 (e.g. **clarithromycin**, **telithromycin**).

Clozapine + Miscellaneous

There are isolated cases of apparent interactions between clozapine, and ampicillin, buspirone, haloperidol, loperamide, modafinil, nefazodone, nicotinic acid, tryptophan, or vitamin C. Grapefruit juice, influenza vaccine, reboxetine, and venlafaxine do not appear to interact with clozapine. Cocaine levels may be increased by clozapine.

Clinical evidence, mechanism, importance and management

(a) Ampicillin

An isolated report describes a 17-year-old taking clozapine (12.5 mg increased to 50 mg three times daily) who was given ampicillin 500 mg four times daily, starting on day 15 of clozapine treatment. On the next day the patient became easily distracted, very drowsy and salivated excessively. These adverse reactions stopped when the ampicillin was replaced by doxycycline.[1]

(b) Buspirone

A man who had been taking clozapine for a year developed acute and potentially lethal gastrointestinal bleeding and marked hyperglycaemia about 5 weeks after starting buspirone, and one week after the buspirone dosage was raised to 20 mg daily. No gut pathology (e.g. ulceration) was detected and there were no problems when he was subsequently given clozapine alone, so the reaction was attributed to the drug combination.[2]

(c) Cocaine

A single-dose study in 8 cocaine addicts found that clozapine caused a dose-dependent rise in the serum levels of a 2-mg/kg intranasal dose of cocaine. Cocaine levels rose by 6%, 49% and 67% after clozapine was given in doses of 12.5 mg, 25 mg or 50 mg, respectively. Subjective questioning revealed a reduction in the positive effects of cocaine. One subject also experienced a near-syncopal attack which required medical attention.[3]

(d) Grapefruit juice

Grapefruit juice did not affect the metabolism of clozapine in two studies in a total of 36 patients with schizophrenia.[4,5]

(e) Haloperidol

A 68-year-old man taking clozapine 600 mg daily and venlafaxine, lorazepam, aspirin, vitamin E and multivitamins, was given haloperidol 4 mg daily to control persistent paranoid delusions and hallucinations. After 27 days he was found collapsed and was lethargic, tachycardic, feverish and delirious. Neuroleptic malignant syndrome was suspected so the antipsychotics were withheld, and the patient recovered over the following 7 days. Clozapine was later re-started without a recurrence of symptoms.[6]
A case of elevated haloperidol levels has been reported in a 40-year-old man who was given haloperidol intramuscular injections 50 mg every 4 weeks. He was also given clozapine in increasing doses from 50 to 250 mg daily. Over this time his haloperidol levels increased from 12 nanogram/mL to 166 nanogram/mL, although it is not clear whether he had attained steady-state levels when the first measurement was reported.[7]

(f) Influenza vaccine

In an open-label study in 14 patients the metabolism of clozapine was not altered following a single intramuscular dose of influenza vaccine (*Influvac* 2001 to 2002 formula, Solvay).[8]

(g) Loperamide

A patient taking clozapine 500 mg daily died after taking loperamide 6 mg daily during an episode of food poisoning. The authors of the report attribute the death to toxic megacolon brought on by the additive effects of clozapine and loperamide on gut transit.[9] Toxic megacolon can sometimes occur with loperamide alone, especially in the presence of an infection, and clozapine can cause constipation by virtue of its antimuscarinic effects.

(h) Mirtazapine

A study in 9 patients taking clozapine in doses ranging from 100 to 650 mg daily found no significant change in the pharmacokinetics of clozapine after the addition of mirtazapine 30 mg daily.[10]

(i) Modafinil

A 42-year-old man taking clozapine 450 mg daily was given modafinil, titrated up to 300 mg daily, to combat sedation. After about one month of concurrent use he developed dizziness and an unsteady gait, and his clozapine serum level was found to be 1400 nanograms/mL. His clozapine level had been 761 nanograms/mL while taking clozapine 400 mg daily, and because the 50 mg clozapine dose increase was not thought large enough to almost double his clozapine level, an interaction with modafinil was suspected.[11]

(j) Nefazodone

A 40-year-old man who had been successfully treated with risperidone and clozapine 425 to 475 mg daily started taking nefazodone 200 mg daily, increasing to 300 mg daily, for the treatment of persistent depression. After one week on the higher dose he became dizzy and hypotensive and it was noted that his clozapine plasma level had risen from 133 to 233 nanograms/mL. This was thought to be due to an inhibitory effect of nefazodone on the cytochrome P450 isoenzyme CYP3A4.[12] In contrast, a small study in 6 patients taking clozapine found that the addition of nefazodone had no significant effects on the pharmacokinetics of clozapine.[13]

A possible case of neutropenia was attributed to the addition of nefazodone to sodium valproate and clozapine. The patient had been taking sodium valproate and clozapine for many months when nefazodone was started, in increasing doses up to 200 mg twice daily. Within one week her neutrophil count had dropped to 1.8×10^9/L, and remained low until the nefazodone was discontinued. The patient's clozapine level was reported to remain stable during this time and the patient had not had any previous episodes of leucopenia during treatment with clozapine.[14]

(k) Nicotinic acid/Tryptophan/Vitamin C

A man with schizophrenia taking tryptophan, lorazepam, vitamin C, benzatropine and nicotinic acid, developed a severe urticarial rash covering his face, neck and trunk 3 days after starting clozapine 150 mg daily. All of the drugs except lorazepam were stopped, and the rash subsided. It did not recur when clozapine was restarted, even at a dose of 600 mg daily, nor when small doses of benzatropine and fluphenazine were briefly added. The authors draw the inference that tryptophan, vitamin C and nicotinic acid may have been responsible for this alleged interaction with clozapine.[15]

(l) Reboxetine

A small study in 7 patients found that reboxetine 8 mg daily had no effect on the metabolism of clozapine or its major metabolite.[16]

(m) Ritonavir

Ritonavir is a potent inhibitor of the cytochrome P450 isoenzymes CYP3A4 and CYP2D6, and is therefore expected to increase plasma levels of clozapine. This may result in serious haematologic abnormalities, although there appear to be no published studies or case reports of this effect. The UK manufacturers of ritonavir therefore contraindicate concurrent use.[17]

(n) Venlafaxine

In 11 patients, venlafaxine in doses of up to 150 mg daily did not affect the pharmacokinetics of established clozapine treatment in doses of up to 950 mg daily.[18]

Clozapine + Phenobarbital

Clozapine serum levels are possibly reduced by phenobarbital.

Clinical evidence

A patient had a seizure 10 days after his dose of clozapine was titrated up to 300 mg twice daily. Phenobarbital 60 mg daily was given to prevent further seizures and after 4 months the dose of clozapine was tapered down to 400 mg daily. When phenobarbital was gradually withdrawn the patient experienced moderate sedation and drowsiness and clozapine levels were found to have increased by about 75%, when compared with the levels found during the concurrent use of phenobarbital.[1] Similarly, mean clozapine plasma levels in 7 patients taking clozapine and phenobarbital were 35% lower than those of 15 patients taking clozapine alone.[2]

Mechanism

Not established, but it seems likely that phenobarbital (a recognised potent enzyme inducer) increased the metabolism of clozapine by the liver, thereby reducing its effects. It has been suggested that this is due to induction of the cytochrome P450 isoenzyme CYP1A2 and CYP3A4.

Importance and management

Evidence for an interaction between clozapine and phenobarbital is limited, but it appears to be clinically important: one sub-group analysis appears to suggest that treatment with clozapine is less effective if antiepileptics (including phenobarbital) are also taken.[3] Monitor clozapine efficacy and be alert for the need to increase the clozapine dose if phenobarbital is started. **Primidone** is metabolised in the body to phenobarbital. It would therefore be expected to interact similarly.

Clozapine + Phenytoin

Clozapine serum levels are possibly reduced by phenytoin.

Clinical evidence

Two patients taking clozapine had reduced clozapine levels (falls of 65 to 85%) and worsening psychoses when phenytoin was also given.[1] Another patient developed neutropenia, which was attributed to the concurrent use of phenytoin and clozapine. When the phenytoin was stopped clozapine levels rose from 114 nanograms/mL to 137 nanograms/mL, suggesting a pharmacokinetic interaction,[2] rather than just additive adverse effects.

Mechanism

Not established, but it seems likely that phenytoin (a recognised potent enzyme inducer) increased the metabolism of clozapine by the liver, thereby reducing its effects. It has been suggested that this is due to induction of the cytochrome P450 isoenzyme CYP1A2 and possibly CYP3A4.

Importance and management

Evidence for an interaction between clozapine and phenytoin is limited, but it appears to be clinically important: one sub-group analysis appears to suggest that treatment with clozapine is less effective if antiepileptics (including phenytoin) are also taken.[3] Monitor clozapine efficacy and be alert for the need to increase the clozapine dose if phenytoin is given.

Clozapine + Proton pump inhibitors

Omeprazole appears to reduce the serum levels of clozapine.

Clinical evidence, mechanism, importance and management

A retrospective study identified 13 patients taking clozapine and **omeprazole** in who the proton pump inhibitor was subsequently changed to **pantoprazole**. This resulted in an increase in the mean clozapine serum level from 445 nanograms/mL to 579 nanograms/mL in 3 non-smokers, but in the 10 smokers there was a slight *reduction* in levels, from 364 to 323 nanograms/mL. Both **omeprazole** and smoking are known to induce the cytochrome P450 isoenzyme CYP1A2, which is the major isoenzyme involved in the metabolism of clozapine. The authors suggest that when **omeprazole** was stopped in the non-smokers there was no CYP1A2 induction, hence clozapine levels rose, whereas in the smokers CYP1A2 induction continued, so their levels were only slightly affected by stopping **omeprazole**.[1]

A case report describes two patients (both smokers) whose clozapine levels were reduced, from 762 to 443 nanograms/mL and from 369 to 204 nanograms/mL, respectively, after **omeprazole** was started. However, no changes in clinical condition were noted.[2]

The interaction between clozapine and **omeprazole** appears to be relatively modest, with clozapine levels effectively reduced by about up to 45% by **omeprazole**. Nevertheless, it would seem prudent to monitor clozapine efficacy if **omeprazole** is started. Other proton pump inhibitors do not appear to have been studied.

2. Frick A, Kopitz J, Bergemann N. Omeprazole reduces clozapine plasma concentrations. *Pharmacopsychiatry* (2003) 36, 121–3.

Clozapine + Quinolones

A small number of case reports suggest that ciprofloxacin may increase clozapine levels and cause clozapine toxicity. A study supports these observations.

Clinical evidence

An elderly man with multi-infarct dementia and behavioural disturbances, taking clozapine, glibenclamide (glyburide), trazodone and melatonin, was hospitalised for agitation on the last day of a 10-day course of **ciprofloxacin** 500 mg twice daily. When the **ciprofloxacin** course was completed, his plasma clozapine serum levels fell from 90 nanograms/mL to undetectable levels (lower limit of detection being 50 nanograms/mL).[1]

A 64-year-old woman with schizophrenia whose symptoms had been controlled with clozapine 125 mg twice daily for 5 years became dizzy and somnolent within a few days of starting **ciprofloxacin** 500 mg twice daily. Clozapine and norclozapine levels were found to be 1043 nanograms/mL and 432 nanograms/mL, respectively. It was thought that she was no longer able to tolerate the clozapine and it was discontinued and replaced with ziprasidone which did not control her psychotic symptoms. It was then suggested that the high clozapine levels and adverse effects could have been due to an interaction with **ciprofloxacin**. Ziprasidone was tapered and clozapine re-introduced and titrated back up to her original dose of 125 mg twice daily. Clozapine and norclozapine levels were found to be

686 nanograms/mL and 244 nanograms/mL and there were no symptoms of toxicity.[2] A woman who was taking clozapine developed a raised level (1498 nanograms/mL), confusion and irritability when she started to take **ciprofloxacin** for a urinary tract infection. Clozapine was stopped, and the symptoms resolved. Subsequently clozapine was re-introduced and a level of 787 nanograms/mL was achieved.[3]

In a study, 7 patients with schizophrenia taking clozapine were given **ciprofloxacin** 250 mg twice daily for 7 days. The mean serum clozapine and *N*-desmethylclozapine levels were increased by 29% and 31%, respectively, but no additional adverse effects were reported. Interindividual variation in serum levels was high, so it seems likely that some patients may demonstrate a clinically significant interaction.[4]

Mechanism

This interaction probably occurs because ciprofloxacin inhibits the cytochrome P450 isoenzyme CYP1A2, the major isoenzyme involved in the metabolism of clozapine. Clozapine metabolism is therefore reduced, resulting in elevated clozapine levels.

Importance and management

An interaction between clozapine and ciprofloxacin is established and clinically relevant. Monitor for clozapine adverse effects (e.g. agitation, dizziness, sedation, hypersalivation) if ciprofloxacin is added. There seem to be no other reports of an interaction between clozapine and other quinolones, but as they all inhibit CYP1A2 to a varying extent (see 'Theophylline + Quinolones', p.1452) some interaction seems possible.

Clozapine + Rifampicin (Rifampin)

Case reports suggest that rifampicin reduces clozapine levels.

Clinical evidence

A schizophrenic patient taking clozapine developed tuberculosis and was given rifampicin, isoniazid and pyrazinamide. Within 2 to 3 weeks his trough serum clozapine levels had fallen dramatically from about 250 nanograms/mL to 40 nanograms/mL, but rose again rapidly when the rifampicin was replaced by ciprofloxacin.[1] A second case report describes a patient who was stable taking clozapine 300 mg daily, but who had symptoms of hypersalivation and sedation. He was given rifampicin 600 mg daily for tuberculosis, and after 2 weeks the adverse effects of clozapine began to resolve, but his psychosis started to re-emerge. His clozapine dose was increased to 550 mg daily without much improvement in his condition. Rifampicin was stopped after 6 months, at which point his psychotic symptoms markedly improved and the clozapine adverse effects of sedation and hypersalivation reappeared.[2]

Mechanism

Clozapine is metabolised by the cytochrome P450 isoenzyme CYP1A2, with some contribution from other isoenzymes, including CYP3A4. Rifampicin is a potent enzyme inducer, which affects both of these isoenzymes. It therefore seems likely that rifampicin increases clozapine metabolism leading to a decrease in its levels.

Importance and management

Evidence for an interaction between rifampicin and clozapine is limited, but the effects seen in the cases are consistent with the way rifampicin interacts with other drugs. Clozapine serum levels should be well monitored if rifampicin is added. The cases indicate that an increase in the dose of clozapine may not be successful in managing this interaction, and therefore it may be prudent to consider the use of other drugs. In the first case ciprofloxacin was successfully given, although note that this drug *increases* clozapine levels, see 'Clozapine + Quinolones', p.878.

Clozapine + Risperidone

The concurrent use of clozapine and risperidone can be effective and well tolerated but two isolated reports describe a rise in serum clozapine levels when risperidone was added and the development of atrial ectopics. Dystonia has been seen when clozapine was replaced by risperidone.

Clinical evidence, mechanism, importance and management

A man with a schizoaffective disorder taking clozapine started to take risperidone, firstly 500 micrograms twice daily, and then after a week 1 mg twice daily. Clinical improvement was seen and it was found that after 2 weeks his serum clozapine levels had risen by 74%, from 344 nanograms/mL to 598 nanograms/mL, without any adverse effects.[1] The serum clozapine levels of another patient more than doubled when risperidone was given. No signs of clozapine toxicity were seen, but mild oculogyric crises were reported.[2] A patient with schizophrenia taking clozapine and trihexyphenidyl, who developed tachycardia of 120 bpm, which was controlled with propranolol, developed atrial ectopics when risperidone 1.5 mg daily was added. The ectopics stopped when the risperidone was withdrawn and started again when it was re-introduced. Clozapine plasma levels were normal throughout the duration of risperidone treatment.[3] Another report describes 4 patients developed dystonia after their treatment was changed from clozapine to risperidone.[4] A single case of agranulocytosis has been seen 6 weeks after risperidone was added to stable clozapine treatment. The patient needed 3 doses of G-CSF before the white cell count returned to normal.[5] Another case report describes neuroleptic malignant syndrome in a 20-year-old man within 2 days of clozapine being added to risperidone treatment. The drugs were stopped and he recovered over the following 10 days. He subsequently received clozapine alone without problem.[6]

Contrasting with these reports is a study in 12 patients with schizophrenia, which found that the addition of risperidone to clozapine was both effective and well tolerated, although 4 patients complained of mild akathisia. Serum clozapine levels were not significantly changed.[7] Furthermore, a retrospective study in 18 patients also found that risperidone did not alter clozapine serum levels.[8]

The suggested reason for the raised clozapine levels is that both drugs compete for metabolism by the cytochrome P450 isoenzyme CYP2D6 resulting in a reduction in the metabolism of the clozapine,[1,2] although this does not explain why only some patients are affected. The dystonias are attributed to cholinergic rebound and ongoing dopamine blockade caused by a rapid switch of medication. The recommendation is that withdrawal of clozapine should be tapered and possibly that an antimuscarinic drug should be given.[4] The raised clozapine levels seem to be isolated cases and are therefore of doubtful general significance.

Clozapine + SSRIs

Fluvoxamine dramatically raises clozapine levels; fluoxetine and paroxetine have more modest effects. Small increases in clozapine levels may occur with sertraline. Studies suggest that citalopram

generally does not interact, although one case report describes raised clozapine levels in a patient taking citalopram.

Clinical evidence

(a) Citalopram

A preliminary study in 5 patients found that their mean plasma clozapine levels were unchanged by citalopram.[1] Another study in 8 patients found similar results.[2] However, a patient who was stable taking clozapine developed sedation, hypersalivation and confusion shortly after he started to take citalopram 40 mg daily. When total clozapine serum levels were measured they were found to be 1097 nanograms/mL. The citalopram dose was reduced to 20 mg daily, the symptoms resolved over the following 2 weeks, and the total clozapine level dropped to 792 nanograms/mL.[3]

(b) Fluoxetine

Several studies and case reports have found increased clozapine levels of 30 to 75%, and increased levels of the metabolite norclozapine of 34 to 52% after fluoxetine was added to established clozapine treatment.[4-6] In two cases the levels of clozapine and norclozapine were raised more than fivefold by fluoxetine. One patient developed hypertension but the other experienced no troublesome adverse effects and his mood and psychotic symptoms improved.[7,8]

A patient who had been taking clozapine 500 mg and lorazepam 3 mg daily, developed myoclonic jerks of his whole body 79 days after fluoxetine 20 mg was added. These decreased over the next 2 days when the fluoxetine and lorazepam were stopped.[9] The death of a 44-year old patient who was taking clozapine and fluoxetine was felt to be due to an increase in clozapine levels caused by fluoxetine.[10] Another case report attributes an SSRI withdrawal reaction to an interaction between fluoxetine and clozapine, although it is unclear what part the clozapine had to play in this.[11]

In contrast, there are reports of successful use,[12] and no pharmacokinetic changes[13] when clozapine and fluoxetine were used together.

A case has also been reported of a patient with schizophrenia and depression, whose cognitive symptoms improved when he took clozapine and fluoxetine, but when treatment was changed to sertraline, this improvement was not sustained. The authors tentatively suggested that the fluoxetine elevated plasma clozapine levels by inhibition of CYP2D6, whereas this effect was not seen with sertraline as it is a much weaker inhibitor of this enzyme.[14] However, this explanation has been questioned, since the role of other drug metabolising enzymes was not considered.[15]

(c) Fluvoxamine

Up to tenfold elevations in plasma clozapine levels have been seen in several studies and case reports when clozapine was given with fluvoxamine.[16-27] These elevations occurred as early as 14 days after concurrent use began,[26] but were often not associated with any significant adverse effects, even after treatment had continued for a year in one patient.[19] Another study, which compared 12 patients taking clozapine with 11 patients taking clozapine and fluvoxamine, found that in the combined treatment group, clozapine doses were about half those used when clozapine was given alone. A trend towards decreased granulocyte levels was also seen in the clozapine with fluvoxamine group, but not when clozapine was used alone.[28]

Another patient had extremely high plasma clozapine levels of up to 4160 micrograms/L as a result of taking fluvoxamine.[29]

Other cases have also demonstrated worsening psychosis[30] or extrapyramidal adverse effects[31] (including, rigidity, tremors and akathisia) and sedation within days of giving fluvoxamine with clozapine.

A study in 68 patients taking either clozapine alone or clozapine and fluvoxamine found a trend towards less weight increase after 12 weeks of treatment in the group of patients also taking fluvoxamine. Those patients taking clozapine alone were found to have significantly higher glucose and triglyceride levels.[32] Note that fluvoxamine treatment alone can result in weight loss.

(d) Paroxetine

The serum levels of clozapine and norclozapine rose by 57% and 50%, respectively, in 16 schizophrenic patients after they took an average of 31.2 mg of paroxetine daily. One patient taking clozapine 300 mg daily developed reversible cerebral intoxication when given paroxetine 40 mg daily.[5] Another patient with a delusional disorder developed an antimuscarinic syndrome with doubled serum clozapine levels within about 3 weeks of the addition of paroxetine.[33] A further study in 9 patients found that the serum levels of clozapine and norclozapine rose by 31% and 20%, respectively, when paroxetine 20 to 40 mg daily was given for 3 weeks. Two patients experienced mild and transient sedation 2 to 3 days after starting paroxetine. The rise in clozapine levels was not associated with an increase in efficacy and was well tolerated.[34] In contrast, a study in 14 patients taking clozapine 2.5 to 3 mg/kg daily found that the addition of paroxetine 20 mg daily had no effect on the serum levels of clozapine.[24] This, or similar work, has been published elsewhere.[35]

An increase in the plasma levels of clozapine, thought to be due to concurrent treatment with paroxetine, has been suggested as the causative factor in the development of a fatal venous thromboembolism in a 47-year-old woman.[36]

A fatal case of neuroleptic malignant syndrome, which started to develop two days after the introduction of clozapine 25 mg daily to established treatment with paroxetine 20 mg daily, has been reported. The patient had previously taken clozapine alone with no problem.[37]

(e) Sertraline

In 10 patients with schizophrenia the serum levels of clozapine and norclozapine increased by 30% and 52%, respectively, when they started to take an average of 92.5 mg of sertraline daily.[5] Another patient taking clozapine 600 mg daily had a 40% reduction in total clozapine serum levels within one month of stopping sertraline 300 mg daily.[38]

The serum clozapine levels of a patient with schizophrenia doubled within a month of adding sertraline 50 mg daily and her psychosis worsened. When the sertraline was stopped she improved and her serum clozapine levels fell once again.[30] In contrast, a study in 8 patients who were taking clozapine 200 to 400 mg daily and were also given sertraline 50 to 100 mg per day for 3 weeks, found no significant changes in the levels of clozapine and its major metabolites.[34]

A case report describes sudden cardiac death in a 26-year-old man, which the authors attributed to an interaction between clozapine and sertraline.[39] However, this interaction has been questioned as it is said that the patient had other risk factors that were more likely to have caused the fatality.[40]

Mechanism

The SSRIs (including **escitalopram**) are known to inhibit the cytochrome P450 isoenzyme CYP2D6 to a varying extent. Fluvoxamine is also a potent inhibitor of CYP1A2. Both of these isoenzymes are involved in the metabolism of clozapine, the most significant being CYP1A2, so their inhibition causes clozapine levels to rise. The levels of clozapine and norclozapine rise together, and so it has been suggested that the metabolic step inhibited is after the *N*-dealkylation step.[5]

Importance and management

The interactions of the SSRIs with clozapine are established. Concurrent use need not be avoided, but it would be prudent to monitor the outcome closely when any SSRI is used with clozapine because of the rises in serum clozapine and norclozapine levels that can occur, and because of the rare potential for deterioration in clinical status. Adjust the clozapine dose as necessary. The authors of one study suggest particularly close monitoring if the clozapine dose exceeds 300 mg or 3.5 mg/kg daily.[5] The interaction is greatest with fluvoxamine, so other SSRIs may be a more prudent choice, although close monitoring is still required.

Clozapine + Tobacco or Cannabis

Smoking tobacco appears to decrease clozapine levels and clozapine toxicity may occur due to increased levels on smoking cessation.

Clinical evidence

(a) Cannabis

A 37-year-old man who smoked both tobacco and cannabis daily, and took clozapine 700 mg daily, experienced elevated clozapine plasma levels and signs of clozapine toxicity, one month after he stopped smoking both tobacco and cannabis. One week after reducing the dose of clozapine to 500 mg daily, his psychotic symptoms disappeared and plasma levels returned to normal.[1]

(b) Tobacco

Although one group of workers found that smoking did not affect clozapine levels,[2] and another found only a trend towards a reduction in clozapine levels in smokers,[3] the majority of the available data supports an interaction between smoking and clozapine. Several studies have found that smokers had clozapine levels that were up to 50% lower than those of non-smokers.[4-6] One study in 11 patients found a mean *increase* in clozapine levels of about 72% on smoking *cessation*,[7] and a retrospective study found that the clozapine clearance was 86% higher in 9 smokers than in 3 non-smokers.[8] A study in 80 patients with schizophrenia, taking clozapine 25 mg to 700 mg daily, found that the concentration-dose ratio of clozapine in the 45 patients who smoked at least 15 cigarettes daily was 2.4-fold lower than in those patients who did not smoke.[9]

A number of case reports also support the existence of an interaction. One case report describes 2 patients with psychoses resistant to treatment with clozapine. Both patients were heavy smokers and one also consumed large amounts of caffeine, which would have been expected to increase plasma clozapine levels (see also 'Clozapine + Caffeine', p.874), but it was considered that the CYP1A2 induction due to smoking increased clearance of both clozapine and caffeine.[10] Two case reports describe elevations in clozapine plasma levels when the patients stopped smoking abruptly;[11,12] in one case this was associated with seizures. Another three case reports suggest that smoking cessation may have resulted in clozapine adverse effects, including seizures, although no plasma levels were available.[13-15]

A report describes a patient, stable while taking clozapine 500 mg daily, who used *Nicotrol* inhalers as a substitute for smoking when he was admitted to a 'smoke-free' hospital. He re-started smoking after discharge from hospital and his paranoid symptoms and hallucinations returned and his clozapine levels fell from 417 nanograms/mL to 192 nanograms/mL.[16]

Mechanism

Tobacco smoke contains aromatic hydrocarbons that are potent inducers of the cytochrome P450 isoenzyme CYP1A2, which is the major isoenzyme involved in clozapine metabolism. Smoking therefore increases clozapine metabolism and lower levels result. Nicotine patches and other nicotine products used as replacement therapy do not induce CYP1A2.[16]

Importance and management

An interaction between smoking and clozapine is established. It has been suggested that smoking 7 to 12 cigarettes daily is probably sufficient for maximum induction of clozapine metabolism and that a 50% lower starting dose is suggested for non-smokers.[5] In smokers who are resistant to clozapine, using single doses of clozapine at night when the patients are not smoking, or augmentation of treatment with another drug such as low-dose amisulpride has been suggested.[10] It has also been suggested that if a patient taking clozapine starts to smoke, a 50% increase in clozapine dose should be anticipated. Likewise, a patient who stops smoking may experience a 50% increase in clozapine levels within 2 to 4 weeks of stopping smoking. One report recommends that patients with high baseline clozapine levels should be monitored if they stop smoking.[7] In all cases, dose adjustments should be guided by the clinical status of the patient, and clozapine levels where available.[10,17]

Clozapine + Topiramate

Topiramate does not affect the plasma levels of clozapine.

Clinical evidence, mechanism, importance and management

In a study, 10 patients receiving long-term treatment with clozapine 250 mg to 500 mg daily were given topiramate in a dose that was increased gradually to 200 mg daily. The plasma levels of clozapine and its metabolite norclozapine were not significantly affected by topiramate and the combination was well tolerated.[1] This suggests that the dose of clozapine is unlikely to need adjusting if topiramate is also given.

1. Migliardi G, D'Arrigo C, Santoro V, Bruno A, Cortese L, Campolo D, Cacciola M, Spina E. Effect of topiramate on plasma concentrations of clozapine, olanzapine, risperidone, and quetiapine in patients with psychotic disorders. *Clin Neuropharmacol* (2007) 30, 107–13.

Clozapine + Valproate

Valproate may increase or decrease serum clozapine levels but the effects appear to be modest.

Clinical evidence

A controlled study in 11 patients found that when valproate (at an average dose of 1.06 g daily) was given with clozapine, the steady-state serum clozapine levels were increased by 39% and the levels of the demethylated metabolite of clozapine were increased by 23%. However, correction of these levels for dose and weight reduced the total clozapine metabolite values to only 6% above those of the controls. No increase in clozapine adverse effects was seen.[1] Another study found that the concurrent use of sodium valproate and clozapine had no significant effect on the pharmacokinetics of either drug.[2]

In contrast, a study in 4 schizophrenics taking clozapine 550 to 650 mg daily found that when valproate semisodium (divalproex sodium) 750 mg to 1 g daily was added, the serum clozapine levels began to fall, and by 3 weeks had dropped by an average of 41%. However, no deterioration in clinical condition occurred.[3] In another study in 7 patients given clozapine, the clozapine levels were decreased by a more modest 15% when valproic acid was given.[4] An isolated report describes a 37-year-old man taking clozapine, who developed sedation, confusion, slurred speech and impaired functioning on two occasions when valproate semisodium was added.[5] Clozapine levels were doubled in a patient after valproic acid treatment was stopped.[6] The authors of an analysis of reports on the use of mood stabiliser combinations obtained from a MEDLINE search noted that there may be additive adverse effects of weight gain and drowsiness with the combination of clozapine and valproate.[7]

Mechanism

Unclear. It has been suggested that valproate may increase the metabolism of clozapine, although it is unclear which pathway is affected. Alternatively it has been suggested that valproate impairs clozapine absorption.[6]

Importance and management

Evidence for an interaction between clozapine and valproate appears to be limited to these reports, and the situation is not entirely clear. A subgroup analysis of 20 patients who received clozapine and antiepileptics including valproate suggested that this group of patients showed less clinical improvement than patients who were not also taking an antiepileptic. However, the indication for the antiepileptic drug was not always clear and combined treatment may have been used in patients who were more severely ill, or less responsive to clozapine alone, and the effects of valproate were not separated from those of the enzyme-inducing antiepileptics, which are known to reduce clozapine levels.[8]

In general, the effects on clozapine levels in the case reports were relatively modest, and the studies suggesting a lack of interaction indicate that most patients are unlikely to experience a clinically relevant effect. Nevertheless, the isolated cases suggest that it may be prudent to be alert for additive adverse effects (such as weight gain and CNS depressant effects) if both drugs are given.

Flupentixol and related drugs + SSRIs

There is an isolated reported of parkinsonian-like symptoms in a patient taking amitriptyline, flupentixol, and fluoxetine. The pharmacokinetics of zuclopenthixol appear not to be affected by citalopram.

Clinical evidence, mechanism, importance and management

A study in schizophrenic patients found that over a 12-week period the serum levels of zuclopenthixol were not significantly altered by **citalopram** 40 mg daily.[1] Dose adjustments are therefore unlikely to be necessary on concurrent use.

Parkinson-like symptoms developed in a patient taking amitriptyline and flupenthixol when **fluoxetine** was given.[2] Movement disorders may occur simply as a result of the additive adverse effects of antipsychotics and SSRIs. **Fluoxetine** alone has been shown to occasionally cause movement disorders.[3,4] This appears to be an isolated case; however, bear it in mind if extrapyramidal effects become troublesome.

Glutethimide + Tobacco

A study in 7 subjects found that glutethimide worsened psychomotor performance in smokers more than in non-smokers, possibly due to an increase in glutethimide absorption.[1] However there would seem to be no need for particular caution if smokers take glutethimide.

Haloperidol + Alosetron

A placebo-controlled study in 10 patients taking haloperidol found that alosetron 1 mg daily, given during weeks 2 and 3 of the

8-week study period, did not alter the pharmacokinetics of haloperidol.[1]

1. Gupta SK, Kunka RL, Metz A, Lloyd T, Rudolph G, Perel JM. Effect of alosetron (a new 5-HT_3 receptor antagonist) on the pharmacokinetics of haloperidol in schizophrenic patients. *J Clin Pharmacol* (1995) 35, 202–7.

Haloperidol + Amfetamines

Acute dystonia occurred in two healthy subjects when they were given haloperidol with dexamfetamine. Haloperidol inhibits the central stimulant effects of amfetamines.

Clinical evidence, mechanism, importance and management

Two healthy young women were given haloperidol 5 mg and **dexamfetamine** 5 mg as part of a neuropharmacological study. After 29 hours one of them developed stiffness of her neck and limbs, parkinsonian facies, her tongue protruded, and she had oropharyngeal spasm. After 34 hours the other woman developed an oculogyric crisis and acute dystonia of the neck with her back slightly arched. Both recovered rapidly after being given 10 mg of intramuscular procyclidine.[1]

The reasons for this interaction are not fully understood, but it may be due to acute dopamine receptor blockade with a secondary increase in dopamine release on supersensitive receptors. The general significance of these isolated cases is unclear.

The manufacturers of **amfetamine**, **dexamfetamine** and **lisdexamfetamine** note that haloperidol inhibits the central stimulant effects of amfetamines by blocking dopamine and noradrenaline re-uptake.[2-4] Therefore these amfetamines may be less effective in those taking haloperidol. Be alert for this effect on concurrent use.

Haloperidol + Antacids

There seem to be no clinical studies or reports confirming the anecdotal evidence of a possible reduction in the effects of haloperidol by antacids.

Clinical evidence, mechanism, importance and management

In 1982 a questioner in a letter asked whether haloperidol interacts with antacids because he had a patient responding well to treatment with haloperidol who had begun to deteriorate when *Amphojel* (**aluminium hydroxide**) was added. In a written answer it was stated[1] that there are no reports of this interaction but several clinicians had said that based on clinical impressions oral haloperidol and antacids should not be given together.

With other antacid interactions separating the doses by as much as possible (1 to 2 hours) to avoid admixture in the gut usually minimises any effects. This may also prove of use if haloperidol appears to be less effective when an antacid is taken.

Haloperidol and related drugs + Azoles

Itraconazole increases the plasma levels of haloperidol, and its metabolite, reduced haloperidol. Other azoles may have similar effects on both haloperidol and bromperidol.

Clinical evidence

(a) Bromperidol

A study in 8 patients found that the plasma levels of bromperidol 12 mg or 24 mg daily, were increased by **itraconazole** 200 mg daily for 7 days. The average increase was about 87%, but there was wide variation between patients, with some being unaffected and others having increases of up to 302%. Levels of the metabolite of bromperidol, reduced bromperidol, were similarly increased, by up to 415%.[1]

(b) Haloperidol

A study in 13 patients with schizophrenia taking haloperidol 6 mg or 12 mg twice daily found an increase in the levels of haloperidol and its metabolite, reduced haloperidol, when **itraconazole** 200 mg daily was given for 7 days. Haloperidol levels were increased by 30%, and levels of the metabolite, reduced haloperidol, were increased by 24%. There was also an increase in neurological adverse effects during **itraconazole** treatment.[2] In a randomised study 15 healthy subjects were given **itraconazole** 200 mg twice daily for 10 days with a single 5-mg dose of haloperidol on day 7. **Itraconazole** increased the AUC of haloperidol by 55% in the 8 subjects with normal levels of CYP2D6 and by 81% in those lacking or totally deficient in CYP2D6. No significant changes in QT prolongation were seen.[3]

Mechanism

It is likely that itraconazole inhibited the metabolism of bromperidol and haloperidol by the cytochrome P450 isoenzyme CYP3A4. The wide variation in results may be attributed to interindividual variation in CYP3A4 activity. This interaction may be of more importance in those patients who have less active CYP2D6, the predominant isoenzyme involved in the metabolism of haloperidol, because CYP3A4, which is inhibited by itraconazole, will then become more important in haloperidol metabolism.

Importance and management

The clinical significance of the raised butyrophenone levels is unclear, although one study found an increase in neurological adverse effects with haloperidol. It may be prudent to monitor concurrent use, decreasing the haloperidol or bromperidol dose if adverse effects (e.g. sedation, agitation, movement disorders) become troublesome. It is likely that other azoles that are potent inhibitors of CYP3A4, such as **ketoconazole**, would interact similarly, but this does not appear to have been studied. See 'azoles', (p.233), for more on the enzyme-inhibitory properties of the azoles.

Haloperidol + Buspirone

Two studies found that buspirone can cause a rise in plasma haloperidol levels, while another study found that no interaction occurred.

Clinical evidence, mechanism, importance and management

A pharmacokinetic study in 27 schizophrenic patients taking haloperidol 10 to 40 mg daily found that buspirone 5 mg three times daily for 2 weeks, followed by 10 mg three times daily for 4 weeks, did not significantly affect the steady-state plasma levels of haloperidol.[1]

These findings contrast with those of a 6-week study, in which 6 out of 7 schizophrenics had 15 to 122% rises in their plasma haloperidol levels when they were given buspirone.[2] The authors also mention a single-dose study in healthy subjects, which found a 30% rise in haloperidol levels when subjects were given buspirone.[2]

It is not known why these findings differ, but since no adverse reactions have been reported, there would seem to be no reason for avoiding concurrent use. However, be aware that some patients seem to experience large rises in haloperidol levels, so consider this potential interaction if the ad-

verse effects of haloperidol (e.g. sedation, agitation, movement disorders) become troublesome.

Haloperidol and related drugs + Carbamazepine

Haloperidol plasma levels are roughly halved by carbamazepine; bromperidol levels are also reduced by carbamazepine. Haloperidol can raise carbamazepine levels. The plasma levels of haloperidol do not appear to be affected by oxcarbazepine.
Neurotoxicity and Stevens-Johnson syndrome have been seen in patients taking haloperidol and carbamazepine.

Clinical evidence

(a) Bromperidol

When 13 patients with schizophrenia taking bromperidol 12 or 24 mg daily were given carbamazepine 200 mg twice daily for 4 weeks, the plasma levels of bromperidol and reduced bromperidol (a metabolite) were decreased by 37% and 23%, respectively. Despite this fall in levels, the Clinical Global Impression scores (a measure of illness severity) fell slightly, suggesting an improvement in disease control.[1]

(b) Haloperidol

A study in 9 patients with schizophrenia taking haloperidol (average dose 30 mg daily) found a 55% reduction in plasma haloperidol levels (a mean fall from 45.5 to 21.2 nanograms/mL) when they were given carbamazepine for 5 weeks (precise dose not stated). They also took trihexyphenidyl 10 mg daily and oxazepam 30 mg at night, as necessary. Carbamazepine serum levels and the control of the disease remained unchanged.[2]

Other studies and reports have similarly found 40 to 60% falls in plasma haloperidol levels in patients taking carbamazepine,[3-7] with the occasional patient having undetectable levels.[4,8] Haloperidol clearance was found to be increased by 32% in a retrospective study in patients who were also taking enzyme-inducing antiepileptics, which included carbamazepine.[9] Decreases in plasma haloperidol levels of unspecified amounts have also been described in patients taking carbamazepine.[10-13] A study in 9 patients taking haloperidol 6 mg twice daily who were then given carbamazepine, with the daily dose increased at fortnightly intervals from 100 to 300 and to 600 mg, found a dose-dependent reduction in haloperidol levels. Mean plasma haloperidol levels were reduced by 25%, 61%, and 82%, respectively.[14] A few patients have had clinical worsening or increased adverse effects.[4-6,8] Three patients had two- to fivefold increases in plasma haloperidol levels and clinical improvement when carbamazepine 1.2 to 1.4 g daily was stopped, but extrapyramidal adverse effects developed within one to 30 days.[15] Three cases of neurotoxicity (drowsiness, slurred speech, confusion) have also been described in patients taking haloperidol and carbamazepine.[10,16,17] One study found that concurrent use increased the incidence of QT prolongation.[18]

A case report describes 3 schizophrenic patients taking haloperidol whose treatment was changed from carbamazepine to **oxcarbazepine**. After 2 weeks their plasma haloperidol levels had dramatically risen (from 6 to 18 nanomol/L, from 6 to 14 nanomol/L and from 17 to 27 nanomol/L). This was accompanied by severe extrapyramidal adverse effects, which necessitated dose reductions in 2 of the patients.[19]

A study in Japanese patients with schizophrenia found that haloperidol raised serum carbamazepine levels by about 30%, despite a 25% dose reduction.[11]

A patient taking haloperidol (and 'fluphenazine', (p.894)) developed Stevens-Johnson syndrome 12 days after starting to take carbamazepine. She had erythema multiforme skin lesions and at least two mucous membranes were affected. After treatment, she restarted her previous drugs, except carbamazepine, without problems.[20] Another case of Stevens-Johnson syndrome has been reported in a patient taking carbamazepine, lithium carbonate, haloperidol and trihexyphenidyl.[21]

Mechanism

Carbamazepine, is a recognised enzyme inducer, therefore it seems highly likely that the reduced plasma bromperidol and haloperidol levels occur because their metabolism by the liver is markedly increased by carbamazepine. Oxcarbazepine does not appear to interact, probably because it is not as potent an enzyme inducer as carbamazepine.

The reason for the raised carbamazepine levels with haloperidol is not understood.

Importance and management

The interactions of haloperidol with carbamazepine are well documented and appear to be clinically important, but only a few patients have been reported to show clinical worsening. Although there are advantages in adding carbamazepine to haloperidol in treating some patients[22] be alert for the need to increase the haloperidol dosage. A study, in which intramuscular haloperidol was used, recommended shortening the interval between injections rather than raising the dosage, but it was not stated by how much.[23] Remember too that if carbamazepine is withdrawn it may be necessary to reduce the haloperidol dosage. Also be alert for the development of dystonic reactions and for a rise in serum carbamazepine levels. Similar precautions may be needed with bromperidol, but this needs confirmation. Limited evidence suggest that no special precautions are necessary with oxcarbazepine.

Stevens-Johnson syndrome with carbamazepine alone is rare, and the risk appears to be mostly confined to the first 8 weeks of treatment.[24] It may be more common in patients being treated for conditions other than epilepsy.[25] It is not possible to say whether the concurrent use of haloperidol increases the risk of its development, but until more is known it would be prudent to monitor the outcome, particularly during the first 2 weeks of combined use.

Haloperidol + Chlorpromazine

Some patients may have a large increase in haloperidol levels when they are also given chlorpromazine.

Clinical evidence, mechanism, importance and management

Haloperidol was given to 43 patients in doses of 2 to 21 mg daily for 2 months, and then chlorpromazine 50 to 300 mg daily was added for a further 2 months. Haloperidol plasma levels were found to increase by an average of 29%, and levels of the metabolite, reduced haloperidol, were increased by 161%. However, the variation in effect was large.

