The pharmacokinetic and pharmacodynamic data indicate a likely absence of interactions between oral combined hormonal contraceptives and these quinolones. In addition, reports of cases of contraceptive failure with these or any other quinolone antibacterial seem to be lacking. No special extra contraceptive precautions would therefore seem to be necessary during concurrent use. However, if one accepts the theory that there is an as yet unidentifiable tiny group of women for whom enterohepatic recirculation of ethinylestradiol is important, then it could be argued that insufficient patients were assessed in the above studies to include anyone from this group, and that the general precautions should be applied. However, if one tends to the theory that the anecdotal cases of contraceptive failure with antibacterials that reduce gut bacteria are indistinguishable from the normal accepted contraceptive failure rate, no special precautions are necessary with these quinolones, or indeed, any other antibacterials that do not induce liver enzymes.

However, for simplicity, and on pragmatic grounds, the UK Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit has recommended that additional contraceptives, such as condoms, should be used for short courses of any antibacterial, which would include the quinolones, see 'Combined hormonal contraceptives + Antibacterials; Penicillins', p.1170, for more detailed information. This applies to both the oral and the patch form of the combined hormonal contraceptive,[7] and therefore it should also be applied to the vaginal ring. Nevertheless, because the FFPRHC has excluded the need for additional precautions with tetracycline and the patch on the basis of one short pharmacokinetic study (see 'Combined hormonal contraceptives + Antibacterials; Tetracyclines', p.1173), then most of the quinolones here should be similarly exempted from the need for additional precautions with oral combined hormonal contraceptives. Note that the WHO does not recommend any additional precautions while taking any antibacterials (excluding rifampicin (rifampin)) with combined hormonal contraceptives given orally, as the patch, or as the vaginal ring.[8]

The slight reduction in moxifloxacin with oral combined hormonal contraceptives is unlikely to be clinically relevant, although the authors considered that it might be if a pathogen has only borderline sensitivity to the antibacterial.[4] However, note that changes of the magnitude seen in this study are not generally considered to be clinically relevant.

Combined hormonal contraceptives + Antibacterials; Sulfonamides and/or Trimethoprim

Co-trimoxazole (sulfamethoxazole with trimethoprim) *increases* ethinylestradiol levels and the suppression of ovulation in women taking oral combined hormonal contraceptives. However, there are about 15 anecdotal cases on record of contraceptive failure attributed to co-trimoxazole. There are also isolated cases of contraceptive failure attributed to various sulfonamides and trimethoprim.

Clinical evidence

(a) Co-trimoxazole (Trimethoprim with Sulfamethoxazole)

In a study in 9 women taking an oral triphasic combined hormonal contraceptive (**ethinylestradiol** with **levonorgestrel**) the use of co-trimoxazole 960 mg twice daily for 7 days starting on day 10 of the cycle increased **ethinylestradiol** plasma levels by 30 to 50%. **Levonorgestrel** plasma levels remained unaltered. No subjects ovulated, as assessed by progesterone and FSH levels: FSH levels actually decreased, indicating increased suppression of ovulation.[1]

In contrast, 5 cases of oral hormonal contraceptive failure attributed to the use of co-trimoxazole were identified in the adverse reactions register of the CSM in the UK for the years 1968 to 1984 (58 cases were attributed to other antibacterials).[2,3] Contraceptive failure has been reported in another 10 patients taking co-trimoxazole,[4-8] and 3 further cases of contraceptive failure are attributed to the use of co-trimoxazole or trimethoprim.[9]

(b) Sulfonamides

One woman taking an oral combined hormonal contraceptive is briefly reported to have developed breakthrough bleeding and to have become pregnant while taking **sulfamethoxypyridazine**.[10,11] One case of a pregnancy, in a woman who had taken a sulfonamide (unspecified) and an oral hormonal contraceptive (unspecified), was identified in the adverse reactions register of the CSM in the UK for the years 1968 to 1984 (a total of 62 cases were attributed to other antibacterials).[3] Three further cases of contraceptive failure have been attributed to the use of **sulfafurazole** (**sulfisoxazole**) and a sulfonamide (unspecified).[12]

(c) Trimethoprim

Two pregnancies were attributed to the use of trimethoprim with an oral hormonal contraceptive (unspecified) in the adverse reactions register of the CSM in the UK for the years 1968 to 1984 (a total of 61 cases were attributed to other antibacterials).[3] Another survey of oral hormonal contraceptive failure identified one pregnancy due to trimethoprim (23 of a total of 137 cases were attributed to antibacterials),[6] while an earlier survey attributed 3 cases of contraceptive failure to either **co-trimoxazole** or trimethoprim.[9] One case with trimethoprim alone, and one with trimethoprim and nitrofurantoin, are briefly mentioned in another report.[7]

Mechanism

Antibacterials that decimate gut bacteria might be expected to interrupt the enterohepatic recirculation of ethinylestradiol leading to contraceptive failure, but the evidence that this is clinically important is scant (see also 'Combined hormonal contraceptives + Antibacterials; Penicillins', p.1170). A possible explanation for the rise in ethinylestradiol levels is that co-trimoxazole inhibits the liver enzymes concerned with the metabolism of this oestrogen. Therefore, as demonstrated, co-trimoxazole might be expected to increase rather than reduce the suppression of ovulation. This would be expected to offset any possible reduced enterohepatic recycling.

Importance and management

Not established. The pharmacokinetic and pharmacodynamic evidence indicates that co-trimoxazole is not likely to reduce the effectiveness of oral combined hormonal contraceptives. Although there are a number of reports of contraceptive failure attributed to co-trimoxazole, these are anecdotal and unconfirmed, whereas the controlled studies suggest *increased* contraceptive efficacy. It is probable that the cases are coincidental, and fit

within the normal failure rate of oral combined hormonal contraceptives. In 1999, the UK Family Planning Association considered that it was almost certain that co-trimoxazole and sulfonamides did not interact with oral combined hormonal contraceptives.[13] However, for simplicity and on pragmatic grounds, in 2005, the UK Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit advised that additional contraceptives, such as condoms, should be used for short courses of any antibacterials (non-enzyme inducing),[14] which would include co-trimoxazole, sulfonamides and trimethoprim. They applied this advice to both the oral and the patch form of the combined hormonal contraceptive, and, therefore it should also be applied to the vaginal ring. In contrast, the WHO does not recommend any additional precautions while taking any antibacterials (excluding rifampicin) with combined hormonal contraceptives given orally, as the patch, or as the vaginal ring.[15] For further comment and advice see also 'Combined hormonal contraceptives + Antibacterials; Penicillins', p.1170.

Aside from contraceptive failure the other aspect of using co-trimoxazole is the potential for increased ethinylestradiol levels. The main concern is whether this would increase the risk of adverse effects of the oestrogen, but there are no data on the clinical significance of these modest (30 to 50%) increases on various adverse effects. It could be argued that a 40% increase would turn a standard-strength contraceptive (35 micrograms) into a high-dose contraceptive (50 micrograms). Further study is needed on this issue.

Combined hormonal contraceptives + Antibacterials; Tetracyclines

Case reports describe contraceptive failure, which was attributed to doxycycline, lymecycline, minocycline, oxytetracycline and tetracycline; some of these cases where the antibacterial was taken long-term, but the interaction (if such it is) appears to be rare. Controlled studies have not shown any effect of tetracycline or doxycycline on contraceptive steroid levels from combined hormonal contraceptives given orally, as the patch, or as the vaginal ring.

Clinical evidence

(a) Oral hormonal contraceptives

1. Case reports of pregnancy. A woman taking an oral combined hormonal contraceptive (**ethinylestradiol** with **levonorgestrel**) became pregnant, the evidence indicating that she had conceived during or in the week after taking **tetracycline** 500 mg every 6 hours for 3 days and then 250 mg every 6 hours for 2 days. There was no evidence of either nausea or vomiting, which might have been an alternative explanation for the contraceptive failure.[1] A case of breakthrough bleeding attributed to **tetracycline** was also mentioned in this report.[1] Two other case reports describe pregnancies in women taking an oral combined hormonal contraceptive and long-term **tetracycline** 500 mg daily[2] or long-term **minocycline** 100 mg daily.[3] The latter report also briefly mentions 2 cases of contraceptive failure with **doxycycline**.[3]

Twelve reports of pregnancies were attributed to the use of tetracyclines (unspecified) and an oral hormonal contraceptive (unspecified) in the adverse reactions register of the CSM in the UK for the years 1968 to 1984 (51 cases were attributed to other antibacterials).[4] In an earlier report, the tetracyclines in 6 cases were named as **tetracycline** and **oxytetracycline**.[5] A survey of oral hormonal contraceptive failure identified 7 failures due to **doxycycline**, **lymecycline** or **minocycline** (37 of a total of 163 cases were attributed to antibacterials),[6] and a follow-up survey identified 3 further cases involving short courses of **tetracycline**.[7] Similar surveys identified 5 contraceptive failures with **tetracycline**,[8-10] and 2 failures with **doxycycline**.[9] Breakthrough bleeding was attributed to **doxycycline** or **oxytetracycline** in 3 other cases.[11]

2. Case-control and cohort studies. In a dermatological practice, of 124 women taking an oral hormonal contraceptive and antibacterials (mostly tetracyclines or erythromycin), 2 became pregnant, with a calculated failure rate of 1.2%. One patient was taking long-term **minocycline** and **ethinylestradiol** with **norethisterone**, and one had taken a 5-day course of **oxytetracycline** while taking **ethinylestradiol** with **levonorgestrel**. This failure rate was reported to be sixfold higher than a normal failure rate of 0.2%.[12] However, a rate of 0.2% represents perfect rather than typical use of oral combined hormonal contraceptives. In a similar analysis,[13] one of 34 women became pregnant after taking long-term **tetracycline** and **ethinylestradiol** with **norethisterone**. This failure rate of 1.4% was not considered to be significantly different from a normal failure rate of 0.27%. In a larger, better-designed, case-control study, 356 women were identified who had received oral hormonal contraceptives and antibacterials (cephalosporins, penicillins, tetracyclines) over a 5-year period in three dermatological practices. The failure rate in these women (1.6% per year, 3 pregnancies occurred in women taking long-term **minocycline** and 2 taking a cephalosporin) was indistinguishable from the failure rate seen in control patients taking oral hormonal contraceptives and no antibacterials (1% per year).[14]

3. Controlled studies. Two controlled studies have shown that tetracyclines do not affect the pharmacokinetics of contraceptive steroids.[15,16] In the first, in 7 healthy women taking an oral combined hormonal contraceptive, **tetracycline** 500 mg every 6 hours for 10 days had no effect on the AUC of **ethinylestradiol** and **norethisterone** (measured on days one, 5 and 10).[15] Similarly, in 23 healthy women taking an oral combined hormonal contraceptive, **doxycycline** 100 mg twice daily for 7 days had no effect on the serum levels of **ethinylestradiol** and **norethisterone** (measured on days 5 to 7). In addition, ovulation did not occur, as assessed by progesterone levels, but 2 women did experience breakthrough bleeding.[16]

The pharmacokinetics of **tetracycline** (AUC_{0-4} and peak level) were not significantly different between 7 healthy women taking an oral combined hormonal contraceptive (**ethinylestradiol** with **norethisterone**) and 4 healthy women not taking any medication.[15]

(b) Patch

In a controlled study in 24 women, there was no pharmacokinetic interaction between a combined hormonal contraceptive patch (**ethinylestradiol** with **norelgestromin**) and **tetracycline**. The patch was used for one week alone, and then, one month later, for one week with **tetracycline** 500 mg four times daily started 3 days before the patch was applied.[17]

(c) Vaginal ring

In a crossover study involving 16 healthy women using the *NuvaRing* vaginal contraceptive ring, a 10-day course of **doxycycline** 200 mg on day one then 100 mg daily started on day one of a cycle did not alter the pharmacokinetics of **etonogestrel** or **ethinylestradiol**.[18]

Mechanism

Not understood. If an interaction occurs, suppression of intestinal bacteria resulting in a fall in enterohepatic recirculation of ethinylestradiol is the usual suggested explanation, but there is no evidence that this is clinically important. For a full discussion of this mechanism, see 'Combined hormonal contraceptives + Antibacterials; Penicillins', p.1170.

Importance and management

The interactions between the oral combined hormonal contraceptives and tetracyclines summarised here are all that have been identified in the literature. Much of the evidence is anecdotal with insufficient controls (if any). These interactions are not adequately established and the whole issue remains controversial. Bearing in mind the extremely wide use of both drugs, any increase in the incidence of contraceptive failure above the accepted failure rate is clearly very low indeed. On the other hand, the personal and ethical consequences of an unwanted pregnancy can be very serious. For simplicity, and on pragmatic grounds, the UK Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit recommends that an additional form of contraception, such as condoms, should be used while taking a short course of any antibacterial that does not induce liver enzymes, and for 7 days after the antibacterial has been stopped,[19] and this would include tetracyclines. See 'Combined hormonal contraceptives + Antibacterials; Penicillins', p.1170, for more detailed information. However, for the combined hormonal contraceptive patch, the FFPRHC specifically exclude tetracycline from the requirement for additional contraceptive protection[19] on the basis of the one short pharmacokinetic study available. Similarly, the UK manufacturer's information for the vaginal ring excludes doxycycline from the requirement for additional protection.[20] If this type of study is sufficient evidence to exclude the need for additional precautions, then no additional precautions are required with doxycycline and oral combined hormonal contraceptives containing ethinylestradiol with norethisterone on the basis of the controlled study cited. Moreover, the absence of a pharmacokinetic interaction with one tetracycline can be extrapolated to others; therefore, it would be reasonable to conclude that no additional contraceptive precautions are likely to be needed with doxycycline and the patch, and for tetracycline with the ring, etc. Note that the WHO does not recommend any additional precautions while taking any antibacterials (excluding rifampicin (rifampin)) with combined hormonal contraceptives given orally, as the patch, or as the vaginal ring.[21]

In the case of long-term use of tetracyclines for acne, at least 7 cases of contraceptive failure have been reported. Nevertheless, in statistical terms the only well-designed case-controlled study in dermatological practice indicated that the incidence of contraceptive failure due to this interaction could not be distinguished from the general and recognised failure rate of oral combined hormonal contraceptives.[14] The FFPRHC also says that after 3 weeks of antibacterial treatment the gut flora becomes resistant to the antibacterial. Therefore women taking an antibacterial long-term no longer need additional contraceptive protection after the initial 3 weeks of concurrent use, unless the antibacterial is changed.[19]

For reports of facial pigmentation due to minocycline and ethinylestradiol, see 'Tetracyclines; Minocycline + Ethinylestradiol', p.393.

Combined hormonal contraceptives or HRT + Antibacterials; Troleandomycin

Severe pruritus and jaundice have been seen in women taking oral hormonal contraceptives shortly after starting treatment with troleandomycin. One case has also been reported with oestrogens for HRT.

Clinical evidence

A report describes 10 cases of cholestatic jaundice and pruritus in women taking oral hormonal contraceptives and troleandomycin. All had been using the contraceptive for 7 to 48 months and were given the antibacterial in daily doses of 1 to 3 g. The pruritus was intense, and started within 2 to 24 days of the first dose of troleandomycin, and preceded the jaundice. In 8 of the patients the pruritus and jaundice persisted for over a month.[1] A later report and letter by the same authors describes a total of 24 cases of this reaction.[2,3]

There are numerous other reports of this adverse reaction in a total of over 40 other women.[4-12] The adverse reactions (fatigue, anorexia, severe itching, jaundice) can begin very rapidly, sometimes even within 2 days of starting the troleandomycin, and may last up to 14 weeks or more.[3,4,12]

One report also describes a similar reaction in a 48-year-old woman taking **oestrogens** for HRT.[4]

Mechanism

Uncertain. Hepatotoxicity has been associated with the use of both types of drug, but it is not common. The reaction suggests that their damaging effects on the liver may be additive or synergistic.[10,11] Troleandomycin may cause an increase in the levels of contraceptive steroids, as it is a liver enzyme inhibitor.[12,13]

Importance and management

A well established, well documented and clinically important interaction. The incidence is unknown. Concurrent use should be avoided. Other macrolides may be suitable alternatives, but see 'Combined hormonal contraceptives + Antibacterials; Macrolides', p.1168.

Combined hormonal contraceptives + Antihistamines

The pharmacokinetics of single doses of doxylamine and diphenhydramine do not appear to be altered by oral combined hormonal contraceptives.

Clinical evidence, mechanism, importance and management

The pharmacokinetics of a single 25-mg dose of **doxylamine** in 13 women and the pharmacokinetics of a single 50-mg dose of **diphenhydramine** in 10 women were not significantly altered by the use of low-dose oral combined hormonal contraceptives.[1] Cases of oral contraceptive failure have been attributed to the use of **doxylamine**, **chlorphenamine**, and an unnamed antihistamine,[2] but these antihistamines were all used in conjunction with penicillins, which are a possible cause of contraceptive failure (see 'Combined hormonal contraceptives + Antibacterials; Penicillins', p.1170). The effect of the antihistamines on the pharmacokinetics and pharmacodynamics of contraceptive steroids appear not to have been studied. No particular precautions would seem necessary during concurrent use.

Combined hormonal contraceptives + Antimalarials

No clinically significant interaction appears to occur between oral combined hormonal contraceptives and chloroquine, primaquine or quinine, or between oral hormonal contraceptives and mefloquine. There is some evidence to suggest that an oral combined hormonal contraceptive modestly reduced the conversion of proguanil to its active metabolite, cycloguanil, but this may not be clinically important.

Clinical evidence and mechanism

(a) Chloroquine

A pharmacokinetic study in 12 healthy women taking an oral combined hormonal contraceptive (**ethinylestradiol** 30 micrograms with **norethisterone** 1 mg) found that the prophylactic use of chloroquine phosphate 500 mg once a week for 4 weeks caused a small 15% increase in the AUC of **ethinylestradiol**, and no change in the levels of **norethisterone**. Chloroquine use did not alter the inhibition of ovulation caused by the contraceptive, as assessed by mid-luteal progesterone levels and the lack of breakthrough spotting and bleeding. In a further group of 7 women, the same oral combined hormonal contraceptive did not alter the pharmacokinetics of a single 500-mg dose of chloroquine phosphate.[1] Another study in 6 healthy women given a single dose of an oral combined hormonal contraceptive (**ethinylestradiol** 30 micrograms with **levonorgestrel** 150 micrograms) confirmed that a single 300-mg dose of chloroquine had no significant effect on the pharmacokinetics of either the oestrogen or the progestogen.[2] Furthermore studies in *rhesus monkeys* infected with malaria, suggest that the curative efficacy of chloroquine is not altered by the use of oral combined hormonal contraceptives (**ethinylestradiol** with **norethisterone** or **norgestrel**).[3]

(b) Mefloquine

A study in 12 Thai women with falciparum malaria, 6 of whom were taking unnamed oral hormonal contraceptives, found that their response to mefloquine (parasite and fever clearance) was not affected by oral hormonal contraceptives. Similarly, the pharmacokinetics of mefloquine were not affected by oral hormonal contraceptives in patients with malaria.[4]

(c) Primaquine

A study in 6 healthy women given a single dose of an oral combined hormonal contraceptive (**ethinylestradiol** 30 micrograms with **levonorgestrel** 150 micrograms) confirmed that a single 45-mg dose of primaquine had no significant effect on the pharmacokinetics of either the oestrogen or the progestogen.[2]

(d) Proguanil

In women who were CYP2C19 extensive metabolisers (that is, those with normal levels of this isoenzyme), the use of an oral combined hormonal contraceptive (**ethinylestradiol** with **levonorgestrel**) reduced the levels of cycloguanil (the active metabolite of proguanil) by 34% after 3 weeks, when compared with the cycloguanil levels before starting the contraceptive.[5] It was suggested that the oestrogen might have inhibited the metabolism of proguanil by the cytochrome P450 isoenzyme CYP2C19. However, inhibition of CYP2C19 makes extensive metabolisers into poor metabolisers (that is, those lacking or deficient in this isoenzyme), and there is some evidence that CYP2C19 poor metaboliser status does not reduce the efficacy of proguanil for prophylaxis[6] or treatment[7] of malaria (see also 'Proguanil + Fluvoxamine', p.267).

(e) Quinine

A controlled study in Thai women found that the pharmacokinetics of a single 600-mg dose of quinine sulfate in 7 women taking oral hormonal contraceptives were not significantly different from those in 7 other women not taking contraceptives. The contraceptives being used were oral combined hormonal contraceptives in 6 women (**ethinylestradiol** with **levonorgestrel** or **norgestrel**) and a progestogen-only oral contraceptive in one (**norethisterone**).[8] There seem to be no reports that quinine affects the reliability of the oral contraceptives.

Importance and management

No clinically significant interaction appears to occur between the oral combined hormonal contraceptives and chloroquine, primaquine or quinine, or between oral hormonal contraceptives and mefloquine. There would seem to be no reason for avoiding concurrent use.

The production of the active metabolite of proguanil appears to be modestly decreased by oral combined hormonal contraceptives, and the authors of the study recommended that the dose of proguanil should be increased by 50% in women taking these contraceptives.[5] However, there is evidence that this pharmacokinetic interaction may not be clinically relevant, see also 'Proguanil + Fluvoxamine', p.267.

Combined hormonal contraceptives + Aprepitant

Aprepitant reduced the levels of ethinylestradiol given as an oral combined hormonal contraceptive. Fosaprepitant, a prodrug of aprepitant, is expected to interact similarly.

Clinical evidence

The manufacturers[1,2] note that aprepitant 100 mg daily for 14 days given with an oral combined hormonal contraceptive (**ethinylestradiol** 35 micrograms with **norethisterone** 1 mg) decreased the AUC of **ethinylestradiol** and **norethisterone** by 43% and 8%, respectively. Reduced contraceptive steroid levels were reported in another study using a recommended antiemetic regimen including aprepitant (125 mg on the first day, then 80 mg daily for 2 days with dexamethasone 12 mg on the first day, then 8 mg daily for 3 days and ondansetron 32 mg on the first day), which was started on day 8 of a 21-day cycle of an oral combined hormonal contraceptive (**ethinylestradiol** with **norethisterone**).[1,2] Within 2 days of

starting the antiemetics (day 10) the **ethinylestradiol** AUC was reduced by 19% and the **norethisterone** level was unchanged.[2] However, the trough level of **ethinylestradiol** was reduced by as much as 64% and that of **norethisterone** by 60% during days 9 to 21.[1,2]

In yet another study, a single 40-mg dose of aprepitant was given on day 8 of a 21-day cycle of an oral combined hormonal contraceptive (**ethinylestradiol** with **norgestimate**). The AUC of **ethinylestradiol** decreased by 4% and 29% on day 8 and day 12, respectively, while the AUC of norelgestromin (the metabolite of **norgestimate**) increased by 18% on day 8 and decreased by 10% on day 12.[2]

Mechanism

During the first few days of use, aprepitant is an inhibitor of the cytochrome P450 isoenzyme CYP3A4 and therefore it would be expected to *increase* the levels of the contraceptive steroids. However, aprepitant then becomes an inducer of CYP3A4 (which usually becomes apparent after the end of a standard 3-day course), reaching a maximal inductive effect within 3 to 5 days of stopping aprepitant, and hence reduces the levels of the contraceptive steroids. This effect lasts only a few days and then reduces to become clinically insignificant within 2 weeks of stopping aprepitant.[1]

Importance and management

Although the effects of these reduced contraceptive steroids levels on ovulation were not assessed, it is likely that they could result in reduced efficacy. The manufacturer therefore recommends that alternative or additional contraceptive methods should be used during, and for 2 months (UK advice)[1] or one month (US advice)[2] after, aprepitant use. The same advice is given for **fosaprepitant**, which is a prodrug of aprepitant, for intravenous use.[3,4] This seems a sensible precaution.

Combined hormonal contraceptives + Ascorbic acid (Vitamin C)

Ascorbic acid does not appear to cause a clinically important alteration in the levels of ethinylestradiol or levonorgestrel, but there are a few unconfirmed anecdotal reports of contraceptive failure associated with ascorbic acid.

Clinical evidence

One study in 5 women taking oral combined hormonal contraceptives found that ascorbic acid 1 g raised serum **ethinylestradiol** levels by 16% at 6 hours post-dose and by 48% at 24 hours post-dose.[1] However, a later well-controlled study found that ascorbic acid 1 g daily caused no significant changes in **ethinylestradiol** serum levels in 37 women taking an oral combined hormonal contraceptive (**ethinylestradiol** 30 micrograms with **levonorgestrel** 150 micrograms).[2] A similar study by the same workers found that ascorbic acid 1 g did not affect the pharmacokinetics of **levonorgestrel**.[3]

A single case report describes a woman taking an oral combined hormonal contraceptive (**ethinylestradiol** with **levonorgestrel**) who experienced heavy breakthrough bleeding in three cycles within 2 to 3 days of stopping ascorbic acid 1 g daily. This did not occur in three other cycles when no ascorbic acid was taken. It was suggested that this was due to a fall in **ethinylestradiol** levels when the vitamin C was stopped, which could increase the risk of contraceptive failure.[4] One report attributed contraceptive failure in one case to ascorbic acid and multivitamins.[5] Another two studies of pregnancies in oral hormonal contraceptive users found that vitamin C had been taken in 44 of 209 cases[6] and 15 of 137 cases,[7] although other drugs and/or factors may possibly have been involved in some of these cases.

Mechanism

Both ascorbic acid and ethinylestradiol undergo sulfate conjugation. It was suggested that large doses of ascorbic acid might compete for the metabolism of ethinylestradiol, and therefore increase its levels.[1] This would be expected to increase the efficacy of the hormonal contraceptive. However, some have suggested that enhanced levels could be followed by rebound ovulation,[4] but there is no evidence to support this.

Importance and management

Documentation about an interaction between ascorbic acid and contraceptives is limited. From the point of view of reliability, there seems to be little reason for avoiding the use of hormonal contraceptives and ascorbic acid. No special precautions are required.

Combined hormonal contraceptives + Azoles

There are isolated reports of breakthrough bleeding and failure of oral combined hormonal contraceptives with fluconazole (including single 150 mg doses), itraconazole and ketoconazole. Conversely, fluconazole, itraconazole and voriconazole have been shown to modestly *increase* the serum levels of the contraceptive steroids. Similarly, ketoconazole markedly increased the levels of estradiol and dienogest. Be aware of the possibility of an increase in adverse effects. Intravaginal miconazole slightly increases the serum levels of ethinylestradiol and etonogestrel during the use of an intravaginal contraceptive ring. Oral combined hormonal contraceptives modestly increase voriconazole levels.

Clinical evidence

(a) Fluconazole

Up to 1990 the UK manufacturer of fluconazole had received 11 reports of menstrual disorders possibly associated with single-dose fluconazole 150 mg. Eight of these were in women taking an oral hormonal contraceptive who developed breakthrough bleeding (5 cases), no withdrawal bleeding (one case), and unintended pregnancies (2 cases).[1] Three other cases of unintended pregnancy have been very briefly mentioned elsewhere.[2]

However, one study found that a single 150-mg dose of fluconazole *increased* the AUC of **ethinylestradiol** by 29% in women taking an oral combined hormonal contraceptive (**ethinylestradiol** with **norethisterone** or **levonorgestrel**).[3] Similarly, fluconazole 300 mg once weekly for 4 weeks caused a 24% increase in the AUC of **ethinylestradiol** and a 13% increase in the AUC of **norethisterone**.[4] Moreover, the manufacturer has data on file showing that multiple doses of fluconazole 200 mg daily raised the levels of **ethinylestradiol** by 40% and of **levonorgestrel** by 24%,[5] whereas a lower dose of fluconazole (a single 50-mg dose or 50 mg of fluconazole daily for 10 days) had no significant effect on the pharmacokinetics of **ethinylestradiol** and **norgestrel**.[6] One other study in 10 women taking oral combined hormonal contraceptives found no changes in progesterone levels (suggesting no ovulation occurred) and no menstrual disorders while they were taking fluconazole 50 mg daily.[7] Furthermore, during clinical studies in which single 150-mg doses of fluconazole were used by over 700 women taking oral hormonal contraceptives, no clinical evidence of an interaction was seen.[8]

(b) Itraconazole

A 25-year-old woman who had been taking an oral combined hormonal contraceptive (**ethinylestradiol** 30 micrograms with **levonorgestrel** 150 micrograms) for a year, without problems, became pregnant when she was given itraconazole 200 mg daily for 3 months for a fungal infection.

The patient was said to be compliant, had suffered no gastrointestinal upset, and was not taking any other drugs that might have accounted for the failure of the pill.[2]

The Netherlands Pharmacovigilance Foundation (LAREB) have 9 cases of menstrual changes on their records in women taking an oral hormonal contraceptive during or after taking itraconazole 100 to 400 mg daily for one to 4 weeks. Seven women reported delayed withdrawal bleeding (2 to 5 days). In 2 of them the menstrual flow was decreased and one transiently had a positive pregnancy test after having previously experienced an intermenstrual blood loss. The remaining two reports were of amenorrhoea during one cycle, and breakthrough bleeding. The women were taking **ethinylestradiol** with either **desogestrel** or **levonorgestrel**.[9] A later extension of this report from LAREB, covering the period 1991 to 1997, describes 12 women taking contraceptives containing **ethinylestradiol** with **desogestrel**, whose withdrawal bleeding was either delayed or did not occur at all while taking itraconazole. Three other women taking **ethinylestradiol** with **levonorgestrel** had breakthrough bleeding, and yet another taking **ethinylestradiol** with **cyproterone** became pregnant while taking itraconazole.[10]

However, the manufacturer has data on file of a study showing that itraconazole 200 mg daily for 15 days had no effect on the pharmacokinetics of **ethinylestradiol**, and *increased* the bioavailability of **norethisterone** by about 40%. In this study, a single dose of **ethinylestradiol** with **norethisterone** was given before the first dose and with the last dose of itraconazole.[11]

(c) Ketoconazole

An early report described 7 out of 147 women taking oral combined hormonal contraceptives (**ethinylestradiol** with **norgestrel**) who experienced breakthrough bleeding or spotting within 2 to 5 days of starting a 5-day course of ketoconazole 400 mg daily. No pregnancies occurred.[12] One unintended pregnancy attributed to contraceptive failure due to ketoconazole has been very briefly mentioned elsewhere.[2]

In one controlled study in postmenopausal women given an oral combined hormonal contraceptive (**estradiol** 2 mg with **dienogest** 3 mg) for 14 days, ketoconazole 400 mg daily for 7 days increased the steady-state AUC of **estradiol** by 65% and that of **dienogest** by 186%.[13,14]

(d) Miconazole

A study found that both single and multiple-dose intravaginal regimens of miconazole pessaries or cream slightly increased the AUC of **ethinylestradiol** and **etonogestrel** during the use of an intravaginal ring (*NuvaRing*). The AUC over days 8 to 21 was increased by 16% for **ethinylestradiol** and 17% for **etonogestrel** with a single vaginal dose of miconazole 1.2 g given on day 8.[15]

(e) Voriconazole

The steady-state AUC of **ethinylestradiol** and **norethisterone** (given as an oral combined hormonal contraceptive) were increased by 61% and 53%, respectively, by the concurrent use of voriconazole for 4 days (400 mg twice daily on day one, then 200 mg twice daily). Moreover, the maximum levels and AUC of voriconazole were increased by 14% and 46%, respectively, by these contraceptive steroids, when compared with voriconazole given alone.[16]

Mechanism

The azole antifungals are, to varying degrees, inhibitors of the cytochrome P450 isoenzyme CYP3A4. They would therefore be expected to increase the levels of the contraceptive steroids to varying extents, as has been shown for fluconazole, itraconazole, ketoconazole, intravaginal miconazole and voriconazole. Therefore the azoles would *not* be expected to increase the incidence of breakthrough bleeding or contraceptive failure when used with combined hormonal contraceptives. It should be noted that the manufacturers list menstrual irregularities as adverse effects of itraconazole, ketoconazole and **posaconazole** irrespective of the use of hormonal contraceptives,[17-19] and menstrual disorders have also been reported with fluconazole alone.[1] The increase in voriconazole levels was expected to be due to inhibition of CYP2C19 by ethinylestradiol.[19]

Importance and management

The picture presented by these reports is somewhat confusing and contradictory. The anecdotal reports of contraceptive failure and the cases of breakthrough bleeding would suggest that these antifungals can, rarely, make oral hormonal contraception less reliable in some individuals. However, the problem with this interpretation is that the pharmacokinetic data suggest that, if anything, an *enhanced* effect of the oral combined hormonal contraceptives is likely. Note that, of all the drugs proven to decrease the efficacy of oral combined hormonal contraceptives, all have also been shown to decrease the steroid levels. Menstrual disorders have occurred with the azole antifungals alone, and may not be indicative of reduced contraceptive efficacy. As there are so few reports of pregnancy, it could just be that they fall within the accepted failure rate of oral combined hormonal contraceptives, and it was just coincidental they occurred when the antifungal was being taken. Note that the manufacturers do not advise any special precautions when taking hormonal contraceptives and these azole antifungals.[5,17,20] However, some authors have considered that the data warrant consideration being given to the use of additional contraceptive measures.[10] The theoretical teratogenic risk[5,17-20] from these azole antifungals may have a bearing on this, and the UK manufacturers of a number of the azoles recommend using effective contraception during azole treatment because of this.[5,17,19,20]

The main concern regarding the increased levels of ethinylestradiol or progestogens is whether this would increase the risk of adverse effects of these contraceptive steroids. There are no data on the effect of these modest 24 to 61% increases in steroid levels on adverse effects. It could be argued that a 40% increase for ethinylestradiol would turn a standard-strength contraceptive (35 micrograms) into a high-dose contraceptive (50 micrograms), and, indeed, in one study, the AUC of ethinylestradiol 35 micrograms with voriconazole was comparable to that seen in earlier studies with a 50 microgram dose of ethinylestradiol.[16] Further study is needed. There is also the potential for increased voriconazole adverse effects.

Combined hormonal contraceptives + Barbiturates or Phenytoin

Combined hormonal contraceptives are less reliable during the use of phenytoin, and barbiturates such as phenobarbital and primidone. Intermenstrual breakthrough bleeding and spotting can take place, and unintended pregnancies have occurred. Controlled studies have found that phenytoin and phenobarbital can reduce contraceptive steroid levels.

Clinical evidence

A woman with epilepsy taking phenytoin 200 mg and sultiame 50 mg daily (with ferrous gluconate and folic acid) became pregnant despite the regular use of an oral combined hormonal contraceptive (**ethinylestradiol** 50 micrograms with **norethisterone** 3 mg).[1] Since this first report in 1972, at least 33 pregnancies have been reported in the literature in women taking a range of oral hormonal contraceptives (mostly combined) and a barbiturate (such as **phenobarbital** or **primidone**) and/or phenytoin (see 'Table 28.2', (below)). Note that most of these cases were with an oral combined hormonal contraceptive containing at least 50 micrograms of **ethinylestradiol**. In addition, between the years 1968 to 1984, a further 39 pregnancies were reported to the CSM in the UK in women using an oral combined hormonal contraceptive while taking phenytoin (20 users) and/or **phenobarbital** (25 users) and/or **primidone** (7 users) with or without other antiepileptics.[2] In this report, over half the cases of contraceptive failure with antiepileptics related to high-dose oral combined hormonal contraceptives (50 micrograms of oestrogen).[2]

In one study, breakthrough bleeding (which was regarded as loss of reliability of the contraceptive) occurred in 30 of 51 women taking an oral combined hormonal contraceptive (**ethinylestradiol** with **norethisterone** or **mestranol** with **chlormadinone**) given **phenobarbital**.[3] In another study, 7 out of 11 patients taking **phenobarbital** and one of 2 patients taking phenytoin had breakthrough bleeding.[4] The incidence of breakthrough bleeding was 90% with preparations containing **ethinylestradiol** 30 micrograms and 29% with preparations containing **ethinylestradiol** 75 micrograms. Similarly, with preparations containing **ethinylestradiol** 50 micrograms, decreasing the dose of **norgestrel** from 500 to

Table 28.2 Case reports of pregnancies in women taking combined oral contraceptives with barbiturates and/or phenytoin

Antiepileptic	*Oestrogen*	*Progestogen*	*Number of cases*	*Refs*

125 micrograms increased breakthrough bleeding from 50% to 62%.[4]

A pharmacokinetic study in 6 women taking an oral combined hormonal contraceptive found that the AUCs of **ethinylestradiol** 50 micrograms and **levonorgestrel** 250 micrograms were lowered by 49% and 42%, respectively, by phenytoin 200 to 300 mg daily for 8 to 12 weeks.[5] In another study, **phenobarbital** 30 mg twice daily did not significantly alter the plasma levels of contraceptive steroids in 4 women taking oral combined hormonal contraceptives (**ethinylestradiol** with **norethisterone** or **norgestrel**), but 2 of the women did have 54% and 60% reductions, respectively, in their **ethinylestradiol** levels. These 2 women had breakthrough bleeding, but the suppression of ovulation was maintained.[6]

Mechanism

The likeliest explanation for the unreliability and failure of oral hormonal contraceptives is that phenytoin and the barbiturates (known potent liver enzyme inducers) increase the metabolism and clearance of the contraceptive steroids from the body, thereby reducing their effects, and in some instances, allowing ovulation to occur.

Importance and management

The interactions between the oral combined hormonal contraceptives and phenobarbital and phenytoin are clinically important and fairly well documented. Primidone is metabolised to phenobarbital and appears to interact similarly. The risk of breakthrough bleeding and spotting is high (bleeding disturbances are usually regarded as an indication of reduced efficacy if cycles were previously regular[7]). However, the actual incidence of contraceptive failure when oral combined hormonal contraceptives are given with these drugs is unknown. It appears that the incidence of unintended pregnancies is quite small: in one series, a failure rate of 3.1 per 100 woman years was calculated, compared with an expected 0.7 per 100 woman years.[8] Note that this failure rate is still less than that seen with barrier methods such as condoms.

Reliable contraception in most patients is said to be achievable with ethinylestradiol 80 to 100 micrograms daily.[4,9,10] If these larger doses are required for good cycle control, there should be no increase in adverse effects because the enzyme-inducing effects of the antiepileptics reduce the blood levels of the steroids. However, note that many of the cases of unintended pregnancies cited were with products containing 50 micrograms of ethinylestradiol or more, and one review of contraceptive interactions suggested that women taking low-dose oestrogen-containing contraceptives may not be at a greater risk of an interaction.[11]

Nevertheless, as the personal and ethical consequences of an unplanned pregnancy can be very serious, it is important to take the necessary practical steps to reduce this increased risk. Moreover, pregnancy in women with epilepsy should ideally be planned so that therapy can be reviewed to minimise the risks of foetal malformation.[9] In this regard, it is of concern that some surveys have shown a lack of knowledge of these interactions and their management among prescribers,[12] and the frequent use of enzyme-inducing antiepileptics with hormonal contraceptives containing less than 50 micrograms of ethinylestradiol.[13]

The UK Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit have issued guidance on the use of drugs that induce liver enzymes with hormonal contraceptives, including phenytoin, phenobarbital and primidone. They recommend that:[14]

- **Copper** or **levonorgestrel-releasing intrauterine devices** (IUD) and **depot progestogen-only injections** (see 'Progestogen-only contraceptives + Enzyme inducers', p.1206), are the preferred alternative contraceptive methods, particularly for women taking the enzyme inducer in the long-term, as these are unaffected by liver-enzyme inducers.
- For the **combined hormonal contraceptives** given as a **patch**, using more than one patch is not recommended. Additional, non-hormonal methods of contraception, such as condoms, should be used by patients using the combined hormonal contraceptive patch, both when taking the liver-enzyme inducers and for at least 4 weeks after stopping the drug. If liver-enzyme inducers are to be used long-term, then alternatives to the patch should be considered.

Similar advice applies to the **vaginal ring** preparation.[15]

- Women who wish to use an oral **combined hormonal contraceptive** should take an ethinylestradiol dose of at least 50 micrograms daily (either by using two tablets of a 30-microgram preparation or one tablet of a 20-microgram preparation with one tablet of a 30-microgram preparation). The dose may be increased further above 50 micrograms if breakthrough bleeding occurs. Additional non-hormonal methods of contraception, such as condoms, should also be used by patients using oral combined hormonal contraceptives, both when taking the liver-enzyme inducers and for at least 4 weeks after stopping the drug. This advice certainly applies when taking a short-course of an enzyme-inducing drug. However, some consider that with the long-term use of enzyme-inducing antiepileptics, when oral combined hormonal contraceptives are the chosen method of contraception, additional contraceptive precautions are required only until a regular regimen has been established.[16] Alternatively, the use of a non-interacting antiepileptic drug could be considered, particularly in patients taking combined hormonal contraceptives long-term. Note that 'ethosuximide', (p.1182), 'gabapentin', (p.1183), 'levetiracetam', (p.1185), 'sodium valproate', (p.1195), 'tiagabine', (p.1193), and 'vigabatrin', (p.1196) do not appear to interact with the hormonal contraceptives.

Pill-free intervals. There are no studies to show whether omitting or reducing the pill-free interval reduces the risk of ovulation with liver enzyme inducers, so the UK Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit make no recommendation for this. However, enzyme-inducing drugs are likely to increase the length of the pill-free interval (see 'Interaction studies', (p.1165)), and this might contribute to their effects in reducing contraceptive efficacy. Some therefore recommend that with the enzyme-inducing antiepileptics, in addition to increasing the ethinylestradiol dose, the usual 7-day pill-free interval should be avoided, and that the pill should be taken in a tricycling regimen (i.e. a monophasic preparation continuously for 3 or 4 packets, then a short pill-free interval of 4 days).[16] Others contend that it is actually the progestogen dose that is more important in inhibiting ovulation in combined hormonal contraceptives, and that continuous use (without any pill-free interval) of a combined hormonal contraceptive containing a high dose of progestogen should be used in a woman taking an enzyme-inducing antiepileptic. However, they say that additional protection may still be worthwhile as contraceptive efficacy cannot be guaranteed.[17]

Combined hormonal contraceptives + Bile-acid binding resins

Colesevelam given at the same time as an oral combined hormonal contraceptive, modestly reduces the absorption of ethinylestradiol, but has less effect when given 4 hours after the contraceptive. Colestipol and colestyramine might be expected to interact similarly.

Clinical evidence

(a) Colesevelam

The manufacturers state that, in studies in healthy subjects, colesevelam 3.75 g, taken at the same time as an oral combined hormonal contraceptive, reduced the AUC of **ethinylestradiol** 35 micrograms by 24% but had no effect on the AUC of **norethisterone** 1 mg. Giving the contraceptive 4 hours before the colesevelam reduced this effect on ethinylestradiol (AUC reduced by 12% with a 4-hour separation).[1,2]

(b) Colestyramine

A brief review of the drug interactions of contraceptives reported that the half-life of **ethinylestradiol** was reduced from 8.2 hours to 4.8 hours in a healthy subject taking 4 g of colestyramine three times daily (duration of treatment not stated).[3]

Mechanism

Colestyramine, colestipol, and colesevelam are bile-acid binding resins, intended to bind to bile acids within the gut, but they can also bind with some drugs thereby reducing the amount available for absorption. As ethinylestradiol undergoes enterohepatic circulation (i.e. after absorption it is excreted in the bile and reabsorbed), it has been suggested that its reabsorption may be reduced by these bile-acid binding resins.[3] However, separation of administration would not normally be expected to minimise the effect on enterohepatic recirculation, and, in any case, the importance of enterohepatic recirculation of ethinylestradiol to its efficacy is not established.

Importance and management

The reduction in exposure to ethinylestradiol is small when taken at the same time as colesevelam. However, on the basis of these results, the manufacturers of colesevelam recommend taking oral hormonal contraceptives at least 4 hours before colesevelam.[1,2] This might be a prudent precaution.

There appears to be no specific data relating to colestipol and only the report in one subject for colestyramine. However, as both of these drugs are known to affect the absorption of many drugs, it may be prudent to apply the standard recommendation of taking other drugs at least one hour before or 4 hours after colestipol, and one hour before or 4 to 6 hours after colestyramine, to minimise the risk of an interaction.

Combined hormonal contraceptives + Candesartan

Candesartan cilexetil 8 mg daily had no effect on the pharmacokinetics of ethinylestradiol and levonorgestrel given as an oral combined hormonal contraceptive, and no ovulation occurred during concurrent use.[1] No special precautions would therefore appear to be needed if both drugs are given. Consider also 'Drospirenone-containing contraceptives or HRT + Potassium-sparing drugs', p.1197, for a possible interaction between angiotensin II receptor antagonists and drospirenone, and 'Antihypertensives + Hormonal contraceptives or HRT', p.1050.

Combined hormonal contraceptives + Carbamazepine or Oxcarbazepine

Combined hormonal contraceptives are less reliable during treatment with carbamazepine and oxcarbazepine. Breakthrough bleeding and spotting can take place, and unintended pregnancies have occurred with carbamazepine. Controlled studies have shown that carbamazepine and oxcarbazepine can reduce contraceptive steroid levels.

Clinical evidence

(a) Carbamazepine

A pharmacokinetic study compared the effects of topiramate or carbamazepine on an oral combined hormonal contraceptive containing **ethinylestradiol** 35 micrograms with norethisterone 1 mg. In the 10 patients who received carbamazepine (600 mg daily from day one to day 21 of a cycle), the AUC of **norethisterone** and **ethinylestradiol** were reduced by 58% and 42%, respectively, on day 20 of the cycle.[1] In another earlier study, carbamazepine 300 to 600 mg daily reduced the AUC of **ethinylestradiol** by 42% and **levonorgestrel** by 40% in 4 women given a single dose of an oral combined hormonal contraceptive (**ethinylestradiol** 50 micrograms with **levonorgestrel** 250 micrograms) before and after 8 to 12 weeks of carbamazepine use.[2]

In an early study, 6 of 12 women taking an oral combined hormonal contraceptive (**ethinylestradiol** with **norethisterone**) developed spotting or breakthrough bleeding while taking carbamazepine (this is regarded as a possible loss of reliability of the contraceptive).[3] A similar study reported breakthrough bleeding in 4 of 6 patients taking carbamazepine and an oral combined hormonal contraceptive,[4] and the same author later briefly reported 37 out of 59 patients had breakthrough bleeding while taking this combination.[5]

One woman taking a low-dose oral combined hormonal contraceptive (not specified) conceived 6 weeks after starting carbamazepine, initially 200 mg daily then 600 mg daily.[6] In another case, the failure of an oral combined hormonal contraceptive containing **ethinylestradiol** 30 micrograms was attributed to carbamazepine.[7] Six pregnancies were identified in women who took carbamazepine and an oral hormonal contraceptive (unspecified) in the adverse reactions register of the CSM in the UK for the years 1968 to 1984. However, it is unclear how many of these 6 women were taking carbamazepine alone, as the authors note that some women were taking multiple antiepileptics.[8] Two further pregnancies have been reported in women taking oral combined hormonal contraceptives and antiepileptics including carbamazepine and phenytoin,[9] and one in a woman who was switched from phenytoin to carbamazepine.[10]

(b) Oxcarbazepine

Preliminary observations revealed that 4 of 6 women receiving oxcarbazepine had breakthrough bleeding when they were given an oral combined hormonal contraceptive containing **ethinylestradiol** 30 micrograms. This resolved in two women when they took double the dose of **ethinylestradiol**.[5] In a pharmacokinetic study in 10 healthy women taking an oral triphasic combined hormonal contraceptive, oxcarbazepine 300 mg three times daily for 4 weeks reduced the AUCs of **ethinylestradiol** and **levonorgestrel** by 47% and 36%, respectively. Three women had menstrual bleeding disturbances.[11] Similar results were reported in a later study with oxcarbazepine 1.2 g daily and an oral combined hormonal contraceptive (**ethinylestradiol** 50 micrograms with **levonorgestrel** 250 micrograms).[12] No cases of unintended pregnancy appear to have been published.

Mechanism

The most likely explanation for these interactions is that both carbamazepine and oxcarbazepine reduce the levels of the contraceptive steroids, presumably by inducing their metabolism. This may result in loss of contraceptive efficacy.

Importance and management

The reduction in contraceptive steroid levels caused by carbamazepine and oxcarbazepine is well established. However, the actual incidence of contraceptive failure when oral hormonal contraceptives are given with these drugs is unknown. Given the few published reports, it appears that unintended pregnancies with carbamazepine are rare, and still less frequent than that seen with barrier methods such as condoms. There appear to be no published reports of pregnancies in patients taking an oral hormonal contraceptive and oxcarbazepine. Nevertheless, given the personal and ethical consequences of an unwanted pregnancy, any reduction in contraceptive efficacy is of concern. The UK Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit has issued guidelines on the management of women taking liver enzyme induc-

ers such as carbamazepine or oxcarbazepine with hormonal contraceptives. These are discussed in further detail under 'Combined hormonal contraceptives + Barbiturates or Phenytoin', p.1177.

Combined hormonal contraceptives + Coxibs

High-dose etoricoxib raises ethinylestradiol levels by 50 to 60%, and it may be appropriate to select a low-dose combined oral contraceptive if etoricoxib is required. Rofecoxib increases contraceptive steroid levels to a small extent. Celecoxib appears to have no effect on oral combined hormonal contraceptive levels. One case of pulmonary embolism has been reported in a patient taking valdecoxib with an oral combined hormonal contraceptive.

Clinical evidence

(a) Celecoxib

Celecoxib had no clinically significant effects on the pharmacokinetics of an oral combined hormonal contraceptive containing **ethinylestradiol** 35 micrograms with **norethisterone** 1 mg.[1]

(b) Etoricoxib

In a placebo-controlled, crossover study in women taking an oral triphasic hormonal contraceptive (**ethinylestradiol** 35 micrograms with **norethisterone** 0.5 to 1 mg) for 21 days, the addition of etoricoxib 120 mg daily taken at the same time or 12 hours after the contraceptive increased the $AUC_{0\text{-}24}$ of **ethinylestradiol** by 50% and 60%, respectively.[2] The **norethisterone** AUC showed minimal changes (9% and 22% increase). In a further study, a lower dose of etoricoxib 60 mg daily taken with the same contraceptive increased the **ethinylestradiol** AUC by 37% with a non-significant 11% increase in **norethisterone** level.[2]

(c) Rofecoxib

In a placebo-controlled, crossover study in 18 healthy women taking an oral combined hormonal contraceptive (**ethinylestradiol** 35 micrograms with **norethisterone** 1 mg), rofecoxib 175 mg daily for 2 weeks raised the AUCs of **ethinylestradiol** and **norethisterone** by 13% and 18%, respectively. No abnormal menstrual bleeding was reported.[3]

(d) Valdecoxib

A single case of left iliac vein thrombosis and bilateral multiple pulmonary emboli has been reported in a 25-year-old woman taking an oral combined hormonal contraceptive (**ethinylestradiol** with **norgestimate**) which developed within a month of starting valdecoxib 20 mg twice daily. The patient had been taking the same contraceptive (containing ethinylestradiol doses of 35 micrograms and then 25 micrograms) for 3 years before taking valdecoxib with no adverse effects. No risk factors were identified apart from prolonged stasis (a 6-hour car journey) and the hormonal contraceptive use.[4]

Mechanism

It is thought that etoricoxib increases ethinylestradiol levels because it inhibits sulfotransferase activity thereby inhibiting ethinylestradiol metabolism. Rofecoxib possibly interacts similarly, although to a lesser extent, and celecoxib appears not to interact. Coxibs as a class and some non-selective NSAIDs appear to be associated with a small increased risk of rare thrombotic events (especially myocardial infarction and stroke). Combined hormonal contraceptives are also associated with a small increased risk of rare thrombotic events. It is possible that these effects could be additive or synergistic.

Importance and management

The increase in ethinylestradiol levels with etoricoxib 120 mg daily would be expected to be similar to switching from a standard-dose contraceptive (ethinylestradiol 30 micrograms) to a high-dose preparation (50 micrograms), and could therefore have clinical consequences. The manufacturer suggests that this increase in ethinylestradiol levels should be considered when choosing the contraceptive because of the possible increased risk of adverse events such as veno-thrombotic events.[5] It may therefore be appropriate to use a contraceptive with a lower dose of ethinylestradiol if etoricoxib is required regularly, particularly at higher doses, and especially as coxibs themselves are associated with an increased risk of thrombotic events.

The small changes in ethinylestradiol levels seen with rofecoxib (now withdrawn), although statistically significant, are modest, and unlikely to be clinically important.

The general relevance of the one case of pulmonary embolism with valdecoxib (now withdrawn) and an oral combined hormonal contraceptive is unclear. However, it cannot be excluded that combined use of these two products contributed to this rare adverse effect. Note that risk factors for venous thromboembolism and cardiovascular disease are taken into account when prescribing a combined hormonal contraceptive alone, or a coxib alone, and therefore it may be prudent to re-evaluate these risks when a coxib is required in a woman using a combined hormonal contraceptive, and vice versa.

Combined hormonal contraceptives + Endothelin receptor antagonists

Bosentan modestly reduces the levels of ethinylestradiol and norethisterone given as an oral combined hormonal contraceptive, and is likely to reduce contraceptive efficacy. In contrast, sitaxentan increases contraceptive steroid levels, and might possibly increase adverse effects. Ambrisentan had minimal effects on the pharmacokinetics of contraceptive steroids.

Clinical evidence

(a) Ambrisentan

Ambrisentan 10 mg daily for 12 days slightly decreased the AUC of **ethinylestradiol** by 4% and slightly increased that of **norethisterone** by 14% when a single dose of an oral combined hormonal contraceptive was given to healthy women.[1,2]

(b) Bosentan

In a randomised, crossover study in 19 healthy women, a single dose of an oral combined hormonal contraceptive (**ethinylestradiol** 35 micrograms with **norethisterone** 1 mg) was given alone and on the last day of bosentan 125 mg twice daily for one week. Bosentan reduced the mean AUC of norethisterone by 14% (maximum reduction 56%) and the mean AUC of

ethinylestradiol by 31% (maximum reduction 66%). Note that there was marked inter-individual variability. The maximum concentration and half-life of both contraceptive steroids were not affected.[3]

(c) Sitaxentan

Sitaxentan increased the AUC of norethisterone by 47% and that of ethinylestradiol by 59% when healthy women were given an oral combined hormonal contraceptive containing **ethinylestradiol** 35 micrograms with **norethisterone** 1 mg. The efficacy of the contraceptive, as measured by FSH, LH, and progesterone levels, was unaffected.[4]

Mechanism

The contraceptive steroids are partially metabolised by the cytochrome P450 isoenzyme CYP3A4, and it was thought that the changes in their pharmacokinetics may have been caused by induction of CYP3A4 by bosentan. However other mechanisms could not be excluded.[3] How sitaxentan increases contraceptive steroid levels is unclear, but it has some CYP2C9 and CYP3A4/5 inhibitory activity.[4]

Importance and management

The endothelin antagonists (ambrisentan, bosentan and sitaxentan) are contraindicated in pregnancy because of their potential teratogenic effects, and for this reason, effective contraception during use is considered especially important. The clinical relevance of the reduction in contraceptive steroid levels seen with **bosentan** is not certain. Nevertheless, a 31% reduction in ethinylestradiol exposure is equivalent to changing a 30 microgram preparation to a 20 microgram preparation, and greater reductions were seen in some patients. Contraceptive failure might therefore be expected in some patients. The UK manufacturer recommends that additional or alternative methods to hormonal contraceptives (any form) are used.[5] Similarly, the US manufacturer also recommends that hormonal contraceptives (oral, injectable, implants, transdermal) should not be used as the sole form of contraception (with the exception of the levonorgestrel intrauterine system, which may be used alone).[6] Given the reduction in contraceptive steroid levels, this seems a sensible precaution.

In contrast, **sitaxentan** increases contraceptive steroid levels. The 59% increase in ethinylestradiol levels is equivalent to changing a 30 microgram preparation to a 50 microgram preparation. This might have the potential to increase adverse effects. The manufacturer specifically notes that the increase in exposure to oestrogen may increase the risk of venous thromboembolism, and in women who smoke, they recommend that prophylaxis of venous thromboembolism with vitamin K antagonists should be considered as is traditionally used in pulmonary arterial hypertension.[4] It would seem prudent to consider low-dose contraceptives and be cautious about contraceptive adverse effects.

Ambrisentan had no clinically relevant effect on the pharmacokinetics of oral combined hormonal contraceptives, and no additional precautions would seem to be necessary on concurrent use. However, as with other teratogenic drugs, the US manufacturer's advice is to use two methods of reliable contraception,[2] whereas the UK manufacturer gives no specific advice except to say that reliable contraception should be used.[1]

Combined hormonal contraceptives + Ethosuximide

Ethosuximide probably does not alter the efficacy of oral combined hormonal contraceptives.

Clinical evidence, mechanism, importance and management

Four pregnancies were identified in women who took ethosuximide and an oral contraceptive (unspecified) in the adverse reactions register of the CSM in the UK for the years 1968 to 1984. However, the authors note that ethosuximide was the sole antiepileptic prescribed in only one of the cases reported.[1] As ethosuximide is not an inducer of hepatic enzymes, it is likely that this one case is a chance association. Another case describes pregnancy in a woman who had been taking ethosuximide, phenytoin, and phenobarbital, with an oral combined hormonal contraceptive for 6 years.[2] If indeed this case does represent an interaction, the known enzyme-inducers phenytoin and phenobarbital are more likely to be implicated than ethosuximide (see 'Combined hormonal contraceptives + Barbiturates or Phenytoin', p.1177). There do not appear to have been any pharmacokinetic or pharmacodynamic studies of the use of ethosuximide with oral contraceptives and no further case reports have been published. The UK Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit guidelines on the management of hormonal contraceptives and drug interactions list ethosuximide as an antiepileptic that does not induce liver enzymes.[3] No special contraceptive precautions appear to be necessary on concurrent use.

Combined hormonal contraceptives + Ezetimibe

Ezetimibe did not alter the pharmacokinetics of an oral contraceptive containing ethinylestradiol and norgestrel.