Chlorpromazine was thought to raise haloperidol levels by inhibiting haloperidol metabolism by the cytochrome P450 isoenzyme CYP2D6. The large inter-individual variation suggested that differences in cytochrome P450 genotypes may affect haloperidol metabolism,[1] and therefore some patients may be at risk of developing adverse effects related to high haloperidol levels when taking chlorpromazine. Concurrent use need not be avoided, but consider this interaction if haloperidol adverse effects (e.g. sedation, agitation, movement disorders) become troublesome. Of more concern is the potential for additive effects on the QT interval, see 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290.

Haloperidol + Granisetron

Granisetron appears not to increase the adverse effects of haloperidol.

Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects found that, while haloperidol 3 mg alone caused some impaired psychometric performance (increased drowsiness, muzziness, lethargy, mental slowness, etc.), the addition of granisetron 160 micrograms/kg did not seem to make performance significantly worse.[1] If both drugs are used, no additional precautions would seem necessary.

1. Leigh TJ, Link CGG, Fell GL. Effects of granisetron and haloperidol, alone and in combination, on psychometric performance and the EEG. *Br J Clin Pharmacol* (1992) 34, 65–70.

Haloperidol + Grapefruit juice

In a study in 12 patients with schizophrenia taking haloperidol 6 mg twice daily, the ingestion of 200 mL of regular-strength grapefruit juice three times daily for 7 days did not affect the pharmacokinetics of haloperidol.[1]

1. Yasui N, Kondo T, Suzuki A, Otani K, Mihara K, Furukori H, Kaneko S, Inoue Y. Lack of significant pharmacokinetic interaction between haloperidol and grapefruit juice. *Int Clin Psychopharmacol* (1999) 14, 113–8.

Haloperidol + Imipenem

Marked but transient hypotension was seen when three patients receiving intravenous imipenem were given low dose intravenous haloperidol.

Clinical evidence, mechanism, importance and management

Three patients in intensive care who were receiving intravenous imipenem 500 mg (with cilastatin) every 6 hours for 2, 3, and 7 days, respectively, developed a rapid and short-lived episode of hypotension when they were given a 2.5-mg dose of intravenous haloperidol. For example, the blood pressure of one of the patients fell from 117/75 mmHg to 91/49 mmHg. After 30 minutes her blood pressure had risen to 100/57 mmHg. No treatment for hypotension was given to any of the patients and the reaction was brief and self-limiting. Two of the patients were also taking famotidine and erythromycin. No acute ECG changes were seen.[1]

The reason for this fall in blood pressure is not understood, but the authors attribute what happened to the concurrent use of haloperidol and imipenem, although they point out that intravenous haloperidol alone can cause orthostatic hypotension. One suggestion is that competitive protein binding displacement might have transiently increased the levels of free haloperidol,[1] although this has been questioned. Furthermore, it has been suggested that the clinical condition of the patients may have had a greater part to play in the development of hypotension than any drug interaction.[2]

The authors advise that if haloperidol is used, low doses should be given, and the outcome well monitored. They say that no pressor agent was needed in these cases, but they suggest the possible use of metaraminol, phenylephrine or noradrenaline (norepinephrine) rather than dopamine, the vasopressor effects of which might be blocked or reversed by haloperidol.[1]

2. Hauben M. Comments on "Hypotension associated with intravenous haloperidol and imipenem". *J Clin Psychopharmacol* (2001) 21, 345–7.

Haloperidol + Indometacin

Profound drowsiness and confusion have been described in patients given haloperidol with indometacin.

Clinical evidence, mechanism, importance and management

A crossover study in 20 patients, designed to find out the possible advantages of combining haloperidol 5 mg daily with indometacin 25 mg three times daily, was eventually abandoned because 13 patients (11 taking haloperidol and 2 taking placebo) failed to complete the study. Profound drowsiness or tiredness caused 6 of the haloperidol-treated patients to withdraw. The authors of this paper said that the concurrent use of indometacin produced drowsiness and confusion greater than anything expected with haloperidol alone, which was sufficiently severe that in some cases independent functioning was affected.[1]

Evidence for this interaction appears to be very limited. If concurrent use is thought appropriate, consider warning patients about this potentially severe effect. It might be wiser to avoid concurrent use because many patients requiring this type of treatment may not be hospitalised and under the day-to-day scrutiny of the prescriber.

1. Bird HA, Le Gallez P, Wright V. Drowsiness due to haloperidol/indomethacin in combination. *Lancet* (1983) i, 830–1.

Haloperidol + Nefazodone

Nefazodone does not appear to significantly affect the pharmacokinetics of haloperidol.

Clinical evidence, mechanism, importance and management

In a study in 12 healthy subjects taking haloperidol 5 mg daily, nefazodone 200 mg twice daily for about 7 days (to achieve steady-state pharmacokinetics), increased the AUC of haloperidol by 36% but its maximum plasma levels were unaltered. The pharmacokinetics of the nefazodone were unaltered.[1] It seems fairly unlikely that this change is enough to be of clinical relevance and therefore no dose adjustment seems necessary on concurrent use.

1. Barbhaiya RH, Shukla UA, Greene DS, Breuel H-P, Midha KK. Investigation of pharmacokinetic and pharmacodynamic interactions after coadministration of nefazodone and haloperidol. *J Clin Psychopharmacol* (1996) 16, 26–34.

Haloperidol + Phenobarbital and/or Phenytoin

Haloperidol plasma levels are roughly halved by phenobarbital and phenytoin.

Clinical evidence

A study in epileptic patients, 2 taking phenobarbital, 3 taking phenytoin, and 4 taking both drugs, found that after taking haloperidol 10 mg three times daily for 6 weeks their serum haloperidol levels were about half of those in a control group who were not taking antiepileptics (19.4 nanograms/mL compared with 36.6 nanograms/mL). Antiepileptic levels remained unchanged.[1] A patient had a marked rise in serum haloperidol levels and clinical improvement when phenytoin 300 mg daily was stopped.[2] Haloperidol clearance was increased by 32% in a study in patients who were also taking enzyme-inducing antiepileptics, which included phenobarbital or phenytoin.[3] A retrospective study found that phenobarbital reduced the haloperidol concentration/dose ratio, suggesting that phenobarbital may affect the metabolism of haloperidol.[4]

Mechanism

Phenobarbital and phenytoin are recognised enzyme inducers, therefore it seems highly likely that the reduced plasma haloperidol levels occur because its metabolism by the liver is markedly increased by these antiepileptics.

Importance and management

The interactions of haloperidol with phenytoin and phenobarbital are moderately well documented but their clinical effects do not seem to have been studied. Be alert for the need to increase the haloperidol dose if either of these antiepileptics is also given. The authors of one study suggest a two- to threefold increase in the haloperidol dose may be needed.[1] Another study, in which intramuscular haloperidol was used, recommended shortening the interval between injections rather than raising the dose, but it was not stated by how much.[5] Remember too that if the antiepileptics are withdrawn it may be necessary to reduce the haloperidol dose.

Haloperidol + Quinidine

Haloperidol levels can be markedly increased by quinidine.

Clinical evidence, mechanism, importance and management

An experimental study in 13 healthy subjects found that quinidine bisulfate 250 mg, taken about one hour before a single 5-mg dose of haloperidol approximately doubled the maximum plasma levels and the AUC of haloperidol. The reasons for this effect are not understood.[1] The clinical importance of this interaction has not been assessed, but it seems likely that the beneficial and adverse effects of haloperidol will be increased if quinidine is added.

Concurrent use need not be avoided, but consider this interaction if haloperidol adverse effects (e.g. sedation, agitation, movement disorders) become troublesome. Of more concern is the potential for additive effects on the QT interval, see 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290.

Haloperidol + Rifampicin (Rifampin) and/or Isoniazid

The serum levels of haloperidol can be reduced by rifampicin, and possibly raised by isoniazid.

Clinical evidence

A study in schizophrenic patients taking haloperidol, 7 of whom were also taking a range of antimycobacterial drugs (ethambutol, isoniazid, rifampicin), and 18 of whom were taking isoniazid only, found that those receiving multiple drugs including rifampicin had significantly lower haloperidol serum levels. The half-life of haloperidol in 2 patients taking rifampicin was 4.9 hours compared with 9.4 hours in 3 other patients not taking rifampicin.[1] Three of the patients taking isoniazid (without rifampicin or ethambutol) had *increased* serum haloperidol levels.[1]

The trough serum haloperidol levels of 15 schizophrenics fell to 37% of the expected level after they took rifampicin 600 mg daily for 7 days.[2] After 28 days the serum level had dropped further, to 30% of the expected level. In another group of 5 patients taking haloperidol and rifampicin, the serum haloperidol levels rose to 229% of the previous level 7 days after rifampicin was stopped, and to 329% 28 days after rifampicin was stopped.[2] The clinical effects of the haloperidol appeared to be reduced by the rifampicin.[2]

Mechanism

The likeliest explanation for the reduced haloperidol levels is that rifampicin, a recognised potent enzyme inducer, increases the metabolism and loss of haloperidol from the body.

Importance and management

The interaction between haloperidol and rifampicin would appear to be established and clinically important. Be alert for any evidence of reduced haloperidol effects if rifampicin alone is used, and possibly increased effects if isoniazid alone is used. Adjust the haloperidol dosage if necessary.

Haloperidol + Risperidone

A case report describes neuroleptic malignant syndrome in a patient taking risperidone and haloperidol.

Clinical evidence, mechanism, importance and management

A case report describes a 57-year-old man who had been taking haloperidol 4 mg three times daily uneventfully for several years. At a review, his treatment was changed to risperidone, in increasing doses to 3 mg twice daily, and mirtazapine 15 mg at night. Despite being advised to stop haloperidol when he started risperidone, the patient continued to take haloperidol, and by the third day of concurrent use he had become pyrexial, and exhibited rigidity of his trunk and extremities. He was diagnosed as having neuroleptic malignant syndrome, and so he was given dantrolene, bromocriptine and lorazepam: he recovered over the next 2 months.

The effects seen in this patient were thought to be due to the additive dopamine antagonism caused by both the haloperidol and risperidone. Mirtazapine may have also contributed, although the patient only took two doses before he was admitted. The authors suggest that if antipsychotic treatment is to be changed, it is advisable to slowly reduce the dose of the old antipsychotic and, simultaneously, slowly increase the dose of the new drug to avoid the risk of a psychotic relapse, and the patient should be closely monitored during this time for signs of neuroleptic malignant syndrome.[1]

Haloperidol + Ritonavir

Ritonavir may raise haloperidol levels.

Clinical evidence, mechanism, importance and management

The manufacturers of ritonavir predict that antiretroviral doses of ritonavir may increase the plasma levels of haloperidol by inhibiting its metabolism

by the cytochrome P450 isoenzyme CYP2D6.[1] Haloperidol has been seen to interact in this way with other known CYP2D6 inhibitors (see 'Haloperidol + Quinidine', p.886). The manufacturers advise monitoring for haloperidol adverse effects (e.g. sedation, agitation, movement disorders) during concurrent use. This seems a prudent precaution.

Haloperidol + SSRIs

Fluoxetine, fluvoxamine, and possibly sertraline may raise haloperidol levels, which may increase its adverse effects. A number of case reports describe extrapyramidal adverse effects following the use of fluoxetine and haloperidol.

Clinical evidence

(a) Citalopram

A study in schizophrenic patients found that, over a 12-week period, the serum levels of haloperidol were not significantly altered by citalopram 40 mg daily.[1]

(b) Fluoxetine

A woman taking haloperidol 2 to 5 mg daily for 2 years with only occasional mild extrapyramidal symptoms began to experience severe extrapyramidal symptoms (tongue stiffness, parkinsonism, akathisia) shortly after starting to take fluoxetine 40 mg twice daily and was virtually incapacitated for 3 days. Both drugs were stopped and she recovered over a period of one week.[2] Three other patients developed movement disorders after receiving both drugs:[3-5] in one case severe antimuscarinic adverse effects also occurred.[4]

A report describes 8 patients who had a 20% rise in plasma haloperidol levels when fluoxetine 20 mg daily was added. Although no overall increase in extrapyramidal effects was seen, one patient developed tremor, and another developed akathisia.[6] Similarly 15 patients had an increase of nearly 30% in their haloperidol plasma levels after fluoxetine was given, and 5 of 17 patients had aggravated parkinsonian symptoms.[7] Another report describes a more than 100% rise in plasma haloperidol levels, accompanied by clinical improvement, in 7 patients given fluoxetine 20 to 40 mg with haloperidol.[8]

(c) Fluvoxamine

A study in 12 patients with schizophrenia found that haloperidol levels were increased by 20%, 39%, and 60% by fluvoxamine 25, 75, and 150 mg daily, respectively, which suggested the extent of the interaction was related to the dose of fluvoxamine.[9] A study in 3 patients with schizophrenia found that the addition of fluvoxamine caused their serum haloperidol levels to rise, and when the fluvoxamine was stopped the levels fell. This was not a formal pharmacokinetic study, but while taking fluvoxamine 150 to 200 mg daily the haloperidol serum levels of one patient rose from 17 to 38 nanograms/mL. The fluvoxamine was then stopped and 54 days later his serum haloperidol levels had fallen to 9 nanograms/mL. This patient became lethargic and showed worsening of all of the clinical and cognitive functions assessed while taking these drugs.[10] It should be noted that all three patients were also taking benzatropine, which can caused additive antimuscarinic effects when given with SSRIs (see 'Antimuscarinics + SSRIs', p.787). Another limited study also observed a rise in the serum levels of haloperidol in patients taking fluvoxamine.[11]

(d) Paroxetine

In one study the sedative effects and impairment of psychomotor performance caused by haloperidol 3 mg were not increased by paroxetine 30 mg.[12]

(e) Sertraline

In a randomised, placebo-controlled study, 21 healthy subjects were given a single 2-mg dose of haloperidol on days 2 to 25. On days 9 to 25 the subjects were given sertraline, increased over 7 days to 200 mg daily. All subjects took psychomotor tests on days 1, 2 and 25 to assess the effect of haloperidol. Their cognitive function was impaired for 6 to 8 hours after taking haloperidol, but this effect had disappeared after 23 hours. Overall, sertraline did not appear to worsen the cognitive impairment caused by haloperidol.[13] Another study found similar pharmacodynamic results, and also found that the pharmacokinetics of haloperidol are unaffected by sertraline.[14] In contrast, a study in 16 hospitalised patients who were taking haloperidol found that the addition of sertraline 50 mg daily for 2 weeks resulted in an increase in plasma haloperidol concentrations, and a reduction in the plasma concentrations of the metabolite (reduced haloperidol).[15]

Mechanism

Movement disorders and raised haloperidol serum levels seem most common with fluoxetine, possibly because it inhibits the metabolism of haloperidol by the cytochrome P450 isoenzyme CYP2D6.[16] However, paroxetine also inhibits CYP2D6 and an interaction with haloperidol has not been reported, whereas sertraline has only weak effects on CYP2D6 and an interaction has been reported. Therefore the movement disorders may simply occur as a result of the additive adverse effects of antipsychotics and SSRIs. Fluoxetine alone has been shown to occasionally cause movement disorders.[3,17]

Importance and management

On the whole significant interactions between haloperidol and the SSRIs appear rare. The combination can be useful and so the isolated cases of extrapyramidal adverse effects should not prevent concurrent use. However, if extrapyramidal effects become troublesome bear this interaction in mind as a possible cause. The significance of the rise in haloperidol levels caused by fluoxetine and fluvoxamine is unclear; be aware that haloperidol adverse effects (e.g. sedation, agitation, movement disorders) may be increased in some patients and consider reducing the haloperidol dose if problems occur. Note that this pharmacokinetic interaction has also been predicted by the manufacturers of **escitalopram**.[18]

Haloperidol + Tobacco

Smokers of tobacco may possibly need larger doses of haloperidol than non-smokers.

Clinical evidence, mechanism, importance and management

Steady-state haloperidol levels were found to be lower in a group of 23 cigarette smokers than in another group of 27 non-smokers (16.83 nanograms/mL compared with 28.8 nanograms/mL) and the clearance was increased by 44%.[1] Other studies have broadly confirmed these findings.[2,3]

Although the reason for the reduction in haloperidol levels has not been established, it seems likely that some of the components of tobacco smoke act as enzyme inducers, which increase the rate at which the liver metabolises haloperidol, thereby reducing its serum levels and, possibly, clinical effects. Be alert for the need to increase the dose of haloperidol in patients who smoke, and reduce the dose if smoking is stopped.

Haloperidol + Topiramate

Topiramate slightly increases haloperidol levels.

Clinical evidence, mechanism, importance and management

In a study, healthy subjects were given topiramate 50 mg twice daily, titrated over 2 days to 100 mg twice daily. They were also given a single 5-mg dose of haloperidol 4 days before starting topiramate and on day 7 of topiramate use. Topiramate slightly increased the plasma levels of haloperidol and its reduced metabolite. The mean AUC of haloperidol and its active reduced metabolite were increased by 11% and 31%, respectively, suggesting that exposure to the active metabolite (which possesses 20 to 50% of the activity of haloperidol) was increased by topiramate.[1] In another study, the mean AUC of a single 2-mg dose of haloperidol was increased by 15% in the presence of topiramate 50 to 100 mg twice daily.[2]

Evidence for an interaction between haloperidol and topiramate appears to be limited, but an interaction is established. However, the rise in haloperidol levels is modest, and unlikely to be of clinical significance. Nevertheless, the authors of one of the studies suggest that a haloperidol dose adjustment [reduction] should be considered, if adverse effects occur during concurrent use.[1]

2. Doose DR, Kohl KA, Desai-Krieger D, Natarajan J, van Kammen DP. No clinically significant effect of topiramate on haloperidol concentration. *Eur Neuropsychopharmacol* (1999) 9, S357.

Haloperidol + Valproate

No clinically relevant interaction appears to occur between haloperidol and valproate.

Clinical evidence, mechanism, importance and management

A study in 6 patients given haloperidol 6 to 10 mg daily found no significant interaction with valproic acid.[1] Similarly, haloperidol was not found to interact with valproate in two further studies,[2,3] although in one of these studies an increase of 64% in haloperidol plasma levels was seen, which was not considered to be clinically significant.[2]

Evidence for an interaction between haloperidol and valproate appears to be limited to these brief studies, but they suggest that a clinically relevant interaction is unlikely.

Haloperidol + Venlafaxine

Venlafaxine can increase the serum levels of haloperidol. This is consistent with an isolated report, which describes a man taking haloperidol who developed urinary retention when venlafaxine was added.

Clinical evidence, mechanism, importance and management

A study in 24 healthy subjects found that steady-state venlafaxine 75 mg every 12 hours reduced the renal clearance of a single 2-mg dose of haloperidol by 42%. This resulted in a 70% rise in the AUC of haloperidol and an 88% rise in its maximum serum levels.[1-3] This rise in haloperidol levels would seem to be consistent with an isolated report of a 75-year-old man taking haloperidol 1 mg and alprazolam 500 micrograms daily, who suddenly developed urinary retention when venlafaxine 37.5 mg daily was added. Urinary retention resolved spontaneously when all the drugs were stopped.[4]

It was suggested that venlafaxine inhibits the cytochrome P450 isoenzyme CYP2D6, which is concerned with the metabolism of haloperidol. As a result the serum levels of the haloperidol rise, thereby increasing its antimuscarinic effects,[4] which in this case resulted in urinary retention.

The evidence for an interaction between haloperidol and venlafaxine is limited but it appears to be established. Be aware that increased haloperidol adverse effects (e.g. sedation, agitation, movement disorders) may occur if venlafaxine is also given. It may be necessary to reduce the haloperidol dosage.

Loxapine + SSRIs

Galactorrhoea and amenorrhoea developed in a patient given loxapine and fluvoxamine.

Clinical evidence, mechanism, importance and management

A 38-year-old woman developed amenorrhoea, followed shortly by galactorrhoea, about 6 weeks after starting to take **fluvoxamine** and loxapine. The galactorrhoea resolved within 3 weeks of stopping the **fluvoxamine**, and menstruation occurred one week later. Her prolactin levels were found to be 80 micrograms/L (reference range 4 to 30 micrograms/L).[1]

Galactorrhoea is a known adverse effect of loxapine, and the SSRIs can increase prolactin levels,[2] which may have triggered this adverse effect.

The general relevance of this isolated case is unclear. Consider an interaction as a possible cause if a patient taking loxapine and an SSRI develops galactorrhoea.

2. Rosen RC, Lane RM, Menza M. Effects of SSRIs on sexual function: a critical review. *J Clin Psychopharmacol* (1999) 19, 67–85.

Molindone + SSRIs

An isolated report describes extrapyramidal adverse effects following the use of paroxetine with molindone.

Clinical evidence, mechanism, importance and management

An elderly woman taking molindone 10 mg twice daily developed severe and disabling extrapyramidal symptoms (severe bradykinesia, tremor, inability to feed herself, delirium) within about 2 weeks of starting **paroxetine** 10 mg daily. The symptoms resolved when molindone was stopped, and no problems occurred when **fluoxetine** alone was started.[1]

Movement disorders may just be a result of the additive adverse effects of molindone and SSRIs. **Fluoxetine** alone has been shown to occasionally cause movement disorders.[2,3]

The combination of an antipsychotic and an SSRI can be useful and so

the isolated case of extrapyramidal adverse effects should not prevent concurrent use. However, if extrapyramidal effects become troublesome bear this interaction in mind as a possible cause.

Olanzapine + Carbamazepine or Oxcarbazepine

Carbamazepine appears to lower olanzapine levels, whereas oxcarbazepine does not appear to affect the pharmacokinetics of olanzapine.

Clinical evidence, mechanism, importance and management

(a) Carbamazepine

Multiple-dose studies in healthy subjects have shown that carbamazepine increases the metabolism of olanzapine. The clearance of olanzapine was increased by 44% and its elimination half-life was reduced 20% by carbamazepine, but these changes were not considered significant enough to necessitate dose adjustments.[1] In another study in healthy subjects, pretreatment with carbamazepine 200 mg twice daily for 2 weeks increased the clearance of a single 10-mg dose of olanzapine by 46%. The maximum plasma level and AUC were decreased by about 25% and 34%, respectively.[2] Another study found that 5 patients taking olanzapine and carbamazepine had a concentration/dose ratio 36% lower than 22 patients taking olanzapine alone.[3] A later study by the same authors found similar results, and also found that this increased olanzapine metabolism was probably due to an increase in glucuronidation, which was induced by the carbamazepine.[4]

A retrospective study identified 10 patients taking olanzapine and carbamazepine. The patients taking carbamazepine were taking olanzapine doses that were double those of subjects taking olanzapine alone. When corrected for dose it was found that the concentration/dose ratio of olanzapine was 71% lower in those also taking carbamazepine.[5] A 23 year-old woman required an olanzapine dose reduction from 15 mg daily to 10 mg daily to maintain similar serum olanzapine concentrations after discontinuing treatment with carbamazepine 600 mg per day.[6]

These findings suggest that, in some patients at least, the modest decreases in olanzapine levels caused by carbamazepine may be clinically relevant. It would seem prudent to monitor the outcome of concurrent use for olanzapine efficacy and adjust the olanzapine dose if necessary.

(b) Oxcarbazepine

A study in 13 patients taking olanzapine 5 to 20 mg daily found that the addition of oxcarbazepine for 5 weeks, at an initial dose of 300 mg daily increased to a range of 900 mg to 1.2 g after one week, had no significant effects on the pharmacokinetics of olanzapine. Concurrent use was generally well tolerated.[7] No particular additional monitoring or dose adjustment therefore appears necessary if oxcarbazepine and olanzapine are given concurrently.

Olanzapine + Lamotrigine

Olanzapine reduces lamotrigine levels and lamotrigine may increase olanzapine levels.

Clinical evidence, mechanism, importance and management

A study in 43 healthy subjects found that steady-state olanzapine pharmacokinetics were not affected by lamotrigine 200 mg daily. However, the AUC and maximum plasma concentrations of lamotrigine were reduced by 24% and 20%, respectively. Although this reduction was not considered to be clinically significant, the authors suggested that interpatient variation indicated that some patients may require adjustment of their lamotrigine dose if olanzapine is started or discontinued.[1]

A further study in 14 healthy subjects given lamotrigine 50 mg daily, and a single 5-mg dose of olanzapine found no significant changes in the AUC and maximum plasma concentrations of lamotrigine when given with olanzapine, although the time to maximum plasma levels of lamotrigine was increased from 1.8 hours to 4.2 hours. This may be due to antimuscarinic effects of olanzapine slowing the gastrointestinal absorption of lamotrigine.[2] As only a single dose of olanzapine, and low doses of both drugs were used, the clinical significance of this finding is unclear.

A study in 14 patients taking olanzapine in doses of 10 mg to 20 mg daily, and who were also given lamotrigine in increasing doses over 8 weeks to 200 mg daily found no changes in the pharmacokinetics of olanzapine with a lamotrigine dose of 100 mg daily, but when the dose was increased to 200 mg daily, an increase of 16% in olanzapine plasma levels occurred. This increase would not be expected to be clinically significant.[3]

The effects found in these studies were small, and therefore suggest that dose adjustments are unlikely to be necessary if lamotrigine and valproate are given concurrently.

Olanzapine + Miscellaneous

Activated charcoal causes a fall in olanzapine levels and venlafaxine moderately raise olanzapine levels. Additive dopaminergic effects have been seen in one patient taking olanzapine and haloperidol. Olanzapine appears not to interact to a clinically relevant extent with aluminium/magnesium hydroxide antacids, cimetidine or diazepam. However, excessive sedation and hypotension may occur if parenteral benzodiazepines are given with intramuscular olanzapine.

Clinical evidence, mechanism, importance and management

(a) Antacids

The manufacturers of olanzapine say that single doses of an **aluminium/magnesium-containing antacid** had no effect on the pharmacokinetics of olanzapine.[1] No special precautions would seem to be needed during concurrent use.

(b) Benzodiazepines

In vivo studies have found that no pharmacokinetic interaction occurs between olanzapine and **diazepam**.[1] This confirms *in vitro* studies using human liver microsomes,[1] which found that olanzapine did not inhibit the cytochrome P450 isoenzymes CYP3A4 or CYP2C19, which are concerned with the metabolism of **diazepam**. It was noted that mild increases in heart rate, sedation and dry mouth were seen in patients taking both drugs, but no dosage adjustments were thought to be necessary.[2] There would therefore appear to be no reason for avoiding concurrent use.

Similarly, intramuscular **lorazepam** 2 mg, given one hour after intramuscular olanzapine 5 mg increased the drowsiness seen with either drug alone. The pharmacokinetics of both drugs were not affected.[3,4] One case report describes hypotension occurring following the intramuscular use of a single 2-mg dose of **lorazepam** in a patient receiving intramuscular olanzapine 10 mg, the most recent dose being given 30 minutes before the **lorazepam**. His blood pressure dropped from 124/74 mmHg to 66/30 mm Hg; 12 hours later his blood pressure had returned to normal.[5] Intramuscular olanzapine has been associated with hypotension, bradycardia, respiratory depression, and rarely death, particularly in patients who have also received benzodiazepines. The manufacturers therefore say that

concurrent use is not recommended. If both drugs are needed, parenteral benzodiazepines should not be given for 1 hour after intramuscular olanzapine. If a parenteral benzodiazepine has already been given, intramuscular olanzapine should only be given with careful consideration and monitoring of sedation and respiration.[4]

(c) Charcoal, activated

The manufacturers report that activated charcoal reduces the bioavailability of oral olanzapine by 50 to 60%,[1,3] and recommend that administration be separated by 2 hours.[1]

(d) Cimetidine

The manufacturers say that cimetidine has no effect on the bioavailability of olanzapine.[1,3] No special precautions would seem to be needed during concurrent use.

(e) Haloperidol

A 67-year-old man with a long history of bipolar disorder was taking haloperidol 10 mg daily, with valproate and benzatropine. Because he had previously had parkinsonian symptoms, olanzapine was started, to be increased as the haloperidol was decreased. On day 6 his parkinsonian symptoms became particularly marked. The haloperidol was stopped and 2 days later the symptoms had resolved. It is thought that either the small amount of dopaminergic activity of olanzapine combined with that of the haloperidol brought on these symptoms, or that olanzapine affected the metabolism of haloperidol, resulting in increased levels and therefore greater dopaminergic activity.[6] The significance of this interaction is not clear, but it would be wise to be aware of it if both drugs are used.

(f) Venlafaxine

A retrospective study found that venlafaxine caused a modest 27% increase in olanzapine plasma levels. The clinical significance of this finding is unclear.[7] but probably small.

Olanzapine + Probenecid

Probenecid may increase the AUC and maximum plasma levels of olanzapine.

Clinical evidence, mechanism, importance and management

Twelve healthy subjects were given a single 5-mg dose of olanzapine alone, or on day 2 of a 4-day course of probenecid 500 mg twice daily. The AUC and maximum plasma levels of olanzapine were increased by about 20%, but overall bioavailability was not affected. The probenecid is thought to have caused these small effects by reducing the glucuronidation of olanzapine.[1] As this was a single dose study, the clinical implications of this interaction when olanzapine is taken regularly, are unclear; however they are probably small

Olanzapine + Quinolones

The olanzapine levels of a patient were reduced when ciprofloxacin was stopped. A patient taking olanzapine developed QT interval prolongation when intravenous ciprofloxacin was also given.

Clinical evidence

The olanzapine levels of a patient were rapidly reduced, by more than 50%, when **ciprofloxacin** 250 mg twice daily was stopped. On the day of the last dose of a 7-day course of **ciprofloxacin** her olanzapine plasma level was 32.6 nanograms/mL, but within 3 days it had fallen to 14.6 nanograms/mL.[1]

A case report describes a 70-year old woman taking azathioprine, olanzapine 10 mg daily and valsartan, who developed marked QTc interval prolongation after receiving intravenous **ciprofloxacin** 800 mg daily for 3 days. Her QTc interval returned to its initial value after **ciprofloxacin** was stopped.[2]

Mechanism

Olanzapine is metabolised by the cytochrome P450 isoenzyme CYP1A2, which can be inhibited by ciprofloxacin. Concurrent use therefore decreases olanzapine metabolism, which leads to increased olanzapine levels, and the adverse effects seen.

Importance and management

Evidence for an interaction between olanzapine and ciprofloxacin is limited, but what is known is in line with the way both drugs interact with other substances. An interaction is therefore established. The UK manufacturer of olanzapine recommends that a lower starting dose of olanzapine should be given to patients taking ciprofloxacin, and dose decrease should be considered if ciprofloxacin is started.[3] Note that other quinolones can inhibit CYP1A2 to varying degrees (for example see 'Theophylline + Quinolones', p.1452) and may therefore be expected to interact similarly.

3. Zyprexa (Olanzapine). Eli Lilly and Company Ltd. UK Summary of product characteristics, July 2009.

Olanzapine + Ritonavir

Ritonavir almost halves olanzapine levels.

Clinical evidence, mechanism, importance and management

In a study, 14 healthy non-smoking subjects were given a single 10-mg dose of olanzapine after they had taken ritonavir for 11 days (initially 300 mg twice daily, escalating to 500 mg twice daily). Ritonavir decreased the AUC and maximum plasma levels of olanzapine by 53% and 40%, respectively, and reduced its half-life from 32 hours to 16 hours.[1]

The authors suggest that ritonavir increased the metabolism of olanzapine by inducing the cytochrome P450 isoenzyme CYP1A2, which is the main metabolic route of olanzapine. They also suggest that ritonavir may have increased olanzapine glucuronidation, by inducing glucuronyltransferases, which may also have contributed to the decrease in olanzapine levels.

Evidence is limited to this one study, but ritonavir is an established enzyme inducer. It seems likely that increased olanzapine doses may be needed in the presence of ritonavir. If concurrent use is necessary monitor for olanzapine efficacy and increase the dose if necessary.

Olanzapine + SSRIs

Fluvoxamine causes a rise in serum olanzapine levels, which is associated with increased adverse effects. Fluoxetine, paroxetine and sertraline appear to moderately raise olanzapine levels while citalopram appears to have no effect. A case of retarded ejaculation has been seen in one patient taking olanzapine and paroxetine, and the serotonin syndrome has been reported in patients taking citalopram or fluoxetine with olanzapine.

Clinical evidence

(a) Fluvoxamine

In a placebo-controlled study, 10 male smokers were given fluvoxamine 50 to 100 mg daily for 11 days, with olanzapine 2.5 to 7.5 mg daily on days 4 to 11. During the initial 4 days of concurrent use somnolence was increased by 19 to 115%, when compared to the group taking olanzapine and placebo, but the subjects accommodated to this over the next 4 days. Fluvoxamine increased the olanzapine maximum plasma levels and AUC by 84% and 119%, respectively, and the olanzapine clearance fell by 50%.[1] A retrospective study found that in patients taking fluvoxamine and olanzapine the concentration/dose ratio was 2.3-fold higher than those taking olanzapine alone.[2] In another study 10 schizophrenic patients were given fluvoxamine 50 mg daily from days 1 to 14 followed by fluvoxamine 100 mg daily from days 15 to 28. A single 10-mg dose of olanzapine was given on day 10 and again on day 24. The maximum plasma level of olanzapine was raised by 12% and 64% by 50 mg and 100 mg of fluvoxamine, respectively. Increased sedation was also seen, which was more frequent with fluvoxamine 100 mg daily.[3]

Other studies have found 50 to 81% increases in olanzapine levels with fluvoxamine 100 mg daily, and these increases took up to 8 weeks to occur. There was a marked variation between individuals in the extent of the interaction.[4-6] In one study, plasma levels of olanzapine were maintained when the dose of olanzapine was reduced by an average of 4.5 mg daily following the addition of fluvoxamine 25 mg daily.[7]

A number of case reports demonstrate the clinical relevance of this interaction. In one case, the olanzapine plasma levels of a 21-year-old woman were 6 times the recommended upper limit while she was taking fluvoxamine. During this time she developed rigidity and tremor. After the olanzapine dose was reduced from 15 mg to 5 mg daily the levels were still almost double the recommended level.[8] In another case, a patient taking fluvoxamine 200 mg daily developed hypersalivation (an adverse effect of olanzapine), without any extrapyramidal symptoms, when olanzapine 10 mg daily was also given..[9]

(b) Other SSRIs

In a study in 15 healthy nonsmokers, **fluoxetine** 60 mg daily for 8 days increased the maximum serum levels of a single 5-mg dose of olanzapine by 15%. In the same study, a single 60-mg dose of **fluoxetine** increased the maximum serum levels and AUC of a single 5-mg dose of olanzapine by 18%. No serious or unexpected adverse effects that could be attributed to an interaction were reported.[10] A case report describes a patient who had been taking **fluoxetine** 80 mg daily for several weeks with no adverse effects who developed serotonin syndrome within 3 weeks of starting to take olanzapine 5 mg daily. His symptoms resolved after discontinuing **fluoxetine**, and he was later able to tolerate a 20 mg daily dose of **fluoxetine** and olanzapine with no further adverse effects.[11] Serotonin syndrome has also been reported in a patient taking olanzapine, **citalopram** and lithium, see 'Lithium + Olanzapine', p.1363.

A patient taking fluvoxamine had olanzapine levels double the upper recommended limit; when **paroxetine** was substituted for fluvoxamine the olanzapine levels became almost normal.[8] Another patient taking **paroxetine** developed retarded ejaculation 2 months after he started to take olanzapine 15 mg daily. This adverse effect resolved when the olanzapine was given in divided doses.[12]

A retrospective study found that **sertraline** had no effect on the concentration/dose ratio of olanzapine, suggesting that it does not affect the pharmacokinetics of olanzapine.[2] Another study found that **paroxetine**, **fluoxetine** and **sertraline** increased olanzapine levels by about 32%, but **citalopram** had no effect.[6]

Mechanism

Fluvoxamine inhibits the cytochrome P450 isoenzyme CYP1A2, which is the major isoenzyme involved in the metabolism of olanzapine,[1] resulting in increased olanzapine levels and adverse effects. CYP2D6 also has a minor role in olanzapine metabolism. Many SSRIs can affect CYP2D6, with fluoxetine and paroxetine having the most potent effect. These SSRIs therefore raise olanzapine levels, but only to a very modest extent.

Importance and management

There is a good body of evidence that demonstrates that fluvoxamine can greatly raise olanzapine levels. The extent of the rise seen, and the case reports of adverse effects suggests that a lower dose of olanzapine is likely to be needed in the presence of fluvoxamine. Monitor for olanzapine adverse effects (e.g. somnolence, weight gain, dizziness). Other SSRIs do not appear to interact to any great extent, and olanzapine dose adjustments would not be expected to be necessary. However, the case report with paroxetine suggests that additive adverse effects are a possibility, and this should be borne in mind if adverse effects become troublesome.

Olanzapine + Tobacco

Smoking tobacco increases the clearance of olanzapine.

Clinical evidence, mechanism, importance and management

Retrospective study has found that cigarette smoking reduces olanzapine levels,[1-3] in one study by 12%[1] and by about 50% in another,[3] and that smokers needed higher doses of olanzapine than non-smokers (10 mg compared with 12.5 mg) yet had lower olanzapine levels (60 nanomol/L compared with 92 nanomol/L).[4] Similarly, a study found that the clearance of olanzapine was about 50% greater in 274 smokers than in 249 non-smokers.[5] A further study in 17 psychiatric patients found that the olanzapine concentration-dose ratio was directly related to the activity of the cytochrome P450 isoenzyme CYP1A2: both CYP1A2 activity and olanzapine levels were sixfold higher in smokers than non-smokers.[6]

A case report describes a patient whose schizophrenia was successfully managed with olanzapine 15 mg daily whilst in hospital and smoking up to 12 cigarettes a day. However, on discharge his cigarette consumption increased to 80 per day, and his schizophrenic symptoms worsened. Olanzapine plasma levels reduced from 52 nanograms/mL to 30 nanograms/mL as his cigarette consumption increased to 80 per day.[7]

A patient taking olanzapine 30 mg daily developed extrapyramidal symptoms, probably as a result of increased plasma levels of olanzapine, following a reduction of his tobacco consumption. These effects improved following a reduction in his olanzapine dose to 20 mg daily.[8]

These findings suggest that the effects of olanzapine are reduced to some extent by smoking, but as the dose of olanzapine is individually titrated to effect it seems likely that routine dose adjustments will account for this interaction. However, if a patient decides to stop smoking, or begins to smoke more tobacco, it may be prudent to monitor the patient more closely, as dose decreases or increases may become necessary.

Olanzapine + Topiramate

In a study, 12 patients receiving long-term treatment with olanzapine 10 mg to 20 mg daily were given topiramate in a dose that was increased gradually to 200 mg daily. Plasma levels of olanzapine were not significantly affected by topiramate and the combination was well tolerated.[1]

1. Migliardi G, D'Arrigo C, Santoro V, Bruno A, Cortese L, Campolo D, Cacciola M, Spina E. Effect of topiramate on plasma concentrations of clozapine, olanzapine, risperidone, and quetiapine in patients with psychotic disorders. *Clin Neuropharmacol* (2007) 30, 107–13.

Olanzapine + Tricyclic and related antidepressants

No pharmacokinetic interaction occurs between imipramine and olanzapine, and mirtazapine does not affect the pharmacokinetics of olanzapine. The additive effects of clomipramine and olanzapine were thought to have caused a seizure in one patient.

Clinical evidence, mechanism, importance and management

A randomised, crossover study in 9 healthy men who were given single doses of olanzapine 5 mg and **imipramine** 75 mg found no clinically relevant pharmacokinetic or pharmacodynamic interactions between the two drugs.[1] However, one case report describes seizures, thought to be caused by the additive effects of olanzapine and **clomipramine**. Neither drug alone had produced this reaction in the patient.[2]

A study in 7 patients with schizophrenia investigated the effect of adding **mirtazapine** 30 mg at bedtime, for 6 weeks, to treatment with olanzapine. **Mirtazapine** had a negligible effect on the metabolism of olanzapine and the combination was well tolerated.[3]

No dose adjustments would seem to be necessary if olanzapine is given with a tricyclic, but be aware that both olanzapine and the tricyclics have the potential to lower the seizure threshold and that their effects may be additive.

Olanzapine + Valproate

Valproate appears to lower olanzapine levels, and the combination appears to increase the risk of hepatic injury in children.

Clinical evidence, mechanism, importance and management

A retrospective study identified 52 children (under 18-years-old) who were taking olanzapine alone (17 patients), valproate semisodium (divalproex sodium) alone (23 patients) or both drugs together (12 patients). At least one peak liver enzyme level (ALT, AST or lactate dehydrogenase) was found to be above the normal range in 59% of those taking olanzapine alone, in 26% of those taking valproate alone, and in 100% of the patients taking both drugs. Liver enzymes were persistently elevated in 42% of the patients taking both drugs, and 2 of these patients had levels that were three times the upper limit of normal. Treatment was discontinued due to pancreatitis in one and steatohepatitis in the other.

The authors of his study recommend measuring liver enzymes every 3 to 4 months for the first year of concurrent use, thereafter monitoring every 6 months if no adverse effects are detected.[1]

In 4 patients, a significant reduction in olanzapine plasma levels of between 32 and 79% was found when valproate was given. The authors suggested that this occurred due to the valproate inducing the enzymes involved in the metabolism of olanzapine.[2]

The authors of an analysis of reports on the use of mood stabiliser combinations noted that there may be additive adverse effects of weight gain and drowsiness when olanzapine is given with valproate.[3]

The clinical relevance of these two latter reports is uncertain.

Paliperidone + Miscellaneous

The bioavailability of paliperidone may be increased by a high fat/high caloric meal, carbamazepine, St John's wort, rifampicin (rifampin) and valproate. Additive pharmacological effects can be expected if paliperidone is taken with other drugs that have a CNS depressant action, that prolong the QT interval, cause hypotension or lower seizure threshold.

Clinical evidence, mechanism, importance and management

Paliperidone (9-hydroxyrisperidone) is the active metabolite of risperidone.