Clinical evidence, mechanism, importance and management

In a randomised, crossover study, 18 healthy women who had been taking an oral triphasic hormonal contraceptive (containing **ethinylestradiol** with **norgestrel**) were also given ezetimibe 10 mg daily or placebo on days 8 to 14 of two consecutive contraceptive cycles. Ezetimibe did not significantly affect the pharmacokinetics of **ethinylestradiol** or **norgestrel**.[1] Therefore, no additional precautions seem necessary if ezetimibe is given to women taking contraceptives containing these hormones.

Combined hormonal contraceptives + Felbamate

In one study, felbamate increased the clearance of gestodene from an oral combined hormonal contraceptive without altering ovulation suppression.

Clinical evidence, mechanism, importance and management

In a randomised, placebo-controlled study 23 healthy women were given an oral combined hormonal contraceptive (**ethinylestradiol** 30 micrograms with **gestodene** 75 micrograms) for 3 months or more. During months one and 2 they were also given either felbamate in a dose of up to 2.4 g daily, or a placebo, from day 15 of month one to day 14 of month 2. None of the women showed any evidence of ovulation during the entire 3 months, although one had intermenstrual spotting. However, felbamate reduced the **gestodene** AUC by 42% and the **ethinylestradiol** AUC by 13%.[1] The reasons for this effect are not understood. What this change means in terms of the reliability of the hormonal contraceptive is not known, but some reduction in its efficacy might be expected. More study is needed to assess the clinical relevance and to see whether other progestogens are similarly affected.

Combined hormonal contraceptives + Gabapentin

In a controlled study, gabapentin did not alter the levels of ethinylestradiol or norethisterone in women taking an oral combined hormonal contraceptive.

Clinical evidence, mechanism, importance and management

In 13 healthy women taking an oral combined hormonal contraceptive (**ethinylestradiol** 50 micrograms with **norethisterone** 2.5 mg) gabapentin 400 mg every 8 hours for 7 days had no effect on the AUC of **ethinylestradiol** or **norethisterone**. Ovulation suppression was not assessed.[1] On this basis, the UK Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit guidelines on the management of hormonal contraceptives and drug interactions lists gabapentin as an antiepileptic that does not induce liver enzymes.[2] No special contraceptive precautions appear to be required during concurrent use.

Combined hormonal contraceptives + Grapefruit juice

Grapefruit juice modestly increases the levels of ethinylestradiol after a single dose. A case report describes a deep vein thrombosis in a woman taking an oral combined hormonal contraceptive, for which grapefruit consumption was suggested as a contributing factor.

Clinical evidence

In 13 healthy young women given a single 50-microgram dose of ethinylestradiol, grapefruit juice increased the mean maximum plasma level and $AUC_{0\text{-}8}$ of **ethinylestradiol** by 37% and 30%, respectively, when compared with a control drink (herb tea). The mean 28% rise in the $AUC_{0\text{-}12}$ was not significant, but there was wide intersubject variation. The subjects drank grapefruit juice 100 mL or herb tea 30 minutes before the **ethinylestradiol**, a further 100 mL with the **ethinylestradiol**, and then 200 mL every 3 hours for 12 hours after taking the **ethinylestradiol**.[1] The herbal tea used was not specified.

A 42-year-old woman who had been taking an oral combined hormonal contraceptive (**ethinylestradiol** with **drospirenone**) for a year and levothyroxine for 4 years developed a deep vein thrombosis in her left leg, consistent with May-Turner syndrome. Three days earlier she had begun an aggressive weight-loss diet including 225 g of grapefruit every morning. Her only other risk factors were a 1.5-hour car journey and factor V Leiden mutation (detected on a subsequent screen). She was only slightly overweight and did not smoke.[2]

Mechanism

It is thought that the increase in ethinylestradiol bioavailability probably occurs because grapefruit juice inhibits the cytochrome P450 isoenzyme CYP3A4, mainly in the intestine, which metabolises ethinylestradiol.[1]

Deep vein thrombosis is a rare adverse effect of combined hormonal contraceptives, the risk of which appears to be higher with higher doses, and with some progestogens and in those with factor V Leiden (a type of thrombophilia). It was suggested that grapefruit may have increased ethinylestradiol levels in this patient, which enhanced hypercoagulability. This, coupled with the stasis of blood flow as a result of compression of the stenosed iliac vein, thought to be caused by hip flexion during the car journey, resulted in an acute thrombosis.[2]

Importance and management

The study suggests that drinking a litre of grapefruit juice over 12 hours might modestly increase ethinylestradiol levels, but the clinical relevance of this is uncertain. Moreover, whether the findings can be directly extrapolated to daily consumption of one glass of grapefruit juice at a similar time to the combined hormonal contraceptive is also uncertain. Further study is needed. The authors suggest that diet may be a factor in the known inter-individual variability of contraceptive steroid levels.[1] It is possible that whole grapefruit consumption may have been a contributing factor in the case of venous thrombosis, but also possible that it was just coincidental as this patient did have several other risk factors. The general relevance of this one case is therefore uncertain.

Combined hormonal contraceptives + Imatinib

A woman taking an oral combined hormonal contraceptive developed gallstones after starting imatinib.

Clinical evidence, mechanism, importance and management

A 31-year-old woman taking a low-dose oral combined hormonal contraceptive developed nausea and abdominal pain after taking imatinib 400 mg daily for 4 months. Ultrasound showed multiple gallstones and increased gallbladder wall thickness. The contraceptive was stopped, and the imatinib temporarily stopped, and the gallstones remained stable in size on periodic monitoring.[1]

Imatinib is an inhibitor of the cytochrome P450 isoenzyme CYP3A4, by which oestrogens are partially metabolised. The authors suggested that an increase in oestrogen levels could possibly lead to increased cholesterol excretion, reduced bile salt excretion and gallstone development. However, this needs confirmation. The clinical relevance of this single case report is unclear.

Combined hormonal contraceptives + Lacosamide

Lacosamide did not alter the pharmacokinetics of ethinylestradiol and levonorgestrel given as an oral combined hormonal contraceptive. Suppression of ovulation was also unaffected.

Clinical evidence, mechanism, importance and management

In a study in healthy women, the pharmacokinetics of an oral combined hormonal contraceptive (**ethinylestradiol** 30 micrograms with **levonorgestrel** 150 micrograms) were not affected by lacosamide 400 mg daily (except for a minor 20% increase in the **ethinylestradiol** maximum level), and the suppression of ovulation was not altered (there were no changes in progesterone levels).[1,2] These findings indicate that no special or additional precautions are needed if oral contraceptives and lacosamide are used concurrently.

Combined hormonal contraceptives + Lamotrigine

In one study, lamotrigine for two weeks did not alter the plasma levels of ethinylestradiol and levonorgestrel or the suppression of ovulation in women taking an oral combined hormonal contraceptive. However, another study of six weeks use found a slight reduction in levonorgestrel levels, and some loss in suppression of FSH and LH, but no evidence of ovulation.
Combined hormonal contraceptives reduce the levels of lamotrigine, which can lead to a decrease in seizure control.

Clinical evidence

(a) Contraceptive efficacy

The preliminary results of a study suggested that lamotrigine 150 mg daily for 10 to 14 days had no significant effect on the mean plasma levels of **ethinylestradiol** and **levonorgestrel** in women taking an oral combined hormonal contraceptive (**ethinylestradiol** 30 micrograms with **levonorgestrel** 150 micrograms). No ovulation occurred (assessed by progesterone levels) and no changes in menstrual pattern were observed. Furthermore, lamotrigine did not induce hepatic enzymes (assessed by 6-β-hydroxycortisol excretion).[1] Nevertheless, another study by the manufacturer in 16 healthy women taking an oral combined hormonal contraceptive (**ethinylestradiol** 30 micrograms with **levonorgestrel** 150 micrograms) and given lamotrigine for 6 weeks (titrated to 300 mg daily) found a slight reduction in the AUC and the maximum serum levels of **levonorgestrel** of 19% and 12%, respectively, compared with hormone levels before starting lamotrigine, although this was not statistically significant. The AUC and maximum levels of **ethinylestradiol** were not affected. There was a 4.7-fold increase in FSH and 3.4-fold increase in LH; however, there was no increase in the levels of progesterone, indicating that ovulation did not occur. Intermenstrual bleeding was reported in 32% of subjects when they were taking lamotrigine, and no bleeding was reported when they were not taking lamotrigine.[2]

(b) Lamotrigine efficacy

In 2001, a case series described 6 women with epilepsy in whom lamotrigine plasma levels were decreased by 41 to 64% by an oral combined hormonal contraceptive (**ethinylestradiol** with **desogestrel** or **norethisterone**). Five had increased seizure frequency or recurrence of seizures after starting an oral hormonal contraceptive, and one had lamotrigine adverse effects on stopping the contraceptive.[3] In a subsequent study comparing lamotrigine levels in 22 women taking combined hormonal contraceptives with those in 30 women not taking contraceptives, lamotrigine levels were 54% lower in the women taking contraceptives.[4] Three further similar studies have confirmed this finding of lower levels of lamotrigine in users of oral combined hormonal contraceptives compared with non-users.[5-7] Moreover, other studies in women with epilepsy have found that lamotrigine plasma concentrations varied with combined hormonal contraceptive monthly cycles.[8,9] In one, the median lamotrigine plasma concentration was 15% higher during the hormonal contraceptive washout week than during the phase of hormonal contraceptive intake, although there was a wide interpatient variability.[8] In another, reductions in lamotrigine levels were seen within one to 3 days of starting the combined hormonal contraceptive (oral or vaginal ring), were maximal at 21 days, and increased to within 80 to 100% of baseline levels in the contraceptive-free week.[9]

In a controlled study in 16 healthy women, the maximum serum concentration and AUC of lamotrigine were decreased by about 39% and 52%, respectively while they were taking an oral combined hormonal contraceptive (**ethinylestradiol** 30 micrograms with **levonorgestrel** 150 micrograms) when compared with a 3-week period when they received lamotrigine 300 mg daily alone.[2] Similarly, in a crossover study in 7 women with epilepsy, taking lamotrigine and **ethinylestradiol** 35 micrograms with **norgestimate** 250 micrograms or placebo, lamotrigine plasma levels were 84% higher during the placebo phase, when compared with the oral hormonal contraceptive phase. Three patients experienced seizures while taking the contraceptive; two were given an increased dose of lamotrigine, and one was given clobazam.[10]

In a study in women taking lamotrigine with sodium valproate, lamotrigine dose concentration ratios did not differ between women also taking oral combined hormonal contraceptives (7) and those not taking these (15).[11]

Mechanism

The reason for the slight reduction in levonorgestrel levels with lamotrigine is unknown, and this on its own is unlikely to be clinically important. Nevertheless, the increase in FSH and LH levels and increase in intermenstrual bleeding suggest some reduction in the suppression of ovulation. Ethinylestradiol increases the glucuronidation of lamotrigine, thereby increasing its clearance. This effect is cyclical when combined hormonal contraceptives are taken cyclically (usual practice). It is suggested that, when lamotrigine glucuronidation is strongly inhibited by valproate (see 'Lamotrigine + Valproate', p.620), ethinylestradiol does not appear to have any effect.

Importance and management

The above studies show that there is some concern regarding the efficacy of oral combined hormonal contraceptives while taking lamotrigine, and, in addition, there is good evidence that combined hormonal contraceptives reduce lamotrigine levels and efficacy, in an apparent cyclical manner. Based on the small reduction in levonorgestrel levels, and the rises in FSH and LH, the manufacturer of lamotrigine suggests that the possibility of decreased contraceptive efficacy cannot be ruled out,[12,13] and the UK manufacturer actually advises that the use of non-hormonal contraceptives is preferable.[12] If a hormonal contraceptive is used as the only form of contraception, they advise that women should be alert for signs of breakthrough bleeding, which may be a sign of reduced contraceptive efficacy.[12,13] In 2005, the UK Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit issued guidance on the use of lamotrigine in patients taking hormonal contraceptives in response to the UK manufacturer's guidance. They concluded that there is no good evidence that non-hormonal methods of contraception are preferable in patients taking lamotrigine.[14] If an oral combined hormonal contraceptive is used with lamotrigine, the WHO recommend one with at least 30 micrograms of ethinylestradiol.[15]

When combined hormonal contraceptives are started in women already taking lamotrigine (as monotherapy or with other drugs that are *not* strong inducers or inhibitors of lamotrigine glucuronidation), the maintenance dose of lamotrigine may need to be increased by as much as twofold (according to clinical response). If this group of patients stop taking a combined hormonal contraceptive, the lamotrigine dose should be reviewed (and may need to be decreased by as much as 50%) to reduce the risk of adverse effects such as dizziness, ataxia, and diplopia occurring.[12,14] Note that apart from interindividual variations, lamotrigine plasma concentrations vary with the hormonal contraceptive monthly cycle, and this may complicate management (possible adverse effects such as during the hormone-free interval, or possible break-through seizures during the hormone-taking phase). It has been suggested that this cyclical nature of the interaction could be overcome by using a combined hormonal contraceptive continuously without a hormone-free interval.[16]

The situation is probably somewhat different in women already taking lamotrigine with a drug that strongly alters lamotrigine metabolism. In this case, the modest effect of ethinylestradiol is unlikely to be apparent. Therefore, in those already taking lamotrigine with strong inducers of lamotrigine glucuronidation, such as phenytoin and carbamazepine, changes in the dose of lamotrigine are unlikely to be necessary when starting combined hormonal contraceptives. The same appears to be true in those already taking lamotrigine with valproate, which is a strong inhibitor of lamotrigine glucuronidation.

Combined hormonal contraceptives + Leflunomide

Leflunomide did not alter the contraceptive activity of an oral combined hormonal contraceptive in one study.

Clinical evidence, mechanism, importance and management

In a study in 32 healthy women taking a oral triphasic hormonal contraceptive (**ethinylestradiol** with **levonorgestrel**) leflunomide 100 mg daily for 3 days, then 20 mg daily for 17 days, did not reduce contraceptive activity (as assessed by progesterone levels). In addition, the pharmacokinetics of the active metabolite of leflunomide (A771726) were as expected, suggesting that the contraceptive steroid had no effect on this metabolite.[1,2] No interaction would therefore be expected.

Note that leflunomide is potentially teratogenic and therefore reliable contraception is required in women of child-bearing age both during and for about 2 years after the use of leflunomide.

2. Sanofi-Aventis. Personal communication. September 2009.

Combined hormonal contraceptives + Leukotriene antagonists

Montelukast and zafirlukast do not alter the pharmacokinetics of contraceptive steroids, and contraceptive activity was not altered by zafirlukast.

Clinical evidence, mechanism, importance and management

(a) Montelukast

The manufacturers of montelukast say that it does not affect the pharmacokinetics of an oral hormonal contraceptive (**ethinylestradiol** 35 micrograms with **norethisterone** 1 mg).[1,2] No special precautions are therefore needed if both drugs are given together.

(b) Zafirlukast

A single-blind, parallel-group study in 39 healthy women taking unnamed oral hormonal contraceptives found that zafirlukast 40 mg twice daily had no effect on the serum levels of **ethinylestradiol** nor on its contraceptive activity.[3] This study suggests that no special precautions are needed if both drugs are given together.

2. Singulair (Montelukast sodium). Merck & Co., Inc. US Prescribing information, August 2009.
3. Accolate (Zafirlukast). AstraZeneca Pharmaceuticals LP. US Prescribing information, August 2009.

Combined hormonal contraceptives + Levetiracetam

Levetiracetam did not alter the plasma levels of ethinylestradiol and levonorgestrel given as an oral combined hormonal contraceptive. Suppression of ovulation was also unaffected.

Clinical evidence, mechanism, importance and management

The pharmacokinetics of an oral combined hormonal contraceptive (**ethinylestradiol** with **levonorgestrel**) were not affected by levetiracetam 500 mg twice daily, nor was the suppression of ovulation altered (there were no changes in LH or progesterone levels). The pharmacokinetics of levetiracetam also remained unaffected.[1] Similarly, in placebo-controlled study in 18 healthy women taking an oral combined hormonal contraceptive (**ethinylestradiol** 30 micrograms with **levonorgestrel** 150 micrograms) with levetiracetam 500 mg twice daily, levetiracetam did not affect the steady-state pharmacokinetics of either steroid, or alter the effect on the suppression of ovulation, as measured by progesterone and LH levels.[2] These findings indicate that no special or additional precautions are needed if these hormonal contraceptives and levetiracetam are used concurrently. Note that the UK Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit guidelines on the management of drug interactions with hormonal contraceptives lists levetiracetam as an antiepileptic that does not induce liver enzymes.[3]

1. Giuliano RA, Hiersemenzel R, Baltes E, Johnscher G, Janik F, Weber W. Influence of a new antiepileptic drug (Levetiracetam, ucb L059) on the pharmacokinetics and pharmacodynamics of oral contraceptives. *Epilepsia* (1996) 37, 90.
2. Ragueneau-Majlessi I, Levy RH, Janik F. Levetiracetam does not alter the pharmacokinetics of an oral contraceptive in healthy women. *Epilepsia* (2002) 43, 697–702.

Combined hormonal contraceptives + Maraviroc

Maraviroc did not alter the pharmacokinetics of an oral combined hormonal contraceptive.

Clinical evidence, mechanism, importance and management

In a study in healthy women, maraviroc 100 mg twice daily for 10 days had no effect on the AUC of the contraceptive steroids given as an oral combined hormonal contraceptive (**ethinylestradiol** 30 micrograms with **levonorgestrel** 150 micrograms) daily on days 2 to 8, when compared with a placebo.[1]

This study suggests that maraviroc is unlikely to alter the efficacy of oral combined hormonal contraceptives by a pharmacokinetic mechanism.

1. Abel S, Russell D, Whitlock LA, Ridgway CE, Muirhead GJ. Effect of maraviroc on the pharmacokinetics of midazolam, lamivudine/zidovudine, and ethinyloestradiol/levonorgestrel in healthy volunteers. Br J Clin Pharmacol (2008) 65 (Suppl 1), 19–26.

Combined hormonal contraceptives + Moclobemide

Moclobemide did not alter the effect of an oral combined hormonal contraceptive on the suppression of ovulation.

Clinical evidence, mechanism, importance and management

A study in 7 women taking oral combined hormonal contraceptives found no evidence of any significant alterations in estradiol, progesterone, FSH, or LH levels when they took moclobemide 200 mg three times daily for one cycle. This suggests that ovulation did not occur. No serious adverse reactions occurred. It was considered that the efficacy of the hormonal contraceptive is likely to be maintained during concurrent use.[1]

1. Amrein R, Güntert TW, Dingemanse J, Lorscheid T, Stabl M, Schmid-Burgk W. Interactions of moclobemide with concomitantly administered medication: evidence from pharmacological and clinical studies. *Psychopharmacology (Berl)* (1992) 106, S24–S31.

Combined hormonal contraceptives + Modafinil

Modafinil slightly reduces the levels of ethinylestradiol given as part of an oral combined hormonal contraceptive.

Clinical evidence

In 16 healthy women taking an oral combined hormonal contraceptive (**ethinylestradiol** with **norgestimate**), modafinil 200 mg daily for 7 days followed by 400 mg daily for 21 days decreased the AUC and the maximum plasma levels of **ethinylestradiol** by 18% and 11%, respectively. Increases in plasma FSH and LH were not significant.[1]

Mechanism

Modafinil is an inducer of the cytochrome P450 isoenzyme CYP3A4, which is partially responsible for the metabolism of ethinylestradiol.

Importance and management

The small changes seen in ethinylestradiol levels in the presence of modafinil are lower than those seen with other enzyme inducers known to reduce the reliability of combined hormonal contraceptives (e.g. see

'Combined hormonal contraceptives + Barbiturates or Phenytoin', p.1177). However, it cannot be ruled out that they would be sufficient to cause the failure of combined hormonal contraceptives in very rare cases. As with rufinamide (see 'Combined hormonal contraceptives + Rufinamide', p.1190), it would seem reasonable to avoid the use of contraceptives with a low 20-micrograms dose of ethinylestradiol. However, the UK manufacturer actually recommends that additional or alternative methods of contraception to hormonal contraceptives should be used during and for 2 months after stopping modafinil.[2] The US manufacturer gives similar guidance, but advises that additional or alternative contraceptive methods need only be continued for one month after stopping modafinil.[3] Note that they apply this advice to other forms of hormonal contraception including implants and patches.[3] The UK Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit has issued guidance on the use of liver enzyme inducers with hormonal contraceptives, see 'Combined hormonal contraceptives + Barbiturates or Phenytoin', p.1177, for further information.

Combined hormonal contraceptives + Mycophenolate

Mycophenolate mofetil does not alter the pharmacokinetics of contraceptive steroids, or the suppression of ovulation, in women given oral combined hormonal contraceptives.

Clinical evidence

The manufacturer says that no pharmacokinetic interaction was seen in a single-dose study in 15 healthy women taking mycophenolate mofetil and *Orthonovum* (**ethinylestradiol** 35 micrograms with **norethisterone** 1 mg).[1]

A study of mycophenolate mofetil 1 g twice daily, given with an oral combined hormonal contraceptive (containing **ethinylestradiol** 20 to 40 micrograms and either **levonorgestrel** 50 to 150 micrograms, **desogestrel** 150 micrograms or **gestodene** 50 to 100 micrograms) over 3 consecutive menstrual cycles in 18 women not previously taking immunosuppressants, found no clinically relevant influence of mycophenolate on the suppression of ovulation by the contraceptives.[2,3] The AUC of **ethinylestradiol** and **desogestrel** were not changed, but the mean **levonorgestrel** AUC was decreased by about 15%. Note that large interpatient variability was seen in AUCs, especially for **ethinylestradiol**.[3]

Mechanism

None.

Importance and management

Mycophenolate mofetil is unlikely to reduce the contraceptive efficacy of oral combined hormonal contraceptives. The small 15% decrease in levonorgestrel levels seen is unlikely to be clinically relevant.

Note that, because mycophenolate is associated with an increased risk of pregnancy loss and of congenital malformations, the manufacturers state that effective contraception must be used before mycophenolate mofetil, during, and for 6 weeks after it has been stopped.[2,3] In this regard, the US manufacturer specifically advises that oral hormonal contraceptives should be used with caution, and additional birth control methods used.[3] Similar advice is given for mycophenolate sodium.[4,5]

Combined hormonal contraceptives + Nefazodone

A woman experienced increased oral combined hormonal contraceptive adverse effects while taking nefazodone.

Clinical evidence, mechanism, importance and management

Within a week of starting to take nefazodone 50 mg twice daily, a woman taking a low-dose oral combined hormonal contraceptive (**ethinylestradiol** 20 micrograms with **desogestrel** 150 micrograms) reported breast tenderness, bloating, weight gain, and increased premenstrual irritability. She had previously experienced identical symptoms while taking an oral combined hormonal contraceptive with a higher dose of oestrogen. Nefazodone was discontinued after 6 weeks, and within 24 hours the adverse effects resolved.[1] Nefazodone is a known inhibitor of the cytochrome P450 isoenzyme CYP3A4, by which **ethinylestradiol** is metabolised, and might therefore be expected to increase **ethinylestradiol** levels. However, the general importance of this isolated case is unknown. Note that nefazodone has generally been withdrawn due to adverse hepatic effects.

1. Adson DE, Kotlyar M. A probable interaction between a very low-dose oral contraceptive and the antidepressant nefazodone: a case report. *J Clin Psychopharmacol* (2001) 21, 618–19.

Combined hormonal contraceptives + NNRTIs

Nevirapine modestly reduced ethinylestradiol and norethisterone levels from an oral combined hormonal contraceptive. Efavirenz had no effect on ethinylestradiol levels and markedly decreased those of active norgestimate metabolites from an oral combined hormonal contraceptive, while ethinylestradiol had no effect on efavirenz levels. Potential contraceptive failures have been reported in two women taking efavirenz, but a low incidence of contraceptive failure was noted in one study. Etravirine slightly increased ethinylestradiol levels and did not change norethisterone levels or the suppression of ovulation in women taking an oral combined hormonal contraceptive. Delavirdine is predicted to increase ethinylestradiol levels.
Note that whatever other methods of contraception are being used, barrier methods are also advisable to reduce the risk of HIV transmission.

Clinical evidence

(a) Efavirenz

Efavirenz 400 mg daily for 10 days modestly *increased* the AUC of a single dose of **ethinylestradiol** by 37% while the maximum plasma levels remained unchanged. **Ethinylestradiol** had no effect on the AUC or maximum plasma levels of efavirenz.[1] However, in a later multiple dose study in 21 women taking an oral combined hormonal contraceptive (**ethinylestradiol** with **norgestimate**),[2,3] efavirenz 600 mg daily for 14 days had no effect on the AUC of **ethinylestradiol** and markedly *decreased* the AUC of **norelgestromin** (the principal active metabolite of norgestimate) by 64% and that of **levonorgestrel** (a secondary active metabolite) by 83%.

A retrospective review identified 22 women who were prescribed an oral hormonal contraceptive and also received an NNRTI. Two of the 16 women taking efavirenz experienced contraceptive failure. However, medication adherence could not be confirmed.[4]

As part of a 6-month clinical study in West Africa, 548 women received efavirenz with two NRTIs for HIV infection. The percentage of women using contraceptives was 58%, 70%, 77%, 79%, 80% and 80% at each month of the study (about two-thirds were using an **intramuscular progestogen** and one-third an oral **combined hormonal contraceptive**). There were just 7 pregnancies in the study, giving an overall incidence of 2.6/100 person-years.[5] The paper did not mention which, if any, contraceptives these 7 women were using at the time of conception. However, even if all these 7 pregnancies constituted failure of an oral combined hormonal contraceptive, this is still only 7 pregnancies in about 140 women over 6 months. Nevertheless, the authors note that it is possible that these women had low fertility related to their disease, and that fertility might increase over time with effective treatment.[5]

(b) Etravirine

In a study in 16 women taking an oral combined hormonal contraceptive (**ethinylestradiol** 35 micrograms **norethisterone** 1 mg), etravirine 200 mg twice daily from day one to 15 of a cycle increased the AUC of **ethinylestradiol** by 22% and did not change the AUC of **norethisterone**, when compared with a cycle without etravirine. In addition, the suppression of ovulation, as measured by FSH, LH and progesterone levels, was not altered.[6]

(c) Nevirapine

A study in 10 HIV-positive women found that nevirapine 200 mg daily for 2 weeks then twice daily for a further 2 weeks decreased the median AUC and elimination half-life of **ethinylestradiol** by 29% and 31%, respectively, and decreased the median AUC of **norethisterone** by 19%. The women received two single doses of an oral combined hormonal contraceptive (**ethinylestradiol** 35 micrograms with **norethisterone** 1 mg); 2 days before the nevirapine and on the last day of the nevirapine. Nevirapine was added to established antiretroviral therapy (commonly three drugs including nelfinavir or indinavir), which had been unchanged for at least 4 weeks.[7] A retrospective study identified 22 women who were prescribed oral hormonal contraceptives and also received an NNRTI. None of the 6 women taking nevirapine experienced contraceptive failure. However, medication adherence could not be confirmed.[4]

Mechanism

Both efavirenz and nevirapine are established inducers of the cytochrome P450 isoenzyme CYP3A4, by which ethinylestradiol is partially metabolised, and etravirine has also shown CYP3A4 inducing effects. As such they might be expected to modestly decrease contraceptive steroid levels, as has been shown for nevirapine.[7] For efavirenz, the finding of increased ethinylestradiol levels after a single ethinylestradiol dose and no change after multiple dose, is unexpected, but the marked decrease in norgestimate metabolites fits with the enzyme-inducing properties. For etravirine, the finding of a modest increase in ethinylestradiol levels with no change in norethisterone levels is also unexpected, and the mechanism is uncertain.

Importance and management

Although data are limited, the pharmacokinetic interaction with **nevirapine** is as would be predicted. Although it is not known whether these modest reductions in contraceptive levels would reduce the anti-ovulatory efficacy of the oral combined hormonal contraceptive, it would be prudent to assume they could. The manufacturers recommend that oral combined hormonal contraceptives and other hormonal methods of birth control should not be used as the sole method of contraception in women taking nevirapine. They suggest that a barrier method (e.g. condoms) should also be used, and note that this is also advisable to reduce the risk of HIV transmission.[8,9]

The original finding that **efavirenz** increased ethinylestradiol levels (after a single dose) suggested that efavirenz might not adversely alter the efficacy of oral combined hormonal contraceptives. Nevertheless, in a later study in women using these contraceptives, although efavirenz had no effect on ethinylestradiol levels, it did markedly decrease levels of the active metabolites of norgestimate, which suggests that a reduction in the activity of the contraceptive is possible. For a case of failure of the etonogestrel implant, which was attributed to efavirenz, see 'Progestogen-only contraceptives + Enzyme inducers', p.1206. The manufacturer notes that a reliable method of barrier contraception must be used in addition to other methods of contraception such as hormonal contraceptives.[3,10]

Similar advice is given by the Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit in the UK, who classify both efavirenz and nevirapine as drugs that can induce liver enzymes and may reduce the levels of ethinylestradiol and progestogens. They therefore recommend that their guidance on hormonal contraceptives and liver enzyme inducers is followed,[11] see 'Combined hormonal contraceptives + Barbiturates or Phenytoin', p.1177 for further detail.

For **etravirine**, based on available data, no reduction in contraceptive efficacy would be expected when using an oral combined hormonal contraceptive containing ethinylestradiol and norethisterone. The slight increase in ethinylestradiol levels (22%) is probably not clinically relevant.

The manufacturer of **delavirdine** notes that it may increase the levels of ethinylestradiol, but further study is needed to confirm and quantify this.[12] Until more is known, some caution is be prudent.

Combined hormonal contraceptives + Pregabalin

Pregabalin did not affect the pharmacokinetics of the contraceptive steroids or alter the suppression of ovulation in women given ethinylestradiol and norethisterone as an oral combined hormonal contraceptive. In addition, the pharmacokinetics of pregabalin did not appear to be affected by this contraceptive.

Clinical evidence, mechanism, importance and management

In 16 healthy women, pregabalin 200 mg every 8 hours for 21 days had no effect on the steady-state pharmacokinetics of **ethinylestradiol** or **norethisterone** given as an oral combined hormonal contraceptive. In addition, the ovulation suppressant effect of the contraceptive was not reduced, as measured by progesterone levels. The pharmacokinetics of pregabalin did not appear to be affected by the contraceptive.[1] No special precautions therefore appear to be required during concurrent use.

1. Bockbrader HN, Posvar EL, Hunt T, Randinitis EJ. Pharmacokinetics of pregabalin and a concomitantly administered oral contraceptive show no-drug drug interaction. *Epilepsia* (2004) 45 (Suppl 3), 153.

Combined hormonal contraceptives + Protease inhibitors

Ritonavir and nelfinavir, given alone, markedly *reduce* the levels of ethinylestradiol. Ritonavir-boosted protease inhibitors modestly (atazanavir) to markedly (darunavir, fosamprenavir, lopinavir and tipranavir) *reduce* ethinylestradiol levels and this might result in reduced contraceptive efficacy. Conversely, indinavir alone slightly, and atazanavir or amprenavir alone modestly to markedly *increases* the levels of ethinylestradiol and norethisterone.

An oral combined hormonal contraceptive did not affect the levels of amprenavir (derived from fosamprenavir) or saquinavir, and other limited evidence suggests that hormonal contraceptives do not alter antiretroviral activity of HAART (mostly protease-inhibitor based) regimens.

Note that whatever other methods of contraception are being used, barrier methods are also advisable to reduce the risk of HIV transmission.

Clinical evidence

(a) Amprenavir

The UK manufacturer briefly noted that amprenavir *increased* the minimum plasma concentrations of **ethinylestradiol** and **norethisterone**, given as an oral combined hormonal contraceptive, by 32% and 45%, respectively. Conversely, the amprenavir minimum concentration and AUC were *decreased* by 20% and 22%, respectively.[1]

(b) Atazanavir

In a study in 22 healthy women given an oral combined hormonal contraceptive (**ethinylestradiol** with **norethisterone**), atazanavir 400 mg daily for the first 2 weeks of a cycle *increased* the levels of **ethinylestradiol** by 48% and *increased* the AUC of **norethisterone** about twofold (110%).[2] Note that, atazanavir with ritonavir decreased ethinylestradiol levels, see under *Ritonavir-boosted protease inhibitors*, below.

(c) Indinavir

Indinavir 800 mg three times daily given with an oral combined hormonal contraceptive (**ethinylestradiol** 35 micrograms with **norethisterone** 1 mg) for 8 days caused a modest 22% and 26% increase in the AUCs of ethinylestradiol and norethisterone, respectively.[3,4] In a retrospective study there were no reports of contraceptive failure in 9 patients taking indinavir (overall there were 8 contraceptive failures out of 33 women taking protease inhibitors). However, medication adherence could not be confirmed.[5]

(d) Nelfinavir

The manufacturer briefly notes that in women taking an oral combined hormonal contraceptive (**ethinylestradiol** 35 micrograms with **norethisterone** 400 micrograms) for 15 days, nelfinavir 750 mg three times daily for one week *decreased* the AUCs of **ethinylestradiol** and **norethisterone** by 47% and 18%, respectively.[6,7] In a retrospective study, 7 of 21 women taking nelfinavir experienced contraceptive failure, which was the highest rate of failure of the protease inhibitors being taken (overall there were 8 contraceptive failures out of 33 women taking protease inhibitors). However, medication adherence could not be confirmed.[5]

(e) Ritonavir

In a study in 23 healthy women ritonavir 500 mg every 12 hours for 16 days *decreased* the AUC of **ethinylestradiol** by 41% and decreased its elimination half-life from 17 hours to 13 hours. The women received a single dose of an oral combined hormonal contraceptive (**ethinylestradiol** 50 micrograms with **ethynodiol** 1 mg), 14 days before the ritonavir and on day 15 of ritonavir.[8] In a retrospective study there were no reports of contraceptive failure in 6 women taking ritonavir (overall there were 8 contraceptive failures out of 33 women taking protease inhibitors). However, medication adherence could not be confirmed.[5]

(f) Ritonavir-boosted protease inhibitors

1. Atazanavir. The manufacturer notes that when ritonavir-boosted atazanavir 100/300 mg once daily was given with an oral combined hormonal contraceptive (**ethinylestradiol** with **norgestimate**), there was a 19% decrease in the AUC of ethinylestradiol and an 85% increase in the AUC of the active metabolite of norgestimate.[9] This is in contrast to the increase seen after unboosted atazanavir, see *Atazanavir*, above

2. Darunavir. In a study in healthy women taking an oral combined hormonal contraceptive (**ethinylestradiol** with **norethisterone**), ritonavir-boosted darunavir 100/600 mg twice daily for the first 2 weeks of a cycle *decreased* the concentration of **ethinylestradiol** by 44% and *decreased* the AUC of **norethisterone** by 14%.[10]

3. Fosamprenavir. When ritonavir-boosted fosamprenavir 100/700 mg twice daily was given with an oral combined hormonal contraceptive containing **ethinylestradiol** 35 micrograms with **norethisterone** 500 micrograms daily the AUC of ethinylestradiol was *decreased* by 37% and the AUC of norethisterone *decreased* by 34%. The pharmacokinetics of amprenavir (derived from fosamprenavir) were not significantly affected; however, the AUC and maximum level of **ritonavir** were 45% and 63% higher, respectively, compared with historical data in female subjects taking fosamprenavir and ritonavir alone.[11] In this study, clinically significant increases in liver transaminases occurred in some healthy subjects.[11]

4. Lopinavir. A study in 12 healthy subjects found that ritonavir-boosted lopinavir 100/400 mg twice daily for 14 days *decreased* the AUC of **ethinylestradiol** and **norethisterone** (given as an oral combined hormonal contraceptive for 21 days) by 42% and 17%, respectively.[12]

5. Tipranavir. Ritonavir-boosted tipranavir 100/500 mg twice daily or 200/750 mg twice daily for 10 days *decreased* the AUC and maximum level of **ethinylestradiol** by about 50%, but did not significantly alter the pharmacokinetics of **norethisterone** given as a single dose of an oral combined hormonal contraceptive.[13,14] In this study, 33% of women developed a rash, which is a higher incidence than is usually seen with ritonavir-boosted tipranavir.[13]

(g) Saquinavir

A study in 8 healthy women found that the pharmacokinetics of a single 600-mg dose of saquinavir were not affected by an oral combined hormonal contraceptive containing **ethinylestradiol** 30 micrograms with **gestodene** 75 micrograms taken for 21 days.[15] In a retrospective study there was one report of contraceptive failure out of 5 women taking saquinavir (overall there were 8 contraceptive failures out of 33 women taking protease inhibitors). However, medication adherence could not be confirmed.[5]

Mechanism

Ritonavir more commonly *inhibits* the cytochrome P450 isoenzyme CYP3A4 and the results for ritonavir are the opposite of those originally predicted based on *in vitro* data showing *inhibition* of ethinylestradiol metabolism (by cytochrome P450 subfamily CYP3A-mediated 2-hydroxylation).[16] However, ethinylestradiol is also substantially metabolised by conjugation, and the clinical findings suggest that ritonavir induces glucuronosyltransferase (UGT) activity, thereby reducing ethinylestradiol levels.[8] Nelfinavir probably interacts similarly. The effect of ritonavir appears so strong that it is apparent with all ritonavir-boosted protease inhibitors studied (atazanavir, darunavir, fosamprenavir, lopinavir and tipranavir). Atazanavir alone may increase ethinylestradiol levels by inhibition of UGT.[17] Indinavir also slightly increases contraceptive steroid levels.

Importance and management

The pharmacokinetic interaction between the ethinylestradiol component of combined hormonal contraceptives and nelfinavir or ritonavir and all ritonavir-boosted protease inhibitors (atazanavir, darunavir, fosamprenavir, lopinavir and tipranavir) appears to be established and is likely to be clinically important. Similar *decreases* in the plasma levels of ethinylestradiol caused by other drugs have resulted in reduced efficacy and reliability of oral combined hormonal contraceptives, and one retrospective report suggests that this has occurred with nelfinavir.[5] If ritonavir (including all ritonavir-boosted protease inhibitors) or nelfinavir are being used would seem prudent to follow similar guidance to that used for other enzyme-inducing drugs, see 'Combined hormonal contraceptives + Barbiturates or Phenytoin', p.1177. Note that guidance from the WHO states that when an oral combined hormonal contraceptive is chosen, a preparation containing a minimum of 30 micrograms of ethinylestradiol should be used.[18] Also, whatever other methods of contraception are being used, barrier methods are always advisable to reduce the risk of HIV transmission, and the WHO notes that this will also compensate for any reduction in the effectiveness of the contraceptive.[18] With atazanavir and amprenavir, in the instances these are used *without ritonavir*, the marked increase in norethisterone and ethinylestradiol levels suggest some caution is appropriate. The US manufacturer of atazanavir recommends that an oral combined hormonal contraceptive with no more than 30 micrograms of ethinylestradiol be used,[9] whereas the UK manufacturer of atazanavir recommends avoiding oral hormonal contraceptives.[17] Note that the increases in contraceptive steroid levels with indinavir alone are unlikely to be clinically relevant.

The manufacturers of tipranavir specifically note that women using oestrogens with tipranavir may also have an increased risk of non-serious rash.[13,14]

Amprenavir levels are decreased by combined hormonal contraceptives, but the effects are modest. There is some evidence to suggest that hormonal contraceptives (including oral combined hormonal contraceptives) do not alter the antiretroviral efficacy of HAART (mostly protease-inhibitor based),[19] but evidence is preliminary and more study is needed.

Combined hormonal contraceptives + Remacemide

Remacemide appears not to interact with oral combined hormonal contraceptives.

Clinical evidence, mechanism, importance and management

The preliminary results of a study suggested that remacemide 200 mg twice daily for 14 days had no effect on the pharmacokinetics of **ethinylestradiol**, **desogestrel**, or **levonorgestrel**, when compared with placebo, in women taking an oral combined hormonal contraceptive (**ethinylestradiol** 30 micrograms with **levonorgestrel** 150 micrograms or **desogestrel** 150 micrograms). Inhibition of ovulation was maintained (assessed by measurement of progesterone, FSH, and LH levels).[1] It appears that no special contraceptive precautions are needed during concurrent use.

1. Blakey GE, Lockton JA, Corfield J, Oliver SD, Back D. Absence of interaction of remacemide with oral contraceptives. *Epilepsia* (1999) 40 (Suppl 2), 95.

Combined hormonal contraceptives + Retigabine

Retigabine did not alter the plasma levels of ethinylestradiol or norgestrel given as an oral combined hormonal contraceptive.

Clinical evidence, mechanism, importance and management

The preliminary results of a study suggested that retigabine 150 mg three times daily from day 10 to 13 of a cycle had no effect on the pharmacokinetics of **ethinylestradiol** or **norgestrel** in women taking an oral combined hormonal contraceptive (**ethinylestradiol** 30 micrograms with **norgestrel** 300 micrograms).[1] This suggests that no special contraceptive precautions are needed during concurrent use.

1. Paul J, Ferron GM, Richards L, Getsy J, Troy SM. Retigabine does not alter the pharmacokinetics of a low-dose oral contraceptive in women. *Neurology* (2001) 56 (Suppl 3), A335–A336.

Combined hormonal contraceptives + Rifamycins

Combined hormonal contraceptives are less reliable during treatment with rifampicin (rifampin). Breakthrough bleeding and spotting commonly occur, and pregnancy may not be prevented. Rifabutin also reduces the reliability of combined hormonal contraceptives, although it interacts to a lesser extent. Oral rifaximin appears not to alter the pharmacokinetics of contraceptive steroids.

Clinical evidence

(a) Rifabutin

In two studies, rifabutin 300 mg daily for just 10 or 14 days reduced the plasma levels of **ethinylestradiol** and **norethisterone** in women taking an oral combined hormonal contraceptive, but to about half the extent of rifampicin (rifampin). The AUC for **ethinylestradiol** decreased by about 35% in both studies, and the AUC of **norethisterone** decreased by 17%. In one study, spotting occurred in 21.7% of women when they took rifabutin (compared with 3.7% in the control cycle and 36% with rifampicin).[1] Ovulation did not occur with rifabutin or rifampicin in either study,[1,2] although in one study an increase in FSH and LH occurred with rifabutin, which was less than that seen with rifampicin.[1] It is probable that use of rifabutin long term would have a greater effect on ovulation parameters, as contraceptive steroid levels would be reduced for the whole cycle.

(b) Rifampicin (Rifampin)

1. Estradiol-containing contraceptives. In one controlled study in 16 postmenopausal women given an oral combined hormonal contraceptive (**estradiol** valerate 2 mg with **dienogest** 3 mg) for 17 days, rifampicin 600 mg daily for 5 days from day 12 to 16 decreased the steady-state AUC of **estradiol** by 44% and that of **dienogest** by 83%.[3,4]

2. Ethinylestradiol-containing contraceptives. A report in 1971 noted a marked increase in the frequency of intermenstrual breakthrough bleeding (regarded as loss of reliability of the contraceptive) in women taking an oral combined hormonal contraceptive and rifampicin.[5] In a later report by the same researchers, 62 out of 88 women taking an oral combined hormonal contraceptive had menstrual cycle disorders of various kinds (spotting, bleeding, failure to menstruate) while taking a rifampicin-based regimen for tuberculosis, compared with only one of 26 given a streptomycin-based regimen. In addition, 5 pregnancies occurred in women taking the rifampicin-based regimen.[6,7] Other case reports have confirmed this interaction, and there have been a total of at least 11 other pregnancies reported.[8-15] Oral combined hormonal contraceptives commonly mentioned in these reports include **ethinylestradiol** with **norgestrel** or **norethisterone**.[9,11-15]

There are four pharmacodynamic studies of the effects of rifampicin on oral combined hormonal contraceptives that assessed measures of ovulation (FSH, LH, progesterone),[1,2,16,17] three of which also assessed the contraceptive steroid pharmacokinetics.[1,2,17] One of these found that 11 out of 21 women taking an oral triphasic hormonal contraceptive (**ethinylestradiol** 30 to 40 micrograms with **levonorgestrel** 50 to 125 micrograms) ovulated (assessed by increased progesterone levels of above 10 nanomol/L and presence of a follicle) while taking rifampicin 300 mg daily for 21 days, and 8 had intermenstrual bleeding.[16] Similarly, in another study, 2 out of 7 women taking an oral combined hormonal contraceptive (**ethinylestradiol** 30 micrograms with **norethisterone** 1 mg) ovulated one month after starting rifampicin 8 to 10 mg/kg as part of an antimycobacterial regimen (started on day 23 of a cycle and ovulation assessed on day 19 to 23 of the next cycle). In addition, rifampicin reduced the AUC of **norethisterone** by 30% and that of **ethinylestradiol** by 12% (which was not statistically significant), although there was wide variation.[17] Conversely, two other well-controlled studies did not detect ovulation in 34 women taking an oral combined hormonal contraceptive (**ethinylestradiol** 35 micrograms with **norethisterone** 1 mg) and rifampicin 300 or 600 mg daily,[1,2] although in these studies, the rifampicin was given for just 10 or 14 days from day 1 or day 7 of the cycle. Nevertheless, both studies reported some increase in LH and FSH levels with rifampicin, and an increased incidence of spotting was noted in one of these studies (36% versus 3.7% in the control cycle).[1] Furthermore, both of these studies found that rifampicin 300 mg daily for 10 days or 600 mg daily for 14 days reduced the AUCs of **ethinylestradiol** and **norethister-**

one by about 63% and 55%, respectively. These pharmacokinetic results confirm the findings of earlier studies using single doses of contraceptive steroids.[18,19]

Rifampicin plasma levels[20] and efficacy[5] are reported to be unchanged by oral combined hormonal contraceptives.

(c) Rifaximin

In a crossover study in 26 healthy women, rifaximin 200 mg every 8 hours for 3 days had no effect on the pharmacokinetics of **ethinylestradiol**, **norgestrel** or **deacetylnorgestimate** after administration of a single dose of two tablets of an oral combined hormonal contraceptive (**ethinylestradiol** 35 micrograms with **norgestimate** 250 micrograms).[21]

Mechanism

Rifampicin (rifampin) is a potent non-specific enzyme inducer, which has been shown to increase the hydroxylation of ethinylestradiol fourfold in an *in vitro* study,[22,23] and twofold in an *in vivo* study.[24] Another study found that the metabolism of ethinylestradiol derived from mestranol was similarly affected.[25] As a result, the reduced steroid levels may be insufficient to prevent the re-establishment of a normal menstrual cycle with ovulation, which would explain the breakthrough bleeding and pregnancies that have occurred. Rifabutin similarly acts as an enzyme inducer, but it is less potent than rifampicin (about half as potent in reducing contraceptive steroid levels).[2] Rifaximin is also an inducer of cytochrome P450 isoenzymes, but its oral absorption is negligible (0.4%) and it therefore appears to have no effect on the metabolism of the contraceptive steroids.

Importance and management

The interaction between the oral combined hormonal contraceptives and **rifampicin** is well documented, well established and clinically important. Menstrual cycle disturbances of 36 to 70%,[1,5,6] and an ovulation rate of 29 to 52% when used for 21 days or more[16,17] show very clearly that women receiving oral combined hormonal contraceptives should use an alternative or additional form of contraception while taking rifampicin, and for 4 to 8 weeks after its withdrawal.[26,27] This would equally well able to other forms of combined hormonal contraceptives.

Direct information about the interaction between oral combined hormonal contraceptives and **rifabutin** seems to be limited to the pharmacodynamic studies cited, but it is supported by the well-recognised enzyme-inducing properties of rifabutin. It would clearly be prudent for women receiving rifabutin to take the same precautions as with rifampicin, although the risks are probably somewhat lower because rifabutin is a less potent enzyme inducer.

Oral **rifaximin** appears not to alter the pharmacokinetics of contraceptive steroids and would therefore not be expected to alter contraceptive efficacy.

Combined hormonal contraceptives + Rotigotine

The manufacturer notes that the pharmacodynamics and pharmacokinetics of oral contraceptives containing ethinylestradiol 30 micrograms and levonorgestrel 150 micrograms were unaltered by the use of rotigotine 3 mg/24 hours.[1]

1. Neupro (Rotigotine). UCB Pharma Ltd. UK Summary of product characteristics, August 2009.

Combined hormonal contraceptives + Rufinamide

Rufinamide caused a modest decrease in the plasma levels of ethinylestradiol and norethisterone given as an oral combined hormonal contraceptive.

Clinical evidence, mechanism, importance and management

The preliminary results of a study in 18 healthy women taking an oral combined hormonal contraceptive suggest that rufinamide 800 mg twice daily for 14 days from day 22 of cycle one to day 7 of cycle two decreased the AUC of **ethinylestradiol** 35 micrograms by 22% and of **norethisterone** 1 mg by 14% measured on day 7 of cycle two. Inhibition of ovulation was not assessed.[1]

Rufinamide is a weak inducer of the cytochrome P450 isoenzyme CYP3A4,[2] by which the contraceptive steroids are metabolised.

These small reductions in plasma levels of the contraceptive hormones are similar to those seen with high-dose topiramate (see 'Combined hormonal contraceptives + Topiramate', p.1193) and less than those seen with carbamazepine (see 'Combined hormonal contraceptives + Carbamazepine or Oxcarbazepine', p.1180), and their clinical relevance is unknown. However, given these findings, low-dose contraceptives (**ethinylestradiol** 20 micrograms) should probably be considered unsuitable for use with rufinamide. Note that the UK manufacturer advises that the prescriber should use clinical judgement when assessing whether oral hormonal contraceptives, or the doses of the contraceptive steroid components, are adequate based on the individual patients clinical situation,[2] whereas the US manufacturer recommends that additional non-hormonal methods of contraception are used.[3] Further study is needed.

Combined hormonal contraceptives + Sirolimus

Sirolimus did not alter the pharmacokinetics of a single dose of an oral combined hormonal contraceptive.

Clinical evidence, mechanism, importance and management

A single-dose study found that the pharmacokinetics of an oral combined hormonal contraceptive (**ethinylestradiol** 30 micrograms with **norgestrel** 300 micrograms) were unaffected by sirolimus,[1,2] and sirolimus whole blood exposure was unaffected by the contraceptive.[2] This suggests that the efficacy of the contraceptive is unlikely to be changed by sirolimus. Nevertheless, the UK manufacturer cautiously points out that the effects of long-term sirolimus on oral contraception are unknown.[1] Effective contraception is advised during the use of sirolimus, and for 12 weeks after sirolimus is stopped, because its effects on the foetus are uncertain.

2. Zimmerman JJ. Exposure-response relationships and drug interactions of sirolimus. *AAPS J* (2004) 6, e28.

Combined hormonal contraceptives + Spermicides

Nonoxinol-9 had no effect on the absorption of contraceptive steroids from the combined hormonal contraceptive vaginal ring.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study in healthy women using the combined hormonal contraceptive vaginal ring (**ethinylestradiol** with **etonogestrel**), a single dose of a vaginal gel spermicide (4% **nonoxinol-9**) given on day 8 of a cycle had no effect on the AUC of **ethinylestradiol** or **etonogestrel** measured over three time periods (day 8 to 9, day 8 to 10 and day 8 to 21).[1]

This study suggests that **nonoxinol-9** is unlikely to alter the efficacy of the combined hormonal contraceptive ring.

Combined hormonal contraceptives + St John's wort (*Hypericum perforatum*)

St John's wort may slightly reduce the levels of desogestrel, ethinylestradiol, and norethisterone from oral combined hormonal contraceptives, although there is some evidence that an extract with low hyperforin may not interact. Both breakthrough bleeding and, more rarely, contraceptive failure have been reported in women also taking St John's wort.

Clinical evidence

(a) Controlled studies

1. Hypericin 0.3%. A study in 17 healthy women taking **ethinylestradiol** 20 micrograms with **desogestrel** 150 micrograms daily found that St John's wort (300 mg two or three times daily) did not affect the AUC or maximum levels of **ethinylestradiol**. However, the AUC and maximum levels of the active metabolite of **desogestrel** were significantly decreased, by about 40% and 20%, respectively. There was no evidence that ovulation occurred. However, the frequency of breakthrough bleeding increased significantly from 35% to around 80%.The St John's wort preparation (*Jarsin*) in this study contained a methanolic extract (LI160).[1]
Similarly, another study in 12 healthy women taking **ethinylestradiol** 35 micrograms with **norethisterone** 1 mg found that St John's wort 300 mg three times daily for 8 weeks caused some changes to the pharmacokinetics of the contraceptive steroids, but the only statistically significant changes were a 15% increase in the oral clearance of **norethisterone** and a 48% reduction in the half-life of **ethinylestradiol**. Nevertheless, no ovulation occurred, as indicated by unaffected serum levels of LH, FSH and progesterone. However there was an increase in breakthrough bleeding (7 subjects reported breakthrough bleeding while taking St John's wort compared with 2 in the control phase). A sample of the St John's wort capsules in this study (Rexall-Sundown Pharmaceuticals) were analysed and found to contain 0.37% hypericin and 3% hyperforin.[2] Furthermore, a crossover study in 16 subjects also found small reductions in the levels of low-dose **ethinylestradiol** 20 micrograms with **norethisterone** 1 mg (median reductions in AUC of 16% and 13%, respectively) while they were taking St John's wort 300 mg three times daily. Furthermore, they found increased progesterone levels of more than 3 nanograms/mL (an indication that ovulation occurred) in 3 patients while taking St John's wort compared with one subject while taking placebo. The incidence of breakthrough bleeding was also increased (56% versus 31%). This study also used an alcoholic St John's Wort extract standardised to 0.3% hypericin, which contained 3.7% hyperforin.[3] In a secondary analysis of this study, the anti-androgenic effects of **ethinylestradiol** with **norethisterone**, utilised in the treatment of hirsutism and acne, were not significantly affected by St John's wort.[4]

2. Hypericin 0.2% with low hyperforin. In a study, 16 healthy women who took **ethinylestradiol** 20 micrograms with **desogestrel** 150 micrograms daily on days one to 21 of a 28 day cycle were given an extract of St John's wort with a low hyperforin content of less than 0.2%, (Ze117, standardised to 0.2% hypericin), 250 mg twice daily on days 7 to 21. In contrast to the studies above, the AUCs of **ethinylestradiol** and the active metabolite of **desogestrel** were not significantly altered by St John's wort. None of the women experienced any breakthrough bleeding or spotting, and measurements of plasma hormone levels indicated that the contraceptive efficacy was unchanged.[5] However, this study would have been more conclusive if the extract had been given for a whole cycle and the pharmacokinetics of the steroids had been compared on the same day of each cycle.

(b) Contraceptive failure and breakthrough bleeding

Controlled studies have found that the frequency of breakthrough bleeding in women taking combined hormonal contraceptives increased significantly when St John's wort was taken, see under *Hypericin 0.3%*, above.

The Adverse Drug Reactions Database of the Swedish Medical Products Agency has on record 2 cases of pregnancy due to the failure of an oral combined hormonal contraceptive, which was attributed to the use of products containing St John's wort (*Esbericum* and *Kira*). One woman was taking **ethinylestradiol** and **norethisterone** and the other was taking **ethinylestradiol** and **levonorgestrel**.[6] This follows an earlier report from the Swedish Medical Products Agency of 8 cases of breakthrough bleeding in women aged 23 to 31 years taking long-term oral hormonal contraceptives and St John's wort. Breakthrough bleeding occurred within about a week of starting St John's wort in 5 of the cases, and was known to have resolved in 3 cases when the St John's wort was stopped.[7]

The CSM in the UK has on record a further 7 cases of pregnancy in women taking St John's wort and oral hormonal contraceptives in the 2-year period from February 2000 to February 2002.[8] Six of these women were taking oral combined hormonal contraceptives (**ethinylestradiol** with **desogestrel**, **levonorgestrel**, **norethisterone** or **norgestimate**), generally for at least 7 months before starting St John's wort. Preparations were standard dose in 5 cases (**ethinylestradiol** 30 or 35 micrograms) and low dose (20 micrograms) in one case. The unplanned pregnancies occurred after they had been taking the St John's wort for on average about 4 months (one to 9 months).[9] Another earlier brief report describes 3 women taking an oral combined hormonal contraceptive (**ethinylestradiol** 30 micrograms with **desogestrel** 150 micrograms) who developed breakthrough bleeding one week (2 cases) and 3 months (one case) after starting to take St John's wort.[10] A single case of pregnancy has also been reported in a patient taking St John's wort and **ethinylestradiol** with **dienogest**.[11] The German Federal Institute for Drugs and Medical Devices has received a total of 8 case reports of contraceptive failure in women also taking St John's wort.[12]

Mechanism

St John's wort can modestly induce the metabolism of the contraceptive steroids by the cytochrome P450 isoenzyme [CYP3A4], thereby reducing their serum levels and their effects.[7,10,13] This can lead to breakthrough bleeding and, in some cases, contraceptive failure. This is consistent with the way St John's wort appears to lower the serum levels of some other drugs. Note that St John's wort is a herbal preparation, and the specific constituents responsible for enzyme induction are currently unknown, although there is some evidence that hyperforin may be responsible. Also, the levels of individual constituents can vary between different preparations of the herb.

Importance and management

The interaction between hormonal contraceptives and St John's wort is established, although the effect on contraceptive steroid levels appears to be slight, and therefore probably not relevant in many women. Its incidence is not known but the evidence so far suggests that breakthrough bleeding may be a problem (and may be a sign of reduced efficacy), although pregnancy resulting from this interaction appears to be uncommon. However, as it is not known which patients are particularly likely to be at risk, women taking oral hormonal contraceptives should either avoid St John's wort (the recommendation of the CSM/MCA and the FFPRHC in the UK[13,14]) or follow the advice given for other enzyme-inducing drugs, see 'Combined hormonal contraceptives + Barbiturates or Phenytoin', p.1177, for details of this guidance. Given that there are many established antidepressants that do not interact with contraceptives, this would seem prudent advice. Note that the combined hormonal contraceptive patch and vaginal ring may also be affected.

Although the considerable worldwide popularity of St John's wort is fairly recent, its use has been widespread in Germany and has been used for very many years in both Germany and Austria. Nevertheless, there seems to be no published evidence that oral hormonal contraceptive failure in those countries is more frequent than anywhere else. This would seem to confirm that contraceptive failure leading to pregnancy occurring as a result of this interaction is very uncommon, although it is always possible that it has failed to be identified as a possible cause. Further study is needed to confirm whether St John's wort extracts with a low hyperforin content (0.2% as opposed to about 3%) do not interact with contraceptives, as these may be an alternative.