(a) Antihypertensives

Paliperidone may cause orthostatic hypotension, and should therefore be given cautiously to patients also taking other drugs which can also cause this effect. The manufacturers specifically mention other **antipsychotics** and **tricyclic antidepressants**,[1] and **hypotensive** medication.[2]

(b) Carbamazepine

Carbamazepine 200 mg twice daily caused a 37% decrease in the mean steady-state AUC and peak levels of paliperidone. This is mainly due to a 35% increase in renal clearance of paliperidone associated with the induction of renal P-glycoprotein by carbamazepine. Higher doses of carbamazepine may produce greater decreases in paliperidone levels. The manufacturer advises that if carbamazepine is started, the dose of paliperidone should be re-evaluated and increased if necessary, with decreases in dose if carbamazepine is then discontinued. The induction effects of carbamazepine on paliperidone levels become maximal after 2 to 3 weeks.[1,2] Note that **rifampicin** (**rifampin**) and **St John's wort** (*Hypericum perforatum*) are also a P-glycoprotein inducers, and they may therefore be expected to interact similarly.[1]

(c) CNS depressants

Paliperidone can cause adverse effects on the CNS, and therefore its use with other drugs which have a CNS depressant activity is not recommended. The manufacturers specifically mention **anxiolytics**, **antipsychotics**, **hypnotics**, **opioids** and **alcohol**.[1,2]

(d) Drugs that lower seizure threshold

The manufacturer advises caution if paliperidone is used with other drugs known to lower the seizure threshold. The manufacturer specifically mentions **butyrophenones**, **mefloquine**, **phenothiazines**, **SSRIs**, **tramadol**, and **tricyclic antidepressants**.[1]

(e) Drugs that prolong the QT interval

Paliperidone may prolong the QT interval (12.3 millisecond increase in one study at twice the recommended exposure to paliperidone).[2] The manufacturers advise that the concurrent use of other drugs that prolong the QT interval should be avoided. They specifically mention **class Ia antiarrhythmics** (e.g. **disopyramide**, **quinidine**, **procainamide**), **class III antiarrhythmics** (e.g. **amiodarone**, **sotalol**), **antipsychotics** (e.g. **chlorpromazine**, **thioridazine**), antibacterials (e.g. **gatifloxacin**, **moxifloxacin**), **mefloquine**, and some antihistamines [presumably **terfenadine** and **astemizole**].[1,2]

(f) Food

Giving paliperidone with a high fat/high caloric meal increased its maximum levels and AUC by 50 to 60%, when compared with the fasting

state.[1] The UK manufacturer says that paliperidone should normally be consistently taken on an empty stomach, or with breakfast,[1] whereas the US manufacturer says that paliperidone may be taken without regard to food.[2]

(g) Trimethoprim

A randomised study in 30 healthy subjects who were given a single 6-mg dose of paliperidone alone, and after a 5-day course of trimethoprim 200 mg twice daily, found that trimethoprim did not affect the pharmacokinetics of paliperidone.[3]

(h) Valproate

Paliperidone does not appear to affect valproate levels. However, extended-release valproate semisodium (divalproex sodium) 500 mg twice daily increased the AUC and maximum levels of a 12 mg dose of paliperidone by 50%. The US manufacturer advises considering a dose reduction of paliperidone if both drugs are given.[2]

Perospirone + Miscellaneous

Perospirone levels are reduced by carbamazepine, and increased by itraconazole, possibly ketoconazole, and some macrolides.

Clinical evidence, mechanism, importance and management

(a) Carbamazepine

Carbamazepine reduced the plasma levels of a single 8-mg dose of perospirone to below the detection limit.[1] This is likely to be as a result of carbamazepine-induced induction of perospirone metabolism by CYP3A4.

(b) Itraconazole or Ketoconazole

Giving itraconazole 200 mg daily for 5 days, with a single 8-mg dose of perospirone on day 6 resulted in a 6-fold increase in perospirone maximum plasma levels. A similar increase in the AUC and the half-life of perospirone was also seen.[2] An *in vitro* study found that the metabolism of perospirone was markedly reduced by ketoconazole and it was estimated that *in vivo* perospirone clearance could be reduced by 64 to 90%.[3] As itraconazole and ketoconazole are potent inhibitors of CYP3A4, increases in levels of perospirone are likely due to inhibition of its metabolism. The authors of the *in vitro* study suggest that concurrent use of other inhibitors of CYP3A4, such as some **macrolides** may also increase levels of perospirone.[3]

Phenothiazines + Antacids

Antacids containing aluminium/magnesium hydroxide or magnesium trisilicate can reduce the serum levels of chlorpromazine. *In vitro* studies suggest that this interaction may possibly also occur with other antacids and phenothiazines.

Clinical evidence

A study in 10 patients taking **chlorpromazine** 600 mg to 1.2 g daily found that 30 mL of *Aludrox* (**aluminium**/**magnesium hydroxide gel**) reduced the urinary excretion of **chlorpromazine** by 10 to 45%.[1]

A study was prompted by the observation of one psychiatric patient, taking **chlorpromazine** who relapsed within 3 days of starting to take an unnamed antacid. When 6 patients were given 30 mL of *Gelusil* (**aluminium hydroxide** with **magnesium trisilicate**) with **chlorpromazine** suspension, the serum **chlorpromazine** levels measured 2 hours later were reduced by about 20% (from 168 to 132 nanograms/mL).[2] *In vitro* studies have also found that other phenothiazines (**trifluoperazine**, **fluphenazine**, **perphenazine**, **thioridazine**) are adsorbed to a considerable extent onto a number of antacids (**magnesium trisilicate**, **bismuth subnitrate**, **aluminium hydroxide** with **magnesium carbonate**) but there do not appear to be any clinical studies of the possible clinical effects of these interactions.[3]

Mechanism

Chlorpromazine and other phenothiazines become adsorbed onto these antacids,[2,4] which would seem to account for the reduced bioavailability.

Importance and management

Information regarding an interaction between antacids and phenothiazines seems to be limited to the reports cited. Reductions of up to 45% in serum antipsychotic levels would be expected to be clinically important, but so far only one case describing reduced efficacy seems to have been reported.[2] Separating the doses as much as possible (1 to 2 hours) to avoid admixture in the gut should minimise any effects. In the case of chlorpromazine an alternative would be to use calcium carbonate-glycine or magnesium hydroxide gel, which seem to affect its gastrointestinal absorption to a lesser extent.[4] Other phenothiazines and antacids are known to interact *in vitro*,[3] but the clinical importance of these interactions awaits further study.

Phenothiazines + Barbiturates

The levels of chlorpromazine, and possibly thioridazine, are decreased by phenobarbital. Phenothiazines also appear to reduce barbiturate levels. However, the clinical importance of these reductions is uncertain. Pentobarbital, promethazine and hyoscine in combination are said to increase the incidence of perioperative agitation.

Clinical evidence

(a) Phenothiazine levels reduced

A study in 12 patients with schizophrenia taking **chlorpromazine** 100 mg three times daily found that **phenobarbital** 50 mg three times daily reduced **chlorpromazine** plasma levels by 25 to 30%, which was accompanied by changes in certain physiological measurements, which clearly reflected a reduced response to chlorpromazine..[1]

In another study in 7 patients, the plasma levels of **thioridazine** were reduced by **phenobarbital**, but the clinical effects of this were uncertain.[2] However, another study found that **phenobarbital** caused no changes in serum **thioridazine** levels, but the levels of its active metabolite (mesoridazine) were reduced.[3]

(b) Phenobarbital levels reduced

A study in patients with epilepsy found that their serum phenobarbital levels fell by 29% when they were given phenothiazines, which included **chlorpromazine**, **thioridazine** or **mesoridazine**, and increased when the phenothiazine was withdrawn.[4] This study confirms another, in which **thioridazine** 100 to 200 mg daily was found to reduce serum phenobarbital levels by about 25%.[5]

(c) Pentobarbital

There is some limited evidence that the concurrent use of pentobarbital, **promethazine** and hyoscine increases the incidence of pre-operative, peri-operative and postoperative agitation, and it has been suggested that this triple combination should be avoided.[6]

Mechanism

Uncertain. The barbiturates are potent liver enzyme inducers, and so it is presumed that they increase the metabolism of the phenothiazines by the liver.

Importance and management

These interactions appear to be established, but the documentation is limited. Their importance is uncertain, but be alert for evidence of reductions in response to both drugs if a phenothiazine and a barbiturate are given, and to increased responses if one of the drugs is withdrawn. The only combinations implicated are phenobarbital with chlorpromazine, mesoridazine, and thioridazine, but it seems possible that other phenothiazines and barbiturates will behave similarly.

Phenothiazines + Cannabis or Tobacco

Smokers of tobacco may possibly need larger doses of chlorpromazine, fluphenazine, or thioridazine than non-smokers. A similar effect may occur with chlorpromazine in cannabis smokers.

Clinical evidence

(a) Chlorpromazine

A comparative study found that the frequency of drowsiness in 403 patients taking chlorpromazine was 16% in non-smokers, 11% in light smokers, and 3% in heavy smokers (more than 20 cigarettes daily).[1] Another report describes a patient taking chlorpromazine who experienced increased sedation and dizziness and higher plasma chlorpromazine levels when he gave up smoking.[2] A study in 31 patients found that the clearance of chlorpromazine was increased by 38% by tobacco smoking, by 50% by cannabis smoking, and by 107% when both tobacco and cannabis were smoked.[3]

(b) Fluphenazine

A retrospective study in 40 psychiatric inpatients found that the plasma fluphenazine levels of non-smokers were more than double those of smokers (1.83 nanograms/mL compared with 0.89 nanograms/mL) when they were given oral fluphenazine hydrochloride. The clearance of both oral and intramuscular fluphenazine was 1.67-fold and 2.33-fold greater, respectively, in the smokers than in the non-smokers.[4] No behavioural differences were seen.[4]

(c) Thioridazine

A study in 76 patients taking thioridazine found that the dose-corrected steady-state plasma levels of thioridazine were significantly lower in smokers than in non-smokers (4 nanomol/L per mg compared with 7.4 nanomol/L per mg, respectively). Levels of the thioridazine metabolites, mesoridazine and sulforidazine, were also lower in smokers.[5]

Mechanism

Not established. The probable reason is that some of the components of tobacco smoke act as enzyme inducers, which increase the rate at which the liver metabolises these antipsychotics, thereby reducing their serum levels and clinical effects.

Importance and management

Established interactions but of uncertain clinical importance. Be alert for the need to increase the doses of these antipsychotics in patients who smoke, and reduce the doses if smoking is stopped.

Phenothiazines + Carbamazepine or Oxcarbazepine

Fluphenazine levels are reduced by carbamazepine. The plasma levels of chlorpromazine do not appear to be affected by oxcarbazepine. The concurrent use of thioridazine and carbamazepine does not appear to affect the pharmacokinetics of either drug. Case reports describe Stevens-Johnson syndrome and neuroleptic malignant syndrome in patients taking phenothiazines with carbamazepine.

Clinical evidence

(a) Chlorpromazine

Oxcarbazepine was substituted for carbamazepine in 4 difficult to treat schizophrenic patients. All patients were also taking chlorpromazine, and in 3 cases other antipsychotic medication (lithium, zuclopenthixol or clozapine). After 3 weeks of taking the oxcarbazepine all 4 patients had rises in their chlorpromazine levels, of 28%, 63%, 76%, and 90%, respectively. In one case this rise was associated with increased extrapyramidal adverse effects.[1]

A case report describes a patient taking amoxapine and chlorpromazine 350 mg daily, who developed ataxia, nausea and agitation when carbamazepine, titrated to 900 mg daily, was started. The adverse effects were attributed to high levels of the carbamazepine metabolite carbamazepine-10,11-epoxide.[2] See also, *Trifluoperazine*, below.

(b) Fluphenazine

A patient receiving intramuscular fluphenazine decanoate 37.5 mg weekly had a rise in his serum fluphenazine levels from 0.6 nanograms/mL to 1.17 nanograms/mL 6 weeks after stopping carbamazepine 800 mg daily. A moderate improvement in his schizophrenic condition occurred.[3] See also, *Trifluoperazine*, below.

(c) Levomepromazine

A 54-year old man living in a psychiatric hospital, who had been taking haloperidol, levomepromazine, **sultopride**, and metixene long-term was prescribed carbamazepine 400 mg daily for impulsive behaviour. The following day he became unstable on his feet, and after 3 days could no longer walk by himself. He had a fever of 40°C, muscle rigidity, diaphoresis, and serum creatine phosphokinase was elevated to 923 units/L. He was diagnosed as having neuroleptic malignant syndrome, and recovered after body cooling and administration of fluids, with symptoms resolving over 12 days.[4]

(d) Thioridazine

Thioridazine 100 to 200 mg daily was found to have no effect on the steady-state levels of carbamazepine or carbamazepine-10,11-epoxide in 8 epileptic patients.[5] Carbamazepine had no significant effect on thioridazine plasma levels in 6 patients.[6]

(e) Trifluoperazine

Two patients taking **trifluoperazine** (with fluphenazine and chlorpromazine in one case) developed Stevens-Johnson syndrome within 8 to 14 days of starting to take carbamazepine. Both had erythema multiforme skin lesions and at least two mucous membranes were affected. After treatment, they restarted all their previous drugs, except carbamazepine, without problems.[7]

Mechanism

Carbamazepine is a recognised enzyme inducer, therefore it seems highly likely that the reduced plasma chlorpromazine levels occur because its metabolism by the liver is markedly increased by carbamazepine.

In the case describing neuroleptic malignant syndrome it was suggested that carbamazepine may have reduced levels of the antimuscarinic

(anticholinergic) antipsychotics (levomepromazine and sultopride), resulting in cholinergic rebound, and inducing NMS.[4]

Importance and management

Evidence appears to be limited to the reports cited, many of which suggest that no interaction normally occurs. Nevertheless, it would seem prudent to be alert for a diminished response to treatment with a phenothiazine if carbamazepine is added: it may be necessary to increase the dose of the phenothiazine. Oxcarbazepine does not appear to interact, probably because it is not an enzyme inducer.

The isolated case of high carbamazepine-10,11-epoxide levels in the patient taking chlorpromazine appears to be the only reported case of an interaction. Its general significance is therefore unknown. Similarly, the general relevance of the case of neuroleptic malignant syndrome is unknown.

Stevens-Johnson syndrome with carbamazepine alone is rare, and the risk appears to be mostly confined to the first 8 weeks of treatment.[8] It may be more common in patients being treated for conditions other than epilepsy.[9] It is not possible to say whether the concurrent use of antipsychotics increases the risk of its development, but until more is known it would be prudent to monitor the outcome, particularly during the first 2 weeks of combined use.

Phenothiazines + SSRIs

A number of case reports describe extrapyramidal adverse effects following the use of fluoxetine or paroxetine with phenothiazines. Thioridazine levels are increased by fluvoxamine, and predicted to be increased by fluoxetine, or paroxetine, which increases the risk of QT interval prolongation.

Clinical evidence

(a) Chlorpromazine

A study in patients with schizophrenia found that over a 12-week period the serum levels of chlorpromazine were not significantly altered by **citalopram** 40 mg daily.[1]

(b) Cyamemazine

A study in patients taking cyamemazine found that **fluvoxamine** 150 mg daily had no effect on cyamemazine serum levels, but the authors of the report also say that no firm conclusions should be drawn from this finding because the number of patients was too small.[2]

(c) Fluphenazine

A severe dystonic reaction (painful jaw tightness and throat 'closing up') occurred in a man taking **fluoxetine** 40 mg daily when he also took fluphenazine 2.5 mg on two consecutive nights.[3]

(d) Levomepromazine

A study in patients taking levomepromazine found that **fluvoxamine** 150 mg daily did not affect its serum levels, but the authors of the report also say that no firm conclusions should be drawn from this finding because the number of patients was too small.[2] A further study in 15 patients also found that levomepromazine 5 to 25 mg daily had no significant effect on the pharmacokinetics of **fluvoxamine**. Additionally, patients in this study found that the levomepromazine counteracted the insomnia caused by **fluvoxamine**.[4]

A study in three groups of 8 healthy subjects taking **citalopram** 40 mg daily for 10 days found that a single 50-mg oral dose of levomepromazine increased the initial steady-state levels of desmethylcitalopram, the primary metabolite of **citalopram** by 10 to 20%, which was not considered to be clinically significant.[5]

A study in patients with schizophrenia found that over a 12-week period the serum levels of levomepromazine were not significantly altered by **citalopram** 40 mg daily.[1]

(e) Metopimazine

A French regional pharmacovigilance centre reported 37 cases of extrapyramidal adverse effects linked to the concurrent use of an SSRI and a neuroleptic. In 2 cases metopimazine was given.[6]

(f) Pericyazine

A study describes a patient who developed extrapyramidal symptoms when given pericyazine and **fluoxetine**.[7]

(g) Perphenazine

1. Citalopram. A study in patients with schizophrenia found that, over a 12-week period, the serum levels of perphenazine were not significantly altered by citalopram 40 mg daily.[1]

2. Fluoxetine. The combination of perphenazine and fluoxetine was found to be effective in the treatment of psychotic depression in 30 patients, and the adverse effects (which included dry mouth, blurred vision, constipation, tremor or rigidity, orthostasis and hypotension) were thought to be easier to tolerate than an antipsychotic with a tricyclic antidepressant.[8] However, one woman developed marked extrapyramidal symptoms within 2 weeks of starting perphenazine 4 mg twice daily and fluoxetine 20 mg daily.[9]

3. Paroxetine. The effects of a single 100-microgram/kg oral dose of perphenazine on the performance of psychomotor tests were assessed after 4, 6, 8 and 10 hours in 5 subjects. The tests were then repeated after the subjects also took paroxetine 20 mg daily for 10 days. The scores for these tests were worsened by the perphenazine, when compared with a placebo, and further worsened by the presence of the paroxetine. In addition to over-sedation and impairment of the performance of psychomotor tests and memory, 2 of the subjects developed akathisia 10 hours after taking both drugs. The AUC of the perphenazine was increased sevenfold and its maximum plasma levels were increased sixfold.[10]

(h) Thioridazine

A study in patients with schizophrenia found that, over a 12-week period, the serum levels of thioridazine were not significantly altered by **citalopram** 40 mg daily.[1]

A study in 10 patients with schizophrenia found that when **fluvoxamine** 50 mg daily was added to established treatment with thioridazine 30 to 200 mg daily, thioridazine plasma levels were increased by 225%. There were no reported changes in either clinical status or adverse effects.[11]

(i) Trifluoperazine

A New Zealand study describes a patient who developed extrapyramidal symptoms when given trifluoperazine and **fluoxetine**.[7]

Mechanism

Fluoxetine and paroxetine can inhibit the metabolism of some phenothiazines by the cytochrome P450 isoenzyme CYP2D6.[10] Raised phenothiazine levels may increase the risk of phenothiazine adverse effects, such as movement disorders. However, movement disorders may just be a result of the additive adverse effects of antipsychotics and SSRIs. Furthermore, fluoxetine alone has been shown to occasionally cause movement disorders.[7,12]

Importance and management

On the whole significant interactions between the phenothiazines and SSRIs appear rare (although see thioridazine, below). The combination can be useful and so the isolated cases of extrapyramidal adverse effects should not prevent concurrent use. However, if extrapyramidal effects become troublesome bear this interaction in mind as a possible cause. The rise in **perphenazine** levels caused by paroxetine seems to result in a greater number of more serious adverse effects and so consideration should be given to reducing the dose of perphenazine if paroxetine is start-

ed. Citalopram may be a suitable alternative as it does not appear to affect perphenazine levels.

Note that, the US manufacturers of fluoxetine,[13] and paroxetine,[14] contraindicate the concurrent use of **thioridazine** as they suggest that its metabolism (by CYP2D6) may be inhibited by these SSRIs, leading to raised thioridazine levels and the risk of QT prolongation. The use of thioridazine is also contraindicated for 5 weeks after fluoxetine has been stopped.[13] The manufacturers of fluvoxamine also contraindicate concurrent use;[15] the study cited above found a large increase in thioridazine levels so this seems prudent. Smaller increases would be expected with other SSRIs, and it has been suggested that the dose of thioridazine may need to be adjusted [reduced] when it is given with **escitalopram**.[16]

SSRI antidepressants may lower the seizure threshold, and therefore concurrent use with other drugs, which can also lower the seizure threshold, such as phenothiazines, should be undertaken with caution.

Phenothiazines + Trazodone

Undesirable hypotension occurred in two patients taking chlorpromazine or trifluoperazine with trazodone. Thioridazine causes a moderate rise in trazodone plasma levels. A fatal case of jaundice and hepatic encephalopathy has been reported with the use of trifluoperazine, thioridazine and trazodone.

Clinical evidence, mechanism, importance and management

A depressed patient taking **chlorpromazine** began to complain of dizziness and unstable gait within 2 weeks of starting to take trazodone 100 mg one to three times daily. His blood pressure had fallen to between 92/58 and 126/72 mmHg. Within 2 days of stopping the trazodone his blood pressure had restabilised.[1]

A patient taking **trifluoperazine** was given trazodone 100 mg daily and within 2 days she complained of dizziness and was found to have a blood pressure of 86/52 mmHg. Within one day of stopping the trazodone her blood pressure was back to 100/65 mmHg.[1] It would seem that the hypotensive adverse effects of the two drugs can be additive, although an interaction was not confirmed as the trazodone was not taken alone.

A study, undertaken to confirm the involvement of the cytochrome P450 isoenzyme CYP2D6 in the metabolism of trazodone, found that when 11 patients with depression were given trazodone 150 to 300 mg at bedtime for 18 weeks, and then with **thioridazine** 20 mg twice daily for one week, the plasma levels of the trazodone and its active metabolite, *m*-chlorophenylpiperazine, rose by 36% and 54%, respectively.[2] No adverse reactions were described. However, a case of fatal hepatic necrosis with cholestasis has been attributed to the concurrent use of trazodone and phenothiazines. A 72-year-old woman taking **trifluoperazine**, trazodone and lithium carbonate developed an elevated alanine aminotransferase level. **Trifluoperazine** was replaced with **thioridazine**, but 9 weeks later she became jaundiced and developed hepatic encephalopathy, and died 6 weeks after the onset of jaundice. The authors consider that the combination of the phenothiazines and trazodone were the cause of her hepatic necrosis: both phenothiazines and trazodone have been reported to individually cause hepatic adverse effects.[3]

Evidence for an interaction between trazodone and the phenothiazines appears to be limited. The isolated case of hepatic adverse effects is of unknown general importance, but it serves as a reminder to consider the additive adverse effects of drugs when prescribing them in combination. The reports of hypotensive effects are also isolated. It would seem prudent to warn patients of the possibility of additive hypotensive effects (e.g. dizziness, postural hypotension) and advise them to seek medical advice if this becomes troublesome.

Phenothiazines + Tricyclic antidepressants

The concurrent use of tricyclic antidepressants and phenothiazines is common, but the tricyclic levels are increased by many of the phenothiazines, and the levels of some phenothiazines are also increased by the tricyclics. It has been suggested that concurrent use might contribute to an increased incidence of tardive dyskinesia. Nevertheless, fixed-dose combined preparations are available. Tricyclics have also been shown to reverse the therapeutic effects of chlorpromazine. Occasionally the concurrent use of a tricyclic and a phenothiazine can lead to adverse effects such as faecal impaction.

Clinical evidence

(a) Effect of phenothiazines on tricyclic antidepressants

An extended study of 4 patients given intramuscular **fluphenazine decanoate** 12.5 mg weekly, with benzatropine 2 mg three times daily and **imipramine** 300 mg daily, found that the mean combined plasma concentrations of **imipramine** and its metabolite, desipramine, were 850 nanograms/mL. This appeared high, when compared with 60 other patients who were taking **imipramine** 225 mg daily and had levels of 180 nanograms/mL.[1]

A comparative study of 99 patients taking **amitriptyline** or **nortriptyline** alone, and 60 other patients also taking **perphenazine** 10 mg daily, found that although the tricyclic antidepressant dosages were the same, the plasma tricyclic antidepressant levels were up to 70% higher in those also taking **perphenazine**.[2]

Other studies have described increased tricyclic antidepressant levels with phenothiazines. There is currently evidence for this interaction between:

- **imipramine**,[3-5] and **chlorpromazine**
- **nortriptyline**,[6] and **levomepromazine**
- **amitriptyline**,[7] **imipramine**,[5,8,9] **desipramine**[10] or **nortriptyline**,[6,11-13] and **perphenazine**
- **desipramine**,[14] **imipramine**[15] or **nortriptyline**,[6] and **thioridazine**
- **nortriptyline**[16] and **thioridazine** (with paroxetine).

However, other studies have found no interaction between:

- **amitriptyline**[6,11,17] or **nortriptyline**,[18] and **perphenazine**
- **amitriptyline**[6] and **thioridazine**
- **amitriptyline**[6] and **levomepromazine**.

It should be noted that in the case of **amitriptyline**, although the levels were not affected, levels of nortriptyline, its metabolite, were raised.[6]

(b) Effect of tricyclic antidepressants on phenothiazines

In a controlled study in 8 patients with schizophrenia taking **butaperazine** 20 mg daily, the 6 patients taking **desipramine** 150 mg or more daily had a rise in serum **butaperazine** levels of between 50 and 300%. The other 2 patients, taking **desipramine** 100 mg or less, had no changes in **butaperazine** levels.[19] Other studies have found a rise in phenothiazine levels when tricyclic antidepressants are added. So far, interactions with **chlo-**

rpromazine and **amitriptyline**,[20] **imipramine**[20] or **nortriptyline**[21] have been documented. One study in 23 patients found transitory increases in the levels of **chlorpromazine**, **mesoridazine**, **methotrimeprazine**, **perphenazine**, **thioproperazine**, **thioridazine**, and **trifluoperazine** when **amitriptyline** was also given for 12 weeks.[22]

One study in 7 patients with chronic schizophrenia also reported that giving **nortriptyline** 50 mg three times daily to patients taking **chlorpromazine** 100 mg three times daily resulted in profound worsening of the clinical state, with marked increases in agitation and tension, despite the fact that the **chlorpromazine** levels were actually raised. The **nortriptyline** was withdrawn.[21] A temporary reversion to a disruptive behaviour pattern has been seen in other patients taking **chlorpromazine** when **amitriptyline** was given.[23] One patient experienced a severe catatonic reaction that was attributed to the use of **thioridazine** and **amitriptyline**,[24] and the case of a woman who became anxious with widely staring eyes, a persistent jerking of her head and at times the inability to speak was thought to be due to the use of **imipramine** and **chlorpromazine**.[25] Ventricular tachycardia has also been reported in a 38-year-old woman taking **desipramine** and **thioridazine**, which responded to treatment with lidocaine.[26]

(c) Other effects

The tricyclic antidepressants have antimuscarinic side effects, which can, in conjunction with the use of an antipsychotic, lead to life-threatening interactions. These are discussed further in the monograph 'Antipsychotics + Antimuscarinics', p.833.

Mechanism

The rise in the serum levels of both drugs is thought to be due to a mutual inhibition of the liver enzymes concerned with the metabolism of both drugs, which results in their accumulation.[3,4,8,19,21]

Importance and management

Established interactions, but the advantages and disadvantages of concurrent use are the subject of debate. These two groups of drugs are widely used together in the treatment of schizophrenic patients who show depression, and for mixed anxiety and depression. A number of fixed-dose combinations have been marketed (e.g. amitriptyline with perphenazine, and nortriptyline with fluphenazine). However, the safety of using both drugs together has been questioned.

One of the problems of phenothiazine use is the development of tardive dyskinesias, and some evidence suggests that the higher the dosage, the greater the incidence.[27] The symptoms can be transiently masked by increasing the dosage,[28] and so it has been suggested that the presence of a tricyclic antidepressant might not only be a factor causing tardive dyskinesia to develop, but might also mask the condition.[19,29] It has been recommended that the addition of full antidepressant doses of nortriptyline to average antipsychotic doses of chlorpromazine should be avoided because the therapeutic actions of the chlorpromazine may be reversed.[21] See also Antagonism of antipsychotic effects, under 'Antipsychotics + Antimuscarinics', p.833.

Attention has also been drawn to excessive weight gain associated with several months use of amitriptyline with thioridazine for the treatment of chronic pain,[30] but note that excessive weight gain is a recognised adverse effect of antipsychotics alone.

For reports of paralytic ileus with faecal impaction in patients taking chlorpromazine and amitriptyline, imipramine, or nortriptyline, thioridazine and imipramine, and levomepromazine with imipramine (and benzatropine); for reports of severe constipation in a patients given thioridazine and doxepin (with biperiden); and for reports of atropine-like psychoses in patients taking chlorpromazine and doxepin (with benzatropine) see, 'Antipsychotics + Antimuscarinics', p.833.

The tricyclic antidepressants and many antipsychotics increase the QT interval, see 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290, for further information.

Phenothiazines; Chlorpromazine + Antimalarials

Chloroquine, amodiaquine and *Fansidar* (sulfadoxine with pyrimethamine) can markedly increase serum chlorpromazine levels.

Clinical evidence

A total of 15 patients with schizophrenia taking **chlorpromazine** 400 or 500 mg daily for at least 2 weeks were given single doses of either **chloroquine sulfate** 400 mg, **amodiaquine hydrochloride** 600 mg or three tablets of *Fansidar* (**pyrimethamine** 25 mg with **sulfadoxine** 500 mg) one hour before the **chlorpromazine**. Serum **chlorpromazine** levels 3 hours later were found to be raised about threefold by the **chloroquine** and **amodiaquine**, and almost fourfold by the *Fansidar*. The plasma level of 7-hydroxychlorpromazine, one of the major metabolites of **chlorpromazine**, was also elevated, but not those of the other metabolite, chlorpromazine sulfoxide. The serum **chlorpromazine** levels of the patients given **chloroquine** or *Fansidar* were, to some extent, still elevated 4 days later. There was subjective evidence that the patients were more heavily sedated when given the antimalarials.[1]

Mechanism

Not understood. Both chloroquine and *Fansidar* have relatively long half-lives compared with amodiaquine, which may explain the persistence of their effects.

Importance and management

Direct information about this interaction seems to be limited to this study. Its clinical importance is uncertain but it seems possible that these antimalarials could cause chlorpromazine toxicity. Monitor the effects of concur-

rent use closely and anticipate the need to reduce the chlorpromazine dosage. More study is needed.

Phenothiazines; Chlorpromazine + Cimetidine

One study found that chlorpromazine plasma levels are reduced by cimetidine, whereas a case report suggests that cimetidine may increase chlorpromazine levels.

Clinical evidence, mechanism, importance and management

A study in 8 patients taking chlorpromazine 75 to 450 mg daily found that cimetidine 1 g daily in divided doses for one week decreased their steady-state chlorpromazine plasma levels by one-third, from 37 to 24 micrograms/mL. A two-thirds reduction was noted in one patient.[1] The reasons for this effect are not understood but a decrease in chlorpromazine absorption from the gut has been suggested.[1]

In contrast, another report describes 2 patients with schizophrenia taking chlorpromazine 100 mg four times daily who became excessively sedated when they were given cimetidine 400 mg twice daily. The sedation disappeared when the chlorpromazine dosage was halved. When the cimetidine was later withdrawn it was found necessary to give the original chlorpromazine dosage.[2] Chlorpromazine levels were not measured.

There is no simple explanation for these discordant reports, but they emphasise the need to monitor the concurrent use of chlorpromazine and cimetidine. More study is needed. There seems to be no information about other phenothiazines.

2. Byrne A, O'Shea B. Adverse interaction between cimetidine and chlorpromazine in two cases of chronic schizophrenia. *Br J Psychiatry* (1989) 155, 413–15.

Phenothiazines; Chlorpromazine + Combined hormonal contraceptives

A case report describes a marked rise in serum chlorpromazine levels in a woman taking an oral combined hormonal contraceptive.

Clinical evidence, mechanism, importance and management

A case report describes a woman who had been taking chlorpromazine 100 mg three times daily for one week without problems when an oral combined hormonal contraceptive (**ethinylestradiol/norgestrel**) was started. Four days later she developed severe dyskinesias and tremor, and her chlorpromazine levels were found to have increased by about sixfold.[1] This case was briefly mentioned in an earlier report by the same authors.[2]

The reasons for the raised chlorpromazine levels are not understood, but increased absorption or reduced liver metabolism of the phenothiazine are suggested.[1,3]

There seem to be no other reports of adverse reactions between phenothiazines and contraceptives, and the available data are insufficient to justify any general precautions.

Phenothiazines; Chlorpromazine + Tetrabenazine

An isolated report describes severe Parkinson-like symptoms when a woman with Huntington's chorea taking tetrabenazine was given chlorpromazine.

Clinical evidence, mechanism, importance and management

A woman with Huntington's chorea, successfully treated with tetrabenazine 100 mg daily for 9 years, became motionless, rigid, mute and only able to respond by blinking her eyes within one day of being given two intramuscular injections of chlorpromazine 25 mg. This was diagnosed as severe drug-induced parkinsonism, which rapidly responded to the withdrawal of both drugs and treatment with benzatropine given intramuscularly and orally. She had previously tolerated chlorpromazine well.[1] The reason for this reaction is not understood, and its general relevance is unclear, but probably small.

1. Moss JH, Stewart DE. Iatrogenic parkinsonism in Huntington's chorea. *Can J Psychiatry* (1986) 31, 865–6.

Phenothiazines; Fluphenazine + Ascorbic acid (Vitamin C)

A single case report describes a reduction in serum fluphenazine levels and signs of a reduction in its effects when a patient was also given ascorbic acid.

Clinical evidence, mechanism, importance and management

A man with a history of manic behaviour, taking fluphenazine 15 mg daily, had a 25% reduction in his plasma fluphenazine levels, from 0.93 nanograms/mL to 0.705 nanograms/mL, over a 13-day period while taking ascorbic acid 500 mg twice daily. This was accompanied by a deterioration in his behaviour.[1] The reason for this effect is not understood. There seem to be no other reports of this interaction with fluphenazine or any other phenothiazine so that this interaction would not appear to be of general importance.

1. Dysken MW, Cumming RJ, Channon RA, Davis JM. Drug interaction between ascorbic acid and fluphenazine. *JAMA* (1979) 241, 2008.

Phenothiazines; Fluphenazine + Spiramycin

Acute dystonia occurred when a man taking fluphenazine was also given spiramycin.

Clinical evidence, mechanism, importance and management

A man with a schizoaffective disorder taking lorazepam, orphenadrine, fluvoxamine and fluphenazine decanoate 12.5 mg every 2 weeks, developed acute and painful dystonia of the trunk, neck, right arm and leg about one week after his last fluphenazine injection and on the fourth day of taking spiramycin 6 million units daily for gingivitis. The problem resolved when he was given biperiden.[1] The reasons for this adverse reaction are not understood, nor is it entirely clear whether this was an interaction between fluphenazine and spiramycin, although the author suggested that a causal link existed. This seems to be the only report of an alleged interaction between fluphenazine and a macrolide antibacterial and it is therefore of little or no general importance.

1. Benazzi F. Spiramycin-associated acute dystonia during neuroleptic treatment. *Can J Psychiatry* (1997) 42, 665–6.

Phenothiazines; Perphenazine + Disulfiram

A single case report describes a man taking perphenazine whose psychotic symptoms re-emerged when he started to take disulfiram.

Clinical evidence, mechanism, importance and management

A man taking perphenazine 8 mg twice daily developed marked psychosis soon after starting to take disulfiram 100 mg daily.[1] His serum perphenazine levels had fallen from a range of 2 to 3 nanomol/L to less than 1 nanomol/L. Doubling the dosage of perphenazine had little effect, and no substantial clinical improvement or rise in serum levels occurred until he was given intramuscular perphenazine enantate 50 mg weekly, at which point the levels rose to about 4 nanomol/L. The results of clinical biochemical tests suggested that the disulfiram was acting as an enzyme

inducer, resulting in increased metabolism and clearance of the perphenazine. However, disulfiram normally acts as an enzyme *inhibitor*. Too little is known to assess the general importance of this interaction, and there seems to be no information about an interaction with other phenothiazines.

1. Hansen LB, Larsen N-E. Metabolic interaction between perphenazine and disulfiram. *Lancet* (1982) ii, 1472.

Phenothiazines; Promazine + Attapulgite-pectin

An attapulgite-pectin antidiarrhoeal preparation caused a small reduction in the absorption of promazine in one subject, but in a study, the overall excretion of promazine was only slightly altered.

Clinical evidence, mechanism, importance and management

A study in one healthy subject found that attapulgite-pectin reduced the absorption of a single 50-mg dose of promazine by about 25%, possibly due to adsorption of the phenothiazine onto the attapulgite.[1] Another study found that the presence of activated attapulgite reduced the initial rate of urinary excretion of a single 50-mg dose of promazine, but caused only a small decrease in the overall extent of excretion.[2]

The clinical importance of this interaction and whether other phenothiazines behave similarly does not appear to have been studied; however, the magnitude of the interaction appears small, and seems unlikely to be of clinical relevance. If a problem does occur, separating administration as much as possible (2 hours or more) to avoid admixture in the gut has been shown to minimise the effects of this type of interaction with other drugs.

2. Sorby DL. Effects of adsorbents on drug absorption I. Modification of promazine absorption by activated attapulgite and activated charcoal. *J Pharm Sci* (1965) 54, 677–83.

Phenothiazines; Promethazine + Midodrine

An increased severity of akathisia was seen in one study when promethazine and midodrine were given together.

Clinical evidence, mechanism, importance and management

A placebo-controlled study in 9 healthy subjects who received a single 10-mg oral dose of midodrine followed one hour later by a single 25-mg intravenous dose of promethazine, found that the akathisia which occurred in 6 subjects taking both midodrine and promethazine was significantly more severe than the symptoms experienced in 4 subjects when they received promethazine alone.

It was suggested that as both drugs are metabolised by the cytochrome P450 isoenzyme CYP2D6, competition for metabolism by this isoenzyme reduced the clearance of promethazine.[1]

This appears to be an isolated report, and its general relevance is unclear. However, if patients taking both drugs develop akathisia it may be prudent to suspect an interaction as a possible cause.

1. Platts SH, Shi S-J, Meck JV. Akathisia with combined use of midodrine and promethazine. *JAMA* (2006) 295, 2000–1.

Phenothiazines; Thioridazine + Melatonin

The concurrent use of thioridazine and melatonin may lead to increased CNS effects.

Clinical evidence, mechanism, importance and management

In a single-dose controlled study, there was no pharmacokinetic interaction between thioridazine 50 mg and melatonin 2 mg. However, there was a possible pharmacodynamic interaction, with increased feelings of 'muzzy-headedness' when compared with thioridazine alone.[1,2] Patients should be warned of a possible additive effect.

Phenothiazines; Thioridazine + Naltrexone

Extreme lethargy occurred in two patients taking thioridazine when they were given naltrexone.

Clinical evidence, mechanism, importance and management

Two schizophrenic patients taking thioridazine 50 to 200 mg three times daily for at least one year took part in a pilot project to assess the efficacy of naltrexone for the treatment of tardive dyskinesias. Both patients tolerated the first challenge dose of intravenous naltrexone 800 micrograms without problems, but experienced extreme lethargy and slept almost continuously after the second naltrexone dose of 50 to 100 mg orally. The severe lethargy resolved within 12 hours of stopping the naltrexone.[1] The reasons for this reaction are not understood. Information seems to be limited to this report and the general importance of this interaction is unknown. Note that a case report has described excessive sleepiness and lethargy in a 58-year-old man who took a single 100-mg dose of naltrexone alone,[2] so an interaction is by no means established.

2. Malcolm R, Gabel T, Morton A. Idiosyncratic reaction to naltrexone augmented by thioridazine. *Am J Psychiatry* (1988) 145, 773–4.

Phenothiazines; Thioridazine + Phenylpropanolamine

A single case report describes fatal ventricular fibrillation, which was attributed to the concurrent use of thioridazine and phenylpropanolamine.

Clinical evidence, mechanism, importance and management

A 27-year-old woman with schizophrenia who was taking thioridazine 100 mg daily and procyclidine 2.5 mg twice daily was found dead in bed 2 hours after taking a single capsule of *Contac C* (phenylpropanolamine 50 mg with chlorphenamine 4 mg). The principal cause of death was attributed to ventricular fibrillation.[1] Just why this happened is not understood but it is suggested that it may have been due to the combined effects of the thioridazine (known to be cardiotoxic and to cause T-wave abnormalities) and the phenylpropanolamine (possibly able to cause ventricular arrhythmias).

The general importance of this alleged interaction is uncertain but the authors of the report suggest that ephedrine-like drugs such as phenylpropanolamine should not be given to patients taking thioridazine or **mesoridazine**.

Phenothiazines; Thioridazine + Ritonavir

Antiretroviral doses of ritonavir (300 mg twice daily or more) may increase plasma levels of thioridazine by inhibition of the cytochrome P450 isoenzyme CYP2D6. Monitoring for thioridazine adverse effects is recommended during concurrent use.[1]

Pimozide + CYP3A4 inhibitors

Inhibition of CYP3A4 results in markedly increased pimozide levels and increases the risk of QT interval prolongation and the development of life-threatening arrhythmias.

Clinical evidence, mechanism, importance and management

The sudden death of a patient taking pimozide and **clarithromycin** prompted a study of a possible interaction between the two drugs. Using

human liver microsomes it was found that pimozide is partly metabolised by the cytochrome P450 isoenzyme CYP3A, and that 2 micromol of **clarithromycin** inhibits this enzyme by at least 80%.[1] The practical consequences of this finding were seen in a later study in 12 healthy subjects, which found that **clarithromycin** 500 mg twice daily for 5 days more than doubled the AUC of a single 6-mg oral dose of pimozide and raised its maximum plasma levels by almost 50%. The QTc interval was prolonged by about 17 milliseconds with pimozide alone and by 24 milliseconds when **clarithromycin** was added.[2] The results were the same in both poor and extensive CYP2D6 metabolisers (see 'Genetic factors', (p.4)). CYP2D6 status was considered as this is the other main metabolic route of pimozide. The authors of this study concluded that **clarithromycin** can therefore increase the cardiotoxicity of pimozide during chronic use, irrespective of the CYP2D6 status of the patient.[2] Pimozide alone has been associated with ventricular arrhythmias, prolongation of the QT interval, T-wave changes and sudden and unexpected death, even in the young with no previous evidence of cardiac disease.[3,4] Due to the severity of this interaction the UK manufacturers contraindicate the use of macrolides with pimozide,[5] whereas the US manufacturers contraindicate pimozide with the named macrolides, **azithromycin**, **clarithromycin**, **dirithromycin**, **erythromycin** and **troleandomycin**.[6] However, note that **azithromycin** and **dirithromycin** do not usually interact with other drugs by inhibiting CYP3A4.

The use of many other inhibitors of the cytochrome P450 isoenzyme CYP3A4 with pimozide is also contraindicated as they are similarly expected to increase the plasma levels of pimozide, which is likely to result in QT prolongation and associated arrhythmias. The manufacturers specifically mention **azole antifungals**, **grapefruit juice**, **nefazodone**, **protease inhibitors**, and **zileuton**.[5,6] Drugs that are known to cause clinically relevant CYP3A4 inhibition are listed in 'Table 1.4', (p.6).

Pimozide + SSRIs

Pimozide levels are expected to rise when used with fluoxetine, paroxetine, or sertraline, which would increase the risk of potentially fatal torsade de pointes arrhythmias. Fluvoxamine is predicted to interact similarly. QT prolongation may occur with the concurrent use of pimozide and citalopram. The use of SSRIs and pimozide has also led to extrapyramidal adverse effects, oculogyric crises and sedation in rare cases.