Combined hormonal contraceptives + Statins

Atorvastatin and rosuvastatin may modestly increase the plasma levels of oral combined hormonal contraceptives. Rosuvastatin pharmacokinetics and lipid-lowering effects were unaffected by an oral contraceptive containing ethinylestradiol and norgestimate. The pharmacokinetics of a single dose of pravastatin were also unaffected by oral combined hormonal contraceptives. Lovastatin and simvastatin prevented some of the adverse effects of oral combined hormonal contraceptives on lipids.

Clinical evidence

(a) Atorvastatin

A study in 12 healthy women taking an oral combined hormonal contraceptive (**ethinylestradiol** 35 micrograms with **norethisterone** 1 mg) found that atorvastatin 40 mg daily increased the AUC of **ethinylestradiol** and **norethisterone** by about 19% and 28%, respectively.[1]

(b) Lovastatin

Sixty women were randomised to receive an oral triphasic combined hormonal contraceptive (**ethinylestradiol** 30 to 40 micrograms with **levonorgestrel** 50 to 125 micrograms) alone or with lovastatin 20 mg daily for 3 months. Serum triglycerides increased in those receiving the contraceptive alone (from 90 to 157 mg/dL), but showed little change in those also receiving the lovastatin (105 to 113 mg/dL). LDL-cholesterol did not change in those given the contraceptive alone, but decreased (effect not statistically significant) in those also receiving lovastatin.[2]

(c) Pravastatin

The pharmacokinetics of a single 20-mg dose of pravastatin were found to be unaffected in 15 young women taking oral combined hormonal contraceptives (**ethinylestradiol** with **norethisterone**, **norgestrel** or **levonorgestrel**), when compared with similar women not taking contraceptives. No adverse effects attributable to concurrent use were seen.[3]

(d) Rosuvastatin

In a non-randomised study in 18 healthy women taking an oral triphasic combined hormonal contraceptive (**ethinylestradiol** 35 micrograms with **norgestimate** 180 to 250 micrograms), the addition of rosuvastatin 40 mg daily increased the AUC of **ethinylestradiol** by 26% and increased that of norgestrel, an active metabolite of norgestimate, by 34%. The contraceptive activity was unchanged as measured by FSH, LH and progesterone levels.[4] The pharmacokinetics and lipid-lowering effects of rosuvastatin were also unaffected.[4]

(e) Simvastatin

In a crossover study, 48 women with polycystic ovary syndrome received an oral combined hormonal contraceptive (**ethinylestradiol** 20 micrograms with **desogestrel** 150 micrograms) alone for 12 weeks and with simvastatin 20 mg daily for 12 weeks. Simvastatin prevented the contraceptive-induced 20% increase in triglycerides, and decreased LDL-cholesterol (the contraceptive alone increased this).[5] The effects of simvastatin alone were not assessed in this study, so it is not possible to say whether the contraceptive attenuated any of the benefits of simvastatin.

Mechanism

It is not known why atorvastatin and rosuvastatin increase levels of the contraceptive steroids.

Oral combined hormonal contraceptives are known to be associated with some adverse effects on plasma lipids, which can depend on the progestogen used. Oral contraceptives containing an androgenic progestogen probably have the greatest effects whereas non-androgenic (third generation) progestogen (e.g. desogestrel, gestodene, norgestimate) have less detrimental effects on lipids. Statins appear to attenuate some of the adverse effects of contraceptives on plasma lipids.

Importance and management

The increases in ethinylestradiol and progestogens seen with atorvastatin and rosuvastatin are only moderate and unlikely to be clinically important, but the manufacturers say that they should be considered when selecting an appropriate oral hormonal contraceptive dose for women given these statins.[6-8] If adverse effects such as nausea and breast tenderness are troublesome, it may be appropriate to select a contraceptive with a lower dose.

Note that statins are potentially teratogenic and therefore reliable contraception is required if they are used in women of child-bearing age. However, bear in mind also that the indications for statins may be a contraindication to the use of combined hormonal contraceptives, if other risk factors for arterial disease are present. This is because these contraceptives can have adverse effects on serum lipids. Statins may attenuate some of these effects.

Combined hormonal contraceptives + Sucrose polyesters

Sucrose polyester did not alter the pharmacokinetics of the contraceptive steroids or affect the suppression of ovulation in women given oral combined hormonal contraceptives.

Clinical evidence, mechanism, importance and management

When 28 healthy women took 18 g of sucrose polyester (*Olestra*) daily for 28 days, the pharmacokinetics of the components of an oral combined hormonal contraceptive (**ethinylestradiol** 30 micrograms with **norgestrel** 300 micrograms) were unchanged. Serum progesterone levels also remained unaltered, suggesting no ovulation occurred.[1] This agrees with the findings of earlier single-dose studies, which found that sucrose polyester had no effect on the bioavailability of single doses of **ethinylestradiol** or **norethisterone**.[2] No special contraceptive precautions appear to be necessary in the presence of sucrose polyesters.

2. Roberts RJ, Leff RD. Influence of absorbable and nonabsorbable lipids and lipidlike substances on drug availability. *Clin Pharmacol Ther* (1989) 45, 299–304.

Combined hormonal contraceptives + Tacrolimus

Theoretically, tacrolimus may *increase* the plasma levels of hormonal contraceptives. Combined hormonal contraceptives may increase tacrolimus levels.

Clinical evidence, mechanism, importance and management

The UK manufacturer of tacrolimus says that during clinical use **ethinylestradiol** has been shown to increase tacrolimus levels to a minor extent, and that, *in vitro,* **gestodene** and **norethisterone** are potential inhibitors of tacrolimus metabolism.[1] The mechanism for this is unclear as these contraceptive steroids do not inhibit the cytochrome P450 isoenzyme CYP3A4, by which tacrolimus is principally metabolised.

In addition, tacrolimus is known to be a weak inhibitor of CYP3A4, by which contraceptive steroids are partially metabolised. Therefore, tacrolimus may reduce the clearance of hormonal contraceptives, leading to increased hormone exposure.[1] However, the extent of this interaction does not appear to have been studied, and its clinical relevance is therefore uncertain (it would be expected to be small). Nevertheless, the UK manufacturers suggest that care should be taken when deciding upon contraceptive measures.[1]

1. Prograf (Tacrolimus monohydrate). Astellas Pharma Ltd. UK Summary of product characteristics, May 2009.

Combined hormonal contraceptives + Tegaserod

Tegaserod did not alter the pharmacokinetics of the contraceptive steroids or the suppression of ovulation in women given an oral combined hormonal contraceptive.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study in healthy women taking a triphasic oral combined hormonal contraceptive (**ethinylestradiol** with **levonorgestrel**), tegaserod 6 mg twice daily for a complete cycle had no effect on the AUC of **ethinylestradiol** and caused a minor 8% decrease in the AUC of **levonorgestrel**, which would not be expected to be clinically relevant. In addition, no ovulation occurred as assessed by progesterone levels.[1,2]

This study suggests that tegaserod is unlikely to alter the efficacy of combined hormonal contraceptives.

Combined hormonal contraceptives + Terbinafine

Terbinafine appears unlikely to interact with oral combined hormonal contraceptives.

Clinical evidence, mechanism, importance and management

An *in vitro* study in human liver microsomes found that terbinafine did not inhibit the hydroxylation of **ethinylestradiol**,[1] indicating that, in clinical use, it is unlikely to alter the pharmacokinetics of ethinylestradiol by this mechanism.

The UK manufacturer of terbinafine notes that some cases of menstrual disturbances (breakthrough bleeding and irregular cycle) have been reported in patients taking both oral contraceptives and terbinafine.[2] Nevertheless, in a post-marketing survey that included 314 patients taking both oral contraceptives and terbinafine, the rate of menstrual disorders (4.5%) was within the rate reported in the literature for patients taking oral contraceptives alone.[3] It seems unlikely that terbinafine will alter the efficacy of oral hormonal contraceptives.

Combined hormonal contraceptives + Tiagabine

Tiagabine did not alter the suppression of ovulation or plasma contraceptive steroid levels in women given oral combined hormonal contraceptives.

Clinical evidence, mechanism, importance and management

A study in 10 healthy women found that tiagabine 2 mg four times daily, from day 24 of one cycle to day 7 of the next cycle, had no effect on the mean plasma levels of any of the steroids in two oral combined hormonal contraceptives (**ethinylestradiol** 30 micrograms with **levonorgestrel** 150 micrograms or **desogestrel** 150 micrograms). There was no evidence that the suppression of ovulation was altered in any way (no significant changes in the plasma concentrations of progesterone, FSH, or LH were seen between the first and second cycles, and progesterone levels remained in the non-ovulatory range). Tiagabine did not induce hepatic enzymes, as assessed by 6β-hydroxycortisol excretion. Two women did develop breakthrough bleeding, but given the above findings, this was not thought to represent reduced efficacy of the contraceptive.[1] There would appear to be no reason for any special contraceptive precautions during the concurrent use of tiagabine.

1. Mengel HB, Houston A, Back DJ. An evaluation of the interaction between tiagabine and oral contraceptives in female volunteers. *J Pharm Med* (1994) 4, 141–50.

Combined hormonal contraceptives + Topiramate

Ethinylestradiol levels may be modestly reduced by high-dose topiramate, increasing the risk of breakthrough bleeding in women taking oral combined hormonal contraceptives.

Clinical evidence

In a study, 11 women with epilepsy taking sodium valproate and an oral combined hormonal contraceptive (**ethinylestradiol** 35 micrograms with **norethisterone** 1 mg) were also given three escalating doses of topiramate 200 mg, 400 mg and 800 mg daily (as two divided doses) for 28-day periods. The mean AUC of the **ethinylestradiol** fell by 18%, 21%, and 30%, with the three doses respectively. No significant changes were found in the **norethisterone** AUC. No ovulation occurred, as assessed by progestogen levels, but one patient had breakthrough bleeding.[1] A follow-up study evaluated the effect of lower doses of topiramate on the pharmacokinetics of the same oral combined hormonal contraceptive. Subjects were randomised to take daily doses of topiramate of 50 mg (11 subjects), 100 mg (10 subjects) or 200 mg (2 groups of 12 subjects). This study found minor changes in the pharmacokinetics of both **ethinylestradiol** and **norethisterone**; these changes were not statistically significant, and further reduced when the data from 2 subjects were excluded due to compliance issues (maximum decrease of 12% in the **ethinylestradiol** AUC). The authors noted that the difference between this study and the first study[1] was due to the difference in the doses of topiramate used, as topiramate is a weak liver enzyme-inducer, and this effect is dose-related.[2]

Mechanism

Not understood. It is suggested that high-dose topiramate weakly induces drug-metabolising enzymes, which increases the metabolism of the ethinylestradiol.[1,2]

Importance and management

The interaction between topiramate and the oral combined hormonal contraceptives is established. The small changes in the pharmacokinetics of the oral combined hormonal contraceptive seen here with usual therapeutic doses of topiramate (50 to 400 mg daily) are lower than those seen with other enzyme-inducing antiepileptics such as carbamazepine and phenytoin (see 'Combined hormonal contraceptives + Carbamazepine or Oxcarbazepine', p.1180, and 'Combined hormonal contraceptives + Barbiturates or Phenytoin', p.1177). However, it is possible that they would be sufficient to cause the failure of oral combined hormonal contraceptives in rare cases, particularly at high therapeutic doses of topiramate. The authors of the first study considered that an oral combined hormonal contraceptive containing at least 35 micrograms of ethinylestradiol would be suitable for women taking topiramate,[1] which seems reasonable. Nevertheless, as there is a risk of failure of contraception with the concurrent use of topiramate, and possibly more importantly, because topiramate is teratogenic, the UK manufacturer of topiramate advises the use of a non-hormonal contraceptive or a high-dose oral combined hormonal contraceptive (at least 50 micrograms of oestrogen), and also that patients should be told to report any changes in their bleeding patterns.[3] However, while recognising the possibility of decreased contraceptive efficacy, the US manufacturer gives no advice about ethinylestradiol dose.[4] The UK Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit has issued guidance on the use of liver enzyme inducers, including topiramate, with hormonal contraceptives, see 'Combined hormonal contraceptives + Barbiturates or Phenytoin', p.1177, for details of this guidance.

Combined hormonal contraceptives + Triptans

Oral combined hormonal contraceptives appear to modestly raise the levels of frovatriptan, naratriptan and zolmitriptan, and slightly increase those of sumatriptan. Almotriptan, rizatriptan and sumatriptan appear not to alter the levels of contraceptive steroids. Note that use of combined hormonal contraceptives in migraine (the indication for triptans) appears to increase the risk of stroke.

Clinical evidence

(a) Almotriptan

In a well-controlled study in 21 women, a single 12.5-mg dose of almotriptan given between days 8 and 12 of a cycle had no clinically significant effect on the pharmacokinetics of an oral combined hormonal contraceptive (**ethinylestradiol** 30 micrograms with **desogestrel** 150 micrograms) taken for two cycles.[1]

(b) Frovatriptan

In a retrospective analysis of pharmacokinetic data from phase I studies, the mean maximum concentration and AUC of frovatriptan were 25% and 30% higher, respectively, in women taking oral hormonal contraceptives than in women not taking these contraceptives.[2]

(c) Naratriptan

The manufacturer notes that the clearance of naratriptan was reduced by 32% by oral hormonal contraceptives leading to a slightly higher level of naratriptan.[3] A case of ischaemic colitis has been reported in a 42-year-old woman who had been taking an oral combined hormonal contraceptive (**ethinylestradiol** 30 micrograms with **drospirenone** 3 mg) for 3 years, naratriptan 2.5 mg as needed for 18 months (maximum dose of one tablet in a day and 9 tablets in a month), and topiramate 25 mg twice daily for 4 months.[4]

(d) Rizatriptan

In a placebo-controlled study in 20 healthy young women taking an oral combined hormonal contraceptive (**ethinylestradiol** 35 micrograms with **norethisterone** 1 mg), the concurrent use of rizatriptan (6 days of 10 mg daily followed by 2 days of 10 mg every 4 hours to a total of 3 doses daily) did not affect the pharmacokinetics of either contraceptive steroid. Blood pressure, heart rate and temperature were unaffected and adverse effects were similar to those seen with placebo.[5]

(e) Sumatriptan

A study was designed to investigate the effects of an oral combined hormonal contraceptive (**ethinylestradiol** 35 micrograms with **norethisterone** 1 mg) on the pharmacokinetics of sumatriptan in 26 women who had been taking this contraceptive for at least 3 months. A single 50-mg oral dose of sumatriptan was given once after 21 days of active treatment with the contraceptive, and again after 7 days of placebo (day 28). A 16% higher AUC and a 17% higher maximum concentration of sumatriptan was noted on day 21, compared with day 29. There was an 18% reduction in the maximum concentration of **norethisterone** when it was given with sumatriptan, but no change in its AUC. Similarly, there was no change in the AUC or maximum concentration of **ethinylestradiol** when it was given with sumatriptan.[6]

In a large prospective study of subcutaneous sumatriptan, there was no difference in the incidence of cardiovascular adverse events between 1 188 patients taking oral hormonal contraceptives (types not stated) and 11 151 patients who were not taking contraceptives. Two cardiovascular adverse events occurred within 24 hours of sumatriptan use in women also using oral hormonal contraceptives. One 44-year-old women experienced angina, and the other had palpitations.[7]

(f) Zolmitriptan

The US manufacturer states that, in a retrospective analysis of pharmacokinetic data from several studies, the mean maximum concentration and AUC of zolmitriptan were 30% and 50% higher, respectively, in women taking oral hormonal contraceptives than in women not taking these contraceptives.[8] The effects of zolmitriptan on oral hormonal contraceptive steroids have not been studied.[8]

Mechanism

Uncertain, but ethinylestradiol is known to be a modest inhibitor of the cytochrome P450 isoenzyme CYP1A2, by which a number of these triptans (particularly frovatriptan and zolmitriptan) are at least partially metabolised.

Importance and management

Although data are limited, the minor to modest possible increases in frovatriptan, naratriptan, sumatriptan and zolmitriptan exposure described are not likely to produce clinically relevant adverse effects. Almotriptan, rizatriptan and sumatriptan do not appear to have any clinically important effect on levels of contraceptive steroids. The significance of the single case

report of ischaemic colitis associated with the concurrent use of naratriptan and an oral combined hormonal contraceptive is unclear. Note that ischaemic colitis has, rarely, been reported with naratriptan alone.[9] The manufacturers have found no cases of ischaemic colitis in approximately 450 women taking oral hormonal contraceptives and naratriptan, for prophylaxis for 5 to 6 days.[9]

More importantly, women who suffer from migraine and take an oral combined hormonal contraceptive are at a 6- to 14-fold increased risk of a stroke compared with those not using oral combined hormonal contraceptives who do not suffer from migraine. In addition, in women who suffer from migraine, the use of oral combined hormonal contraceptives was associated with a two- to fourfold increased risk of stroke, compared with non-users of these contraceptives.[10] Migraine with aura (which indicates ischaemia) is generally thought to be a greater risk for stroke. As a result, in the UK, the Faculty of Family Planning and Reproductive Health Care (FFPRHC) guidance states that women of all ages who currently have migraines *with* aura should not use a combined hormonal contraceptive. Women over the age of 35 years who have migraine attacks *without* aura and those of any age with a past history of migraine *with* aura should also not use combined hormonal contraceptives.[11] Women taking any hormonal contraceptive who develop migraine with aura as a new symptom should have their contraceptive choices reviewed. The FFPRHC guidance gives advice on alternative choices of contraceptive method for women with migraine or a history of migraine.[11]

Combined hormonal contraceptives + Urinary antimuscarinics

Fesoterodine, solifenacin and tolterodine do not alter the pharmacokinetics of the contraceptive steroids, or their effects on the suppression of ovulation in women taking oral combined hormonal contraceptives. Darifenacin does not affect the pharmacokinetics of oral combined hormonal contraceptives. Hormonal contraceptives do not appear to alter the pharmacokinetics of oxybutynin.

Clinical evidence

(a) Darifenacin

The manufacturers note that, in a study in 22 healthy women, steady-state darifenacin 10 mg three times daily had no effect on the pharmacokinetics of an oral combined hormonal contraceptive (**ethinylestradiol** with **levonorgestrel**).[1,2]

(b) Fesoterodine

In a randomised, crossover study in 26 healthy women, fesoterodine 8 mg daily for 14 days, beginning on day one of a cycle, had no significant effect on the pharmacokinetics of an oral combined hormonal contraceptive (**ethinylestradiol** 30 micrograms with **levonorgestrel** 150 micrograms). Fesoterodine did not alter suppression of ovulation assessed by progesterone, LH or FSH levels.[3]

(c) Oxybutynin

The pharmacokinetics of a single 10-mg dose of oxybutynin as a controlled release tablet did not differ between women taking contraceptive steroids, women not taking contraceptive steroids, and men.[4]

(d) Solifenacin

In a randomised, crossover study in healthy women, solifenacin 10 mg daily for 10 days, beginning on day 12 of a cycle, had no significant effect on the pharmacokinetics of an oral combined hormonal contraceptive (**ethinylestradiol** 30 micrograms with **levonorgestrel** 150 micrograms). Solifenacin did not alter suppression of LH or FSH.[5]

(e) Tolterodine

A randomised, crossover study in 24 women found that tolterodine 2 mg twice daily on days one to 14 of two 28-day contraceptive cycles had no effect on the pharmacokinetics of the steroids in an oral combined hormonal contraceptive (**ethinylestradiol** 30 micrograms with **levonorgestrel** 150 micrograms). The pharmacokinetics of the tolterodine were also not significantly altered, and the serum levels of estradiol and progesterone indicated that suppression of ovulation continued during both periods of treatment.[6]

Mechanism

None known.

Importance and management

The evidence from these controlled studies suggest that the urinary antimuscarinics tested (darifenacin, fesoterodine, solifenacin and tolterodine) are unlikely to alter the efficacy of oral combined hormonal contraceptives. No special precautions would therefore seem to be needed if these drugs are used concurrently.

Combined hormonal contraceptives + Ursodeoxycholic acid (Ursodiol)

Ursodeoxycholic acid did not alter levels of ethinylestradiol from an oral combined hormonal contraceptive.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study in 8 healthy women taking an oral combined hormonal contraceptive (**ethinylestradiol** with **gestodene**), ursodeoxycholic acid 8 to 10 mg/kg daily for 21 days had no effect on the AUC of **ethinylestradiol**.[1]

This study suggests that ursodeoxycholic acid is unlikely to alter the efficacy of oral combined hormonal contraceptives.

1. Baisini O, Benini F, Petraglia F, Kuhnz W, Scalia S, Marschall H-U, Brunetti G, Tauschel H-D, Lanzini A. Ursodeoxycholic acid does not affect ethinylestradiol bioavailability in women taking oral contraceptives. *Eur J Clin Pharmacol* (2004) 60, 481–7.

Combined hormonal contraceptives + Valproate

Sodium valproate does not appear to alter the efficacy of oral combined hormonal contraceptives. In one single-dose study, sodium valproate did not alter the AUC of ethinylestradiol or levonorgestrel. Ethinylestradiol may modestly reduce valproate

levels, an effect which is cyclical. There is one published case where this resulted in an increase in seizure frequency.

Clinical evidence

(a) Contraceptive efficacy

In a series of 32 patients taking an oral hormonal contraceptive, none of 7 taking sodium valproate 600 mg to 1.8 g daily had breakthrough bleeding, whereas about two-thirds of those taking carbamazepine or phenobarbital had breakthrough bleeding (a sign of possible reduced contraceptive efficacy). Most of the 7 patients taking valproate were taking oral combined hormonal contraceptives containing 50 micrograms of **ethinylestradiol**; one was taking less than 50 micrograms, and one was using an oral **progestogen-only contraceptive**. One of the 7 patients had previously experienced breakthrough bleeding while taking phenobarbital, but this stopped when it was replaced with sodium valproate. Two further patients did not have breakthrough bleeding while taking sodium valproate and benzodiazepines, but breakthrough bleeding started when phenytoin was also given.[1]

In a pharmacokinetic study, sodium valproate 200 mg twice daily had no effect on the AUC of a single dose of an oral combined hormonal contraceptive (**ethinylestradiol** 50 micrograms with **levonorgestrel** 250 micrograms) given to women with epilepsy 8 to 16 weeks after they started sodium valproate. However, a 50% *increase* in the peak plasma levels of **ethinylestradiol** was noted.[2]

Conversely, one pregnancy was identified in a woman who took sodium valproate and an oral hormonal contraceptive (unspecified) in the adverse reactions register of the CSM in the UK for the years 1968 to 1984. However, the authors consider this one case to be a chance association.[3]

(b) Valproate efficacy

In 9 women with epilepsy taking valproic acid 500 mg to 1.5 g daily, the serum levels of total and unbound valproic acid were 21% and 41% lower, respectively, during combined hormonal contraceptive intake compared with the pill-free period. These women were taking oral contraceptives containing **ethinylestradiol** and either **gestodene** (5 women) or **drospirenone** (2 women), or the transdermal patch containing **ethinylestradiol** and **norelgestromin** (2 women). The pill-free interval was 7 days in seven women and 4 days in two women.[4] In another study in 12 women taking valproate monotherapy, a very similar median 23.4% lower serum valproate level was seen during the third week of an oral combined hormonal contraceptive cycle when compared with the fourth pill-free week. These women were taking **ethinylestradiol** with either **norethisterone**, **levonorgestrel** or **norgestimate**.[5]

In one case report, lower valproate levels and more frequent seizures occurred in a woman taking an oral combined hormonal contraceptive (**ethinylestradiol** 35 micrograms with **ethynodiol** 1 mg) during the active pill phase, when compared with the inactive 7-day period. Specifically, over a 5-month period, she had 12 seizures during 105 days of active pill use and none during the 35 days of inactive pill use, and total and unbound valproate levels were 36% and 46% lower, respectively, during active pill use.[6] No further cases appear to have been published.

Mechanism

Valproate is metabolised by glucuronide conjugation, and therefore its levels may be reduced due to induction of glucuronosyltransferases by ethinylestradiol. Valproate is an inhibitor of glucuronidation, and might therefore be expected to increase ethinylestradiol levels, but only an increase in maximum levels and not the AUC was seen in the one single-dose study available.

Importance and management

Although specific data are limited, it appears that valproate is unlikely to reduce the efficacy of combined hormonal contraceptives. No special contraceptive precautions are required during concurrent use. Note that the UK Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit guidelines on the management of hormonal contraceptives and drug interactions lists valproate as an example of an antiepileptic that does not induce liver enzymes and causes no reduction in ethinylestradiol or progestogens.[7] The general relevance of the modest cyclical reduction in valproate levels during active pill taking, and the case report of an increase in seizure frequency is unclear, and further study is needed. However, bear the possibility of this interaction in mind.

Combined hormonal contraceptives + Vigabatrin

Vigabatrin appears not to alter the pharmacokinetics of ethinylestradiol or levonorgestrel given as an oral combined hormonal contraceptive.

Clinical evidence, mechanism, importance and management

Vigabatrin 3 g daily had no statistically significant effect on the pharmacokinetics of **ethinylestradiol** and **levonorgestrel** in 13 healthy women given a single dose of an oral combined hormonal contraceptive (**ethinylestradiol** 30 micrograms with **levonorgestrel** 150 micrograms); although 2 of the women had a 39% and a 50% fall in the AUC of **ethinylestradiol**. Vigabatrin did not induce hepatic enzymes as assessed by antipyrine clearance and 6β-hydroxycortisol excretion.[1]

This study would seem to confirm the lack of reports of an interaction between hormonal contraceptives and vigabatrin, but the authors of the report introduce a small note of caution because it is not clear whether the reduced **ethinylestradiol** AUCs seen in two of the women resulted from an interaction or were simply normal individual variations.[1] Note that the UK Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit guidelines on the management of hormonal contraceptives and drug interactions list vigabatrin as an example of an antiepileptic that does not induce liver enzymes.[2] No special precautions are recommended.

Combined hormonal contraceptives + Ziprasidone

Ziprasidone did not alter the levels of ethinylestradiol and levonorgestrel from an oral combined hormonal contraceptive.

Clinical evidence, mechanism, importance and management

In a placebo-controlled, crossover study, 18 healthy women taking an oral contraceptive (**ethinylestradiol** 30 micrograms with **levonorgestrel** 150 micrograms) for at least 3 cycles were also given ziprasidone 20 mg twice daily for 8 days, from day 8 to 15 of a cycle. The only change in the pharmacokinetics of the two steroids was an increase of about 30-minutes in the time to maximum plasma concentration of the **levonorgestrel**, but this is not clinically relevant. On the basis of this pharmacokinetic study,

ziprasidone appears unlikely to affect the efficacy of oral combined hormonal contraceptives.[1]

1. Muirhead GJ, Harness J, Holt PR, Oliver S, Anziano RJ. Ziprasidone and the pharmacokinetics of a combined oral contraceptive. *Br J Clin Pharmacol* (2000) 49 (Suppl 1), 49S–56S.

Combined hormonal contraceptives + Zonisamide

Zonisamide did not affect the levels of ethinylestradiol or norethisterone in women taking an oral combined hormonal contraceptive, and the suppression of ovulation was not altered.

Clinical evidence, mechanism, importance and management

Zonisamide 100 mg daily titrated to 200 to 400 mg daily taken from day 15 of cycle two to day 13 of cycle three had no effect on the pharmacokinetics of **ethinylestradiol** or **norethisterone** in healthy women taking an oral combined hormonal contraceptive (**ethinylestradiol** 35 micrograms with **norethisterone** 1 mg). There was no change in FSH and LH levels, and the levels of progesterone indicated the absence of ovulation.[1] This suggests that no special contraceptive precautions are needed during concurrent use.

Drospirenone-containing contraceptives or HRT + Potassium-sparing drugs

Drospirenone, given as the progestogen component of oral combined hormonal contraceptives or HRT, has the potential to cause hyperkalaemia and may have additive effects with other potassium-sparing drugs.

Clinical evidence

(a) Drospirenone in combined hormonal contraceptives

In a small study in 27 women with acne, there was no significant increase in serum potassium level 4 to 6 weeks after starting **ethinylestradiol** 30 micrograms with drospirenone 3 mg and **spironolactone** 100 mg daily. Although this study was non-comparative, it does provide some useful evidence about concurrent use.[1]

In a matched cohort study, there was no difference in the rate of diagnosed hyperkalaemia between 22 429 women who started contraception with **ethinylestradiol** with drospirenone and 44 858 women who started other oral hormonal contraceptives (one versus 4) over an average follow-up of 7.6 months. In addition, there was no difference in the rate of clinical outcomes that could be related to hyperkalaemia.[2]

(b) Drospirenone in HRT

In a controlled study in 24 postmenopausal women taking **enalapril** 10 mg twice daily there was no change in serum potassium levels after taking **estradiol** 1 mg with drospirenone 3 mg daily for 14 days, when compared with placebo. In addition, no subject developed hyperkalaemia (defined as serum potassium greater than 5.5 mmol/L).[3] Similarly, in a larger study in postmenopausal women taking an **ACE inhibitor** or an **angiotensin II receptor antagonist**, there was no significant difference in incidence of hyperkalaemia (potassium level 5.5 mmol/L or more) between those receiving **estradiol** 1 mg with drospirenone 3 mg daily for 28 days and placebo (7.3% versus 2.6%). This study included women with diabetes, women without diabetes, and women without diabetes who were also given a 5-day course of **ibuprofen** 400 mg three times daily.[4] Nevertheless, the UK manufacturer notes that the concurrent use of all these three types of medications together (drospirenone in HRT with an **NSAID** and an **ACE inhibitor** or **angiotensin II receptor antagonist**) may cause a small increase in serum potassium, which is more pronounced in diabetic women.[5]

In yet another study in 33 healthy postmenopausal women, there was no difference in potassium levels between the concurrent use of **estradiol** 1 mg with drospirenone 3 mg daily for 17 days and **indometacin** 50 mg three times daily for the last 5 days, and **indometacin** alone. In addition there was no difference in the incidence of hyperkalaemia (5 women versus 3 women). However, in 14 women, at least one potassium level above 4.4 mmol/L was seen both during combined treatment and with indometacin alone). Of the other women, 12 had raised potassium levels only during the combined treatment, whereas only one woman had a raised potassium levels during the use of indometacin alone,[6] which seems to suggest some additive effect.

The US manufacturer also notes a study of the effect of drospirenone 3 mg daily on serum potassium levels in women with normal renal function (11 women) and mild renal impairment (10 women) or moderate renal impairment (7 women). During the study, 7 patients continued to use **potassium-sparing drugs** (not specified). Drospirenone had no significant effect on potassium levels and no hyperkalaemia occurred. However, in 5 of the 7 patients also taking **potassium-sparing drugs**, there was a rise in potassium level of up to 0.33 mmol/L).[7]

Mechanism

Drospirenone, an analogue of spironolactone, has weak antimineralocorticoid and potassium-sparing effects, and therefore may increase the risk of hyperkalaemia if it is given with other drugs that can increase potassium levels. Drospirenone 3 mg is said to have activity similar to that of spironolactone 25 mg.[8]

Importance and management

The risk of hyperkalaemia developing in women taking the drospirenone-containing oral combined hormonal contraceptive or HRT with other drugs that can increase serum potassium appears to be low, especially if renal function is normal. However, in the UK, severe renal impairment is a contraindication to use. If the woman has mild or moderate renal impairment, it is recommended that serum potassium is measured during the first cycle/month of treatment with contraceptives or HRT containing drospirenone, especially if they are also taking any other drugs that increase serum potassium.[5,9] In the US, renal impairment [any degree] is a contraindication to the use of drospirenone preparations.[7,8]

In the US, it is recommended that consideration be given to monitoring serum potassium during the first cycle in women [with normal renal function] who regularly take any drugs that increase serum potassium (ACE inhibitors, **aldosterone antagonists**, angiotensin II receptor antagonists, **heparin**, NSAIDs, **potassium-sparing diuretics** and **potassium supplements** are named.[7,8] The same advice used to be given in the UK for all women given the drospirenone-containing oral combined hormonal contraceptive. However, for women without renal impairment, current UK advice is to monitor potassium during the first treatment cycle if they are also taking another aldosterone antagonist (e.g. spironolactone and eplerenone) or a potassium-sparing diuretic, and there is no requirement for monitoring with ACE inhibitors or NSAIDs.[9] Note that in one survey of 58 US physicians, only 40% of 466 women starting ethinylestradiol with drospirenone and taking concurrent potassium-sparing drugs had a potassium test. Physicians who did not do the test were more likely to disagree with the need for it in patients taking ACE inhibitors, angiotensin II receptor antagonists, heparin and NSAIDs.[10]

Nevertheless, for the drospirenone-containing HRT preparation, the UK manufacturer notes that the concurrent use of more than one drug that can raise potassium levels (an NSAID with an ACE inhibitor or angiotensin II receptor antagonist) may cause a small increase in serum potassium levels, which is more pronounced in diabetic women.[5]

For mention of the risks of hypertension with combined hormonal contraceptives, and the fact that drospirenone HRT appears to slightly decrease blood pressure, see ‘Antihypertensives + Hormonal contraceptives or HRT’, p.1050.

Emergency hormonal contraceptives + Antibacterials

There is a theoretical possibility that the emergency contraceptive efficacy of norgestrel with ethinylestradiol could be affected by antibacterials such as the penicillins and tetracyclines. The efficacy of levonorgestrel given for emergency contraception is not likely to be affected by these antibacterials.

Clinical evidence, mechanism, importance and management

(a) Combined oestrogen and progestogen

The manufacturer has stated that the efficacy of **norgestrel** with **ethinylestradiol** (*Schering PC4*) may be reduced by **ampicillin** and other antibacterials.[1] This is presumably an extrapolation from the rare cases of combined hormonal contraceptive failure seen with various other antibacterials that do not induce liver enzymes, which, it has been suggested, could be due to reduced enterohepatic recycling of **ethinylestradiol** (see 'Combined hormonal contraceptives + Antibacterials; Penicillins', p.1170). However, it has been suggested that it is likely that sufficient hormone is absorbed initially for the emergency contraceptive to be effective[2] (it is taken as 2 doses within 12 hours of each other).

Note that **rifampicin** (**rifampin**) and **rifabutin** are likely to reduce the efficacy of *Schering PC4*, as they induce the metabolism of oestrogens and progestogens, see 'Emergency hormonal contraceptives + Enzyme inducers', below.

Note that the use of an oestrogen with a progestogen as an emergency contraceptive has been superseded by a progestogen-only preparation (see below), as the latter is associated with a higher efficacy and less oestrogen-related adverse effects.

(b) Progestogen only

Levonorgestrel is metabolised to inactive substances before it is conjugated,[3] and does not undergo enterohepatic recycling of the active moiety.[4] Therefore, there is no reason to expect that its efficacy as an emergency contraceptive would be affected by antibacterials that alter gut flora and do not induce liver enzymes.[4] No special precautions are necessary with these antibacterials. However, **rifampicin** (**rifampin**) and **rifabutin** are likely to reduce the efficacy of levonorgestrel given as an emergency contraceptive, as they induce the metabolism of progestogens, see 'Emergency hormonal contraceptives + Enzyme inducers', below.

Emergency hormonal contraceptives + Enzyme inducers

Two cases of pregnancy despite the use of emergency hormonal contraception were attributed to the use of St John's wort. The efficacy of both the progestogen-only and combined emergency hormonal contraceptive is likely to be reduced by enzyme inducers that have been shown to affect oral combined hormonal contraceptives, such as rifampicin (rifampin), the enzyme-inducing antiepileptics and some antiretrovirals.

Clinical evidence, mechanism, importance and management

Between 2000 and 2002 the CSM in the UK had received reports of 2 women taking **St John's wort** who became pregnant despite taking emergency hormonal contraception.[1] One of them had also been taking an oral combined hormonal contraceptive and took *Levonelle-2* (**levonorgestrel**).[1,2]

Various enzyme inducers have specifically been shown to decrease the levels of contraceptive steroids and/or reduce their effects on the suppression of ovulation when used as components of oral combined hormonal contraceptives (see 'Table 28.1', (p.1165)). This would also be expected when **ethinylestradiol** with **norgestrel**, or **levonorgestrel** alone, are used as postcoital emergency hormonal contraceptives. It would be easy to specifically evaluate the pharmacokinetic changes that occur with single doses of emergency hormonal contraceptive products when given with enzyme-inducing drugs, although no such studies appear to have been published. However, it is difficult to envisage a practical study design that would show to what extent this reduced metabolism results in reduced efficacy of emergency contraception.

In the UK in 2005, the Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit noted that there appeared to be no good evidence on how to manage this interaction, but they recommended increasing the contraceptive dose by approximately 50% (**levonorgestrel** 2.25 mg).[3] The BNF in the UK recommends doubling the dose (giving a single 3-mg dose of levonorgestrel).[4] A **copper IUD** may also be used as an effective alternative.[3] In some countries it is possible to buy emergency hormonal contraception without a prescription; however, in the UK it has been advised that patients taking enzyme inducers should not be supplied the emergency hormonal contraceptive but should be referred to a doctor or family planning service.[3,5] Given the potential consequences of an unwanted pregnancy, these seem sensible precautions.

Emergency hormonal contraceptives; Ulipristal + Miscellaneous

The efficacy of ulipristal emergency contraception is expected to be reduced by enzyme-inducing drugs. The absorption of ulipristal may be reduced in women taking antacids, proton pump inhibitors or H_2-receptor antagonists. Ulipristal has the potential to reduce the efficacy of hormonal contraceptives, and after ulipristal emergency contraception, a non-hormonal contraceptive should be used until the next menstrual period.

Clinical evidence, mechanism, importance and management

(a) Contraceptive steroids

The manufacturer notes that ulipristal acetate binds to the progesterone receptor with high affinity, and therefore could theoretically interfere with the action of progestogen-containing products. They say that it might reduce the efficacy of **combined hormonal contraceptives** and **progestogen-only contraception**. Therefore, after using ulipristal emergency contraception, it is recommended that a reliable barrier method of contraception should be used until the next menstrual period starts.[1] In addition, the manufacturer specifically states that the concurrent use of ulipristal acetate and emergency hormonal contraception containing **levonorgestrel** is not recommended.[1]

(b) CYP3A4 inducers

The manufacturer states that ulipristal is metabolised by the cytochrome P450 isoenzyme CYP3A4 *in vitro*. No specific drug interaction studies have been performed *in vivo*; however, it is predicted that CYP3A4 inducers (the manufacturer names **rifampicin** (**rifampin**), **phenytoin**, **phenobarbital**, **carbamazepine**, **ritonavir**, and **St John's wort**) may reduce plasma concentrations of ulipristal acetate, which may result in decreased efficacy.[1] For a list of enzyme inducers that have affected combined hormonal contraceptives, see 'Table 28.1', (p.1165). However, note that not all of these drugs interact by inducing CYP3A4 (e.g. **ritonavir** probably interacts by inducing glucuronidation). Because ulipristal is a synthetic

steroid derivative, it is possible that it will undergo similar interactions.

The manufacturer advises that ulipristal should not be used for emergency contraception in women taking CYP3A4 inducers. They say that, because enzyme induction wears off slowly, effects on the plasma concentrations of ulipristal acetate may occur even if a woman has stopped taking an enzyme inducer within the last 2 to 3 weeks.[1] Until more is known, this advice is prudent.

(c) CYP3A4 inhibitors

Potent CYP3A4 inhibitors (the manufacturer names **ketoconazole**, **itraconazole**, **telithromycin**, **clarithromycin**, and **nefazodone**) are predicted to increase exposure to ulipristal acetate. The manufacturer notes that the clinical relevance of this is unknown.[1]

(d) Drugs that increase gastric pH

The manufacturer notes that drugs that increase gastric pH such as **proton pump inhibitors**, **antacids** and **H_2-receptor antagonists** may reduce the plasma concentrations of ulipristal acetate and may result in decreased efficacy. Because of this, they say that concurrent use is not recommended.[1]

1. EllaOne (Ulipristal acetate). HRA Pharma UK Ltd. UK Summary of product characteristics, May 2009.

Gestrinone + Enzyme inducers

The manufacturer says that rifampicin (rifampin) and antiepileptics may reduce the effects of gestrinone.

Clinical evidence, mechanism, importance and management

The manufacturer suggests that **rifampicin** (**rifampin**) and **antiepileptics** (not named, but by implication those that are enzyme inducers, see 'Table 28.1', (p.1165)) may accelerate the metabolism of gestrinone.[1] Be aware that gestrinone may not be as effective if any of these drugs are given concurrently.

1. Dimetriose (Gestrinone). Sanofi-Aventis. UK Summary of product characteristics, February 2008.

Hormonal contraceptives + Danazol or Gestrinone

There is a theoretical risk that the effects of danazol or gestrinone and hormonal contraceptives might be altered or reduced by concurrent use.

Clinical evidence, mechanism, importance and management

(a) Danazol

Danazol inhibits ovulation, but it is not considered reliable enough to be used as a hormonal contraceptive.[1-3] Danazol should not be used during pregnancy, because it can cause virilisation of a female foetus. The manufacturer advises the use of reliable non-hormonal contraceptive methods while taking danazol,[4] and by inference the avoidance of hormonal contraceptives. They state that there is a theoretical risk that danazol and exogenously administered oestrogens and/or progestogens, including oral hormonal contraceptives, might possibly compete for the same oestrogen, progestogen, and androgen receptors, thereby altering the effects of both drugs.[3] This would also apply to other hormonal contraceptives such as progestogen implants and injections. However, as yet there appears to be no direct evidence that any interaction actually occurs.

(b) Gestrinone

Although gestrinone, at the dose used for endometriosis, can inhibit ovulation, it is not sufficiently reliable to be used as a contraceptive. The manufacturer strongly emphasises the importance of using a barrier method of contraception while taking gestrinone because they say that not only are the effects of gestrinone possibly modified by oral hormonal contraceptives, but its use in pregnancy is totally contraindicated (high doses have been shown to be embryotoxic in some *animal* species).[5]

Hormonal contraceptives + Griseofulvin

The effects of the oral hormonal contraceptives may possibly be disturbed (either intermenstrual bleeding or amenorrhoea) if griseofulvin is taken concurrently. A few isolated reports describe women taking oral hormonal contraceptives who became pregnant while taking griseofulvin.

Clinical evidence

In 1984, regulatory authorities in the UK and the Netherlands noted that they had received a total of 22 reports of possible interactions between oral hormonal contraceptives and griseofulvin. These included 15 reports of transient intermenstrual bleeding and 5 of amenorrhoea, occurring during the first or second cycle, after griseofulvin 500 mg to 1 g daily was started. Four of these patients were rechallenged with griseofulvin (2 with intermenstrual bleeding and 2 with amenorrhoea) and all developed their original reactions. The other two women were reported to have become pregnant while taking griseofulvin and a sulfonamide ('co-trimoxazole', (p.1172) in one instance and an unknown sulfonamide in the other).[1] One other case of contraceptive failure has been reported from an analysis of the database of the CSM in the UK from 1968 to 1984,[2] but note this case may be included in the two already reported.[1] One other case report describes a woman taking an oral triphasic combined hormonal contraceptive who became pregnant about 2 months after she started to take griseofulvin 330 mg twice daily,[3] and another report describes a woman taking an oral hormonal contraceptive who became pregnant 6 weeks after starting to take griseofulvin 500 mg daily for 3 months and a 7-day course of erythromycin.[4] Note that erythromycin has also been reported to interact, see 'Combined hormonal contraceptives + Antibacterials; Macrolides', p.1168. Irregular menses and reduced menstrual flow have been described in another woman taking an oral combined hormonal contraceptive (**ethinylestradiol** 35 micrograms with **norethisterone** 500 micrograms to 1 mg) with griseofulvin 250 to 500 mg daily. When the contraceptive was substituted with another with more oestrogen (**ethinylestradiol** 50 micrograms with **norgestrel** 500 micrograms), the menstrual cycle became normal again.[5]

Mechanism

Not understood. Early evidence led to the suggestion that griseofulvin may possibly induce the activity of the liver enzymes concerned with the metabolism of the contraceptive steroids, thereby reducing their effects.[1] For this reason, griseofulvin has often been classified as an enzyme inducer. However, there is no *in vitro* or clinical evidence to support this. The apparent lack of interactions of griseofulvin with many other drugs that are substrates of liver enzymes suggests that griseofulvin is not a clinically important enzyme inducer, although this can only be confirmed by a controlled clinical study.

Importance and management

Information about an interaction between griseofulvin and oral hormonal contraceptives is very limited, but there is some evidence to suggest that menstrual disturbances may occur. The risk of contraceptive failure is uncertain but probably very small. However, it is important to ensure adequate contraception during and for one month after taking griseofulvin because it can induce aneuploidy (abnormal segregation of chromosomes during cell division), which carries the potential risk of teratogenicity.[6] Therefore, for maximal contraceptive protection, additional contraceptive measures (such as a barrier method) should be used routinely with oral combined hormonal or progestogen-only contraceptives while taking griseofulvin and for one month afterwards. Note that some UK authorities[7] also recommend additional contraceptive precautions on the basis of griseofulvin being an enzyme inducer, but see *Mechanism*, above.

It has been suggested that **progestogen-only oral contraceptives** are not the contraceptive of choice in those taking griseofulvin, not because of reduced efficacy, but because of increased menstrual irregularities.[8]

Hormonal contraceptives + NRTIs

There do not appear to have been any reports of hormonal contraceptive failure or a reduction in the efficacy of NRTIs during concurrent use. Tenofovir does not appear to affect the pharmacokinetics of ethinylestradiol or norgestimate. Hormonal contraception (oral combined hormonal contraceptives or medroxyprogesterone acetate) did not alter the pharmacokinetics of zidovudine.
Note that whatever other methods of contraception are being used, barrier methods are also advisable to reduce the risk of HIV transmission.

Clinical evidence and mechanism

(a) Tenofovir

In a study in 20 women taking an oral combined hormonal contraceptive containing **ethinylestradiol** and **norgestimate**, tenofovir 300 mg daily for 7 days had no effect on the pharmacokinetics of **ethinylestradiol** or **norgestimate**. The pharmacokinetics of tenofovir were also not affected when compared with historical data.[1]

(b) Zidovudine

In a study in 14 women, there was no difference in the AUCs of either plasma zidovudine or intracellular zidovudine phosphorylates when zidovudine 200 mg three times daily for 7 days was given before or after starting hormonal contraception. One dose of the zidovudine was given intravenously. There was a modest 40% increase in the AUC ratio of glucuronidated zidovudine to zidovudine after intravenous administration only; however, this was not statistically significant. Six women were given an oral combined hormonal contraceptive (**ethinylestradiol** 35 micrograms **norethisterone** 1 mg) and 8 women were given depot **medroxyprogesterone acetate**. There were no differences in any of the pharmacokinetic parameters between the two types of contraceptive, although note that the study was insufficiently powered to reliably assess this.[2] It had been expected that contraception would increase the zidovudine AUC because an *in vitro* study found that **ethinylestradiol** inhibited the glucuronidation of zidovudine by 50% or more.[3] Although the clinical study only included a small number of women taking the oral combined hormonal contraceptive, it does discount a marked effect of this on zidovudine levels. Note also that other drugs that had a similar effect *in vitro* did not alter zidovudine pharmacokinetics in subsequent clinical studies, see 'NRTIs; Zidovudine + Drugs that inhibit glucuronidation', p.960.

Importance and management

Tenofovir does not appear to alter the pharmacokinetics of oral combined contraceptives, and would not therefore be expected to alter their efficacy by this mechanism. Oral combined hormonal contraceptives and medroxyprogesterone acetate do not appear to alter zidovudine levels. There appears to be no published evidence at present of any clinically relevant interactions between the other NRTIs (**abacavir**, **didanosine**, **emtricitabine**, **lamivudine**, **stavudine** and **zalcitabine**) and hormonal contraceptives, and note that no pharmacokinetic interaction would be expected. A study[4] found no evidence to suggest that hormonal contraceptives (mostly oral combined hormonal contraceptives or depot medroxyprogesterone acetate) affect the efficacy of HAART. The specific HAART drugs were not named; however, most patients were noted to be on a regimen containing an NRTI and a protease inhibitor, but no NNRTI.

Note that whatever other methods of contraception are being used, barrier methods are also advisable to reduce the risk of HIV transmission.

Hormonal contraceptives + Orlistat

Studies suggest that orlistat does not alter the suppression of ovulation in women taking oral combined hormonal contraceptives. However, isolated pregnancies have occurred with oral contraceptives in women also taking orlistat, and the UK manufacturer says that severe orlistat-induced diarrhoea might be a risk for this.

Clinical evidence

Two groups of 10 healthy women taking an oral combined hormonal contraceptive were given **orlistat** 120 mg three times daily or a placebo on days one to 23 of two menstrual cycles.[1] Orlistat had no effect on ovulation (measured by LH and progesterone levels). The contraceptives used all subjects contained **ethinylestradiol**, but the progestogens differed: 10 contained **desogestrel**, 4 **levonorgestrel**, 3 **gestodene**, 2 **cyproterone acetate** and one **lynestrenol**. However, there is a brief published case of a woman who had been taking an oral low dose combined hormonal contraceptive (**ethinylestradiol** 20 micrograms with **desogestrel** 150 micrograms) for 2 years who was found to be pregnant within 9 weeks of starting to take orlistat 120 mg three times daily.[2]

Mechanism

The UK manufacturers state that orlistat may indirectly reduce the bioavailability of oral hormonal contraceptives (as it can cause severe diarrhoea), and that this may lead to unexpected pregnancies in individual cases.[3] The one published case does not mention to what extent the woman had orlistat-induced diarrhoea.

Importance and management

It seems feasible that if orlistat causes significant diarrhoea this could increase the risk of contraceptive failure with oral hormonal contraceptives, whether combined or progestogen-only. Therefore, the UK manufacturer recommends using an additional contraceptive in case patients develop severe diarrhoea.[3] Note that the contraceptive effect of the combined hormonal contraceptive given as a patch is said not to be affected by diarrhoea.

Hormonal contraceptives + Proton pump inhibitors

Lansoprazole and pantoprazole did not appear to alter the effect of oral combined hormonal contraceptives on the suppression of ovulation. Oral combined hormonal contraceptives modestly inhibit the metabolism of omeprazole, but the levonorgestrel progestogen-only pill appears to have no effect.

Clinical evidence

(a) Lansoprazole

In a placebo-controlled, crossover study, 24 healthy women were given an oral combined hormonal contraceptive (**ethinylestradiol** 30 micrograms with **levonorgestrel** 150 micrograms) for two monthly cycles, with and

without lansoprazole 60 mg daily. The levels of the oral hormonal contraceptive steroids were not significantly altered by lansoprazole, nor were endogenous progesterone levels raised, suggesting that ovulation did not occur.[1] The manufacturer has information about three other unpublished studies in a total of 59 women, which have also found no evidence to suggest that lansoprazole interacts with oral hormonal contraceptives in any way which would affect their reliability.[2]

(b) Omeprazole

A study in 10 healthy women given an oral combined hormonal contraceptive (**ethinylestradiol** 40 micrograms with **levonorgestrel** 75 micrograms) for 10 days found that the contraceptive increased the AUC of a single 40-mg dose of omeprazole (*Losec MUPS*) by 38%. This increase was not seen when the subjects were given **levonorgestrel** 60 micrograms daily alone for 10 days, taken as two tablets of a progestogen-only oral contraceptive.[3] Similarly, in a pharmacokinetic probe study in 10 women, an oral combined hormonal contraceptive (**ethinylestradiol** 35 microrams with **norgestimate** 180 to 250 micrograms) caused about a 50% increase in the ratio of omeprazole to its metabolite 5-hydroxyomeprazole, which indicates an inhibition of omeprazole metabolism.[4] This confirms earlier similar findings of a higher omeprazole to hydroxyomeprazole ratio in women taking oral hormonal contraceptives compared with non-users of these contraceptives.[5]

(c) Pantoprazole

A study over four menstrual cycles was completed by 64 women. The women were confirmed to be ovulating before taking a low-dose oral triphasic hormonal contraceptive (**ethinylestradiol** with **levonorgestrel**), and not ovulating during contraceptive use. They continued not ovulating when pantoprazole 40 mg daily was given, so it was concluded that pantoprazole does not affect the efficacy of oral hormonal contraception.[6]

Mechanism

Ethinylestradiol appears to be a minor to modest inhibitor of the cytochrome P450 isoenzyme CYP2C19, by which omeprazole is principally metabolised.[4,5] As this is also the main route of metabolism of most of the other proton pump inhibitors (see 'Gastrointestinal drugs', (p.1142)), they may be similarly affected. Levonorgestrel does not have this effect.

Importance and management

The proton pump inhibitors tested (lansoprazole, pantoprazole) do not appear to alter the suppression of ovulation in women taking oral combined hormonal contraceptives and would therefore not be expected to alter their reliability. There is nothing to suggest that omeprazole will be any different.

Oral combined hormonal contraceptives cause a modest increase in omeprazole levels (and may similarly affect some other proton pump inhibitors), but this is unlikely to be clinically relevant. The progestogen-only oral contraceptive containing levonorgestrel does not have this effect.

Hormonal contraceptives + Retinoids

There seems to be no evidence that the reliability of the oral combined hormonal contraceptives is affected by acitretin, etretinate or isotretinoin. It is unclear whether the effects of the progestogen-only oral contraceptives are altered by acitretin, but, in any case, progestogen-only oral contraceptives are not generally considered reliable enough for use with these teratogenic drugs. The adverse effects of isotretinoin on lipids may be additive with those of oral contraceptives.

Clinical evidence

(a) Combined hormonal contraceptives

1. Acitretin. Eight women taking an oral combined hormonal contraceptive (**ethinylestradiol** with **levonorgestrel**) were given acitretin 25 to 40 mg daily for at least two cycles. The suppression of ovulation in response to the contraceptive was not affected by acitretin, as assessed by plasma progesterone levels.[1]

2. Etretinate. In a study in 12 women taking an oral combined hormonal contraceptive (**ethinylestradiol** with **levonorgestrel**, **norethisterone**, **norgestrel**, or **cyproterone**) the use of **etretinate** 0.7 to 1 mg/kg did not affect the suppression of ovulation in response to the contraceptive.[2]

3. Isotretinoin. A pharmacokinetic study in 9 women taking an oral combined hormonal contraceptive found that the plasma levels of **ethinylestradiol** and **levonorgestrel** were not significantly changed in the first and third cycle after starting isotretinoin 500 micrograms/kg when compared with before starting the retinoid. Suppression of ovulation was maintained.[3] In another study in 26 women taking an oral triphasic combined hormonal contraceptive (**ethinylestradiol** 35 micrograms with **norethisterone** 500 micrograms to 1 mg), the pharmacokinetics of the contraceptive steroids were almost identical when isotretinoin 1 mg/kg daily was also given. The only changes were a 9% decrease in the ethinylestradiol AUC on day 6 (but not day 20), and an 11% decrease in the maximum level of norethisterone on day 20. FSH showed a significant 44% decline (day 20) after starting isotretinoin, suggesting a greater suppression of ovulation, but there was no significant changes in LH or progesterone. However large inter-patient variability in the results was noted and 2 patients had increases in progesterone levels, possibly indicating that ovulation had occurred, one of these in the phase before isotretinoin treatment (noted to be non-compliant), and one during isotretinoin.[4]

The US manufacturer notes that pregnancies have occurred in women taking isotretinoin while using combined hormonal contraceptives, given orally, as the patch, or as the vaginal ring, and that these reports are more frequent in women using only one form of contraception.[5]

The adverse effects of isotretinoin and combined hormonal contraceptives on plasma lipids may be additive. A case-control study found that women who had hypertriglyceridaemia and/or hypercholesterolaemia while taking isotretinoin were 2 to 12 times as likely to be also taking an oral hormonal contraceptive.[6]

(b) Progestogen-only contraceptives

One woman taking an oral progestogen-only contraceptive (**levonorgestrel** 30 micrograms) had a significant increase in her progesterone levels after 3 cycles while taking **acitretin** 400 micrograms/kg daily. Plasma progesterone levels rose from 2.15 nanograms/mL before taking the **acitretin** to 3.87 to 13.46 nanograms/mL with **acitretin**. This rise in progesterone levels was taken as evidence that ovulation had occurred.[1]

The US manufacturer notes that pregnancies have occurred in women taking **isotretinoin** while using contraceptive implants or injections.[5]

Mechanism, importance and management

The available data suggest that these retinoids do not usually alter the efficacy of oral combined hormonal contraceptives. The case with acitretin suggests that it might reduce the efficacy of progestogen-only oral contraceptives. However, note that progestogen-only oral contraceptives do not reliably suppress ovulation in all cycles, and that this is not considered their primary mechanism of action (see 'Hormonal contraceptives and sex hormones', (p.1165)). The single report cannot therefore be taken as proof that acitretin reduces the efficacy of progestogen-only contraceptives.

Also note that because the retinoids are established human teratogens, it is very important that women taking them do not become pregnant. For this reason, progestogen-only oral contraceptives are generally not considered suitable for use with retinoids.[7] Unless contraindicated, oral combined hormonal contraceptives were considered the method of choice.[7-9] The oral combined hormonal contraceptive should be started one month before the retinoids and continued for one month after stopping isotretinoin,[8,9] and for 2 years after stopping etretinate or acitretin.[7] In the US, it is standard practice to mandate that a second form of contraception, such as a barrier method, should also be used.[5] This is also preferred by the UK manufacturer of isotretinoin.[10] This is because, even though hormonal methods of contraception are highly effective, they do, on rare occasions, fail.[8] The very small reduction in ethinylestradiol levels seen in one study with isotretinoin is unlikely to be clinically relevant. However, because of this small reduction and the wide variability in hormonal levels, the

authors state that their results reinforce the advice of using two forms of contraception,[4] one of which should usually be a barrier method, such as condoms.[5] Note that an oral contraceptive containing a non-androgenic (third generation) progestogen (e.g. desogestrel, gestodene, norgestimate) is preferred, as these have less detrimental effects on lipids,[7] and some favour the use of the anti-androgen cyproterone.[9]

Hormonal contraceptives + Thalidomide

The pharmacokinetics of ethinylestradiol and norethisterone are not affected by thalidomide. The concurrent use of combined hormonal contraceptives and thalidomide is associated with a theoretical increased risk of thromboembolic events in some patients.