Clinical evidence

(a) Fluoxetine

A patient taking fluoxetine and pimozide had a worsening of extrapyramidal symptoms, and another patient taking both drugs developed marked sinus bradycardia of 35 to 44 bpm with somnolence.[1] This report was the subject of later discussion on the mechanism of the interaction.[2,3] Another patient also developed extrapyramidal symptoms,[4] while a further patient became stuporous when given both drugs.[5]

(b) Paroxetine

A boy of about 10 years, with various disorders (motor tics, enuresis, attention deficit hyperactivity disorder, Tourettes's disorder, impulsivity, albinism) was treated for a year with pimozide 2 mg twice, and later three times daily.[6] Within 3 days of starting paroxetine 10 mg in the morning, he began to complain of his eyes hurting and his mother noted that about 4 hours after taking the paroxetine his eyes were rolled back in his head but the problem had resolved by the evening. This oculogyric crisis occurred on a further occasion, and so the paroxetine was stopped. There was no other evidence of either extrapyramidal or hyperserotonergic reactions. This case needs to be viewed in its particular context (oculogyric crises are associated with albinism) so that it may not be of general importance.

In a study, paroxetine 60 mg daily, caused a 151% rise in the AUC of a single 2-mg dose of pimozide and a 62% rise in its maximum plasma levels.[7]

(c) Sertraline

In a study in 15 healthy subjects, sertraline 200 mg daily increased the AUC and maximum plasma levels of a single 2-mg dose of pimozide by about 40%. No changes in the QTc interval were seen.[8]

A fatality has been reported with an overdose of moclobemide, sertraline and pimozide, with blood levels suggesting that none of the drugs individually would have been fatal.[9]

Mechanism

The SSRIs can, to varying degrees, inhibit the cytochrome P450 isoenzyme CYP2D6 (and fluvoxamine possibly also inhibits CYP3A4) by which pimozide is metabolised. Concurrent use would therefore be expected to lead to raised pimozide levels.

Importance and management

Evidence of an adverse interaction between the SSRIs and pimozide is limited; however, the interaction is potentially severe as raised pimozide levels can cause torsade de pointes arrhythmias, which can be fatal. The manufacturers of pimozide contraindicate its use with SSRIs, and in the UK they specifically name sertraline, paroxetine, and **citalopram**; which has been seen to cause QT prolongation with pimozide, and its isomer, **escitalopram**.[7] The US manufacturer additionally contraindicates **fluvoxamine**.[10] Neither manufacturer mentions fluoxetine (except with regard to the possibility of additive bradycardia[10]), but as it is known to have greater effects on CYP2D6 than either sertraline or citalopram, it would seem prudent to also consider it as contraindicated.

Quetiapine + Antipsychotics

Haloperidol and risperidone do not appear to affect the pharmacokinetics of quetiapine, whereas thioridazine moderately reduces quetiapine levels. A case report describes a seizure in a patient taking olanzapine and quetiapine.

Clinical evidence, mechanism, importance and management

In 12 patients with schizophrenia or bipolar disorder taking quetiapine 300 mg twice daily, **thioridazine** 200 mg twice daily reduced the steady-state quetiapine AUC and its maximum plasma levels by about 41% and 48%, respectively. It was suggested that the decreased quetiapine levels were due to an increase in its metabolism, although the mechanism for this effect is unclear.[1] These reductions are only moderate, but until more information is available it would seem prudent to monitor concurrent use for efficacy, being alert for the need to raise the quetiapine dose.

Two groups of 12 patients with schizophrenia or bipolar disorder taking quetiapine 300 mg twice daily were also given **haloperidol** 7.5 mg twice daily or **risperidone** 3 mg twice daily for 9 days. These antipsychotics had no significant effect on the pharmacokinetics of quetiapine.[1] Quetiapine dose adjustments are therefore not expected to be necessary if either **haloperidol** or **risperidone** is given. However, a case report describes considerable QT prolongation in a patient who took quetiapine 2 g with **risperidone**. The authors consider this significant as the overdose was small, and because no QT prolongation was seen in toxicity studies of quetiapine when doses as large as 9.6 g were used,[2] although there is a sin-

gle case of a prolonged QTc interval associated with a quetiapine overdose of 9.6 g.[3]. As neither drug is commonly associated with QT prolongation, the general relevance of this case report is unknown.

Another case report describes a seizure lasting 30 to 60 seconds in a 27-year-old woman, which occurred one day after quetiapine 100 mg daily was added to treatment with **olanzapine** 15 mg daily and sertraline 100 mg daily.[4] The seizure was attributed to an interaction between quetiapine and **olanzapine**, although it seems possible that the sertraline also may have contributed. This case highlights the importance of considering seizure potential when prescribing multiple antipsychotic medications.

Quetiapine + CYP3A4 inducers

The plasma levels of quetiapine are reduced by carbamazepine, and the clearance of quetiapine is increased by phenytoin. The barbiturates and rifampicin (rifampin) are predicted to interact similarly. Case reports suggest that quetiapine may increase carbamazepine-10,11-epoxide levels.

Clinical evidence

(a) Carbamazepine

In a study, 14 patients took quetiapine 300 mg twice daily for 28 days, with carbamazepine 200 mg three times daily for 20 days. It was found that the AUC and maximum plasma levels of quetiapine were reduced by 87% and 80%, respectively.[1]

A 52-year-old woman taking carbamazepine 700 mg twice daily was given quetiapine, increased to 700 mg daily over 5 weeks. At this point she was noted to have become more aggressive and agitated, and unsteady. Her carbamazepine level had increased from 7.7 micrograms/mL to 11.2 micrograms/mL and her level of the metabolite carbamazepine-10,11-epoxide had risen from 2.1 micrograms/mL to 5.2 micrograms/mL. Symptoms resolved when carbamazepine was replaced with **oxcarbazepine**. A second patient taking carbamazepine also had raised carbamazepine-10,11-epoxide levels after starting quetiapine, but was asymptomatic.[2]

(b) Phenytoin

When 17 patients taking quetiapine 250 mg three times daily were given phenytoin 100 mg three times daily for 10 days, the oral clearance of quetiapine was increased fivefold.[3]

Mechanism

Quetiapine is metabolised by the cytochrome P450 isoenzyme CYP3A4. Both carbamazepine and phenytoin are known potent inducers of this enzyme, and therefore concurrent use results in an increase in quetiapine clearance and a decrease in its metabolism.

The reason for the raised carbamazepine-10,11-epoxide levels is less clear. It has been suggested that quetiapine inhibits the metabolism (glucuronidation) of this metabolite.[2]

Importance and management

Although evidence suggesting that carbamazepine and phenytoin decrease quetiapine levels is limited, it is in line with the way these antiepileptics commonly interact, and is therefore established. It would seem prudent to monitor the outcome of concurrent use, and increase the quetiapine dose as necessary. The manufacturers of quetiapine reasonably predict that other potent CYP3A4 inducers, such as the **barbiturates** and **rifampicin** (**rifampin**), will interact similarly,[4,5] and therefore similar precautions are warranted.

The general relevance of the reports of increased carbamazepine-10,11-epoxide levels is unknown, and more study is warranted to establish an interaction. However, it would be prudent to consider monitoring carbamazepine-10,11-epoxide levels if adverse effects develop. Limited evidence suggests that oxcarbazepine may be an alternative if the interaction cannot be managed by carbamazepine dose reductions.

Quetiapine + CYP3A4 inhibitors

The plasma levels of quetiapine are increased by erythromycin and ketoconazole. Azoles, macrolides, and protease inhibitors are expected to interact similarly.

Clinical evidence

(a) Erythromycin

A study in 19 Chinese patients who received quetiapine 200 mg twice daily and erythromycin 500 mg three times daily found that erythromycin increased the maximum plasma concentration and AUC of quetiapine by 68% and 129%, respectively.[1]

(b) Ketoconazole

In a study, 12 healthy subjects were given ketoconazole 200 mg daily, with a single 25-mg dose of quetiapine on day 4. The AUC and maximum plasma levels of quetiapine were increased about 6.2-fold and 3.4-fold, respectively.[2]

Mechanism

Ketoconazole is a potent inhibitor of the cytochrome P450 isoenzyme CYP3A4 by which quetiapine is metabolised. Concurrent use therefore reduces quetiapine metabolism and increases its levels. Erythromycin is only a moderate inhibitor of this isoenzyme, and therefore has a more modest effect on quetiapine levels.

Importance and management

An interaction between quetiapine and ketoconazole or erythromycin is established. If quetiapine is given with either of these drugs it would seem prudent to monitor closely for quetiapine adverse effects (e.g. dizziness, anxiety, orthostatic hypotension). Expect to need to reduce the quetiapine dose, particularly with ketoconazole.

The manufacturers of quetiapine[3,4] reasonably predict that other **macrolides** and **azoles** will interact similarly, although note that they are likely to differ in the extent of the interaction. See 'azoles', (p.233), and 'Ergot derivatives + Macrolides', p.683, which can be used as a guide to the relative potency of these drugs on CYP3A4 substrates.

The **protease inhibitors** are also expected to dramatically raise quetiapine levels.[3,4]

4. Seroquel (Quetiapine fumarate). AstraZeneca. US Prescribing information, December 2009.

Quetiapine + Miscellaneous

Quetiapine does not appear to interact to a clinically relevant extent with cimetidine, fluoxetine, or lorazepam. Isolated cases of

adverse outcomes have been reported with diphenhydramine and lovastatin.

Clinical evidence, mechanism, importance and management

(a) Cimetidine

In a study in 7 men with psychotic disorders, quetiapine 150 mg three times daily was given with cimetidine 400 mg three times daily for 4 days. There were some slight alterations in the pharmacokinetics of the quetiapine, but these were within the intraindividual changes seen and so were not considered significant.[1] The dose of quetiapine does not need to be adjusted in patients given cimetidine.

(b) Diphenhydramine

A patient taking diphenhydramine 100 mg daily developed urinary retention when she increased her dose of quetiapine from 900 mg daily to 2.4 g daily. When the dose of quetiapine was reduced back to 900 mg daily, her urinary retention resolved. A further episode occurred when the patient again increased her quetiapine dose. Although quetiapine does not normally have antimuscarinic adverse effects at usual therapeutic doses, it is suggested by the authors that the likelihood of these adverse effects is increased at doses of quetiapine greater than 900 mg daily. This effect may have occurred as a result of additive antimuscarinic activity of both diphenhydramine and high-dose quetiapine.[2]

(c) Lorazepam

The pharmacokinetics and pharmacodynamic effects of a single 2-mg dose of lorazepam were studied in 10 men taking quetiapine 250 mg three times daily. It was found that the maximum serum lorazepam level was not significantly changed by quetiapine, and the alterations in the performance of a number of psychometric tests were small and considered not to be clinically relevant.[3]

(d) Lovastatin

A patient taking quetiapine 800 mg daily and sertraline 100 mg daily developed a prolonged QTc interval of 569 milliseconds after starting to take lovastatin 10 mg daily. Following a reduction in the lovastatin dose to 5 mg daily, her QTc interval returned to her baseline of 424 milliseconds. It is suggested that lovastatin competitively inhibited the metabolism of quetiapine by CYP3A4, as both drugs are substrates for this enzyme, resulting in increased quetiapine levels.[4] However, the full contribution of sertraline to this case was only briefly considered, and full details relating to the cardiac effects and calculation of the QTc interval are not given.[5]

(e) SSRIs

Fluoxetine 60 mg daily for 5 days had no clinically significant effect on the steady-state plasma levels of quetiapine 300 mg twice daily.[6] No dose adjustments would therefore appear to be necessary if **fluoxetine** and quetiapine are used concurrently.

Quetiapine + Topiramate

Topiramate does not affect the plasma levels of quetiapine.

Clinical evidence, mechanism, importance and management

In a study, 7 patients receiving long-term quetiapine 200 mg to 600 mg daily were given topiramate in a dose that was increased gradually to 200 mg daily. The plasma levels of quetiapine were not significantly affected by topiramate and the combination was well tolerated.[1] There would therefore appear to be no need to adjust the dose of quetiapine in patients also given topiramate.

1. Migliardi G, D'Arrigo C, Santoro V, Bruno A, Cortese L, Campolo D, Cacciola M, Spina E. Effect of topiramate on plasma concentrations of clozapine, olanzapine, risperidone, and quetiapine in patients with psychotic disorders. *Clin Neuropharmacol* (2007) 30, 107–13.

Quetiapine + Tricyclic and related antidepressants

Imipramine does not appear to affect the pharmacokinetics of quetiapine. Isolated cases of adverse outcomes have been reported in patients taking quetiapine with doxepin (and pantoprazole) or mirtazapine. The use of quetiapine may falsely elevate tricyclic levels by interfering with immunoassay results.

Clinical evidence

(a) Doxepin

A patient taking doxepin 150 mg daily and lorazepam 500 micrograms daily was admitted to hospital with confusion and depression. Quetiapine 750 mg daily and pantoprazole 40 mg daily were started, and the doses of his existing medication were adjusted to doxepin 100 mg daily and lorazepam 4.5 mg daily. At this point his quetiapine level was found to be 1838 to 1860 nanograms/mL, but as there was only slight improvement in the symptoms of schizophrenia, the dose of quetiapine was increased to 900 mg daily. Pantoprazole and doxepin were discontinued and the dose of lorazepam was reduced to 2 mg daily. At this point his quetiapine levels were found to be just 109 nanograms/mL. The lorazepam dose was decreased further to 500 micrograms daily and quetiapine levels were found to be 68 nanograms/mL.[1]

(b) Imipramine

Imipramine 75 mg twice daily for 5 days had no clinically significant effect on the steady-state plasma levels of quetiapine 300 mg twice daily.[2]

(c) Mirtazapine

An isolated case report describes increased prolactin levels after the introduction of mirtazapine 15 mg daily in a woman who was taking quetiapine 400 mg daily. Her prolactin level normalised when the mirtazapine was stopped, but rechallenge again produced an increase in prolactin levels, although this was transient and appeared to resolve within one month.[3]

Mechanism

The reasons for the elevated quetiapine levels are not known but the authors suggest that they may have been due to the concurrent use of doxepin and pantoprazole. As lorazepam was given continuously and was present when quetiapine levels were low, it was considered unlikely to be involved in the interaction.[1]

The authors of the case of raised prolactin levels suggest that the mirtazapine may have caused an increase in quetiapine-induced dopamine receptor blockade, or alternatively an agonist action at opioid receptors altered dopamine receptor function.[3]

Importance and management

Evidence for an interaction between the tricyclic and related antidepressants and mirtazapine appear to be limited to these disparate case reports, which are largely unexplained. The one pharmacokinetic study involving imipramine found no interaction. Therefore, in general, no particular precautions would appear necessary if quetiapine is given with a tricyclic antidepressant.

Immunoassay methods for identifying tricyclic antidepressants in blood and urine have given false positive results in the presence of quetiapine.[4-6] In one case, HPLC analysis gave normal results.[6]

Quetiapine + Valproate

Valproate may modestly raise quetiapine levels.

Clinical evidence, mechanism, importance and management

An analysis of the plasma levels of quetiapine in 9 patients who were also taking valproate, found a 77% increase in the concentration dose ratio of quetiapine, when compared with those patients not taking valproate.[1] A study in 33 patients given quetiapine 150 mg twice daily or valproate semisodium (divalproex sodium) 500 mg twice daily either alone or concurrently found that valproate increased the maximum plasma levels of quetiapine by 17% but did not affect its AUC. Valproate levels and AUC were decreased by 11% by quetiapine. These changes were not statistically significant.[2]

The effect of valproate on quetiapine levels appears to be modest, but consider the possibility of an interaction if quetiapine adverse effects (e.g. dizziness, anxiety, orthostatic hypotension) are increased.

1. Aichhorn W, Marksteiner J, Walch T, Zernig G, Saria A, Kemmler G. Influence of age, gender, body weight and valproate comedication on quetiapine plasma concentrations. *Int Clin Psychopharmacol* (2006) 21, 81–5.

Ramelteon + Azoles

Fluconazole and ketoconazole increase the levels of ramelteon. Other azoles may interact similarly.

Clinical evidence, mechanism, importance and management

A study in 28 healthy subjects found that **fluconazole** 400 mg on day one then 200 mg daily for 3 days significantly increased the AUC and maximum plasma level of a single 16-mg dose of ramelteon, given on day 4, by about 150%.[1] Further study found that **ketoconazole** 200 mg daily for 4 days increased the AUC and maximum plasma concentration of single-dose ramelteon by 84% and 36%, respectively. As ramelteon undergoes extensive first-pass metabolism, these increases in systemic exposure were considered to be moderate, suggesting that neither CYP2C9 nor CYP3A4 is the predominant enzyme involved in the metabolism of ramelteon.[1] Nevertheless, the manufacturer suggests that ramelteon should be given with caution with strong CYP2C9 inhibitors such as **fluconazole** and strong CYP3A4 inhibitors such as **ketoconazole**.[2] It may therefore be prudent to be alert for an increase in the sedative effects, and the duration of effects, of ramelteon, and consider a reduction in dose if the effects become excessive. Information about other azoles generally appears to be lacking, but all of them, would be expected to interact to a greater or lesser extent. Note that a large proportion of **miconazole** oral gel (both prescription and non-prescription doses) may be swallowed and therefore adequate systemic absorption may occur to produce an interaction.

2. Rozerem (Ramelteon). Takeda Pharmaceuticals America, Inc. US Prescribing information, October 2008.

Ramelteon + Dextromethorphan

A study in 36 healthy subjects found that giving ramelteon 32 mg with dextromethorphan 30 mg had no effect on the pharmacokinetics of either drug.[1] Ramelteon does not, therefore, appear to affect the metabolism of CYP2D6 substrates (see 'Table 1.3', (p.6), for a list) and, therefore dose adjustments of these drugs would not be expected to be necessary if ramelteon is also given.

1. Tolbert D, Karim A, Cao C, Zhao Z, Johnson J, Sainati SM. Study to assess drug interaction between ramelteon (TAK-375) and dextromethorphan in healthy adults. *Sleep* (2004) 27 (Abstract Suppl), A50.

Ramelteon + Miscellaneous

Rifampicin (rifampin) and to a much lesser extent food, may decrease the efficacy of ramelteon. CYP1A2 inhibitors (such as some quinolones) are expected to increase ramelteon levels.

Clinical evidence, mechanism, importance and management

(a) CYP1A2 inhibitors

Ramelteon is metabolised by the cytochrome P450 isoenzyme CYP1A2. Based on the profound interaction with fluvoxamine (see 'Ramelteon + SSRIs', below) the manufacturer advises caution with other CYP1A2 inhibitors. Note that many of the quinolones can, to varying extents, inhibit CYP1A2, most notably **enoxacin** and **ciprofloxacin**. Concurrent use of these drugs and ramelteon should be closely monitored for increased sedation, and the dose of ramelteon reduced as necessary. A list of CYP1A2 inhibitors is given in 'Table 1.2', (p.4).

(b) Food

A high-fat meal increased the AUC of a single 16-mg dose of ramelteon by 31% and decreased the maximum plasma concentration by 22%, compared with the fasted state. The time to maximum plasma concentration was also delayed by about 45 minutes when ramelteon was given with food. The manufacturer therefore recommends that ramelteon should not be taken with or immediately after a high-fat meal.[1]

(c) Rifampicin (Rifampin)

Rifampicin 600 mg daily for 11 days decreased the total exposure to a single 32-mg dose of ramelteon and its active metabolite by about 80%. Efficacy may be reduced when ramelteon is used in combination with strong enzyme inducers such as rifampicin.[1]

1. Rozerem (Ramelteon). Takeda Pharmaceuticals America, Inc. US Prescribing information, October 2008.

Ramelteon + SSRIs

Fluvoxamine dramatically increases and fluoxetine modestly increases ramelteon levels.

Clinical evidence, mechanism, importance and management

A study in 28 healthy subjects found that **fluoxetine** 40 mg daily for 11 days increased the AUC and maximum plasma level of a single 16-mg dose of ramelteon by 50% and 40%, respectively. This increase in systemic exposure was not considered to be clinically important as ramelteon has high interindividual variability and a wide therapeutic window. No dose adjustment of ramelteon is considered to be necessary if **fluoxetine** is also taken.[1]

The manufacturer of ramelteon reports that the AUC and maximum plasma level of ramelteon were increased approximately 190-fold and 70-fold, respectively, by **fluvoxamine**. The manufacturer therefore contraindicates the use of ramelteon with **fluvoxamine**.[2]

The effects of other SSRIs do not appear to have been studied; however, **paroxetine** generally interacts in the same way as **fluoxetine**, and none of the other SSRIs would be expected to interact in the same way as **fluvoxamine**, as they are not CYP1A2 inhibitors.

Risperidone + Carbamazepine or Oxcarbazepine

Carbamazepine reduces risperidone levels, and risperidone may cause a small increase in carbamazepine levels. Oxcarbazepine dose not significantly affect the pharmacokinetics of risperidone.

Clinical evidence

(a) Carbamazepine

A 22-year-old man taking risperidone 4 mg daily and carbamazepine 600 mg daily for schizophrenia had lower than expected risperidone levels, so his risperidone dose was doubled and the carbamazepine tailed off. Ten days after carbamazepine had been discontinued it was noted that his plasma levels of the major active metabolite of risperidone, 9-hydroxyrisperidone, was 49 micrograms/L; it had only been 19 micrograms/L when he was taking carbamazepine.[1] There are 4 other cases of this interaction between risperidone and carbamazepine.[2-4] In one case, the addition of carbamazepine to established risperidone treatment resulted in a reduction in the risperidone and 9-hydroxyrisperidone levels of about 75% and 65%, respectively, accompanied by the return of the patients psychotic symptoms.[4] In two other cases, a 20-year-old and an 81-year-old man developed parkinsonian symptoms when carbamazepine was stopped. The symptoms resolved when the doses of risperidone were reduced by about two-thirds.[2]

These cases are supported by a study in 5 patients taking carbamazepine and risperidone for schizophrenia or bipolar disorders. The dose-normalised plasma level of risperidone and its active metabolite, 9-hydroxyrisperidone, were 68% and 64% lower, respectively, in the presence of carbamazepine, when compared with patients taking risperidone alone.[5] Another study in 11 patients who had been taking risperidone for 2 to 68 weeks found that carbamazepine 200 mg twice daily for a week approximately halved the plasma levels of risperidone and its active moiety (risperidone plus 9-hydroxyrisperidone).[6] In another study in patients with acute mania, the levels of active risperidone were 40% lower in patients given risperidone with carbamazepine when compared with those given risperidone and either lithium or divalproex sodium. The efficacy of the combination of risperidone with a mood stabiliser (lithium, divalproex sodium, carbamazepine) was found to be significantly increased if patients taking carbamazepine were excluded from the analysis.[7]

Risperidone may also affect carbamazepine levels. In one study in 8 patients, risperidone 1 mg daily for 2 weeks raised carbamazepine levels by about 20%.[8]

(b) Oxcarbazepine

A study in 12 patients taking risperidone 2 to 6 mg daily found that the addition of oxcarbazepine for 5 weeks, at an initial dose of 300 mg daily, increased to 900 mg to 1.2 g after one week, had no significant effects on the pharmacokinetics of risperidone. Concurrent use was generally well tolerated.[9]

Mechanism

Risperidone is mainly metabolised by the cytochrome P450 isoenzyme CYP2D6, and it has been suggested that carbamazepine induces this route of metabolism thereby reducing risperidone levels. However, there do not appear to be any interactions with carbamazepine that occur as a result of this mechanism. Carbamazepine is a known potent inducer of CYP3A4, a more minor route of risperidone metabolism, and it seems more likely that this is the mechanism behind the interaction. The extent of the interaction appears to be related to CYP2D6 genotype (see 'Genetic factors', (p.4)), when the metabolism of risperidone by CYP3A4 becomes more important. Oxcarbazepine is not known to affect the metabolism of drugs by CYP2D6 or CYP3A4 to a clinically relevant extent.

Importance and management

An interaction between carbamazepine and risperidone appears to be established. It would seem important to monitor the levels of risperidone and 9-hydroxyrisperidone in patients given carbamazepine, being alert for the need to raise the risperidone dose, possibly by as much as two-thirds. The dose of risperidone will need to be reduced if carbamazepine is stopped. The increase in carbamazepine levels seen with risperidone is almost certainly too small to be of clinical relevance.

No special consideration or monitoring appears necessary if oxcarbazepine is given with risperidone.

Risperidone + Ginkgo (*Ginkgo biloba*)

An isolated case describes priapism in a patient taking risperidone and ginkgo.

Clinical evidence

A 26-year-old paranoid schizophrenic who had been taking risperidone 3 mg daily for the past 3 years developed priapism that had lasted for 4 hours, 2 weeks after starting to take ginkgo 160 mg daily for occasional tinnitus. The priapism required treatment, and both ginkgo and risperidone were stopped. Risperidone was then restarted and the patient reported no further episodes of priapism at follow-up 6 months later.[1]

Mechanism

Unclear. Risperidone alone does rarely cause priapism, probably because of its alpha-adrenergic properties, and ginkgo might have vascular effects that could be additive with the effects of risperidone. Ginkgo is unlikely to affect the metabolism of risperidone by inhibiting the cytochrome P450 isoenzyme CYP2D6 because it has no clinical effect on other CYP2D6 substrates.

Importance and management

Evidence for an interaction between ginkgo and risperidone appears to be limited to this isolated case. Its general relevance is therefore unclear. Bear it in mind in the event of an unexpected response to treatment.

1. Lin Y-Y, Chu S-J, Tsai S-H. Association between priapism and concurrent use of risperidone and Ginkgo biloba. *Mayo Clin Proc* (2007) 82, 1288–91.

Risperidone + Itraconazole

Itraconazole increases the plasma levels of risperidone and its active metabolite, 9-hydroxyrisperidone.

Clinical evidence

A study in 19 patients who were taking risperidone 2 to 8 mg daily found that the addition of itraconazole 200 mg daily for a week increased the plasma levels of risperidone and its active metabolite, 9-hydroxyrisperidone, by 82% and 70%, respectively. The levels returned to pre-treatment values one week after the itraconazole was stopped.[1]

Mechanism

Itraconazole is a known inhibitor of the cytochrome P450 isoenzyme CYP3A4 and it was suggested that it inhibited the metabolism of risperidone by this route, resulting in the increased levels seen.

Importance and management

Evidence appears to be limited to one study, which suggests that risperidone levels are expected to increase if itraconazole is given concurrently. Be aware of any signs of increased risperidone adverse effects (e.g. agitation, insomnia, headache), and consider reducing the dose as necessary.

1. Jung SM, Kim KA, Cho HK, Jung IG, Park PW, Byun WT, Park JY. Cytochrome P450 3A inhibitor itraconazole affects plasma concentrations of risperidone and 9-hydroxyrisperidone in schizophrenic patients. *Clin Pharmacol Ther* (2005) 78, 520–8.

Risperidone + Lamotrigine

One small study found no interaction between risperidone and lamotrigine, although a case report describes increased risperidone levels in a patient given lamotrigine, and a retrospective study suggests that lamotrigine increases the variability of risperidone levels.

Clinical evidence

An isolated case report describes markedly increased risperidone levels in a patient given increasing doses of lamotrigine. When the lamotrigine dose was increased from 175 mg daily to 200 mg daily, the risperidone level increased from 69 nanograms/mL to 263 nanograms/mL. A further increase in the lamotrigine dose to 225 mg daily, while maintaining the risperidone dose of 8 mg daily resulted in a risperidone plasma level of 412 nanograms/mL, and the patient complained of dizziness and tiredness.[1] A retrospective review of 5 patients taking risperidone and lamotrigine, for whom pharmacokinetic data were available both before and after the addition of lamotrigine, revealed a wide variation in alterations of risperidone levels, from a reduction of 41% to a rise of 74% after the addition of lamotrigine: on average there was a 7% decrease in risperidone levels.[2] A study in 10 patients taking risperidone 3 to 6 mg daily, and who were also given lamotrigine (increasing over 8 weeks to 200 mg daily) found no changes in the pharmacokinetics of risperidone.[3]

Mechanism

Risperidone is metabolised by CYP2D6, but since lamotrigine is not a known inhibitor of this enzyme, a pharmacokinetic interaction was not thought to explain the change in levels.[1]

Importance and management

The retrospective review and small study above did not find any evidence of a consistent effect of lamotrigine on risperidone pharmacokinetics. However, in view of the case report, and also the fact that some individuals in the review demonstrated large changes in risperidone levels some caution seems warranted. It would be prudent to monitor patients for an increase in adverse effects (e.g. agitation, insomnia, headache), or a lack of therapeutic effect, if lamotrigine is given with risperidone.

Risperidone + Levomepromazine

Levomepromazine does not appear to affect the pharmacokinetics of risperidone, but concurrent use may lead to additive adverse effects.

Clinical evidence, mechanism, importance and management

In a study, 20 patients who had been taking risperidone for at least 2 weeks were also given levomepromazine in doses of 5 to 75 mg daily. There were no changes in the pharmacokinetics of risperidone or its active metabolite, 9-hydroxyrisperidone, and there was no aggravation of extrapyramidal effects.[1]

A case report describes a woman with schizophrenia taking risperidone 8 mg daily who became agitated and restless at night 3 months after starting to take levomepromazine up to 50 mg at night. Risperidone was stopped, but after 10 days her condition had not improved, and so levomepromazine was also stopped. Within a day she began to feel less agitated. The authors suggested that her symptoms represented delayed-onset akathisia, which was attributed to additive adverse effects of both drugs.[2] However, as the patient did not take levomepromazine alone an interaction is not established in this case.

It would seem that levomepromazine may be given with risperidone without dose adjustment. Although not established, the case report serves as a reminder to consider adverse effects when prescribing two drugs with a similar adverse effect profile.

1. Yoshimura R, Shinkai K, Kakihara S, Goto M, Yamada Y, Kaji K, Ueda N, Nakamura J. Little effects of low dosage of levomepromazine on plasma risperidone levels. *Pharmacopsychiatry* (2005) 38, 98–100.
2. Shimizu E, Watanabe H, Iyo M. Delayed-onset nocturnal akathisia due to risperidone and levomepromazine: a case report. *Eur Psychiatry* (2002) 17, 294–5.

Risperidone + Melperone

Melperone appears to raise risperidone levels.

Clinical evidence

A patient taking risperidone 6 mg daily was switched from melperone 50 mg daily to pipamperone 40 mg daily. After 8 days, the patient's risperidone levels had decreased from 2.1 micrograms/L to 1 microgram/L and the 9-hydroxyrisperidone levels had increased from 21 micrograms/L to 40 micrograms/L, which was taken to suggest that melperone raises risperidone levels. This suggestion is supported by a second patient, whose dose-corrected risperidone plasma level decreased by about 69% and 9-hydroxyrisperidone plasma level increased by about 68% after the dose of risperidone was increased from 5 mg daily to 6 mg daily, and melperone was stopped. In a third patient, taking risperidone, melperone, venlafaxine and metoprolol, the dose-corrected risperidone level fell by 20% when melperone was stopped: the 9-hydroxyrisperidone level was unchanged.[1]

Mechanism

Risperidone is metabolised by the cytochrome P450 isoenzyme CYP2D6. It was suggested that melperone raises risperidone levels by inhibiting this metabolism.

Importance and management

Evidence for an interaction between risperidone and melperone appears to be limited to these three cases, and the authors suggest that further study is needed to establish their clinical relevance. Until more is known it seems prudent to be alert for risperidone adverse effects (e.g. agitation, insomnia, headache), and, as the levels of the active metabolite are reduced, it would also seem prudent to monitor efficacy if melperone is also given.

1. Köhnke MD, Lutz U, Wiatr G, Schwärzler F, Weller B, Schott K, Buchkremer G. Cytochrome P450 2D6 dependent metabolization of risperidone is inhibited by melperone. *Eur J Clin Pharmacol* (2006) 62, 333–4.

Risperidone + Phenytoin

An isolated report describes extrapyramidal symptoms in a patient taking risperidone when he was also given a single dose of phenytoin.

Clinical evidence

A 31-year-old man with schizophrenia was given risperidone and the dose was titrated up from 1 mg twice daily to 3 mg twice daily over 3 days without any adverse effects. Three days later a single 200-mg dose of phenytoin was accidentally given and 8 hours later he developed laboured breathing and severe hyperextension of the neck and oculogyric crisis. Risperidone was temporarily discontinued and he recovered after treatment with benzatropine and diazepam.[1]

Mechanism

It was suggested that risperidone levels may have been increased by competitive inhibition since both drugs are hydroxylated by cytochrome P450

isoenzymes. Further, both risperidone and phenytoin are highly protein bound and the author also suggests that phenytoin may have increased risperidone blood levels by displacing it from its binding sites.[1]

Importance and management

Evidence for an interaction between risperidone and phenytoin appears to be limited to this one case report, and its general significance is unclear. Note that, in contrast to this case report the US manufacturer of risperidone predicts that phenytoin will *reduce* risperidone levels.[2] This is in line with the way other enzyme-inducing drugs are known to interact (see 'Risperidone + Carbamazepine or Oxcarbazepine', p.904).

In the absence of further information, if phenytoin is given it would seem appropriate to monitor for risperidone adverse effects (e.g. agitation, insomnia, headache), and a lack of therapeutic effect, and adjust the dose accordingly.

2. Risperdal (Risperidone). Ortho-McNeil-Janssen Pharmaceuticals, Inc. US Prescribing information, July 2009.

Risperidone + Probenecid

In a study in 12 healthy subjects, probenecid 500 mg twice daily for 4 days did not affect the pharmacokinetics of a single 1-mg dose of risperidone given on day 2.[1]

1. Markowitz JS, DeVane CL, Liston HL, Bouton DW, Risch SC. The effects of probenecid on the disposition of risperidone and olanzapine in healthy volunteers. *Clin Pharmacol Ther* (2002) 71, 30–8.

Risperidone + Protease inhibitors

Neuroleptic malignant syndrome, ataxia and severe lethargy leading to coma, and extrapyramidal adverse effects have been seen in patients given risperidone with indinavir and ritonavir.

Clinical evidence

A 35-year-old man with AIDS was diagnosed with a Tourette's-like disorder and given risperidone 1 mg twice daily. After 2 weeks the risperidone was increased to 2 mg twice daily and he was also given **indinavir** 800 mg twice daily with **ritonavir** 200 mg twice daily. He discontinued the antiretrovirals after 5 days due to nausea, but started them again 1 month later when the tic disorder had improved. After one week he became short of breath and fatigued, with worsening tremor and other extrapyramidal adverse effects. The antiretrovirals were stopped and the risperidone dose increased to 3 mg twice daily. Over the next 3 days his symptoms worsened and began to interfere with daily living. Risperidone was discontinued and clonazepam started, and his symptoms resolved.[1] Another patient developed neuroleptic malignant syndrome 3 days after starting to take risperidone with **indinavir** and **ritonavir**. This patient also recovered when the risperidone was stopped.[2] A third patient taking **indinavir** and **ritonavir** was given risperidone 3 mg twice daily to treat symptoms of mania. After 2 doses he became ataxic, drowsy and disorientated, which further developed into lethargy and coma. He recovered 24 hours after stopping all medication.[3]

Mechanism

Indinavir inhibits the cytochrome P450 isoenzyme CYP3A4 and ritonavir inhibits CYP2D6 and CYP3A4, which are the main isoenzymes involved in the metabolism of risperidone. Therefore concurrent use would be expected to raise risperidone levels. The symptoms reported in the cases above may have all been due to increased risperidone levels.[1,3]

Importance and management

These appear to be the only reports of an interaction between risperidone and protease inhibitors, but they are in line with the way these drugs are generally known to interact. It is unclear if indinavir given alone would have had these effects.

If risperidone is given to any patient taking ritonavir (including ritonavir given as a pharmacokinetic enhancer) it would seem prudent to be alert for risperidone adverse effects (e.g. agitation, insomnia, headache, extrapyramidal effects). If these become troublesome consider decreasing the risperidone dose.

3. Jover F, Cuadrado J-M, Andreu L, Merino J. Reversible coma caused by risperidone-ritonavir interaction. *Clin Neuropharmacol* (2002) 25, 251–3.

Risperidone + Reboxetine

Reboxetine does not appear to alter the pharmacokinetics of risperidone.

Clinical evidence, mechanism, importance and management

Reboxetine 8 mg daily was given to 7 patients with schizophrenia taking risperidone 4 to 6 mg daily for 3 weeks. Reboxetine had no significant effects on the pharmacokinetics of either risperidone or its active metabolite, 9-hydroxyrisperidone.[1] This appears to be the only study investigating the concurrent use of risperidone and reboxetine. It suggests that if both drugs are given risperidone dose adjustments are unlikely to be necessary.

1. Spina E, Avenoso A, Scordo MG, Ancione M, Madia A, Levita A. No effect of reboxetine on plasma concentrations of clozapine, risperidone, and their active metabolites. *Ther Drug Monit* (2001) 23, 675–8.

Risperidone + Rifampicin (Rifampin)

The levels of risperidone and its active metabolite are reduced by rifampicin.

Clinical evidence

In a study in 10 healthy subjects, rifampicin 600 mg daily for 5 days decreased the maximum plasma level and AUC of a single 4-mg dose of risperidone by 50% and 72%, respectively.[1] In another study, 10 healthy subjects were given rifampicin 600 mg daily for 7 days, with a single 1-mg dose of risperidone on day 6. Rifampicin reduced the maximum plasma level and AUC of risperidone by 38% and 51%, respectively and reduced the maximum plasma level and AUC of 9-hydroxyrisperidone (the active metabolite of risperidone) by 46% and 47%, respectively.[2]

Mechanism

Rifampicin is a potent inducer of the cytochrome P450 isoenzyme CYP3A4, which is partly responsible for the metabolism of risperidone. Concurrent use would therefore be expected to increase risperidone metabolism and reduce its levels. It has also been suggested that P-glycoprotein may have played a part in this interaction.[2]

Importance and management

The interaction between risperidone and rifampicin would appear to be established. Reduced levels of risperidone and its active 9-hydroxy metabolite would be expected to lead to reduced efficacy. It would therefore be prudent to monitor the outcome of concurrent use to ensure that risperidone is effective, increasing the dose if necessary.

1. Mahatthanatrakul W, Nontaput T, Ridtitid W, Wongnawa M, Sunbhanich M. Rifampin, a cytochrome P450 3A inducer, decreases plasma concentrations of antipsychotic risperidone in healthy volunteers. *J Clin Pharm Ther* (2007) 32, 161–7.
2. Kim K-A, Park P-W, Liu K-H, Kim K-B, Lee H-J, Shin J-G, Park J-Y. Effect of rifampin, an inducer of CYP3A and P-glycoprotein, on the pharmacokinetics of risperidone. J Clin Pharmacol (2008) 48, 66–72.

Risperidone + SSRIs

Fluoxetine, fluvoxamine, and paroxetine appear to raise risperidone levels. Sertraline appears to only moderately increase risperidone levels at high doses. The combination of SSRIs and

risperidone is generally useful, but has resulted in a number of adverse effects including priapism, extrapyramidal effects and serotonin syndrome.

Clinical evidence

(a) Citalopram

A study in 7 patients found that citalopram had no effect on the plasma levels of risperidone or its active metabolite, 9-hydroxyrisperidone.[1]

A case report describes a 29-year-old man with idiopathic priapism, about one 4-hour erection every 1 to 2 months, which typically woke him up, who began to experience much longer bouts of priapism lasting 6 to 8 hours when he was given risperidone 4 mg daily. Within about 4 weeks of adding citalopram 40 mg daily to a slightly reduced risperidone dose (3 mg daily), he began to have almost daily erections lasting 12 hours. Three days after his dosages were changed to risperidone 3 mg twice daily with citalopram 20 mg daily he had an episode of such persistent priapism that emergency detumescence was needed. When both drugs were stopped he improved markedly and then only had occasional 4-hour erections, as before.[2]

(b) Fluoxetine

A pharmacokinetic study in 10 patients found that fluoxetine 20 mg daily raised the levels of risperidone 2 or 3 mg twice daily from 12 nanograms/mL to 19 nanograms/mL after 3 weeks of concurrent use and to 56 nanograms/mL after 4 weeks of concurrent use. All patients experienced a rise in risperidone levels, but this varied from a twofold rise to a tenfold rise. One patient withdrew from the study because of severe akathisia and another two patients needed to be given biperiden to control parkinsonian adverse effects.[3] Similar results were found in another study.[4]

A 30-year-old woman taking valproate, clonazepam, and risperidone 3 mg daily for schizophrenia was also given fluoxetine 5 mg daily for a depressive disorder. The depression improved, but she noticed painful bilateral breast enlargement, which resolved when risperidone was stopped. Similar symptoms were noted when the risperidone was later restarted.[5]

Extrapyramidal adverse effects have developed in a number of patients taking fluoxetine with risperidone.[6-8] Other adverse effects, including urinary retention, constipation and sedation also occurred in one of these patients.[7] A patient with obsessive-compulsive disorder, who was partially successfully treated with fluoxetine 60 mg daily, saw his condition return to his pre-fluoxetine state when risperidone 3 mg daily was started. His condition gradually improved over a 3-month period after the risperidone was stopped.[9]

(c) Fluvoxamine

A 24-year-old woman taking risperidone 3 mg twice daily developed fever, limb rigidity, and confusion 3 days after starting fluvoxamine 50 mg daily. She required ventilation after her condition worsened, and she was eventually diagnosed as having either serotonin syndrome or neuroleptic malignant syndrome. Both drugs were stopped and her condition resolved. She subsequently, uneventfully took fluvoxamine 100 mg twice daily.[10]

A study in 6 patients who had been taking risperidone 3 to 6 mg daily for at least 4 weeks, with fluvoxamine 100 mg daily for a further 8 weeks, found no changes in the pharmacokinetics of risperidone or its metabolite. However, in 5 other patients included in this study, the dose of fluvoxamine was increased to 200 mg daily for weeks 5 to 8, and there was an 85% increase in plasma risperidone levels by the end of week 8. There was no change in the pharmacokinetics of the active metabolite of risperidone, 9-hydroxyrisperidone, and no adverse reactions to risperidone were noted.[11]

(d) Paroxetine

In a study, 10 patients taking risperidone 2 to 4 mg twice daily were given paroxetine 20 mg daily. After 4 weeks of concurrent use, the levels of risperidone and its active metabolite, 9-hydroxyrisperidone, had increased by 45%. Although the combination was generally well-tolerated one patient developed parkinsonian adverse effects.[12] In another study, 12 patients taking risperidone 2 mg twice daily were given paroxetine in doses increasing from 10 mg daily to 20 mg and 40 mg at 4 week intervals. The plasma levels of risperidone were increased 3.8-fold, 7.1-fold and 9.7-fold when given with paroxetine 10 mg, 20 mg and 40 mg daily, respectively. There was no change in the pharmacokinetics of the active metabolite of risperidone, 9-hydroxyrisperidone. Negative symptoms of schizophrenia were improved, but there was an increased incidence of extrapyramidal adverse effects when patients took paroxetine 20 mg or 40 mg daily.[13]

A case report describes two elderly patients taking paroxetine who developed serotonin syndrome within a couple of days of a risperidone dose increase. One patient's treatment had recently been changed from venlafaxine to paroxetine, which may have contributed to the reaction.[14] Another case report describes a 53-year-old man who developed symptoms suggestive of serotonin syndrome 10 weeks after starting to take risperidone 3 mg daily and paroxetine 20 mg daily. A deterioration in his condition occurred within 2 hours of doubling the dose of both drugs, and his symptoms resolved 2 days after stopping both drugs.[15] Another case report describes a patient taking risperidone, paroxetine and valproate semisodium, who discontinued risperidone after developing reduced facial expressions, stiffness and akathisia. In this patient the half-life of risperidone was estimated to be almost 24 hours (expected half-life only 3 hours).[16]

(e) Sertraline

A 69-year-old man taking venlafaxine for depression with psychosis started taking risperidone 0.5 mg twice daily. Five days later trazodone was started, venlafaxine was gradually stopped and sertraline 25 mg daily was started. Over the next 2 weeks the dose of risperidone was increased to 3 mg daily and the dose of sertraline was increased to 150 mg daily. The patient became tremulous with myoclonus, had cogwheel rigidity of bilateral upper extremities, and a fine tremor. He was diagnosed with serotonin syndrome: risperidone, sertraline and trazodone were stopped, and the symptoms resolved within 24 hours.[17]

A study in 11 patients taking risperidone 4 to 6 mg daily found that sertraline 50 to 100 mg daily for 8 weeks did not affect the mean pharmacokinetics of risperidone. However, in 2 patients sertraline was increased to 150 mg daily by week 8, and in these patients the risperidone levels were increased by 36% and 52%, respectively. No significant adverse effects were reported in any of the patients.[18]

Mechanism

Fluoxetine and paroxetine inhibit the cytochrome P450 isoenzyme CYP2D6 by which risperidone is metabolised. Concurrent use therefore decreases risperidone metabolism, and its levels rise. This can lead to extrapyramidal adverse effects and, it has been suggested, the increased prolactin levels and gynaecomastia seen in one patient.[5] Sertraline is thought to have a dose-dependent effect on CYP2D6 inhibition,[18] but the effects are modest, even in high dose.

Many of the other reactions (sedation, urinary retention, priapism) appear to be a result of additive adverse effects of the SSRIs and risperidone. Serotonin syndrome can result when two drugs with serotonin effects are given together, see 'Additive or synergistic interactions', (p.9).

Importance and management

The elevated risperidone levels seen with fluoxetine and paroxetine appear to be well-documented and clinically significant. Concurrent use should be well monitored and the risperidone dose reduced accordingly: a one-third reduction has been suggested with fluoxetine.[4]

The other SSRIs have less effect on CYP2D6 than fluoxetine and paroxetine and would therefore not be expected to have an effect, or only modest effects, on risperidone levels; this is borne out by the studies with citalopram (no effect), fluvoxamine (modest increase with high dose fluvoxamine) and sertraline (modest increase with high dose sertraline). It would therefore seem prudent to bear a possible interaction in mind if risperidone adverse effects (e.g. agitation, insomnia, headache) occur.

The case reports of the serotonin syndrome appear to be rare, but they should be borne in mind when prescribing SSRIs and risperidone together. See 'serotonin syndrome', (p.9), for more information about managing this adverse effect.

Risperidone + Tetracycline

A patient taking risperidone and sertraline experienced a worsening of his tics when tetracycline was added.

Clinical evidence, mechanism, importance and management

A 15-year-old boy taking risperidone 1.5 mg twice daily and sertraline 100 mg daily was given tetracycline 250 mg twice daily. His tics worsened, and did not respond to an increase in his sertraline dosage from 100 to 150 mg daily. After stopping the tetracycline, his tics improved within a few weeks. The exact mechanism of this interaction is unclear, but it has been suggested that the tetracycline somehow reduced the activity of the risperidone. Induction of CYP2D6 by tetracycline was thought unlikely: inactivation of the risperidone or its active metabolite was considered a possible explanation.[1] This appears to be the only reported case of this interaction and its general significance is unknown.

1. Steele M, Couturier J. A possible tetracycline-risperidone-sertraline interaction in an adolescent. *Can J Clin Pharmacol* (1999) 6, 15–17.

Risperidone + Topiramate

Topiramate does not affect the plasma levels of risperidone.

Clinical evidence, mechanism, importance and management

In a study, 9 patients taking long-term clozapine 3 to 6 mg daily were given topiramate in a dose that was increased gradually to 200 mg daily. The plasma levels of risperidone and its metabolite 9-hydroxyrisperidone were not significantly affected by topiramate and the combination was well tolerated.[1]

1. Migliardi G, D'Arrigo C, Santoro V, Bruno A, Cortese L, Campolo D, Cacciola M, Spina E. Effect of topiramate on plasma concentrations of clozapine, olanzapine, risperidone, and quetiapine in patients with psychotic disorders. *Clin Neuropharmacol* (2007) 30, 107–13.

Risperidone + Tricyclic and related antidepressants

Amitriptyline and mirtazapine do not appear to affect the pharmacokinetics of risperidone, and limited evidence suggests that risperidone does not affect the pharmacokinetics of mirtazapine. Risperidone appears to increase the plasma levels of maprotiline. Extrapyramidal reactions have been reported in one patient taking amitriptyline with risperidone.

Clinical evidence, mechanism, importance and management

(a) Amitriptyline

A study in 12 schizophrenic patients found that amitriptyline 50 to 100 mg daily had no effect on the serum levels of risperidone 3 mg twice daily.[1] However, a 26-year-old man taking amitriptyline 25 mg daily developed extrapyramidal reactions after his dosage of risperidone was increased from 2 to 4 mg daily.[2] On another occasion extrapyramidal adverse effects developed after risperidone 2 mg daily was added to treatment with amitriptyline 25 mg and fluoxetine 20 mg daily.[2] Both pharmacokinetic and pharmacodynamic reasons for this reaction have been suggested.[3] The cases illustrate that there is the potential for an adverse interaction, which should be borne in mind when prescribing both drugs.

(b) Maprotiline

A 39-year-old patient with a schizodepressive disorder taking pipamperone and lorazepam, and also taking maprotiline 175 mg daily for a severe depressive episode, had plasma levels of maprotiline of 145 nanograms/mL and 166 nanograms/mL after 4 and 6 weeks, respectively. After 8 weeks, she was given risperidone to treat acute psychotic symptoms. The dose of risperidone was titrated over 5 days up to 5 mg daily and the dose of pipamperone was increased from 40 to 80 mg at night. She had a rapid remission of the psychotic symptoms and almost complete remission of the depression, but gradually developed antimuscarinic adverse effects. Ten days after starting risperidone and with maprotiline at a slightly lower dose of 150 mg daily, maprotiline plasma levels had increased to 266 nanograms/mL. The doses of maprotiline and risperidone were reduced to 100 mg and 3 mg daily, respectively, and this reduced the severity of the adverse effects.[4]

Two other patients have been reported to have gradual increases in maprotiline levels over 6 to 7 weeks during the concurrent use of risperidone. One of the patients was also taking **nortriptyline**, but its levels were unaltered.[4]

This interaction is unconfirmed but be aware of the possibility of an interaction if maprotiline adverse effects are troublesome.

(c) Mirtazapine

A pilot study in 6 psychiatric patients taking risperidone 1 to 3 mg twice daily for 1 to 4 weeks followed by 2 to 4 weeks of combined treatment with mirtazapine 15 to 30 mg at night, found that mirtazapine did not affect the plasma levels of risperidone or its 9-hydroxy metabolite. Data from another patient suggest that giving risperidone with mirtazapine does not result in clinically relevant changes in the plasma levels of mirtazapine. Concurrent use did not appear to increase the incidence of adverse effects, but the number of patients was limited.[5] Similarly, a later study in 8 patients taking risperidone in doses ranging from 3 to 8 mg daily found no significant change in the pharmacokinetics of risperidone and its metabolite, 9-hydroxyrisperidone when they were also given mirtazapine 30 mg daily.[6]

Risperidone + Valproate

There are case reports describing oedema in patients taking risperidone and valproate. Valproate appears not to affect the metabolism of risperidone. Studies suggest that risperidone does not alter the pharmacokinetics of valproate, although cases of increased and decreased levels have been reported.

Clinical evidence, mechanism, importance and management

A study comparing 10 patients taking **sodium valproate** and risperidone with 23 patients taking risperidone alone found no significant difference in the levels of risperidone and its metabolite, 9-hydroxyrisperidone, between the two groups, suggesting that **sodium valproate** does not affect risperidone pharmacokinetics.[1] Similarly, in a study in 12 patients with schizophrenia given **valproic acid** 400 to 800 mg daily and risperidone 2 to 6 mg daily, **valproic acid** did not affect plasma levels of risperidone or 9-hydroxyrisperidone.[2]

The effect of risperidone on valproate levels has also been studied. A study in 21 patients with bipolar disorder who were given **valproate semisodium** (**divalproex sodium**) 1 g daily with risperidone 2 mg daily for 2 days increasing to 4 mg daily for 12 days found no significant changes in the pharmacokinetics of valproate. Adverse effects were unaltered.[3] However, the valproate levels of a 10-year-old boy increased from 143 micrograms/mL to 191 micrograms/mL 5 days after he started to take risperidone (initially 2 mg daily, then later 3 mg daily). This was attributed to an interaction, the exact mechanism of which is unclear.[4,5] Conversely, a 15-year-old girl experienced a *reduction* in her valproate levels, from 80 micrograms/mL to 57 micrograms/mL when risperidone 1 mg three times daily was added to established treatment with **valproic acid**.[6] Another case report describes the development of generalised acute oedema in a schizophrenic patient when risperidone (titrated to 10 mg daily) was added to established **sodium valproate** treatment. The oedema was unresponsive to diuretics, but resolved when the risperidone dose was reduced to 2 mg. When the risperidone dose was later increased to 8 mg the oedema reappeared, so the risperidone was withdrawn.[7] A second case of oedema has been reported in a 35-year-old man who had taken **valproate semisodium** uneventfully for over 6 years. After taking risperidone for two-and-a-half weeks, significant oedema developed, which responded to treatment with hydrochlorothiazide and triamterene.[8] Note that both drugs can cause oedema alone.[9,10]

In general the data seem to suggest that no special precautions are necessary if valproate and risperidone are given together, but it is worth bearing these cases in mind in the event of oedema, or otherwise unexpected changes in valproate levels.

Risperidone + Venlafaxine

No clinically relevant pharmacokinetic interaction appears to occur between risperidone and venlafaxine.

Clinical evidence, mechanism, importance and management

In a study in 30 healthy subjects, steady-state venlafaxine 75 mg every 12 hours was found to increase the AUC of a single 1-mg oral dose of risperidone by about 32%, but the pharmacokinetic profile of the risperidone plus its active metabolite (9-hydroxyrisperidone) was not significantly changed, nor were any adverse events seen.[1]

The modest effects on risperidone levels are not expected to be clinically significant, and therefore the dose of risperidone does not need adjusting if venlafaxine is given.

1. Amchin J, Zarycranski W, Taylor KP, Albano D, Klockowski PM. Effect of venlafaxine on the pharmacokinetics of risperidone. *J Clin Pharmacol* (1999) 39, 297–309.

Ritanserin + Miscellaneous

Ritanserin does not interact with alcohol, and cimetidine and ranitidine do not affect ritanserin pharmacokinetics to a clinically relevant extent.

Clinical evidence, mechanism, importance and management

A study in 20 healthy subjects given ritanserin 10 mg with and without **alcohol** 0.5 g/kg found no pharmacokinetic or pharmacodynamic interactions between these drugs.[1] **Cimetidine** 800 mg daily or **ranitidine** 300 mg daily given to 9 healthy subjects for 11 days caused only small changes in the pharmacokinetics of a single 10-mg dose of ritanserin given on day 3. These changes were attributed to altered absorption,[2] but were of little or no clinical significance.

Sertindole + Miscellaneous

Erythromycin, a CYP3A4 inhibitor, increases sertindole levels, which increases the risk of QT prolongation. Other CYP3A4 inhibitors are predicted to interact similarly. Fluoxetine and paroxetine also increase sertindole levels. Carbamazepine, phenobarbital, phenytoin and rifampicin (rifampin), CYP3A4 inducers, reduce plasma sertindole levels. No clinically relevant interactions occur between sertindole and alprazolam, antacids, food or tobacco smoking.

Clinical evidence, mechanism, importance and management

(a) Antacids or Food

In a study in 16 healthy subjects, a standardised breakfast or *Maalox* [**aluminium/magnesium hydroxide**] 45 mL had no significant effect on the AUC of a single 4-mg dose of sertindole, and only minor and unimportant changes occurred in maximum serum levels.[1,2] No special precautions are needed if sertindole is given with *Maalox*, and it may be given without regard to meals.

(b) Benzodiazepines

A pharmacokinetic study in 14 healthy subjects found only minor changes in pharmacokinetics of a single 1-mg dose of **alprazolam** in the presence of sertindole 12 mg daily. The changes were considered to be clinically unimportant.[3]

(c) CYP3A4 inducers

The metabolism of sertindole is markedly increased by enzyme inducers, such as **rifampicin** (**rifampin**), **phenobarbital**, **phenytoin** and **carbamazepine**, and plasma sertindole levels may be reduced by two- to threefold. The manufacturers therefore say that the daily dose of sertindole may need to be increased towards the upper end of the maximum dose range to accommodate this interaction.[4,5]

(d) CYP3A4 inhibitors

In a study, 10 healthy subjects were given a single 4-mg dose of sertindole before and after they took **erythromycin** 250 mg every 6 hours for 10 days. The mean maximum serum levels of sertindole were increased by 15%, but this was not considered to be clinically significant. However, the incidence of adverse effects rose (diarrhoea, abdominal pain, dizziness), although no ECG changes were seen.[6,7] Nevertheless the manufacturers contraindicate **erythromycin** because raised sertindole levels may prolong the QT interval,[4] which can lead to life-threatening arrhythmias. For more information on QT interval prolongation, see 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290.

Erythromycin probably increases sertindole levels by inhibiting its metabolism by the cytochrome P450 isoenzyme CYP3A4. The manufactur-

ers of sertindole reasonably predict that other CYP3A4 inhibitors will interact similarly. They name **clarithromycin**, **indinavir**, **itraconazole**, **ketoconazole**, **diltiazem**, **verapamil**, and **cimetidine**, and contraindicate the use of these drugs with sertindole. Note that in one study **diltiazem**, **nifedipine** and **verapamil** resulted in a 20% reduction in the sertindole clearance.[5]

This list is not inclusive and other drugs may also reduce sertindole metabolism. For example, the manufacturer of **miconazole oral gel** contraindicates its use with sertindole.[8] For a list of CYP3A4 inhibitors, see 'Table 1.4', (p.6).

(e) Drugs that prolong the QT interval

In a study, 14 healthy subjects were given sertindole 20 mg daily for 5 days followed by a single 120-mg dose of **terfenadine**. The pharmacokinetics of neither drug was significantly changed, nor that of the metabolite of **terfenadine** (carboxyterfenadine), although it was concluded that sertindole may be a modest inhibitor of the first pass metabolism of **terfenadine**.[9,10] However, it was found that the combination caused an additive increase of 49 milliseconds in the QTc interval and therefore these two drugs are contraindicated by the manufacturer.[4] Other drugs may prolong the QT interval, and the manufacturers contraindicate their concurrent use. They specifically name **astemizole**, **terfenadine**, class Ia antiarrhythmics (**quinidine**), class III antiarrhythmics (**amiodarone**, **dofetilide**, **sotalol**), **erythromycin**, **gatifloxacin**, **cisapride**, **lithium**, **thioridazine**, and **moxifloxacin**.

See also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290, for a further list of QT-prolonging drugs.

(f) SSRIs

Fluoxetine and **paroxetine** are inhibitors of the cytochrome P450 isoenzyme CYP2D6. Concurrent use results in a two- to three-fold increase in sertindole plasma levels. The manufacturers advise that low maintenance doses of sertindole may be needed and recommend close ECG monitoring when doses are adjusted.[4] An isolated case report describes a man with paranoid psychosis and unipolar depression whose condition unexpectedly seriously worsened when **paroxetine** was stopped while continuing to take sertindole.[11]

(g) Tobacco

The clearance of sertindole is increased by tobacco smoking (probably because of the induction of cytochrome P450 isoenzymes) but no sertindole dosage alteration is thought necessary.[5]

Sulpiride + Miscellaneous

Sucralfate and an aluminium/magnesium hydroxide antacid can reduce the absorption of sulpiride. An isolated case describes extrapyramidal adverse effects in a patient taking sulpiride and fluoxetine.

Clinical evidence, mechanism, importance and management

(a) Antacids and Sucralfate

A study in 6 healthy subjects found that the bioavailability of a single 100-mg dose of sulpiride was reduced by 40% by **sucralfate** 1 g and by 32% by 30 mL of *Simeco* (**aluminium**/**magnesium hydroxide** and **simeticone**). When either the **sucralfate** or the antacid were taken 2 hours before sulpiride the reduction in bioavailability was only about 25%, and no change in bioavailability was seen in one subject when the **sucralfate** was given 2 hours after the sulpiride.[1]

The mechanism by which antacids reduce sulpiride absorption has not been established, but it seems possible that sulpiride becomes adsorbed onto the antacid, reducing the amount available for absorption.

Information about an interaction between sulpiride and antacids appears to be limited to this one study, which did not establish the clinical relevance of the effect found. With other antacid interactions, separating the doses by as much as possible (1 to 2 hours) to avoid admixture in the gut usually minimises any effects. It may be prudent to consider separating dosing if sulpiride seems less effective in a patient taking an antacid.

(b) Fluoxetine

Parkinson-like symptoms developed in a patient taking sulpiride and maprotiline when fluoxetine was also given.[2] This isolated case of extrapyramidal adverse effects should not prevent concurrent use; however, if extrapyramidal effects become troublesome bear this interaction in mind as a possible cause.

Tiotixene + Miscellaneous

Tiotixene levels are reduced by the enzyme-inducers carbamazepine, phenytoin, primidone and tobacco smoke. Enzyme inhibitors may reduce the clearance of tiotixene. Paroxetine does not alter tiotixene levels.

Clinical evidence, mechanism, importance and management

(a) Antiepileptics, enzyme-inducing

A retrospective study in 42 patients found that the mean clearance of tiotixene in those taking liver enzyme inducer drugs (**carbamazepine**, **phenytoin**, **primidone**) was threefold greater than in the control group. Of the group taking enzyme inducers, 5 patients had non-detectable serum tiotixene levels, and not surprisingly showed no clinical response.[1] It may be necessary to increase the tiotixene dosage if any of these antiepileptics is also given. Remember too that if the antiepileptics are withdrawn it may be necessary to reduce the tiotixene dose.

(b) Paroxetine

A study in 10 healthy subjects found that paroxetine 20 mg daily for 3 days did not significantly affect the pharmacokinetics of a single 20-mg dose of tiotixene. It was suggested that CYP2D6 is not the main isoenzyme involved in the metabolism and clearance of tiotixene.[2]

(c) Tobacco

Tobacco smoking increased the clearance of tiotixene in patients taking enzyme inhibitors or no other drugs, but not in patients taking enzyme inducers. Those who smoked were found to need on average 45% more tiotixene than the non-smokers taking no other interacting drugs.[1]

(d) Other drugs

A group of patients taking **cimetidine**, **doxepin**, **isoniazid**, **nortriptyline**, or **propranolol** had a tiotixene clearance of 9.51 L/minute, which was 71% less than that seen in patients taking tiotixene alone.[1] It was suggested that these drugs inhibited the metabolism of tiotixene, thereby reducing its clearance. It is unclear whether this reduction in clearance significantly increases tiotixene levels, and therefore the clinical relevance of this finding is unclear. However, a case report describes adverse effects in a patient

taking tiotixene and chlorpromazine with **propranolol**, see 'Beta blockers + Phenothiazines', p.1014.

Trifluoperazine + Venlafaxine

An isolated case report describes neuroleptic malignant syndrome in a patient taking trifluoperazine, which developed after he took a single dose of venlafaxine. It was also suggested that the symptoms may have been due to the serotonin syndrome.
106 Clinical evidence, mechanism, importance and management

A patient who had taken trifluoperazine 1 mg three times daily for 10 years was also given venlafaxine 75 mg daily. Twelve hours after the first dose of venlafaxine he presented with profound anxiety, malaise, profuse sweating, tremor and rigidity. His blood pressure was found to fluctuate between 130/80 and 165/100 mmHg, with a pulse of 163 bpm, a temperature of 38.3°C, and a respiratory rate of 25 breaths/minute. Blood and urine tests were normal except for a high creatine phosphokinase concentration and neutrophilia. The drugs were stopped and the patient recovered after taking a single 70-mg dose of dantrolene and bromocriptine 15 mg twice daily for 48 hours.

It was suggested that the patient had developed neuroleptic malignant syndrome, which may have occurred as a result of dopamine inhibition by the two drugs.[1] It was subsequently suggested that the symptoms seen may have been due to 'serotonin syndrome', (p.9), resulting from serotonergic over-activity when the single dose of venlafaxine was added to established treatment with trifluoperazine.[2]

Ziprasidone + Carbamazepine

Carbamazepine does not appear to affect the pharmacokinetics of ziprasidone.

Clinical evidence, mechanism, importance and management

In a randomised study, healthy subjects were given ziprasidone 20 mg twice daily with either placebo (10 subjects), or carbamazepine 200 mg twice daily (9 subjects) for 5 doses. It was found that carbamazepine reduced the AUC and maximum serum levels of ziprasidone by 36% and 27%, respectively.[1]

Carbamazepine, a known, potent inducer of the cytochrome P450 isoenzyme CYP3A4 probably increased the metabolism of ziprasidone by this pathway, resulting in the reduction in ziprasidone levels seen. However, this reduction is modest, and not expected to be clinically significant. Therefore no ziprasidone dose adjustment would seem to be necessary if carbamazepine is also given.

1. Miceli JJ, Anziano RJ, Robarge L, Hansen RA. Laurent A. The effect of carbamazepine on the steady-state pharmacokinetics of ziprasidone in healthy volunteers. *Br J Clin Pharmacol* (2000) 49 (Suppl 1), 65S–70S.

Ziprasidone + Ketoconazole

Ketoconazole moderately increases ziprasidone levels.

Clinical evidence, mechanism, importance and management

In a randomised, placebo-controlled study, 14 healthy subjects were given a 40-mg dose of ziprasidone before and after taking ketoconazole 400 mg daily for 6 days. It was found that ketoconazole increased the AUC and maximum serum levels of ziprasidone by 33% and 34%, respectively. This modest rise in levels probably occurs because ketoconazole inhibits the cytochrome P450 isoenzyme CYP3A4 by which ziprasidone is metabolised. However, it was concluded that the increase is not clinically relevant.[1] No ziprasidone dose adjustments would therefore seem to be needed on concurrent use.

1. Miceli JJ, Smith M, Robarge L, Morse T, Laurent A. The effects of ketoconazole on ziprasidone pharmacokinetics – a placebo-controlled crossover study in healthy volunteers. *Br J Clin Pharmacol* (2000) 49 (Suppl 1), 71S–76S.

Ziprasidone + Miscellaneous

The manufacturers warn of the possible risks of giving ziprasidone with drugs that prolong the QT interval. Ziprasidone may enhance the effects of antihypertensive drugs. Ziprasidone appears not to interact to a clinically relevant extent with an aluminium/magnesium hydroxide antacid, benzatropine, cimetidine, dextromethorphan, lorazepam, propranolol or tobacco smoking.

Clinical evidence, mechanism, importance and management

(a) Antacids or Cimetidine

A single 40-mg oral dose of ziprasidone were given to 10 healthy subjects either alone, with cimetidine 800 mg daily for 2 days, or with three 30-mL doses of ***Maalox*** **(aluminium/magnesium hydroxide)**. The only change in the pharmacokinetics of ziprasidone was a 6% increase in the AUC with cimetidine. It was concluded that no special precautions are needed if either of these drugs and ziprasidone are given concurrently.[1]

(b) Antihypertensives

The manufacturers note that because ziprasidone may cause hypotension, it may enhance the effects of certain antihypertensive drugs.[2]

(c) Dextromethorphan

In a single-dose study in 8 healthy subjects, ziprasidone 80 mg did not affect the pharmacokinetics of dextromethorphan 30 mg, taken 2 hours later. This suggests that the dose of dextromethorphan does not need to be adjusted if ziprasidone is also given. Furthermore, dextromethorphan is used as a probe substrate for the cytochrome P450 isoenzyme CYP2D6, and therefore this study also suggests that ziprasidone is unlikely to affect the pharmacokinetics of other CYP2D6 substrates.[3] For a list of CYP2D6 substrates, see 'Table 1.3', (p.6).

(d) Drugs that prolong the QT interval

Studies in healthy subjects found that ziprasidone 160 mg increased the QTc interval by about 10 milliseconds. While only a relatively moderate increase in the QT interval actually occurs with ziprasidone, because of the possibility of additive effects with some other drugs (and the attendant risk of torsade de pointes), to be on the safe side the manufacturer of ziprasidone contraindicates its use with other drugs that can prolong the QT interval.[2] For a list of QT-prolonging drugs, see 'Table 9.2', (p.290).

A case report describes a 70-year-old man who took **quetiapine** and ziprasidone and who developed cardiac arrhythmias with extrasystoles, and a prolonged QTc interval of 482 milliseconds, an increase of 65 milliseconds from his value with **quetiapine** alone. On stopping **quetiapine** and reducing the dose of ziprasidone, his QTc interval normalised.[4]

(e) Tobacco

The manufacturer of ziprasidone suggests that as ziprasidone is not metabolised by the cytochrome P450 isoenzyme CYP1A2, smoking should not affect its pharmacokinetics. This is borne out by studies in patients, which did not reveal any differences in the pharmacokinetics of ziprasidone between **tobacco smokers** and non-smokers.[2]

(f) Other drugs

The manufacturer of ziprasidone states that population pharmacokinetic analysis of schizophrenic patients who were enrolled in clinical studies showed that no significant pharmacokinetic interactions occurred with **benzatropine**, **lorazepam** or **propranolol**.[2]

4. Minov C. QTc-Zeitverlängerung unter ziprasidon in kombination mit quetiapin. *Psychiatr Prax* (2004) 31, S142–4.

Zopiclone + Gemfibrozil

Gemfibrozil does not increase zopiclone levels, but the levels of its two major metabolites may be slightly increased.

Clinical evidence, mechanism, importance and management

A placebo-controlled, crossover study in 10 healthy subjects found that gemfibrozil 600 mg twice daily for 3 days did not affect the pharmacokinetics of a single 7.5-mg oral dose of zopiclone. However, the AUCs of its two major metabolites, *N*-oxide zopiclone and *N*-desmethylzopiclone, were raised twofold and by 20%, respectively; these metabolites may have some, but weaker pharmacological activity than zopiclone. It appears that gemfibrozil, which is a potent CYP2C8 inhibitor, does not significantly affect the metabolism of zopiclone, but it may affect the further metabolism of its major metabolites. Although the pharmacodynamic effects of zopiclone, such as drowsiness, were not affected by gemfibrozil, it was suggested that, due to the increased levels of the metabolites, slightly enhanced effects could not be excluded.[1]

1. Tornio A, Neuvonen PJ, Backman JT. The CYP2C8 inhibitor gemfibrozil does not increase the plasma concentrations of zopiclone. *Eur J Clin Pharmacol* (2006) 62, 645–51.

Zotepine + Miscellaneous

There appears to be little or no information about adverse interactions between zotepine and other drugs, but the manufacturers warn about the concurrent use of antihypertensives, anaesthetics, antipsychotics, and drugs that prolong the QTc interval. Two cases of deep vein thrombosis have been reported in patients taking zotepine with paroxetine. Some benzodiazepines and fluoxetine may increase plasma levels of zotepine. Two cases of hypothermia have been reported in patients taking benzodiazepines, valproate and zotepine when the dose of zotepine was increased. The pharmacokinetics of zotepine appear not to be affected by tobacco smoking.

Clinical evidence, mechanism, importance and management

(a) Antihypertensives

Zotepine has alpha-adrenergic blocking properties, which may cause orthostatic hypotension, especially when treatment is first started or if the dose is increased. The manufacturers advise caution when it is given with hypotensive agents, including some **anaesthetics**, the implication being that any orthostatic hypotension may possibly be worsened. If patients feel faint and dizzy when they stand up, they should be advised to get up more slowly, and if necessary, a smaller dose should be used.[1]

(b) Antimuscarinics

Biperiden 6 mg daily for 2 weeks was found not to affect the pharmacokinetics of zotepine in a study in 21 patients.[2]

(c) Antipsychotics

The manufacturer of zotepine points out that, as with some other antipsychotics, zotepine has clear pro-convulsive effects, which may be additive with other antipsychotics, particularly if high doses of either or both drugs are used. They therefore recommend that zotepine doses above 300 mg daily or the concurrent use of high doses of other antipsychotics should be avoided.[1]

(d) Benzodiazepines

A study in 17 patients found that plasma zotepine levels were higher and its elimination half-life prolonged by **diazepam**.[3] The manufacturer reports that in a clinical interaction study, **diazepam** increased the plasma levels of zotepine by about 25%, and that norzotepine levels are also increased. They advise caution if diazepam and zotepine are given concurrently.[1]

A patient who was taking zotepine 50 mg daily, **valproate** 1 g daily and **lormetazepam** 2 mg daily, had his dose of zotepine increased gradually to 200 mg daily because of persistent auditory hallucinations. The **valproate** and **lormetazepam** doses were not altered. Four weeks later he presented with poor appetite, dizziness and a low body temperature (34.8°C). The dose of zotepine was reduced and his temperature increased to 36°C. The authors reported another case of hypothermia, in a patient taking **clonazepam**, **valproic acid** and zotepine. The patient's temperature became normal when the dose of zotepine was reduced from 200 mg to 150 mg, and fell when the dose was increased to 200 mg. It was suggested that zotepine may decrease body temperature by chronic suppression of 5-HT transmission and by increasing the rate of metabolism of dopamine and noradrenaline. Further, the cytochrome P450 isoenzyme CYP3A4-mediated metabolism of zotepine may be inhibited by benzodiazepines resulting in higher zotepine levels and a greater effect on body temperature. **Valproate** may also lower body temperature in a dose dependent manner and so it is possible that the combination of three drugs in each of the patients contributed to the observed hypothermia.[4]

(e) Desipramine

No pharmacokinetic interaction was seen when zotepine was given with desipramine.[1]

(f) Drugs that prolong the QT interval

The manufacturer of zotepine advises caution if it is given with drugs known to prolong the QTc interval because zotepine also shows a dose-related QTc interval prolongation,[1] the implication being that the effects may be additive. See also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290.

(g) SSRIs

Two case reports have described mobile, elderly male patients who developed deep vein thrombosis when taking **paroxetine** and zotepine. In the first case the patient was taking **paroxetine** 40 mg daily, and zotepine was added to his treatment 3 weeks later, initially at a dose of 75 mg daily, then increased to 150 mg daily. After 17 days of treatment with zotepine 150 mg daily the patient developed significant swelling of the right leg, and a deep vein thrombosis was diagnosed by Doppler studies and venography. The second patient also received **paroxetine** 40 mg daily to which zotepine 150 mg daily was added, and within 3 days of starting zotepine, the patient had developed painful swelling of the right calf, dyspnoea and tachycardia. A deep vein thrombosis was confirmed. They were part of a review of 150 patients consecutively admitted to a psychiatric ward. They were the only two patients who received this combination of drugs, and the only two who developed a thromboembolism. The mechanism of this interaction is unclear.[5]

In a clinical interaction study, **fluoxetine** increased the plasma concentrations of zotepine by about 10% and approximately doubled those of norzotepine. The manufacturer advises caution if they are given concurrently.[1]

(h) Tobacco

A study in healthy subjects found that there were no significant differences in the pharmacokinetics of zotepine in smokers (8 subjects) and non-smokers (6 subjects).[3]

21

Antivirals

This section is concerned with the drugs used to treat viral infections, including hepatitis, herpes, influenza, and HIV infection. These drugs may be grouped by the viral infections they are used to treat, and also by drug class (see 'Table 21.1', (p.914)). Where antivirals affect other drugs the interactions are generally covered elsewhere.

Antivirals active against herpes and hepatitis

Nucleoside and nucleotide analogues

The nucleoside analogues are principally eliminated unchanged by the kidneys by a process of active tubular secretion as well as glomerular filtration. The few interactions with these drugs mainly involve altered renal clearance (e.g. probenecid), but since they have a wide therapeutic range, even these interactions are of debatable clinical relevance. Cytochrome P450-mediated interactions are not important for this group of drugs. However, the possibility of effects on other transport systems cannot be ruled out at present, see 'Adefovir + Miscellaneous', p.916.

Antiretrovirals active against HIV

Treatment of HIV infection commonly requires a combination of 3 to 4 antiretrovirals, termed highly active antiretroviral therapy (HAART). In addition, patients often receive a large number of other drugs for comorbid conditions. This markedly increases the risk of drug interactions and complicates their assessment.

(a) CCR5 antagonists

CCR5 antagonists are a class of antiretrovirals referred to as entry inhibitors. Maraviroc is a substrate of CYP3A4 and because of this, CYP3A4 inducers (e.g. efavirenz) lower its levels and CYP3A4 inhibitors (e.g. protease inhibitors) increase its levels. Maraviroc is not expected to have a clinically relevant effect on most cytochrome P450 isoenzymes, although it may possibly inhibit intestinal P-glycoprotein.

(b) Fusion inhibitors

The fusion inhibitor, enfuvirtide, is a peptide. It does not cause cytochrome P450-mediated drug interactions, and is not affected by potent inducers or inhibitors of cytochrome P450 isoenzymes. However, modest interactions, the underlying mechanism of which is unknown, have been reported with some of the 'protease inhibitors', (p.918), such as ritonavir and tipranavir.

(c) Integrase inhibitors

Raltegravir, one of the first integrase inhibitors to be licensed, is metabolised by glucuronidation (primarily by UGT1A1). Hence, drugs that inhibit ('atazanavir', (p.991)) or induce ('rifampicin (rifampin)', (p.990)) this enzyme may affect the metabolism of raltegravir. Raltegravir is not a substrate for cytochrome P450 isoenzymes, and raltegravir does not appear to inhibit or induce many of the major cytochrome P450 isoenzymes, nor does it inhibit P-glycoprotein. However, it appears that drugs that affect gastric pH may also affect the levels of raltegravir, see 'Raltegravir + Miscellaneous', p.990, for further discussion.

(d) Non-nucleoside reverse transcriptase inhibitors (NNRTIs)

The NNRTIs are extensively metabolised by the cytochrome P450 isoenzyme system, particularly by CYP3A4. They are also inducers (nevirapine, efavirenz, and to a lesser degree, etravirine) or inhibitors (delavirdine) of CYP3A4. NNRTIs would therefore be expected to interact with each other, and with the protease inhibitors, but not with NRTIs (see below). They also have the potential to interact with other drugs metabolised by CYP3A4, and are affected by CYP3A4 inhibitors and inducers. Delavirdine and efavirenz may also inhibit some other P450 isoenzymes: etravirine is also a weak inhibitor of some P450 isoenzymes. For a summary of these effects, see 'Table 21.2', (p.914).

(e) Nucleoside reverse transcriptase inhibitors (NRTIs)

NRTIs are prodrugs, which need to be activated by phosphorylation within cells to a triphosphate anabolite. Drugs may therefore interact with NRTIs by increasing or decreasing intracellular activation. NRTIs may also interact with each other by this mechanism. This interaction mechanism is studied *in vitro*, and clinical data are often not available, or the clinical relevance is unclear. Nevertheless, it is generally recommended that drugs inhibiting the intracellular activation of NRTIs are not used concurrently (e.g. 'doxorubicin and stavudine', (p.959), or 'zidovudine and stavudine', (p.950)). 'Hydroxycarbamide', (p.949), may increase the intracellular activation of NRTIs.

NRTIs are water soluble, and are mainly eliminated by the kidneys (didanosine, lamivudine, stavudine, and zalcitabine) or undergo hepatic glucuronidation (abacavir, zidovudine). The few important interactions with these drugs primarily involve altered renal clearance. For zidovudine (and possibly abacavir) some interactions are reported to occur via altered glucuronidation, but the clinical relevance of these are less clear (e.g. 'rifampicin (rifampin)', (p.942)). Cytochrome P450-mediated interactions are not important for this class of drugs.

Some of the didanosine preparations (e.g. chewable tablets) are formulated with antacid buffers that are intended to facilitate didanosine absorption by minimising acid-induced hydrolysis in the stomach. These preparations can therefore alter the absorption of other drugs that are affected by antacids (e.g. azole antifungals, quinolone antibacterials, tetracyclines). This interaction may be minimised by separating administration by at least 2 hours. Alternatively, the enteric-coated preparation of didanosine (gastro-resistant capsules) may be used.

(f) Protease inhibitors

The protease inhibitors are extensively metabolised by the cytochrome P450 isoenzyme system, particularly by CYP3A4. All of them inhibit CYP3A4, with ritonavir being the most potent inhibitor, followed by indinavir, nelfinavir, amprenavir, and saquinavir. The protease inhibitors therefore have the potential to interact with other drugs metabolised by CYP3A4, and are also affected by CYP3A4 inhibitors and inducers. Ritonavir and nelfinavir also affect some other cytochrome P450 isoenzymes, as summarised in 'Table 21.2', (p.914). Protease inhibitors therefore have the potential to interact with each other, and with NNRTIs, but are not likely to interact with NRTIs. In addition, protease inhibitors are substrates as well as inhibitors of P-glycoprotein.

The plasma level of protease inhibitors is thought to be critical in maintaining efficacy and minimising the potential for development of viral resistance. Therefore even modest reductions in levels are potentially clinically important.

Table 21.1 Classification of Antivirals

Group	*Drugs*
Antivirals for hepatitis viruses	
Nucleoside analogues	Entecavir, Lamivudine, Telbivudine
Nucleotide analogues	Adefovir, Tenofovir
Miscellaneous	Interferon alfa, Peginterferon alfa, Ribavirin
Antivirals for herpes viruses	
Guanine nucleoside analogues	Aciclovir, Famciclovir, Ganciclovir, Penciclovir, Valaciclovir, Valganciclovir
Other nucleoside analogues	Idoxuridine, Trifluridine, Vidarabine
Nucleotide analogues	Cidofovir, Fomivirsen
Miscellaneous	Foscarnet sodium, Inosine pranobex
Antivirals for HIV infection (antiretrovirals)	
CCR5 antagonists	Maraviroc
HIV-fusion inhibitors	Enfuvirtide
Non-nucleoside reverse transcriptase inhibitors (NNRTIs)	Delavirdine, Efavirenz, Etravirine, Nevirapine
Nucleoside reverse transcriptase inhibitors (NRTIs)	Abacavir, Didanosine, Emtricitabine, Lamivudine, Stavudine, Zalcitabine, Zidovudine
Nucleotide reverse transcriptase inhibitors	Tenofovir
Protease inhibitors	Amprenavir, Atazanavir, Darunavir, Fosamprenavir, Indinavir, Lopinavir, Nelfinavir, Ritonavir, Saquinavir, Tipranavir
Antivirals for influenza	
Neuraminidase inhibitors	Oseltamivir, Zanamivir
Others	Amantadine, Rimantadine

Table 21.2 Summary of the effect of the protease inhibitors and NNRTIs on cytochrome P450 isoenzymes

Antiviral	*Substrate*	*Inhibits*	*Induces*
Protease inhibitors			
Amprenavir or Fosamprenavir	CYP3A4	CYP3A4	
Atazanavir	CYP3A4	CYP3A4	
Darunavir	CYP3A4	CYP3A4	
Indinavir	CYP3A4	CYP3A4	
Lopinavir	CYP3A4	CYP3A4	
Nelfinavir	CYP3A4, CYP2C19, CYP2C9, CYP2D6	CYP3A4	
Ritonavir	CYP3A4, CYP2D6	CYP3A4, CYP2D6	CYP3A4
Saquinavir	CYP3A4	CYP3A4	
Tipranavir	CYP3A4	CYP3A4, CYP2D6	CYP3A4
NNRTIs (Non-nucleoside reverse transcriptase inhibitors)			
Delavirdine	CYP3A4, CYP2D6	CYP3A4, CYP2C9, CYP2D6, CYP2C19	
Efavirenz	CYP3A4, CYP2B6	CYP3A4, CYP2C9, CYP2C19	CYP3A4
Etravirine	CYP3A4, CYP2C9, CYP2C19	CYP2C9, CYP2C19	CYP3A4
Nevirapine	CYP3A4		CYP3A4

Antivirals active against influenza

The oral neuraminidase inhibitor oseltamivir is metabolised by esterases in the liver, and the carboxylate metabolites are then renally excreted. A clinically relevant interaction with other drugs that affect renal tubular excretion does not usually appear to occur, see 'Oseltamivir + Drugs that affect renal clearance', p.961. It is not metabolised by cytochrome P450 isoenzymes. Zanamivir, the inhaled influenza antiviral, is also not metabolised by the liver and is not protein bound, therefore it is not expected to be affected by any significant drug interactions.

Aciclovir and related drugs + Antacids

Valaciclovir does not interact with an aluminium/magnesium hydroxide antacid.

Clinical evidence, mechanism, importance and management

On three separate occasions, 18 healthy subjects were given a single 1-g oral dose of **valaciclovir**, either alone, 65 minutes before, or 30 minutes after they took 30 mL of *Maalox* (**aluminium**/**magnesium hydroxide**). The pharmacokinetics of aciclovir (the active metabolite of valaciclovir) remained unchanged. It was concluded that no special precautions are needed if these drugs are taken together, and the authors of the report also suggest that it is unlikely that other antacids will interact.[1]

1. de Bony F, Bidault R, Peck R, Posner J. Lack of interaction between valaciclovir, the L-valyl ester of acyclovir, and Maalox antacid. *J Antimicrob Chemother* (1996) 37, 383–7.

Aciclovir and related drugs + Cephalosporins

Retrospective data from children suggest that ceftriaxone might have increased the renal toxicity of intravenous aciclovir. Cefalexin does not appear to alter the absorption of valaciclovir to a clinically relevant extent.

Clinical evidence, mechanism, importance and management

(a) Cefalexin

In a single-dose, crossover study involving 16 healthy subjects, the concurrent use of cefalexin 500 mg and **valaciclovir** 500 mg caused only a minimal mean 7% reduction in the AUC of aciclovir (the metabolite of **valaciclovir**). However, this reduction was only seen if one subject who had an increase in aciclovir AUC was excluded from the analysis. Furthermore, there was considerable interindividual variability in the effects of cefalexin.

Both cefalexin and **valaciclovir** are substrates for human peptide transporter 1 (hPEPT1), and *in vitro* and *animal* data indicated that cefalexin might markedly reduce **valaciclovir** absorption.[1] However, the findings in this clinical study show a minimal interaction. No special precautions appear to be needed on concurrent use.