Clinical evidence, mechanism, importance and management

In studies in 10 women who had undergone surgical sterilisation and 10 postmenopausal women, the pharmacokinetics of single doses of **ethinylestradiol** 70 micrograms with **norethisterone** 2 mg were not affected by pretreatment with thalidomide 200 mg daily for 3 weeks.[1,2]

These studies indicate that thalidomide is unlikely to have a pharmacokinetic interaction with hormonal contraceptives.

Note that thalidomide is a powerful teratogen, and therefore it is essential that women of child-bearing age use reliable contraception while taking this drug. The UK manufacturer advises one reliable method,[3] whereas the US manufacturer mandates two reliable forms of contraception.[4] Moreover, the UK manufacturer considers that the increased risk of thromboembolic events in patients receiving thalidomide for multiple myeloma might be further increased by the use of **combined hormonal contraceptives**, so they do not recommend these contraceptives. They state that, if a hormonal contraceptive is used, progestogen-only contraceptives should be used, and they specifically recommend implants, depot injections, the levonorgestrel intrauterine system or an oral progestogen that inhibits ovulation (oral desogestrel).[3] However, the US manufacturer makes no mention of the theoretical increased risk of thrombosis specifically with combined hormonal contraceptives, and does not exclude their use (in conjunction with another form of contraception).[4] It must also be borne in mind that the reliability of hormonal contraceptives may be compromised by the concurrent use of drugs other than thalidomide.

Hormonal contraceptives + Tobacco or Nicotine

There is some evidence that smoking tobacco increases the risk of breakthrough bleeding with oral combined hormonal contraceptives, although smoking appears not to alter contraceptive steroid levels. The risk of cardiovascular disease in women taking combined hormonal contraceptives is greatly increased if they smoke, particularly in the older age group. Progestogen-only contraceptives are an alternative. Combined hormonal contraceptives may modestly increase nicotine metabolism.

Clinical evidence

(a) Cardiovascular effects

Early after the introduction of oral combined hormonal contraceptives it was realised that they increase the risk of cardiovascular effects such as thromboembolism, myocardial infarction, and stroke, and that the risks were markedly increased in women who also smoked.[1-5] For example, one of these studies found a relative risk of non-fatal myocardial infarction in women taking an oral hormonal contraceptive of 4.5 in non-smokers and 39 in heavy smokers.[4] Another study found a relative risk of subarachnoid haemorrhage in women taking oral hormonal contraceptives of 6.5 for non-smokers and 22 for smokers.[5] Heavy smokers (who smoke more than 15 cigarettes daily) have a threefold increased risk of myocardial infarction and a twofold increase in the risk of stroke compared with non-smokers, and these risks are further increased by the use of oral combined hormonal contraceptives.[6] A study involving 17 032 women aged 25 to 39 years at entry, who had used oral hormonal contraceptives (mainly containing 50 micrograms of oestrogen), a diaphragm, or an intrauterine device, found that the risk of death from ischaemic heart disease was slightly, but not statistically significantly, raised in all oral hormonal contraceptive users. However, smoking had a substantial effect on mortality from ischaemic heart disease; in heavy smokers (more that 15 cigarettes daily) the mortality rate ratios for oral hormonal contraceptive use for 48 months or less, for 49 to 96 months, and for 97 months or more compared with non-use were 2.4, 4.8, and 2.8, respectively.[7]

(b) Contraceptive efficacy

An analysis of data from three large clinical studies in a total of 2956 women found that smoking was associated with an increased incidence of spotting and bleeding in users of oral combined hormonal contraceptives. The relative risk was 1.3 during the first cycle of use and increased to 1.9 by the sixth cycle.[8] Similarly, in a study of women who became pregnant while taking oral hormonal contraceptives, smokers were more likely to have menstrual disturbances, and smokers taking an oral combined hormonal contraceptive had a 20% greater pill failure rate than expected,.[9] This association was not noted for **progestogen-only oral contraceptive** failure.[9] Conversely, in a large cohort study in the UK, the failure rate of oral hormonal contraceptives was not increased in smokers.[10] In one study in 311 women taking oral hormonal contraceptives, plasma levels of **ethinylestradiol** and **norgestrel** were similar in smokers and non-smokers,[11] and another study found only a small increase in **ethinylestradiol** clearance in smokers.[12]

(c) Nicotine metabolism

In a non-randomised comparison, the metabolism of nicotine after a single intravenous infusion was modestly faster in 53 women using oral hormonal contraceptives than in 153 women not using these contraceptives. This was demonstrated by a 28% faster clearance, and a 19% shorter half-life, of nicotine. In the 50 women using oral combined hormonal contraceptives, nicotine clearance was 30% faster, whereas in the just 3 women who were taking a **progestogen-only contraceptive**, nicotine clearance appeared to be 12% slower. Nevertheless, there was no difference in mean daily cigarette consumption between women using oral hormonal contraceptives and those not.[13] Another study presented similar findings that nicotine metabolism was faster in girls using hormonal contraception than those not using these contraceptives.[14]

Mechanism

The cardiovascular effects reported do not appear to be attributable to any effect of smoking on the metabolism of contraceptives steroids (see below). Rather, the adverse effects of oral combined hormonal contraceptives on cardiovascular risk factors, such as plasma lipids and coagulation parameters, appear to be additive or synergistic with those of smoking.

Smoking does not appear to alter the levels of contraceptive steroids to a clinically relevant extent. Nicotine is metabolised by cytochrome P450 isoenzyme CYP2A6 to cotinine. The limited available evidence suggests

that this may be modestly induced by oral combined hormonal contraceptives.

Importance and management

The cardiovascular interaction between smoking and **combined hormonal contraceptives** is well established. In the UK, the Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit and Royal College of Obstetricians and Gynaecologists guidelines on criteria for the use of contraceptives recommend that the combined hormonal contraceptive should not be used in women aged over 35 years who are current smokers or who stopped smoking less than one year ago as the risks, particularly of cardiovascular disease, outweigh the benefits.[6,15] Women over the age of 35 years with no additional risk factors (such as diabetes, hypertension etc.) and who stopped smoking more than one year ago may consider using a combined hormonal contraceptive. This is because the risk of cardiovascular disease reduces by as much as 50% one year after stopping smoking, although it may not become comparable to that of a non-smoker for up to 4 to 10 years.[6,15] Women aged under 35 years who smoke and have no other associated risk factors may use a combined hormonal contraceptive, but should be informed about the increased risk of cardiovascular disease. Any woman with multiple risk factors for cardiovascular disease (older age, smoking, diabetes, hypertension, obesity, family history of arterial disease, migraine) should not take the combined hormonal contraceptive.[15,16] The BNF in the UK recommends that women who smoke 40 or more cigarettes a day should not receive oral combined hormonal contraceptives.[16] In women who smoke, for whom an oral combined hormonal contraceptive is not contraindicated, ones with the lowest doses of ethinylestradiol may be safer.[17] In the UK, **progestogen-only oral contraceptives** are considered suitable for women who are heavy smokers,[15] although it should be remembered that they have a higher failure rate than the oral combined hormonal contraceptives.

Smoking may increase the incidence of breakthrough bleeding. This may decrease the acceptability of the oral hormonal contraceptive, and lead to the use of less effective contraceptive methods.[8] However, it also raises the question of whether smoking increases the failure rate of oral hormonal contraceptives. The only evidence that this may occur is anecdotal. Further study is needed.

Oral combined hormonal contraceptives might modestly increase nicotine metabolism, but the relevance of this to **nicotine replacement therapy**, if any, remains to be determined.

HRT + Ascorbic acid (Vitamin C)

There is some evidence that ascorbic acid may modestly increase estradiol levels in women receiving HRT.

Clinical evidence

In 25 postmenopausal women receiving *transdermal* **estradiol** HRT, ascorbic acid 500 mg twice daily for one month caused a non-significant 21% increase in plasma **estradiol** levels. However, in the 9 women with initially low **estradiol** levels, ascorbic acid doubled the levels, and this was statistically significant.[1]

Mechanism

Ascorbic acid may reverse the oxidation of the oestrogens.[1]

Importance and management

Evidence for an interaction between ascorbic acid and HRT appears to be limited to this one study. The authors say that their findings do not support the general use of ascorbic acid as an adjuvant to HRT, but that further study is needed. No special precautions are required.

1. Vihtamäki T, Parantainen J, Koivisto A-M, Metsä-Ketelä T, Tuimala R. Oral ascorbic acid increases plasma oestradiol during postmenopausal hormone replacement therapy. *Maturitas* (2002) 42, 129–35.

HRT + Azoles

Ketoconazole modestly increased the levels of estrone, a metabolite of estradiol.

Clinical evidence, mechanism, importance and management

A study in 6 postmenopausal women given a single 2-mg dose of **estradiol** found that **ketoconazole** 100 mg twice daily for 4 days increased the AUC and maximum plasma levels of **estrone** (a metabolite of estradiol) by 16% and 30%, respectively.[1] These small increases are unlikely to be clinically relevant.[1]

1. Annas A, Carlström K, Alván G, AL-Shurbaji A. The effect of ketoconazole and diltiazem on oestrogen metabolism in postmenopausal women after single dose oestradiol treatment. *Br J Clin Pharmacol* (2003) 56, 334–6.

HRT + Enzyme inducers

Enzyme inducers that increase the metabolism of contraceptive steroids might also be expected to reduce the efficacy of HRT. An isolated case describes reduced efficacy of oral conjugated oestrogens in a patient taking phenytoin.

Clinical evidence, mechanism, importance and management

A report describes a 28-year-old woman taking oral **conjugated oestrogens** (*Premarin*) 1.25 mg daily after hysterectomy and ovariectomy, who had a dramatic increase in the incidence of hot flushes when she began to take **phenytoin** 300 mg daily. Her estrone and estradiol levels were found to be very low, and they subsequently increased four- to sixfold after the **phenytoin** was stopped, at which point the incidence of hot flushes decreased.[1] This seems to be the only report of this interaction, and there do not appear to be any pharmacokinetic drug interaction studies of HRT preparations with enzyme inducing drugs. Nevertheless, **rifampicin** (**rifampin**) caused a 44% reduction in the AUC of **estradiol** used as the oestrogen component of an oral combined hormonal contraceptive, which is similar to its interaction with ethinylestradiol, see 'Combined hormonal contraceptives + Rifamycins', p.1189. Therefore, it is not unreasonable to assume that other enzyme inducers that increase the metabolism of contraceptive steroids (see 'Table 28.1', (p.1165)) would also increase the metabolism of oestrogens used for HRT. These drugs may therefore reduce the efficacy of HRT preparations. This would be most likely to be noticed where HRT is prescribed for menopausal vasomotor symptoms, but might

be difficult to detect where the indication is osteoporosis. The interaction is not relevant to HRT applied locally for menopausal vaginitis. Further study is needed to confirm the importance of this possible interaction.

HRT + Grapefruit juice

Grapefruit juice caused a minor increase in estrogen levels after a single oral dose of estradiol. One epidemiological study found that the consumption of whole grapefruit caused a minor increased risk for breast cancer, and that this was additive with the effect of HRT, whereas another similar study did not confirm this.

Clinical evidence

In a study in 8 women given a single 2-mg dose of **estradiol**, simultaneous administration of 200 mL of **grapefruit juice** produced a small 16% increase in the AUC of estrone, a metabolite of **estradiol**, and a 40% increase (not statistically significant) in the AUC of **estradiol**.[1]

In a large cohort study, eating more than a quarter of a **whole grapefruit** per day increased the relative risk of breast cancer in current users of HRT by about one-third (relative risk 2.55 versus 2.01 in users of oestrogen and progestogen, and 2.12 versus 1.56 in users of oestrogen alone). A similar increased risk of breast cancer with grapefruit was seen in women not using HRT (1.44 versus 1). This study was unable to assess the effect of **grapefruit juice**, because the original dietary questionnaire had combined this with orange juice.[2] In contrast, a later very similar study did not find an association between eating the same amount of whole grapefruit daily and breast cancer, including in women taking HRT.[3]

Mechanism

It appears that grapefruit juice has some minor inhibitory effect on the metabolism of estradiol (see also 'Combined hormonal contraceptives + Grapefruit juice', p.1183). Increasing oestrogen levels may increase the risk of adverse effects, including estrogen-associated breast cancer.

Importance and management

The small pharmacokinetic study provides some reassurance that grapefruit juice has only a minor effect on oestrogen levels after estradiol administration. However, a larger study is needed to provide a more conclusive picture. One epidemiological study found that the risk of breast cancer with daily consumption of whole grapefruit caused a minor increased risk of breast cancer that was additive with the effect of menopausal HRT. However, the effect was very much smaller than the increased risk with HRT alone. Moreover, another study did not find an association between grapefruit and breast cancer risk. Interpretation of these studies is complicated by the fact they did not control for grapefruit juice consumption.

HRT + NSAIDs

Etoricoxib appears to raise the levels of conjugated oestrogens from HRT. The findings of one observational study raise the possibility that the risk of myocardial infarction might be higher with the concurrent use of NSAIDs and HRT.

Clinical evidence

High-dose etoricoxib 120 mg daily for 28 days taken with HRT containing 0.625 mg of conjugated oestrogens (*Premarin)* increased the AUC of unconjugated estrone, equilin and 17-β estradiol by 41%, 76%, and 22%, respectively.[1]

In a large population-based epidemiological study, the odds ratio of a myocardial infarction was increased in women taking HRT with an NSAID (1.7), was lower in women taking HRT without an NSAID (0.64) and unchanged in women taking an NSAID with no HRT (1.02), relative to women not taking HRT or an NSAID. In this study, the three most widely used NSAIDs, **diclofenac**, **ibuprofen**, and **naproxen**, accounted for 75% of NSAID use.[2]

Mechanism

Etoricoxib inhibits the conjugation of oestrogens by sulfation (see also 'Combined hormonal contraceptives + Coxibs', p.1181. It was suggested that NSAIDs might inhibit the postulated beneficial atheroprotective effects of estrogens.[2] However, it is also possible that the rare adverse cardiovascular effects of HRT and NSAIDs could be additive or synergistic.

Importance and management

The levels of these oestrogens with high-dose etoricoxib are less than half those seen with twice the dose of conjugated oestrogens (1.25 mg) taken alone.[1] The effects of usual recommended lower doses of etoricoxib have not been studied. The manufacturers say that these increases should be taken into account when selecting HRT in patients taking etoricoxib, because of the possible increased risk of HRT adverse effects.[1]

The findings of the epidemiological study suggest that the concurrent use of HRT and NSAIDs might have adverse cardiovascular effects. The authors suggested that this showed that NSAIDs possibly inhibit the beneficial effects of HRT,[2] but subsequent randomised studies have not shown HRT to have beneficial cardiovascular effects, and may possibly even cause an increase in cardiovascular events in the first year of use. An alternative hypothesis is that the rare adverse cardiovascular effects of HRT could be additive or synergistic with the small increased risk of rare thrombotic events (especially myocardial infarction and stroke) seen with coxibs and some NSAIDs. Further study is needed.

HRT + Senna

Senna does not appear to affect the pharmacokinetics of estradiol.

Clinical evidence

In a clinical study in 19 women, the maximum daily tolerated dose of senna tablets (*Senokot*) was taken for 10 to 12 days with a single 1.5-mg dose of **estradiol glucuronide** given 4 days before the end of the assessment period. Senna had no significant effect on the median AUC of estradiol or estrone.[1]

Mechanism

It was thought that reducing intestinal transit time with senna might lead to reduced blood levels of estradiol.

Importance and management

This limited evidence suggests that there is unlikely to be a clinically relevant pharmacokinetic interaction between anthraquinone-containing laxatives and estradiol.

IUDs; Copper + Anti-inflammatory drugs

There are a few early reports suggesting that the very occasional contraceptive failure of a copper IUD may have been due to an interaction with a corticosteroid, aspirin or NSAID.

Clinical evidence, mechanism, importance and management

The cases of 4 women who, despite being fitted with copper IUDs, each had two successive pregnancies have been reported. Two were taking **corticosteroids** regularly and the other two often took **aspirin** for migraine.[1,2] Unwanted pregnancies have also been reported in 3 women with copper IUDs who were taking **corticosteroids**,[3-5] and in 2 women taking NSAIDs (**indomethacin** and **naproxen**).[5] A later case-control study found that **aspirin** and NSAIDs were used more frequently in 717 women who became pregnant while using IUDs than in 717 non-pregnant IUD users (the majority of IUDs were copper). The difference was significant only for **aspirin** (102 IUD failures, 59 control failures). It is possible that this finding could have resulted from bias in recall or reporting.[2] The suggested mechanism for any interaction was that part of the efficacy of copper IUDs may be based on local inflammatory effects, and that anti-inflammatory drugs might reduce this.

The evidence for this possible interaction is very slim and inconclusive, and there appear to be no further reports of any problems. Modern copper-containing IUDs are one of the most effective methods of contraception. Also, intermittent use of anti-inflammatory drugs such as NSAIDs is widespread. A recent Cochrane Database Systematic Review of studies on the use of NSAIDs to reduce pain and/or bleeding with IUDs recommends the use of NSAIDs as first-line drugs to reduce these adverse effects.[6] One manufacturer of copper IUDs states that the evidence does not justify general precautions.[7] No special precautions therefore appear to be necessary.

Medroxyprogesterone or Megestrol + Aminoglutethimide

Aminoglutethimide markedly reduces the plasma levels of medroxyprogesterone and megestrol given orally. Intravenous medroxyprogesterone acetate appears not to be affected.

Clinical evidence

(a) Medroxyprogesterone acetate

In 6 postmenopausal women with breast cancer aminoglutethimide 250 mg two to four times daily approximately halved the plasma levels of medroxyprogesterone acetate 500 mg three times daily.[1] Another study in 6 postmenopausal women found that aminoglutethimide 250 mg four times daily reduced medroxyprogesterone levels by 63% after oral, but not intravenous, use.[2] In another study in 6 women with advanced breast cancer, it was found that as the dose of aminoglutethimide was gradually reduced from 250 mg twice daily and finally withdrawn, the plasma levels of medroxyprogesterone steadily climbed to three times their initial level, although the dose remained constant at a total of 800 mg daily.[3]

(b) Megestrol

Aminoglutethimide 250 mg four times daily reduced the serum levels of megestrol 160 mg daily by 78% in 6 postmenopausal women.[2]

Mechanism

The most likely reason for this interaction is that aminoglutethimide acts as an enzyme inducer, increasing the metabolism of the progestogens, thereby decreasing their levels. When the aminoglutethimide is withdrawn, the enzyme induction ceases, and the progestogen level rises.

Importance and management

Both interactions appear to be established and are possibly clinically important. A 50% reduction in the plasma levels of medroxyprogesterone and megestrol should be expected during concurrent use, and this may reduce the adrenal suppressive effect.[1] The authors of one report[3] say that to achieve adequate plasma medroxyprogesterone acetate levels in breast cancer (above 100 nanograms/mL) a daily dose of 800 mg of *Provera* is probably necessary in the presence of aminoglutethimide 125 or 250 mg twice daily. This is double the usual recommended dose for this condition.

Note that intravenous medroxyprogesterone does not appear to be affected. It is therefore uncertain whether depot medroxyprogesterone acetate will be affected, although the manufacturer includes the possibility of the interaction in their product information.[4,5] However, if the mechanism for the aminoglutethimide interaction is correct (enzyme induction), this suggests that depot medroxyprogesterone would be unlikely to be affected, as it is said not to interact with enzyme inducers, see 'Progestogen-only contraceptives + Enzyme inducers', p.1206.

Progestogen-only contraceptives + Antibacterials

The reliability of progestogen-only methods of hormonal contraception are probably not affected by antibacterials that do not induce liver enzymes, such as the penicillins and tetracyclines.

Clinical evidence

Four of the 63 contraceptive failures attributed to antibacterials in the records of the CSM in the UK for 1968 to 1984 occurred with a progestogen-only contraceptive (unspecified).[1] In another study, 2 of 37 cases of contraceptive failure attributed to antibacterials occurred with a progestogen-only contraceptive (unspecified).[2]

Note that, pharmacokinetic data show that the progestogen component (**levonorgestrel**, **norethisterone**) of oral *combined* hormonal contraceptives is not affected by **ampicillin**,[3,4] **clarithromycin**,[5] **doxycycline**,[6] **metronidazole**,[4] **moxifloxacin**,[7] or **tetracycline**;[8] whereas **desogestrel** exposure was slightly increased by **clarithromycin**,[5] and **levonorgestrel** exposure was slightly increased by **telithromycin**.[9] The progestogen component of the vaginal ring (**etonogestrel**) was not affected by **ampicillin** or **doxycycline**.[10]

Mechanism

The mechanism behind the rare cases of failure of oral *combined* hormonal contraceptives seen with various non-enzyme-inducing antibacterials is postulated to be reduced enterohepatic recycling of ethinylestradiol (see 'Combined hormonal contraceptives + Antibacterials; Penicillins', p.1170). As progestogens are largely metabolised to inactive substances before they are conjugated, they do not undergo enterohepatic recycling of the active substance. Progestogens are partially metabolised by the cytochrome P450 isoenzyme CYP3A4, so antibacterials that inhibit this isoenzyme, such as some of the macrolides, may actually increase progestogen exposure.

Importance and management

There is no reason to expect that the contraceptive efficacy of the various progestogen-only contraceptive methods (tablets, implants, injections, IUDs) would be affected by antibacterials that alter gut flora and do not induce liver enzymes.

It is generally accepted that no interaction occurs,[11] and it is likely that the few cases seen with progestogen-only contraceptives are chance associations.[1] In the UK, the Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit does not recommend any additional contraceptive precautions when antibacterials that do not induce liver enzymes are taken with any method of progestogen-only hormonal contraception, including the emergency contraceptive pill.[12] However, note that rifampicin (rifampin) and rifabutin are likely to reduce the efficacy of some forms of progestogen-only contraceptives, as they induce the metabolism of progestogens, see 'Progestogen-only contraceptives + Enzyme inducers', p.1206.

Progestogen-only contraceptives + Azoles

In one study itraconazole markedly increased the levels of the active metabolite of desogestrel, whereas fluconazole had no effect.

Clinical evidence

In a crossover study in 11 healthy women, **itraconazole** 200 mg daily for 4 days increased the AUC of 3-keto-desogestrel (etonogestrel) by about 72% after a single 150-microgram oral dose of **desogestrel** was given one hour after the last itraconazole dose. There was no change in 3-keto-desogestrel maximum level or elimination half-life. Conversely, **fluconazole** 200 mg daily for 4 days had no effect.[1]

Note that, pharmacokinetic data show that the AUC of **norethisterone** (given as the progestogen component of an oral *combined* hormonal contraceptive) is increased by **voriconazole** (53%)[2] and **itraconazole** (40%),[3] but only minimally by **fluconazole** (13%).[4] Similarly, **levonorgestrel** was only modestly affected by **fluconazole** (24%)[5] and **etonogestrel** was only modestly affected by **miconazole** (17%).[6]

Mechanism

Itraconazole is principally an inhibitor of the cytochrome P450 isoenzyme CYP3A4, whereas fluconazole is principally an inhibitor of CYP2C9. The data here suggest that the active metabolite of desogestrel, 3-keto-desogestrel (etonogestrel) is mainly metabolised by CYP3A4.

Importance and management

Although based on a single-dose study, the available information suggests that fluconazole is unlikely to alter the efficacy of the desogestrel progestogen-only contraceptive by a pharmacokinetic mechanism. However, the marked increase in levels of the active metabolite of desogestrel with itraconazole suggests that itraconazole (and other potent CYP3A4 inhibitors) might increase the incidence of adverse effects of desogestrel. Further study is needed.

Progestogen-only contraceptives + Enzyme inducers

The contraceptive efficacy of oral progestogen-only contraceptives, levonorgestrel implants, and etonorgestrel implants is probably reduced by enzyme inducers, and there are a number of reports of pregnancies in women given these contraceptives with an enzyme-inducing antiepileptic, St John's wort, rifampicin (rifampin) or efavirenz. Conversely, the efficacy of medroxyprogesterone depot injection may not be affected by enzyme inducers, and no pharmacokinetic interaction has been seen with this contraceptive and efavirenz, nevirapine and nelfinavir. Similarly, the contraceptive reliability of the norethisterone depot injection and the levonorgestrel-releasing intrauterine system is not thought to be affected by enzyme inducers.

Clinical evidence, mechanism, importance and management

(a) Implants

In a study, a **levonorgestrel** implant (*Norplant*) was inserted in 8 women taking enzyme-inducing antiepileptics (**phenytoin** and/or **carbamazepine**) and 10 women taking no other drugs. At 3, 6 and 9 months after insertion, plasma **levonorgestrel** levels were 38% lower in the 6 women taking **phenytoin** alone or in combination with **carbamazepine** or valproate than in the women not taking these enzyme inducers. Low **levonorgestrel** levels were also seen in the two women taking **carbamazepine** alone. Two of the women became pregnant (one taking **phenytoin** 25 mg daily, occurring about 11 months after insertion of the implant, and one taking **phenytoin** 400 mg daily with **carbamazepine** 400 mg daily, occurring 20 months after insertion of the implant).[1]

In three other cases women using **levonorgestrel** implants with enzyme-inducing antiepileptics became pregnant.[2-4] In one, a woman taking **phenytoin** 300 mg daily became pregnant 9 months after the insertion of the implant. **Levonorgestrel** levels increased by 50% after discontinuation of the **phenytoin**, and progesterone levels fell, suggesting greater suppression of ovulation.[2] Similarly, one woman taking **phenobarbital** 210 mg daily became pregnant about 17 months after the insertion of the **levonorgestrel** implant (this woman subsequently also became pregnant while using an oral combined hormonal contraceptive containing 35 micrograms of ethinylestradiol and a back up method).[3] Another report[4] briefly mentions that one woman taking enzyme-inducing antiepileptics became pregnant while using a **levonorgestrel** implant, and mentions that the manufacturer had 30 other similar cases on file as of 1995.

There are 4 published case reports of pregnancy in women using the **etonogestrel** implant (*Implanon*) with enzyme-inducing drugs. Once case occurred in a patient taking **carbamazepine** 600 mg daily, 1 month after insertion of the implant.[5] A pregnancy (ectopic) that occurred in a woman who had received the implant was considered to be due to the use of **rifampicin** (**rifampin**).[6] Another pregnancy occurred in a woman who had been fitted with this implant for approximately 2 years, about 6 months after starting **rifampicin** 300 mg twice daily for hidradenitis suppurativa.[7] There is also a case of contraceptive failure (ectopic pregnancy) in a woman taking **efavirenz**, lamivudine and zidovudine, 2.5 years after insertion of the **etonorgestrel** implant.[8]

In addition, an Australian post-marketing report for the 3 years from May 2001 describes 8 other cases of contraceptive failure with the **etonorgestrel** implant in patients who were taking enzyme-inducing antiepileptics (7 of the 8 were taking **carbamazepine**).[9] An updated report in 2007 gives 32 pregnancies in users of the **etonorgestrel** implant possi-

bly related to other medicines (26 with **carbamazepine**, 4 with **phenytoin**, one with **methylphenobarbital** and one with **rifampicin**.[10]

The data here show that contraceptive failure can occur with the progestogen implants (both **levonorgestrel** and **etonorgestrel**) if potent enzyme inducers are also taken. Limited evidence from the one study with the **levonorgestrel** implant suggests that the incidence might be high (2 out of 8 women). In the UK, the Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit recommends that the progestogen-only implant may be continued with short courses of enzyme inducers, but only if additional contraceptive methods such as condoms are used during and for at least 4 weeks after the drug is stopped. They recommend that alternatives to the progestogen-only implant should be considered with the long-term use of liver enzyme inducers.[11] A list of enzyme inducers can be found in 'Table 28.1', (p.1165)).

(b) Injectable preparations

1. Medroxyprogesterone acetate depot. In a study in women taking NRTIs with **efavirenz** (17), **nevirapine** (16), or **nelfinavir** (21), there was no significant change in the pharmacokinetics of depot medroxyprogesterone acetate 150 mg, when compared with 16 women not taking any antiretrovirals or taking just NRTIs. Suppression of ovulation was maintained. Furthermore, viral load and CD4 counts were not altered.[12,13] In another similar study, there was no difference in pharmacokinetics of depot medroxyprogesterone acetate between 15 women taking **efavirenz** plus two NRTIs (lamivudine and zidovudine) compared with 15 women not taking any antiretrovirals. No ovulation occurred in the women taking the antiretrovirals.[14] For mention of another study that found a low incidence of pregnancy in women taking an **efavirenz**-based regimen and using an intramuscular progestogen or an oral combined hormonal contraceptive, see 'Combined hormonal contraceptives + NNRTIs', p.1186.

The UK manufacturer states that the clearance of medroxyprogesterone acetate is approximately equal to hepatic blood flow, and as such, would not be expected to be affected by drugs that alter hepatic enzyme activity.[15] Whatever the explanation, the limited data with the antiretrovirals above seems to support a lack of an interaction. Therefore, the UK manufacturer says that no dose adjustment is needed,[15] and this is also the advice given by the FFPRHC,[11] although some have recommended giving the injection more frequently.[16]

2. Norethisterone depot. There are data showing that **rifamycins** and **carbamazepine** can reduce the plasma levels of norethisterone when it is used as a component of an oral combined hormonal contraceptive (see 'Combined hormonal contraceptives + Rifamycins', p.1189, and 'Combined hormonal contraceptives + Carbamazepine or Oxcarbazepine', p.1180). The UK manufacturer of *Noristerat* notes that enzyme inducers may theoretically reduce the efficacy of the norethisterone enantate injection.[17] Nevertheless, the dose of norethisterone provided by the depot injection is very much higher than that provided by oral combined hormonal contraceptives, and it is therefore possible that it remains effective even in women taking enzyme-inducing drugs.[18]

It has been recommended by some that the interval between injections be shortened in women taking enzyme-inducing drugs. However, in the UK, the guidance from the FFPRHC Clinical Effectiveness Unit is to continue with the normal injection schedule for norethisterone.[11]

(c) Oral progestogen-only contraceptives

In a review of pregnancies reported to the CSM in the UK between the years 1968 to 1984 in women taking antiepileptics and oral hormonal contraceptives, 3 cases were identified in women taking progestogen-only pills (progestogen not stated). The antiepileptics used in these specific cases were not stated, but most of the women were taking enzyme-inducing antiepileptics such as **phenytoin**, **phenobarbital**, **primidone** and **carbamazepine** (alone or as combinations).[19] In 2002, the UK regulatory authority had one case on record of an unplanned pregnancy that occurred 4 months after starting **St John's wort** in a woman who had been taking **norethisterone** for 2 years.[20]

There do not appear to have been any clinical pharmacokinetic studies of enzyme inducers with any of the oral progestogen-only contraceptives (**desogestrel**, **levonorgestrel**, **norethisterone**). Nevertheless, various enzyme inducers have specifically been shown to decrease the levels of these progestogens when used as components of oral combined hormonal contraceptives (see 'Table 28.1', (p.1165)). Therefore, it can be assumed that there is also a risk of contraceptive failure with oral progestogen-only contraceptives.[21] This is of particular concern as oral progestogen-only contraceptives are not as effective as oral combined hormonal contraceptives, especially the **levonorgestrel** and **norethisterone** preparations, which are given in very low doses that do not consistently inhibit ovulation. Some have suggested at least doubling the dose of the oral progestogen-only contraceptive.[22] However, others consider that this is not an option as it tends to increase the rate of irregular bleeding (a common adverse effect of these contraceptives). They consider that oral progestogen-only contraceptives are not suitable for use in women taking enzyme-inducing antiepileptics,[18,21] and this is the view taken in the UK by the FFPRHC.[11]

(d) Progestogen-releasing intrauterine system (IUS)

Some enzyme inducers increase the metabolism and reduce the efficacy of the oral combined hormonal contraceptives (see 'Table 28.1', (p.1165), for a list). The manufacturer has not studied the influence of these drugs on the pharmacokinetics of the **levonorgestrel**-releasing IUS (*Mirena*).[23] The systemic absorption of **levonorgestrel** from the IUS leads to lower blood levels than are seen with standard oral progestogen-only contraceptives, and many women using a **levonorgestrel** IUS continue to ovulate. Thus, the contraceptive effects of the **levonorgestrel** IUS are thought to be mainly local,[23] and it might therefore not be as susceptible to enzyme-inducing drugs.[18] Nevertheless, the manufacturer has said that they cannot be sure that the foreign body effect (i.e. the effect whereby the presence of the IUS prevents implantation) and/or locally acting hormone will provide reliable contraception when systemic hormone levels and suppression of ovaries are reduced by drug interactions.[24] However, this appears to be overly cautious. In a pilot study in 47 women (most with epilepsy) using a **levonorgestrel** IUS with at least one enzyme-inducing drug there was only one apparent contraceptive failure for 1075 months of use for contraception. This occurred 2 years after insertion of the IUS in a 42-year-old woman taking **primidone** 500 mg daily and **phenytoin** 300 mg daily. In this study, enzyme-inducing drugs being taken were **carbamazepine**, **efavirenz**, **nevirapine**, **phenytoin**, **phenobarbital**, **primidone**, **rifabutin**, **ritonavir** and **topiramate**.[25]

In the UK, the FFPRHC Clinical Effectiveness Unit considers that the **levonorgestrel**-releasing IUS is unlikely to be affected by enzyme inducers and recommends that no additional contraceptive protection is required.[11] It is therefore a suitable contraceptive for women taking these drugs.[18]

Progestogen-only contraceptives + Lamotrigine

Preliminary evidence suggests that desogestrel might increase lamotrigine levels and adverse effects. However, there was no difference in lamotrigine levels between non-users of hormonal contraceptives and users of the levonorgestrel IUD, or a variety of other progestogen-only contraceptives in two other studies.

Clinical evidence

In a preliminary report[1] of one study in 10 women stable taking lamotrigine, an oral progestogen-only contraceptive, **desogestrel** 75 micrograms daily for 12 weeks, caused a 20 to 100% increase in lamotrigine levels in 7 out of the 10 women. The increase in maximum levels was said to be greater than the increase in trough levels, and some women (number not stated) had dose-dependent increases in lamotrigine adverse effects about 30 minutes to 3 hours after their lamotrigine dose. The increase in lamotrigine dose occurred about 2 weeks after starting the desogestrel, and increased up to weeks 8 to 12.

In another study which compared lamotrigine levels in 16 women taking progestogen-only contraceptives with those in 18 women not using hormonal contraceptives, the lamotrigine serum-concentration to dose ratio did not differ between the two groups. The progestogen-only contraceptives used included oral **desogestrel** (3 women), oral **norethisterone** (one woman), **etonogestrel** implant (7 women), **levonorgestrel** implant (one woman), depot **medroxyprogesterone acetate** (one woman) or the **levonorgestrel** IUD (3 women). There were no obvious differences between these contraceptives, although the number of women in each group is too limited to be certain.[2] In another similar study, there was no difference in the lamotrigine serum-concentration to dose ratio between 12 women with a **levonorgestrel** IUD and 20 women not using hormonal contraception.[3]

Mechanism

Unknown. In contrast to the finding here for continuous desogestrel alone, a combined hormonal contraceptive containing ethinylestradiol and desogestrel caused a reduction in lamotrigine levels, see ‘Combined hormonal contraceptives + Lamotrigine’, p.1183.

Importance and management

There are very limited data on the effect of using progestogen-only contraceptives with lamotrigine. Available data suggest that the levonorgestrel IUD has no effect on lamotrigine levels, but that desogestrel might increase them in some women. This is in contrast to the effects of combined hormonal contraceptives, which are known to decrease lamotrigine levels, as a result of the ethinylestradiol component (see ‘Combined hormonal contraceptives + Lamotrigine’, p.1183). Until more is known, it may be prudent to increase monitoring of lamotrigine levels and efficacy when desogestrel is started or stopped.

There are no data on whether the efficacy of progestogen-only contraceptives is altered by lamotrigine. In one study with a combined oral contraceptive there was a slight reduction in levonorgestrel levels combined with an increase in FSH and LH levels and an increase in intermenstrual bleeding, which suggests some reduction in suppression of the hypothalamic-pituitary-ovarian axis. However, the clinical relevance of this is uncertain. If one assumes that some reduction in the efficacy of hormonal contraceptives is likely, then the advice given for other enzyme-inducing drugs should be followed. Namely, the efficacy of high-dose injectable progestogens (medroxyprogesterone acetate and norethisterone) and the levonorgestrel IUD is unlikely to be affected, whereas the efficacy of oral pills and the implants may be. See ‘Progestogen-only contraceptives + Enzyme inducers’, p.1206, for a further discussion.

Immunosuppressants

The immunosuppressants dealt with in this section are principally used for diseases considered to have an auto-immune component or in organ and tissue transplantation. They include the corticosteroids, calcineurin inhibitors (ciclosporin and tacrolimus), monoclonal antibodies (e.g. basiliximab), cytokine modulators (e.g. etanercept and infliximab) and various others, as classified in 'Table 29.1', (below). When any of these drugs acts as the interacting agent the relevant monograph is categorised in the section dealing with the drug whose effects are changed. The cytotoxic drugs that are also used for immunosuppression (e.g. azathioprine, cyclophosphamide and methotrexate) are found in the section on antineoplastic drugs.

Immunosuppressant interactions

A. Pharmacological interactions

The most important pharmacological interactions of these drugs relate to their immunosuppressant effects. These will be additive with other immunosuppressants and, for example, increases the risk of infection. The risk of this sort of interaction obviously depends on the potency of the immunosuppressant and the duration of use. The additive risk can be such that certain combinations should be avoided, e.g. anakinra with TNF antagonists such as 'etanercept', (p.1273). Similarly, the use of live vaccines is not usually recommended in patients receiving immunosuppressants, see 'Immunosuppressants + Vaccines', p.1276.

B. Pharmacokinetic interactions

Many of the potent immunosuppressants discussed in this section have their doses titrated carefully to a given pharmacological effect or therapeutic level. For this reason, the use of drugs that cause a modest pharmacokinetic interaction may have clinically relevant consequences.

(a) Calcineurin inhibitors

1. Ciclosporin. Ciclosporin undergoes extensive metabolism, principally by the hepatic cytochrome P450 isoenzyme CYP3A4. The primary route of its excretion is biliary. Hence, drugs may alter ciclosporin levels by inhibiting or inducing its metabolism or altering its biliary secretion. An important dose-related adverse effect of ciclosporin is nephrotoxicity (raised serum creatinine and urea levels). In the transplant setting, the ciclosporin dose adjustments are usually based on the monitoring of its levels and serum creatinine. In general, trough levels (pre-dose levels, C_0) are measured in whole blood. More recently, there has been interest in the use of monitoring ciclosporin levels 2 hours post dose (C_2 levels). With the lower doses of ciclosporin used in various autoimmune disorders, the dose is usually titrated to efficacy, and ciclosporin levels are not necessarily routinely monitored.
Ciclosporin is itself an inhibitor of P-glycoprotein and also a modest inhibitor of CYP3A4. It may therefore have pharmacokinetic interactions with other drugs (covered in other sections). More recently, it has been found that ciclosporin may also interacts with some drugs via inhibition of drug transporter proteins.

2. Tacrolimus. Tacrolimus is a substrate of the cytochrome P450 isoenzyme CYP3A4 and P-glycoprotein, principally in the intestine. This is demonstrated by the fact that inhibitors or inducers of this isoenzymes and drug transporter increase or decrease the oral bioavailability of tacrolimus to a greater extent than they alter its clearance. In general, interactions of tacrolimus are similar to those of ciclosporin. Tacrolimus doses are adjusted on the basis of therapeutic drug monitoring. Tacrolimus is itself a modest inhibitor of CYP3A4.

(b) Corticosteroids

Some corticosteroids such as methylprednisolone are substrates for the cytochrome P450 isoenzyme CYP3A4 and therefore may interact with CYP3A4 inhibitors or inducers e.g. 'azoles', (p.1257), 'macrolides', (p.1264), or 'rifampicin (rifampin)', (p.1270). Inhaled corticosteroids e.g. fluticasone may, in certain circumstances, also interact, see 'Corticosteroids + Protease inhibitors', p.1268.

(c) Monoclonal antibodies

Monoclonal antibodies generally have few reported interactions, partly because studies can be difficult to design due to long elimination half-lives, and also because metabolising enzymes are generally not involved in monoclonal antibody elimination.

(d) Mycophenolate

Mycophenolate is rapidly hydrolysed to the active mycophenolic acid, which is subsequently metabolised by glucuronidation by glucuronyl-

Table 29.1 Immunosuppressant drugs†

Group	*Drugs*
Corticosteroids	
Glucocorticoids	Beclometasone, Budesonide, Ciclesonide, Deflazacort, Dexamethasone, Fluticasone, Hydrocortisone, Methylprednisolone, Prednisolone, Prednisone, Triamcinolone
Mineralocorticoids	Aldosterone, Fludrocortisone, Liquorice
Monoclonal antibodies	
Tumour necrosis factor (TNF) antagonists	Adalimumab, Certolizumab pegol, Golimumab, Infliximab
Miscellaneous	Abatacept, Anakinra, Basiliximab, Daclizumab, Muromonab-CD3, Natalizumab, Rituximab, Tocilizumab
Other immunosuppressants	
Calcineurin inhibitors	Ciclosporin (Cyclosporine), Tacrolimus
Tumour necrosis factor (TNF) antagonists	Etanercept
Miscellaneous	Everolimus, Leflunomide (DMARD), Mycophenolate, Sirolimus

†For other immunosuppressants that may also be used as cytotoxics, such as azathioprine, cyclophosphamide, methotrexate and mercaptopurine, see under Antineoplastics.

transferases (UGT enzymes). Drugs that induce or inhibit glucuronidation may interact with mycophenolate. The glucuronide metabolite undergoes enterohepatic recycling being cleaved by gut bacteria to mycophenolic acid, which is then reabsorbed leading to a second peak in plasma levels. Drugs that interfere with this process, such as bile acid sequestrants and some antibacterials, may reduce this enterohepatic recycling. Mycophenolate is not metabolised by the cytochrome P450 isoenzyme system, so is not subject to interactions via this system. Note that blood levels of mycophenolic acid are not routinely monitored.

(e) Sirolimus and related drugs

Sirolimus (previously known as rapamycin) is a substrate of CYP3A4 and P-glycoprotein, principally in the intestine. It is therefore subject to drug interactions similar to those of tacrolimus. Its doses are adjusted on the basis of therapeutic drug monitoring. **Everolimus** is an analogue of sirolimus that was developed to improve the oral bioavailability of sirolimus. **Temsirolimus** is an ester prodrug of sirolimus. They therefore interact similarly to sirolimus.

Abatacept + Miscellaneous

An increased risk of serious infection is reported if abatacept is given with tumour necrosis factor antagonists. Abatacept does not appear to affect the clearance of methotrexate, NSAIDs or corticosteroids. Live vaccines should not been given to patients taking abatacept.

Clinical evidence, mechanism, importance and management

(a) Anakinra

The US manufacturer recommends that anakinra is not given with abatacept because of insufficient information regarding the safety and efficacy of using these two drugs together.[1]

(b) Tumour necrosis factor antagonists

In clinical studies it was noted that tumour necrosis factor antagonists did not alter the clearance of abatacept.[1,2] However, patients who received treatment with abatacept and unnamed tumour necrosis factor antagonists [e.g. infliximab, adalimumab] experienced a higher incidence of infections and serious infections, 63% and 4.4%, respectively, when compared with treatment with tumour necrosis factor antagonists alone, 43% and 0.8%, respectively.[1] The manufacturers say that concurrent use is not recommended.[1,2]

(c) Vaccines

As no data are available on the use of live vaccines in patients receiving abatacept, the manufacturers recommend that live vaccines should not be given concurrently or within 3 months of discontinuation of abatacept. The response to some vaccines may be reduced.[1,2]

(d) Other drugs

The manufacturers note that population pharmacokinetic data suggests that the clearance of abatacept is not affected by **corticosteroids**, **methotrexate**, or **NSAIDs**.[1,2] There were no safety issues noted when abatacept was given with **sulfasalazine**, **hydroxychloroquine** or **leflunomide**.[2]

1. Orencia (Abatacept). Bristol-Myers Squibb. US Prescribing information, April 2008.
2. Orencia (Abatacept). Bristol-Myers Squibb Pharmaceuticals Ltd. UK Summary of product characteristics, May 2009.

Anakinra + Miscellaneous

Live vaccines should not be given with anakinra. No interaction has been reported between anakinra and corticosteroids, NSAIDs or other antirheumatics. The use of anakinra with infliximab increases the risk of severe infection.

Clinical evidence, mechanism, importance and management

(a) Methotrexate

The manufacturers note that, in studies in *rats* concurrent use of methotrexate with anakinra did not affect the clearance of either drug or result in an increase in their adverse effects.[1,2] The clinical safety and efficacy of the combined use of anakinra and methotrexate has been proven in clinical studies,[2] and concurrent use is licensed.[1,2]

(b) Vaccines

The manufacturer states that live vaccines should not be given to patients receiving anakinra as the clinical safety of concurrent use has not been established. Patients may be at risk of developing generalised infections. The manufacturers also note that vaccination may be less effective in patients receiving anakinra.[1,2]

(c) Other drugs

The manufacturers state that no interaction has been reported between anakinra and **corticosteroids**, **NSAIDs** or other disease-modifying anti-rheumatic drugs (DMARDs).[2] **Infliximab** inhibits the activity of tumour necrosis factor (TNFα). In clinical studies the use of anakinra with another TNFα inhibitor, etanercept, has been associated with an increased risk of serious infection and neutropenia and no additional benefit, when compared to the use of these drugs alone.[3,4] As a result of this the manufacturers of **infliximab** note that similar toxicity may occur if anakinra is given with **infliximab** and therefore advise against concurrent use.[3,4]

Ciclosporin + ACE inhibitors or Angiotensin II receptor antagonists

Acute renal failure developed in four kidney transplant patients taking ciclosporin when they were given enalapril. Oliguria was seen in another patient taking ciclosporin with captopril. Other studies have found no significant changes in renal function with candesartan and losartan or with enalapril. Hyperkalaemia may develop in patients taking ACE inhibitors or angiotensin II receptor antagonists with ciclosporin.

Clinical evidence

(a) ACE Inhibitors

Two kidney transplant patients taking ciclosporin developed acute renal failure 10 to 42 days after starting to take **enalapril** 5 to 10 mg twice daily. Recovery was complete when the **enalapril** was stopped in one of the patients, and when both **enalapril** and ciclosporin were stopped in the other. The latter patient had no problems when ciclosporin was restarted. In both cases renal function had recovered after 10 to 30 days. Neither had any previous evidence of renal artery stenosis or chronic rejection, which are conditions known to predispose to renal failure during the use of an ACE inhibitor. Two other patients appeared to tolerate concurrent use well.[1] Two further kidney transplant patients developed acute renal failure when given **enalapril**. Neither had renal arterial stenosis or acute rejection.[2] The manufacturer briefly mentions that transient oliguria was seen in a kidney transplant patient given ciclosporin and **captopril**.[3]

A study in 13 kidney transplant patients taking ciclosporin found that concurrent treatment with **enalapril** 5 or 10 mg daily for 3 weeks caused a larger increase in potassium levels (mean increase of 0.5 mmol/L) than in those patients given **losartan** 50 mg daily (mean increase of 0.2 mmol/L). Potassium levels were not increased above 5.5 mmol/L in any of the patients studied. Uric acid levels were also increased by **enalapril** but decreased by **losartan**, although this was not statistically significant. No changes in ciclosporin trough levels were seen during the study and the serum creatinine levels remained stable.[4] Another study in kidney transplant patients taking ciclosporin with either **enalapril** (33 patients) or **enalapril** plus amlodipine (32 patients) found that the potassium and serum creatinine levels did not increase in the group given **enalapril** and amlodipine whereas they increased by 0.2 mmol/L and 9 micromol/L, respectively, in the group given **enalapril** alone. Ciclosporin levels remained stable in all patients.[5]

(b) Angiotensin II receptor antagonists

A study in kidney transplant patients taking ciclosporin with **losartan** found that the serum creatinine level was only slightly and non-significantly increased in 5 patients. Losartan was stopped in 3 patients because of a rise in creatinine levels. Transient hyperkalaemia (potassium above 5.5 mmol/L) developed in 4 patients but the potassium had fallen to below 5.5 mmol/L by week 12 in all patients. Ciclosporin levels remained stable during the study and no significant dose changes were made, although one patient was withdrawn from the study due to ciclosporin toxicity which the authors state was not related to the use of losartan.[6] Another study in 14 kidney transplant patients taking ciclosporin with **losartan** 50 to 100 mg daily for 8 weeks found serum creatinine, potassium and ciclosporin levels were unaffected.[7] Another study in 41 kidney transplant patients with proteinuria taking ciclosporin found that the addition of **candesartan** 4 to 12 mg daily had no significant effects on the creatinine clearance or ciclosporin levels.[8]

Mechanism

Not understood. One suggestion is that ciclosporin reduces renal blood flow and reduces perfusion through the glomerulus, which is worsened when angiotensin II is inhibited by the ACE inhibitor.[1] One study suggest-

ed that the larger increase in potassium levels may be related to changes in aldosterone levels seen with enalapril.[4]

Importance and management

There have been few specific case reports of renal failure and hyperkalaemia with ciclosporin and ACE inhibitors or angiotensin II receptor antagonists. Data from the few examples of efficacy studies cited above, suggest that the incidence of renal failure and hyperkalaemia is low, nevertheless care and good monitoring are needed if ACE inhibitors or angiotensin II receptor antagonists and ciclosporin are used concurrently. Also note that the manufacturers of ciclosporin warn about the possible increased risk of hyperkalaemia when ciclosporin is used with ACE inhibitors or angiotensin II receptor antagonists.[9,10] Monitor potassium levels more closely in the initial weeks of concurrent use, bearing in mind that an increase in potassium levels may be due to worsening renal function as well as these drugs.

Ciclosporin + Acetazolamide

There is some limited evidence to suggest that oral acetazolamide can cause a marked and rapid rise in ciclosporin levels, possibly accompanied by renal toxicity.

Clinical evidence, mechanism, importance and management

A study in 3 men found that 72 hours after they started taking acetazolamide (dose not stated) their trough serum ciclosporin levels rose by more than sixfold, from a range of 54 to 270 nanograms/mL up to a range of 517 to 1827 nanograms/mL.[1] Another man with a heart transplant had a fivefold increase in his serum ciclosporin levels, marked renal impairment, and neurotoxicity when he was given oral acetazolamide for raised intra-ocular pressure secondary to panuveitis.[2] The increase in ciclosporin serum levels has also been seen in *animal* studies.[3]

Information seems to be limited to these reports but it seems that the concurrent use of ciclosporin and acetazolamide should be closely monitored, being alert of the need to reduce the ciclosporin dose. The interaction can apparently develop very rapidly.

Ciclosporin + Aciclovir and related drugs

Aciclovir does not normally seem to affect ciclosporin levels or worsen renal function on concurrent use, but cases of nephrotoxicity and increased ciclosporin levels have been reported. Valaciclovir, a prodrug of aciclovir, is expected to interact similarly. Limited evidence suggests ganciclovir does not affect ciclosporin levels or worsen renal function on concurrent use. However, four patients given ciclosporin and ganciclovir developed an acute but reversible eye movement disorder.

Clinical evidence

(a) Aciclovir

A retrospective study in kidney transplant patients taking ciclosporin (serum levels in the range 100 to 250 nanograms/mL) found that in 12 patients, oral aciclovir 800 mg four times daily for 3 months had no significant effect on their ciclosporin serum levels or on nephrotoxicity when compared with 9 control subjects.[1] No significant changes in renal function were seen in 11 patients taking ciclosporin when they were given intravenous aciclovir 750 to 1500 mg/m^2 daily for at least 7 days to treat herpes infections.[2] No significant changes in serum creatinine or ciclosporin levels were seen during the 14 days following kidney transplant in 17 patients given aciclovir 800 mg daily.[3] Fifty-three kidney transplant patients were given ciclosporin and aciclovir 800 mg to 3.2 g daily for 12 weeks. The aciclovir was withdrawn from 2 patients because of unexplained and temporary increases in serum creatinine levels. The serum ciclosporin levels were not reported.[4] Five patients (2 adults and 3 children) taking ciclosporin, prednisone and azathioprine were given aciclovir 200 mg five times daily for 6 days for herpes zoster or chicken pox. Ciclosporin serum levels remained unchanged and renal function improved.[5]

In contrast to the cases cited above, 3 of 7 bone marrow transplant patients given ciclosporin and intravenous aciclovir 500 mg/m^2 every 8 or 12 hours (depending on renal function) developed nephrotoxicity, which was fatal in one case. Histological evidence suggested ciclosporin nephrotoxicity.[6] The manufacturer briefly notes that an increase in serum creatinine was seen in patients taking ciclosporin in one report, and increased aciclovir levels accompanied by reversible acute tubular necrosis in another.[7] Yet another report describes a threefold increase in ciclosporin serum levels, which occurred when a child with a heart transplant was given intravenous aciclovir.[8]

(b) Ganciclovir

In a retrospective analysis, 7 patients taking ciclosporin with ganciclovir 3 mg/kg every 12 hours for 5 to 7 days during antirejection therapy with antithymocyte globulin or muromonab-CD3 had no significant change in their ciclosporin levels (increase of 7.8%) and the ciclosporin dose was not altered. In these patients, serum creatinine levels remained stable.[9]

Another retrospective study identified 582 allogeneic bone marrow transplant patients taking ciclosporin and about 45% of whom were given ganciclovir at some time during the first 3 months after the transplant. Four patients (0.7%) developed an acute eye movement disorder (unilateral or bilateral sixth nerve palsies) within 4 to 34 days of starting ganciclovir. Three of the four patients also had bilateral ptosis, which resolved 24 to 48 hours after withdrawal of both drugs from 3 patients and after the withdrawal of just ciclosporin from the other patient. Objective eye movement abnormality with diplopia recurred in one patient when both drugs were restarted, but not when ciclosporin alone was given.[10]

Mechanism

The renal toxicity of aciclovir and related drugs may occasionally be additive or synergistic with that of ciclosporin. The reason for the eye movement disorders with ganciclovir is not known but the authors of the report suggest an interaction as eye movement disorders are not known to occur with either drug alone.[10]

Importance and management

The evidence available indicates that ciclosporin levels and renal function are usually unaltered by the concurrent use of aciclovir, but the handful of cases where problems have arisen clearly indicate that renal function should be well monitored. One group of workers suggest that aciclovir, in doses of 250 mg/m^2 by slow infusion, does not adversely affect renal function in well-hydrated patients taking ciclosporin if their ciclosporin levels are carefully monitored.[2] Similar precautions should be used with **valaciclovir**, a prodrug of aciclovir. Note that the manufacturers recommend that renal function is closely monitored if high doses of valaciclovir (more than 4 g daily),[11] or aciclovir infusion[12] are given with drugs that affect renal function, such as ciclosporin.

Limited evidence suggests that ganciclovir does not alter ciclosporin levels or renal function, but, like aciclovir, ganciclovir can cause increases in

serum creatinine and accumulates in renal impairment, so some caution is warranted on concurrent use. The same advice would appear to apply to **valganciclovir**, the prodrug of ganciclovir.

The report of eye movement disorders with ganciclovir cited here seems to be the only report of this interaction; therefore its general relevance is uncertain.

Ciclosporin + Alcohol

An isolated report describes a marked increase in serum ciclosporin levels in a patient after an episode of binge drinking, but a subsequent study found that moderate, single doses of alcohol in other patients had no such effect. A large amount of red wine, taken concurrently with ciclosporin in the fasted state, decreased ciclosporin bioavailability.

Clinical evidence

The serum ciclosporin levels of a kidney transplant patient doubled, from 101 nanograms/mL to 205 nanograms/mL, and remained high for about 4 days after he went on a 2-day alcohol binge. However, a subsequent study in 8 other patients with kidney transplants found no changes in serum ciclosporin or creatinine levels when they took their regular dose of ciclosporin followed by 50 mL of 100% alcohol in orange juice consumed over a one-hour period (about equivalent to 4 oz of whisky).[1]

A crossover study in 12 fasted, healthy subjects given a single 8 mg/kg dose of ciclosporin (*Sandimmun*) with water or 350 mL (12 oz) of Californian red wine found that red wine caused a 50% increase in the oral clearance of ciclosporin. The ciclosporin AUC was reduced by 30% and the maximum blood levels were reduced by 38% (from 1258 to 779 micrograms/L), but there was no change in elimination half-life. There was a high degree of variability, with increases in oral clearance ranging from 1.5 to 129%, with Caucasians experiencing a greater degree of change than Asians. In this study, half of the wine was consumed 15 minutes before the ciclosporin, and the other half was consumed at the same time as taking ciclosporin and in the 15 minutes afterwards. In their discussion the authors briefly note that, in a separate study of theirs, white wine did not have an effect on ciclosporin clearance.[2]

Mechanism

The mechanism by which red wine decreases ciclosporin absorption is not known. White wine[2] and pure alcohol[1] do not appear to affect ciclosporin pharmacokinetics, so the interaction is not believed to be an effect of alcohol itself. Antioxidants in red wine such as resveratrol may inactivate the cytochrome P450 isoenzyme CYP3A4, but this would be expected to increase ciclosporin levels. The solubility of ciclosporin is decreased in red wine, and it is possible that substances in red wine bind ciclosporin in the gastrointestinal tract and reduce its bioavailability.[2] Another study by the same authors suggested that ciclosporin absorption is possibly impaired by P-glycoprotein induction by red wine.[3]

A study in *animals* found that pretreatment with oral ciclosporin had no effect on the pharmacokinetics of alcohol or acetaldehyde. This suggests that any difference in the alcohol consumption of patients taking ciclosporin is unlikely to have a pharmacokinetic basis.[4]

Importance and management

The authors of the first study[1] say that they currently advise their kidney transplant patients to avoid heavy drinking, but that an occasional drink probably does not affect ciclosporin levels. The second study[2] suggests that it may be wise to avoid red wine close to a ciclosporin dose. However, it cannot be assumed that this interaction would occur with an occasional single glass of red wine taken with a meal and separate from ciclosporin dosing, and the mechanism of reduced absorption suggests this would be unlikely. Note that patients may be advised to avoid alcohol if they are taking ciclosporin after transplantation.