(b) Ceftriaxone

A retrospective analysis of 17 children who had received intravenous aciclovir and ceftriaxone for suspected meningo-encephalitis revealed that 12 children developed a significant increase in serum creatinine, and three of these developed acute renal failure. This rate of renal toxicity is higher than that seen with aciclovir alone, and was attributed to the concurrent use of ceftriaxone. The dose of aciclovir correlated with nephrotoxicity. The authors concluded that caution is required with the combination, and that renal function should be monitored if both drugs are needed.[2]

Aciclovir and related drugs + Cimetidine

Single-dose studies have found that cimetidine increases the AUC of aciclovir and valaciclovir. No clinically important interaction appears to occur if famciclovir is given with cimetidine.

Clinical evidence

(a) Aciclovir or Valaciclovir

Twelve healthy subjects were given a 1-g dose of valaciclovir alone or with cimetidine 800 mg, taken 10 hours and one hour earlier. The $AUC_{0\text{-}3}$ for the prodrug valaciclovir was increased by 73% by cimetidine, and the $AUC_{0\text{-}24}$ for the active metabolite of valaciclovir, aciclovir, was increased by 27%. The renal clearance of aciclovir was reduced by 22%, although the total urinary recovery of aciclovir was unchanged.[1]

(b) Famciclovir

In a study, 12 healthy subjects were given cimetidine 400 mg twice daily for 8 days with a single 500-mg dose of famciclovir, a prodrug for penciclovir, on the last day. The AUC of penciclovir was increased by about 18% by cimetidine, but there was no change in renal clearance.[2,3]

Mechanism

The increase in aciclovir AUC with cimetidine is attributable to a reduction in its renal excretion, probably due to competition for secretion by the kidney tubules.[1] When 'probenecid', (p.916), a competitor for renal tubular secretion, and cimetidine were both given the effects on aciclovir were greater than either drug alone.[1]

Importance and management

These interactions are established but, because aciclovir has such a wide therapeutic index,[4] the authors of the study suggest that its interaction with cimetidine is probably clinically unimportant.[1] It seems likely that no changes in the usual doses of aciclovir or valaciclovir will be needed in patients also taking cimetidine. However, the UK manufacturer states that caution is required with high doses of valaciclovir, and that alternatives to cimetidine could be considered in this situation.[4] No special precautions would seem necessary if cimetidine is used with famciclovir.

Aciclovir + Cytarabine

High-dose cytarabine reduces the bioavailability of oral, but not intravenous, aciclovir.

Clinical evidence, mechanism, importance and management

In a study, 5 patients given high-dose intravenous cytarabine 1.5 g/m^2 twice daily for 6 days were given a single 800-mg dose of oral aciclovir or a single 250-mg/m^2 dose of intravenous aciclovir one or 2 days before the start of the course of cytarabine, and again on either day 14 or 15. Cytarabine did not affect the bioavailability of intravenous aciclovir. However, cytarabine reduced the maximum serum levels of oral aciclovir by 43% and the absolute bioavailability of aciclovir was reduced by 38%. The clinical importance of this reduction is not known.[1] Until more is known bear the possibility of this interaction in mind should a reduced response occur in a patient taking oral aciclovir and given a course of cytarabine.

1. Sitar DS, Aoki FY, Bow EJ. Acyclovir bioavailability in patients with acute myelogenous leukemia treated with daunorubicin and cytarabine. J Clin Pharm (2008) 48, 995–8.

Aciclovir and related drugs + Hydrochlorothiazide

Hydrochlorothiazide does not affect the pharmacokinetics or safety profile of valaciclovir.

Clinical evidence, mechanism, importance and management

A study in a group of elderly subjects (65 to 83 years old) given **valaciclovir** 500 mg or 1 g, three times daily for 8 days, found that its safety profile was unchanged in the presence of hydrochlorothiazide, and was similar to that in young healthy subjects.[1] The pharmacokinetics of the active metabolite of **valaciclovir**, aciclovir, were not significantly different.[1] There would seem to be no reason for avoiding the concurrent use of either **valaciclovir** or aciclovir and hydrochlorothiazide.

1. Wang LH, Schultz M, Weller S, Smiley ML, Blum MR. Pharmacokinetics and safety of multiple-dose valaciclovir in geriatric volunteers with and without concomitant diuretic therapy. *Antimicrob Agents Chemother* (1996) 40, 80–5.

Aciclovir and related drugs + Probenecid

Probenecid reduces the renal excretion and increases the plasma levels of aciclovir, valaciclovir, and ganciclovir. Famciclovir and valganciclovir are predicted to interact similarly.

Clinical evidence

(a) Aciclovir or Valaciclovir

Twelve healthy subjects were given valaciclovir 1 g alone, or with probenecid 1 g, taken 2 hours earlier. Probenecid increased the $AUC_{0\text{-}3}$ for the prodrug valaciclovir by 22%, and the $AUC_{0\text{-}24}$ for its active metabolite, aciclovir, by 48%. The renal clearance of aciclovir was reduced by 33%, although the total urinary recovery of aciclovir was unchanged. The authors report that both drugs were well tolerated.[1] An earlier study had found that oral probenecid 1 g caused a similar increase in the AUC of intravenous aciclovir.[2]

(b) Ganciclovir

In a pharmacokinetic study, 11 HIV-positive patients were given probenecid 500 mg every 6 hours with oral ganciclovir 1 g every 8 hours. The AUC of ganciclovir was increased by 53%, and the renal clearance was reduced by 19% (10 subjects only) in the presence of probenecid.[3]

Mechanism

The increases in the AUCs of aciclovir and ganciclovir are attributable to a reduction in their renal excretion by probenecid, probably due to competition for secretion by the kidney tubules.[1,3] The effects on aciclovir of combining probenecid and *cimetidine*, which also affects the renal excretion of aciclovir, were greater than either drug alone, consider 'Aciclovir and related drugs + Cimetidine', p.915.

Importance and management

Although the information is limited to the studies above, the modest pharmacokinetic interaction between probenecid and aciclovir, valaciclovir and ganciclovir appears to be established. However, because aciclovir has such a wide therapeutic index, a clinically important interaction is not expected and it seems unlikely that a dose adjustment of aciclovir or valaciclovir will be needed in patients taking probenecid. However, the UK manufacturer states that caution is required with high doses of valaciclovir, and that alternatives to probenecid could be considered in this situation.[4]

It may be prudent to be alert for increased ganciclovir adverse effects and toxicity (such as diarrhoea, nausea, neutropenia and thrombocytopenia) if probenecid is used concurrently. **Valganciclovir** is a prodrug of ganciclovir, and the manufacturers recommend that patients taking valganciclovir with probenecid should be closely monitored for ganciclovir toxicity.[5,6]

The manufacturers of **famciclovir** suggest that a similar interaction might also occur with probenecid, resulting in an increase in the plasma levels of penciclovir (the active metabolite of famciclovir).[7,8]

Adefovir + Miscellaneous

No clinically significant interaction appears to occur between adefovir and co-trimoxazole, didanosine, ibuprofen, indinavir, lamivudine, or paracetamol. Adefovir appears to reduce delavirdine and saquinavir levels. No pharmacokinetic interaction occurs between tacrolimus and adefovir, however, additive nephrotoxicity may occur between adefovir and tacrolimus or ciclosporin. Drugs that affect renal function may theoretically reduce adefovir excretion.

Clinical evidence, mechanism, importance and management

(a) Antiretrovirals

In a population pharmacokinetic analysis, combination of **saquinavir** with adefovir appeared to result in a 49% increase in the clearance of saquinavir.[1] In a further pharmacokinetic study in 37 HIV-positive patients by the same group, **ritonavir-boosted saquinavir** was given with **delavirdine** or adefovir or both drugs, and **saquinavir** with **nelfinavir** was given with **delavirdine** or adefovir or both. The addition of adefovir to **ritonavir-boosted saquinavir** with delavirdine resulted in a 50% lower **saquinavir** concentration when compared to the regimen without adefovir. The concentration of **delavirdine** was reduced by about 50% in patients who also received adefovir. No difference in **delavirdine** concentrations occurred between the **ritonavir** and **nelfinavir**-containing regimens. The concentrations of **nelfinavir** and low-dose **ritonavir** were unchanged, and the AUC of adefovir was not significantly affected between the different treatment groups. The authors suggest that this reduction in **saquinavir** and **delavirdine** levels may possibly be due to induction of P-glycoprotein by adefovir. As this appears to have resulted in a reduced virological effect in the parent study (ACTG 359), the authors advise against the concurrent use of **delavirdine** and adefovir, and suggest that further study is needed.[2] It would be prudent to use similar caution if **ritonavir-boosted saquinavir** is given with adefovir until further information is available.

The US manufacturer reports that, in a study in 21 healthy subjects, there was no pharmacokinetic interaction between adefovir 10 mg once daily and enteric-coated **didanosine** 400 mg.[3] The concurrent use of adefovir 60 mg with **didanosine** buffered tablets increased the AUC of **didanosine** by 29%, which is not clinically relevant.[4] The manufacturers also note that, in a study in 18 subjects, there was no pharmacokinetic interaction between adefovir 10 mg once daily and **lamivudine** 100 mg daily.[3,4] See also *Lamivudine* and *Tenofovir*, below.

(b) Ciclosporin or Tacrolimus

In a study in 16 stable liver transplant patients taking tacrolimus 2 to 10 mg daily, adefovir 10 mg daily taken for 14 days had no significant effect on the pharmacokinetics of tacrolimus. Adefovir pharmacokinetics were also unaffected by tacrolimus, when compared with historical data. No significant changes in renal function were found during concurrent use in this short-term study.[5]

The UK manufacturer predicts that, as ciclosporin is metabolised by the same route as tacrolimus, a pharmacokinetic interaction between adefovir and ciclosporin is also unlikely. However, the US manufacturer states that the effect of adefovir on ciclosporin levels is unknown.[3] Both manufacturers[3,4] advise close monitoring if either tacrolimus or ciclosporin is given with adefovir as both drugs can cause nephrotoxicity, see below, *Drugs affecting renal function*.

(c) Drugs affecting renal function

The manufacturers advise caution with concurrent use of drugs that may affect renal function or cause nephrotoxicity and those that are renally excreted, as this may lead to an increase in adefovir levels. They specifically name intravenous **aminoglycosides**, **amphotericin B**, **ciclosporin**, **cidofovir**, **foscarnet**, **pentamidine**, **vancomycin**, and **tacrolimus**.[3,4] Note, however, that a study reported no pharmacokinetic interaction and no change in renal function with concurrent use of **tacrolimus** and adefovir, see above *(b) Ciclosporin or Tacrolimus*, above. The US manufacturers also list **NSAIDs**;[3] however, note that **ibuprofen** does not appear have a clinically relevant interaction with adefovir, see *Drugs undergoing, or affecting, tubular secretion*, below.

(d) Drugs undergoing, or affecting, tubular secretion

Adefovir is excreted by the kidneys, by a combination of glomerular filtration and active secretion via the renal transporter, human Organic Anion Transporter 1 (hOAT1). The potential for pharmacokinetic interactions with **cidofovir**, **co-trimoxazole**, **ibuprofen**, **lamivudine**, **paracetamol** and **tenofovir** (other drugs that also undergo, or may affect tubular secretion) has been investigated.[3,4]

1. Co-trimoxazole (Trimethoprim with Sulfamethoxazole). The manufacturers note that in a study in 18 healthy subjects, there was no pharmacokinetic interaction between adefovir 10 mg once daily and co-trimoxazole 960 mg twice daily.[3,4]

2. Ibuprofen. The concurrent use of adefovir 10 mg and ibuprofen 800 mg three times daily modestly increased the AUC and maximum level of adefovir by 23% and 33%, respectively. These changes were considered to be due to higher bioavailability rather than a reduction in renal clearance, and are not considered clinically relevant. Adefovir did not alter ibuprofen pharmacokinetics.[3,4] See also, *Drugs affecting renal function*, above.

3. Lamivudine. The manufacturers note that in a study in 18 healthy subjects, there was no pharmacokinetic interaction between adefovir 10 mg once daily and lamivudine 100 mg once daily.[3,4]

4. Paracetamol. The manufacturers note that in a study in 20 healthy subjects, there was no pharmacokinetic interaction between adefovir 10 mg once daily and paracetamol 1 g four times daily.[3,4]

5. Tenofovir. In a study in 24 healthy subjects there was no pharmacokinetic interaction between a single 10-mg dose of adefovir dipivoxil given alone and on day 7 of tenofovir disoproxil fumarate 300 mg daily for 7 days. In particular, renal clearances of both drugs were not changed on concurrent use.[6] However, the manufacturers advise against the concurrent use of adefovir with tenofovir.[3,4]

(e) Interferons

The US manufacturer reports that the pharmacokinetics of adefovir were unaffected by pegylated interferon alpha-2a. However, the results of a study to investigate the effects of a single 10-mg dose of adefovir on the pharmacokinetics of pegylated interferon alpha-2a 180 micrograms were inconclusive due to the high pharmacokinetic variability of pegylated interferon.[3] The UK manufacturer still advises caution with concurrent use, even though they state that the possibility of an interaction is small, as adefovir and pegylated interferons are excreted by different pathways.[4]

Cidofovir + Miscellaneous

Cidofovir with probenecid modestly decreased the levels of trimethoprim and sulfamethoxazole (co-trimoxazole), and caused moderate increases in didanosine levels, but did not alter fluconazole pharmacokinetics. None of these drugs altered cidofovir pharmacokinetics.

Clinical evidence

(a) Co-trimoxazole (Trimethoprim with Sulfamethoxazole)

In a study, 6 HIV-positive subjects were given co-trimoxazole 960 mg daily with a single 3-mg/kg dose of cidofovir with probenecid given on day 7. The AUC and maximum plasma concentrations of both trimethoprim and sulfamethoxazole were decreased by about 30% and renal clearance was significantly increased. The pharmacokinetics of cidofovir were not affected.[1]

(b) Didanosine

In a study, 6 HIV-positive subjects were given didanosine 100 or 200 mg twice daily for 7 days with a single 3-mg/kg dose of cidofovir with probenecid given on day 7. The AUC of didanosine was increased by 60%, but the pharmacokinetics of cidofovir were not affected.[1]

(c) Fluconazole

In a study, 6 HIV-positive subjects were given fluconazole 100 mg daily for 13 days with a single 3-mg/kg dose of cidofovir with probenecid given on day 13. The pharmacokinetics of both drugs were unaffected.[1]

Mechanism

It was suggested that cidofovir with probenecid might alter the renal elimination of these drugs.[1]

Importance and management

The modest decreases in trimethoprim and sulfamethoxazole levels, and moderate increases in didanosine levels caused by cidofovir with probenecid are considered unlikely to be clinically relevant because of the infrequent dosing schedule of cidofovir with probenecid. No dose adjustments are considered necessary.[1]

1. Luber A, Lalezari J, Rooney J, Jaffe H, Flaherty J. Drug-drug interaction study with intravenous cidofovir (CDV) and either trimethoprim/sulfamethoxazole (TMP/SMX), didanosine (DDI), or fluconazole (FLU) in HIV-infected individuals. *Intersci Conf Antimicrob Agents Chemother* (2002) 42, 27.

Cidofovir + Probenecid

Probenecid reduces the nephrotoxicity of cidofovir.

Clinical evidence, mechanism, importance and management

In a study 24 HIV-positive patients with cytomegalovirus retinitis were given either a single, oral 2-g dose of probenecid, taken one hour before intravenous cidofovir 5 mg/kg, or the standard licensed regimen of oral probenecid 2 g taken 3 hours before the same dose of cidofovir, with a 1 g dose of probenecid taken at 2 and 8 hours after cidofovir administration. No significant difference in the pharmacokinetics of cidofovir or in the adverse effects of probenecid was reported between the two regimens, and no increase in renal toxicity was seen in the patients given the lower probenecid dose.[1]

Probenecid inhibits the renal tubular secretion of cidofovir, and this reduction in the renal elimination of cidofovir reduces the incidence of nephrotoxicity.[1,2] The study[1] suggests that the reduced-dose probenecid regimen may also be beneficial and clinically important in reducing cidofovir nephrotoxicity. However, the authors recommend that further study using the single-dose regimen is needed, particularly with longer treatment courses and in patients with pre-existing renal impairment.[1]

Note that it is recommended that probenecid should always be used concurrently with cidofovir;[3,4] when using probenecid with cidofovir the interactions of probenecid should be considered.

Enfuvirtide + Cytochrome P450 substrates

Enfuvirtide does not affect the metabolism of dapsone or debrisoquine, and has no clinically significant effect on the metabolism of caffeine, chlorzoxazone, or mephenytoin.

Clinical evidence, mechanism, importance and management

A single oral dose of five drugs (**caffeine** 100 mg, **chlorzoxazone** 250 mg, **dapsone** 100 mg, **debrisoquine** 10 mg and **mephenytoin** 100 mg) was given to 12 HIV-positive subjects, before, and after they were given subcutaneous enfuvirtide 90 mg twice daily for 6 days. Enfuvirtide had no effect on the urinary **dapsone** recovery ratio (a measure of the activity of the cytochrome P450 isoenzyme CYP3A4), plasma monoacetyldapsone-to-**dapsone** ratio (a measure of *N*-acetyltransferase (NAT) activity) or urinary **debrisoquine** recovery ratio (a measure of CYP2D6 activity). Enfuvirtide had little effect (less than 30% change) on the plasma paraxanthine-to-**caffeine** ratio (a measure of CYP1A2 activity), the plasma 6-hydroxychlorzoxazone-to-**chlorzoxazone** ratio (a measure of CYP2E1 activity) and urinary recovery of 4-hydroxy**mephenytoin** (a measure of CYP2C19 activity). Subjects in this study were taking up to three NRTIs in stable doses, and were not taking any NNRTIs or protease inhibitors.[1]

This type of study is being increasingly used to assess the potential for

new drugs to cause clinically important cytochrome P450-mediated drug interactions. The results indicate that enfuvirtide is unlikely to cause clinically important changes in the pharmacokinetics of drugs metabolised by CYP3A4, NAT and CYP2D6. They also give some reassurance that drugs metabolised by CYP1A2, CYP2E1 and CYP2C19 are unlikely to be significantly affected. No substrate for CYP2C9 was included in this study, but enfuvirtide does not affect CYP2C9 *in vitro*.[1]

1. Zhang X, Lalezari JP, Badley AD, Dorr A, Kolis SJ, Kinchelow T, Patel IH. Assessment of drug-drug interaction potential of enfuvirtide in human immunodeficiency virus type 1–infected patients. *Clin Pharmacol Ther* (2004) 75, 558–68.

Enfuvirtide + Protease inhibitors

Ritonavir and ritonavir-boosted saquinavir slightly increase enfuvirtide exposure. Enfuvirtide appears to slightly increase the trough levels of ritonavir-boosted lopinavir. Enfuvirtide appears to moderately increase ritonavir-boosted tipranavir trough levels, and, although a case of hepatotoxicity has been reported, the overall incidence of hepatotoxicity does not appear to be increased with concurrent use.

Clinical evidence, mechanism, importance and management

(a) Lopinavir with ritonavir

In a sub-analysis of the RESIST study data, the mean lopinavir trough values in 60 patients taking ritonavir-boosted lopinavir with enfuvirtide were only slightly raised by 19%, when compared to 240 patients taking ritonavir-boosted lopinavir without enfuvirtide.[1] This minor increase in lopinavir levels would not be expected to be clinically relevant. Therefore, no ritonavir-boosted lopinavir dose adjustment appears to be needed when it is taken with enfuvirtide.

(b) Ritonavir and Saquinavir with ritonavir

In a study in 24 HIV-positive patients, subcutaneous enfuvirtide 90 mg twice daily was given for 7 days with either ritonavir 200 mg twice daily or ritonavir-boosted saquinavir 100 mg/1 g twice daily given for the last 4 days. Ritonavir caused a minor 24% increase in the AUC of enfuvirtide, and ritonavir-boosted saquinavir caused a 14% increase in the AUC of enfuvirtide. Such small increases in enfuvirtide exposure are not clinically relevant. Therefore, no special precautions appear to be needed during the concurrent use of either ritonavir 200 mg twice daily or ritonavir-boosted saquinavir with enfuvirtide.[2]

(c) Tipranavir with ritonavir

In a study in 55 HIV-positive patients, the mean trough level of ritonavir-boosted tipranavir was reported to be increased by about 50% in patients also given subcutaneous enfuvirtide 90 mg twice daily. Similarly, the mean trough level of ritonavir was nearly doubled in those patients given enfuvirtide. Two subjects who stopped enfuvirtide had a subsequent decrease in their tipranavir trough levels by about 25% and 50%, respectively, and a patient who started enfuvirtide while taking tipranavir had an increase in tipranavir trough levels of about 72%.[3] A patient who had been taking zidovudine 300 mg twice daily, lamivudine 150 mg twice daily and subcutaneous enfuvirtide 90 mg twice daily for 12 months, developed hepatotoxicity 2 weeks after starting ritonavir-boosted tipranavir 200/500 mg twice daily. When enfuvirtide was stopped for 6 weeks, the patient's liver enzyme levels decreased by 50%. However, when enfuvirtide was restarted, the liver enzymes began to rise again, so ritonavir-boosted tipranavir was stopped, and the increase in the liver enzymes resolved. An increase in tipranavir levels caused by enfuvirtide was thought to have led to hepatotoxicity, although no drug levels were measured.[4] The mechanism for this increase in tipranavir levels with enfuvirtide is unknown, as enfuvirtide has no significant effects on cytochrome P450 isoenzymes, the main metabolic route for both tipranavir and ritonavir. However, subsequent data from a sub-study of the RESIST study reported that despite the increases in tipranavir trough levels seen in patients given ritonavir-boosted tipranavir with enfuvirtide (a median increase in tipranavir trough levels of 31%), no additional increase in the incidence of hepatotoxicity occurred.[1]

This suggests that, in most patients, the increase in tipranavir trough levels with concurrent enfuvirtide is unlikely to lead to serious adverse effects. However, due to reports of hepatotoxicity with ritonavir-boosted tipranavir alone, routine close monitoring of liver function is recommended.

Enfuvirtide + Rifampicin (Rifampin)

Rifampicin does not affect the pharmacokinetics of enfuvirtide.

Clinical evidence, mechanism, importance and management

Subcutaneous enfuvirtide 90 mg twice daily for 3 days was given to 12 HIV-positive subjects before, and during the last 3 days, of a 10-day course of rifampicin 600 mg daily. The AUC of enfuvirtide and its metabolite were not significantly altered by rifampicin.[1]

Enfuvirtide is a peptide and would not be expected to be affected by enzyme inducers such as rifampicin. The findings of this study support this. Therefore no dose adjustments of enfuvirtide are required when it is given with rifampicin.

1. Boyd MA, Zhang X, Dorr A, Ruxrungtham K, Kolis S, Nieforth K, Kinchelow T, Buss N, Patel IH. Lack of enzyme-inducing effect of rifampicin on the pharmacokinetics of enfuvirtide. *J Clin Pharmacol* (2003) 43, 1382–91.

Entecavir + Miscellaneous

No pharmacokinetic interaction appears to occur between entecavir and adefovir, lamivudine or tenofovir. However, interactions with other renally excreted drugs cannot be excluded. No interactions mediated by cytochrome P450 isoenzymes are expected with entecavir.

Clinical evidence, mechanism, importance and management

(a) Renally excreted drugs

A study in 22 healthy subjects given entecavir 1 mg daily, and/or **adefovir** 10 mg daily found no pharmacokinetic interaction and concurrent use was well tolerated.[1] The manufacturers note that there was no pharmacokinetic interaction between entecavir and **lamivudine**, **adefovir** or **tenofovir** at steady state.[2,3]

As entecavir is predominantly eliminated by the kidney, the concurrent use of drugs that reduce renal function or compete for active renal tubular secretion may increase the serum concentrations of either entecavir or the concurrent drug. However, the manufacturers say that, apart from the drugs listed above, the effects of the concurrent use of entecavir with drugs that are either excreted renally or affect renal function have not been evaluated, and they therefore recommend that patients should be monitored closely for adverse reactions when entecavir is given.[2,3]

(b) Cytochrome P450-mediated interactions

The manufacturers say that entecavir is not a substrate, an inducer or an inhibitor of cytochrome P450 isoenzymes. Therefore drug interactions are unlikely to occur with entecavir by this mechanism.[2,3]

Famciclovir + Miscellaneous

No clinically important pharmacokinetic interactions appear to occur when famciclovir is given with allopurinol, digoxin or theo-

phylline. Raloxifene is predicted to inhibit the metabolism of famciclovir to penciclovir.

Clinical evidence, mechanism, importance and management

When 12 healthy subjects were given famciclovir 500 mg after taking **allopurinol** 300 mg daily for 5 days there were no clinically relevant changes in the pharmacokinetics of either drug.[1] It was concluded that xanthine oxidase does not play an important role in the metabolism of famciclovir to penciclovir.[1,2]

Similarly, in studies in healthy subjects given famciclovir, **theophylline**[3] and **digoxin**[4] had no clinically significant effect on the pharmacokinetics of famciclovir. The pharmacokinetics of **theophylline** and **digoxin** were also unaffected by famciclovir.[4,5] Therefore, no dose adjustments would seem to be necessary if any of these drugs are given with famciclovir.

Famciclovir is converted to its active drug, penciclovir, by aldehyde oxidase. An *in vitro* study[6] reported that **raloxifene** is a potent aldehyde oxidase inhibitor, and the manufacturer of famciclovir predicts that raloxifene may affect the metabolic activation of famciclovir.[7] However, other *in vitro* inhibitors of aldehyde oxidase, such as cimetidine, do not appear to interact with famciclovir to a clinically relevant extent, see 'Aciclovir and related drugs + Cimetidine', p.915, and there appear to be no published reports of an interaction in clinical practice.

Foscarnet + NRTIs

No pharmacokinetic interactions occur between foscarnet and didanosine, zalcitabine or zidovudine.

Clinical evidence, mechanism, importance and management

(a) Didanosine

In a three-phase study, 12 HIV-positive patients were given 4 doses of intravenous foscarnet 90 mg/kg, 4 doses of oral didanosine 200 mg, and 4 doses of both drugs together. Based on the data obtained from these patients (drug clearance, volume of distribution, half-life, mean residence time), no pharmacokinetic interactions were said to occur between these two drugs. This suggests that no dose adjustments will be needed during concurrent use.[1] The antiretroviral effects of foscarnet and didanosine were synergistic.[2]

(b) Stavudine

Foscarnet does not affect stavudine intracellular activation.[3]

(c) Zalcitabine

Intravenous foscarnet 90 mg/kg every 12 hours and oral zalcitabine 750 micrograms every 8 hours were given to 12 HIV-positive subjects for 2 days. There were no clinically significant alterations in the pharmacokinetics of either drug.[4] However, the manufacturers of zalcitabine[5,6] suggested that the concurrent use of zalcitabine and foscarnet should be well monitored, because foscarnet may possibly decrease the renal clearance of the zalcitabine, thereby increasing its serum levels and its toxicity, particularly peripheral neuropathy. The antiretroviral effects of foscarnet and zalcitabine were synergistic.[2]

(d) Zidovudine

The antiviral effects of foscarnet and zidovudine appear to be additive or synergistic. No significant alteration in the pharmacokinetics of either drug was seen in a 14-day study in 5 patients with AIDS given both drugs.[7] Foscarnet does not appear to affect zidovudine intracellular activation,[8] and the manufacturer notes that there was no evidence of increased myelotoxicity when foscarnet was used with zidovudine.[9] No special precautions are required on concurrent use.

Foscarnet + Pentamidine

Marked hypocalcaemia, including one fatality, has been reported in four patients given foscarnet with intravenous pentamidine. Additive renal impairment may also occur on concurrent use.

Clinical evidence, mechanism, importance and management

Four patients with suspected AIDS-related cytomegaloviral chest infections developed signs of hypocalcaemia within 10 days of starting treatment with foscarnet and intravenous pentamidine (doses not stated). All 4 had paraesthesia of the hands and feet, and 3 of them had Chvostek's and Trousseau's signs (signs of tetany). The serum calcium levels of 3 of them fell but normalised when one of the drugs was stopped. The fourth patient had severe hypocalcaemia of 1.42 mmol/L and died.[1]

Both drugs have been associated with hypocalcaemia in HIV-positive patients, and in these 4 patients their effects appear to have been additive. The manufacturer of foscarnet also reports that renal impairment has also been reported on the concurrent use of intravenous pentamidine.[2] Therefore close monitoring of calcium levels and renal function is advised if foscarnet is used with parenteral pentamidine.

2. Foscavir (Foscarnet trisodium hexahydrate). AstraZeneca UK Ltd. UK Summary of product characteristics, May 2007.

Foscarnet + Probenecid

Probenecid does not alter the pharmacokinetics of foscarnet.

Clinical evidence, mechanism, importance and management

A study in 10 HIV-positive patients found that probenecid 1 g twice daily for 3 days had no effect on the pharmacokinetics of foscarnet 90 mg/kg given intravenously over 2 hours. The authors conclude that, because of the lack of interaction with probenecid, almost all of the renal elimination of foscarnet is by glomerular filtration, with only a minimal contribution of active tubular secretion.[1] No special precautions seem to be necessary if both drugs are given.

1. Noormohamed FH, Youle MS, Higgs CJ, Gazzard BG, Lant AF. Renal excretion and pharmacokinetics of foscarnet in HIV sero-positive patients: effect of probenecid pretreatment. *Br J Clin Pharmacol* (1997) 43, 112–15.

Foscarnet + Quinolones

Two patients developed tonic-clonic seizures when they were given foscarnet with ciprofloxacin.

Clinical evidence

An HIV-positive patient taking multiple drugs (including ciprofloxacin 750 mg twice daily, clarithromycin, cimetidine, fluconazole, morphine, rifampicin (rifampin) and vancomycin) was also given intravenous foscarnet 60 mg/kg every 8 hours for a cytomegalovirus infection. He was only given half of the first dose, but 9 hours later he developed a tonic-clonic seizure. On completing the infusion of the first dose he again experienced similar seizure activity. About 45 minutes after the start of the second foscarnet dose, he had a third grand mal seizure. No further seizures occurred when the foscarnet was stopped.[1] Another HIV-positive patient was given foscarnet 60 mg/kg every 8 hours for 10 days without problem, until he started ciprofloxacin 750 mg twice daily, clofazimine, ethambutol, pyrazinamide and rifampicin for mycobacterial sepsis. Within 2 days, a few minutes after the start of the foscarnet infusion, he developed a seizure. This resolved when the foscarnet was stopped, and recurred when the foscarnet was restarted.[1]

Mechanism

Both foscarnet and ciprofloxacin have the potential to cause seizures and it seems that some enhancement of this activity occurs if they are used in combination. Subsequent study in *mice* has shown that the combination of ciprofloxacin and foscarnet does increase the likelihood of seizures, and that the interaction is likely to be due to altered GABA-receptor binding. An interaction was not found for **enoxacin** and foscarnet.[2]

Importance and management

Direct information seems to be limited to these two cases. It is impossible to know for certain if the seizures were due to the combined effects of these two drugs or not, but the evidence seems to point in that direction. The general importance of this interaction is uncertain, but it would seem prudent to monitor very closely if these drugs are used together.

Ganciclovir or Valganciclovir + Imipenem

Based on an early possible report,[1] the manufacturer notes that generalised seizures have been reported in patients who received ganciclovir and imipenem with cilastatin. They recommend that ganciclovir and its prodrug, valganciclovir, should not be used with imipenem unless the benefits outweigh the risks.[2-4] No further reports of this interaction appear to have been published, or reported to the manufacturer.[1] Note that both ganciclovir and imipenem alone may cause seizures.

Ganciclovir + Trimethoprim

No clinically relevant pharmacokinetic interaction occurs between ganciclovir and trimethoprim. However, there may be an increased risk of myelosuppression on concurrent use.

Clinical evidence, mechanism, importance and management

In a study in 12 HIV-positive subjects, trimethoprim 200 mg daily for 7 days reduced the clearance of ganciclovir 1 g every 8 hours by 13%, and increased its half-life by 18%. The trimethoprim minimum plasma concentration was raised by 13% by ganciclovir. The combination was well tolerated and none of these changes were considered clinically significant, so no dose alteration appears necessary on concurrent use.[1] However, both ganciclovir and trimethoprim are known to be myelosuppressive,[2] and the manufacturer of ganciclovir and its prodrug, **valganciclovir**, notes that there is the possibility that the risk of this toxicity may be increased when they are used together. Therefore, they recommend that the combination should only be used if the benefits outweigh the risks of treatment.[3-5] Full blood counts should be closely monitored if concurrent use is necessary.

Idoxuridine + Miscellaneous

The topical solution of idoxuridine, *Herpid*, contains the solvent dimethyl sulfoxide as an absorption enhancer. This can increase the absorption of many substances, and therefore no other topical medications should be used concurrently on the same areas as *Herpid*.[1]

1. Herpid (Idoxuridine). Astellas Pharma Ltd. UK Summary of product characteristics, January 2008.

Influenza vaccines + Paracetamol (Acetaminophen)

Paracetamol does not affect antibody production in response to influenza vaccination, and may possibly reduce the adverse effects of influenza vaccination. The pharmacokinetics of paracetamol do not appear to be affected by influenza vaccination.

Clinical evidence, mechanism, importance and management

In a study in healthy subjects, the pharmacokinetics of a single 650-mg dose of intravenous paracetamol were unaffected when it was given 7 and 21 days after 0.5 mL of trivalent influenza vaccine given intramuscularly.[1] Paracetamol 1 g four times daily for 2 days had no effect on the production of influenza virus antibodies in a group of 39 elderly patients given an inactivated influenza virus vaccine, and paracetamol appeared to reduce the adverse effects of the vaccine (e.g. fever), although this was not statistically significant.[2]

In a placebo-controlled study, 262 healthy subjects were given a single 0.5-mL intramuscular dose of inactivated, trivalent, whole-virus influenza vaccine with paracetamol 325 mg or 650 mg given at the same time as the influenza vaccine and then every 4 hours for a total of 4 doses. The incidence of sore arm at the vaccination site was reduced by 25% and 28% in the subjects given the lower and higher dose of paracetamol, respectively. The concurrent use of paracetamol also reduced the incidence of vaccine-related nausea by 20% and 90% in those subjects given the lower and higher dose of paracetamol, respectively. However, paracetamol had no statistically significant effect on other vaccine-related adverse effects such as fever, headache and muscle pain. Paracetamol did not appear to affect the antibody response to the vaccine, as no difference in the haemagglutination inhibition antibody was reported between the placebo and paracetamol groups.[3]

From the limited data available, no special precautions appear to be necessary on the concurrent use of paracetamol and influenza vaccine.

Influenza vaccine; Live + Antivirals active against influenza

The manufacturers advise that antivirals active against influenza such as oseltamivir, rimantadine and zanamivir should not be given until 2 weeks after the administration of *live* influenza virus vaccines, and that these vaccines should not be given until 48 hours after stopping the antiviral.[1-4] This is because of the theoretical concern that these antiviral drugs will inhibit replication of live vaccine virus, and therefore reduce its effect. Note that most influenza vaccines are inactivated (split virion or surface antigen), and that these would not be expected to be affected by antivirals active against influenza.

2. Tamiflu (Oseltamivir phosphate). Roche Pharmaceuticals. US Prescribing information, August 2008.
3. Flumadine (Rimantadine hydrochloride). Forest Pharmaceuticals, Inc. US Prescribing information, April 2007.
4. Relenza (Zanamivir). GlaxoSmithKline. US Prescribing information, September 2009.

Influenza vaccine; Live + Aspirin

The manufacturer advises that *live* influenza vaccines should not be given to children or adolescents who are given aspirin. This possible interaction is linked to the association of Reye's syndrome with aspirin and wild-type influenza infection. Concurrent use is contraindicated.[1]

1. FluMist (Influenza virus vaccine live, intranasal). MedImmune Vaccines, Inc. US Prescribing information, June 2009.

Interferons + ACE inhibitors

A case series suggests that severe granulocytopenia can develop if ACE inhibitors and interferon are given concurrently.

Clinical evidence

Patients with cryoglobulinaemia were treated with 3 million units of recombinant **interferon alfa-2a** (35 patients) or natural **interferon beta** (3 patients), usually given daily for 3 months, then on alternate days for periods of 6 to 17 months. Severe toxicity developed in 3 patients, who were the only ones amongst the group to also be taking ACE inhibitors. Granulocytopenia developed in 2 patients within a few days of starting **enalapril** 10 mg daily or **captopril** 50 mg daily, and subsided 1 to 2 weeks after both drugs were stopped. Another patient, already taking **enalapril** 5 mg daily, developed severe granulocytopenia when interferon was started, and again when re-challenged with both drugs. None of the other 35 patients receiving interferon alone developed any significant haematological problems. The reasons for this severe reaction are not understood but the authors of the report suggest that it may be an autoimmune response.[1]

A follow-up letter commenting on this report described 2 further patients with hepatitis C infection, cryoglobulinaemia and glomerulonephritis, who took **captopril** 75 mg or **enalapril** 20 mg daily for several weeks, and who had granulocytopenia within 9 days of being given 3 million units of recombinant **interferon alfa-2a**, daily or on alternate days. However, this resolved without any change in treatment. Another patient with multiple myeloma given **interferon alfa-2a** 3 million units three times weekly and long-term **benazepril** 10 mg daily had a normal granulocyte count after 3 months.[2]

Mechanism

Interferons alone are associated with myelosuppression, particularly granulocytopenia. ACE inhibitors have, rarely, caused neutropenia and agranulocytosis.

Importance and management

These two reports appear to be the only information suggesting an interaction. Regular full blood counts are generally recommended when interferons are used, and therefore, no extra precautions would appear to be required if ACE inhibitors are also given.

2. Jacquot C, Caudwell V, Belenfant X. Granulocytopenia after combined therapy with interferon and angiotensin-converting enzyme inhibitors: evidence for a synergistic hematologic toxicity. *Am J Med* (1996) 101, 235–6.

Interferons + Miscellaneous

Prednisone and paracetamol have disparate effects on some measures of the antiviral activity of interferon, but the clinical relevance of this is unclear. Isolated cases of acute hepatitis have been seen when interferon was given with paracetamol.

Clinical evidence, mechanism, importance and management

(a) Aspirin or Paracetamol

Single intramuscular doses of recombinant human **interferon alfa-2a** 18 million units were given to groups of 8 healthy subjects alone, or after 24 hours after starting either aspirin 650 mg every 4 hours or paracetamol 650 mg every 4 hours for a total of 8 days. Neither aspirin nor paracetamol reduced the interferon adverse effects of fever, chills, headache, or myalgia.[1] In a later similar study by the same research group, the effect of the same drugs and doses (started 3 days before the interferon) was evaluated with a lower dose of **interferon alfa-2a** (3 million units). When the data for aspirin or paracetamol (or prednisone, see below) were combined, the subjects had a 47% reduction in symptom score, when compared with control subjects not taking any of these three drugs. In this study, aspirin did not consistently alter measures of the antiviral activity of interferon, but paracetamol appeared to enhance them.[2] Taken together, the results of these two studies suggest that these drugs may reduce the flu-like adverse effects of interferon, perhaps more so at lower doses of interferon. The clinical relevance of the measures of antiviral activity of interferon is uncertain, so the disparate effects found with paracetamol are unclear.

The authors of a report describing an unusual acute form of hepatitis, occurring in 3 patients receiving **interferon alfa-2a**, vinblastine and paracetamol, suggested that this might have been due to a drug interaction.[3] Another two similar cases have been reported with **interferon alfa-2b** and paracetamol, but no liver toxicity occurred when one of these patients was given **indometacin** with interferon instead.[4] The general relevance of these isolated reports is unclear.

Note that the manufacturers of interferon alfa-2a, **interferon beta-1a** and **interferon gamma-1b** advise that paracetamol,[5,6] NSAIDs[7] or an antipyretic analgesic[8,9] may be used to manage the flu-like adverse effects of interferon treatment. The manufacturer of interferon gamma-1b also states that the potential adverse effects of anti-inflammatory drugs, such as NSAIDs, on the efficacy of interferon gamma is unknown, however they give no specific guidance on concurrent use.[5]

(b) Corticosteroids

A single intramuscular dose of recombinant human **interferon alfa-2a** 18 million units was given to 8 healthy subjects alone, or to 8 similar healthy subjects 24 hours after starting **prednisone** 40 mg daily, for a total of 8 days. **Prednisone** did not reduce the interferon adverse effects of fever, chills, headache, or myalgia, but appeared to reduce one of the two measures of interferon activity.[1] In a later similar study by the same research group, the effect of the same dose of **prednisone**, started 3 days before the interferon, was evaluated with a lower dose of **interferon alfa-2a** (3 million units). Subjects taking **prednisone** had a 43% reduction in symptom score, and also had fewer hours of fever, when compared with control subjects taking **interferon alfa-2a** alone. In this study, **prednisone** did not consistently alter measures of the antiviral activity of interferon.[2] Taken together the results of these two studies suggest **prednisone** may reduce the flu-like adverse effects of interferon, perhaps more so at lower doses of interferon.

The manufacturers of **interferon beta-1a** and **interferon beta-1b** state that although it has not been specifically studied, corticosteroids may be used with interferon beta during relapses of multiple sclerosis, and that

concurrent use for up to 28 days has not resulted in any significant interaction.[7,8] The manufacturer of **interferon gamma-1b** states that it does not affect the therapeutic efficacy of corticosteroids when used to treat osteopetrosis or chronic granulomatous disease.[5] Therefore, it would appear that concurrent use of corticosteroids with interferons for specific conditions may be beneficial.

Interferons + Ribavirin

There was no evidence of any changes in pharmacokinetic parameters when ribavirin and interferon alfa-2b were given together.[1] Another study using peginterferon alfa-2b also found no pharmacokinetic interactions with ribavirin.[2] The combination of interferon alfa and ribavirin has enhanced efficacy against hepatitis C.

1. Khakoo S, Glue P, Grellier L, Wells B, Bell A, Dash C, Murray-Lyon I, Lypnyj D, Flannery B, Walters K, Dusheiko GM. Ribavirin and interferon alfa-2b in chronic hepatitis C: assessment of possible pharmacokinetic and pharmacodynamic interactions. *Br J Clin Pharmacol* (1998) 46, 563–70.

Maraviroc + Co-trimoxazole

Co-trimoxazole has no significant effect on the pharmacokinetics of maraviroc.

Clinical evidence

In a study, co-trimoxazole (sulfamethoxazole with trimethoprim) 960 mg twice daily had no clinically relevant effect on the pharmacokinetics of maraviroc 300 mg twice daily (a 11% increase in AUC and a 19% increase in maximum level).[1]

Mechanism

Maraviroc undergoes some degree of renal clearance (about 20% of its total clearance).[1] Co-trimoxazole affects renal tubular transport and so it was predicted that it may possibly affect maraviroc levels.[1]

Importance and management

The pharmacokinetic data suggest that no maraviroc dose adjustment is likely to be needed if it is given with co-trimoxazole.

1. Abel S, Russell D, Whitlock LA, Ridgway CE, Muirhead GJ. The effects of cotrimoxazole or tenofovir co-administration on the pharmacokinetics of maraviroc in healthy volunteers. Br J Clin Pharmacol (2008) 65 (Suppl 1), 47–53.

Maraviroc + Ketoconazole and other CYP3A4 inhibitors

Ketoconazole increases the AUC of maraviroc about fivefold. Other potent CYP3A4 inhibitors would be expected to interact similarly.

Clinical evidence

In a study in 12 healthy subjects, **ketoconazole** 400 mg daily increased the AUC and maximum level of maraviroc 100 mg twice daily fivefold and 3.4-fold, respectively. No serious adverse effects were reported.[1]

Mechanism

Maraviroc is a substrate of the cytochrome P450 isoenzyme CYP3A4 and P-glycoprotein. Ketoconazole is a potent inhibitor of CYP3A4. Therefore, the levels of maraviroc would be expected to be significantly increased if it is taken with ketoconazole. Other inhibitors of CYP3A4 would be expected to interact similarly. From *in vitro* data, the potential for maraviroc to affect the pharmacokinetics of concurrent drugs is low.[2]

Importance and management

The effects of **ketoconazole** on maraviroc metabolism are established and clinically important. Increases in maraviroc levels of this magnitude are likely to result in increased adverse effects. The manufacturers of maraviroc advise that the dose of maraviroc should be reduced to 150 mg twice daily in the presence of ketoconazole.[2,3] **Itraconazole** is predicted to interact similarly, and the same dose reduction of maraviroc is advised.[2] Other azoles also inhibit CYP3A4 (see 'azoles antifungals', (p.233)), and although not specifically mentioned by the manufacturers, some caution is probably warranted, and consideration should be given to reducing the maraviroc dose. **Fluconazole** has less of an effect on CYP3A4 than the other azoles, so no dose alteration is needed when it is taken with maraviroc, although caution is advised.[2]

The manufacturers also predict that the macrolide antibacterials **clarithromycin** and **telithromycin** will significantly increase maraviroc levels, and they recommend reducing the maraviroc dose to 150 mg twice daily.[2,3]

Consider also 'Maraviroc + Protease inhibitors', p.923, and for a list of other inhibitors of CYP3A4, which might be expected to interact similarly, although to varying extents, see 'Table 1.4', (p.6).

3. Selzentry (Maraviroc). Pfizer Labs. US Prescribing information, June 2009.

Maraviroc + Miscellaneous

Maraviroc has no clinically relevant effect on the pharmacokinetics of lamivudine with zidovudine or midazolam. Food may modestly reduce the absorption of maraviroc. No interaction is expected between maraviroc and enfuvirtide. Tenofovir has no significant effect on the pharmacokinetics of maraviroc. No dose adjustment of maraviroc is expected to be needed if it is taken with buprenorphine, methadone, peginterferon, ribavirin, or statins.

Clinical evidence, mechanism, importance and management

(a) Debrisoquine

In a study in 72 healthy subjects, maraviroc 25 to 300 mg twice daily had no significant effect on the metabolism of debrisoquine; however, maraviroc 600 mg daily resulted in an 3.3-fold increase in the debrisoquine metabolic ratio.[1] Debrisoquine is a probe substrate for the cytochrome P450 isoenzyme CYP2D6, and the study above indicates that maraviroc, taken at usual clinical doses, is unlikely to significantly increase the levels of drugs metabolised by CYP2D6.

(b) Enfuvirtide

The US manufacturers advise that no maraviroc dose adjustment is need if it is taken with enfuvirtide.[2]

(c) Food

The UK manufacturer reports that in healthy subjects, a high-fat breakfast reduced the AUC and maximum concentration of a single 300-mg dose of maraviroc by about 33%. However, they state that as there were no food restrictions during clinical studies of maraviroc, and this did not influence the efficacy or safety outcomes of these studies. Therefore maraviroc may be taken with or without food.[3]

(d) Midazolam

In a placebo-controlled study in 12 healthy subjects, maraviroc 300 mg twice daily for 7 days slightly increased the AUC of a single 7.5-mg dose of oral midazolam taken on day 7 by 18%. This increase is unlikely to be clinically relevant.[4] Midazolam is a probe substrate for the cytochrome P450 isoenzyme CYP3A4, and the findings suggest that maraviroc is unlikely to have an important effect on other CYP3A4 substrates.

(e) NRTIs

In a placebo-controlled, crossover study in 11 healthy subjects, maraviroc 300 mg twice daily had no clinically relevant effect on the pharmacokinetics of **zidovudine** with **lamivudine** 300/150 mg twice daily, when they were taken together for one week.[4] In a placebo-controlled, crossover study in 16 healthy subjects, the concurrent use of maraviroc 300 mg twice daily and tenofovir disoproxil fumarate 300 mg daily had no effect on the pharmacokinetics of maraviroc.[5] Therefore no dose adjustments of zidovudine with lamivudine are needed when it is taken with maraviroc 300 mg twice daily.[3] The US manufacturers state that no dose adjustment of maraviroc is needed when it is used with NRTIs.[2]

(f) Tenofovir

In a placebo-controlled, crossover study in 16 healthy subjects, the concurrent use of maraviroc 300 mg twice daily and tenofovir disoproxil fumarate 300 mg daily had no effect on the pharmacokinetics of maraviroc.[5] Maraviroc undergoes some degree of renal clearance (about 20% of total clearance) and tenofovir is predominantly excreted renally, so it was predicted that it may possibly affect maraviroc levels.[5] However, the pharmacokinetic data suggest that no maraviroc dose adjustment is likely to be needed if it is given with tenofovir.

(g) Other drugs

The manufacturer states that, although there have been no specific drug interaction studies, no dose adjustment of maraviroc 300 mg twice daily is needed if it is taken with **buprenorphine**, **methadone**, **peginterferon**, **ribavirin**, and **statins**, as an interaction would not be expected.[3]

5. Abel S, Russell D, Whitlock LA, Ridgway CE, Muirhead GJ. The effects of cotrimoxazole or tenofovir co-administration on the pharmacokinetics of maraviroc in healthy volunteers. Br J Clin Pharmacol (2008) 65 (Suppl 1), 47–53.

Maraviroc + NNRTIs

Efavirenz reduces the levels of maraviroc by about 50%. Nevirapine and etravirine modestly increase the levels of maraviroc; delavirdine is predicted to interact similarly. Maraviroc is predicted not to affect the pharmacokinetics of efavirenz or nevirapine.

Clinical evidence

(a) Efavirenz

In a placebo-controlled study in 12 healthy subjects, efavirenz 600 mg daily for 14 days reduced the steady-state AUC and maximum plasma level of maraviroc 100 mg twice daily by about 45% and 51%, respectively. Doubling the dose of maraviroc to 200 mg twice daily overcame this reduction in maraviroc levels, resulting in a minor 15% *increase* in AUC and a 16% *increase* in maximum level, when compared with maraviroc 100 mg twice daily alone.[1] Similarly, in another study in HIV-positive patients, the AUC of a single 300-mg dose of maraviroc was about 52% lower in two groups of 8 patients compared with patients given maraviroc alone; one group was taking efavirenz, lamivudine and zidovudine and the other was taking efavirenz, didanosine and tenofovir.[2] Note that the NRTIs zidovudine, lamivudine and tenofovir, do not have a clinically significant effect on maraviroc pharmacokinetics (see 'Maraviroc + Miscellaneous', p.922).

In a study in 12 healthy subjects, ritonavir-boosted lopinavir 100/400 mg twice daily was given with maraviroc 300 mg twice daily for 21 days, with efavirenz 600 mg daily added on day 8. Efavirenz halved the increase in the AUC of maraviroc seen with ritonavir-boosted lopinavir: on day 7 the maraviroc AUC was increased by 150% by efavirenz, lopinavir and ritonavir, compared with an increase of 300% seen with lopinavir and ritonavir.[3] Similarly, efavirenz 600 mg daily more than halved the effect of ritonavir-boosted saquinavir 100 mg/1 g twice daily on the AUC of maraviroc 100 mg twice daily: efavirenz, saquinavir an lopinavir increased the AUC of maraviroc by 400%, compared with 877% seen with saquinavir and ritonavir.[3] For further details on the effects of the protease inhibitors on the metabolism of maraviroc, see 'Maraviroc + Protease inhibitors', p.923.

(b) Etravirine

The manufacturer reports that, in a study, etravirine 200 mg twice daily reduced the AUC and maximum level of maraviroc 300 mg twice daily by 53% and 60%, respectively. Maraviroc had no clinically significant effect on the AUC, maximum or minimum level of etravirine.[3]

(c) Nevirapine

In a study in 8 HIV-positive patients taking nevirapine 200 mg twice daily with lamivudine and tenofovir, the AUC of a single 300-mg dose of maraviroc was unchanged but its maximum plasma level was about 54% *higher*, when compared with HIV-positive subjects taking maraviroc alone.[2] Note that the NRTIs lamivudine and tenofovir, do not have a clinically significant effect on maraviroc pharmacokinetics (see 'Maraviroc + Miscellaneous', p.922).

Mechanism

Maraviroc is a substrate of the cytochrome P450 isoenzyme CYP3A4, hence its levels are reduced by efavirenz, an inducer of CYP3A4. Nevirapine and etravirine are also inducers of CYP3A4; however, the study above suggests that their effects on the metabolism of maraviroc are modest.

In contrast, **delavirdine** inhibits CYP3A4, and would therefore be expected to increase maraviroc levels.

Importance and management

The pharmacokinetic interaction between maraviroc and **efavirenz** is of clinical importance. The reduction in maraviroc plasma levels could result in a decrease in therapeutic efficacy and the development of viral resistance. In one study,[1] doubling the dose of maraviroc overcame this interaction. The manufacturers therefore recommend that the dose of maraviroc should be increased to 600 mg twice daily in patients taking efavirenz and *not* taking protease inhibitors or other potent inhibitors of CYP3A4.[3,4] Note that the UK manufacturer[3] does not recommend concurrent use of maraviroc in patients taking both efavirenz and the potent CYP3A4 inducer rifampicin, see 'Maraviroc + Rifampicin (Rifampin) and other CYP3A4 inducers', p.924, for further information. **Etravirine** should be prescribed with a protease inhibitor: no dose adjustment of etravirine is required if it is taken with maraviroc and protease inhibitors.[5] For information on dosing recommendations for maraviroc when using the NNRTIs efavirenz or etravirine with maraviroc and the protease inhibitors, see 'Maraviroc + Protease inhibitors', p.923.

Nevirapine is also an inducer of CYP3A4, however it appears to have no significant effect on the AUC of maraviroc and caused only a modest *increase* in maraviroc levels. Therefore, no dose adjustment of maraviroc appears to be needed in patients taking nevirapine.[3,4]

Delavirdine *inhibits* CYP3A4 and the manufacturers predict that it will significantly increase maraviroc levels. They therefore recommend reducing the maraviroc dose to 150 mg twice daily if delavirdine is also given.[4]

Maraviroc is not expected to have an effect on efavirenz or nevirapine pharmacokinetics.[3]

Maraviroc + Protease inhibitors

Atazanavir and saquinavir, and ritonavir-boosted atazanavir, darunavir and lopinavir markedly increase the AUC of maraviroc by about three- to fivefold. Ritonavir-boosted saquinavir has

an even greater effect, whereas ritonavir-boosted tipranavir has no significant effect on the pharmacokinetics of maraviroc.

Clinical evidence

(a) Atazanavir

In a study in 12 healthy subjects, atazanavir 400 mg daily increased the AUC and maximum level of maraviroc 300 mg twice daily (both drugs taken for 7 days) 3.6-fold and twofold, respectively. Atazanavir 300 mg daily with ritonavir 100 mg daily increased the AUC of maraviroc almost fivefold and increased the maximum concentration of maraviroc about 2.5-fold.[1]

(b) Darunavir

In a study in 12 subjects, darunavir 600 mg twice daily with ritonavir 100 mg twice daily increased the AUC, the maximum concentration and the minimum concentration of maraviroc 150 mg twice daily by fourfold, 2.3-fold, and eightfold, respectively.[2,3]

(c) Lopinavir

In a study in 5 HIV-positive patients taking ritonavir-boosted lopinavir 100/400 mg twice daily with stavudine and lamivudine, the AUC of a single 300-mg oral dose of maraviroc was increased 2.6-fold and the maraviroc maximum concentration was increased by nearly twofold, when compared with HIV-positive subjects taking maraviroc 300 mg daily alone.[4] In a study in 12 healthy subjects, ritonavir-boosted lopinavir 100/400 mg twice daily increased the AUC and maximum level of maraviroc 300 mg twice daily almost fourfold and twofold, respectively.[5] Adding efavirenz 600 mg daily nearly halved the effect of ritonavir-boosted lopinavir on the AUC and maximum concentration of maraviroc (to a smaller increase of 2.5-fold and 20%, respectively), and also led to an increase in adverse effects, such as dizziness.[5] Another cohort study was planned to investigate the concurrent use of ritonavir-boosted lopinavir, saquinavir and efavirenz with maraviroc; however, this was discontinued due to a high rate of gastrointestinal adverse effects with the combination of ritonavir-boosted lopinavir, saquinavir and maraviroc.[5]

(d) Saquinavir

In a study in 12 healthy subjects, saquinavir 1.2 g three times daily increased the AUC and maximum level of maraviroc 100 mg twice daily 4.2-fold and 3.3-fold, respectively.[1] In another study in healthy subjects by the same group, ritonavir-boosted saquinavir 100/400 mg twice daily for 7 days increased the AUC and maximum concentration of maraviroc 100 mg twice daily by about 9.7-fold and 4.8-fold, respectively. Adding efavirenz 600 mg daily nearly halved this effect, although the AUC and maximum concentrations of maraviroc were still raised fivefold and 2.3-fold, respectively.[5]

(e) Tipranavir

A study in 12 healthy subjects found that ritonavir-boosted tipranavir 200/500 mg twice daily had no clinically significant effect on the AUC or maximum plasma levels of maraviroc 150 mg twice daily. An initial rise in maraviroc trough plasma levels was seen on days one to 4, but this resolved thereafter.[1]

Mechanism

Maraviroc is a substrate of the cytochrome P450 isoenzyme CYP3A4 and P-glycoprotein. CYP3A4 is inhibited to various degrees by the protease inhibitors. Therefore, the levels of maraviroc would be expected to be significantly increased if it is taken with the protease inhibitors.

From *in vitro* data, the potential for maraviroc to affect the pharmacokinetics of concurrent drugs is low.[2]

Importance and management

The effect of the protease inhibitors on maraviroc metabolism is established and clinically important. Increases in maraviroc levels of this magnitude are likely to result in increased adverse effects. The manufacturers advise that the dose of maraviroc should be reduced to 150 mg twice daily when it is taken with *most* protease inhibitors. This dose reduction is also recommended when maraviroc is given with most protease inhibitors and the NNRTIs **efavirenz** or **etravirine**.[2,3] However, some protease inhibitors are excepted from this dosing recommendation. In the UK, the manufacturer recommends that when maraviroc is used with ritonavir-boosted **fosamprenavir**, the usual dose of maraviroc 300 mg twice daily should be used; this maraviroc dose should also be used if the NNRTIs efavirenz or etravirine are also added.[2] In both the UK and the US, the manufacturers recommend that when maraviroc is used with ritonavir-boosted **tipranavir**, the usual dose of maraviroc 300 mg twice daily should be used.[2,3] However while the UK manufacturer[2] recommends increasing maraviroc dose to 600 mg twice daily if the NNRTI efavirenz is also added, the US manufacturer[3] does not appear to give any specific guidance if efavirenz is also added to ritonavir-boosted tipranavir.

Note that the UK manufacturer of maraviroc states that if **rifabutin** is started in a patient taking maraviroc with protease inhibitors no further dose adjustment is needed.[2] See 'Maraviroc + Rifampicin (Rifampin) and other CYP3A4 inducers', p.924, for further information on the effect of rifabutin or rifampicin on the pharmacokinetics of maraviroc.

5. Abel S, Jenkins TM, Whitlock LA, Ridgway CE, Muirhead GJ. Effects of CYP3A4 inducers with and without CYP3A4 inhibitors on the pharmacokinetics of maraviroc in healthy volunteers. Br J Clin Pharmacol (2008) 65 (Suppl 1), 38–46.

Maraviroc + Rifampicin (Rifampin) and other CYP3A4 inducers

Rifampicin reduces the plasma levels of maraviroc by about two-thirds. Other inducers of CYP3A4, such as carbamazepine, phenobarbital, phenytoin, rifabutin and St John's wort, are predicted to have a similar effect.

Clinical evidence

In a placebo-controlled study in 12 healthy subjects, **rifampicin** 600 mg daily for 14 days reduced the steady-state AUC, the maximum plasma level and the minimum plasma level of maraviroc 100 mg twice daily by about two-thirds. Doubling the dose of maraviroc to 200 mg twice daily overcame this increase in metabolism, resulting in an AUC comparable to that of maraviroc 100 mg twice daily alone. No serious adverse effects were reported.[1]

Mechanism

Maraviroc is a substrate of the cytochrome P450 isoenzyme CYP3A4, hence its levels are significantly reduced by rifampicin, a potent inducer of CYP3A4; other inducers of CYP3A4 would therefore also be expected to reduce maraviroc levels. For a list of CYP3A4 inducers, see 'Table 1.4', (p.6). Note that maraviroc is also a substrate for P-glycoprotein, and rifampicin, which also induces P-glycoprotein, may further reduces maraviroc levels by this mechanism.

Importance and management

The pharmacokinetic interaction between maraviroc and rifampicin is clinically significant as the reduction in maraviroc plasma levels could result in a decrease in therapeutic efficacy and the development of viral resistance. Therefore, the manufacturers advise that the dose of maraviroc should be increased to 600 mg twice daily in patients taking rifampicin but *not* in those also taking a potent inhibitor of CYP3A4.[2,3] For further information on the effects of CYP3A4 inhibitors, such as ketoconazole or the protease inhibitors, on maraviroc, see 'Maraviroc + Ketoconazole and other CYP3A4 inhibitors', p.922, and 'Maraviroc + Protease inhibitors', p.923.

Other inducers of CYP3A4 are also predicted to reduce maraviroc levels. The US manufacturer[3] specifically recommends a dose increase of maraviroc to 600 mg twice daily in patients taking **carbamazepine**, **phenytoin** or **phenobarbital**, known potent inducers of CYP3A4. It would seem prudent to also consider this dose increase with **primidone** (which is metabolised to phenobarbital) and **fosphenytoin** (a prodrug of phenytoin). **St John's wort** is another known inducer of CYP3A4 and is expected to significantly reduce the levels of maraviroc and potentially reduce its antiviral effects: the manufacturers advise against its concurrent use with maraviroc.[2,3] Note that The UK manufacturer of maraviroc[2] does not rec-

ommend the concurrent use of maraviroc in patients taking both rifampicin and efavirenz, which is also an enzyme inducer. For further information on the effects of efavirenz on maraviroc, see 'Maraviroc + NNRTIs', p.923.

Rifabutin is a weaker inducer of CYP3A4 than rifampicin, and its use with maraviroc does not appear to have been studied. Note that if **rifabutin** is started in a patient taking maraviroc with a protease inhibitor, (except ritonavir-boosted fosamprenavir or tipranavir), the UK manufacturer advises that the dose of maraviroc is reduced to 150 mg twice daily.[2]

For a list of CYP3A4 inducers, see 'Table 1.4', (p.6).

1. Abel S, Jenkins TM, Whitlock LA, Ridgway E, Muirhead GJ. Effects of CYP3A4 inducers with and without CYP3A4 inhibitors on the pharmacokinetics of maraviroc in healthy volunteers. Br J Clin Pharmacol (2008) 65, (Suppl 1), 38–46.
2. Celsentri (Maraviroc). Pfizer Ltd. UK Summary of product characteristics, November 2009.
3. Selzentry (Maraviroc). Pfizer Labs. US Prescribing information, June 2009.

NNRTIs + Antiepileptics; Enzyme-inducing

Carbamazepine significantly reduces the levels of delavirdine, efavirenz and nevirapine, and is predicted to reduce the levels of etravirine. Other enzyme-inducing antiepileptics (e.g. phenytoin and phenobarbital) are expected to interact similarly, and cases of antiretroviral treatment failure have been reported.
Efavirenz and nevirapine reduce carbamazepine levels.

Clinical evidence

(a) Delavirdine

The manufacturer of delavirdine reports that in 8 subjects taking delavirdine 300 to 400 mg three times daily, **carbamazepine**, **phenytoin**, and **phenobarbital** reduced the minimum level of delavirdine by 90%. No information on other pharmacokinetic parameters is available.[1]

(b) Efavirenz

In a crossover study, 26 healthy subjects took either efavirenz 600 mg daily for 35 days with **carbamazepine** titrated from 200 mg daily to 400 mg daily from days 15 to 35, or carbamazepine titrated from 200 mg to 400 mg daily for 35 days with efavirenz 600 mg daily from days 22 to 35. **Carbamazepine** significantly reduced the AUC, peak plasma levels and trough plasma levels of efavirenz by 36%, 21% and 47%, respectively. Efavirenz reduced the AUC, peak plasma levels and trough plasma levels of **carbamazepine** by 27%, 20% and 35%, respectively. However, no significant increase was seen in the pharmacokinetics of the 10,11-epoxide metabolite of carbamazepine. No significant increase in serious adverse effects was reported with either combination.[2]

A case of undetectable efavirenz levels has been reported in one HIV-positive patient taking **phenytoin** 400 mg daily with efavirenz 800 mg daily. The dose of efavirenz was increased to 600 mg twice daily but the efavirenz levels did not increase until the **phenytoin** was stopped and lamotrigine and levetiracetam were started.[3] Another case of low efavirenz levels has been reported in a patient taking **phenytoin** 300 mg twice daily. When phenytoin was changed to levetiracetam, the patient's efavirenz levels rose from 0.58 micrograms/mL to 2.5 micrograms/mL within 3 weeks.[4]

One report describes efavirenz treatment failure in a patient given **oxcarbazepine**. However, in this particular case, efavirenz levels had been checked before and during **oxcarbazepine** treatment and were unchanged, and on further questioning the patient admitted poor adherence to the HAART regimen.[5]

(c) Nevirapine

In a study, healthy subjects were given a single dose of nevirapine alone or with a single dose of **carbamazepine** 400 mg, **phenobarbital** 200 mg or **phenytoin** 184 mg, or with a 3-day or 7-day course of **phenytoin** 184 mg daily. The half-life and time to first undetectable level of nevirapine were reduced by the single dose of **carbamazepine** and the two courses of **phenytoin** but not by the single doses of **phenytoin** or **phenobarbital**. Nevirapine plasma levels 8 hours after administration of the enzyme inducers were not affected.[6]

Mechanism

The NNRTIs are all primarily metabolised by the cytochrome P450 isoenzyme CYP3A4, and so their metabolism would be expected to be increased by drugs that are potent inducers of this isoenzyme, such as carbamazepine, phenytoin and phenobarbital. Efavirenz is also an inducer of CYP3A4, and so it can increase the metabolism of carbamazepine. Nevirapine would be expected to interact similarly (see 'Table 21.2', (p.914)).

Importance and management

The manufacturer of **delavirdine** does not recommend the concurrent use of carbamazepine, phenytoin or phenobarbital as it could result in the loss of efficacy of delavirdine and lead to the development of delavirdine resistance.[1] Note that primidone is metabolised to phenobarbital, and fosphenytoin is a prodrug of phenytoin, so these drugs should probably also be avoided.

From the study and case reports, the concurrent use of carbamazepine and **efavirenz** reduce the levels of both drugs, and this may also lead to treatment failure. The manufacturers therefore recommend that an alternative to carbamazepine should be considered.[7,8] The UK manufacturer states that no data are available on the potential interactions of efavirenz with phenytoin or phenobarbital.[7] Both manufacturers say that when efavirenz is given with these drugs, there is the potential for a reduction or increase in the plasma concentrations of both the antiepileptic as well as efavirenz. They recommend periodic monitoring of the plasma levels of phenytoin (and therefore probably fosphenytoin) or phenobarbital (and therefore probably primidone) on concurrent use.[7,8] Note that efavirenz may itself cause seizures, therefore the manufacturers recommend caution in patients with a history of convulsions.[7,8]

The US manufacturer of **nevirapine** recommends caution on the concurrent use of carbamazepine.[9]

Etravirine is also metabolised by CYP3A4, the manufacturer predicts that its levels will be reduced by carbamazepine, phenytoin or phenobarbital. They therefore advise against concurrent use.[10]

A number of other antiepileptics have been suggested as alternatives to the enzyme-inducing antiepileptics in patients taking NNRTIs. These include **gabapentin**, **lamotrigine**, **levetiracetam** and **vigabatrin**.[2-4,7]

NNRTIs + Azoles; Fluconazole

Fluconazole doubles nevirapine exposure. Fluconazole causes a minor rise in efavirenz steady-state levels, and does not alter delavirdine levels. Fluconazole is predicted to increase etravirine levels. Fluconazole levels are not altered by these NNRTIs.

Clinical evidence, mechanism, importance and management

(a) Delavirdine

In a study, 8 HIV-positive subjects were given delavirdine mesilate 300 mg three times daily for 30 days, with fluconazole 400 mg daily on days 16 to 30. When compared with 5 subjects given delavirdine alone, fluconazole had no significant effect on the pharmacokinetics of delavirdine. Fluconazole pharmacokinetics were not significantly affected by the concurrent use of delavirdine, when compared with previously reported data for healthy subjects, HIV-positive patients, and patients with AIDS.[1]

On the basis of these results, it would appear that no dose adjustments are needed if delavirdine and fluconazole are used together.

(b) Efavirenz

In a study, 20 healthy subjects were given fluconazole 400 mg daily for one day and then 200 mg daily for 6 days with efavirenz 400 mg daily. The pharmacokinetics of fluconazole were not affected by efavirenz, but the AUC of efavirenz was slightly raised, by 15%.[2] These effects are slight, and therefore it would appear that no dose adjustments are needed if efavirenz and fluconazole are used together.

(c) Etravirine

The manufacturers of etravirine predict that as fluconazole is an inhibitor of the cytochrome P450 isoenzyme CYP2C9, it will increase the levels of etravirine, which is partly metabolised by this route; however, this has not been specifically studied. Nevertheless, the UK manufacturer advises that no dose adjustment of etravirine is expected to be needed when it is taken with fluconazole.[3] Etravirine is not expected to affect the metabolism of fluconazole.[4]

(d) Nevirapine

In a study in 19 subjects, nevirapine 200 mg daily for 14 days and then 200 mg twice daily for 14 days did not have any clinically relevant effect on the pharmacokinetics of fluconazole 200 mg daily.[5] However, the concurrent use of fluconazole 200 mg daily[6] and nevirapine doubled the exposure to nevirapine, compared with historical control data.[5,6] In a retrospective study of patients who had received nevirapine-based HAART, there was no increase in the incidence of clinical hepatitis, elevated aminotransferases or skin rashes, when the outcomes of 225 patients not taking fluconazole, 392 patients taking fluconazole 400 mg weekly, and 69 patients taking fluconazole 200 mg daily with nevirapine were compared.[7] A retrospective study, by the same authors, in HIV-positive patients taking nevirapine-based HAART compared the trough levels of nevirapine and rate of adverse effects in patients also taking fluconazole with those not taking fluconazole. In 41 patients taking nevirapine with fluconazole 200 mg daily or 400 mg daily, the mean nevirapine trough levels were 9.8 mg/L and 12.2 mg/L, respectively, compared with a mean nevirapine trough level of 6.5 mg/L in the 81 patients not taking fluconazole. No significant increase in liver function tests occurred in the patients taking fluconazole compared with the control group, although one case of clinical hepatitis was reported with the concurrent use of fluconazole. The incidence of rash was higher in the control group compared with those patients also taking fluconazole.[8] Nevertheless, the manufacturers advise that, if fluconazole and nevirapine are used concurrently, patients should be closely monitored for nevirapine-associated adverse effects (such as rash and hepatitis).[5,6]

NNRTIs + Azoles; Itraconazole

Itraconazole had no effect on efavirenz levels in one study, whereas efavirenz modestly decreased itraconazole levels. Nevirapine may also decrease itraconazole levels. Etravirine is predicted to decrease itraconazole levels, and itraconazole is expected to increase etravirine levels.

Clinical evidence

(a) Efavirenz

In a study in healthy subjects, efavirenz 600 mg daily decreased the steady-state maximum plasma levels and the AUC of itraconazole 200 mg twice daily by 37% and 39%, respectively, and caused a similar decrease in the levels of the metabolite, hydroxyitraconazole. The steady-state maximum plasma levels and the AUC of efavirenz were not affected by itraconazole.[1,2]

A retrospective study identified 10 HIV-positive patients taking antiretroviral drugs, with itraconazole 200 mg or 400 mg daily for disseminated histoplasmosis. The 4 patients taking NNRTI-based regimens (efavirenz or nevirapine) had subtherapeutic itraconazole levels (less than 0.05 micrograms/mL). Two patients taking a protease inhibitor with an NNRTI had itraconazole levels between 0.5 and 0.7 micrograms/mL. Three patients had their NNRTI stopped due to subtherapeutic itraconazole levels. One patient taking a protease inhibitor with an NNRTI had a 500% increase in itraconazole levels when the NNRTI was stopped.[3]

A case of subtherapeutic itraconazole levels has been reported in an HIV-positive patient taking efavirenz, stavudine and lamivudine with disseminated histoplasmosis. The patient had been taking itraconazole 200 mg daily with some signs of clinical improvement, but itraconazole levels more than one year after the start of treatment were undetectable. The dose of itraconazole was subsequently increased to 200 mg twice daily but the levels remained undetectable and the urine levels of *Histoplasma* antigen remained raised. Stopping efavirenz and changing to a protease inhibitor-based regimen resulted in an increase in itraconazole levels and a reduction in the urine levels of *Histoplasma* antigen.[4] Note that protease inhibitors can raise itraconazole levels, see 'Protease inhibitors + Azoles; Itraconazole', p.964.

Another case of significantly reduced itraconazole levels, and an *increase* in the minimum plasma levels of its active metabolite hydroxyitraconazole, has also been reported.[5]

(b) Nevirapine

In a study in 12 healthy subjects, itraconazole 200 mg daily for 7 days had no significant effects on the pharmacokinetics of nevirapine 200 mg daily, also taken for 7 days. However, nevirapine decreased the AUC and maximum plasma concentration of itraconazole by 61% and 38%, respectively.[6]

Mechanism

The metabolism of itraconazole by the cytochrome P450 isoenzyme CYP3A4 is induced by efavirenz. Nevirapine and **etravirine** might interact similarly as they also induce CYP3A4, to varying degrees.

Importance and management

On the basis of the pharmacokinetic study, the manufacturers of **efavirenz** say that alternatives to itraconazole should be considered.[1,2] If there are no appropriate alternatives, it might be prudent to increase the dose of itraconazole, with increased monitoring for efficacy and toxicity of the combination.

As **nevirapine** also appears to reduce itraconazole levels, itraconazole efficacy should be monitored carefully; anticipate the need to increase the dose of itraconazole. No dose adjustments of efavirenz or nevirapine are needed if they are taken with itraconazole.

The manufacturers of **etravirine** predict that, as itraconazole is both an inhibitor and substrate of CYP3A4, it will increase the levels of etravirine, and etravirine will reduce itraconazole levels.[7,8] The US manufacturer advises that dose adjustments of itraconazole may be required, depending on other concurrent drugs.[8] However, the UK manufacturer advises that no dose adjustment of either itraconazole or etravirine is needed on concurrent use.[7]

NNRTIs + Azoles; Ketoconazole

Nevirapine markedly reduces the AUC of ketoconazole. Efavirenz interacts similarly, whereas delavirdine may increase ketoconazole levels. NNRTI plasma levels may be raised by ketoconazole.

Clinical evidence

(a) Delavirdine

The manufacturer notes that, in 26 patients taking ketoconazole, the minimum plasma level of delavirdine was 50% higher than population pharmacokinetic data.[1]

(b) Efavirenz

In a study in 12 HIV-positive patients, efavirenz 600 mg daily for 15 days reduced the $AUC_{0\text{-}24}$ and maximum plasma concentration of a single 400-mg dose of ketoconazole by 72% and 44%, respectively.[2]

(c) Nevirapine

The manufacturers of nevirapine quote a study in which nevirapine 200 mg twice daily was given with ketoconazole 400 mg daily. The ketoconazole AUC was markedly reduced by 72% and its maximum plasma levels were reduced by 44%.[3,4] In addition, the nevirapine plasma levels were raised by 15 to 28%, when compared with historical control data.[3]

Mechanism

Ketoconazole is likely to inhibit the metabolism of the NNRTIs by the cytochrome P450 isoenzyme CYP3A4. Efavirenz and nevirapine both induce the metabolism of ketoconazole by CYP3A4. In theory, **etravirine**, a weak CYP3A4 inducer may interact similarly, whereas delavirdine is likely to inhibit ketoconazole metabolism by CYP3A4.

Importance and management

A clinically significant interaction appears to occur between the NNRTIs and ketoconazole, which may lead to antifungal treatment failure. The manufacturers of **nevirapine** state that ketoconazole and nevirapine should not be used together, because of the likely reduced efficacy of ketoconazole.[3,4] **Efavirenz** appears to cause a similar reduction in ketoconazole levels; the possible effect of ketoconazole on efavirenz does not appear to have been studied.[5]

The manufacturers of **etravirine** state that, as ketoconazole is a potent inhibitor of CYP3A4, it would be expected to increase plasma levels of etravirine, whereas etravirine is expected to reduce plasma levels of ketoconazole.[6,7] The US manufacturer advises that dose adjustments of ketoconazole may be required, depending on other concurrent drugs.[7] However, the UK manufacturer advises that no dose adjustment of either ketoconazole or etravirine is required on concurrent use.[6]

NNRTI levels might be raised by ketoconazole, which might increase adverse effects. Cautious monitoring of both the efficacy of ketoconazole and of an increase in the adverse effects of the NNRTIs would be prudent if concurrent use is necessary.

NNRTIs + Azoles; Posaconazole

Efavirenz reduces the levels of posaconazole. No change in efavirenz levels appears to occur with posaconazole. Etravirine levels are predicted to be raised by posaconazole.

Clinical evidence, mechanism, importance and management

In a study in 10 healthy subjects, **efavirenz** 400 mg daily reduced the AUC and maximum concentration of posaconazole by 50% and 45%, respectively.[1] Posaconazole is a substrate for glucuronosyltransferases, and it is suggested that **efavirenz** induces this route of metabolism to reduce the levels of posaconazole.[1] Posaconazole is an inhibitor of the cytochrome P450 isoenzyme CYP3A4, and would therefore be expected to inhibit the metabolism of **efavirenz**. However, the same study reported that posaconazole had no significant effect on the pharmacokinetics of **efavirenz**.[1] The manufacturer of posaconazole advises avoiding concurrent use of **efavirenz** unless the benefits outweigh the risks.[2]

The levels of **etravirine** are predicted to be increased by posaconazole; however, the UK manufacturer states that no dose adjustment is needed on concurrent use.[3]

NNRTIs + Azoles; Voriconazole

Voriconazole modestly increases efavirenz levels, and is predicted to increase the levels of delavirdine, etravirine, and nevirapine. Efavirenz markedly decreases voriconazole levels: nevirapine is predicted to interact similarly, whereas delavirdine and etravirine are predicted to increase voriconazole levels.

Clinical evidence

In a study in 17 healthy subjects, **efavirenz** 400 mg daily decreased the steady-state maximum plasma levels and the AUC of voriconazole 200 mg twice daily by 62% and 78%, respectively. At the same time, the steady-state maximum plasma levels and the AUC of **efavirenz** were increased by 37% and 44%, respectively. No increase in adverse effects was reported with the concurrent use of efavirenz and voriconazole, compared with efavirenz alone.[1] In a dose-adjustment study in 15 healthy subjects, when compared with voriconazole 200 mg twice daily alone, the AUC and maximum plasma concentration of voriconazole 300 mg twice daily were 55% and 36% lower, respectively, when **efavirenz** 300 mg daily for 7 days was also taken. The **efavirenz** AUC was equivalent to that seen with efavirenz 600 mg daily alone. When the voriconazole dose was increased to 400 mg twice daily in 14 of the subjects, the AUC of voriconazole was just 7% lower than that seen with voriconazole 200 mg twice daily alone. The AUC of **efavirenz** was increased by 17% and the maximum plasma concentration was equivalent, when compared with efavirenz 600 mg daily alone.[2]

There is one case of a patient taking a variety of antiretrovirals and antibacterials who developed oral candidiasis while taking voriconazole 200 mg twice daily, which was attributed to an interaction with **efavirenz**. The dose of voriconazole was titrated upwards to 350 mg twice daily to achieve higher trough levels. The candidiasis was eventually found to be resistant to voriconazole, and it was suggested that this developed because of under-dosing in the presence of **efavirenz**.[3]

Mechanism

The metabolism of voriconazole by the cytochrome P450 isoenzyme CYP3A4 is induced by efavirenz and therefore concurrent use lowers voriconazole levels. Nevirapine is predicted to interact similarly, whereas delavirdine has been reported to inhibit the metabolism of voriconazole *in vitro*.[4] **Etravirine** is a weak inducer of CYP3A4, and is a weak inhibitor of CYP2C9 and CYP2C19. As voriconazole is primarily metabolised by CYP2C19 as well as CYP2C9 and CYP3A4, an increase in voriconazole

levels may be expected on concurrent use.[5,6] All of the NNRTIs are substrates of CYP3A4, which is inhibited by voriconazole, and therefore voriconazole may raise the levels of the NNRTIs.

Importance and management

On the basis of the pharmacokinetic studies the manufacturers state that **efavirenz** should not be given with voriconazole, unless the doses of both drugs are adjusted.[4,7-9] The recommendation is to double the usual dose of voriconazole to 400 mg twice daily, and to halve the usual efavirenz dose to 300 mg daily. The dose of efavirenz should be increased back to 600 mg daily when the voriconazole course is finished.[4,7-9]

Nevirapine significantly reduces the levels of other antifungals metabolised by CYP3A4, such as 'ketoconazole', (p.927), and it would be expected to have a similar effect on voriconazole metabolism, whereas **delavirdine** might increase voriconazole levels. NNRTI levels might also be raised by voriconazole, which might increase adverse effects. The manufacturers of voriconazole suggest that patients given delavirdine or nevirapine should be carefully monitored for evidence of drug toxicity and/or loss of efficacy during concurrent use.[4,7]

The manufacturers of **etravirine** state that the levels of both etravirine and voriconazole are likely to be raised on concurrent use.[5,6] The US manufacturer advises that dose adjustments of voriconazole may be required depending on other concurrent drugs.[6] However, the UK manufacturer advises that no dose adjustment of either voriconazole or etravirine are required on concurrent use.[5]

NNRTIs + Drugs that affect gastric pH

Antacids roughly halve the AUC of delavirdine, and the H_2-receptor antagonists or proton pump inhibitors would be expected to interact similarly. Aluminium/magnesium antacids and H_2-receptor antagonists do not appear to interact to a clinically relevant extent with efavirenz or nevirapine. Omeprazole modestly increases the AUC of etravirine whereas ranitidine slightly reduces the AUC of etravirine.

Clinical evidence, mechanism, importance and management

(a) Delavirdine

Delavirdine is poorly soluble at pHs greater than 3, so the effect of giving delavirdine 300 mg ten minutes after an **antacid** was studied in 12 healthy subjects. The AUC and maximum serum levels of delavirdine were reduced by 48% and 57%, respectively, suggesting that delavirdine should not be given with **antacids**.[1] The manufacturer recommends separating administration by at least one hour.[2] Although it has not been studied, it is predicted that other drugs that reduce gastric acidity, such as **H_2-receptor antagonists** and **proton pump inhibitors**, will also reduce the absorption of delavirdine, and their long-term use with delavirdine is not recommended.[2]

Note that **didanosine** tablets are buffered with an **antacid**, and may reduce the levels of delavirdine. See 'NNRTIs + NRTIs', p.930, for further information.

(b) Efavirenz

The manufacturer notes that **aluminium/magnesium hydroxide** antacids and **famotidine** did not have any effect on the absorption or pharmacokinetics of efavirenz.[3,4] Therefore, no efavirenz dose adjustment is necessary with these drugs.[4] Other drugs that reduce gastric acidity are not expected to affect efavirenz absorption.[3]

(c) Etravirine

In a study in 16 healthy subjects, **ranitidine** 150 mg twice daily for 7 days slightly decreased the AUC of a single 100-mg dose of etravirine by 14%.[5] In 17 healthy subjects, **omeprazole** 40 mg daily for 7 days increased the AUC of a single 100-mg dose of etravirine by 41%, when compared with the AUC in 18 healthy subjects given etravirine alone. However, no significant change in the maximum concentration of etravirine occurred with either drug.[5]

In a study in 12 healthy subjects to investigate the effect of etravirine on the cytochrome P450 isoenzyme CYP2C19, a single 40-mg dose of **omeprazole** was given on days one and 14 of a 14-day course of etravirine 200 mg twice daily. Etravirine increased the ratio of the AUC of **omeprazole** to 5-hydroxyomeprazole by 29% on day one and 3.9-fold on day 14, of etravirine use.[6]

The mechanism of this modest increase in the AUC of etravirine with **omeprazole** is unclear. Subsequent pharmacokinetic analysis by the same group suggested that inhibition of the cytochrome P450 isoenzyme CYP2C19 by **omeprazole** may be involved.[5] However, this modest increase in the AUC of etravirine is not considered clinically relevant. Similarly, the minor decrease in etravirine AUC with **ranitidine** is not clinically significant therefore no special precautions are needed with concurrent use. The moderate increase in omeprazole levels would not be expected to be clinically significant or result in adverse effects as omeprazole has a wide therapeutic margin

The manufacturers therefore recommend that no dose adjustment is needed if etravirine is taken with a **proton pump inhibitor** or an **H_2-receptor antagonist**.[7,8]

(d) Nevirapine

In a study in 24 healthy subjects it was found that 30 mL of *Maalox* (**aluminium/magnesium hydroxide**) caused some moderate changes in the pharmacokinetics of nevirapine 200 mg, but none of them was considered to be clinically relevant.[9] The manufacturer states that nevirapine has no significant effect on the pharmacokinetics of **cimetidine**, and **cimetidine** causes only a slight 7% increase in the trough levels of nevirapine.[10] Therefore, no special precautions would seem to be necessary when nevirapine is taken with an **antacid** or with **cimetidine**.