Ciclosporin + Alfalfa (*Medicago sativa*) and Black cohosh (*Cimicifuga racemosa*)

An isolated report describes acute rejection and vasculitis with black cohosh and/or alfalfa in a renal transplant patient taking ciclosporin.

Clinical evidence

A stable kidney transplant patient taking azathioprine 50 mg daily and ciclosporin 75 mg twice daily began to take alfalfa and black cohosh supplements (specific products not stated) on medical advice for severe menopausal symptoms. Her serum creatinine rose from between about 97 to 124 micromol/L up to 168 micromol/L after 4 weeks and, to 256 micromol/L after 6 weeks with no associated change in her ciclosporin levels. Biopsy revealed severe acute rejection with vasculitis and she was treated with corticosteroids and anti-T lymphocyte immunoglobulin with partial improvement in renal function.[1]

Mechanism

Alfalfa has been reported to cause worsening of lupus and immunostimulation and it was suggested that immunostimulation may have contributed to the acute rejection in this patient.[1]

Importance and management

The evidence for an interaction between alfalfa and/or black cohosh and immunosuppressants is limited, with the mechanism suggesting that alfalfa is the more likely culprit, although an effect of black cohosh cannot be ruled out. As the effects were so severe in this case it would seem prudent to avoid the use of alfalfa supplements in patients receiving immunosuppressants for serious indications, such as organ or tissue transplantation. Similarly, it would seem prudent to avoid the use of alfalfa in those taking immunosuppressants for indications such as eczema, psoriasis or rheumatoid arthritis; however, if these patients particularly wish to take alfalfa a short-term trial of concurrent use is likely to be less hazardous, but patients should be counselled about the possible risks (i.e. loss of disease control).

Ciclosporin + Allopurinol

Isolated cases of markedly raised ciclosporin levels have been reported in patients given standard doses of allopurinol for the treatment of gout. However, in two clinical studies, a trend towards lower ciclosporin levels with low-dose allopurinol has been seen.

Clinical evidence, mechanism, importance and management

The ciclosporin levels of a kidney transplant patient rose by about threefold, accompanied by an increase in serum creatinine from 124 micromol/L to 194 micromol/L, after allopurinol 100 mg daily was taken for 12 days for the treatment of gout.[1] Another previously stable kidney transplant patient had a two- to threefold rise in her ciclosporin level when allopurinol 200 mg daily was given for gout. Her serum creatinine remained unchanged throughout.[2] The general importance of these two reports of increased ciclosporin levels is unknown, although increases in ciclosporin levels are associated with increased risk of nephrotoxicity.

Two clinical studies in kidney transplant patients taking ciclosporin, azathioprine and prednisolone, with low-dose allopurinol 25 mg daily or on alternate days to improve the efficacy of azathioprine, found a reduction in ciclosporin levels (32% in one group), as well as a beneficial reduction in the acute rejection rate.[3] Note that azathioprine levels can be raised significantly by allopurinol usually requiring a dose reduction, see 'Thiopurines + Allopurinol', p.773. The case reports above and the clinical studies are probably insufficient to recommend increased monitoring of ciclosporin levels in all patients given allopurinol, but bear them in mind in the event of an unexpected response to treatment.

Ciclosporin + Amiodarone

Increased ciclosporin serum levels have been reported in patients starting amiodarone, and nephrotoxicity has occurred as a result of increased levels. Conversely, one report describes slightly lower ciclosporin levels and increased amiodarone levels and another case describes pulmonary toxicity in patients stopping amiodarone and starting ciclosporin.

Clinical evidence

Eight patients with heart transplants and 3 patients with heart-lung transplants taking ciclosporin were also given amiodarone (dose not stated) for atrial flutter or fibrillation. Their serum ciclosporin levels rose by 9% despite a 13 to 14% reduction in the ciclosporin dose, serum creatinine levels rose by 38% (from 157 to 216 micromol/L), and blood urea nitrogen rose by 30%.[1] In another report, one patient is said to have had a 50% decrease in the clearance of ciclosporin when given amiodarone (1 g, then 600 mg daily for 5 days, then 400 mg daily).[2] Eight other patients with heart or heart-lung transplants were effectively treated with amiodarone (dose not stated) for atrial flutter and/or atrial fibrillation, but they had a 31% rise in their serum ciclosporin levels, from 248 nanograms/mL to 325 nanograms/mL despite a 44% reduction in the ciclosporin dose (from 6.2 to 3.5 mg/kg daily). Serum creatinine levels increased by 39%.[3] The serum ciclosporin levels of a kidney transplant patient doubled when amiodarone 600 mg twice daily was given.[4]

In contrast, in 5 heart transplant patients in whom amiodarone was discontinued and ciclosporin subsequently initiated, the metabolism of ciclosporin appeared to be increased for 4 to 5 weeks compared with patients who had not received amiodarone (total plasma metabolites 1437 nanograms/mL and 720 nanograms/mL, respectively). The mean maintenance ciclosporin level was only slightly reduced, in those who had received amiodarone compared with those who had not been given amiodarone (225 nanograms/mL and 240 nanograms/mL, respectively).[5] In this study, 2 patients had amiodarone levels monitored, and it was found that the plasma levels of amiodarone and its main metabolite, desethylamiodarone were increased over 4 to 5 weeks. During this period increased adverse effects, including pulmonary toxicity in one patient, were seen.[5]

Mechanism

Uncertain. It has been suggested that increased ciclosporin levels are a result of a reduction in the metabolism of ciclosporin by amiodarone.[2] Conversely, in the one report suggesting decreased ciclosporin levels and increased amiodarone levels, it was suggested that blocking of P-glycoprotein in the intestinal mucosa and liver by both amiodarone and ciclosporin may result in decreased excretion and increased toxicity of amiodarone as well as accumulation of ciclosporin metabolites.[5]

Importance and management

The increase in ciclosporin levels on starting amiodarone would appear to be an established and clinically important interaction. Concurrent use need not be avoided but close monitoring is needed and ciclosporin dose reductions may also be required to minimise the potential nephrotoxicity. Remember to re-adjust the ciclosporin dose if the amiodarone is stopped, bearing in mind that it may take weeks before amiodarone is totally cleared from the body.

The general significance of the increase in amiodarone levels, apparent decrease in ciclosporin levels and the occurrence of pulmonary toxicity in patients who had stopped amiodarone and started ciclosporin is unclear.

Ciclosporin + Amphotericin B

There is some good evidence to suggest that the risk of nephrotoxicity is increased if ciclosporin and amphotericin B are used concurrently. However, other limited evidence suggests that the concurrent use of a liposomal form of amphotericin B (*AmBisome*) with ciclosporin does not increase nephrotoxicity or hepatotoxicity. Ciclosporin blood levels may be increased or decreased by amphotericin B.

Clinical evidence

(a) Ciclosporin levels

A retrospective analysis in allogeneic bone marrow transplant patients found that those patients taking high-dose prednisone with a continuous infusion of ciclosporin and prophylactic amphotericin B 5 to 10 mg daily had 13 to 23% lower plasma levels of ciclosporin in the first 4 weeks post-transplant when compared with those given the same GVHD (graft-versus-host-disease) prophylactic regimen who did not receive amphotericin B. No obvious dose reductions or changes in renal function were noted in these patients. It was also noted in this study that patients with ciclosporin plasma levels of 500 nanograms/mL had a 2.2-fold increased risk of developing GVHD when compared with patients with levels of 1000 nanograms/mL.[1] Similarly, a 23-year-old man had a reduction in his blood level of ciclosporin from about 100 nanograms/mL to 50 nanograms/mL within 10 days of starting intravenous amphotericin B.[2]

In contrast, a study in 187 transplant patients given an average dose of ciclosporin 10 mg/kg daily found that ciclosporin blood levels increased significantly from 275 nanograms/mL to 328 nanograms/mL during the use of liposomal amphotericin B (*AmBisome)* and decreased to 242 nanograms/mL one week after amphotericin B was stopped.[3] A retrospective study in 22 patients who had undergone allogeneic stem cell transplants found a non-significant increase in mean ciclosporin blood levels (from 259 nanograms/mL to 296 nanograms/mL) when given amphotericin B (0.6 to 2 mg/kg daily for 3 to 112 days). However, a lower maximum mean ciclosporin blood level of 775 nanograms/mL was seen in those patients who received amphotericin B compared with 1240 nanograms/mL in 62 patients receiving ciclosporin without amphotericin B, although again the difference was not significant.[4]

(b) Toxic effects

1. Nephrotoxicity. The concurrent use of ciclosporin and amphotericin B increased the incidence of nephrotoxicity in 47 patients with bone marrow transplants. Out of 10 patients who had received both drugs, 5 doubled and 3 tripled their serum creatinine levels within 5 days. In contrast, only 8 out of 21 (38%) taking ciclosporin alone and 3 out of 16 (19%) taking meth-

otrexate and amphotericin B doubled their serum creatinine within 14 to 30 days and 5 days, respectively.[5] Similarly, in a retrospective study, 14 potential drug-drug interactions were identified in patients given both ciclosporin and amphotericin B, and of these, 7 resulted in a clinically significant interaction (raised creatinine in all cases, with one patient developing nephrotoxicity).[6]

Two studies of the risk factors associated with amphotericin B identified the concurrent use of ciclosporin as posing a particularly significant risk for the development of the moderate to severe nephrotoxicity seen in 8 to 12% of patients given amphotericin B.[7,8] Two other studies in bone marrow transplant patients taking ciclosporin found that amphotericin B contributed significantly to nephrotoxicity and renal failure.[9,10] Renal impairment can apparently develop even after amphotericin B has been withdrawn.[9] Marked nephrotoxicity is described in one patient in another report.[11] A retrospective study of patients taking ciclosporin also found an increase in creatinine levels during the concurrent use of a continuous infusion of amphotericin B (*Fungizone*) in 22 patients (compared with 62 patients taking ciclosporin alone); however, severe reductions in renal function (creatinine clearance less than 30 mL/minute) were not found.[4] A study including 8 severely ill infants undergoing bone marrow transplantation for severe immunodeficiency, found no evidence of significant nephrotoxicity or hepatotoxicity when liposomal amphotericin B (*AmBisome*) was given with ciclosporin. The average course of treatment lasted for 29 days.[12]

2. Neurotoxicity. An isolated case report described severe tremors, later becoming myoclonic, attributed to the concurrent use of liposomal amphotericin B (*AmBisome*) and ciclosporin. Serum ciclosporin levels were unaltered and creatinine levels only rose slightly.[13] This alleged neurotoxicity was challenged in a letter citing 187 transplant patients who had received ciclosporin and *AmBisome*, none of whom developed neurotoxicity attributable to an interaction.[14]

3. Other adverse effects. In a retrospective analysis in bone marrow transplant patients, renal tubular acidosis and hypomagnesaemia were noted to be the most common adverse effects of the concurrent use of low-dose amphotericin B 5 to 10 mg daily with ciclosporin.[1]

Mechanism

Amphotericin B and ciclosporin are both nephrotoxic, and their adverse effects on the kidneys might be additive. The mechanism of the effects of amphotericin B on ciclosporin blood levels is not understood, especially as contrasting effects have been noted. However, in one *animal* study, amphotericin B decreased ciclosporin bioavailability by inducing the cytochrome P450 subfamily CYP3A and P-glycoprotein.[2]

Importance and management

The increased nephrotoxicity associated with ciclosporin and amphotericin B appears to be established and clinically important. The authors of one report[5] suggest that, in patients needing amphotericin B, renal toxicity may be decreased without losing the immunosuppressant effect of ciclosporin by withholding ciclosporin until the serum level is less than about 150 nanograms/mL.

The reports supporting a lack of significant nephrotoxicity all used liposomal amphotericin B, a formulation that is recommended when amphotericin toxicity (particularly nephrotoxicity) is considered to be a significant risk. This would seem to suggest that in patients taking ciclosporin, the less nephrotoxic forms of amphotericin B are advisable. Renal function should be closely monitored during concurrent use.

The changes in ciclosporin blood levels reported with amphotericin B are inconsistent. However, these studies should be borne in mind when using both drugs, and ciclosporin levels as well as renal function and electrolytes should be closely monitored.

Ciclosporin + Anabolic steroids or Androgens

The ciclosporin levels of two patients were raised when they were also given methyltestosterone. Hepatotoxicity has been seen in three patients given ciclosporin and norethandrolone.

Clinical evidence

(a) Methyltestosterone

A man with a kidney transplant who had been stable taking ciclosporin, prednisolone and azathioprine for 23 months was given methyltestosterone 5 mg three times daily for impotence. After 4 weeks he developed anorexia and pruritus. He was found to have a raised bilirubin level and his ciclosporin level had risen from 70 nanograms/mL to 252 nanograms/mL, with an accompanying decrease in his renal function. The methyltestosterone was withdrawn and he was later restabilised.[1] Another case describes abnormally high ciclosporin levels (in excess of 2000 nanograms/mL) when a patient taking methyltestosterone was given ciclosporin 15 mg/kg daily.[2]

(b) Norethandrolone

Three out of four patients with bone marrow aplasia taking ciclosporin and prednisone developed liver toxicity. The adverse effects developed in 2 of them when norethandrolone was added. No toxicity occurred when they were given either of the drugs alone.[3] A 14-year-old girl developed jaundice associated with toxic hepatitis during the post-transplant period, which was attributed to the concurrent use of ciclosporin and norethandrolone.[4]

Mechanism

Uncertain. In the first case, the increase in ciclosporin levels was attributed to cholestatic jaundice brought on by the methyltestosterone.[1] Both norethandrolone and ciclosporin are known to be hepatotoxic, so additive hepatotoxicity may occur.

Importance and management

Information is limited. However, it would seem prudent to avoid the use of androgens or anabolic steroids in patients taking ciclosporin wherever possible. If no alternative is available, it may be prudent to increase the frequency of liver function monitoring.

Ciclosporin + Antibacterials; Aminoglycosides

Studies indicate that nephrotoxicity may be increased by the concurrent use of ciclosporin and gentamicin. This has also been seen with tobramycin. Cases of renal impairment have been reported when ciclosporin was given with amikacin and gentamicin.

Clinical evidence

A comparative study in patients given **gentamicin** 30 mg with lincomycin just before kidney transplantation found that the concurrent use of ciclosporin increased the incidence of nephrotoxicity from 5% to 67%.[1] When **gentamicin** and lincomycin were replaced with ampicillin, ceftazidime and lincomycin the incidence of nephrotoxicity was 10%.[1] Another study describes increased nephrotoxicity associated with the concurrent use of ciclosporin and **tobramycin** in bone marrow transplant recipients.[2,3]

One case report describes reversible acute worsening of renal function in a kidney transplant patient receiving ciclosporin with **gentamicin**,[4] and another case report describes impaired renal function in a heart transplant patient taking ciclosporin and given **amikacin**.[5]

A retrospective analysis of the medical records of bone marrow transplant patients suggested that aminoglycosides can be safely given with a continuous infusion of ciclosporin without excessive nephrotoxicity, if the patient is carefully monitored.[6]

Mechanism

Uncertain. As both ciclosporin and the aminoglycosides can individually be nephrotoxic, it seems that their toxicities can be additive.

Importance and management

Established and clinically important interactions. In general the concurrent use of two drugs with nephrotoxic potential should be avoided; however the concurrent use of ciclosporin and aminoglycosides is clinically valuable. Renal function should be monitored with either drug alone, but if concurrent use is undertaken then it would seem prudent to increase the frequency of this monitoring.

Ciclosporin + Antibacterials; Aztreonam

Aztreonam does not appear to alter ciclosporin levels.

Clinical evidence, mechanism, importance and management

A study in 20 kidney transplant patients taking ciclosporin found that when aztreonam (dose not stated) was added for the treatment of various infections the ciclosporin serum levels were not significantly changed. The ciclosporin blood levels before, during, and after aztreonam treatment were 517 nanograms/mL, 534 nanograms/mL, and 592 nanograms/mL, respectively.[1] On the basis of this study it appears that no ciclosporin dose adjustment is needed on the concurrent use of aztreonam.

1. Alonso Hernández A. Effects of aztreonam on cyclosporine levels in kidney transplant patients. *Transplantology J Cell Organ Transplant* (1993) 4, 85–6.

Ciclosporin + Antibacterials; Cephalosporins

Isolated case reports suggest that ceftazidime, ceftriaxone, and latamoxef may increase ciclosporin levels, whereas one report suggests ceftazidime, ceftriaxone, and cefuroxime do not, although ceftazidime caused deterioration in some measures of renal function.

Clinical evidence, mechanism, importance and management

Two kidney transplant patients had two- to fourfold rises in ciclosporin blood levels within 2 to 3 days of starting **ceftriaxone** 1 g twice daily. Levels fell when the antibacterial was stopped. The reason for this effect is uncertain but it was suggested that **ceftriaxone** possibly inhibits the metabolism of ciclosporin by the liver.[1] However, a report of 51 kidney transplant patients stated that **ceftriaxone** and **cefuroxime** had no effect on ciclosporin blood levels and also that they were not nephrotoxic. This report also stated that **ceftazidime** did not affect serum ciclosporin levels, but it increased blood urea nitrogen and creatinine levels, indicating that it was nephrotoxic.[2] A report briefly mentions that **ceftazidime** and **latamoxef** have also been implicated in an increase in ciclosporin plasma levels.[3] However, the manufacturers of **ceftazidime** state that there is no evidence to suggest that **ceftazidime** itself is nephrotoxic when used in the recommended doses, although dose adjustment is required in renal impairment.[4] A study in 28 bone marrow transplant patients taking ciclosporin found no evidence that **ceftazidime** 2 g three times daily worsened renal function.[5]

Information about these cephalosporins is very limited indeed. The general relevance of these reports is uncertain, but bear them in mind in the event of unexpected response to treatment.

Ciclosporin + Antibacterials; Chloramphenicol

A marked rise in ciclosporin levels has been reported in patients who have also been given intravenous or oral chloramphenicol.

Clinical evidence

A retrospective study identified 3 transplant patients taking ciclosporin who had received a total of 6 courses of intravenous chloramphenicol, each lasting for at least 12 days. By day 4 of concurrent use ciclosporin blood levels had increased on average by about 40%. Ciclosporin doses tended to be slightly reduced over the course of treatment, and by day 10, ciclosporin levels were about 31% below baseline.[1]

A woman with a heart-lung transplant and with a trough ciclosporin level of 84 nanograms/mL started to take oral chloramphenicol (dose not stated) to treat an infection with *Xanthomonas maltophilia*. On the next day the ciclosporin levels had risen to 240 micrograms/L. The chloramphenicol was continued but the ciclosporin dose was reduced from 300 to 225 mg daily. By day 8 the ciclosporin levels were back within the therapeutic range.[2]

Two kidney transplant patients had marked increases in ciclosporin blood levels (almost doubled in one case) when they were given chloramphenicol for urinary tract infections.[3]

There is another report of this interaction, but the case is greatly complicated by the presence of ciprofloxacin, vancomycin, ceftazidime, and a recent course of rifampicin (rifampin) taken by the patient.[4]

Mechanism

Uncertain. The authors suggest that chloramphenicol might reduce the metabolism of ciclosporin by the liver.[4]

Importance and management

Information seems to be limited to these reports, so although the interaction appears to be established, its incidence is obviously uncertain. It would be prudent to monitor ciclosporin levels if systemic chloramphenicol is added, being alert for the need to reduce the ciclosporin dose. The

retrospective study highlights the need to monitor levels closely throughout the whole chloramphenicol course.[1] It seems doubtful that there would be enough chloramphenicol absorbed from eye drops to interact with ciclosporin, but this needs confirmation.

Ciclosporin + Antibacterials; Clindamycin

Two patients had a marked reduction in their serum ciclosporin levels when they took clindamycin.

Clinical evidence, mechanism, importance and management

A lung transplant patient receiving ciclosporin in a dose to maintain levels of 100 to 150 nanograms/mL required ciclosporin dose increases to achieve this level when clindamycin 600 mg three times daily was given. Initially the levels were almost halved by the addition of clindamycin. Ciclosporin was reduced to the original dose when the clindamycin was stopped.[1] In a second lung transplant patient, the use of clindamycin 600 mg three times daily necessitated ciclosporin dose increases from 325 mg daily to 1.1 g daily over 4 weeks to maintain serum levels of about 200 nanograms/mL.

The reasons for the interaction are not understood, but the authors suggest close monitoring of ciclosporin levels to prevent under-dosing if clindamycin is given;[1] however, this seems exceptionally cautious as these two cases appear to be all that have been reported.

1. Thurnheer R, Laube I, Speich R. Possible interaction between clindamycin and cyclosporin. *BMJ* (1999) 319, 163.

Ciclosporin + Antibacterials; Imipenem with Cilastatin

Several transplant patients with impaired renal function have experienced adverse CNS effects (including convulsions and tremors) while taking imipenem with cilastatin and ciclosporin. Imipenem with cilastatin appears to decrease the nephrotoxicity of ciclosporin, but its effect on ciclosporin levels is uncertain.

Clinical evidence

(a) Ciclosporin levels

In one heart transplant patient, the dose of ciclosporin required to maintain a therapeutic level needed to be reduced from 240 mg to 180 mg daily when imipenem with cilastatin was given for mediastinitis.[1] Another patient had a rise in ciclosporin blood levels from about 400 nanograms/mL to 1000 nanograms/mL in the 4 days after receiving two doses of imipenem with cilastatin. This patient also developed CNS toxicity, see *CNS effects and seizures*, below.[2]

Conversely, in a randomised controlled study of the use of imipenem with cilastatin to reduce ciclosporin nephrotoxicity, there was no difference in the ciclosporin levels or dose between the 10 patients who received imipenem with cilastatin and the 10 patients who received placebo.[3] Similar findings were reported in another study.[4]

However, in a retrospective analysis, mean ciclosporin levels were *lower* in 64 patients given imipenem with cilastatin (208 nanograms/mL) than in the 40 patients who were not given imipenem with cilastatin (265 nanograms/mL). No difference in the incidence of graft versus host disease was found between the two groups.[5]

(b) CNS effects and seizures

A kidney transplant patient taking ciclosporin developed a urinary-tract infection for which she was given imipenem with cilastatin 500 mg intravenously every 12 hours (dose adjusted for renal function). About 20 minutes after the second dose she became confused, disorientated, agitated, and developed motor aphasia and intense tremor. This was interpreted as being a combination of the adverse CNS effects of both drugs. The imipenem and cilastatin was not given again, and the effects subsided over the next few days.[2] This patient also developed raised ciclosporin levels, see *Ciclosporin levels*, above.[2]

Similarly, 4 transplant patients who were taking ciclosporin developed seizures when they were given imipenem with cilastatin 1 g daily, and a fifth patient developed myoclonia. These patients all had chronic renal impairment.[6] Moreover, in one randomised study of the use of imipenem with cilastatin to reduce ciclosporin nephrotoxicity, 2 patients were withdrawn from the study because of seizures.[3]

In contrast, in an analysis of the incidence of seizure in patients who had been given ciclosporin and imipenem with cilastatin or either drug alone, there was no difference between the groups. Three of 77 patients (3.8%) given ciclosporin alone and 2 of 45 patients (4.4%) who were given ciclosporin and imipenem with cilastatin had seizures, whereas none of the 44 patients who received imipenem with cilastatin alone had seizures.[7]

(c) Reduction in nephrotoxicity

Various randomised prospective studies and retrospective studies have been published suggesting that serum creatinine levels are lower and the risk of acute renal failure is reduced in patients given ciclosporin and imipenem with cilastatin. In a meta-analysis of the data, the odds ratio for developing acute renal failure was 0.24 with the combination compared with ciclosporin alone.[8]

Mechanism

Focal tremors, myoclonus and convulsions are known adverse effects of imipenem with cilastatin and are most likely to occur in patients with renal impairment. Ciclosporin can also cause tremor, and rarely, convulsions, hence the effects of both drugs might be additive.

Cilastatin might possibly reduce the nephrotoxicity of ciclosporin because of its effect as an inhibitor of dehydropeptidase I, an enzyme found in the brush border of the renal tubules. Alternatively, it has been suggested it might reduce nephrotoxicity by reducing the levels of ciclosporin by altering ciclosporin metabolism,[9,10] but evidence for reduced ciclosporin levels is not conclusive.

Importance and management

An interaction between imipenem with cilastatin and ciclosporin leading to an increase in CNS adverse effects is not established. What occurred may simply represent the increased risk of seizures when imipenem with cilastatin is used in patients with renal impairment. The manufacturers of imipenem with cilastatin recommend that patients who develop focal tremors, myoclonus and convulsions while receiving the antibacterial should be started on an antiepileptic drug. If symptoms persist the dose should be reduced, or the drug withdrawn.[11,12]

The effect of imipenem with cilastatin on ciclosporin levels is uncertain, but bear these reports in mind if unexpected effects are seen with concurrent use.

Note that the risk of nephrotoxicity is possibly reduced in patients taking ciclosporin given cilastatin, although the use of imipenem with cilastatin for this purpose is investigational.

Ciclosporin + Antibacterials; Macrolides

Ciclosporin levels can be markedly raised by clarithromycin, erythromycin, josamycin, pristinamycin, and possibly midecamycin. Rokitamycin, telithromycin and troleandomycin are predicted to interact similarly. Roxithromycin appears to interact minimally, while no interaction is normally seen with azithromycin, dirithromycin or spiramycin, although there are two isolated reports of an interaction with azithromycin.

Clinical evidence

(a) Azithromycin

In a study in 8 healthy subjects were given ciclosporin 3.75 to 7.5 mg/kg alone and then after taking azithromycin 500 mg initially then 250 mg daily for 4 days. Azithromycin did not alter ciclosporin levels.[1] Similarly, in another controlled study in 8 patients with kidney transplants stabilised on ciclosporin, there was no clinically relevant change in ciclosporin levels after azithromycin 500 mg daily for 3 days (7% increase in AUC).[2] A number of other studies have also found no evidence of a clinically significant interaction between ciclosporin and azithromycin used for respiratory tract infections (dose not stated)[3] or for ciclosporin-induced gingival overgrowth (500 mg daily for 3 days).[4,5] However, there are two isolated reports describing a marked increase in ciclosporin levels in 2 patients, which were attributed to the use of azithromycin (500 mg on day one, then 250 mg daily for 4 days;[6] and 500 mg daily for 9 days[7]).

(b) Clarithromycin

In a study in 8 healthy subjects, ciclosporin 3.75 to 7.5 mg/kg was given alone and after clarithromycin 250 mg every 12 hours for 7 days. The maximum ciclosporin levels were raised by 50% by clarithromycin. In another study, a mean 30% reduction in the dose of ciclosporin was needed in 6 transplant patients also given clarithromycin.[8] Clarithromycin 500 mg twice daily as part of a *Helicobacter pylori* eradication regimen caused a two- to threefold increase in ciclosporin levels in 27 kidney transplant patients.[9,10] The ciclosporin levels in 4 renal transplant patients with stable renal function increased by about 72% when clarithromycin 250 mg twice daily for 6 days was added to treat gingival hyperplasia. Ciclosporin levels returned to baseline levels within 7 days of stopping clarithromycin. Only two patients required a ciclosporin dose reduction.[11]

Numerous case reports also describe this interaction: the AUC or levels of ciclosporin have been increased two- to threefold,[12-15] with changes being seen within 3 to 6 days of clarithromycin 250 or 500 mg twice daily being started.[12,15] Another patient had a seven- to twelvefold rise in serum ciclosporin levels and acute renal failure within 3 weeks of starting to take clarithromycin 1 g daily.[16] Another case report in a heart transplant patient taking ciclosporin found that the addition of rifampicin to clarithromycin negated the increase in ciclosporin levels seen with clarithromycin alone, and the ciclosporin dose requirement with both clarithromycin and rifampicin was similar to that before clarithromycin or rifampicin were started.[17]

(c) Dirithromycin

In a study in 8 healthy subjects, dirithromycin 500 mg daily for 14 days did not significantly affect the pharmacokinetics of a single 15-mg/kg oral dose of ciclosporin.[18]

(d) Erythromycin

A study in 9 transplant patients taking ciclosporin found that erythromycin increased the mean trough serum levels of 3 kidney transplant patients sevenfold (from 147 to 1125 nanograms/mL), and of 6 heart transplant patients four- to fivefold (from 185 to 815 nanograms/mL). Acute nephrotoxicity occurred in all 9 patients, and 7 had mild to severe hepatotoxicity caused by the increased ciclosporin levels.[19]

Markedly raised ciclosporin blood levels and/or toxicity have been described in a number of other studies and case reports with erythromycin given orally or intravenously to about 50 other patients.[20-35] The interaction has also been demonstrated in controlled studies in healthy subjects.[1,36] Oral erythromycin may possibly have a greater effect than intravenous erythromycin.[31,37]

Erythromycin-related ototoxicity, possibly associated with the use of ciclosporin, has been reported in liver transplant patients.[38]

(e) Josamycin

A man with a renal transplant who was taking azathioprine, prednisone and ciclosporin 330 mg daily had a marked rise in his plasma ciclosporin levels from about 90 nanograms/mL to 600 nanograms/mL when he took josamycin 2 g daily for 5 days. He responded in the same way when later rechallenged with josamycin. Another patient also reacted in the same way.[39] Two- to fourfold rises in ciclosporin levels have been seen in 9 other patients given josamycin 2 to 3 g (50 mg/kg) daily.[40-42] Another patient had a 40% rise in ciclosporin levels when given josamycin 500 mg twice daily.[43]

(f) Midecamycin

The steady-state ciclosporin blood levels of 10 kidney transplant patients were roughly doubled when they took midecamycin 800 mg twice daily.[44] A 43-year-old kidney transplant patient taking ciclosporin, azathioprine and prednisone, began further treatment on day 27 after the transplant with midecamycin diacetate 600 mg twice daily and co-trimoxazole three times daily for pneumonia. By day 33 the concentration/dose ratio of ciclosporin had doubled, and ciclosporin levels had reached 700 nanograms/mL, accompanied by a rise in serum creatinine levels. When the midecamycin was replaced by cefuroxime, the concentrations of both ciclosporin and creatinine fell to their former levels within 3 days.[45] Ciclosporin levels in another kidney transplant patient taking ciclosporin 120 mg twice daily increased from 95 nanograms/mL to 380 nanograms/mL 3 days after starting midecamycin 800 mg twice daily.[46] Blood levels of ciclosporin in a kidney transplant patient also increased from 97 nanograms/mL to 203 nanograms/mL 4 days after starting midecamycin diacetate 600 mg twice daily.[47]

(g) Pristinamycin

A kidney transplant patient had a tenfold increase in plasma ciclosporin levels from 30 nanograms/mL to 290 nanograms/mL after taking pristinamycin 2 g daily for 8 days. Blood creatinine levels rose from 75 micromol/L to 120 micromol/L. Another patient given pristinamycin 1.25 g had a rise in ciclosporin levels from 78 nanograms/mL to 855 nanograms/mL after 6 days. Ciclosporin and creatinine levels fell to normal levels within 2 days of stopping both drugs.[48]

In a study in 10 patients, pristinamycin 50 mg/kg daily raised the ciclosporin blood levels by 65% (from 560 to 925 nanograms/mL). Ciclosporin levels fell when the pristinamycin was stopped.[49] Within 5 days of starting to take pristinamycin 4 g daily the ciclosporin levels of another patient more than doubled. His serum creatinine levels also rose. Both fell back to baseline levels within 3 days of stopping the antibacterial.[50]

(h) Roxithromycin

Eight patients with heart transplants taking ciclosporin 8 mg/kg daily, prednisolone and azathioprine for at least one month, were given roxithromycin 150 mg twice daily for 11 days. A 38% rise in plasma ciclosporin levels occurred at the time the roxithromycin was given, and a 60% rise occurred 4 hours later. Ciclosporin levels fell again when roxithromycin was stopped. A small (10%) increase in serum creatinine levels occurred, but there was no evidence of a deterioration in renal function.[51] One study in kidney transplant patients taking ciclosporin found that the half-life of roxithromycin was doubled, from 17 to 34.4 hours.[52]

(i) Spiramycin

The ciclosporin plasma levels of 6 heart transplant patients taking corticosteroids, azathioprine and ciclosporin remained unchanged when they were given spiramycin 3 million units twice daily for 10 days.[53] Similarly, no interaction was found between ciclosporin and spiramycin in other studies in patients with renal transplants.[54-57]

Mechanism

In vitro studies with human liver microsomes have found that clarithromycin, erythromycin, josamycin, rokitamycin, roxithromycin and troleandomycin (but not spiramycin) inhibit ciclosporin metabolism, which is catalysed by the cytochrome P450 subfamily CYP3A.[16,58] This would be expected to result in raised ciclosporin levels. Telithromycin is also an inhibitor of CYP3A4 and may increase ciclosporin levels.[59,60] Erythromycin[31,35] and clarithromycin[14] also possibly increase the absorption of ciclosporin from the gut by inhibiting the cytochrome P450 isoen-

zyme CYP3A4 in the gut wall or increasing uptake by inhibiting P-glycoprotein.

Azithromycin is believed to be metabolised by routes independent of the cytochrome P450 enzyme system. Intravenous azithromycin was thought to have increased ciclosporin levels through P-glycoprotein inhibition and/or competition for biliary excretion in one case report.[7]

Importance and management

The interaction between ciclosporin and **erythromycin** or **clarithromycin** is well documented, well established and potentially serious. If concurrent use is thought appropriate, monitor the ciclosporin blood levels closely and reduce the dose as required; a reduction of about 35% may be needed.[33] The dose should be increased again when the macrolide is stopped. The effect of intravenous erythromycin is less than oral erythromycin so if the route of administration is changed, be alert for the need to change the ciclosporin dose.[31,37]

Information about the interactions with **josamycin**, **midecamycin**, and **pristinamycin** is much more limited, but as they appear to behave like erythromycin, the same precautions should be taken. There seems to be no direct clinical information about **telithromycin**, **troleandomycin** and **rokitamycin** but they would also be expected to interact like erythromycin. Note that troleandomycin is usually a more potent inhibitor of CYP3A4 than erythromycin, so it may be expected to have a larger effect on ciclosporin levels.

Dirithromycin and **spiramycin** do not appear to interact with ciclosporin, and **roxithromycin** appears only to interact very minimally. Also bear in mind that roxithromycin serum levels may be increased.

Most evidence indicates that azithromycin does not affect ciclosporin levels, although some authors[7] recommend increased monitoring because of the isolated reports of increased ciclosporin levels. Bear the case reports in mind should an unexplained increase in ciclosporin levels occur on concurrent use.

Ciclosporin + Antibacterials; Metronidazole

Three reports describe an increase in ciclosporin levels in patients given metronidazole.

Clinical evidence, mechanism, importance and management

The ciclosporin blood levels of a kidney transplant patient rose from 850 nanograms/mL to 1930 nanograms/mL when metronidazole 2.25 g daily and cimetidine 800 mg daily were started. The ciclosporin levels then fell to about 1500 nanograms/mL when the metronidazole dose was

halved and cimetidine was stopped. Because the levels of ciclosporin were still so high, the dose of ciclosporin was reduced from 7.1 to 5.7 mg/kg daily, which resulted in a further decrease in the ciclosporin level to about 1200 to 1380 nanograms/mL. When metronidazole was stopped, the ciclosporin levels fell to a range of 501 to 885 nanograms/mL.[1]

Another kidney transplant patient developed a raised serum creatinine (increased from 223 micromol/L to 304 micromol/L) with virtually doubled ciclosporin blood levels when metronidazole 1.5 g daily was given.[2]

Ciclosporin levels in yet another kidney transplant patient doubled (from 134 to 264 micrograms/L) accompanied by a modest elevation in serum creatinine when metronidazole 400 mg three times daily was also given. The levels fell again when metronidazole was stopped.[3]

These three cases appear to be the only reports of an interaction, one of which is confused by the presence of cimetidine (see also 'Ciclosporin + H_2-receptor antagonists', p.1241). There is insufficient evidence to advocate monitoring every patient given the combination, but it would be prudent to at least bear this interaction in mind if using metronidazole in patients taking ciclosporin.

Ciclosporin + Antibacterials; Penicillins

Ampicillin does not interact adversely with ciclosporin. Limited evidence suggests that intravenous flucloxacillin might decrease ciclosporin levels. Increased nephrotoxicity has been seen in lung transplant patients given prophylactic nafcillin, whereas an isolated report describes a fall in ciclosporin levels in a patient treated with nafcillin. A case of raised ciclosporin levels in a patient taking ticarcillin has been described.

Clinical evidence

(a) Ampicillin

Seventy-one kidney transplant patients taking ciclosporin had no changes in serum urea, creatinine or ciclosporin levels when ampicillin was given.[1]

(b) Flucloxacillin

In a retrospective study in 7 kidney transplant recipients, it was noted that the use of intravenous flucloxacillin for septicaemia reduced ciclosporin trough levels by 55%. The ciclosporin dose needed to be increased 2.2-fold, but despite this, biopsy-proven rejection occurred in 3 patients within 10 days of starting flucloxacillin. Ciclosporin trough levels returned to normal within about 2 days of stopping the flucloxacillin.[2]

(c) Nafcillin

A retrospective study of 19 lung transplant patients taking ciclosporin found that those given nafcillin for one week as prophylaxis against staphylococci had a greater degree of renal impairment than those not taking nafcillin. Serum creatinine levels rose steadily over 6 days until the nafcillin was stopped, whereas patients not taking nafcillin had no changes in creatinine levels. Three of the nafcillin group temporarily needed haemodialysis. Ciclosporin doses in the nafcillin group were higher but the blood levels in both groups were not significantly different. The incidence of viral infections was also greater in the nafcillin group.[3]

A kidney transplant patient taking ciclosporin and prednisone experienced a marked fall in her serum ciclosporin levels on two occasions when given nafcillin 2 g every 6 hours. Trough blood levels fell from 229 nanograms/mL to 119 nanograms/mL after 3 days, and then to 68 nanograms/mL after 7 days of nafcillin and rose when the nafcillin was stopped. On the second occasion ciclosporin levels fell from 272 nanograms/mL to 42 nanograms/mL after 9 days of treatment with nafcillin.[4]

(d) Ticarcillin

A patient had a rise in his plasma ciclosporin levels from 90 nanograms/mL to 230 nanograms/mL within 5 days, and from 120 nanograms/mL to 300 nanograms/mL within 10 days, of starting ticarcillin 10 g daily.[5]

Mechanism

The authors of the study using nafcillin[3] suggest that it may have interfered with the ciclosporin assay, resulting in an underestimate of the actual levels, so that the nephrotoxicity was simply due to higher ciclosporin levels.[3] The fall in ciclosporin levels in the individual patient taking nafcillin[4] is not understood, nor is the rise in levels seen in the patient taking ticarcillin.[5] *In vitro* evidence[6] suggests that flucloxacillin at high concentrations might act as an inducer of the cytochrome P450 isoenzyme CYP3A4 and P-glycoprotein, both of which are involved in the metabolism of ciclosporin. However, in clinical use, there is little evidence to suggest that flucloxacillin interacts in this way.

Importance and management

Information seems to be limited to the studies and cases cited. No special precautions would seem necessary with ampicillin, but an alternative to nafcillin would seem prudent. The general importance of the interaction with flucloxacillin is uncertain given that flucloxacillin is not generally considered to affect the metabolism of other drugs. However, in light of these findings, it might be prudent to bear the possibility of an interaction in mind if high-dose intravenous flucloxacillin is required. Further study is required to establish an interaction. The isolated report with ticarcillin is of unknown general significance.

Ciclosporin + Antibacterials; Quinolones

Ciclosporin levels are normally unchanged by the use of ciprofloxacin, but increased levels and nephrotoxicity may occur in a small number of patients. There is also some evidence that the immunosuppressant effects of ciclosporin are reduced by ciprofloxacin. One study, and two case reports describe rises in ciclosporin levels in patients given norfloxacin, but another study found no change. Similar results have been found with levofloxacin. No significant pharmacokinetic interaction appears to occur between ciclosporin and enoxacin, ofloxacin, pefloxacin and trovafloxacin.

Clinical evidence

(a) Ciprofloxacin

A single-dose study in 10 healthy subjects found that after taking ciprofloxacin 500 mg twice daily for 7 days the pharmacokinetics of oral ciclosporin 5 mg/kg were unchanged.[1] Five other studies confirm the lack of a pharmacokinetic interaction in:

- kidney transplant patients taking ciprofloxacin 750 mg twice daily for 13 days;[2]
- kidney transplant patients taking ciprofloxacin 500 mg twice daily for 7 days;[3]
- bone marrow transplant patients given ciprofloxacin 500 mg twice daily for 4 days;[4]
- heart transplant patients given ciprofloxacin 250 to 500 mg for 7 to 140 days;[5]
- heart transplant patients given ciprofloxacin 800 mg to 1.5 g daily.[6]

There were no changes in serum ciclosporin levels or evidence of nephrotoxicity.

In contrast, a handful of cases of nephrotoxicity have been reported, with three cases of increased ciclosporin levels.[7,8] A heart transplant patient developed acute renal failure within 4 days of being given ciprofloxacin 750 mg every 8 hours.[9] Another patient who had undergone a kidney transplant developed reversible nephrotoxicity.[10] Decreased renal function in a heart-lung transplant patient has been described in another report.[7] This patient and another also had increased ciclosporin blood levels

when given ciprofloxacin 500 mg three times daily.[7] Acute interstitial nephritis in a heart transplant patient has also been reported.[11-13] A patient taking ciclosporin for red cell aplasia had an increase in ciclosporin levels from 120 nanograms/mL to 297 nanograms/mL, requiring a dose reduction from 250 mg to 200 mg daily, when intravenous ciprofloxacin 200 mg two or three times daily [exact dose unclear] was started. A ciclosporin dose increase back to 250 mg daily was required when the ciprofloxacin course was finished.[8]

A case-control study in 42 kidney transplant patients suggested that the proportion of cases experiencing at least one episode of biopsy-proved rejection within one to 3 months of receiving a transplant were significantly greater in those who had taken ciprofloxacin (45%) than in those who had not (19%). There was also a marked increase in the incidence of rejection associated with ciprofloxacin use (29%) compared with the controls (2%).[14]

(b) Enoxacin

Enoxacin 400 mg twice daily for 5 days had little effect on either blood or plasma levels of single doses of ciclosporin in 10 healthy subjects.[15]

(c) Levofloxacin

In a study in 12 healthy subjects, levofloxacin 500 mg twice daily for 6 days had no effect on the pharmacokinetics of ciclosporin when a single dose of the oral solution (*Sandimmune*) was given on day 5.[16] A case report in a patient taking oral ciclosporin 250 mg daily (as the emulsion formulation) found no change in ciclosporin levels when he was given intravenous levofloxacin 500 mg daily for 9 days.[8]

In contrast, in a study in 5 kidney transplant patients taking ciclosporin (microemulsion formulation), the AUC was increased by 26% and the trough level by 36% when levofloxacin 500 mg twice daily for 6 days was taken for a urinary-tract infection. The authors concluded that this interaction may be clinically significant, and warned about extrapolating the results from single-dose studies in healthy subjects (as above) to patients with transplants.[17]

(d) Norfloxacin

In a retrospective analysis, 6 kidney transplant patients given norfloxacin 400 mg twice daily for 3 to 23 days for urinary tract infections,[18] and 4 heart transplant patients given norfloxacin 400 mg for 7 to 140 days had no changes in their serum ciclosporin levels.[5] However, two reports describe rises, one marked, in serum ciclosporin levels in a heart transplant patient and a kidney transplant patient given norfloxacin.[19] Similarly, a retrospective study of paediatric kidney transplant patients, found that the ciclosporin dose at discharge was lower in 5 children who were also taking norfloxacin 5 to 10 mg/kg daily compared with a control group of 6 children not taking norfloxacin (4.5 mg/kg versus 7.4 mg/kg daily).[20]

(e) Ofloxacin

Thirty-nine patients with kidney transplants taking ciclosporin and prednisolone had no evidence of nephrotoxicity nor of any other interaction when they were given ofloxacin 100 to 400 mg daily for periods of 3 to 500 days.[21]

(f) Pefloxacin

A study in kidney transplant patients taking corticosteroids, azathioprine and ciclosporin found that the pharmacokinetics of the ciclosporin were not significantly changed by pefloxacin 400 mg twice daily for 4 days.[22]

(g) Trovafloxacin

A placebo-controlled crossover study in 7 stable kidney transplant patients taking ciclosporin (*Sandimmune*) found that the pharmacokinetics of ciclosporin were not significantly altered by trovafloxacin 200 mg daily for 7 days.[23]

Mechanism

Uncertain. On the basis of *in vitro* analysis, it was suggested that norfloxacin inhibits the cytochrome P450 isoenzyme CYP3A4, which would result in a reduction in ciclosporin metabolism.[20] However, there is no direct evidence from a controlled study that norfloxacin raises ciclosporin levels, and norfloxacin is not known as a clinically important inhibitor of CYP3A4, so further study is needed.

The interaction between ciclosporin and ciprofloxacin resulting in increased rejection episodes, may possibly be due to some antagonism by ciprofloxacin of the ciclosporin-dependent inhibition of interleukin-2, which thereby opposes its immunosuppressant action.[14]

Importance and management

Information seems to be limited to these reports. Evidence for an interaction between ciclosporin and levofloxacin or norfloxacin is limited and a significant pharmacokinetic interaction seems generally unlikely. However, as some changes in ciclosporin levels have been reported, it would be prudent to bear the possibility of an interaction in mind should any unexplained change in ciclosporin levels occur in patients taking either of these quinolones. No pharmacokinetic interaction usually occurs between ciclosporin and ciprofloxacin but very occasionally and unpredictably an increase in serum ciclosporin levels and/or nephrotoxicity occurs. There is also some evidence that the immunosuppressant effects of ciclosporin may be reduced.[14] Bear these interactions in mind if both drugs are given.

There seem to be no reports of problems with the concurrent use of ciclosporin and enoxacin, ofloxacin, pefloxacin or trovafloxacin.

Ciclosporin + Antibacterials; Quinupristin/Dalfopristin

Quinupristin/dalfopristin increased the AUC and maximum levels of single-dose ciclosporin in healthy subjects. In an isolated case report, quinupristin/dalfopristin increased ciclosporin levels by about threefold. There is limited evidence suggesting that ciclosporin might increase the risk of myalgia and/or arthralgia occurring with quinupristin/dalfopristin.

Clinical evidence

(a) Ciclosporin levels

In a study in 24 subjects given a single 300-mg dose of ciclosporin, taken 1.5 hours before the fourth of 9 infusions of quinupristin/dalfopristin (7.5 mg/kg given at intervals of 8 hours), the AUC and maximum blood levels of ciclosporin were increased by 63% and 30%, respectively, and ciclosporin clearance was decreased by 34%.[1]

A kidney transplant patient taking ciclosporin with trough blood levels of between 80 and 105 nanograms/mL developed a vancomycin-resistant enterococcal infection. After a series of antibacterials had failed to clear the infection she was given intravenous quinupristin/dalfopristin 300 mg every 8 hours. After 3 days of treatment her ciclosporin trough level rose to almost 300 nanograms/mL. A ciclosporin dose reduction from 75 to 50 mg twice daily returned her levels to baseline. However, 2 days after the antibacterials were discontinued she was found to have a trough ciclosporin level of only 34 nanograms/mL. She was subsequently restabilised on her original dose of ciclosporin.[2]

(b) Myalgias or arthralgias

In a case-control study[3] of 50 patients receiving quinupristin/dalfopristin 7.5 mg/kg every 8 hours, 10 of the 25 patients who experienced arthralgia or myalgia were also taking ciclosporin, and the risk of these adverse effects with concurrent use was associated with an odds ratio of 3.8.

Mechanism

Quinupristin/dalfopristin inhibits the cytochrome P450 isoenzyme CYP3A4, by which ciclosporin is metabolised.[4] Myalgias and/or arthralgias are common in patients receiving quinupristin/dalfopristin and their aetiology is uncertain.[4]

Importance and management

The available evidence suggests that quinupristin/dalfopristin is likely to increase ciclosporin levels. The manufacturers advise that ciclosporin levels are closely monitored during concurrent use,[4,5] which would seem prudent. Ciclosporin dose reductions may be necessary. Bear in mind the possibility that ciclosporin use might increase the risk of myalgias and/or arthralgias with quinupristin/dalfopristin. The manufacturer notes that improvement has been noted in some patients with this adverse effect when the quinupristin/dalfopristin dose frequency has been extended.[4]

Ciclosporin + Antibacterials; Sulfonamides and/or Trimethoprim

In isolated cases, sulfadiazine given orally or sulfadimidine given intravenously with trimethoprim have caused a reduction in ciclosporin levels. Sulfametoxydiazine possibly caused a minor reduction in ciclosporin levels in one case. Co-trimoxazole increases serum creatinine levels in kidney transplant patients taking ciclosporin. Isolated reports have shown a similar effect with trimethoprim.

Clinical evidence

(a) Co-trimoxazole

A large-scale study in 132 kidney transplant patients taking ciclosporin encompassing 33 876 patient days found that the concurrent use of co-trimoxazole was effective and well tolerated. Ciclosporin pharmacokinetics remained unchanged. A 15% rise in serum creatinine levels occurred, which reversed when the co-trimoxazole was stopped. This rise was not interpreted as a sign of nephrotoxicity but appeared to be due to inhibition of the tubular excretion of creatinine by the co-trimoxazole.[1]

Other reports describe a few patients given ciclosporin with co-trimoxazole who developed rises in creatinine levels (interpreted as evidence of nephrotoxicity),[2-5] interstitial nephritis,[6] granulocytopenia and thrombocytopenia.[7,8]

(b) Sulfadiazine or Sulfametoxydiazine

Three heart transplant patients treated for toxoplasmosis had a reduction in their ciclosporin levels when they were given sulfadiazine 4 or 6 g daily. Their dose to ciclosporin level ratios rose by 58%, 82%, and 29%. Two had previously been given sulfametoxydiazine and this had caused a minor reduction in ciclosporin levels in one of them.[9]

(c) Sulfadimidine with Trimethoprim

A heart transplant patient taking ciclosporin and prednisolone developed undetectable serum ciclosporin levels 7 days after starting intravenous sulfadimidine 2 g four times daily and **trimethoprim** 300 to 500 mg twice daily. Doubling the ciclosporin dose had little effect and evidence of transplant rejection was seen. Within 10 days of starting to take the antibacterials orally instead of intravenously the serum ciclosporin levels returned to roughly their former levels and the rejection problems disappeared.[10]

Another report by some of the same authors describes a similar marked fall in serum ciclosporin levels in 5 heart transplant patients (one of them the same as the report already cited[10]) when given sulfadimidine and **trimethoprim** intravenously.[11]

(d) Trimethoprim

In 4 kidney transplant patients taking ciclosporin, serum creatinine concentrations rose during the use of trimethoprim. Renal function deteriorated within 2 or 3 days of starting trimethoprim and returned to normal within a week of stopping this antibacterial.[12]

Mechanism

Uncertain. Co-trimoxazole and trimethoprim can raise serum creatinine levels, possibly due to inhibition of creatinine secretion by the kidney tubules.[13] The reduction in serum ciclosporin levels apparently caused by the sulfonamides is not understood.

Importance and management

The documentation is only moderate, and these interactions are not firmly established. Be aware that intravenous sulfadimidine with trimethoprim may cause a marked reduction in serum ciclosporin levels with accompanying inadequate immunosuppression. Sulfadiazine may also reduce ciclosporin levels. The evidence suggests that oral sulfadimidine with trimethoprim, sulfametoxydiazine, and co-trimoxazole do not interact adversely and are normally safe and effective, although toxicity can apparently occur in a small number of patients. Until more information is available it would be prudent to monitor ciclosporin levels if any sulphonamide is added to established treatment with ciclosporin. The manufacturers recommend close monitoring of renal function when ciclosporin is used with co-trimoxazole[14,15] or trimethoprim[14] and this would seem a prudent precaution.

Ciclosporin + Antibacterials; Vancomycin

Vancomycin may increase the risk of nephrotoxicity when it is given with ciclosporin.

Clinical evidence, mechanism, importance and management

In a subgroup analysis of bone marrow transplant patients who were taking ciclosporin, there was a 42% decrease in creatinine clearance in those receiving intravenous vancomycin 15 mg/kg every 12 hours compared with a 15% decrease in those receiving teicoplanin. All patients also received tobramycin and piperacillin.[1]

Both vancomycin and ciclosporin can individually be nephrotoxic, and this study provides some evidence that their toxicities can be additive. Bear in mind the possibility of increased nephrotoxicity if vancomycin is required in a patient taking ciclosporin.

Ciclosporin + Antidiabetics

Some preliminary evidence suggests that glibenclamide (glyburide) can moderately increase ciclosporin levels. Glipizide approximately doubled ciclosporin levels in 2 patients, but one study found no interaction. A single-dose study found ciclosporin significantly increased repaglinide bioavailability, but not all studies have found this effect. Pioglitazone is not expected to alter ciclosporin levels.

Clinical evidence, mechanism, importance and management

Note that one of the rare adverse effects of ciclosporin is hyperglycaemia, and therefore, even in the absence of a pharmacokinetic interaction, ciclosporin might interfere with diabetic control. However, the effect is rare, and does not justify an increase in monitoring all patients. Studies investigating the effects of specific antidiabetics on ciclosporin are discussed below.

(a) Pioglitazone

In vitro and human studies have shown that pioglitazone does not affect cytochrome P450 isoenzymes, including CYP3A4. Therefore no interaction would be expected with ciclosporin, which is mainly metabolised by CYP3A4.[1]

(b) Repaglinide

A placebo-controlled study in 12 healthy subjects given ciclosporin 100 mg twice daily for two doses, with a single 250-microgram dose of repaglinide on day 2, found that ciclosporin significantly increased the maximum plasma level and AUC of repaglinide by 175% and 244%, respectively. It was suggested that ciclosporin inhibited the metabolism of repaglinide by the cytochrome P450 isoenzyme CYP3A4 as well as affecting the hepatic uptake of repaglinide by organic anion transporters.[2,3]

In a study in kidney transplant patients stabilised on immunosuppressants, 7 patients taking ciclosporin had no significant changes in ciclosporin blood levels and no dose changes were required on starting repaglinide 1 to 3 mg daily (mostly as monotherapy, but in a few cases given with either metformin or rosiglitazone).[4] Six of the 7 patients had a successful outcome. This success rate was higher than that seen with tacrolimus (8 of 14), and others have suggested that this might have been due to the pharmacokinetic interaction, which results in increased repaglinide levels.[3] However, commenting further, the authors noted that they were unable to demonstrate a consistent, increased blood glucose-lowering effect with the concurrent use of repaglinide and ciclosporin when compared with tacrolimus and repaglinide, and that there was no obvious difference in the median repaglinide dose.[5] It is therefore difficult to draw any significant conclusions from this study.

The large increases in repaglinide levels seen in the single-dose study in healthy subjects might well be clinically relevant in some patients. Because of this, the possibility of an increased blood-glucose-lowering effect should be borne in mind if ciclosporin is added to the established use of repaglinide. Patients should be advised to report any adverse effects, particularly an increase in the number of hypoglycaemic events.

In the clinical study where repaglinide was given to patients stabilised on ciclosporin, ciclosporin levels were unaffected. However, note that, in this study repaglinide was started at a low dose and titrated upwards as necessary.[5] It may therefore be prudent to introduce repaglinide in this way.

Note that the UK manufacturer of repaglinide suggests avoiding its use with ciclosporin, and recommends close monitoring if concurrent use is necessary.[6]

(c) Sulfonylureas

A review of 6 post-transplant patients with diabetes,taking ciclosporin found that their steady-state plasma ciclosporin levels rose by 57% when they were given **glibenclamide** (**glyburide**). Hepatic and renal function were unchanged. The reason for this reaction is not known, but it was suggested that **glibenclamide** possibly inhibits the cytochrome P450 isoenzyme CYP3A4, the major isoenzyme involved in the metabolism of ciclosporin, resulting in a reduction in its clearance.[7] However, glibenclamide is not known to be a CYP3A4 inhibitor.

Ciclosporin blood levels in 2 patients were more than doubled, and they needed reductions of 20 to 30% in their ciclosporin dose when they were also given **glipizide** 10 mg daily.[8] In contrast, a study in 11 post-transplant patients with diabetes found no significant alterations in ciclosporin pharmacokinetics when **glipizide** was given.[9]

These interactions are unconfirmed and of uncertain clinical significance. There is insufficient evidence to recommend increased monitoring, but be aware of the potential for an interaction in the case of an unexpected response to treatment. Information about other sulfonylureas appears not to be available.

Ciclosporin + Antiepileptics

Ciclosporin levels are markedly reduced by carbamazepine, phenobarbital, and phenytoin. The dose of ciclosporin may need to be increased two- to fourfold to maintain adequate immunosuppression. Oxcarbazepine caused a small decrease in ciclosporin levels in one case. Valproate appears not to affect ciclosporin levels but two case reports suggest that it may damage renal grafts and cause hepatotoxicity in patients taking ciclosporin.