NNRTIs + Food

Food modestly increases efavirenz levels, and this may increase the frequency of adverse effects. Food increases the bioavailability of etravirine. Food has no clinically relevant effect on the levels of delavirdine or nevirapine; however, orange juice may affect delavirdine absorption.

Clinical evidence, mechanism, importance and management

(a) Delavirdine

In a randomised, crossover study in 13 HIV-positive patients taking delavirdine 400 mg three times daily, there were no changes in the steady-state serum levels of delavirdine taken with food, or taken at least one hour before or 2 hours after food, for 2 weeks. Food had no significant effect on the AUC or trough plasma level of delavirdine, although the peak plasma concentration of delavirdine was reduced by 21%.[1] This differed from a

previous single-dose study, in which there was a 26% fall in the AUC of delavirdine when it was taken with food.[2] There would appear to be no need to avoid taking delavirdine with food.

Orange juice increased delavirdine absorption by 50% to 70% in subjects with gastric hypoacidity, but had less effect (0 to 30%) in those with normal gastric acidity. However, despite the use of **orange juice**, the AUC of delavirdine was still about 50% lower in patients with gastric hypoacidity than those without.[3]

Delavirdine is a weak base that is poorly soluble at neutral pH. Therefore, in subjects with gastric hypoacidity, the absorption of delavirdine is reduced, and substances that lower gastric pH increase its absorption. The manufacturer of delavirdine recommends that, in patients with achlorhydria, delavirdine should be taken with an acidic beverage such as **orange** or **cranberry juice**, although this has not been specifically investigated.[4]

(b) Efavirenz

The manufacturers of efavirenz note that a high-fat meal increased the AUC of a 600-mg efavirenz *tablet* by 28%, when compared with fasting conditions, and increased its maximum concentration by 79%.[5,6] After a similar meal, the AUC and maximum level of the *capsule* formulation was increased by 22% and 39%, respectively, and after a low-fat meal the increases were 17% and 51%, respectively.[6] The manufacturers say that these increases might increase the frequency of adverse effects and they recommend that efavirenz is taken on an empty stomach, preferably at bedtime.[5,6]

(c) Etravirine

In a randomised, crossover study in 20 healthy subjects, a single 100-mg dose of etravirine was taken on an empty stomach, with a light breakfast (a croissant), with a standard breakfast, with a high-fibre breakfast or with a high-fat breakfast. The AUC of etravirine was 51% lower when it was taken on an empty stomach, compared with a standard breakfast. The AUC of etravirine taken after a light breakfast or high-fibre breakfast was 20% and 25% lower respectively, than after a standard breakfast. A high-fat breakfast resulted in a slight 9% increase in the AUC of etravirine. As the absorption of etravirine was nearly halved when it was taken on an empty stomach, it is recommended that etravirine should be taken with food. The differences between the types of meals were not considered to be clinically relevant.[7]

(d) Nevirapine

In a study in 24 healthy subjects, a high-fat breakfast caused some moderate changes in the pharmacokinetics of nevirapine 200 mg, but the AUC was not affected and none of the changes were considered to be clinically relevant.[8] Nevirapine may therefore be taken with or without food.

NNRTIs + Macrolides

Delavirdine may increase the levels of clarithromycin, whereas efavirenz, etravirine, and nevirapine may reduce clarithromycin levels, and increase those of its hydroxy metabolite. Clarithromycin does not appear to affect the pharmacokinetics of delavirdine, efavirenz or nevirapine to a clinically relevant extent, but may modestly increase etravirine levels. There is no pharmacokinetic interaction between azithromycin and efavirenz. A case of a neuropsychiatric reaction has been attributed to the use of clarithromycin in a man taking nevirapine.

Clinical evidence

(a) Delavirdine

In a study in 7 HIV-positive patients, **clarithromycin** 500 mg twice daily for 15 days did not cause a clinically significant change in the pharmacokinetics of delavirdine 300 mg three times daily, when compared with 4 other HIV-positive patients taking only delavirdine. The combination was well tolerated and no serious adverse events occurred.[1] However, although delavirdine levels are unaffected, the manufacturer notes that the AUC of **clarithromycin** was doubled by delavirdine.[2]

(b) Efavirenz

The manufacturers note that the concurrent use of **clarithromycin** 500 mg twice daily and efavirenz 400 mg daily for 7 days reduced the AUC of **clarithromycin** by 39% and increased the AUC of its hydroxy metabolite by 34%. Moreover, 46% of subjects receiving the combination developed a rash.[3,4] Clarithromycin had a minimal effect on the pharmacokinetics of efavirenz.[4] The manufacturers also note that there was no clinically significant pharmacokinetic interaction when a single 600-mg dose of **azithromycin** was given to healthy subjects who had been taking efavirenz 400 mg daily for 7 days.[3,4]

(c) Etravirine

The manufacturer of etravirine notes that concurrent use of etravirine and **clarithromycin** 500 mg twice daily reduced the AUC, and the maximum and minimum concentrations of **clarithromycin** by 39%, 53%, and 34%, respectively. The AUC and maximum concentration of the hydroxy metabolite were increased by 21% and 33%, respectively. In addition, **clarithromycin** increased the AUC and maximum concentration of etravirine by 42% and 44%, respectively.[5]

(d) Nevirapine

In a study in 15 HIV-positive patients, nevirapine 200 mg twice daily reduced the AUC of **clarithromycin** by 30% and reduced the maximum and minimum level of **clarithromycin** by 21% and 46%, respectively. Nevirapine also increased the AUC of the hydroxy metabolite of **clarithromycin** by about 27%.[6] The manufacturers also report that the AUC of nevirapine was increased by 26% by **clarithromycin**, when compared with historical controls. The AUC of **clarithromycin** was reduced by 31% and the AUC of its hydroxy metabolite was increased by 42%.[7,8]

A man developed hyperactivity (poor concentration, anxiety, suicidal and homicidal ideation) when taking **clarithromycin** and antiretroviral drugs, including nevirapine. This was thought to be due to accumulation of the hydroxy metabolite of **clarithromycin**.[9]

Mechanism

The NNRTIs are substrates of the cytochrome P450 isoenzyme CYP3A4, which is inhibited by clarithromycin. Delavirdine is also reported to inhibit CYP3A4, whereas efavirenz and nevirapine induce CYP3A4. Etravirine is also reported to weakly induce CYP3A4.[5] Therefore alterations in the metabolism of these drugs by CYP3A4 results in the altered levels seen.

Importance and management

Delavirdine may increase levels of clarithromycin. The manufacturer of delavirdine recommends that when both drugs are given to patients with renal impairment, the dose of clarithromycin should be reduced.[2]

In contrast, nevirapine may decrease clarithromycin levels and increase the levels of the hydroxy metabolite of clarithromycin. The manufacturer of **nevirapine** suggests that no dose adjustment of clarithromycin is needed; however, they say that alternatives to clarithromycin should be considered for the treatment of *Mycobacterium avium* complex (MAC) infection, as the hydroxy metabolite is not as active against this bacterium.[7,8] The UK manufacturer also advises close monitoring of liver function tests on the concurrent use of nevirapine and clarithromycin.[7]

Efavirenz may also decrease clarithromycin levels and increase the levels of the hydroxy metabolite of clarithromycin The manufacturers of efavirenz say that the clinical significance of the changes to clarithromycin pharmacokinetics is not known, but they suggest alternatives to clarithromycin, such as azithromycin, should be considered.[3,4] They also note that, as a possible interaction with erythromycin has not been studied, dose recommendations for concurrent use with efavirenz cannot be advised.[3]

Etravirine may also decrease clarithromycin levels and increase the levels of the hydroxy metabolite of clarithromycin. The UK manufacturer of **etravirine** also advise that, as the hydroxy metabolite of clarithromycin has reduced activity against *Mycobacterium avium* complex (MAC), an alternative to clarithromycin should considered for treating MAC.[5] The

increase in etravirine levels caused by clarithromycin would not be expected to be of clinical relevance.

NNRTIs + NNRTIs

Nevirapine modestly reduces the levels of efavirenz, whereas efavirenz has no effect on nevirapine levels. Efavirenz and nevirapine may reduce the levels of etravirine.

Clinical evidence, mechanism, importance and management

In a study in HIV-positive patients taking efavirenz 600 mg daily, the addition of **nevirapine** 400 mg daily resulted in a median decrease in the AUC of **efavirenz** of 22%, and a decrease in its minimum plasma concentration of 36%. The steady-state pharmacokinetics of **nevirapine** were not altered by **efavirenz**, when compared with historical control data.[1] However, the UK manufacturer does not recommend this combination as concurrent use could lead to a higher risk of adverse effects and does not improve efficacy over either NNRTI alone.[2]

In a study in 24 healthy subjects, pre-dosing with **efavirenz** 600 mg daily (taken on days one to 14) reduced the AUC, and maximum and trough levels of **etravirine** 400 mg once daily (taken on days 15 to 28) by 32%, 22% and 42%, respectively. When **etravirine** was taken as 200 mg twice daily, the AUC, and maximum and trough levels of **etravirine** were reduced (by 26%, 19%, and 34%, respectively). The authors note that **etravirine** is metabolised by the cytochrome P450 isoenzyme CYP3A4 and its bioavailability is reduced by 40% when given with **efavirenz**, an inducer of this isoenzyme. However, the pharmacokinetic changes were not considered to be of clinical significance.[3] The UK manufacturer of **etravirine** advises that **efavirenz** and **nevirapine** may reduce the levels of **etravirine** and therefore concurrent use is not recommended because it may cause treatment failure.[4]

NNRTIs + NRTIs

Delavirdine absorption is reduced by the buffered preparation of didanosine, but probably not the enteric-coated preparation of didanosine. Delavirdine does not affect the pharmacokinetics of zidovudine. There is no pharmacokinetic interaction between efavirenz and zidovudine or lamivudine; or between nevirapine and didanosine, lamivudine, stavudine, zalcitabine or zidovudine. No interaction is predicted to occur between etravirine and abacavir, didanosine, emtricitabine, lamivudine, stavudine or zidovudine.

Clinical evidence, mechanism, importance and management

(a) Delavirdine

A study in 34 HIV-positive patients taking **zidovudine** 200 mg three times daily found that delavirdine mesilate 400 mg to 1.2 g daily for 9 days had no clinically significant effect on the pharmacokinetics of **zidovudine**.[1]

In a steady-state study, 9 HIV-positive patients taking **didanosine** 200 mg twice daily were also given delavirdine mesilate 400 mg three times daily for 14 days. **Didanosine** caused a 37% reduction in the maximum delavirdine serum levels and a trend towards a lower AUC, but when the drugs were given one hour apart no significant effect occurred. The pharmacokinetics of **didanosine** were not significantly affected by delavirdine.[2] A single-dose study in 12 HIV-positive patients found similar results.[3] The buffered preparation of **didanosine** contains antacids to increase its absorption, and antacids decrease the absorption of delavirdine (see 'NNRTIs + Drugs that affect gastric pH', p.928). The authors of the multiple-dose study advise that as **didanosine** had no clinically significant effect on the AUC of delavirdine, there is no reason to separate the doses.[2] However, the US manufacturer of delavirdine advises that concurrent use with buffered **didanosine** may reduce the levels of both delavirdine and didanosine, and they therefore recommend separating their administration by at least one hour.[4] The enteric-coated preparation of **didanosine**, which does not contain antacids, would not be expected to reduce the absorption of delavirdine.

(b) Efavirenz

The manufacturer notes that there were no clinically significant pharmacokinetic interactions between efavirenz and **lamivudine** or **zidovudine** in HIV-positive patients.[5,6] No dose adjustments are required on concurrent use.[6] No pharmacokinetic interactions are anticipated with other NRTIs.[5,6]

(c) Etravirine

The manufacturer of etravirine states that no significant interaction occurs between etravirine and **didanosine**. Therefore, no dose adjustment is needed on concurrent use. They also state that no interaction would be expected with other NRTIs which are primarily renally excreted, such as **abacavir**, **emtricitabine**, **lamivudine**, **stavudine**, and **zidovudine**.[7]

(d) Nevirapine

The pharmacokinetics of **didanosine** and **zidovudine** with or without nevirapine were assessed in 175 HIV-positive subjects. The bioavailability of **didanosine** was not affected, but the bioavailability of **zidovudine** was decreased by about one-third by nevirapine.[8] In a steady-state study in 24 HIV-positive patients, nevirapine 200 mg every 12 hours was added to regimens of **didanosine**, **didanosine** with **zidovudine**, or **zidovudine** with **zalcitabine**, for a 4-week period. No significant changes in the pharmacokinetics of **didanosine** or **zalcitabine** were seen. However, in the group taking **didanosine** with **zidovudine** the peak **zidovudine** plasma levels and AUC were reduced by 27% and 32%, respectively by nevirapine. The **zidovudine** pharmacokinetics in the group taking **zidovudine** and **zalcitabine** were not affected by nevirapine.[9] The reasons for these changes are not clear, but the clinical consequences are thought to be small, and the safety data indicate that the concurrent use of these drugs is safe and well tolerated. In another study in 4 patients, the simultaneous administration of nevirapine with **didanosine** tablets containing antacids had no effect on nevirapine absorption.[10] In a study in 22 patients, nevirapine 200 mg once daily for 2 weeks then 200 mg twice daily had no effect on the AUC of **stavudine** 30 to 40 mg twice.[11] Nevirapine appears to have no effect on **lamivudine** clearance, based on a population pharmacokinetic study.[12]

The UK manufacturer says that no dose adjustments are needed if **didanosine**, **lamivudine**, **stavudine**, **zalcitabine** or **zidovudine** is taken with nevirapine.[13]

NNRTIs + Protease inhibitors

In general, efavirenz and nevirapine decrease the levels of the protease inhibitors, whereas delavirdine increases them. Amprenavir and nelfinavir decrease the levels of delavirdine. Most protease inhibitors do not appear to affect the levels of efavirenz or nevirapine. There is some evidence of increased adverse effects with antiviral doses of ritonavir and efavirenz, or saquinavir and delavirdine, including raised liver enzymes.

Clinical evidence, mechanism, importance and management

(a) Delavirdine

For a summary of the studies of the pharmacokinetic interactions of delavirdine and various protease inhibitors, see 'Table 21.3', (p.932). In general, these studies show that delavirdine can markedly increase protease inhibitor exposure. In addition, **amprenavir** and **nelfinavir** have been shown to approximately halve the AUC of delavirdine.

Delavirdine and the protease inhibitors are known to be both inhibitors of, and substrates for the cytochrome P450 isoenzyme CYP3A4, see 'Table 21.2', (p.914).

It has been suggested that delavirdine could be used clinically to boost the exposure to protease inhibitors, and this has been tried in at least one study.[1] However, this combination is complicated by the reduction in delavirdine levels caused by some protease inhibitors, and the combination may not be appropriate if the antiviral effect of delavirdine is required.[2] Moreover, if the combination is used, patients should be closely monitored for toxicity as in one study of **nelfinavir** and delavirdine, 4 out of 24 subjects had to stop both drugs before completing the study because of neutropenia, which resolved over several days.[3] The UK manufacturer of **saquinavir** says that liver function should be monitored frequently if delavirdine is also given, because in a small preliminary study hepatic enzymes were raised in 13% of subjects (grade 3 or 4 in 6%) receiving the combination.[4]

(b) Efavirenz

For a summary of the studies of the pharmacokinetic interactions of efavirenz and various protease inhibitors, see 'Table 21.3', (p.932). Most of the protease inhibitors did not affect efavirenz levels, although **ritonavir** caused a 20% increase in levels. Efavirenz is an inducer of the cytochrome P450 isoenzyme CYP3A4, by which the protease inhibitors are metabolised. With the exceptions of **nelfinavir** and **ritonavir**, which showed minor to modest increases in levels, efavirenz reduces the levels of the protease inhibitors, often to levels likely to lead to reduced antiviral efficacy. Ways to overcome this include the addition of low-dose **ritonavir** to boost the levels of the protease inhibitor (recommended for **amprenavir**, **atazanavir**, **fosamprenavir**, **saquinavir**) or increasing the dose for protease inhibitors already boosted by **ritonavir** (recommended for **lopinavir**). For a summary of the manufacturers' recommended regimens for use with efavirenz 600 mg daily, see 'Table 21.4', (p.936). However, the manufacturers of efavirenz note that increased adverse effects, including dizziness, nausea, paraesthesia and elevated liver enzyme levels, occurred with the concurrent use of efavirenz and **ritonavir** 500 or 600 mg twice daily (antiretroviral dose), and the combination was not well tolerated.[5,6] They recommend monitoring liver enzyme levels with this combination.[6] The UK manufacturer says that the tolerability of low-dose **ritonavir** with efavirenz has not been assessed, and they caution that the possibility of an increase in the incidence of efavirenz-associated adverse events should be considered with any **ritonavir**-boosted regimen used with efavirenz, due to a possible interaction.[5]

With **ritonavir**-boosted **lopinavir**, although an increased dose of 133/533 mg twice daily with efavirenz or nevirapine produced similar plasma levels of lopinavir to those seen with the lower dose of 400/100 mg twice daily without an NNRTI, the proportion of patients with a suboptimal minimum lopinavir level tended to be higher in those patients receiving the NNRTI.[7] This suggests that some patients may need a further increase in lopinavir/ritonavir dose. Another study with **ritonavir**-boosted **atazanavir** also found that the increased dose of atazanavir for use with NNRTIs did not appear to overcome the inducer effect of NNRTIs (efavirenz or nevirapine) and led to a 43% lower median minimum atazanavir level, and a greater proportion of patients with suboptimal minimum levels (25% versus 7%).[8] The US guidelines recommend a dose of **atazanavir** 400 mg with **ritonavir** 100 mg if it is given with efavirenz to treatment-naive patients; concurrent use is not recommended in treatment-experienced patients. However, note that the concurrent use of an NNRTI with a protease inhibitor is not a recommended regimen when starting antiretrovirals in treatment-naive patients.[9,10]

(c) Etravirine

For a summary of the studies of the pharmacokinetic interactions of etravirine and various protease inhibitors, see 'Table 21.3', (p.932). Etravirine is a weak inducer of the cytochrome P450 isoenzyme CYP3A4, and it may also inhibit CYP2C19 and P-glycoprotein, and the manufacturers advise that it may therefore significantly affect the levels of the protease inhibitors.[11,12] Hence the concurrent use of etravirine with unboosted protease inhibitors is not recommended.[10-12] Etravirine itself is also partly metabolised by CYP3A4 and therefore some protease inhibitors can affect its levels.[11,12] For a summary of the manufacturers' recommended regimens for use with etravirine, see 'Table 21.4', (p.936). The US guidelines specifically advise against the concurrent use of etravirine with unboosted protease inhibitors or with ritonavir-boosted **atazanavir**, **fosamprenavir** or **tipranavir**.[10]

Note that the concurrent use of an NNRTI with a protease inhibitor is not a recommended regimen when starting antiretrovirals in treatment-naive patients.[9,10]

(d) Nevirapine

For a summary of the studies of the pharmacokinetic interactions of nevirapine and various protease inhibitors, see 'Table 21.3', (p.932). Most protease inhibitors do not appear to affect the levels of nevirapine, although some caused a minor to modest increase. Nevirapine is an inducer of the cytochrome P450 isoenzyme CYP3A4, and so would be expected to reduce the levels of some of the protease inhibitors (see 'Table 21.2', (p.914)), sometimes to levels that are unlikely to be effective. Low-dose **ritonavir** has been used to boost the levels of some protease inhibitors when they were given with nevirapine. For a summary of the manufacturers' recommended regimens for use with nevirapine see 'Table 21.4', (p.936). If nevirapine is used with protease inhibitors, therapy should be closely monitored. For studies suggesting that increased doses of **ritonavir**-boosted **lopinavir** and **atazanavir** may not be sufficient in all patients given NNRTIs (including nevirapine), see *Efavirenz*, above. Note that the concurrent use of an NNRTI with a protease inhibitor is not a recommended regimen when starting antiretrovirals in treatment-naive patients.[9,10]

Table 21.3 Summary of the pharmacokinetic interactions of NNRTIs and protease inhibitors

Drug combination	*No. of healthy subjects (unless specified)*	*Change in AUC (unless specified)*		*Refs*
		NNRTI	**Protease inhibitor**	
Delavirdine studies (usually 400 mg three times daily or 600 mg twice daily)				
Amprenavir	6 HIV-positive children		3-fold increase in Cmax* 5- to 10-fold increase in Cmin*	1
Amprenavir 1200 mg Amprenavir 1200 mg twice daily alone then 600 mg twice daily in combination	12 11	21% increase 47% decrease	4-fold increase 32% increase versus twice the dose given alone	2
Amprenavir 600 mg twice daily	18	61% decrease	130% increase	3
Indinavir 800 mg alone then 600 mg in combination	14	No change	44% increase versus higher dose given alone	4, 5
Nelfinavir 750 mg three times daily	24	42% decrease	92% increase	6
Ritonavir 300 mg twice daily		No change in steady state level	No change in steady state level	4
Ritonavir 600 mg twice daily	12 HIV-positive subjects	No change*	64% increase 81% increase in Cmin	7
Ritonavir 100 mg twice daily	19	No change	80% increase	8
Saquinavir 600 mg three times daily		No change in steady state level	5-fold increase in steady state level	4
Efavirenz studies (600 mg once daily)				
Amprenavir	2 HIV-positive children		Undetectable levels in less than 4 hours†	1
Amprenavir 1200 mg twice daily	7 HIV-positive subjects		About an 80% decrease in trough levels†	9
Amprenavir 1200 mg twice daily	11 HIV-positive subjects	No change*	24% decrease 43% decrease in Cmin	10
Atazanavir 400 mg once daily			74% decrease	11
Atazanavir/Ritonavir 300/100 mg once daily			39% increase	11
Darunavir/Ritonavir 300/100 mg twice daily	12	21% increase, 15% increase in Cmax, 17% increase in Cmin	13% decrease with a 31% decrease in Cmin, 15% decrease in Cmax (darunavir)	12
Fosamprenavir/Ritonavir 1395 mg/200 mg once daily	11		31% decrease in Cmin (amprenavir)	13
Fosamprenavir/Ritonavir 700 mg/100 mg twice daily	14		Slight decrease in Cmin (amprenavir)	13
Fosamprenavir/Ritonavir 1395 mg/300 mg once daily	11		Amprenavir levels comparable to that seen with fosamprenavir/ritonavir 1395/200 mg alone	13
Indinavir 1000 mg three times daily			Decrease of about 31% versus lower dose given alone	14
Indinavir/Ritonavir 800/100 mg twice daily	14	No change*	25% decrease (indinavir) 36% decrease (ritonavir)	15
Indinavir/Ritonavir 800/100 mg twice daily	20 HIV-positive subjects	31% increase in Cmin*	Cmin halved* (indinavir)	16
Lopinavir/Ritonavir 400/100 mg twice daily	24 HIV-positive subjects		44% decrease in Cmin* (lopinavir)	17
Lopinavir/Ritonavir 533/133 mg twice daily	26 HIV-positive subjects		No significant change in Cmin versus lower dose given without efavirenz* (lopinavir)	17
Lopinavir/Ritonavir 500/125 mg twice daily			No change in steady state level (lopinavir) relative to lopinavir/ritonavir 400/100 mg twice daily	18

Table 21.3 Summary of the pharmacokinetic interactions of NNRTIs and protease inhibitors (continued)

Drug combination	*No. of healthy subjects (unless specified)*	*Change in AUC (unless specified)*		*Refs*
		NNRTI	**Protease inhibitor**	
Lopinavir/Ritonavir 300/75 mg/m^2 twice daily	15 HIV-positive children	No change*	No change*	19
Nelfinavir 750 mg three times daily		No change	20% increase (nelfinavir), 37% decrease in M8 metabolite of nelfinavir	20
Nelfinavir/Ritonavir 1875/200 mg once daily	24	No change*	30% increase (nelfinavir) 20% decrease (ritonavir)	21
Ritonavir 500 mg twice daily		21% increase	17% increase	22
Saquinavir/Ritonavir 400/400 mg twice daily	12	No change*	No change in Cmin (ritonavir) 10% decrease in Cmin (saquinavir)	23
Tipranavir/Ritonavir 500/100 mg twice daily	24/21	No change	About a 40% decrease in Cmin (tipranavir)*	24
Etravirine studies (100 mg or 200 mg twice daily)				
Atazanavir/Ritonavir 300/100 mg daily		30% increase with 30% increase in Cmax and 26% increase in Cmin	14% decrease with 38% decrease in Cmin and no change in Cmax (atazanavir)	25
Darunavir/Ritonavir 600/100 mg twice daily	23	37% decrease with 32% decrease in Cmax, 49% decrease in Cmin	No change with etravirine 100 mg, 15% increase with etravirine 200 mg, no significant change in Cmin and Cmax (darunavir)	26
Darunavir/Ritonavir 600/100 mg twice daily	10 HIV-positive subjects	No significant change	No significant change	27
Fosamprenavir/Ritonavir 700/100 mg twice daily		No change	69% increase with 77% increase in Cmin and 62% increase in Cmax (amprenavir)	25
Lopinavir/Ritonavir 400/100 mg twice daily		35% decrease with 45% decrease in Cmin and 30% decrease in Cmax	No significant change in AUC or Cmax and 20% decrease in Cmin (lopinavir)	25
Saquinavir/Ritonavir 1000/100 mg twice daily		33% decrease with 29% decrease in Cmin and 37% decrease in Cmax	No change in AUC or Cmax and 20% decrease in Cmin (saquinavir)	25
Tipranavir/Ritonavir 500/200 mg twice daily		76% decrease with 82% decrease in Cmin and 71% decrease in Cmax	18% increase with 24% increase in Cmin and 14% increase in Cmax (tipranavir)	25
Nevirapine studies (200 mg once daily increased to twice daily)				
Darunavir/Ritonavir 400/100 mg twice daily		27% increase	No change in Cmin* (darunavir)	12
Fosamprenavir 1400 mg twice daily		29% increase with 25% increase in Cmax, 34% increase in Cmin	33% decrease with 35% decrease in Cmin, 25% decrease in Cmax (amprenavir)	28
Fosamprenavir/Ritonavir 700/100 mg twice daily		14% increase with 13% increase in Cmax, 22% increase in Cmin	11% decrease with 19% decrease in Cmin (amprenavir)	28
Indinavir 800 mg three times daily	19 HIV-positive subjects	No change*	28% decrease 48% decrease in Cmin	29
Indinavir 800 mg three times daily alone or 1000 mg three times daily in combination	124 HIV-positive subjects	No change	27% decrease in Cmin versus therapy alone at lower dose	30
Indinavir/Ritonavir 800/100 mg twice daily	21 HIV-positive subjects		57% decrease in Cmin (indinavir)‡	31
Lopinavir/ritonavir 300/75 mg/m^2 twice daily	27 HIV-positive children		22% decrease, 55% decrease in Cmin (lopinavir)	32
Nelfinavir 750 mg three times daily	7 HIV-positive subjects	No change*	50% decrease possibly due to sampling before nelfinavir steady state was reached	33, 34
Nelfinavir 750 mg three times daily	23 HIV-positive positive	No change*	No change	35

NNRTIs + Rifabutin

Rifabutin causes a very marked fall in delavirdine plasma levels: rifabutin levels are raised when the delavirdine dose is increased to compensate for this. Rifabutin does not affect efavirenz levels, whereas efavirenz decreases rifabutin levels. There is usually no important interaction between rifabutin and nevirapine, although some patients may have a higher risk of rifabutin adverse effects. No significant pharmacokinetic interaction appears to occur between etravirine and rifabutin.

Clinical evidence

(a) Delavirdine

In a controlled study in 7 HIV-positive patients taking delavirdine mesilate 400 mg three times daily for 30 days, the addition of rifabutin 300 mg daily from days 16 to 30 caused a fivefold increase in delavirdine clearance, and an 84% fall in its steady-state plasma levels. Rifabutin pharmacokinetics were not significantly altered.[1]

In another study in 5 HIV-positive patients taking rifabutin 300 mg daily, the dose of delavirdine was titrated to achieve a trough level of at least 5 micromol/L. The delavirdine dose had to be increased from 400 mg three times daily to at least 600 mg three times daily to achieve therapeutic levels, when compared with control patients not taking rifabutin. In these control patients similar delavirdine levels were achieved with delavirdine 400 mg three times daily. Delavirdine was reported to increase the AUC and trough level of rifabutin 3.4-fold and 5.5-fold, respectively.[2]

(b) Efavirenz

In a study in healthy subjects, the concurrent use of efavirenz 600 mg daily and rifabutin 300 mg daily for 2 weeks resulted in a modest 38% decrease in the AUC of rifabutin and a 45% decrease in its minimum levels, but no change in efavirenz levels.[3] In one study, doubling the rifabutin dose from 300 mg twice weekly to 600 mg twice weekly when starting efavirenz resulted in rifabutin AUCs that were 20% higher than baseline values.[4] In an analysis, 8 of 35 patients taking efavirenz and given rifabutin 450 mg daily were found to have subtherapeutic rifabutin levels, and they were switched to isoniazid.[5]

A case report describes treatment failure in a patient with tuberculous adenitis taking an efavirenz-containing HAART regimen with rifabutin. The patient had a persistently low rifabutin level (less than 0.1 micrograms/mL) despite large increases in the dose of rifabutin up to 1350 mg daily. When efavirenz was changed to nevirapine the rifabutin levels increased to 0.6 micrograms/mL and the patient developed rifabutin-induced iritis requiring a reduction in the rifabutin dose.[6]

(c) Etravirine

The manufacturer of etravirine reports that the concurrent use of etravirine with rifabutin 300 mg daily resulted in a reduction in the AUC, peak level and trough level of etravirine of about 35%. The AUC, peak level and trough level of rifabutin were also modestly reduced by 17%, 10% and 24%, respectively.[7]

(d) Nevirapine

In one study in 19 patients, the pharmacokinetics of nevirapine were only minimally affected by rifabutin, when compared with historical data.[8] In one HIV-positive patient with low rifabutin levels changing efavirenz to nevirapine resulted in high levels of rifabutin requiring dose reduction[6] (see under *Efavirenz*, above). The manufacturer notes that the concurrent use of rifabutin with nevirapine caused a minor 9% increase in nevirapine clearance and a 17% increase in its AUC, and a 28% increase in the maximum steady-state rifabutin levels.[9,10]

Mechanism

Efavirenz is a potent inducer of the cytochrome P450 isoenzyme CYP3A4, by which rifabutin is metabolised, and therefore concurrent use reduces rifabutin levels. As rifabutin is also an inducer of CYP3A4, it may reduce the levels of the NNRTIs, which are substrates of this isoenzyme.

Importance and management

The interactions between the NNRTIs and rifabutin are clinically significant. The concurrent use of **delavirdine** and rifabutin results in a clinically significant effect on the pharmacokinetics of both drugs, which may lead to treatment failure and an increase in adverse effects, respectively. The CDC in the US and the US manufacturer recommend that rifabutin should be not used with delavirdine.[11,12]

The CDC in the US advise that patients taking **efavirenz** should have the dose of rifabutin increased to 450 mg or 600 mg (taken daily or intermittently).[11] The British HIV Association (BHIVA) also recommend increasing the rifabutin dose to 450 mg daily in patients taking efavirenz.[13] Concurrent use should be closely monitored.

No significant pharmacokinetic interaction appears to occur between **nevirapine** and rifabutin, and no change in the dose of either drug is needed on concurrent use.[11,13] However, in the UK, the use of rifabutin in patients tak-

Table 21.4 Summary of the manufacturers' dose recommendations (unless stated otherwise) for combined use of protease inhibitors and NNRTIs

	Dose of protease inhibitor to be used with standard dose of the NNRTI			
	Delavirdine 400 mg three times daily	**Efavirenz 600 mg daily**	**Etravirine 200 mg twice daily**	**Nevirapine 200 mg twice daily**
Amprenavir	Appropriate dose not established (amprenavir levels increased)	Appropriate dose not established (amprenavir levels reduced)	Avoid	Appropriate dose not established (amprenavir levels may be decreased)
Amprenavir/Nelfinavir		No dose adjustments required		
Amprenavir/Ritonavir*	Appropriate dose not established. Care (unpredictable effect)	No dose adjustments required (amprenavir 600 mg with ritonavir100 or 200 mg twice daily)	Dose reduction may be needed (UK) Avoid - appropriate dose not established (US)	
Amprenavir/Saquinavir		Avoid		
Atazanavir		Avoid	Avoid	Avoid
Atazanavir/Ritonavir*		Not recommended but increase to 400/200 mg once daily† if required (UK) 300/100 mg once daily (US)	No dose adjustments required (UK) Avoid (US)	In the absence of data, avoid
Darunavir/Ritonavir*		Care	No dose adjustments required	No dose adjustments required
Fosamprenavir	Caution (delavirdine potentially subtherapeutic)	Appropriate dose not established	Avoid	Avoid
Fosamprenavir/Ritonavir*		700/100 mg twice daily or 1400/300 mg once daily	Dose reduction required (UK) Avoid - appropriate dose not established (US)	No dose adjustments required (700/100 mg twice daily)
Indinavir	Consider reducing indinavir dose to 600 mg three times daily. Optimum dose not established	Optimum dose not known. Increasing the dose to 1 g three times daily does not compensate for induced metabolism	Avoid (indinavir levels decreased)	Consider increasing to 1 g three times daily. Optimum dose not known
Indinavir/Ritonavir*		Appropriate dose not established. 800/100 mg twice daily has been tried		
Lopinavir/Ritonavir*	Appropriate dose not established	533/133 mg twice daily† or 600/150 mg twice daily. Avoid once daily regimens	No dose adjustments required (UK) Caution – etravirine levels increased (US)	533/133 mg twice daily† or 600/150 mg (US) or 500/125 mg (UK) twice daily. Avoid once daily regimens
Nelfinavir	Appropriate dose not established	No dose adjustments required	Avoid (increase in nelfinavir levels predicted)	No dose adjustment likely (UK). Appropriate dose not established (US)
Ritonavir*	Appropriate dose not established. Ritonavir dose reductions might be appropriate	No dose adjustments required, but not well tolerated. Monitor liver function	Avoid with ritonavir 600 mg twice daily	No dose adjustments required
Saquinavir	Appropriate dose not established. Monitor liver function	Avoid	Avoid	Appropriate dose not established
Saquinavir/Ritonavir*		No dose adjustments required. Monitor liver function	No dose adjustments required	No dose adjustments required
Tipranavir/Ritonavir*		No dose adjustments required	Avoid (etravirine levels decreased)	No dose adjustments required

*The UK manufactuer of efavirenz advises caution, because the possibility of an increase in the incidence of efavirenz-associated adverse events should be considered with any ritonavir-boosted regimen used with efavirenz, due to a possible interaction. This is because the combination of efavirenz with ritonavir at antiviral doses caused increased dizziness, nausea, paraesthesia and elevated transaminase levels.
†This dose increase may not be sufficient in some patients, so some caution is required.

ing nevirapine is not recommended due to limited data.[13] The manufacturers advise that, because of the high intersubject variability, some patients may experience large increases in rifabutin exposure and may be at higher risk of adverse effects, therefore if concurrent use is appropriate, it should be well monitored and undertaken with caution.[9,10]

As there is limited clinical data regarding the use of rifabutin with **etravirine**, the CDC in the US and BHIVA in the UK advise caution on concurrent use. They state that no dose adjustment of either drug is required.[11,13] The manufacturer of etravirine also advises caution on the concurrent use of rifabutin, due to the risk of reduced levels of both drugs.[7]

NNRTIs + Rifampicin (Rifampin)

Rifampicin causes a very marked fall in delavirdine plasma levels, and is predicted to reduce etravirine levels. Neither efavirenz nor nevirapine affect rifampicin levels, but rifampicin modestly reduces the levels of these NNRTIs.

Clinical evidence

(a) Delavirdine

A study using rifampicin in place of rifabutin found that rifampicin caused a 27-fold increase in clearance of delavirdine, and the steady-state plasma levels became almost undetectable.[1] For more information on the effects of rifabutin on delavirdine, see 'NNRTIs + Rifabutin', p.935.

(b) Efavirenz

In a prospective study in 71 HIV-positive patients taking rifampicin and given efavirenz 600 mg daily, the mean 12-hour concentrations of efavirenz at week 6 and week 12 of concurrent use were 4.27 mg/L and 3.54 mg/L, respectively, and 2 patients were reported to have subtherapeutic 12-hour efavirenz concentrations (less than 1 mg/L) at week 12. Further analysis reported that low 12-hour concentrations, indicating low exposure to efavirenz, were associated with an increased risk of treatment failure.[2]

In a cross-sectional analysis of therapeutic drug monitoring in 339 HIV-positive patients taking efavirenz, 56 patients were also taking rifampicin and of these 48 patients (86%) were taking efavirenz 800 mg daily and the rest were taking 600 mg daily. Rifampicin was found to be associated with a 35% decrease in efavirenz plasma levels. However, adjustment for factors such as higher efavirenz doses and mostly black ethnicity in patients taking rifampicin, which were associated with 52% and 59% higher efavirenz levels, respectively, reversed the rifampicin effect, resulting in 48% higher efavirenz levels.[3]

Several studies suggest that efavirenz 800 mg daily with rifampicin is approximately equivalent to efavirenz 600 mg daily alone:

- In patients with HIV and tuberculosis the concurrent use of HAART including efavirenz (600 mg once daily) with antitubercular therapy including rifampicin (480 mg to 720 mg daily) decreased the AUC of efavirenz by 22% and decreased the trough concentration by 25% (although large interpatient variability was observed). Overall the pharmacokinetics of efavirenz 800 mg daily with rifampicin were similar to those of efavirenz 600 mg daily without rifampicin. The pharmacokinetics of rifampicin were not substantially altered by efavirenz.[4]
- Similar results were found in another study in HIV-positive patients taking HAART regimens containing efavirenz with rifampicin 450 mg or 600 mg daily. The mean trough plasma level for efavirenz when it was taken with rifampicin was 1.39 micrograms/mL. Four patients were found to have efavirenz levels of less than 0.1 micrograms/mL from 7 results; however, none of these patients failed HAART therapy and their viral loads remained below 50 copies/mL.[5]
- A slight increase in efavirenz clearance was reported in another small study in 16 HIV-positive patients taking rifampicin with efavirenz 800 mg daily, but no other significant differences in the pharmacokinetic parameters of efavirenz were seen when compared with 13 patients taking efavirenz 600 mg daily without rifampicin. Peak plasma levels were not elevated with efavirenz 800 mg and no increase in adverse effects occurred, although the authors did advise caution due to large interpatient variability.[6]

Further studies indicate that other efavirenz dose adjustments may be required in some patients if rifampicin is also given:

- In a retrospective study, 10 of 20 patients taking efavirenz 600 mg daily (3 patients) or 800 mg daily (7 patients) had therapeutic efavirenz levels while taking rifampicin. One patient taking efavirenz 800 mg daily had excessively raised efavirenz levels (24.47 micrograms/mL). Five patients had further plasma levels analysed. Two patients had subtherapeutic efavirenz levels, one patient had levels at the low end of the therapeutic range, and 2 patients were found to have raised efavirenz levels, one of which had a level of 23.47 micrograms/mL and developed toxicity. One of the patients with low efavirenz levels only achieved a therapeutic range with efavirenz dose increases from 800 mg to 1.2 g daily.[7]
- In 2 HIV-positive patients, rifampicin significantly lowered the plasma levels of efavirenz, necessitating a dose increase of efavirenz. When rifampicin was stopped, the efavirenz dose needed to be reduced by up to one-third to maintain levels within the accepted range of 1 to 4 mg/L.[8]
- A similar 26% reduction in the efavirenz AUC was reported in a study in healthy subjects.[9]

A few studies suggest that efavirenz 600 mg is a suitable dose in patients also given rifampicin. These studies often include patients of low bodyweight:

- In a study in 20 HIV-positive African patients taking efavirenz 600 mg daily and given a rifampicin-containing regimen for tuberculosis, 16 patients were reported to have undetectable viral loads, and only 2 patients failed HIV treatment. Of these two patients only one had subtherapeutic efavirenz levels. Tuberculosis was successfully treated in 19 patients. A large degree of interindividual variability in efavirenz levels was reported, which was greater during rifampicin treatment compared with after rifampicin treatment; however this did not result in antiviral treatment failure.[10]
- In a study in 57 HIV-positive patients with tuberculosis taking efavirenz 600 mg daily, the effect of rifampicin 450 mg or 600 mg daily on the pharmacokinetics of efavirenz 600 mg daily was evaluated in 19 of these patients. Rifampicin decreased the AUC, peak and trough plasma levels of efavirenz by 19%, 18%, and 20%, respectively, although this was not statistically significant. Four of the 57 patients taking rifampicin were found to have subtherapeutic efavirenz levels (less than 1 microgram/mL); 2 of the patients in the control group, who were not taking rifampicin, were also found to have subtherapeutic efavirenz trough levels. In the population studied, CYP2B6 G516T polymorphism, but not rifampicin, significantly affected the pharmacokinetics of efavirenz. It was suggested that modification of efavirenz dose may not be required with concurrent rifampicin.[11]
- In a study in Thai patients taking rifampicin, median efavirenz plasma levels were comparable between those receiving 600 mg daily and 800 mg daily and similar virological outcomes were seen. However, these findings may not be applicable to other populations with bodyweights above 50 kg.[12,13]
- An efficacy study in 1074 HIV-positive patients taking efavirenz 600 mg daily with rifampicin and 961 HIV-positive patients taking efavirenz 600 mg daily without rifampicin found no difference in probability of higher viral load or virological failure in the first 2 years of therapy between the groups.[14]
- A study in 15 children found no difference in efavirenz trough plasma levels between when the patients were taking rifampicin and after stopping rifampicin, although wide interpatient variability was reported. Subtherapeutic efavirenz levels were reported during and after rifampicin treatment in 9 and 8 children, respectively.[15]

Some studies found an association between the cytochrome P450 isoenzyme CYP2B6 metaboliser status and the efavirenz dose required with the concurrent use of rifampicin:

- In a study 26 HIV-positive patients taking efavirenz 600 mg daily as part of a HAART regimen and rifampicin for tuberculosis, the AUC and maximum and trough plasma concentrations of efavirenz did not differ significantly between the patients with cytochrome P450 isoenzyme CYP2B6 extensive metaboliser status (that is, those with normal levels of this isoenzyme) and those with intermediate levels of CYP2B6, who may be expected to have slightly higher levels of efavirenz. Those pa-

tients who were poor metabolisers (those lacking or deficient in CYP2B6) had significantly higher levels of efavirenz despite rifampicin treatment.[16]

- In one analysis, 7 of 9 patients receiving rifampicin and efavirenz 800 mg daily developed significant clinical toxicity and were found to have efavirenz levels markedly higher than the therapeutic range. The individual differences in CYP2B6 expression, although this was not confirmed with genetic testing.[17]