Clinical evidence

(a) Carbamazepine

The ciclosporin serum levels of a kidney transplant patient fell from 346 nanograms/mL to 64 nanograms/mL within 3 days of starting to take carbamazepine 200 mg three times daily. A week later serum levels had fallen to 37 nanograms/mL. They rose again when the carbamazepine was stopped but fell once more when it was restarted and the ciclosporin dose was increased to keep the levels within the therapeutic range.[1]

The mean average steady-state blood levels of ciclosporin (adjusted for dose) in a group of 3 children with kidney transplants taking carbamazepine were 50% lower than in 3 other matched patients not taking carbamazepine.[2] This interaction has also been described in four other individual patients.[3-5] One needed her ciclosporin dose to be doubled in order to maintain adequate blood levels while taking carbamazepine 800 mg daily.[3] When the carbamazepine was replaced by sodium valproate in 3 patients, the ciclosporin doses could be reduced to their previous level.[3,4]

(b) Oxcarbazepine

A kidney transplant patient taking ciclosporin 270 mg daily and valproate, gabapentin, prednisone, doxepin, allopurinol, levothyroxine and pravastatin was also given oxcarbazepine. Fourteen days later, with the dose of oxcarbazepine at 750 mg daily, the ciclosporin trough level fell below 100 nanograms/mL and after a further 2 days was 87 nanograms/mL. The ciclosporin dose was increased to 290 mg daily and the oxcarbazepine dose reduced to 600 mg daily. Ciclosporin levels then remained stable above 100 nanograms/mL and seizure frequency was reduced by 95%.[6]

(c) Phenobarbital

A 4-year-old child with a bone marrow transplant who was receiving phenobarbital 50 mg twice daily had serum ciclosporin levels of less than 60 nanograms/mL even after raising the ciclosporin dose to 18 mg/kg daily. When the phenobarbital dose was reduced to 25% of the original dose the trough serum ciclosporin levels rose to 205 nanograms/mL.[7] Another report describes a patient whose ciclosporin levels increased from 512 nanograms/mL to 810 nanograms/mL after phenytoin and phenobarbital were replaced by sodium valproate.[8]

A threefold increase in ciclosporin clearance was seen in a child with a kidney transplant while taking phenobarbital.[9] Reductions in ciclosporin levels due to phenobarbital have been described in other patients.[10-13]

(d) Phenytoin

The observation that patients taking ciclosporin needed marked dose increases while taking phenytoin[14] prompted a further controlled study in 6 healthy subjects.[15] Phenytoin 300 or 400 mg daily reduced the maximum ciclosporin blood levels and AUC by 37% (from 1325 to 831 micrograms/L) and 47%, respectively.[15]

Other reports describe patients who needed two- to fourfold increases in their ciclosporin doses when they were given phenytoin,[16-19] and one patient who had variable ciclosporin levels and a rejection episode in the first 10 days after a kidney transplant while taking phenytoin.[20]

Another report describes an increase in ciclosporin levels from 512 nanograms/mL to 810 nanograms/mL after phenytoin and phenobarbital were replaced by sodium valproate.[8]

A report of severe gingival overgrowth in a kidney transplant patient was attributed to the additive adverse effects of ciclosporin and phenytoin. Ciclosporin was replaced by tacrolimus, which may have fewer oral adverse effects, and almost complete reversal of gingival overgrowth was achieved within 6 months.[21]

(e) Sodium valproate

In four cases an interacting antiepileptic was successfully replaced by sodium valproate,[3,4,8] see *Carbamazepine*, *Phenobarbital* and *Phenytoin*, above. However, sodium valproate may not always be without problems because interstitial nephritis was suspected in one patient with a renal graft taking ciclosporin and valproate,[10] and fatal valproate-induced hepatotoxicity occurred in another patient taking ciclosporin.[22]

Mechanism

It is thought that phenytoin,[14,15] carbamazepine[1,2] and phenobarbital[7,11] increase the metabolism of ciclosporin by cytochrome P450 in the liver (most probably the isoenzyme CYP3A4) thereby decreasing its serum levels. Oxcarbazepine produced only a small reduction in ciclosporin levels in one case, and the effect is probably due to more modest induction of the cytochrome P450 subfamily CYP3A.[6] Phenytoin also possibly reduces the absorption of ciclosporin.[23]

Importance and management

None of these interactions is extensively documented, but all appear to be established and of clinical importance. Serum ciclosporin levels should be well monitored if carbamazepine, phenobarbital or phenytoin are added and the ciclosporin dose increased appropriately. **Primidone** is metabolised to phenobarbital, and **fosphenytoin** is a prodrug of phenytoin and would therefore also be expected to reduce ciclosporin levels. Information about oxcarbazepine is very limited but small reductions in its dose, together with an increase in ciclosporin dose, may be adequate to control any interaction; however, more study is required.[6] The effects of the interaction may persist for a week or more after the anticonvulsant is withdrawn. Sodium valproate seems not to alter ciclosporin levels, but the case reports of nephritis and hepatotoxicity suggest some caution is warranted.

Ciclosporin + Antimycobacterials

Ciclosporin levels are markedly reduced by rifampicin and transplant rejection can rapidly develop. One case report suggests that rifabutin interacts, although to a lesser extent. Topical rifamycin has been reported to reduce ciclosporin levels in one patient. Ethambutol and isoniazid do not generally appear to interact with ciclosporin although case reports have described alterations in ciclosporin levels.

Clinical evidence

(a) Rifabutin

The clearance of ciclosporin in a patient with a kidney transplant doubled when isoniazid, ethambutol, pyridoxine and rifampicin 600 mg daily were given. When these drugs were replaced by rifabutin 150 mg and clofazimine 100 mg daily, the ciclosporin clearance fell to about its former levels, but after about 3 weeks the clearance was about 20% greater than before the antimycobacterial drugs were given.[1]

(b) Rifampicin (Rifampin)

A study in 39 kidney transplant patients taking ciclosporin at a mean dose of 158 mg daily found that the ciclosporin dose needed to be increased by between 150 to 525 mg daily (an average dose of 469 mg daily) when rifampicin 450 to 600 mg daily was taken as part of a regimen for tubercu-

losis. An increased incidence of acute rejection occurred during treatment with ciclosporin and rifampicin and 16 patients had kidney graft failure and needed to go back on haemodialysis because of this interaction.[2]

A heart transplant patient taking ciclosporin started taking rifampicin 600 mg daily with amphotericin B for the treatment of an *Aspergillus fumigatus* infection. Within 11 days her serum ciclosporin levels had fallen from 473 nanograms/mL to less than 31 nanograms/mL and severe acute graft rejection occurred. The dose of ciclosporin was increased stepwise and the levels climbed to a plateau before suddenly falling again. The dose had to be increased to more than 30 mg/kg daily to achieve serum levels in the range 100 to 300 nanograms/mL.[3]

A considerable number of other reports about individual patients, both adult and paediatric, confirm that a very marked fall in serum ciclosporin levels occurs, often to undetectable levels, accompanied by transplantation rejection in many instances, if rifampicin is given either intravenously or orally without raising the ciclosporin dose.[1,4-28] Ciclosporin levels become toxic within 2 weeks of stopping rifampicin unless the previously adjusted ciclosporin dose is reduced.[4,6]

Three patients needed increases in the dose of ciclosporin when given rifampicin, despite the additional use of erythromycin, which normally reduces ciclosporin requirements.[19,29,30] Another patient whose ciclosporin levels had been raised by clarithromycin had a fall in their levels when rifampicin was added.[31] For further information on the effects of the macrolides on ciclosporin levels, see 'Ciclosporin + Antibacterials; Macrolides', p.1218.

(c) Rifamycin sodium

Rifamycin sodium used to irrigate a wound has been reported to reduce the serum levels of ciclosporin in a kidney transplant patient.[32]

(d) Other antituberculars

Isoniazid[12,22,23,33] and **ethambutol**[22,23] do not normally interact with ciclosporin. However, there is one case report describing a patient who had a gradual rise in serum ciclosporin levels when isoniazid and ethambutol were stopped,[14] and another which attributed a marked rise in ciclosporin levels to the use of isoniazid.[34] Successful treatment of tuberculosis in heart and kidney transplant patients has also been reported using **isoniazid**, **ethambutol**, '**pyrazinamide**', (p.1250), and **streptomycin**.[35]

Mechanism

Rifampicin (rifampin) induces the cytochrome P450 isoenzyme CYP3A4, by which ciclosporin is metabolised resulting in a marked increase in ciclosporin clearance. In addition, rifampicin decreases ciclosporin absorption by inducing its metabolism by the gut wall,[36] thus producing a significant fall in ciclosporin levels. The drug transporter protein P-glycoprotein may also be involved in this interaction. Rifabutin has some enzyme-inducing effects but the extent is quite small compared with rifampicin, and the onset may be delayed.[37]

Importance and management

The interaction between ciclosporin and rifampicin (rifampin) is very well documented, well established and clinically important, and transplant rejection may occur unless the ciclosporin dose is markedly increased. In one study 27% of patients taking rifampicin lost grafts due to rejection, and this was directly attributed to the interaction.[22] The interaction develops within a few days (within a single day in one case[20]). If the concurrent use of rifampicin is essential, monitor the effects closely and increase the ciclosporin dose appropriately: three- to fivefold dose increases (sometimes increasing the dose frequency from two to three times daily) have proved to be effective, with daily monitoring. Remember also to reduce the ciclosporin dose when rifampicin is stopped to reduce the risk of ciclosporin toxicity.

The authors of one large study concluded that it is better to avoid rifampicin in patients taking ciclosporin and to use other antimycobacterials instead.[22] They found that the use of three antitubercular drugs (not including rifampicin) for at least 9 months reduced mortality. Other reports similarly found that regimens without rifampicin were suitable for the treatment of tuberculosis in transplant patients.[23,35] Another suggested alternative is to replace the ciclosporin with a different non-interacting immunosuppressant, such as azathioprine and low-dose prednisolone, if rifampicin is needed.[13]

Other rifamycins may also be an option; limited evidence from one case suggests that rifabutin interacts minimally. However, the manufacturer[38] and the CSM in the UK[39] caution about the possibility of an interaction, and close monitoring of ciclosporin levels would still be advisable.

Topical rifamycin interacted like rifampicin in one patient when it was applied to a wound.[32]

Ciclosporin + Azoles

The evidence suggests that all the azole antifungals can raise ciclosporin levels to a greater or lesser degree. Ketoconazole may cause five- to tenfold rises, while itraconazole, fluconazole and voriconazole may cause two- to threefold rises. A case report suggests that intravenous miconazole interacts similarly and, in theory, miconazole oral gel may also interact. Posaconazole may also modestly raise ciclosporin levels. Rhabdomyolysis has been reported with the combination of ciclosporin and itraconazole, but four of these cases were complicated by the presence of statins.

Clinical evidence

(a) Fluconazole

Oral fluconazole 200 mg daily for 14 days roughly doubled the ciclosporin trough blood levels of 8 kidney transplant patients stabilised on oral ciclosporin, from 27 to 58 nanograms/mL. The AUC increased by 80% but serum creatinine levels were unchanged.[1,2]

Other reports describe two- to threefold rises in ciclosporin blood levels in kidney transplant patients within 6 to 11 days of starting treatment with fluconazole 100 to 300 mg daily.[3-9] One patient developed nephrotoxicity, which resolved when the doses of both drugs were reduced.[10]

In contrast, some patients have had little or no changes in serum ciclosporin or creatinine levels when fluconazole was given.[7,8,11-15] It has been suggested that the interaction is dose-dependent.[8] In addition, the route of administration might influence the interaction. For example, there was only a 20% increase in ciclosporin levels when intravenous ciclosporin was given with high-dose intravenous fluconazole, which was not considered clinically relevant.[16] In a retrospective study in patients receiving intravenous ciclosporin, the ciclosporin blood level rose slightly (from 362 nanograms/mL to 394 nanograms/mL)when intravenous fluconazole was switched to oral fluconazole.[17] One study found a lack of interaction in females and African-American patients, suggesting that gender and ethnicity may also be factors.[18]

(b) Itraconazole

In 4 heart-lung, 2 heart and one lung transplant patient an average 56% reduction (range 33 to 84%) in the ciclosporin doses were needed when itraconazole (dose not stated) was given. Serum creatinine levels rose temporarily until the ciclosporin dose had been readjusted.[19] Two- to threefold rises in ciclosporin levels were seen in another 2 patients given itraconazole 200 mg daily,[20,21] and in one case the raised levels persisted for more than 4 weeks after the itraconazole was stopped.[21] Intravenous itraconazole 200 mg twice daily for 2 days then 200 mg daily caused a mean 80% increase in the levels of ciclosporin in 8 patients receiving intravenous ciclosporin.[22]

Other case reports and studies suggest that dose reductions of about 50 to 80% (where stated) were needed when patients taking ciclosporin were given itraconazole.[23-27] Enhanced itraconazole absorption in the presence of a carbonated drink that increased stomach acidity was found to allow decreases in the ciclosporin dose and increases in its dose interval.[28]

These reports contrast with another describing 14 bone marrow transplant patients taking ciclosporin. Those given itraconazole 100 mg twice daily had no significant changes in ciclosporin or creatinine serum levels.[29] Another patient required only a 10% reduction in ciclosporin dose when given itraconazole 400 mg daily for 40 days.[7]

Rhabdomyolysis has been reported in 3 lung transplant patients[23,30] and 2 heart transplant patients[31,32] when itraconazole was given with ciclosporin. However, in three of these cases the concurrent use of simvastatin and in one case concurrent simvastatin and gemfibrozil would also have been factors,[23,30-32] as both ciclosporin and itraconazole can increase simvastatin levels (see 'Statins + Ciclosporin', p.1326, and also 'Statins + Azoles', p.1321).

In a pharmacokinetic study in patients undergoing stem cell transplantation, the AUC of itraconazole after a single 200-mg intravenous dose did not differ before and after patients were stabilised on ciclosporin. However, the median AUC of the main active itraconazole metabolite, hydroxyitraconazole, was increased by 49%. This is probably not clinically relevant, but may have a bearing in situations when itraconazole levels are monitored.[33]

(c) Ketoconazole

Ketoconazole 200 mg daily caused a marked and rapid rise in the ciclosporin blood levels of 36 renal transplant patients. On the basis of experience with previous patients, the ciclosporin dose was reduced by 70% when ketoconazole was started, and after a year the dose reduction was 85% (from 420 mg to 66 mg daily). Minimal nephrotoxicity was seen.[34-36] A study in children with nephrotic syndrome found the addition of ketoconazole allowed a ciclosporin dose reduction of about 37%. They also found that those given ketoconazole (153 patients) had a lower frequency of renal impairment, were more likely to be able to stop taking steroids and had a better chance of staying in remission than those not given ketoconazole (54 patients).[37] Another similar study by this same research group found comparable results.[38]

Other reports[7,39-52] describe essentially similar rises in ciclosporin levels during the use of ketoconazole. The effects of ketoconazole on ciclosporin were found to be slightly increased (from 80 to 85% or from 77 to 84%) when diltiazem was also given.[26,53]

In a retrospective study an increased incidence of severe liver toxicity was seen in patients also taking ketoconazole when the method of monitoring ciclosporin levels was switched from trough levels (C_0) to taking levels 2 hours post dose (C_2). Liver toxicity developed in 26% of patients monitored solely using C_2 levels compared with no patients monitored using C_0 and C_2 levels.[54] For mention of a report of seizures occurring when ketoconazole was added to ciclosporin and high-dose methylprednisolone, see 'Ciclosporin + Corticosteroids', p.1235.

Topical ketoconazole 2% cream did not alter the response to oral ciclosporin 1 mg/kg daily in the treatment of contact allergic dermatitis.[55]

(d) Miconazole

A single case report describes a rise of about 65% in ciclosporin serum levels within 3 days of intravenous miconazole 1 g every 8 hours being started. Ciclosporin levels rose again during subsequent treatment with miconazole.[56]

(e) Posaconazole

Posaconazole 200 mg daily for 10 days was given to 4 heart transplant patients receiving stable doses of ciclosporin. Three of the 4 required modest dose reductions of between 14 and 29% to maintain ciclosporin levels.[57] In another report, increased ciclosporin levels occurred in just one of 12 transplant patients given posaconazole 800 mg daily. In this patient, the ciclosporin dose was decreased by 45% on starting posaconazole, and the ciclosporin level was normal 17 days later (193 nanograms/mL) at discharge. However, 7 days later the patient had altered mental status and very high ciclosporin levels. She had thrombotic thrombocytopenic purpura and pancytopenia and eventually died. The authors said it is not clear if this case represents a patient medication error, or an interaction.[58] The UK manufacturer also reports cases of ciclosporin toxicity that resulted in significant adverse effects, including nephrotoxicity and one fatal case of leukoencephalopathy, which occurred in posaconazole efficacy studies.[59]

(f) Voriconazole

In a placebo-controlled, crossover study, 14 kidney transplant patients receiving stable doses of ciclosporin were given voriconazole 200 mg every 12 hours for 15 doses. Of the 14 patients, 7 discontinued treatment during the voriconazole phase due to adverse effects, 4 due to raised ciclosporin levels (mean 2.48-fold), one due to raised liver function, one due to asthenia, dyspnoea and oedema, and one due to an underlying condition unrelated to the voriconazole. In the remaining 7 patients voriconazole increased the AUC of ciclosporin by 70%.[60] Ciclosporin levels were significantly *reduced* in a bone marrow transplant patient, from a range of 150 to 184 nanograms/mL to 56 to 111 nanograms/mL, when prophylactic voriconazole was *stopped* due to abnormal liver function tests. The levels returned to range when the voriconazole was restarted.[61]

Mechanism

The azole antifungals inhibit the cytochrome P450 isoenzyme CYP3A4, by which ciclosporin is metabolised, and as a result ciclosporin blood levels rise. The azoles vary in the potency of their effects on CYP3A4, see 'Azoles', (p.233). One review lists them in relative order of their effects on ciclosporin metabolism (most potent first): ketoconazole, followed by

itraconazole and voriconazole (roughly equipotent), and then fluconazole.[62] Further study into the relative potency of posaconazole is required.[62]

Fluconazole and ketoconazole also appear to inhibit the metabolism of ciclosporin by the gut wall.[16,50]

Importance and management

All the available azole antifungals can raise ciclosporin levels to varying degrees. The interaction between ciclosporin and **ketoconazole** is very well established and clinically important. Ciclosporin blood levels rise rapidly and sharply, but they can be controlled by reducing the ciclosporin dose by about 70 to 80%[7,24,34,41,51] thereby preventing kidney damage. A ciclosporin dose reduction of 68 to 89% was required over a 13-month period in one study, with no adverse changes in immunosuppressive activity, resulting in a total cost saving of about 65%, partially offset because of the need for more frequent patient follow-up and the cost of the ketoconazole.[34,35] Other studies have also suggested that this interaction can be exploited to make cost savings.[51,63,64] Reviews of the pros and cons of concurrent use have been published.[36,65] Ketoconazole may possibly have a kidney protective effect.[34,35] A study in kidney transplant patients suggested that variability in absorption and in the response to metabolic inhibition by ketoconazole made the ciclosporin blood level response difficult to predict and monitor.[66] There are also other confounding factors. For example, a patient who was given ketoconazole to increase ciclosporin levels was subsequently given famotidine. The famotidine raised gastric pH, which resulted in a reduction in the ketoconazole absorption, and the ciclosporin levels consequently fell.[67] Bear in mind the possibility that, in patients taking ketoconazole. monitoring the use of ciclosporin with ciclosporin levels taken 2 hours post-dose may not be the best method.[54,68]

Information about the use of ciclosporin with **fluconazole** or **itraconazole** is less extensive, but concurrent use should be closely monitored, being alert for the need to reduce the ciclosporin dose, in some cases by up to 50% or more, although some patients may demonstrate no significant changes at all. There is also some evidence that in the case of fluconazole, the interaction may possibly depend on its dose,[8] gender and ethnicity,[18] and the route of ciclosporin[16] or fluconazole[17] administration. Ciclosporin may increase the levels of the hydroxy metabolite of itraconazole, but the relevance of this is uncertain.

The interaction between *intravenous* **miconazole** and ciclosporin may be potentially serious and of clinical importance. There is no evidence of an interaction with other forms of miconazole. However, a large proportion of miconazole *oral* gel (both prescription and non-prescription doses) may be swallowed and therefore adequate systemic absorption may occur for interactions with other medications. The manufacturers of miconazole oral gel recommend close monitoring and possible dose reduction of ciclosporin if given concurrently.[69] An interaction with *intravaginal* miconazole would not normally be expected because its systemic absorption is usually very low (less than 2%) in healthy women of child-bearing age.[70] Similarly, an interaction with topical miconazole creams would also not be expected.

The manufacturers of **voriconazole** suggest that the dose of ciclosporin should be halved when initiating voriconazole, and that ciclosporin levels should be carefully monitored during voriconazole treatment. It is important that the ciclosporin dose is increased again as necessary if voriconazole is withdrawn.[71,72]

The manufacturers of **posaconazole** recommend that the dose of ciclosporin should be reduced by about 25% when posaconazole is started, with careful monitoring of ciclosporin levels and further dose adjustment as needed, including when posaconazole is stopped.[59,73] However, the authors of one review state that pre-emptive ciclosporin dose reductions when starting azoles are not standard practice among transplant clinicians, because of the concern of an increased risk of rejection[62] (due to subtherapeutic ciclosporin levels). Whatever is done, close monitoring is necessary. In addition, note that the UK manufacturer of posaconazole predicts that its levels will increased by ciclosporin as a result of P-glycoprotein inhibition.[59]

Ciclosporin + Basiliximab

Ciclosporin levels and adverse effects may be altered by basiliximab.

Clinical evidence, mechanism, importance and management

A study in 39 paediatric kidney transplant patients taking ciclosporin found that, in 24 patients who were also given basiliximab 10 or 20 mg on days 0 and 4 after transplantation, lower doses of ciclosporin resulted in significantly higher ciclosporin trough levels and some evidence of early ciclosporin toxicity within the first 10 days. At days 28 to 50, ciclosporin levels declined and 20% higher doses were required to maintain adequate trough levels in the basiliximab group.[1] Another study, in 54 paediatric liver transplant patients, found that the addition of basiliximab to ciclosporin and corticosteroids did not significantly alter the overall ciclosporin dose requirements. However, 9 patients given basiliximab experienced acute rejection at 21 to 28 days after transplantation, and this was associated with low ciclosporin trough levels, requiring an increased ciclosporin dose in 6 of the 9 patients.[2] It was suggested that the effect on ciclosporin was due to an interleukin-2 receptor mediated alteration of the cytochrome P450 enzyme system.[1] This was considered to only play a minor role in the liver transplant patients because of significantly lower target trough levels in these patients.[2] However, a further study found no increase in rejection rates between days 28 to 50 in kidney transplant patients given basiliximab and ciclosporin.[3]

The authors of the first study[1] recommend that the initial dose of ciclosporin should be limited to 400 mg/m^2 in children receiving kidney transplants who are also given basiliximab. Dose reductions were not considered necessary by other authors, but close monitoring was recommended.[2,3]

A retrospective analysis of kidney transplant patients compared the rates of acute rejection within 6 months in patients given ciclosporin, mycophenolate mofetil and prednisone, with or without basiliximab. Overall the rates of acute rejection were 11% and 23% in the basiliximab and no-basiliximab groups, respectively. In 74 patients not given basiliximab, low therapeutic ciclosporin exposure on day 3 was associated with increased acute rejection within the first 6 months post-transplantation (45% with ciclosporin AUC less than 4400 nanogram.h/mL compared with 15% with a ciclosporin AUC of greater than 4400 nanogram.h/mL). In 93 patients given basiliximab, rates of acute rejection were similar (about 10%) in patients with low or therapeutic ciclosporin exposure at day 3. It was suggested that achieving early ciclosporin therapeutic targets may not be required if basiliximab is also used.[4]

Ciclosporin + Benzbromarone

Benzbromarone does not appear to interact with ciclosporin.

Clinical evidence, mechanism, importance and management

Twenty-five kidney transplant patients taking ciclosporin were given benzbromarone 100 mg daily to treat hyperuricaemia. The plasma uric acid levels decreased from 579 micromol/L to 313 micromol/L and the 24-hour urinary uric acid secretion rose from 2082 micromol to 3233 micromol after 4 weeks of treatment. The plasma uric acid levels normalised in 21 of the patients who had creatinine clearances of over 25 mL/minute. No significant adverse effects developed and the ciclosporin serum levels remained unchanged. The authors of the report emphasise the advantages of benzbromarone over allopurinol because of its efficacy, lack of significant adverse effects and because, unlike allopurinol, it does not interact with azathioprine, which often accompanies ciclosporin treatment.[1]

1. Zürcher RM, Bock HA, Thiel G. Excellent uricosuric efficacy of benzbromarone in cyclosporin-A-treated renal transplant patients. A prospective study. *Nephrol Dial Transplant* (1994) 9, 548–51.

Ciclosporin + Berberine

Berberine appears to increase the bioavailability and trough blood levels of ciclosporin.

Clinical evidence, mechanism, importance and management

A study in 6 kidney transplant patients looked at the effects of berberine on the pharmacokinetics of ciclosporin. The patients were taking ciclosporin 3 mg/kg twice daily for an average of 12 days before berberine 200 mg three times daily for 12 days was added. The AUC and trough blood levels of ciclosporin were increased by 35% and 88%, respectively. The peak ciclosporin level was decreased but this was not statistically significant.[1] A clinical study by the same authors in 52 kidney transplant patients stable taking ciclosporin and given berberine 200 mg three times daily for 3 months found that the ciclosporin trough levels were increased by about 24% when the berberine-treated group was compared with 52 similar patients taking ciclosporin without berberine. The ciclosporin levels in 8 patients fell after berberine was stopped. Creatinine clearance was not significantly altered, and no serious adverse effects were reported.[1]

A single-dose study in healthy subjects found conflicting results. Six subjects given a single 6-mg/kg dose of ciclosporin daily found that berberine 300 mg twice daily, taken for 10 days before the dose of ciclosporin, had no significant effects on the pharmacokinetics of ciclosporin. However, a separate study in another 6 subjects given a single 3-mg/kg dose of ciclosporin found that a single 300-mg dose of berberine increased the AUC of ciclosporin by 19%. No adverse events were reported in this study.[2]

Mechanism

The mechanism for the increase in ciclosporin levels seen in the clinical studies is unclear, although it has been suggested that it may be due to inhibition of CYP3A by berberine.

Animal studies[3,4] suggest that ciclosporin may also affect the handling of berberine possibly by inhibiting P-glycoprotein, therefore affecting its intestinal absorption and its distribution into the bile and liver.

Importance and management

Although the increase in ciclosporin levels is not sufficiently severe to suggest that the concurrent use of berberine should be avoided, it may make ciclosporin levels less stable. If concurrent use is undertaken, ciclosporin levels should be well monitored, and the dose of ciclosporin adjusted accordingly.

Ciclosporin + Beta blockers

Carvedilol may modestly increase ciclosporin levels in some patients. In general, atenolol and metoprolol do not appear to interact with ciclosporin.

Clinical evidence

A study in 21 kidney transplant patients found that when **atenolol** was gradually replaced by **carvedilol** in a stepwise manner, starting with **carvedilol** 6.25 mg daily, gradually increasing to 50 mg daily, the ciclosporin dose had to be gradually reduced. At 90 days the ciclosporin dose had been reduced by 20% (from 3.7 to 3 mg/kg daily) to maintain levels within the therapeutic range but considerable inter-individual variations were seen.[1] A retrospective study in 12 heart transplant patients found that **carvedilol** increased the ciclosporin level in 10 patients from a mean of 257 nanograms/mL to 380 nanograms/mL. This required a mean dose reduction of 31 mg daily (10%). In the same study, 20 patients taking **metoprolol** were also assessed. Twelve patients had a decrease and 8 patients an increase in their ciclosporin levels, although the overall mean change was only 1 nanogram/mL. However, in one case, metoprolol appears to have increased the ciclosporin levels from about 300 nanograms/mL to 900 nanograms/mL, but insufficient detail is given to be able to assess this finding. None of these changes with **metoprolol** required any significant ciclosporin dose alterations (mean dose alteration 0.03%).[2] A study in 30 kidney transplant patients found no change in the ciclosporin levels of those taking **atenolol** 25 to 100 mg daily.[3]

Mechanism

Carvedilol appears to increase ciclosporin levels by inhibiting P-glycoprotein.[4]

Importance and management

The modest interaction of carvedilol with ciclosporin would appear to be established. The manufacturers of carvedilol recommend close monitoring of ciclosporin levels with appropriate dose adjustment when carvedilol is added,[5,6] which seems prudent. In general it appears that no ciclosporin dose adjustment would be expected to be needed in patients taking metoprolol. Atenolol does not appear to interact with ciclosporin.

Ciclosporin + Bifendate

Two case reports suggest that bifendate can cause a gradual fall in the serum levels of ciclosporin, and a modest reduction in ciclosporin levels was seen in one study in healthy subjects.

Clinical evidence

Two kidney transplant patients were successfully treated with ciclosporin and prednisolone for 30 months and 36 months. When they were given bifendate 75 mg daily for the treatment of chronic hepatitis, both of them had a gradual fall in their trough serum ciclosporin levels. The ciclosporin levels of the first patient fell from 97.7 nanograms/mL to 78 nanograms/mL at 4 weeks, and fell further, to 49 nanograms/mL, at 6 weeks. The other patient had a fall from 127.5 nanograms/mL to 70.5 nanograms/mL at 8 weeks and to 45 nanograms/mL at 16 weeks. The ciclosporin doses remained unchanged throughout, and despite the low serum levels that occurred, no graft rejection was seen. When the bifendate was stopped, ciclosporin levels gradually climbed again, at about the same rate as their decline, to about their former levels.[1] In a subsequent placebo-controlled study in 18 healthy subjects, bifendate 15 mg three times daily for 14 days decreased the AUC of ciclosporin by 10 to 38% after a single oral dose of ciclosporin, and increased the oral clearance by 10 to 32%.[2]

Mechanism

The reasons for this interaction are not understood. It is possible that bifendate is acting as an inducer of the cytochrome P450 isoenzyme CYP3A4,[2] which is the major isoenzyme involved in ciclosporin metabolism.

Importance and management

The available information suggests that a modest interaction might occur between bifendate and ciclosporin, therefore it would be prudent to monitor the outcome, being alert for the need to increase the ciclosporin dose if bifendate is used. Bifendate is derived from *Schisandra* therefore, until more is known, it might be wise to extend this caution to all herbal preparations containing *Schisandra*. However, in contrast to the above data, an extract from *Schisandra sphenanthera* increased the levels of tacrolimus, which is also a substrate of CYP3A4, see 'Tacrolimus + Schisandra', p.1308.

Ciclosporin + Bile acids or Ursodeoxycholic acid (Ursodiol)

Ursodeoxycholic acid unpredictably increases the absorption and raises the levels of ciclosporin in some but not all patients. Bile acids (cholic and dehydrocholic acids) appear not to interact with ciclosporin.

Clinical evidence

(a) Bile acids

In a study, 11 healthy subjects were given a single oral dose of ciclosporin on three occasions: while fasting, with breakfast, and with breakfast plus bile acid tablets (**cholic acid** 400 mg, **dehydrocholic acid** 100 mg): the mean ciclosporin AUCs were 7283 nanograms/mL, 7453 nanograms/mL and 9078 nanograms/mL, respectively, indicating that the bile acids increased the absorption of ciclosporin by 22%.[1] However, a related study in 19 transplant patients found that their 12-hour trough ciclosporin serum levels were unchanged by the concurrent use of this dose of bile acids over an 8-day period.[1]

(b) Ursodeoxycholic acid (Ursodiol)

When a heart transplant patient who had previously had his entire ileum removed and about one metre of the residual jejunum anastomosed to the transverse colon started taking ursodeoxycholic acid 1 to 2 g daily, it was possible to reduce his ciclosporin dose from 1.6 to 1.2 g daily. However, when the ursodeoxycholic acid was stopped, his ciclosporin serum levels became subtherapeutic and severe acute rejection developed. The ciclosporin levels rose when ursodeoxycholic acid was restarted, and the ciclosporin AUC was increased by more than threefold.[2] Similarly, the trough serum ciclosporin levels of a patient with chronic active hepatitis C increased from 150 nanograms/mL to 500 nanograms/mL when he was given ursodeoxycholic acid, and it was necessary to halve his daily ciclosporin dose to keep the ciclosporin levels at 150 nanograms/mL.[3]

In contrast, various other studies[4-6] and one case report[7] have shown little or no effect of ursodeoxycholic acid on ciclosporin levels. In one of these in liver transplant patients, there was no difference in ciclosporin (*Sandimmun*) dose requirements between 17 patients given ursodeoxycholic acid 15 mg/kg daily for 3 months and 16 patients given placebo.[6] Similarly, in 7 liver transplant patients there were no statistically significant changes in mean ciclosporin levels when a single 600-mg dose of ursodeoxycholic acid was given at the same time as the ciclosporin (*Sandimmun*).[4] Yet another study in 12 liver transplant patients, 6 of whom were cholestatic, found that ciclosporin (*Sandimmun*) was absorbed more rapidly after a single dose of ursodeoxycholic acid in 8 patients, but, although 7 patients had some rise in their AUC, the mean 24-hour AUC was not significantly changed. There was no consistent improvement in ciclosporin pharmacokinetics in the cholestatic patients.[5]

Furthermore, variable effects were seen in another study using the microemulsion formulation of ciclosporin (*Neoral*) in liver transplant recipients. Ursodeoxycholic acid appeared to *reduce* the absorption rate and bioavailability of ciclosporin in 9 patients without cholestasis, but increased the absorption rate and bioavailability in 3 cholestatic patients.[8]

Mechanism

When an interaction occurs it is thought to do so because the ursodeoxycholic acid improves micellation of the oil-containing oral ciclosporin formulation so that its absorption is increased.[2]

Importance and management

Information is limited but bile acids do not appear to interact with ciclosporin. However, the effects of the interaction with ursodeoxycholic acid appears to be variable and unpredictable. It would therefore be prudent to monitor the effects of adding or stopping ursodeoxycholic acid in any patient taking ciclosporin, being alert for the need to adjust the ciclosporin dose.

Ciclosporin + Bupropion

An isolated case describes a large decrease in ciclosporin levels when a 10-year-old boy was given bupropion.

Clinical evidence, mechanism, importance and management

A 10-year-old boy, who had received a heart transplant 6 years previously, started taking bupropion 75 mg twice daily in addition to his usual transplant medication, which included ciclosporin. After taking bupropion for 22 days, his ciclosporin level was found to be only 39 nanograms/mL. The last level taken before bupropion treatment had been 197 nanograms/mL. Despite an increase in his ciclosporin dose from 420 to 500 mg daily, the ciclosporin levels fell further, to 27 nanograms/mL. The ciclosporin dose was then increased to 550 mg daily and bupropion was stopped.[1]

The reason for this probable interaction is unclear, although an interaction via the cytochrome P450 isoenzyme CYP3A4 is a possibility. This appears to be the only reported case of an interaction between ciclosporin and bupropion, and its general importance is unknown.

Ciclosporin + Calcium-channel blockers

Diltiazem, nicardipine and verapamil markedly raise ciclosporin levels, but also appear to possess kidney protective effects. Nifedipine normally appears not to interact, but rises and falls in ciclosporin levels have been seen in a few patients. Amlodipine has modestly increased ciclosporin levels in some studies, but not in others, and it may also have kidney protective properties. A single case describes elevated ciclosporin levels caused by nisoldipine. Felodipine, isradipine, lacidipine and nitrendipine normally appear not to raise ciclosporin levels. Ciclosporin has been seen to markedly increase lercanidipine levels, and modestly increase felodipine levels. The concurrent use of calcium-channel blockers and ciclosporin increases the risk of gingival overgrowth.

Clinical evidence

(a) Ciclosporin levels and nephrotoxicity

1. Amlodipine. Ten hypertensive patients with kidney transplants taking ciclosporin (3 of them also taking azathioprine) were given amlodipine 5 to 10 mg daily for 4 weeks. The hypertension was well controlled, the drugs were well tolerated, and the pharmacokinetics of ciclosporin were unaltered by amlodipine.[1] However, another study in 11 hypertensive kidney transplant patients found that amlodipine, given for 7 weeks, increased the ciclosporin levels by an average of 40%, without affecting creatinine levels.[2] A review identified two other studies that have found increases in ciclosporin levels of 23% and 43% with amlodipine, whereas four studies have found no change.[3] Amlodipine is reported to reduce ciclosporin-associated nephrotoxicity in a study in patients with psoriasis,[4] and in a review of kidney transplant recipients.[3]

2. Diltiazem. A pharmacokinetic study in 9 patients taking ciclosporin found that the addition of diltiazem 180 mg daily increased the trough blood level, maximum blood level and half-life of ciclosporin by 112%, 37%, and 43%, respectively.[5] Sixty-five kidney transplant patients taking ciclosporin and diltiazem were found to need less ciclosporin when compared with 63 control patients not given diltiazem (7.3 mg/kg daily compared with 9 mg/kg daily). There were considerable individual differences in dose requirements.[6] Other studies clearly confirm that diltiazem can raise ciclosporin blood levels.[7-32] In some cases the ciclosporin blood levels were not only controlled by reducing the ciclosporin dose by 30 to 60%, but it appeared that diltiazem had a kidney protective role (reduced nephrotoxicity, fewer rejection episodes and haemodialysis sessions).[11,22,33-37] Another study found that a reduction in ciclosporin dose of about 21% was required for both men and women during the long-term use of diltiazem 90 mg twice daily, despite reports of higher activity of the cytochrome P450 isoenzyme CYP3A4 in women than in men.[38]

3. Felodipine. Thirteen kidney transplant patients had no significant changes in their serum ciclosporin levels when they took felodipine 2.5 to 10 mg daily; serum creatinine levels were also unchanged. Mean blood pressures fell from 161/100 mmHg to 152/90 mmHg.[39] Another study found no significant changes in ciclosporin levels in patients also given felodipine.[40] A single 10-mg dose of felodipine was found to have beneficial effects on blood pressure, renal haemodynamics, and renal tubular sodium and water handling in kidney transplant patients taking ciclosporin. The effects of long-term use were not studied.[41] A single-dose study in 12 healthy subjects found that the maximum serum levels of ciclosporin 5 mg/kg were slightly raised by 16% by felodipine 10 mg, while the AUC and maximum plasma level of felodipine were raised by 58% and 151%, respectively, but blood pressures were unchanged.[42] The same group of researchers also briefly described acute and short-term studies in groups of kidney transplant patients and dermatological patients, which found that felodipine 5 to 10 mg reduced blood pressure and opposed ciclosporin nephrotoxicity.[43] A study in heart transplant patients taking ciclosporin found that felodipine attenuated the hypertrophic effects of ciclosporin on transplanted hearts.[44]

4. Isradipine. Twelve kidney transplant patients had no changes in their ciclosporin levels over 4 weeks while taking up to 2.5 mg of isradipine twice daily.[45] Similar findings are noted in another study.[40] Three other studies in 31 kidney transplant patients confirmed that ciclosporin blood levels are unchanged by isradipine and blood pressures are reduced.[46-48]

5. Lacidipine. Ten kidney transplant patients taking ciclosporin, prednisone and azathioprine started taking lacidipine 4 mg daily. A very small increase in the trough blood levels (6%) and AUC (14%) of the ciclosporin occurred. The blood pressures fell from 142/93 mmHg to 125/79 mmHg, and the 14-hour urinary output rose from 1401 mL to 2050 mL.[49]

6. Lercanidipine. The manufacturer notes that, in healthy subjects given lercanidipine and ciclosporin simultaneously, the plasma levels of lercanidipine were raised threefold by ciclosporin, and the ciclosporin AUC was raised by 21% by lercanidipine. When the ciclosporin was given 3 hours after the lercanidipine, the levels of lercanidipine did not change, and the AUC of ciclosporin increased by 27%.[50]

7. Nicardipine. In a study in 9 patients, nicardipine 20 mg three times daily increased the ciclosporin blood levels by 110% (from 226 to 430 nanograms/mL, range 24 to 341%). Their serum creatinine concentrations rose from 136 micromol/L to 147 micromol/L.[51] Other studies have found increases in serum ciclosporin levels, in some cases as much as two- to threefold, when nicardipine was given.[52-58]

8. Nifedipine. Five of 9 patients who had an increase in ciclosporin levels with nicardipine (see *Nicardipine*, above) had no interaction when they were given nifedipine.[51] No changes in ciclosporin levels were seen in other studies,[36,59-63] but raised[17,20] and reduced levels[64] have been reported in others. Two studies found that nifedipine appeared to protect patients against ciclosporin-induced nephrotoxicity.[65,66] However, there is some evidence that the adverse effects of nifedipine such as flushing and rash may be increased.[67] For a discussion of gingival overgrowth, see under *Gingival overgrowth*, below.

9. Nisoldipine. A 46-year-old man taking azathioprine, prednisolone and ciclosporin after a kidney transplant 18 months previously was given nisoldipine 5 mg twice daily. During the following month his ciclosporin levels rose from a range of 100 to 150 micrograms/L up to 200 micrograms/L and an increase in serum creatinine levels occurred. His ciclosporin dose was gradually reduced from 325 to 250 mg daily, and his ciclosporin and creatinine levels returned to the acceptable range.[68]

10. Nitrendipine. Nitrendipine 20 mg daily for 3 weeks had no significant effect on the ciclosporin blood levels in 16 kidney transplant patients.[69]

11. Verapamil. Twenty-two kidney transplant patients given ciclosporin and verapamil had ciclosporin blood levels that were 50 to 70% higher than in 18 other patients not given verapamil, despite similar ciclosporin doses in both groups. Serum creatinine levels were lower in those taking verapamil. Moreover, only 3 of the 22 patients had rejection episodes within 4 weeks compared with 10 out of 18 patients not given verapamil.[70] Other studies have found that verapamil 120 to 320 mg daily can increase, double or even triple ciclosporin blood levels in individual patients with kidney or heart transplants.[24,40,62,64,71-75]

(b) Gingival overgrowth

Both ciclosporin and calcium-channel blockers are well-known to be associated with gingival overgrowth in transplant recipients, and there is evidence that concurrent use exacerbates this effect. In a randomised, controlled study, **nifedipine** increased the frequency and severity of gingival overgrowth seen with ciclosporin. After 3 months of treatment, 0 of 15 patients taking ciclosporin (17 mg/kg daily gradually reduced to 7 mg/kg daily) had moderate to severe overgrowth (grade 3 or 4) compared with 9 of 17 patients receiving the same ciclosporin regimen with **nifedipine**.[76] Many other cohort studies (two are cited as examples[77,78]) but by no means all (one is cited as an example[79]) have reported similar findings for **nifedipine**.

There are fewer data on other individual calcium-channel blockers. In one cohort study in patients taking ciclosporin, there was a higher incidence of gingival overgrowth in those receiving **amlodipine** than in those receiving **nifedipine** (72% versus 53%).[80] Conversely, in another cohort study, the incidence of gingival overgrowth was higher with **nifedipine** (86%) than **amlodipine** (47%) or **verapamil** (35%).[81] In one study of **verapamil**, patients taking the combination had a slightly higher incidence and severity of gingival overgrowth than ciclosporin alone, but this was not statistically significant.[82] In another study, **diltiazem** did not increase gingival overgrowth, but neither did **nifedipine**.[79]

Various other cohort studies have found that calcium-channel blockers as a class (individual drugs not specified) are associated with an increased risk of gingival overgrowth when used with ciclosporin. One is cited as an example.[83]

Mechanism

The increased ciclosporin levels are largely due to inhibition of ciclosporin metabolism by the cytochrome P450 isoenzyme CYP3A4 in the liver. Diltiazem and verapamil are moderate CYP3A4 inhibitors, however other calcium-channel blockers do not generally cause significant inhibition of CYP3A4, see 'Calcium-channel blockers', (p.1025). Diltiazem also appears to reduce ischaemia-induced renal tubular necrosis.[84] Other calcium-channel blockers also seem to have a kidney-protective effect. The raised felodipine and lercanidipine levels are possibly due to competitive inhibition by ciclosporin of intestinal and liver metabolism (by CYP3A4), or inhibition of P-glycoprotein. Whether ciclosporin affects other calcium-channel blockers similarly does not appear to have been studied.

Both ciclosporin and calcium-channel blockers can cause gingival overgrowth, and this effect is probably additive.

Importance and management

The **pharmacokinetic interactions** of ciclosporin with diltiazem, nicardipine and verapamil are established and relatively well documented. Concurrent use need not be avoided, but ciclosporin levels should be well monitored and dose reductions made as necessary. Even though ciclosporin blood levels are increased, these calcium-channel blockers appear to have a kidney protective effect. One study[85] noted that, although calcium-channel blockers increase ciclosporin blood levels, this is of no harm to the patient, as no changes in renal function were observed. With diltiazem and verapamil the ciclosporin dose can apparently be reduced by about 25 to 50% and possibly more with nicardipine. One case suggests that this is also true with nisoldipine. Several studies suggest that substantial cost savings can be made by giving either diltiazem[13,86,87] or verapamil[24] with ciclosporin. Take care not to substitute one diltiazem product for another after the patient has been stabilised because there is evidence that their bioequivalence differences may alter the extent of the interaction.[27,88] The situation with nifedipine is not totally clear (no effect or decreases or increases), but it appears to have a kidney protective effect[63] as does felodipine. The situation with amlodipine is also uncertain, but isradipine, lacidipine and nitrendipine appear to be non-interacting alternatives. Many of the calcium-channel blockers have a kidney protective effect. The increase in lercanidipine levels is such that the manufacturer says that lercanidipine and ciclosporin should not be given together,[50] and the manufacturer of ciclosporin recommends caution.[89] Ciclosporin modestly increases felodipine levels, which would not be clinically relevant, and its effect on the levels of other calcium-channel blockers does not appear to have been studied.

The increased risk of **gingival overgrowth** when calcium-channel blockers are used with ciclosporin also appears to be established, with most data relating to nifedipine. Note that the UK manufacturer of ciclosporin specifically recommends avoiding nifedipine in patients who develop gingival overgrowth whilst taking ciclosporin.[89] It might be prudent to apply this to all calcium-channel blockers, when possible. Note that tacrolimus has been suggested as an alternative to ciclosporin,

although it is not entirely free from gingival adverse effects. The ACE inhibitors may be suitable alternatives to the calcium-channel blockers, but they are not entirely free of problems when used with ciclosporin (see 'Ciclosporin + ACE inhibitors or Angiotensin II receptor antagonists', p.1211). Note that a useful paper about minimising the risk of gingival overgrowth and its management has been published.[90]

Ciclosporin + Chlorambucil

An isolated report describes a reduction in ciclosporin levels in a patient given chlorambucil.

Clinical evidence, mechanism, importance and management

A woman with B-chronic lymphocytic leukaemia and autoimmune haemolytic anaemia controlled with ciclosporin started taking chlorambucil 5 mg daily because of disease progression. When she reached a total cumulative dose of chlorambucil of 200 mg she suddenly relapsed, and her serum ciclosporin levels were found to have dropped to 60 nanograms/mL from a range of 200 to 400 nanograms/mL. The ciclosporin levels remained low despite a doubling of the ciclosporin dose and withdrawal of the chlorambucil. Only after one month did the anaemia respond and the ciclosporin levels rise again.[1] This appears to be an isolated report so the general significance of this interaction is unclear.

1. Emilia G, Messora C. Interaction between cyclosporin and chlorambucil. *Eur J Haematol* (1993) 51, 179.

Ciclosporin + Chloroquine or Hydroxychloroquine

Three transplant patients had rapid rises in ciclosporin levels, with evidence of nephrotoxicity in two of them, when they were given chloroquine. Neither chloroquine nor hydroxychloroquine altered the incidence of raised creatinine levels seen with low-dose ciclosporin in rheumatoid arthritis.

Clinical evidence

(a) Chloroquine

A kidney transplant patient taking ciclosporin, azathioprine and prednisolone had a threefold rise in ciclosporin blood levels, from 148 nanograms/mL to 420 nanograms/mL, accompanied by a rise in serum creatinine levels within 48 hours of starting chloroquine 900 mg daily for suspected malarial fever. On days 2 and 3 the chloroquine dose was reduced to 300 mg daily. The ciclosporin and creatinine returned to their former levels 7 days after the chloroquine was stopped.[1]

When another kidney transplant patient taking ciclosporin, azathioprine and prednisolone was given chloroquine 100 mg daily for 6 days, his ciclosporin serum levels rose from 105 nanograms/mL to 470 nanograms/mL and his serum creatinine levels rose from 200 micromol/L to 234 micromol/L, accompanied by a rise in blood pressure from 130/80 mmHg to 160/100 mmHg. These changes reversed when the chloroquine was stopped, and occurred again when chloroquine was restarted.[2] The ciclosporin serum levels of another patient were doubled by chloroquine 100 mg daily.[3]

A randomised, controlled study in 88 patients with recent onset rheumatoid arthritis found that the addition of ciclosporin (1.25 or 2.5 mg/kg daily) to chloroquine 100 mg daily was moderately effective, but changes in serum creatinine levels occurred. In the presence of chloroquine, the creatinine was not significantly altered by placebo or ciclosporin 1.25 mg/kg, but was raised by 10 micromol/L by ciclosporin 2.5 mg/kg, indicating that some renal effects can occur.[4] However, as there was no group given ciclosporin alone, it is not possible to say if the renal effects were due to an interaction with chloroquine, or just due to ciclosporin alone. The results of a further study suggest that they were probably due to ciclosporin alone: there was no difference in the incidence of increased creatinine levels between rheumatoid arthritis patients taking ciclosporin 2.5 mg/kg daily alone or the same dose of ciclosporin with chloroquine 150 mg daily. Note that in this study, there was no advantage to using the combination.[5]

(b) Hydroxychloroquine

In a randomised study in rheumatoid arthritis patients receiving ciclosporin 3 mg/kg daily alone or the same dose of ciclosporin with hydroxychloroquine 400 mg daily, there was no difference in incidence of renal impairment or in temporary or permanent reductions in ciclosporin dose between the groups. Note that in this study, there was no advantage to using the combination.[6]

Mechanism

The reason for the increased ciclosporin levels in these few cases is not understood.

Importance and management

Information is limited, but it would be prudent to monitor for increases in serum ciclosporin levels when chloroquine is given to patients receiving high ciclosporin doses. In the setting of the use of low-dose ciclosporin in rheumatoid arthritis, neither chloroquine nor hydroxychloroquine appear to contribute to the known adverse effects of ciclosporin on creatinine and renal function.

Ciclosporin + Cinacalcet

Cinacalcet does not appear to affect ciclosporin trough levels. In some studies it has caused a slight decrease in renal function in patients taking ciclosporin.

Clinical evidence

In a pharmacokinetic study in 8 kidney transplant patients taking ciclosporin, cinacalcet 30 mg daily for 6 days had no effect on the pharmacokinetics of ciclosporin, but there was a minor 9% increase in the AM19 metabolite of ciclosporin. The increase in this metabolite correlated with a small decrease in renal function (from 78 to 72 mL/minute).[1]

In clinical use, no changes in ciclosporin trough levels have been seen. For example, in one 3-month study in 13 transplant patients, there was no change in ciclosporin trough levels after one, 2 and 3 months use of cinacalcet 30 mg daily.[2] In two other reports, no change in ciclosporin dose was needed in patients when they were given cinacalcet, initially 30 mg daily then titrated to effect, for 6 months.[3,4] One of these studies did find a decrease in glomerular filtration rate and a modest increase in serum creatinine levels (from 140 micromol/L to 153 micromol/L at 2 months and 148 micromol/L at 3 months).[2] Another found that serum creatinine and creatinine clearance were stable during 6 months use of cinacalcet.[3]

Mechanism

The slight impairment in renal function in patients taking ciclosporin might be due to cinacalcet increasing levels of the ciclosporin AM19 metabolite, but the mechanism for this is unclear.

Importance and management

Cinacalcet does not appear to alter ciclosporin levels, and so no ciclosporin dose adjustment is likely to be necessary with concurrent use. Further study is needed to establish any possible impairment of renal function when cinacalcet is used with ciclosporin and to assess its clinical relevance. Until more is known, bear the possibility of adverse renal effects in mind.

Ciclosporin + Clodronate

Clodronate does not appear to alter ciclosporin blood levels.

Clinical evidence, mechanism, importance and management

Ten heart transplant patients taking ciclosporin, azathioprine and diltiazem were also given clodronate 800 mg daily for one week. No statistically significant differences were seen in their ciclosporin blood levels or AUCs. Three of them were also taking simvastatin, two were taking ranitidine and one was taking propafenone, furosemide and cyclophosphamide. There would seem to be no reason for avoiding concurrent use, but the authors of the report suggest that longer-term use of clodronate should be well monitored.[1] There seems to be no information about other bisphosphonates.

1. Baraldo M, Furlanut M, Puricelli C. No effect of clodronate on cyclosporin A blood levels in heart transplant patients simultaneously treated with diltiazem and azathioprine. *Ther Drug Monit* (1994) 16, 435.

Ciclosporin + Clonidine

A child taking ciclosporin had a marked rise in his ciclosporin blood levels when clonidine was also given.

Clinical evidence, mechanism, importance and management

A 3-year-old kidney transplant patient taking ciclosporin, azathioprine and prednisone was given a combination of propranolol, hydralazine, furosemide and nifedipine postoperatively in an attempt to control his blood pressure. Minoxidil was added, but was considered unacceptable because of adverse cosmetic effects. When it was replaced with clonidine, the ciclosporin levels increased about threefold to 927 nanograms/mL, despite a ciclosporin dose reduction. Ciclosporin levels returned to the patient's normal range of 150 to 300 nanograms/mL when the clonidine was withdrawn, and blood pressure was controlled by the addition of an ACE inhibitor. It was suggested that clonidine inhibited the metabolism of ciclosporin by cytochrome P450.[1]

As this appears to be the only report of an interaction, there is insufficient evidence to recommend routinely increasing the monitoring of ciclosporin levels in every patient taking these drugs. However, the possibility of an interaction should still be considered if both drugs are given.

1. Gilbert RD, Kahn D, Cassidy M. Interaction between clonidine and cyclosporine A. *Nephron* (1995) 71, 105.

Ciclosporin + Coenzyme Q_{10} (Ubidecarenone)

Coenzyme Q_{10} did not alter ciclosporin levels in a clinical study.

Clinical evidence, mechanism, importance and management

In a study in 11 renal transplant patients, coenzyme Q_{10} 30 mg three times daily for 4 weeks did not alter the serum levels of creatinine or ciclosporin (137 to 155 nanograms/mL). This suggests no ciclosporin dose adjustment is likely to be needed on the concurrent use of coenzyme Q_{10}.[1]

Ciclosporin + Colchicine

A number of cases of serious muscle disorders (myopathy, rhabdomyolysis), a few with multiple organ failure, have been seen when colchicine and ciclosporin were given concurrently. Ciclosporin toxicity has also been seen rarely.

Clinical evidence

A patient taking ciclosporin, azathioprine, prednisone and colchicine 1.2 mg daily immediately after a renal transplant developed colchicine neuromyopathy (possibly rhabdomyolysis), ciclosporin nephrotoxicity and liver function abnormalities within 31 days.[1] Many other reports have described myopathy (muscle weakness, myalgia) or rhabdomyolysis in patients who took ciclosporin and colchicine,[2-13] some with multiple organ failure.[13] These have occurred after just 3 days of colchicine administration[6] or after many months of combined use.[9,12] At the time of the development of toxicity, ciclosporin levels were normal in many cases,[4,6,10,13] but raised in some.[9] Raised creatine kinase levels have been a feature of many cases, but not all.[12] The incidence of myopathy may be high. For example, in one retrospective study, 5 of 10 renal transplant patients who had received colchicine with ciclosporin experienced muscular symptoms after a mean of 12 months of colchicine therapy. This improved after colchicine withdrawal.[8] In another study in four renal transplant patients with familial Mediterranean fever taking colchicine, an attempt to replace azathioprine with ciclosporin failed after 3 weeks because of pronounced adverse effects even before achieving therapeutic levels of ciclosporin. These included elevations in serum creatinine, liver enzymes and bilirubin, and one patient was hospitalised for general muscle weakness and severe myalgia.[4]

Another kidney transplant patient had a transient rise (lasting 2 to 3 days) in serum creatinine and ciclosporin blood levels, from 100 to 200 nanograms/mL up to 1519 nanograms/mL one day after receiving a total of 4 mg of colchicine.[14]

Mechanism

Myotoxiciy is a known adverse effect of colchicine alone, which is more common in renal impairment because this reduces its excretion. Myopathy has also occurred with ciclosporin alone.[2,15] The myotoxic effects of both ciclosporin and colchicine might be additive or synergistic.[16] In addition, patients taking ciclosporin who develop ciclosporin-impaired renal function are likely to accumulate colchicine and be at greater risk of colchicine toxicity.[16] Moreover, ciclosporin might directly increase colchicine levels, because it inhibits P-glycoprotein and might thereby impair colchicine excretion.[10]

Importance and management

The overall picture presented by these reports is not totally clear. However, it appears that the risk of colchicine-induced muscle toxicity is increased in patients taking ciclosporin. If concurrent use is thought to be appropriate, it should be very carefully monitored because the outcome can be serious. Patients should be reminded to report any unexplained muscle pain, tenderness or weakness or dark urine.

Ciclosporin + Colestyramine

Colestyramine does not appear to alter ciclosporin levels.

Clinical evidence, mechanism, importance and management

Five transplant patients taking ciclosporin and colestyramine had their colestyramine suspended for one week. It was then restarted for one week, and given simultaneously with ciclosporin on the day of testing. There was no difference in the peak and trough levels of ciclosporin and a non-significant average increase (6%) in the AUC of ciclosporin, but one patient had a 55% increase and another a 23% decrease in the AUC of ciclosporin.[1] In another pharmacokinetic study in 6 kidney transplant patients, colestyramine 4 g daily caused no significant change in the ciclosporin AUC, peak and trough levels.[2] Ciclosporin was given at 8 am and 8 pm, with colestyramine taken at noon. Similarly, in a 12 month efficacy study, 18 heart transplant patients taking ciclosporin were randomised to receive colestyramine 4 g twice daily taken one to 2 hours after ciclosporin. Colestyramine had no effect on ciclosporin levels.[3]

In general, it appears that colestyramine has little effect on ciclosporin absorption. However, the occasional patient may be affected, and therefore, because of the clinical consequences of the loss of ciclosporin efficacy, it would seem prudent to separate the administration of colestyramine and ciclosporin. It is usually advised that colestyramine is given one hour before or 4 to 6 hours after other drugs.

Ciclosporin + Corticosteroids

Some evidence suggests that ciclosporin levels are raised or unchanged by high-dose methylprednisolone or reduced by prednisone. Ciclosporin can reduce the clearance of corticosteroids. Convulsions have been described during the concurrent use of ciclosporin and high-dose methylprednisolone, and the incidence of diabetes mellitus may also be increased. One case of osteonecrosis has been reported with high-dose topical betamethasone and ciclosporin.

Clinical evidence

(a) Betamethasone

A patient with psoriasis taking ciclosporin and applying an average of betamethasone 30 mg daily (as 15 g to 150 g of topical betamethasone 0.05% cream or ointment) developed avascular osteonecrosis of the femoral heads of both hip joints.[1]

(b) Methylprednisolone

A study found that the pharmacokinetics of methylprednisolone in patients taking ciclosporin and azathioprine varied widely between individual kidney transplant patients, but the mean values were similar to those found in normal subjects.[2] Another later study by the same research group confirmed that ciclosporin did not appear to affect methylprednisolone pharmacokinetics.[3]

The plasma ciclosporin levels of 22 out of 33 patients were reported to be more than doubled by intravenous methylprednisolone used for acute graft rejection, and the ciclosporin dose needed to be reduced in 6 patients.[4,5] Others have similarly observed that high doses of methylprednisolone increased or more than doubled ciclosporin levels.[6-8] However, a study found that trough ciclosporin levels were unchanged when an intravenous dose of ciclosporin was given with high-dose intravenous methylprednisolone, although the clearance of ciclosporin was slightly increased (by 20%) in 8 out of 9 patients.[9] In another analysis of the use of methylprednisolone in 17 rejection episodes in 13 patients, there was no change in ciclosporin levels before during and after methylprednisolone in most cases. Rises in ciclosporin levels occurred only in 3 rejection episodes in 3 patients, and these were not attributed to an interaction.[10]

A report describes 4 young patients (aged 10, 12, 13 and 18 years) who had undergone bone marrow transplants for severe aplastic anaemia and who developed convulsions when given high-dose methylprednisolone (5 to 20 mg/kg daily) and ciclosporin.[11] Convulsions also occurred in a 25-year-old woman given ciclosporin with high-dose methylprednisolone.[12] In another report, seizures occurred in 3 patients taking ciclosporin and high-dose methylprednisolone only after ketoconazole was added to permit a reduction in ciclosporin dose.[13]

A study of 314 kidney transplant patients during the period 1979 to 1987 found that the incidence of diabetes mellitus in those given ciclosporin and methylprednisolone was twice that of other patients given azathioprine and methylprednisolone. The diabetes developed within less than 2 months.[14]

(c) Prednisolone or Prednisone

A pharmacokinetic study in 40 patients found that the clearance of prednisolone was about 30% lower in those taking ciclosporin when compared with those taking azathioprine.[15] Another study in patients with kidney transplants by the same group of researchers reported a 25% lower clearance of prednisolone in the presence of ciclosporin.[16]

Other studies confirm that the clearance of prednisolone is about one-third lower in patients also taking ciclosporin and that it is lower at 3 to 6 months than at 2 to 4 weeks.[4,17] As a result, some patients develop signs of steroid toxicity (cushingoid symptoms and impaired glucose metabolism).[4] In contrast, these studies have all been questioned by the authors of another study, who found that the metabolism of prednisolone after an oral and intravenous dose did not differ between patients taking ciclosporin and those taking azathioprine.[18] Similarly, another study found no change in the pharmacokinetics of intravenous prednisolone before and after starting ciclosporin.[19]

A comparative study over a year, in two groups of kidney transplant patients taking ciclosporin and azathioprine, one group with and the other without prednisone, found that those taking prednisone had lower trough ciclosporin levels (about 10 to 20%) despite using the same or higher doses of ciclosporin.[20]

There is other evidence that low-dose prednisolone does not increase the immunosuppression of ciclosporin, but it can reduce ciclosporin nephrotoxicity.[21]

Mechanism

Uncertain. Some evidence suggests that ciclosporin reduces the metabolism of the corticosteroids by the liver thereby raising their levels,[4] but not all studies have found an interaction. *In vitro*, methylprednisolone inhibited the metabolism of ciclosporin.[22] There is some evidence that prednisolone-induced changes in lipoproteins may correlate with the changes in ciclosporin levels.[23] Corticosteroids are known to cause osteonecrosis and ciclosporin may depress bone resorption as well as bone remodelling.[1]

Importance and management

None of these adverse interactions is well established. Concurrent use is common and advantageous but be alert for any evidence of increased ciclosporin and corticosteroid effects.

It is not clear whether high-dose corticosteroids cause a rise in

ciclosporin levels or not. If they do, the authors of one report point out that this interaction could possibly lead to a misinterpretation of clinical data as a rise in serum creatinine levels in patients with kidney transplants is assumed to be due to rejection, unless proven otherwise. If a corticosteroid is then given, this could lead to increased ciclosporin levels, which might lead to the rejection episode being re-interpreted as ciclosporin nephrotoxicity.[5] It has been suggested that ciclosporin levels measured by [the non-specific] RIA (radioimmunoassay) method should be interpreted with caution in patients taking high-dose corticosteroids as the levels of ciclosporin metabolites, which can interfere with the test, may be altered.[9] However, a study using both [the non-specific] RIA method and HPLC did not find a difference in the interaction between the two methods.[10]

The contribution of ciclosporin and high-dose *topical* corticosteroid to the development of osteonecrosis in the isolated case report is not known.

Ciclosporin + Coumarins

A case report describes reduced ciclosporin levels and reduced warfarin efficacy in patients given both drugs concurrently. A further report describes a rise in serum ciclosporin levels when an unnamed anticoagulant was given. Other reports describe increased or decreased acenocoumarol effects and decreased ciclosporin levels in two patients given both drugs.

Clinical evidence

(a) Acenocoumarol

The anticoagulant dose of a patient taking acenocoumarol needed to be *reduced* by about half to maintain a therapeutic INR when he was given ciclosporin after a kidney transplant. The required dose of ciclosporin slightly decreased.[1] A patient taking acenocoumarol 32 mg per week was given ciclosporin for nephrotic syndrome. After 10 days his acenocoumarol dose needed to be *increased* to maintain a therapeutic INR, and the ciclosporin level was considered too low so the dose was increased from 100 to 150 mg daily. However, a further 10 days later (after the increase in the acenocoumarol dose) the ciclosporin level was even lower. Eventually the patient achieved therapeutic levels in the presence of acenocoumarol with a ciclosporin dose of 200 mg daily.[2]

(b) Warfarin

A man with erythrocyte aplasia effectively treated with ciclosporin for 18 months, relapsed within a week of starting warfarin. His ciclosporin levels had fallen from a range of 300 to 350 nanograms/mL down to 170 nanograms/mL. He responded well when the ciclosporin dose was increased from 3 to 7 mg/kg daily, but his prothrombin activity rose from 17% to 64% and he needed an increase in the warfarin dose to achieve satisfactory anticoagulation.[3] The patient was also taking phenobarbital. A woman with angioimmunoblastic T-cell lymphoma receiving chemotherapy developed a deep vein thrombosis and was therefore given heparin and later warfarin. When ciclosporin 300 mg daily was added, her INR decreased by about 40% and she needed a progressive warfarin dose increase from 18.75 to 27.5 mg per week.[4] Another report briefly states that the serum ciclosporin levels rose in a patient given a warfarin derivative.[5]

Mechanism

Unknown. Ciclosporin is an inhibitor of the cytochrome P450 isoenzyme CYP3A4 and of P-glycoprotein, but this isoenzyme and drug transporter have only a very minor role in coumarin metabolism. Warfarin is not known to affect the pharmacokinetics of other drugs.

Importance and management

Information about the interactions of the coumarins and ciclosporin seems to be limited to these few reports. They simply serve to emphasise the need to monitor concurrent use because the outcome is clearly uncertain.

Ciclosporin + Cyclophosphamide

Cyclophosphamide was found to reduce ciclosporin levels in a retrospective study.

Clinical evidence, mechanism, importance and management

A retrospective study in stem cell transplant patients found that the ciclosporin levels in 47 patients whose pre-transplant conditioning regimens contained cyclophosphamide were lower (149.7 nanograms/mL) than those in 56 patients whose regimens did not contain cyclophosphamide (217.3 nanograms/mL). However, there was no difference in the incidence of acute graft versus host disease of grade 2 or higher.[1] The reason for this possible interaction is not understood, and its clinical relevance is uncertain. Further study is needed.

Ciclosporin + Danazol

Marked increases in ciclosporin levels have been reported in patients taking danazol.

Clinical evidence

A 15-year-old girl, one-year post kidney transplant, taking ciclosporin and prednisone, had a marked rise in serum ciclosporin levels over about

2 weeks (from a range of 250 to 325 micromol/L up to 680 to 860 micromol/L) when she was given danazol 200 mg twice daily, even though the ciclosporin dose was reduced from 350 to 250 mg daily.[1]

Similar rises in ciclosporin levels were seen in another patient, from about 400 to 600 nanograms/mL on one occasion, and from 150 to about 450 nanograms/mL on another occasion, over about a 6-week period when danazol 400 mg daily and later 600 mg daily was given.[2] A 12-year-old boy needed a reduction in his ciclosporin dose from 10 to 2 mg/kg daily when danazol 400 mg twice daily was added.[3] A marked rise in ciclosporin blood levels has been described in 2 other patients when given danazol 200 mg three or four times daily.[4,5]

A pharmacokinetic study in one kidney transplant patient found that danazol 200 mg three times daily given with ciclosporin 120 mg twice daily, reduced the ciclosporin clearance by 50%, prolonged its half-life by 66%, and raised its AUC by 65% when compared with a 20% higher ciclosporin dose of 150 mg twice daily.[6]

A patient with aplastic anaemia taking ciclosporin was given danazol 200 mg daily for pancytopenia and endometriosis. Within 4 days the patient had epigastric pain, and elevated serum ciclosporin and creatinine levels. Danazol was stopped and the ciclosporin dose was halved. Two weeks later abrupt severe hepatic injury occurred and the patient died of liver failure, although this was thought to be due to danazol toxicity rather than the interaction.[7]

Mechanism

Uncertain. It has been suggested that danazol raises ciclosporin levels by inhibiting its metabolism, possibly by inhibiting the cytochrome P450 isoenzyme CYP3A4.[3] However, further study is needed to confirm this suggestion.

Importance and management

Although the information seems to be limited to these few reports the interaction is established. The ciclosporin levels of any patient who is given danazol should be carefully monitored, and dose adjustments made as necessary.

Ciclosporin + Disopyramide

An isolated report describes the development of nephrotoxicity, which was attributed to an interaction between ciclosporin and disopyramide.

Clinical evidence, mechanism, importance and management

Ten months after receiving a kidney transplant, a 40-year-old woman taking ciclosporin and methylprednisolone developed premature ventricular beats and was given oxprenolol. After 2 months she had shown no improvement so she started taking disopyramide 100 mg three times daily. Over the next week her serum creatinine rose from 88 micromol/L to 159 micromol/L, at which point the disopyramide was stopped, and her renal function returned to normal over the next week. As she had previously been stable taking ciclosporin, and, as nephrotoxicity had not been reported with disopyramide, an interaction was suspected.[1]

This interaction is unconfirmed and of uncertain clinical significance. There is insufficient evidence to recommend increased monitoring, but be aware of the potential for an interaction in the case of an unexpected response to treatment.

Ciclosporin + Diuretics

Isolated cases of nephrotoxicity have been described when patients taking ciclosporin were given either amiloride with hydrochlorothiazide, metolazone, or mannitol. Furosemide can possibly protect the kidneys against ciclosporin damage. The concurrent use of ciclosporin with thiazides, but not loop diuretics, may increase magnesium levels. The concurrent use of ciclosporin with potassium-sparing diuretics may cause hyperkalaemia. Eplerenone does not appear to affect the pharmacokinetics of ciclosporin and may reduce ciclosporin nephrotoxicity.

Clinical evidence, mechanism, importance and management

(a) Nephrotoxicity

A 39-year-old man taking ciclosporin, whose second kidney transplant functioned subnormally, and who required treatment for hypertension with atenolol and minoxidil, developed ankle oedema, which was resistant to **furosemide**, despite doses of up to 750 mg daily. When **metolazone** 2.5 mg daily was added for 2 weeks his serum creatinine levels more than doubled (from 193 to 449 micromol/L). When **metolazone** was stopped the creatinine levels fell again. Ciclosporin serum levels were unchanged and neither graft rejection nor hypovolaemia occurred.[1]

The kidney transplant of another patient taking ciclosporin almost ceased to function when **mannitol** was given, and a biopsy indicated severe ciclosporin nephrotoxicity. Transplant function recovered when the **mannitol** was stopped.[2]

A woman taking ciclosporin had a rise in serum creatinine levels from 121 micromol/L to 171 micromol/L three weeks after she started to take *Moduretic* (**amiloride** with [**hydro**]**chlorothiazide**). Trough serum ciclosporin levels were unchanged.[3]

One clinical study suggested that furosemide may have a protective effect against ciclosporin-induced nephrotoxicity.[4]

(b) Magnesium wasting

Although ciclosporin and **loop diuretics** are both known to cause magnesium wasting, a review of magnesium serum levels, magnesium replacement doses and diuretic use in 50 heart transplant recipients indicated that magnesium requirements were not altered by the use of ciclosporin with **loop diuretics**. However, the use of **thiazides** with ciclosporin resulted in *increases* in serum magnesium and decreases in magnesium replacement.[5] Electrolytes, including magnesium, should be monitored as a matter of routine in patients taking ciclosporin with loop or thiazide diuretics.

(c) Hyperkalaemia

No clinically significant pharmacokinetic interaction was noted when **eplerenone** was given with ciclosporin.[6] It has been suggested that aldosterone receptor blockade with **eplerenone** might reduce ciclosporin nephrotoxicity by reducing aldosterone-mediated renal vasoconstriction.[7]

Note that ciclosporin alone can cause hyperkalaemia, especially if renal function is impaired, and the risk might be additive with potassium-sparing drugs. Because of this, the US manufacturers suggest that ciclosporin should not be used with **potassium-sparing diuretics**,[8] whereas the UK manufacturers suggest that caution is required on concurrent use, with close control of potassium levels.[9] Very careful monitoring would appear prudent if concurrent use is considered essential.

Ciclosporin + Endothelin receptor antagonists

Bosentan decreases ciclosporin levels. Ciclosporin markedly increases sitaxentan and bosentan levels. Ambrisentan may be similarly affected.

Clinical evidence

(a) Bosentan

In a study designed to assess the effects of bosentan on ciclosporin renal toxicity, 7 healthy subjects were given bosentan 500 mg and ciclosporin 300 mg, both twice daily, for 7 days. Bosentan did maintain renal plasma flow, which is markedly decreased by ciclosporin. However, bosentan was calculated to have reduced the AUC of ciclosporin by about 50%. In addition, bosentan had no effect on the ciclosporin-induced rise in blood pressure, and headache, nausea, and vomiting were a problem with the combination. Moreover, the steady-state AUC of bosentan was raised 70%, when compared with the AUC of a single dose of bosentan.[1]

It should be noted that bosentan induces its own metabolism, and after 7 days, plasma levels are about 50 to 65% of those seen after a single dose.[2] Therefore, the effect of ciclosporin on the bosentan AUC may be twice those described in this study (i.e. up to a fourfold increase in the AUC of bosentan). The manufacturers of bosentan say that when bosentan is given with ciclosporin its plasma levels were markedly raised (30-fold after a single dose and three- to fourfold at steady state).[2,3]

(b) Sitaxentan

Sitaxentan does not alter ciclosporin levels. However, ciclosporin increases sitaxentan trough levels sixfold.[4]

Mechanism

Uncertain. Bosentan probably reduces ciclosporin levels because it is an inducer of the cytochrome P450 isoenzyme CYP3A4, by which ciclosporin is metabolised. Ciclosporin modestly inhibits CYP3A4, by which bosentan is partly metabolised, but the rise in bosentan levels seen suggests another mechanism is involved. *In vitro* study shows that ciclosporin inhibits the hepatic uptake of bosentan by the organic anion transporting polypeptides (OATPs), and this might explain the interaction.[5] This mechanism has also been suggested for the interaction with sitaxentan.[4] The UK manufacturer lists ciclosporin as an example of a drug, like bosentan, that inhibits the bile salt export pump, and is therefore expected to increase the risk of liver toxicity when used with bosentan.[2]

Importance and management

Although the data are limited, a pharmacokinetic interaction would appear to be established, resulting in reduced ciclosporin levels, and markedly increased bosentan levels. Because of this, the manufacturers of bosentan contraindicate the combination.[2,3] In addition, the UK manufacturer also states that the concurrent use of ciclosporin may increase the risk of liver toxicity.[2] Other endothelin receptor antagonists are less well studied, but the concurrent use of sitaxentan and ciclosporin is similarly contraindicated.[4] There appears to be even less information about **ambrisentan**, but the manufacturers note that it is a substrate of a number of drug transporters. Therefore they advise caution in patients also taking drugs that affect transporter proteins, such as ciclosporin, which is known to inhibit P-glycoprotein.[6,7]

The concurrent use of **tacrolimus** or **sirolimus** with bosentan has not been studied. Based on the information available for ciclosporin, the UK manufacturer of bosentan advises against concurrent use, but if this is required, close monitoring of bosentan adverse effects and immunosuppressant levels is recommended.[2] The US manufacturer of bosentan recommends caution with tacrolimus.[3]

Ciclosporin + Epoetins

It has been suggested that epoetin alfa might alter ciclosporin levels.

Clinical evidence, mechanism, importance and management

Some UK manufactures of epoetin alfa say that, since ciclosporin is bound by red blood cells there is potential for a drug interaction. They recommend that, if epoetin alfa is given, ciclosporin levels should be monitored and the ciclosporin dose adjusted as the haematocrit rises.[1,2]

This is a theoretical interaction, and there does not appear to be any published data to suggest a significant interaction occurs in practice, and the manufacturers of other epoetins make no mention of such an interaction. Furthermore, it seems likely that any rise in the haematocrit will be sufficiently slow that any interaction would be picked up by routine ciclosporin monitoring.

Ciclosporin + Fibrates

The use of bezafibrate with ciclosporin has resulted in significantly increased serum creatinine levels. Reductions, no change, or increased ciclosporin levels have also been seen. The use of fenofibrate has also been associated with reduced renal function and possibly reduced ciclosporin levels. Three studies found no pharmacokinetic interaction between ciclosporin and gemfibrozil while a fourth found gemfibrozil caused a significant reduction in ciclosporin levels and an increase in serum creatinine in some patients.

Clinical evidence

(a) Bezafibrate

A kidney transplant patient had a rise in his previously stable ciclosporin blood levels from a range of 150 to 200 nanograms/mL to about 340 nanograms/mL over a 6-week period after bezafibrate 200 mg twice daily was given. The rise was accompanied by increases in blood urea nitrogen and creatinine levels. Renal biopsy found evidence of possible ciclosporin toxicity, and rejection. The patient recovered when the bezafibrate was stopped.[1]

Two other transplant patients (one kidney and the other heart) had a reversible deterioration in renal function when they were given bezafibrate. This was severe in one, and it occurred on two occasions in the other patient. Neither had any changes in ciclosporin blood levels.[2,3] Two other similar cases have been reported, one of whom was subsequently given gemfibrozil without problems.[4]

Another study over 3 months in 40 heart transplant patients taking ciclosporin found that bezafibrate was associated with a rise in serum creatinine levels, although none of the patients had to be withdrawn from the study. The ciclosporin level tended to be lower (198 nanograms/mL at baseline, compared with 144 nanograms/mL after 3 months).[5]

(b) Fenofibrate

In a study in 10 heart transplant patients, fenofibrate 200 mg daily for 2 weeks effectively reduced the blood cholesterol levels from 7.7 mmol/L to 6.5 mmol/L without significantly altering ciclosporin blood levels over a 2-week period. The only possible adverse effect was an increase in creatinine levels from 145 mmol/L to 157 mmol/L, suggesting some possible nephrotoxicity. No other clinically adverse effects were seen. However, the authors of this study suggested that longer follow-up studies were needed to confirm the safety of using these drugs together.[6] They followed this up with a one-year study[7] in 43 heart transplant patients, only 14 of whom completed the study (67% withdrew for various reasons). Fourteen patients had a rise in blood creatinine levels and a decrease in renal func-

tion, which improved when the fenofibrate was stopped. There was also some evidence of a reduction in ciclosporin levels in 5 patients, who developed rejection, and 14 patients, who had to stop fenofibrate because ciclosporin levels could not be maintained without adversely affecting renal function.

(c) Gemfibrozil

Forty kidney transplant patients taking ciclosporin had a reduction in their hypertriglyceridaemia when gemfibrozil 900 mg daily for 6 months or 600 mg twice daily for 4 months was added, and their ciclosporin blood levels and serum creatinine levels remained unaltered.[8] Two other studies similarly found that gemfibrozil did not affect ciclosporin blood levels.[9,10]

However, in contrast to these findings, another study in 7 kidney transplant patients with hyperlipidaemia found that gemfibrozil 450 mg once or twice daily was associated with a decline in trough ciclosporin levels. Levels declined from 93 nanograms/mL to 76 nanograms/mL after 6 weeks of concurrent use, and after dose increases in 3 patients, the level at 3 months was 88 nanograms/mL. In 8 similar patients not given gemfibrozil, and with the same ciclosporin dose throughout, trough levels changed from 99 nanograms/mL to 98 nanograms/mL at 6 weeks and to 123 nanograms/mL at 3 months. In 2 patients there was a significant increase in serum creatinine, and biopsy revealed chronic rejection in one and ciclosporin toxicity in the other. The study was stopped at 6 months because a drug interaction was suspected.[11]

Mechanism

The mechanism of the interaction between ciclosporin and the fibrates is not known, but changes in distribution of lipoproteins during treatment with fibrates may cause changes in the free fraction of ciclosporin. Ciclosporin absorption may also be reduced.

Importance and management

Neither the incidence nor the reasons for these reactions are known, but because the outcome is uncertain and potentially serious, keep a close check on the effects of adding a fibrate, particularly bezafibrate or fenofibrate, to ciclosporin in any patient. The UK manufacturer of ciclosporin suggests close monitoring of renal function during concurrent use, and withdrawal of the fibrate should significant impairment occur.[12]

Ciclosporin + Food

Food can slightly decrease the bioavailability of ciclosporin from the *Neoral* formulation and slightly increase the bioavailability of ciclosporin from the *Cicloral* formulation. Lipid admixtures for parenteral nutrition appear not to affect intravenous ciclosporin pharmacokinetics.

Clinical evidence

(a) Oral ciclosporin

1. Food or Milk. In early studies with oral ciclosporin,[1] presumably the *Sandimmun* formulation, food and milk increased its bioavailability. For example, patients taking ciclosporin with milk had a 39% higher AUC after food and 23% higher AUC when fasting, compared with other patients taking ciclosporin with orange juice (which is known not to interact, see 'Ciclosporin + Grapefruit and other fruit juices', p.1240). Food more than doubled the AUC of ciclosporin (bioavailability increased from about 21% to 53%) and almost tripled its maximum serum levels, from 783 nanograms/mL to 2062 nanograms/mL.[2] Similarly, when 18 patients with kidney transplants were given ciclosporin mixed with 240 mL of chocolate milk and taken with a standard hospital breakfast, their peak ciclosporin levels rose by 31% (from 1120 to 1465 nanograms/mL), trough blood levels rose by 17% (from 228 to 267 nanograms/mL), and the AUC rose by 45%. Very considerable individual variations occurred.[3]

The *Neoral* formulation was developed to increase ciclosporin bioavailability and reduce variability in absorption,[4] and has now replaced the oral *Sandimmun* formulation. The *Neoral* formulation is less affected by food.[4] With the *Neoral* formulation, the manufacturer notes that food slightly decreases the ciclosporin AUC and maximum level. Giving a dose of ciclosporin within 30 minutes after eating a high-fat meal (669 kcal, 45 grams fat) decreased the ciclosporin AUC by 13% and maximum level by 33%. The effects of a low fat meal (667 kcal, 15 grams fat) were similar.[5]

In a study using the *Cicloral* formulation, the ciclosporin AUC was increased by 21% and the maximum level by 32% when the capsules were taken immediately after a fat-rich breakfast when compared with the fasting state in healthy subjects.[6]

2. Soft drinks. A lung transplant patient taking ciclosporin had large variations in his ciclosporin levels, which ranged between 319 and 761 nanograms/mL, on discharge from hospital, which were unexplained by changes in his current medication or ciclosporin dose changes. It was found that on the days when the ciclosporin levels were increased, the patient had drunk a citrus soft drink (*Sun Drop*) at breakfast. These fluctuations resolved when he stopped drinking the soft drink.[7] However, a subsequent pharmacokinetic study in 12 healthy subjects found that neither *Sun Drop* nor another citrus soft drink, *Fresca*, had any significant effects on the pharmacokinetics of a single 2.5-mg/kg dose of ciclosporin. Both *Sun Drop* and *Fresca* were tested, and found to contain bergamottin 0.078 and 6.5 mg/L, respectively (note that grapefruit contains about 5.6 mg/L). The authors note that factors such as genetic and disease-related variability in ciclosporin metabolism as well as changes in the bergamottin content between batches of the drinks may account for the contrasting results.[8] For more discussion about the effects of grapefruit and other fruit juices see also 'Ciclosporin + Grapefruit and other fruit juices', p.1240.

(b) Intravenous ciclosporin

A study in 10 patients undergoing bone-marrow transplantation and given isocaloric and isonitrogenous parenteral nutrition with or without lipids found that ciclosporin pharmacokinetics after intravenous administration were not affected by lipid-enriched admixtures.[9]

Mechanism

The *Neoral* formulation of ciclosporin contains ethanol as a volatile cosolvent, and undergoes a microemulsification process with fluid in the gastrointestinal tract; therefore, its absorption is less affected by food than the old oral *Sandimmun* formulation.[4] The authors of the report of an interaction with a citrus soda drink confirmed with the manufacturers that it contained furanocoumarins such as bergamottin which are thought to inhibit CYP3A4,[7,8] the major isoenzyme involved in the metabolism of ciclosporin. Compare also 'Ciclosporin + Grapefruit and other fruit juices', p.1240.

Importance and management

Food has a minor effect on the extent of absorption of ciclosporin from the *Neoral* formulation. Nevertheless, in the US the manufacturer recommends that it should be taken on a consistent schedule in relation to time

of day and meals.[5] However, in the UK the manufacturer makes no reference to timing in relation to meals.[4] Similarly, the effect of absorption of ciclosporin from the *Cicloral* formulation is minimal, but the authors of the study suggest that it should be taken on a consistent schedule in relation to time of day and meals.[6]

Lipid admixtures in parenteral nutrition do not appear to affect ciclosporin pharmacokinetics and it is speculated that they may protect against ciclosporin-induced nephrotoxicity. Close supervision and monitoring is required. There is insufficient evidence to allow extrapolation of the results to bone-marrow transplant recipients with risk factors such as dyslipidaemia, liver, or renal impairment.[9]

The isolated report[7] of an interaction between a citrus soft drink (containing furanocoumarins) and ciclosporin was not confirmed by a subsequent single-dose pharmacokinetic study in healthy subjects[8] and therefore its significance is unclear. The case does highlight the influence diet can have on ciclosporin and it should be borne in mind should any unexpected changes in ciclosporin levels occur.

Ciclosporin + Foscarnet

Acute but reversible renal failure occurred in two transplant patients when foscarnet was given with ciclosporin.

Clinical evidence

A man with a kidney transplant taking corticosteroids and ciclosporin developed a cytomegalovirus infection that was treated with foscarnet 85 mg/kg daily. Despite efforts to minimise the nephrotoxic effects of foscarnet (hydration with 2.5 litres of isotonic saline daily and nifedipine 80 mg the day before and during treatment) the patient developed non-oliguric worsening of his renal function after 8 days. Nine days after stopping foscarnet, the former renal function was restored.[1]

A liver transplant patient taking steroids, azathioprine and ciclosporin was given foscarnet 180 mg/kg daily for a hepatitis B infection. Acute renal failure occurred 5 days after the foscarnet was started, and renal function was restored 10 days after the foscarnet was stopped. The ciclosporin blood levels were therapeutic and not significantly altered at any time in either patient.[1]

Mechanism

Not understood. It seems that the nephrotoxic effects of ciclosporin and foscarnet may be additive.

Importance and management

Direct information appears to be limited to this report, but it is consistent with the known potential toxicity of both drugs. Acute renal failure can clearly occur despite the preventative measures taken. The authors of this report[1] say that monitoring of renal function is mandatory when both drugs are given.

Ciclosporin + *Geum chiloense*

A single case report describes a marked and rapid increase in the ciclosporin levels of a man after he drank an infusion of *Geum chiloense.*

Clinical evidence, mechanism, importance and management

A 54-year-old kidney transplant patient taking ciclosporin, prednisone, azathioprine, diltiazem and nifedipine had a sudden and very marked rise in his ciclosporin levels from his usual range of 60 to 90 [nanograms/mL] up to a range of 469 to 600 [nanograms/mL]. He had been taking ciclosporin 2 to 3 mg/kg daily for 15 months since the transplant. His serum creatinine levels were found to be 115 micromol/L. It eventually turned out that about 2 weeks earlier he had started to drink an infusion of *Geum chiloense* (or *Geum quellyon*), a herbal remedy claimed to increase virility and to treat prostatism. When the herbal remedy was stopped, his serum ciclosporin levels rapidly returned to their normal values. The reasons for this apparent interaction are not known.[1]

This appears to be the only case on record but it serves, along with reports about other herbs, to emphasise that herbal remedies may not be safe just because they are 'natural'. In this instance the herbal remedy markedly increased the potential nephrotoxicity of the ciclosporin. Patients should be warned.

Ciclosporin + Grapefruit and other fruit juices

Grapefruit juice, and possibly pomelo juice, but not cranberry or orange juices, can increase the bioavailability of oral ciclosporin.

Clinical evidence

(a) Cranberry juice

In a single-dose study in healthy subjects, cranberry juice 240 mL did not have any significant effects on ciclosporin pharmacokinetics when given at the same time as ciclosporin (*Neoral*).[1]

(b) Grapefruit juice

Many single and multiple-dose pharmacokinetic studies in healthy subjects,[2-5] transplant recipients,[6-11] and other patients with autoimmune diseases[12,13] have shown that if oral ciclosporin is taken at the same time as 150 to 250 mL (5 to 8 ozs) of grapefruit juice, the trough and peak blood levels and the bioavailability of ciclosporin may be significantly increased. The increases reported vary considerably: increases in trough blood levels range from about 15 to 85%,[6,8-11,13] increases in peak blood levels range from 4 to 43%,[2-4,7-11,13] and increases in AUCs range from about 15 to 59%.[2-4,7-11,13,14] In one other study where grapefruit juice was given every 3 hours for 30 hours, with a dose of ciclosporin given at 7.5 hours separated by 1.5 hours from the grapefruit juice, the maximum levels of ciclosporin increased by 22% and the AUC by just 7% (not statistically significant).[15] Where stated, these studies were with the original *Sandimmun* formulation of ciclosporin.

A few studies have looked at the effect of grapefruit juice on the microemulsion formulation of ciclosporin (*Neoral*) in healthy subjects[14,16] or transplant patients.[17,18] In these studies, when grapefruit juice was taken at the same time as ciclosporin, the AUC was increased by 25 to 47% and the maximum levels were largely unchanged (2 to 10% increase). In one study using an intravenous control, grapefruit juice increased the bioavailability of ciclosporin from 38% to 55%.[14] A further study found a greater effect in African-American subjects: the peak levels and AUC were increased by 39% and 60%, respectively, compared with smaller increases of 8% and 44% in Caucasian subjects.[16]

In a study comparing two oral liquid formulations in 6 paediatric kidney transplant patients, giving ciclosporin oral solution (*Sandimmun*) simultaneously with grapefruit juice produced a significant increase (109%) in the 12-hour trough level although the AUC was not significantly changed. When ciclosporin was given as the microemulsion (*Neoral*), grapefruit juice did not significantly affect the pharmacokinetics of ciclosporin.[19]

Grapefruit juice has no effect on ciclosporin levels when the ciclosporin is given *intravenously*.[3]

(c) Orange juices

In single-dose studies in healthy subjects, ciclosporin levels were unaffected by simultaneous administration of orange juice,[2,5,20] tangerine juice,[20] or Seville (bitter) orange juice.[4]

(d) Pomelo juice

In a single-dose study in 12 healthy subjects, pomelo juice 240 mL slightly increased the AUC and maximum level of ciclosporin by about 19% and 12%, respectively, when given at the same time as the ciclosporin (*Neoral*).[1]

Mechanism

It is suggested that grapefruit juice inhibits the activity of the cytochrome P450 isoenzyme CYP3A4, predominantly in the gut wall. Ciclosporin is primarily metabolised by CYP3A4 and so its bioavailability rises; however, because grapefruit juice has minor effects on hepatic CYP3A4 this effect is not seen with intravenous use. A number of active constituents of grapefruit juice have been suggested, but it is probably the furanocoumarins (which include bergamottin and 6',7'-dihydroxybergamottin) that are responsible for this interaction because a furanocoumarin-free grapefruit juice did not interact.[5] Another *in vitro* study suggested that 6',7'-dihydroxybergamottin is not responsible.[4] More study is needed. Pomelo is related to grapefruit and therefore potentially interacts by the same mechanism.

Importance and management

The interaction between grapefruit juice and ciclosporin is established and clinically important, and results in increases in the bioavailability of oral ciclosporin. Patients taking ciclosporin should be warned about drinking grapefruit juice because increased ciclosporin levels are associated with increased nephrotoxicity. In general, grapefruit juice should be avoided. It has been suggested that separation of administration could minimise this interaction. However, apart from one study,[15] all the data relate to drinking grapefruit juice around the same time as taking the ciclosporin dose. The study that separated administration (by 1.5 hours) still found a minor interaction. However, in this study a large quantity of grapefruit juice was consumed over 30 hours, and the study did not test simultaneous administration for comparison. It is therefore unclear if separation of administration would reduce or negate the effect of grapefruit juice on ciclosporin.

It has been suggested[2] that the interaction between grapefruit juice and ciclosporin could be exploited to save money. One group of authors has suggested that grapefruit juice is roughly as effective as diltiazem in raising ciclosporin blood levels, and has the advantage of being inexpensive, nutritious and lacking the systemic effects of diltiazem and ketoconazole which have been used in this way. However, it has also been pointed out that it may be risky to try to exploit this interaction because the increases appear to be so variable and difficult, if not impossible, to control. This is because batches of grapefruit juice vary so much, and also considerable patient variation occurs with this interaction.[21-23] Grapefruit juice has been used to improve ciclosporin efficacy in two patients with psoriasis[24] and four patients with autoimmune haematological disorders.[4]

The US manufacturer suggests that patients taking ciclosporin should avoid **whole grapefruit**, as well as the juice.[25]

The significance of the single report of the small increases in ciclosporin bioavailability and blood levels seen with pomelo juice in healthy subjects is unclear.[1] However, a similar interaction has been seen in a kidney transplant patient taking tacrolimus, see 'Tacrolimus + Grapefruit and other fruit juices', p.1301. There is insufficient evidence to recommend avoiding pomelo juice or pomelo fruit when taking ciclosporin but bear this potential interaction in mind. More study is needed.

Both cranberry juice and orange juices do not appear to interact with ciclosporin.

Ciclosporin + Griseofulvin

An isolated report describes decreased ciclosporin levels in a patient given griseofulvin, whereas another report found no interaction.

Clinical evidence, mechanism, importance and management

A 57-year-old-man, who had been stable for almost one year taking ciclosporin, azathioprine and prednisolone following a kidney transplant, was given griseofulvin 500 mg daily for onychomycosis. Two weeks later his trough ciclosporin levels had dropped from 90 nanograms/mL to 50 nanograms/mL and remained low, despite an increase in his ciclosporin dose from 2.8 to 4.8 mg/kg. When the griseofulvin was later stopped, his ciclosporin levels rose to over 200 nanograms/mL and his dose of ciclosporin was readjusted.[1] In contrast, the authors of another report noted that there was no appreciable interaction when griseofulvin 1 g daily for 8 weeks was used to treat tinea capitis in a kidney transplant patient taking ciclosporin, and graft function remained stable.[2]

The first case appears to be the only report of an interaction with griseofulvin, and its general significance is unclear.

2. Chen CH, Wen MC, Cheng CH, Wu MJ, Yu TM, Chuang YW, Shu KH. Infectious alopecia in a dog breeder after renal transplantation. J Chin Med Assoc (2008) 71, 477–80.

Ciclosporin + H_2-receptor antagonists

Reports are inconsistent. Cimetidine has been reported to increase ciclosporin levels in some studies, whereas others found no interaction. Ranitidine, and probably famotidine, do not appear to affect ciclosporin levels. Both cimetidine and ranitidine

have been reported to cause an increase in serum creatinine levels, in some but not all studies. Isolated cases of thrombocytopenia and hepatotoxicity have been reported with ranitidine and ciclosporin.

Clinical evidence

(a) Cimetidine

A study in 5 liver transplant patients taking ciclosporin found that cimetidine 800 mg given every 12 hours for 3 doses raised peak ciclosporin levels, but no changes in trough levels were seen after 4 hours. Similarly, no change in trough ciclosporin levels was seen in 2 patients who received cimetidine 400 mg four times daily for 4 weeks, and the conclusion was reached that it was safe to use cimetidine over at least a 4-week period.[1] However, a retrospective study reported that heart transplant patients taking cimetidine had a lower dose/level quotient leading to higher ciclosporin blood levels for the same dose.[2] Similarly, a study in 6 healthy subjects found a 30% rise in the AUC of ciclosporin 300 mg given after a 3-day course of cimetidine 400 mg daily.[3] Raised ciclosporin blood levels have also been seen in a patient given cimetidine and metronidazole[4] (see 'Ciclosporin + Antibacterials; Metronidazole', p.1219).

Cimetidine or **ranitidine** increased the mean serum creatinine levels in 7 kidney transplant patients taking ciclosporin by 41% (from 202 to 285 micromol/L). All of the patients had a rise, whereas only 2 out of 5 other patients with heart transplants had a rise in their serum creatinine levels when given either cimetidine or **ranitidine**, nevertheless the mean rise was 37% (from 152 to 209 micromol/L). Ciclosporin levels were not altered.[5] Another study in 7 kidney transplant patients given cimetidine 400 mg daily for 7 days reported a transient minor increase in creatinine serum levels at days 2 and 5, which was not statistically significant. Again ciclosporin levels were not altered.[6] Similarly, in two studies in healthy subjects, cimetidine did not alter ciclosporin blood levels.[7,8]

(b) Famotidine

Several studies have reported that famotidine does not affect ciclosporin blood levels.[9-11] No significant changes in the pharmacokinetics of ciclosporin was seen in a single-dose study in 8 healthy subjects[8] and no changes in serum creatinine or BUN levels were seen in 7 kidney transplant patients.[11] However, a study of heart transplant patients given famotidine found slightly higher ciclosporin blood levels for a given ciclosporin dose.[2]

(c) Ranitidine

One report (see *Cimetidine* above), where the effects of cimetidine and ranitidine were examined together, suggests that ranitidine raises creatinine levels in patients taking ciclosporin, without affecting ciclosporin levels.[5] Similarly, several other reports suggest that ranitidine does not alter ciclosporin blood levels.[6,12-15] Two also note that ranitidine does not alter creatinine levels[6,13] or inulin clearance.[13]

A report describes thrombocytopenia in a man taking ciclosporin after a kidney transplant who was given ranitidine.[16] Another patient experienced hepatotoxicity while taking ciclosporin with ranitidine.[17]

Mechanism

t has been suggested that any rise in serum creatinine levels could simply be because these H_2-receptor antagonists compete with creatinine for secretion by the kidney tubules, and therefore rises are not an indicator of nephrotoxicity[18,19]

Importance and management

Information about the possible interaction of ciclosporin and cimetidine are inconsistent, but there appear to be very few reports of confirmed toxicity. Most of the evidence suggests that famotidine does not affect ciclosporin levels, and ranitidine does not appear to affect ciclosporin levels. The reported increases in serum creatinine levels seen with the H_2-receptor antagonists may not be a reflection of increased nephrotoxicity (see *Mechanism*). Thus there is little to suggest that concurrent use should be avoided, but good initial monitoring is possibly advisable with cimetidine.

Ciclosporin + Hormonal contraceptives and Progestogens

Isolated reports describe hepatotoxicity and raised ciclosporin levels in two patients taking ciclosporin when given oral combined hormonal contraceptives. A couple of reports also describe some increase in ciclosporin levels with norethisterone.

Clinical evidence

(a) Contraceptives

A woman with uveitis taking ciclosporin 5 mg/kg daily had an increase in her trough plasma ciclosporin levels (roughly doubled) on two occasions within 8 to 10 days of starting an oral contraceptive (**ethinylestradiol** 30 micrograms with **levonorgestrel** 150 micrograms). She also experienced nausea, vomiting and hepatic pain, and had evidence of severe hepatotoxicity (very marked increases in AST and ALT, and rises in serum bilirubin and alkaline phosphatase).The woman had previously taken this oral contraceptive for 5 years without problems.[1]

Another report describes hepatotoxicity in a patient taking ciclosporin 2 weeks after she started an oral contraceptive (**ethinylestradiol** 30 micrograms with **desogestrel** 150 micrograms). The contraceptive was stopped, and liver enzyme levels promptly started to fall, but ciclosporin levels continued to rise, and peaked about 10 days later, at a level about threefold higher than they had been.[2]

(b) Norethisterone

A 15-year-old girl taking ciclosporin who had a marked increase in serum ciclosporin levels when she was given danazol (see 'Ciclosporin + Danazol', p.1236), continued to have elevated levels, but not as high, when the danazol was replaced by norethisterone 5 mg three times daily. The levels returned to her previous normal range when the norethisterone was stopped.[3] Two women had a mild rise in ciclosporin levels with no changes in creatinine levels when they were given norethisterone 10 mg daily for 10 days.[4] No changes in ciclosporin levels were seen in another patient who was intermittently given norethisterone.[5]

Mechanism

Uncertain. It seems possible that some of these compounds inhibit the metabolism of ciclosporin by the liver, thereby leading to an increase in its serum levels. The mechanism of the hepatotoxicity is not understood, but in some cases it seems that it occurs simply as a rare adverse effect of the sex hormone.

Importance and management

This interaction between ciclosporin and oral combined hormonal contraceptives or norethisterone is unconfirmed and of uncertain clinical significance. There is insufficient evidence to recommend increased monitoring but be aware of the potential for an interaction in the case of an unexpected response to treatment.

Ciclosporin + Lamivudine

Lamivudine did not alter ciclosporin levels in kidney transplant patients.

Clinical evidence, mechanism, importance and management

In a study, the ciclosporin levels of 4 kidney transplant patients taking were unchanged when lamivudine 100 to 150 mg daily was added to treat chronic hepatitis B. Normal graft function was maintained.[1] Another study in 15 kidney transplant patients also found that lamivudine 50 to 100 mg daily for 4 to 29 months did not affect ciclosporin levels and no acute rejection was seen.[2] Therefore, no ciclosporin dose adjustment seems to be necessary on the concurrent use of lamivudine.

Ciclosporin + Melphalan

Melphalan may increase the nephrotoxic effects of ciclosporin.

Clinical evidence, mechanism, importance and management

A comparative study found that 13 out of 17 patients receiving bone marrow transplants and given ciclosporin 12.5 mg/kg daily with high-dose melphalan (single injection of 140 to 250 mg/m^2) developed renal failure, compared with no cases of renal failure in 7 other patients given melphalan but no ciclosporin.[1] In another study, one out of 4 patients given both drugs developed nephrotoxicity.[2] Renal function should be monitored closely on concurrent use. Note that melphalan is an established part of conditioning regimens given before bone marrow transplantation, for which ciclosporin is used to prevent graft-versus-host disease.

Ciclosporin + Methotrexate

Previous or concurrent treatment with methotrexate may possibly increase the risk of liver and other toxicity in those given ciclosporin. Ciclosporin might cause a moderate rise in serum methotrexate levels, but methotrexate does not appear to affect the pharmacokinetics of ciclosporin.

Clinical evidence

(a) Bone marrow transplant

In a pilot study of the use of reduced-dose ciclosporin and methotrexate for the control of acute graft-versus-host disease in bone marrow transplant patients, a 50% lower ciclosporin dose (1.5 mg/kg/day) appeared to be as effective and appeared to be associated with reduced hepatotoxicity. The methotrexate doses were 10 to 15 mg/m^2 on days 1, 3, 6, and 11 after grafting.[1] Another study in three bone marrow transplant patients found that low-dose methotrexate (15 mg/m^2 on day 1, and 10 mg/m^2 on days 3, 6 and 11) given with ciclosporin did not significantly affect clinical care and no interaction of clinical significance was seen.[2] Nevertheless, in a large retrospective study of kidney function impairment post-haematopoietic stem cell transplantation, the main cause of acute renal failure was found to be ciclosporin use. The concurrent use of methotrexate in patients taking ciclosporin was also found to be associated with an increased risk of acute renal failure in the first 100 days (hazard ratio 1.9).[3]

(b) Psoriasis

A limited comparative study in patients with chronic plaque psoriasis suggested that the previous use of methotrexate, which can cause liver damage, possibly increases the risk of ciclosporin toxicity (higher ciclosporin blood levels and serum creatinine levels, hypertension).[4] This was confirmed by another study in 4 patients with resistant psoriasis taking ciclosporin 2.5 to 5 mg/kg daily in whom the addition of methotrexate 2.5 mg every 12 hours for three doses at weekly intervals increased creatinine levels and liver enzymes (AST, ALT), which resulted in the study being stopped.[5] Nevertheless, successful concurrent use has been described. In one such study in patients with poorly controlled disease on maximum tolerated doses of ciclosporin or methotrexate alone, concurrent use allowed the reduction in dose of the established drug with better control of psoriasis. However, in 6 of 12 patients receiving both drugs for longer than a year, renal impairment developed, which responded to a reduction in the ciclosporin dose in 3 patients, remained stable in 2 patients, and necessitated the withdrawal of ciclosporin in one patient. There was no evidence of impaired liver function.[6]

(c) Rheumatoid arthritis

An open-label pharmacokinetic study in 26 patients with rheumatoid arthritis taking methotrexate 7.5 to 22.5 mg weekly with ciclosporin 1.5 mg/kg every 12 hours for 14 days, found that the AUC of the weekly dose of methotrexate increased by 26%, whereas the plasma levels of its major metabolite (7-hydroxymethotrexate), which is much less active and may be associated with toxicity, were reduced by 80%.[7] Another study in patients with rheumatoid arthritis found that the pharmacokinetics of ciclosporin after the first dose did not differ between those who had been receiving intramuscular methotrexate 10 mg each week for 6 months and those not receiving methotrexate.[8]

A number of efficacy studies have evaluated the concurrent use of methotrexate and ciclosporin in rheumatoid arthritis. In one, there was no difference in the incidence of renal impairment, or patient withdrawals between patients taking ciclosporin 3 mg/kg daily alone or the same dose of ciclosporin with methotrexate 7.5 to 10 mg weekly. However, there was a tendency for more patients to require dose modification when they were given both drugs (56% versus 28%).[9] In another study, there was no difference in ciclosporin dose between 60 patients receiving ciclosporin alone and 60 patients receiving ciclosporin with methotrexate. However, hypertension or an increase in serum creatinine, or both, were more often a reason for discontinuation in the group given both drugs (9 patients versus 2 patients).[10]

Mechanism

Not understood.

Importance and management

The reports cited here give an inconsistent picture. Patients receiving ciclosporin should routinely be monitored for renal adverse effects, and those receiving methotrexate routinely monitored for hepatotoxicity. If both drugs are used concurrently it may be worth increasing the frequency of this monitoring to aid rapid detection of any adverse effects.

Ciclosporin + Methoxsalen

In a single-dose study, oral methoxsalen slightly increased the bioavailability of ciclosporin.

Clinical evidence, mechanism, importance and management

In a single-dose study in 12 healthy subjects, oral methoxsalen 40 mg increased the AUC and peak plasma level of ciclosporin 200 mg by about 14% and 8%, respectively, when given at the same time. In two subjects the ciclosporin AUCs increased by 80% and 2.7-fold, respectively. The half-life and time to peak levels were not affected. As methoxsalen absorption is subject to high interindividual variation, this particular study was unable to detect a significant difference in methoxsalen pharmacokinetics, although ciclosporin tended to reduce the AUC and peak levels of methoxsalen by 25% and 35%, respectively.[1]

Methoxsalen may interact by reducing the absorption of ciclosporin. Further study is required to see if this interaction is clinically significant. Until more is known, bear this interaction in mind in patients taking ciclosporin if its levels are increased.

1. Rheeders M, Bouwer M, Goosen TC. Drug-drug interaction after single oral doses of the furanocoumarin methoxsalen and cyclosporine. *J Clin Pharmacol* (2006) 46, 768–75.

Ciclosporin + Methylphenidate

In an isolated case, the ciclosporin levels of a 10-year-old-boy were raised by 50% after he started to take methylphenidate.

Clinical evidence, mechanism, importance and management

A 10-year-old boy who had received a heart transplant 6 years previously, started taking methylphenidate 5 mg twice daily in addition to his transplant medication, which included ciclosporin. After 4 days his ciclosporin level was found to have risen, from 195 nanograms/mL to 302 nanograms/mL. His ciclosporin dose was therefore reduced from 550 to 500 mg daily, and at the same time the methylphenidate was increased to 7.5 mg twice daily. As the next ciclosporin level was still elevated at 251 nanograms/mL, the ciclosporin dose was further reduced to 450 mg daily. The boy then remained on this dose of ciclosporin with acceptable levels, despite further dose increases in the methylphenidate to an eventual dose of 20 mg daily.[1]

The reason for this probable interaction is unclear. This appears to be the only reported case of an interaction between ciclosporin and methylphenidate, and its general importance is unknown.

1. Lewis BR, Aoun SL, Bernstein GA, Crow SJ. Pharmacokinetic interactions between cyclosporin and bupropion or methylphenidate. *J Child Adolesc Psychopharmacol* (2001) 11, 193–8.

Ciclosporin + Metoclopramide

Metoclopramide moderately increases the absorption of ciclosporin and raises its blood levels.

Clinical evidence, mechanism, importance and management

When 14 kidney transplant patients were given metoclopramide their peak ciclosporin blood levels were increased by 46% (from 388 to 567 nanograms/mL) and the ciclosporin AUC was increased by 22%. The dose of metoclopramide was 10 mg by mouth 30 minutes before, 5 mg with, and 5 mg 30 minutes after the morning dose of ciclosporin, which was given after breakfast.[1] Ciclosporin is largely absorbed by the small intestine so the likely mechanism for this interaction is increased absorption of ciclosporin because metoclopramide hastens gastric emptying.

The clinical importance of this interaction is uncertain. Concurrent use should be well monitored to ensure that any increase in ciclosporin peak levels does not increase adverse effects. Note that the increase in the AUC of ciclosporin is only modest.

1. Wadhwa NK, Schroeder TJ, O'Flaherty E, Pesce AJ, Myre SA, First MR. The effect of oral metoclopramide on the absorption of cyclosporine. *Transplant Proc* (1987) 19, 1730–3.

Ciclosporin + Minoxidil

The concurrent use of ciclosporin and minoxidil can cause excessive hairiness (hypertrichosis).

Clinical evidence, mechanism, importance and management

Six male kidney transplant patients taking ciclosporin (blood levels of 100 to 200 nanograms/mL) were given methyldopa, a diuretic and minoxidil 15 to 40 mg daily for intractable hypertension. After 4 weeks of treatment all of them complained of severe and unpleasant hypertrichosis (excessive hairiness). Two months after stopping minoxidil the hypertrichosis had significantly improved.[1] Both ciclosporin and minoxidil cause hypertrichosis and it would seem that their effects may be additive. The authors of the report point out that this is not a life-threatening problem, but it limits the concurrent use of these drugs in both men and women.[1]

1. Sever MS, Sonmez YE, Kocak N. Limited use of minoxidil in renal transplant recipients because of the additive side-effects of cyclosporine on hypertrichosis. *Transplantation* (1990) 50, 536.

Ciclosporin + Modafinil

Ciclosporin levels were reported to be reduced by modafinil in one patient.

Clinical evidence, mechanism, importance and management

A kidney transplant patient, stable for 9 years taking ciclosporin 200 mg daily, developed Gélineau's syndrome (narcoleptic syndrome) and was given modafinil 200 mg daily. Within a few weeks her ciclosporin blood levels were noted to have fallen, and it was necessary to raise her ciclosporin dose stepwise to 300 mg daily before her blood levels were back to their former values.[1]

Modafinil is a known modest inducer of the cytochrome P450 isoenzyme CYP3A4, the major enzyme involved in the metabolism of ciclosporin. Concurrent use therefore increases ciclosporin metabolism and decreases its levels.

Evidence is limited to this single case report, but, on the basis of the proposed mechanism, a modest interaction would be expected. It would seem prudent to anticipate a reduction in ciclosporin levels if modafinil is used and adjust the ciclosporin dose as necessary. **Armodafinil**, the *R*-isomer of modafinil, would be expected to interact similarly.

1. Le Cacheux Ph, Charasse C, Mourtada R, Muh Ph, Boulahrouz R, Simon P. Syndrome de Gélineau chez une transplantée rénale. Mise en évidence d'une interaction cyclosporine-modafinil. *Presse Med* (1997) 26, 466.

Ciclosporin + Muromonab-CD3

Muromonab-CD3 appears to increase ciclosporin blood levels, and there is an increased risk of reactivation of viral infections with combined use.

Clinical evidence, mechanism, importance and management

In the preliminary report of a retrospective review, when 5 mg of muromonab-CD3 was given daily for 10 days to 10 kidney transplant patients to treat acute rejection, their mean trough ciclosporin levels on day 8 were higher than before the muromonab-CD3 was started, despite a 50% reduction in the ciclosporin dose. When the muromonab-CD3 was withdrawn,

the ciclosporin dose needed to be increased again.[1] The manufacturer notes that there is an increased risk of reactivation of cytomegalovirus when an immunosuppressive regimen including ciclosporin is used after an anti-lymphocyte antibody such as muromonab-CD3.[2]

The reasons for the rise in ciclosporin levels are not understood. Muromonab-CD3 augments the immunosuppressant effects of ciclosporin and consequently increases the risk of infection and reactivation of viral infections. Note that the authors of the first study say that ciclosporin doses are routinely reduced before use of muromonab-CD3 to avoid over-immunosuppression, and therefore the relevance of their retrospective findings on ciclosporin levels is uncertain.

Ciclosporin + Nefazodone

Four cases of raised ciclosporin levels have been seen in patients taking nefazodone and ciclosporin, one with raised creatinine levels and tremor, and one with raised liver enzymes.

Clinical evidence

A kidney transplant patient had a 70% rise in trough serum ciclosporin levels within 3 days of starting to take nefazodone 25 mg twice daily.[1] Another kidney transplant patient had a two- to threefold rise in ciclosporin levels associated with raised creatinine levels and marked generalised tremors after starting nefazodone 100 mg twice daily. The patient was eventually stabilised on a 50% lower dose of ciclosporin.[2] Similarly, a heart transplant patient taking ciclosporin had a tenfold increase in ciclosporin levels shortly after the addition of nefazodone 150 mg twice daily. Levels returned to baseline over 6 days after nefazodone was stopped.[3] A patient taking nefazodone developed significantly raised liver enzymes (AST and ALT) one month after kidney transplantation. His ciclosporin level was high, at 614 nanograms/mL, and both ciclosporin and nefazodone were stopped. He had previously taken nefazodone uneventfully, and subsequently took ciclosporin uneventfully, so the raised liver enzymes were attributed to a pharmacokinetic interaction between the two drugs.[4]

Mechanism

Nefazodone is an inhibitor of the cytochrome P450 isoenzyme CYP3A4, the main isoenzyme by which ciclosporin is metabolised. Concurrent use can therefore lead to increased ciclosporin levels.

Importance and management

Although the evidence is limited, it appears that nefazodone can cause a marked rise in ciclosporin levels, with an increase in adverse effects. Alternative antidepressants should probably be given, or concurrent use very well monitored. Note that nefazodone has generally been withdrawn due to its adverse effects on the liver.

Ciclosporin + NNRTIs

Efavirenz, and to a lesser extent nevirapine, appear to decrease the levels of ciclosporin. The ciclosporin levels of one patient dramatically decreased following the addition of efavirenz. Etravirine is also predicted to interact in this way. In contrast, delavirdine is predicted to inhibit the metabolism of ciclosporin and increase its levels.

Clinical evidence

A patient was diagnosed as HIV-positive 3 years after a kidney transplant, for which he was taking ciclosporin. He was started on **efavirenz** 600 mg daily, lamivudine and zidovudine, and 7 days later, after an initial rise, his ciclosporin level dropped from about 203 nanograms/mL to 80 nanograms/mL. A nadir of 50 nanograms/mL was reached one month later.[1] In a study in 35 HIV-infected patients, ciclosporin was added to established antiretroviral therapy after liver or kidney transplantation. Patients taking **efavirenz** required much higher ciclosporin doses than those taking **nevirapine** (275 mg twice daily compared to 189 mg twice daily at week 2 and 279 mg twice daily compared to 147 mg twice daily at week 12). Patients taking **nevirapine** had similar ciclosporin levels and dose requirements to patients not infected with HIV taking ciclosporin. Dose requirements in the **efavirenz** patients were also much higher than those in patients taking any other antiretroviral. Ciclosporin levels were about 30% lower with **efavirenz** than with **nevirapine** (91 nanograms/mL compared with 130 nanograms/mL at week 2, and 84 nanograms/mL compared with 116 nanograms/mL at week 12).[2] The same authors reported the results of the first 18 patients recruited into this study in an earlier paper, and showed that at 2 years the required ciclosporin dose was slightly lower in patients taking these NNRTIs (1.7 mg/kg compared with 2.6 mg/kg).[3] There were minimal changes in the pharmacokinetics of the NNRTIs during the study.

Mechanism

Efavirenz, etravirine and nevirapine induce the cytochrome P450 isoenzyme CYP3A4 (although etravirine is only a weak inducer[4]). Ciclosporin is extensively metabolised by CYP3A4, so concurrent use would be expected to decrease ciclosporin levels. Note that delavirdine inhibits CYP3A4 and is predicted to increase ciclosporin levels.[5]

Importance and management

The available evidence suggests that **efavirenz** decreases ciclosporin levels and increases the ciclosporin dose requirements. **Nevirapine** may also affect ciclosporin levels but it appears that its effects on ciclosporin levels are much less than those of efavirenz. The manufacturer[4] of **etravirine** predicts that it will also affect ciclosporin levels. Note that as etravirine is only a weak inducer of CYP3A4, any reduction in ciclosporin levels would be expected to be much less than that seen with efavirenz. As subtherapeutic levels of ciclosporin may have significant consequences, including transplant rejection, it would be prudent to monitor ciclosporin levels closely in patients given efavirenz, etravirine or nevirapine.

In contrast, **delavirdine** is predicted to increase ciclosporin levels and so a dose reduction of ciclosporin may be needed. As increased levels may lead to toxicity, it would be prudent to monitor ciclosporin levels and renal function closely in patients also given delavirdine.

Ciclosporin + NSAIDs, Aspirin or Paracetamol (Acetaminophen)

NSAIDs sometimes reduce renal function in individual patients, which is reflected in serum creatinine level rises and possibly in changes in ciclosporin levels, but concurrent use can also be uneventful. Diclofenac levels can be doubled by ciclosporin. There is an isolated report of colitis in a child treated with ciclosporin and diclofenac or indometacin.

Clinical evidence

(a) Aspirin

In a study in healthy subjects, no pharmacokinetic interaction was found when ciclosporin was given with aspirin 960 mg three times daily.[1]

(b) Diclofenac

A study in 20 patients with rheumatoid arthritis given ciclosporin and diclofenac found that 7 of them had a high probability of an interaction (rises in serum creatinine levels and blood pressures), and 9 possibly had an interaction.[2] A kidney transplant patient taking ciclosporin, digoxin, furosemide, prednisolone, and spironolactone had a marked rise in serum creatinine levels immediately after starting to take diclofenac 25 mg three times daily. A fall in serum ciclosporin levels from 409 nanograms/mL to 285 nanograms/mL also occurred.[3] Increased nephrotoxicity was seen in another patient taking ciclosporin for idiopathic uveitis when diclofenac 150 mg daily was given.[4]

A 6-month study in 20 patients with severe rheumatoid arthritis given diclofenac 100 to 200 mg with ciclosporin 3 mg/kg daily found that the AUC of diclofenac was doubled and serum creatinine levels increased from 71 micromol/L to 88.4 micromol/L. The overall pattern of adverse events and laboratory abnormalities were similar to those in patients with rheumatoid arthritis treated with ciclosporin and other NSAIDs. It was suggested that it would be prudent to start with low doses of diclofenac and to monitor well.[5] A study in 24 healthy subjects found that diclofenac 50 mg every 8 hours for 8 days caused no changes in the pharmacokinetics of ciclosporin, but there was some inconclusive evidence that diclofenac serum levels were increased.[6]

A child with rheumatoid arthritis taking ciclosporin 10 mg/kg daily developed colitis when diclofenac was given. The NSAID was stopped and her symptoms resolved while the ciclosporin was continued.[7]

(c) Dipyrone (Metamizole sodium)

A placebo-controlled, crossover study in 6 kidney and 2 heart transplant patients taking ciclosporin, found that while they were taking dipyrone 500 mg three times daily for 4 days the pharmacokinetics of ciclosporin (AUC, trough and peak blood levels, elimination half-life) were unchanged, but the time to reach maximum blood levels was slightly prolonged, from 2.1 hours to 3.8 hours. It is not known what the effects of more prolonged use might be.[8]

(d) Indometacin

A study in 16 healthy subjects found that indometacin 100 mg twice daily for 9 days reduced the maximum blood levels of a single 300-mg dose of ciclosporin by 18% and slowed its absorption (time to maximum concentration increased by 30 minutes) but the extent of absorption was not changed, indicating the absence of a clinically relevant pharmacokinetic interaction. Further, the pharmacokinetics of indometacin were not affected by ciclosporin.[9] A study in rheumatoid arthritis patients taking ciclosporin 2.5 mg/kg daily, found that creatinine clearances were reduced by 6% in those taking indometacin 50 mg four times daily, but this was not considered to be clinically important.[10] An experimental study in healthy subjects found that ciclosporin 10 mg/kg twice daily for 4 days had no effect on effective renal plasma flow or the glomerular filtration rate, but when indometacin 50 mg twice daily was added the effective renal plasma flow fell by 32% and the glomerular filtration rate fell by 37%.[11]

A child with rheumatoid arthritis taking ciclosporin 10 mg/kg daily developed colitis when indometacin was given. The NSAID was stopped and her symptoms resolved while the ciclosporin was continued.[7]

(e) Ketoprofen

A study in rheumatoid arthritis patients taking ciclosporin 2.5 mg/kg daily, found that creatinine clearances were reduced by 2.3% in those taking ketoprofen 50 mg four times daily, but this was not considered to be clinically important.[10] Another report describes increased serum creatinine levels in a patient with rheumatoid arthritis who took ciclosporin and ketoprofen.[12]

(f) Mefenamic acid

The ciclosporin blood levels in a renal transplant patient doubled, accompanied by a rise in creatinine levels from 113 micromol/L to 168 micromol/L, within a day of starting to take mefenamic acid. Levels fell to normal within a week of stopping the mefenamic acid.[13]

(g) Naproxen

When 11 patients with rheumatoid arthritis taking ciclosporin were given naproxen and sulindac, their serum creatinine levels increased by 24% and renal function was reduced (glomerular filtration rate reduced from 98 mL/minute at baseline to 67 mL/minute).[14]

(h) Paracetamol (Acetaminophen)

A study in rheumatoid arthritis patients taking ciclosporin 2.5 mg/kg daily, found that creatinine clearances were reduced by 3.5% in those taking paracetamol 650 mg four times daily, but this was not considered to be clinically important.[10]

(i) Piroxicam

Piroxicam is reported to have increased the serum creatinine levels of a patient with rheumatoid arthritis by an unknown amount (but classed as a significant adverse event). This resolved when the piroxicam was withdrawn.[12] A study in healthy subjects given piroxicam 20 mg daily for 11 days and a single 300-mg dose of ciclosporin on day 10 found no clinically relevant pharmacokinetic interaction.[9]

(j) Sulindac

A study in rheumatoid arthritis patients taking ciclosporin 2.5 mg/kg daily, found that the creatinine clearance was reduced by 2.6% in those taking sulindac 100 mg four times daily, but this was not considered to be clinically important.[10]

A kidney transplant patient had a rise in serum creatinine levels when sulindac was used. Ciclosporin blood levels fell and rose again when the sulindac was stopped.[3] Another report states that the ciclosporin levels of a woman with a kidney transplant were more than doubled within 3 days of her starting to take sulindac 150 mg twice daily.[15] When 11 patients with rheumatoid arthritis taking ciclosporin were given sulindac and naproxen their serum creatinine levels increased by 24% and renal function was reduced (glomerular filtration rate reduced from 98 mL/minute at baseline to 67 mL/minute).[14]

Another report describes a patient with rheumatoid arthritis taking ciclosporin who developed increased serum creatinine levels when given ketoprofen, but not when given sulindac.[12]

Mechanism

Uncertain. One idea is that intact kidney prostacyclin synthesis is needed to maintain the glomerular filtration rate and renal blood flow in patients given ciclosporin, which may possibly protect the kidney from the development of ciclosporin-induced nephrotoxicity. If NSAIDs that inhibit prostaglandin production in the kidney are given, the nephrotoxic effects of the ciclosporin manifest themselves, possibly independently of changes in serum ciclosporin levels.[3] A study in *rats* found that indometacin and ciclosporin together can cause rises in serum creatinine levels that are much greater than with either drug alone.[16]

Ciclosporin may decrease the first-pass metabolism of NSAIDs that are metabolised in this way, such as diclofenac.[17]

The occurrence of colitis in a child receiving ciclosporin and either diclofenac or indometacin appeared to be independent of changes in ciclosporin levels and may be a result of additive effects of both drugs.[7]

Importance and management

Information about the individual NSAIDs listed here is sparse, but when viewed as a group, the overall picture appears to be that concurrent use in rheumatoid arthritis need not be avoided but renal function should be very well monitored. The UK manufacturer of ciclosporin also specifically recommends that patients with rheumatoid arthritis taking ciclosporin and an NSAID should have their liver function measured as well as renal function, because hepatotoxicity is a potential adverse effect of both drugs.[17] It has been suggested that gastrointestinal symptoms should also be carefully evaluated.[7] It is clearly difficult to generalise about what will or will not happen if any particular NSAID is given, but in the case of diclofenac, as its serum levels can be doubled by ciclosporin, it has been recommended that doses at the lower end of the range should be used initially.[5] The UK manufacturer recommends halving the diclofenac dose, and using lower than usual doses of other NSAIDs in patients also taking ciclosporin.[17]

Ciclosporin + Opioids

An isolated report describes neuropsychosis in a patient who was given intravenous ciclosporin and morphine. A single case report describes a patient taking ciclosporin who developed opioid withdrawal on stopping low-dose, transdermal fentanyl.

Clinical evidence, mechanism, importance and management

A patient who underwent kidney transplantation was given ciclosporin 6 mg/kg daily by intravenous infusion over 2 hours and intravenous methylprednisolone postoperatively. He also received patient-controlled analgesia (PCA) as bolus doses of **morphine** 0.5 mg to a total dose of 13 mg on the first day and 11 mg on the second day. On the third day he developed insomnia, anxiety, amnesia, aphasia and severe confusion. The morphine was discontinued and the symptoms subsided after treatment with propofol, diazepam and haloperidol. It was suggested that ciclosporin may have decreased the excitation threshold of neuronal cells, which potentiated the dysphoric effects of **morphine**.[1]

A patient taking ciclosporin following a stem cell transplant developed opioid withdrawal symptoms when transdermal **fentanyl** 25 micrograms/hour was discontinued. The authors suggested that, as withdrawal symptoms are not usual at this dose of fentanyl, ciclosporin may have raised **fentanyl** levels by inhibiting the cytochrome P450 isoenzyme CYP3A4 by ciclosporin. However, they also note that other factors may have played a role, such as the physical and mental status of the patient after the stem cell transplant.[2]

These appear to be isolated cases and almost certainly not of general importance.

Ciclosporin + Orlistat

The absorption of ciclosporin is markedly reduced by orlistat, and cases of low levels have been reported with both the microemulsion formulation (*Neoral*) and the oil formulation (*Sandimmun*), including an episode of acute graft rejection.

Clinical evidence

In the first year after orlistat approval in the US, the FDA in the US noted that they had received six reports of transplant recipients who developed subtherapeutic ciclosporin trough levels (formulation not mentioned) soon after starting to take orlistat.[1] A number of reports have also been published, both with the *Sandimmun* and *Neoral* formulations, as outlined below.

1. Neoral formulation. In a pharmacokinetic study in healthy subjects given low-dose ciclosporin 50 mg twice daily, orlistat 120 mg three times daily with meals reduced the trough level and AUC of ciclosporin by 27% and 34%, respectively, when ciclosporin was also taken with meals. When ciclosporin was taken 3 hours after meals, the reduction in ciclosporin trough levels was similar.[2]

A heart transplant patient taking ciclosporin had an unexpected non-significant acute rejection episode noted on routine endocardial biopsy, with very low trough ciclosporin levels of 38 nanograms/mL, 24 days after starting to take orlistat. Ciclosporin trough levels returned to previous levels of between 90 to 110 nanograms/mL when the orlistat was stopped, suggesting that orlistat had caused about a 60% drop in ciclosporin levels.[3]

Another similar report describes one patient who was found to have about a 50% reduction in ciclosporin levels 44 days after starting orlistat 120 mg twice daily (lunch and dinner), and another who had a 45% reduction in ciclosporin levels, noted 6 days after starting orlistat 120 mg three times daily.[4] One patient who was unable to achieve therapeutic ciclosporin levels after starting orlistat 360 mg daily while taking the *Sandimmun* formulation (see below) was subsequently stabilised on the *Neoral* formulation at a 50% higher dose than his original *Sandimmun* dose.[5]

2. Sandimmun formulation. In a heart transplant patient taking ciclosporin, orlistat 120 mg three times daily for 2 weeks was found to have reduced the trough blood levels of ciclosporin by 50%, to 50 nanograms/mL. A subsequent pharmacokinetic study in this patient confirmed that orlistat reduced the trough and peak levels and the AUC of ciclosporin by 47%, 86% and 75%, respectively.[6] In a further patient taking ciclosporin 250 mg daily, orlistat 360 mg daily reduced the ciclosporin levels by 67% (from 150 to 50 nanograms/mL). Increasing the dose of ciclosporin did not result in an increased level, so the patient was given *Neoral* instead (see above).[5] Another heart transplant patient had a progressive reduction in her ciclosporin level when she started to take orlistat 120 mg three times daily (28% reduction at 5 days and 46% at 10 days), despite taking the orlistat 2 hours before the ciclosporin. Stopping the breakfast dose of orlistat did not result in increased ciclosporin levels, but levels did return to normal when orlistat was stopped. Note that this patient was also reported to have severe diarrhoea secondary to poor adherence to a low-fat diet when taking orlistat, which may have contributed to the low ciclosporin levels seen.[7]

Mechanism

Orlistat inhibits pancreatic lipase and prevents the absorption of dietary fat and lipophilic molecules such as ciclosporin. Absorption of ciclosporin from the oil suspension formulation (*Sandimmun*) is more dependent on the lipid absorption stage and thus may be more affected by orlistat than the microemulsion form (*Neoral*).[5]

Importance and management

An established interaction, that has the potential to be clinically important. It has been suggested that the effects of the interaction may be reduced by using the microemulsion formulation of ciclosporin (*Neoral*),[5] which has generally replaced the corn oil suspension (*Sandimmun*). However, close monitoring is required if the two drugs are used together, either in the standard or microemulsion form, because there is still a risk of subtherapeutic levels. Some authors recommend avoidance of the combination.[4,6] The UK manufacturer of orlistat does not recommend concurrent use, but notes that if it is unavoidable more frequent ciclosporin monitoring is recommended.[8] The US manufacturer also advises against concurrent use. They recommend taking ciclosporin at least 2 hours before or 2 hours after orlistat to reduce the chance of an interaction, and that ciclosporin levels should be monitored more frequently in patients whose levels are being monitored.[9] However, there is evidence that separation of doses does not avoid the interaction.[2,7]

Ciclosporin + Oxybutynin

Oxybutynin did not appear to affect ciclosporin levels in two children.

Clinical evidence, mechanism, importance and management

In a retrospective analysis, one child with a kidney transplant taking ciclosporin had no change in his ciclosporin level and dose over the 2 months before and the 2 months after he started taking oxybutynin 2 mg twice daily. Another patient had no change in ciclosporin levels and dose over the 3 months before and 3 months after stopping oxybutynin 5 mg twice daily.[1]

Although the evidence is limited, it suggests that oxybutynin is unlikely to have an important effect on ciclosporin levels.

1. Springate JE. Oxybutynin does not affect cyclosporin blood levels. *Ther Drug Monit* (2001) 23, 155–6.

Ciclosporin + Pancreatic enzymes

Pancreatic enzyme extracts do not increase the bioavailability of ciclosporin in cystic fibrosis patients.

Clinical evidence, mechanism, importance and management

A study in heart-lung transplant patients with cystic fibrosis found that they needed almost five times the oral dose of ciclosporin than other patients, confirming other studies in these patients that had found a very much reduced bioavailability of oral ciclosporin. This is probably a reflection of the generally poor digestion and absorption in cystic fibrosis patients. The addition of pancreatic enzymes (*Creon*) was not found to improve this poor ciclosporin bioavailability. No adverse effects were reported.[1]

1. Tsang VT, Johnston A, Heritier F, Leaver N, Hodson ME, Yacoub M. Cyclosporin pharmacokinetics in heart-lung transplant recipients with cystic fibrosis. *Eur J Clin Pharmacol* (1994) 46, 261–5.

Ciclosporin + Phosphodiesterase type-5 inhibitors

Sildenafil and vardenafil do not alter ciclosporin levels.

Clinical evidence

(a) Sildenafil

In a clinical study in 5 kidney transplant recipients, sildenafil 25 to 100 mg in repeated doses had no effect on the AUC, trough or maximum levels of ciclosporin over 8 weeks.[1] Similarly, in other clinical studies, sildenafil 50 or 100 mg in repeated doses for 72 hours to 4 weeks had no effect on ciclosporin trough levels.[2-4] No significant changes in blood pressure were reported in one of these studies.[3]

(b) Vardenafil

In a study in 14 renal transplant patients, vardenafil 10 or 20 mg (maximum frequency of once in 24 hours) in repeated doses during a 4-week period had no effect on levels or required dose of ciclosporin and no change in renal function was reported.[5]

Mechanism

None.

Importance and management

No significant pharmacokinetic interaction appears to occur between ciclosporin and sildenafil or vardenafil. Therefore, no ciclosporin dose adjustment would be expected to be necessary in patients taking these drugs. In two studies with 'tacrolimus', (p.1305), there was a decrease in blood pressure with sildenafil; but this was not seen n the one study that assessed this effect. Nevertheless, it has been suggested that sildenafil be started at a low dose in all kidney transplant patients, with the dose increased according to efficacy and tolerability.[6]

Ciclosporin or Tacrolimus + Potassium compounds

Ciclosporin and tacrolimus alone can cause or worsen pre-existing hyperkalaemia, and the concurrent use of potassium compounds may exacerbate this.

Clinical evidence, mechanism, importance and management

Both ciclosporin and tacrolimus can cause hyperkalaemia.[1,2] Hyperkalaemia can in itself be a sign of worsening renal function but may be exacerbated by ciclosporin or tacrolimus. This can be worsened further by the use of potassium supplements.

Note that potassium levels are usually routinely monitored during the use of ciclosporin and tacrolimus, and this monitoring should probably be increased if other drugs that affect potassium levels, such as potassium supplements, are also given. The UK manufacturer of tacrolimus recommends that patients should avoid a high potassium intake, such as in supplements.[1]

Ciclosporin + Prazosin

Preliminary studies found that prazosin caused a small reduction in the glomerular filtration rate in kidney transplant patients taking ciclosporin.

Clinical evidence, mechanism, importance and management

A study in 8 kidney transplant patients found that prazosin 1 mg twice daily for one week did not alter their ciclosporin blood levels, and arterial blood pressures and renal vascular resistance were reduced. However, the glomerular filtration rate (GFR) was reduced by about 10% (from 47 to 42 mL/minute).[1] Previous studies in kidney transplant patients taking azathioprine, prednisone and prazosin found no reduction in GFR.[2] There would seem to be no strong reason for totally avoiding prazosin in patients taking ciclosporin, but the authors of the report point out that the fall in GFR makes prazosin a less attractive antihypertensive than a calcium-channel blocker.

Ciclosporin + Probucol

Probucol modestly to markedly reduces blood ciclosporin levels.

Clinical evidence

A study in 6 heart transplant patients taking ciclosporin found that the concurrent use of probucol 500 mg every 12 hours decreased trough whole blood ciclosporin levels by 42% from 139 nanograms/mL to 81 nanograms/mL, and reduced the AUC_{0-9} by 28%. The clearance was increased by 60% and volume of distribution also increased.[1] Another study similarly found that 9 out 10 kidney transplant patients had a reduction in their trough blood ciclosporin levels while taking probucol.[2]

In 5 patients with nephrotic syndrome, probucol 250 to 500 mg daily decreased trough ciclosporin levels by 36 to 56%.[3] Although not specified, it is assumed that these studies used the original *Sandimmun* formulation. The same group of workers found that in 4 patients with nephrotic syndrome taking ciclosporin (*Neoral*), probucol 500 mg daily decreased the trough ciclosporin levels by 17 to 30%.[4]

Mechanism

Not understood. Probucol appears to reduce the absorption of ciclosporin. Evidence from *in vitro* and *animal* studies found that probucol does not affect ciclosporin absorption via P-glycoprotein-mediated transport.[5]

Importance and management

Information appears to be limited to these studies, but the interaction appears to be established. The ciclosporin dose may need to be increased if probucol is added. Monitor the effects and adjust the dose appropriately. Note that one group of researchers consider that *Neoral* is less affected than *Sandimmun*.[4]

Ciclosporin + Propafenone

In an isolated report, propafenone caused a 60% increase in the ciclosporin levels of a patient.

Clinical evidence, mechanism, importance and management

A heart transplant patient taking ciclosporin, azathioprine and prednisolone developed ventricular tachycardia 9 months after transplantation, for which he was given propafenone 600 or 750 mg daily. After the first day, his ciclosporin level had risen from about 160 nanograms/mL to 190 nanograms/mL, and after 5 days the levels had reached around 260 nanograms/mL. Over the same time period his serum creatinine rose from 168 micromol/L to 212 micromol/L. His ciclosporin dose was reduced from 240 mg daily to a final dose of 200 mg daily after which his renal function and ciclosporin levels were re-established at about the level before propafenone was started.[1] The authors suggest that propafenone interferes with the metabolism of ciclosporin by affecting hepatic cytochrome P450, or that propafenone may enhance the absorption of ciclosporin. Information appears to be limited to this one report, the general importance of which is unknown.

Ciclosporin + Protease inhibitors

Protease inhibitors can markedly increase the levels of ciclosporin. This has been demonstrated for fosamprenavir, indinavir, nelfinavir, saquinavir, and ritonavir-boosted amprenavir, indinavir and lopinavir. Some evidence suggests that ciclosporin may increase indinavir, nelfinavir and saquinavir levels, but in one study, this effect was not sustained.

Clinical evidence

(a) Fosamprenavir

An HIV-positive patient taking ciclosporin 250 to 350 mg twice daily (to maintain a therapeutic ciclosporin trough level of 300 to 400 nanograms/mL) was restarted on his usual HAART regimen of tenofovir, lamivudine and fosamprenavir 1.4 g twice daily on day 12 post-liver transplantation. Within 2 days, the ciclosporin level had increased to 600 nanograms/mL, requiring a ciclosporin dose reduction to 100 mg twice daily; a reduction of about 70%.[1]

(b) Nelfinavir

A pilot study in 7 HIV-positive subjects taking nelfinavir 1.25 g twice daily found that a single 4-mg/kg oral dose of ciclosporin slightly increased the time to maximum serum level for nelfinavir from 2.6 to 3.2 hours. The AUC of nelfinavir was also increased by 55%, but this was not statistically significant. In the same study, a single 2-mg/kg intravenous dose of ciclosporin given over 2.5 hours had little effect on the pharmacokinetics of oral nelfinavir. The pharmacokinetics of oral ciclosporin in this study did not appear to differ from that seen in healthy subjects in other studies, but there was high inter-individual variability.[2] However, in another study by this research group, when ciclosporin was added to established antiretroviral therapy after liver or kidney transplantation in 35 HIV-positive patients, those taking protease inhibitor-based regimens (not specified) required a marked reduction in ciclosporin dose and about a 50% increase in dosing interval at week 2 when compared with those taking an NNRTI-based regimen.[3] Furthermore, the same authors reported the results of the first 18 patients recruited into this study in an earlier paper, and showed that in 5 patients taking nelfinavir or **indinavir**-based antiretroviral regimens, the required ciclosporin dose decreased by 85% from 1.3 mg/kg to just 0.2 mg/kg in the 2 years after transplantation. The AUC of the protease inhibitor generally increased in the first few weeks after starting ciclosporin, but gradually returned to baseline by week 28.[4]

(c) Ritonavir-boosted regimens

Three HIV-positive patients who had undergone liver transplantation required reductions in their ciclosporin doses when they started taking ritonavir-boosted **lopinavir** based HAART. One patient taking ciclosporin 150 mg twice daily had an increase in his ciclosporin levels to 900 nanograms/mL when HAART was started, and needed a dose reduction of 95% to maintain a usual ciclosporin trough level of 75 to 150 nanograms/mL. A second patient also required a similar reduction. The third patient needed a dose reduction of 80% when taking ritonavir-boosted **lopinavir**, but no further ciclosporin dose alteration was needed when his treatment was changed to ritonavir-boosted **indinavir**.[5] In a similar case, a reduction in ciclosporin dose from 200 to 350 mg twice daily to just 25 mg twice daily was required on restarting a ritonavir-boosted **amprenavir** containing regimen (about a 90% reduction).[1] Likewise, a study in 35 HIV-positive patients given ciclosporin post-transplant, found a greater reduction in ciclosporin dose requirements when ritonavir was given with protease inhibitors (not specified) than when the protease inhibitors were given alone (25 mg twice daily compared with 57 to 75 mg twice daily).[3]

(d) Saquinavir

An HIV-positive patient taking lamivudine and zidovudine, and ciclosporin for a kidney transplant, started taking saquinavir 1.2 g three times daily. Within 2 days he started to complain of fatigue, headache and gastrointestinal discomfort. On investigation his ciclosporin level was found to have risen from a range of 150 to 200 nanograms/mL up to 580 nanograms/mL, and his saquinavir AUC was increased 4.3-fold (by comparison with subjects not taking ciclosporin). His ciclosporin dose was reduced by 50% from 150 mg twice daily to 75 mg twice daily, and his saquinavir dose was reduced to 600 mg three times daily, which resulted in ciclosporin levels similar to those achieved previously.[6]

Mechanism

All protease inhibitors can inhibit the cytochrome P450 isoenzyme CYP3A4 to varying degrees, see 'Antivirals', (p.913). Ciclosporin is extensively metabolised by CYP3A4, so any inhibition of this isoenzyme is likely to increase ciclosporin levels. Ciclosporin is also a modest inhibitor of CYP3A4 and P-glycoprotein, which may explain the raised nelfinavir and saquinavir levels.

Importance and management

An established interaction. The inhibition of ciclosporin metabolism by protease inhibitors may lead to marked increases in ciclosporin levels. Therefore ciclosporin levels should be carefully monitored and the dose adjusted accordingly during concurrent use, bearing in mind that large dose reductions may be required in some patients. The dose reductions needed in the various case reports have been 80 to 95% for ritonavir-boosted regimens, 85% for nelfinavir or indinavir, 67% for fosamprenavir and 50% for saquinavir. The clinical significance of the effects of ciclosporin on saquinavir or nelfinavir pharmacokinetics is unclear, but in one study the effect was not sustained.

Ciclosporin + Proton pump inhibitors

Omeprazole does not normally appear to affect ciclosporin levels, but there is an isolated report of doubled ciclosporin levels in one patient, and, conversely, more than halved ciclosporin levels in another. Pantoprazole does not appear to affect ciclosporin levels.

Clinical evidence

(a) Omeprazole

In a placebo-controlled study, ten kidney transplant patients had no clinically or statistically significant changes in trough ciclosporin levels when given omeprazole 20 mg daily for 2 weeks.[1] Eight kidney transplant patients given omeprazole 20 mg daily for 6 days similarly had no significant changes in ciclosporin levels when compared with control patients not taking omeprazole.[2] No significant changes in ciclosporin levels were seen in another kidney transplant patient when omeprazole 20 mg daily was given for 8 weeks.[3]

However, in one retrospective analysis, the dose of ciclosporin required to give a specific level was 28% lower in 21 patients taking omeprazole (dose not stated), when compared with 139 patients not taking omeprazole.[4] There is also a case in which the ciclosporin blood levels of a liver transplant patient roughly doubled (from a range of 187 to 261 nanograms/mL up to 510 nanograms/mL) about 2 weeks after omeprazole 40 mg daily was started. His ciclosporin levels were readjusted by reducing the dose from 130 to 80 mg twice daily. The levels then remained steady at about 171 nanograms/mL for the following 4 months.[5] In contrast, the serum ciclosporin levels of a bone marrow transplant patient fell from 254 nanograms/mL to about 100 nanograms/mL over 14 days in the presence of omeprazole 40 mg daily. The ciclosporin levels increased rapidly when omeprazole was stopped.[6]

(b) Pantoprazole

Two studies in kidney transplant patients found that pantoprazole 40 mg daily did not affect ciclosporin blood levels when given in the evening,[7] or when both drugs were given together in the morning.[8]

Mechanism

Not understood.

Importance and management

There is good evidence that omeprazole 20 mg daily does not alter the pharmacokinetics of ciclosporin, and also evidence that pantoprazole 40 mg daily does not interact. There is no explanation for the opposite findings (an increase or decrease in ciclosporin levels) from the two isolated case reports in patients given omeprazole 40 mg daily. The concurrent use of ciclosporin and these proton pump inhibitors need not be avoided, but it may be prudent to consider the possibility of an interaction if patients taking higher doses of omeprazole have otherwise unexplained changes in ciclosporin levels..

Ciclosporin + Pyrazinamide

Pyrazinamide does not normally appear to interact with ciclosporin, but one isolated report suggests that it may possibly have contributed to the effects of rifampicin in one patient, which resulted in lowered ciclosporin levels. Another patient developed toxic myopathy, which was attributed to the use of pyrazinamide with ciclosporin.

Clinical evidence, mechanism, importance and management

A number of reports mention that anti-tuberculosis regimens containing pyrazinamide and without rifampicin, do not appear to alter ciclosporin levels in kidney transplant patients, and some are cited as examples.[1-3] These regimens frequently consisted of combinations of pyrazinamide, ethambutol, isoniazid and streptomycin. In one early report, a 12-year-old girl with a kidney transplant taking ciclosporin and prednisolone had a rejection episode while taking rifampicin and isoniazid, apparently due to the fall in serum ciclosporin levels caused by the rifampicin. The rejection settled when the rifampicin was replaced by pyrazinamide.[1] However, an anecdotal report suggested that when pyrazinamide was given with rifampicin and isoniazid it appeared to add to the effects of the rifampicin causing an additional reduction in ciclosporin blood levels.[4] Another report attributed the development of toxic myopathy in a kidney transplant patient to the concurrent use of pyrazinamide and ciclosporin.[5]

There would seem to be no reason for avoiding pyrazinamide in patients taking ciclosporin, but be aware of these rare complications.

Ciclosporin + Quinine

An isolated case suggests that quinine reduces ciclosporin levels.

Clinical evidence, mechanism, importance and management

A man with a kidney transplant and mild cerebral falciparum malaria had a gradual decrease in his ciclosporin blood levels, from 328 nanograms/mL to 107 nanograms/mL over 7 days, when he was given quinine 600 mg every 8 hours. A gradual rise in the ciclosporin levels occurred when the quinine was stopped.[1]

The reason for this apparently isolated report is unclear and its general importance is unknown. There is insufficient evidence to recommend

increased monitoring, but be aware of the potential for an interaction in the case of an unexpected response to treatment. The effects of lower quinine doses used for cramps are unclear.

Ciclosporin + Red yeast rice (*Monascus purpureus*)

Red yeast rice has been reported to cause rhabdomyolysis in a kidney transplant patient taking ciclosporin.

Clinical evidence, mechanism, importance and management

A kidney transplant patient taking ciclosporin 300 mg daily developed asymptomatic rhabdomyolysis when she started to take a herbal preparation of red yeast rice containing rice fermented with red yeast, beta-sitosterol, danshen root (*Salvia mitorriza*) and garlic bulb (*Allium sativum*). Two months later, her creatine phosphokinase rose to 1050 units/L but reduced to 600 units/L 2 weeks after stopping the herbal preparation. It is thought that a component of the red yeast rice called monacolin K (identical to lovastatin) probably caused the muscle toxicity.[1] Although this appears to be an isolated case it would be expected to be generally significant as ciclosporin is well known to interact with the statins, and this interaction appeared to be mediated by a statin-like component. Concurrent use need not be avoided, but it would seem prudent to discuss the potential effects with patients and describe the symptoms of myopathy. Patients should report any unexplained muscle pain, tenderness or weakness.

Ciclosporin + Retinoids

An increase in ciclosporin blood levels in one patient was attributed in part to starting etretinate. Two patients had an increase in their ciclosporin levels while taking isotretinoin, although in neither case was this attributed to an interaction. Another patient taking both drugs had no alteration in ciclosporin levels.

Clinical evidence

(a) Etretinate

In one case, a woman with generalised pustular psoriasis taking ciclosporin 200 mg daily had a considerable rise in her ciclosporin blood levels from 176 micrograms/L to 540 micrograms/L 7 days after the ciclosporin dose was increased to 300 mg daily and 3 days after etretinate 50 mg daily was added. An interaction was suspected as contributing to this effect because it was found possible to reduce the ciclosporin dose gradually to 150 mg daily (accompanied by a fall in the trough ciclosporin blood levels to 168 micrograms/L), without any loss in the control of the disease.[1] In small studies or case reports, etretinate has been considered to have a ciclosporin-sparing effect,[2-4] or to have modest or no additional benefit.[5,6].

(b) Isotretinoin

A 27-year old man with a heart transplant taking ciclosporin was given isotretinoin 40 mg daily for 2 months, then 80 mg daily up to 20 weeks. His ciclosporin trough levels remained within the recommended range, and there was no evidence of graft rejection.[7] Another man with a heart transplant taking ciclosporin received isotretinoin 1 mg/kg daily for 4 months. His daily ciclosporin dose was reduced from 7 mg/kg to 6 mg/kg one month after starting isotretinoin because of a rise in ciclosporin level to 587 nanograms/mL. However, it was noted that this may have had nothing to do with the isotretinoin, because the patient required alterations in ciclosporin dose in 3 instances before isotretinoin was started. No laboratory abnormalities or ciclosporin toxicity were seen, and the heart transplant function remained satisfactory.[8] A 13-year-old girl with aplastic anaemia, who was taking ciclosporin, was given isotretinoin 40 mg daily for 20 weeks. She had a threefold increase in her trough ciclosporin level at week 17, which was considered probably unrelated to isotretinoin, and was managed by reducing her ciclosporin dose. Serum lipids did not change during concurrent use.[9]

Mechanism

Uncertain. An *in vitro* study using human liver microsomes found that concentrations of 100 micromol of acitretin, etretinate and isotretinoin inhibited the total ciclosporin metabolism and total primary ciclosporin metabolite production to the same extent (32 to 45%).[1] These figures suggest that the retinoids may inhibit ciclosporin metabolism. However, another *in vitro* study using human liver microsomes did not find that etretinate inhibits the metabolism of ciclosporin.[10]

Importance and management

From the one published case, it is unclear if etretinate has any effect on ciclosporin levels. Similarly, from the cases presented, it is also unclear if isotretinoin alters ciclosporin levels. However, the potential for an interaction cannot entirely be dismissed. Note, that it has been suggested that serum lipids should be monitored if isotretinoin is given with ciclosporin because both drugs can cause an increase in lipids.[7]

Ciclosporin + Sevelamer

Sevelamer did not appear to alter ciclosporin levels in one study; however, a case report describes markedly reduced ciclosporin levels within 6 days of starting sevelamer.

Clinical evidence

In a study in 18 kidney transplant patients taking ciclosporin (with 9 patients also taking mycophenolate), the pharmacokinetics of ciclosporin were unchanged after they took sevelamer as a single 1.6- or 1.2-g dose and when this dose of sevelamer was given three times daily for 4 days.[1] Eight of the patients were children (average age 12 years). The largest change was a 9% decrease in the ciclosporin AUC after 4 days of sevelamer use, but this was not statistically significant. The AUC of one metabolite of ciclosporin, AM1, was reduced by about 30%. In this study, ciclosporin was taken at the same time as sevelamer.[1] In contrast, a transplant patient taking ciclosporin 60 mg daily needed a dose increase to 85 mg daily to maintain ciclosporin levels within about 6 days of starting sevelamer 806 mg three times daily. Her trough ciclosporin level fell from about 79 nanograms/mL, to 62 nanograms/mL on day one, to 42 nanograms/mL on day 3, and then to 35 nanograms/mL on day 6 (figures taken from a graph). When the sevelamer was stopped after 50 days because of gastrointestinal intolerance, ciclosporin levels rose, but then fell again on restarting sevelamer.[2]

Mechanism

Sevelamer may bind with ciclosporin in the gut preventing ciclosporin absorption.[2,3] It may also bind with the ciclosporin metabolite AM1 secreted in the bile, so preventing its reabsorption.[1]

Importance and management

The first study did not find a clinically relevant interaction with 4 days of sevelamer use, but the case report appears to contradict this finding. The reasons for this are unclear. The manufacturers of sevelamer recommend that drugs for which a reduction in bioavailability could be clinically important should be taken at least one hour before or 3 hours after sevelamer, or consideration should be given to monitoring blood levels of these drugs.[4,5] The UK manufacturer specifically names ciclosporin and recommends that close monitoring should be considered both on concurrent use and when sevelamer is stopped.[4] Until more is known, this would appear to be prudent. Further study is required with longer-term administration and to evaluate whether separating doses minimises the extent of the interaction.

Ciclosporin + Sibutramine

One case report describes an increase in ciclosporin levels when orlistat was stopped and sibutramine started. Ciclosporin is predicted to raise sibutramine levels.

Clinical evidence

A kidney transplant patient taking ciclosporin 100 mg twice daily was changed from orlistat to sibutramine 10 mg daily, as orlistat for 27 months had been unsuccessful. One week later her trough ciclosporin level had increased from 79 nanograms/mL to 152 nanograms/mL and her ciclosporin daily dose was reduced by 25 mg. Her ciclosporin level was still raised one week later (at 162 nanograms/mL) and her ciclosporin daily dose was again reduced by 25 mg. No increase in blood pressure or serum creatinine occurred, and the ciclosporin trough levels remained stable over the following 10 months.[1]

Mechanism

Unknown. The authors propose a mechanism via inhibition of the cytochrome P450 isoenzyme CYP3A4;[1] however, sibutramine is not an inhibitor of this isoenzyme.[2] Note that the UK manufacturer of sibutramine predicts that ciclosporin may lead to an increase in levels of the active metabolites of sibutramine, by inhibiting CYP3A4,[2] although note that ciclosporin is only a modest inhibitor of this isoenzyme.

Importance and management

This appears to be the only case report of an increase in ciclosporin levels with sibutramine, and therefore its general relevance is uncertain. The fact that the patient had previously been taking orlistat, which can markedly reduce ciclosporin levels, raises the possibility that the increase in ciclosporin levels in this case was due to stopping orlistat rather than starting sibutramine, but insufficient information was presented to evaluate this possibility. For further information on the interaction of orlistat with ciclosporin, see 'Ciclosporin + Orlistat', p.1247.

The UK manufacturer of sibutramine recommends caution on the concurrent use of ciclosporin because of the possibility of increased sibutramine levels and adverse effects.[2] Further study is needed.

Ciclosporin + Somatostatin analogues

Octreotide causes a marked reduction in ciclosporin levels and inadequate immunosuppression may result. Lanreotide is predicted to interact similarly.

Clinical evidence

A diabetic man with kidney and pancreatic segment transplants was successfully immunosuppressed with azathioprine, methylprednisolone and ciclosporin. When he was also given subcutaneous **octreotide** 100 micrograms twice daily to reduce fluid collection around the pancreatic graft, his trough ciclosporin blood levels fell below the assay detection limit of 50 nanograms/mL. Serum creatinine increased dramatically, which was interpreted as a selective rejection episode of the kidney transplant. Nine other patients with diabetes similarly treated with **octreotide** for peripancreatic fluid collection and fistulas after pancreatic transplantation also had significant falls in their ciclosporin blood levels within 24 to 48 hours, in 3 of them to undetectable levels.[1] A similar interaction was seen in another patient.[2]

Mechanism

Uncertain. A suggestion is that the octreotide reduces the intestinal absorption of ciclosporin.[1,2]

Importance and management

The interaction between octreotide and ciclosporin is established and clinically important, although the documentation is limited. The authors of one report recommend that before giving octreotide the oral dose of ciclosporin should be increased on average by 50% and the serum levels monitored daily.[1] The manufacturer of **lanreotide** says that, as with other somatostatin analogues, it may reduce the absorption of ciclosporin from the gut.[3] As yet there appear to be no reports of this interaction in practice; however, it would be prudent to monitor the outcome of the use of lanreotide with ciclosporin.

Ciclosporin + SSRIs

A small study found no evidence of an interaction between fluoxetine and ciclosporin although one case of doubled ciclosporin levels has been seen. One case of increased ciclosporin levels with an increase in serum creatinine has been reported with fluvoxamine. Limited evidence suggests that citalopram, paroxetine and sertraline do not interact. Serotonin syndrome has been seen in one patient taking ciclosporin and sertraline and another taking ciclosporin and escitalopram.

Clinical evidence

(a) Citalopram

In 5 transplant patients the pharmacokinetics of ciclosporin were not significantly affected by citalopram 10 to 20 mg daily.[1]

(b) Escitalopram

An 84-year-old woman with a kidney transplant taking ciclosporin developed delirium associated with hyperthermia 6 months after starting escitalopram, titrated to 15 mg daily, which was attributed to serotonin syndrome. Her condition improved rapidly on stopping escitalopram.[2]

(c) Fluoxetine

A small, retrospective study in 9 liver transplant and 4 heart transplant patients found no evidence that fluoxetine 5 to 20 mg daily increased ciclosporin blood levels.[3] Another patient had just a minimal 7% increase in ciclosporin levels after starting fluoxetine 20 mg daily.[4] However, the ciclosporin blood levels of a heart transplant patient were doubled by fluoxetine 20 mg daily for 10 days. They fell when the ciclosporin dose was reduced and needed to be increased again when fluoxetine was stopped.[5]

(d) Fluvoxamine

A kidney transplant patient had an approximate 60% increase in ciclosporin blood levels, an increase in serum creatinine levels and fine

tremor 2 weeks after starting fluvoxamine 100 mg daily. The ciclosporin dose was subsequently reduced by 33%.[6]

(e) Paroxetine

Two patients had minimal changes in ciclosporin levels (7.5% decrease and a 23% increase) after starting paroxetine 20 mg daily.[4]

(f) Sertraline

A 53-year-old man taking ciclosporin following a kidney transplant developed serotonin syndrome 5 days after starting to take sertraline 50 mg daily. This resolved on stopping the sertraline.[7]

Three patients had just minimal changes in ciclosporin levels (11.5% increase, 10 to 12% decrease, 9 to 17% decrease) after starting sertraline (25 mg daily, 50 to 100 mg daily, 50 mg daily, respectively).[4] One report briefly mentions that a patient taking ciclosporin had her antidepressant medication switched from nefazodone to sertraline, because sertraline did not affect ciclosporin levels.[8]

Mechanism

Fluvoxamine is a minor inhibitor of the cytochrome P450 isoenzyme CYP3A4, the main isoenzyme by which ciclosporin is metabolised. Concurrent use may therefore lead to increased ciclosporin levels. Fluoxetine is considered a weak inhibitor of CYP3A4 and may interact possibly raise ciclosporin levels by this mechanism. Citalopram, paroxetine and sertraline do not usually inhibit CYP3A4, and would therefore not be expected to interact.

Serotonin syndrome is a rare adverse effect, usually, but not always, associated with the use of more than one serotonergic drug (see 'serotonin syndrome', (p.9)). On the basis that ciclosporin has been reported to increase serotonin turnover within the brain in *mice*, the reaction was attributed to an interaction between the SSRIs and ciclosporin in one of the cases described.[7] However, serotonin syndrome has occurred with SSRIs alone, so ciclosporin may not have played any role in these cases.

Importance and management

Evidence is limited. From the one case with fluvoxamine, it appears that this SSRI can cause a clinically significant increase in ciclosporin levels, resulting in an increase in adverse effects. Concurrent use should be closely monitored, or a non-interacting antidepressant used. Fluoxetine has been used without interaction, but in one case, ciclosporin levels were doubled, so some caution would seem prudent. Citalopram, paroxetine and sertraline do not appear to affect ciclosporin levels to a clinically relevant extent, and may therefore be suitable alternatives. Escitalopram, the *S*-isomer of citalopram, would also not be expected to interact.

The relevance of ciclosporin to the occurrence of serotonin syndrome with escitalopram and sertraline in the two cases cited is uncertain.

Ciclosporin + St John's wort (*Hypericum perforatum*)

Marked reductions in ciclosporin blood levels and transplant rejection can occur within a few weeks of starting St John's wort.

Clinical evidence

A marked fall in ciclosporin blood levels in one kidney transplant patient was identified as being due to the addition of St John's wort extract 300 mg three times daily. When the St John's wort was stopped the ciclosporin levels rose. The authors of this report identified another 35 kidney and 10 liver transplant patients whose ciclosporin levels had fallen by an average of 49% (range 30 to 64%) after starting St John's wort. Two of them had rejection episodes.[1,2] In addition, subtherapeutic ciclosporin levels in 7 kidney transplant patients,[3-7] one liver transplant patient,[8] and 6 heart transplant patients[9-11] have been attributed to self-medication with St John's wort. Acute graft rejection episodes occurred in 7 cases,[3,5,7-9,11] and one patient subsequently developed chronic rejection, requiring a return to dialysis.[5] Another case of subtherapeutic ciclosporin levels occurred in a kidney transplant patient during the concurrent use of a herbal tea containing St John's wort. The patient's ciclosporin levels remained subtherapeutic despite a ciclosporin dose increase from 150 to 250 mg daily. The levels recovered within 5 days of stopping the herbal tea and the ciclosporin dose was reduced to 175 mg daily.[12]

These case reports are supported by a small study in which 11 kidney transplant patients, with stable dose requirements for ciclosporin, were given St John's wort extract (*Jarsin 300*) 600 mg daily for 14 days. Pharmacokinetic changes were noted 3 days after the St John's wort was added. By day 10 the ciclosporin dose had to be increased from an average of 2.7 to 4.2 mg/kg daily in an attempt to keep ciclosporin levels within the therapeutic range. Two weeks after the St John's wort was stopped, only 3 patients had been successfully re-stabilised on their baseline ciclosporin dose. Additionally, the pharmacokinetics of various ciclosporin metabolites were substantially altered.[13]

Another study in 10 kidney transplant patients stable taking ciclosporin found that the content of hyperforin in the St John's wort affected the extent of the interaction with ciclosporin. In patients taking St John's wort with a high hyperforin content (hyperforin 7 mg; hypericin 0.45 mg) the reduction in the $AUC_{0\text{-}12}$ of ciclosporin was 45% greater than that in patients taking St John's wort with a low hyperforin content (hyperforin 0.1 mg; hypericin 0.45 mg). The maximum blood ciclosporin level and the trough ciclosporin level were also reduced by 36% and 45%, respectively, in the patients taking the higher hyperforin-containing St John's wort preparation, when compared with the patients taking the preparation with a lower hyperforin content. The patients taking the high-hyperforin preparation required a mean ciclosporin dose increase of 65% whereas the patients taking the low-hyperforin preparation did not require any ciclosporin dose alterations.[14]

Mechanism

St John's wort is a known inducer of the cytochrome P450 isoenzyme CYP3A4 by which ciclosporin is metabolised. Concurrent use therefore reduces ciclosporin levels. It has also been suggested that St John's wort affects ciclosporin reabsorption by inducing the drug transporter protein, P-glycoprotein, in the intestine.[9,13]

Importance and management

An established and clinically important interaction. The incidence is not known, but all transplant patients taking ciclosporin should avoid St John's wort because of the potential severity of this interaction. Transplant rejection can develop within 3 to 4 weeks. It is possible to accommodate this interaction by increasing the ciclosporin dose[11] (possibly about doubled) but this raises the costs of an already expensive drug. Also, the varying content of natural products would make this hard to monitor. The advice of the CSM in the UK is that patients receiving ciclosporin should avoid or stop taking St John's wort. In the latter situation, the ciclosporin blood levels should be well monitored and the dose adjusted as necessary.[15] The study described above suggests that increased monitoring will be needed for at least 2 weeks after the St John's wort is stopped.[13] There appears to be no information on the clinical relevance of this interaction in patients taking ciclosporin for reasons other than immunosuppression following transplantation. Nevertheless, because of the large reduction in ciclosporin levels seen, treatment failure seems likely, and therefore it would also seem prudent for these patient to avoid the use of St John's wort.

Ciclosporin + Sucrose polyesters

Sucrose polyesters (e.g. *Olestra*) may modestly reduce the bioavailability and peak levels of ciclosporin.

Clinical evidence, mechanism, importance and management

In a study in 7 kidney transplant patients aged 9 to 18 years, a single 0.35-g/kg dose (maximum of 16 g) of sucrose polyesters (*Olestra*), reduced the ciclosporin AUC and peak levels by almost 19% and 27%, respectively, when taken at the same time as the usual dose of ciclosporin (*Neoral*). Ciclosporin trough levels and elimination rate were not affected by sucrose polyesters.[1] The reduced bioavailability was thought to be due to sucrose polyesters reducing the absorption of ciclosporin. Sucrose polyesters (*Olestra*) is marketed as a non-absorbable, non-calorific fat ingredient in snack foods. The authors note that it is mainly consumed by children and adolescents, with the age group of 13 to 17-year-olds being reported to eat 16.2 g of *Olestra* per snack, and therefore this interaction could be of particular significance for young transplant patients taking ciclosporin.[1] However, note that changes in the AUC of ciclosporin of this size are very modest.

Ciclosporin + Sulfasalazine

An isolated report describes elevated ciclosporin levels in a kidney transplant patient that developed when sulfasalazine was stopped.

Clinical evidence, mechanism, importance and management

A patient with a kidney transplant was taking azathioprine, ciclosporin, prednisone and sulfasalazine 1.5 g daily. After initial adjustments the dose of ciclosporin remained at 480 mg daily for 8 months. The dose of prednisone was reduced and treatment stopped at 8 months, and azathioprine was stopped at 12 months, without any need to adjust the ciclosporin dose. However, when sulfasalazine was stopped 13.5 months after transplantation, the mean ciclosporin level increased from 205 nanograms/mL to 360 nanograms/mL within 5 days, and to 389 nanograms/mL after 10 days. The ciclosporin dose was reduced over the following 2 months from 9.6 mg/kg to 5.6 mg/kg to maintain blood levels at about 200 nanograms/mL.[1] The mechanism for this interaction is not understood, although the time course of the interaction, noted after 5 days, probably excludes decreased absorption.

Information appears to be limited to this isolated case report. There is insufficient evidence to recommend increased monitoring in all patients, but be aware of the potential for an interaction in the case of an unexpected response to treatment.

Ciclosporin + Sulfinpyrazone

Sulfinpyrazone can reduce ciclosporin levels, and episodes of transplant rejection have occurred as a result of this interaction.

Clinical evidence

A study in 120 heart transplant patients found that sulfinpyrazone 200 mg daily was effective in the treatment of hyperuricaemia. The mean uricaemia over 4 to 8 months fell by 22% (from 0.51 to 0.4 mmol/L) but unexpectedly the mean trough ciclosporin levels fell by 39% (from 183 to 121 micrograms/L) despite a 7.7% increase in the ciclosporin daily dose. Two of the patients developed rejection: one after 4 months of taking sulphinpyrazone when the ciclosporin levels fell to 50 micrograms/L, and the other after 7 months of taking sulfinpyrazone, when the ciclosporin levels fell to 20 micrograms/L.[1]

Another report describes a patient who needed unusually high doses of ciclosporin while taking sulfinpyrazone,[2] while yet another report describes *increased* ciclosporin levels in a patient taking sulfinpyrazone. In this latter case there is the possibility that the findings may have been an artefact due to interference with the assay method.[3]

Mechanism

Not understood.

Importance and management

Information appears to be limited to these reports, but the interaction would seem to be established and clinically important. If sulfinpyrazone is added to established treatment with ciclosporin, be alert for the need to raise the ciclosporin dose. The mean fall in trough ciclosporin levels seen in the major study cited was 39%.[1] This study does comment on how quickly this interaction develops, but the two cases of transplant rejection occurred after 4 months and 7 months, which implies that it can possibly be slow. Long-term monitoring would therefore be a prudent precaution.

3. Cockburn I. Cyclosporin A: a clinical evaluation of drug interactions. *Transplant Proc* (1986) 18 (Suppl 5), 50–5.

Ciclosporin + Terbinafine

Terbinafine does not appear to have a clinically significant effect on ciclosporin levels in most patients.

Clinical evidence

In a study in 20 healthy subjects, terbinafine 250 mg daily for 6 to 7 days decreased the mean AUC of a single 300-mg dose of ciclosporin by 13% and decreased its maximum blood level by 14%. It was suggested that as the *Sandimmun* formulation was used in the study, inter- and intra-individual variations in ciclosporin absorption caused these differences, rather than any drug interaction.[1] This study has been briefly reported elsewhere.[2] Another study in 11 patients with kidney, heart or lung transplants found that terbinafine 250 mg daily for 12 weeks caused a small but clinically irrelevant decrease in serum ciclosporin levels.[3] Similarly, another study in 30 kidney transplant patients taking ciclosporin and given terbinafine 250 mg daily for 6 to 12 weeks found no significant interaction and none of the patients required ciclosporin dose changes.[4] However, in another report in 4 kidney transplant patients taking ciclosporin, ciclosporin levels were reduced when they were given terbinafine 250 mg daily for fungal skin and nail infections. In 3 of the patients, ciclosporin levels remained within the therapeutic range and therefore no dose adjustment was needed. In the remaining patient, an increase in the ciclosporin dose was required to maintain levels within the therapeutic range, and then a reduction in the ciclosporin dose was needed on stopping terbinafine.[5]

Mechanism

These studies broadly confirm previous *in vitro* work with human liver microsomal enzymes, which found that terbinafine either does not inhibit or causes only modest inhibition of ciclosporin metabolism.[6-8]

Importance and management

In general, the changes in the pharmacokinetics of ciclosporin seen with terbinafine are not clinically unimportant. However, it may be prudent to bear the possibility of an interaction in mind, particularly in patients whose ciclosporin levels are at the lower end of the therapeutic range.

Ciclosporin + Ticlopidine

Three case reports describe marked falls in ciclosporin levels, and one study noted that trough ciclosporin levels were halved by ticlopidine. However, the interaction was not confirmed in a later randomised, controlled study.

Clinical evidence

The ciclosporin blood levels of a patient with nephrotic syndrome were roughly halved on two occasions when he was given ticlopidine 500 mg daily.[1] Another two patients with kidney transplants had similar falls (one patient on two occasions) when ticlopidine 250 mg or 500 mg daily was given.[2,3] In one of these cases, there was a progressive decrease in ciclosporin levels during 4 months of ticlopidine use, requiring an progressive increase in the ciclosporin dose after 2 months of concurrent use. When aspirin was substituted for ticlopidine, ciclosporin levels rose, and the ciclosporin dose was reduced.[3] Similar findings were reported in an uncontrolled study in 12 heart transplant patients taking ciclosporin, who were given ticlopidine 250 mg twice daily. After 3 months, the mean whole blood trough ciclosporin levels were noted to be halved from 136 nanograms/mL to 72 nanograms/mL, without a change in the mean ciclosporin dose. One case of acute rejection occurred, with a ciclosporin level of 74 nanograms/mL.[4] However, in a randomised, placebo-controlled study by the same group in 20 heart transplant patients, the pharmacokinetics of ciclosporin were not altered by ticlopidine at the lower dose of 250 mg daily for 14 days. The mean decrease in trough level and AUC of ciclosporin were 20% and 14%, respectively, which was not statistically significant. Nevertheless, one patient was withdrawn from the study after 3 days because of a 60% fall in ciclosporin levels.[5]

Mechanism

Not understood.

Importance and management

Information appears to be limited to the reports cited, and the reason for the marked difference between the controlled study and the other study and reports is not certain. However, the controlled study used a low dose of ticlopidine and just 2 weeks of concurrent use, whereas in the other study and reports the interaction was noted after a few months of concurrent use. For this reason, it would be prudent to closely monitor ciclosporin levels, both when ticlopidine is first added, and for the first few months of concurrent use.

Ciclosporin + Trimetazidine

Trimetazidine does not appear to alter the pharmacokinetics or immunosuppressive effects of ciclosporin.

Clinical evidence, mechanism, importance and management

In a study in 12 kidney transplant patients taking ciclosporin, trimetazidine 40 mg twice daily for 5 days caused no changes in the pharmacokinetics of ciclosporin, and there were no alterations in interleukin-2 concentrations or soluble interleukin-2 receptors.[1] An associated study by the same group of workers using two models (the lymphoproliferative response of normal human lymphocytes to phytohaemagglutinin and a delayed *mouse* hypersensitivity model), similarly found that trimetazidine did not interfere with the effects of ciclosporin.[2] It was concluded on the basis of these two studies that the concurrent use of ciclosporin and trimetazidine need not be avoided.

Ciclosporin + Vitamins

In two studies, ciclosporin levels were increased by vitamin E in a water-soluble formulation, while in another study vitamin E modestly decreased the ciclosporin AUC. Other studies have also found modestly reduced ciclosporin levels with vitamin E combined with vitamin C, with or without betacarotene.

Clinical evidence

(a) Vitamin E alone

Ten healthy subjects were given a single 10-mg/kg oral dose of ciclosporin (*Sandimmun* formulation) with and without a 0.1-mL/kg oral dose of vitamin E (d-alpha tocopheryl polyethylene glucose 1000 succinate; *Liqui-E*). The AUC of the ciclosporin increased by 60%.[1] In a further study in liver transplant patients, this same formulation of vitamin E (*Liqui-E*) decreased the required dose of oral ciclosporin [probably the *Sandimmun* formulation] by 28% in 19 adults and 32% in 7 children.[2]

In contrast, another study in 12 healthy subjects found that vitamin E (ACO, Sweden) 800 units daily for 6 weeks modestly reduced the AUC of a single 5-mg/kg dose of ciclosporin (*Neoral* formulation) by 21%. In this study, vitamin E did not significantly attenuate the transient reduction in renal plasma flow and glomerular filtration rate (GFR) seen with ciclosporin.[3]

(b) Vitamin E with Vitamin C

A study in 10 kidney transplant patients taking ciclosporin found that the addition of an antioxidant vitamin supplement (product not specified) for 6 months containing vitamin C 500 mg, vitamin E 400 units and **betacarotene** (vitamin A precursor) 6 mg daily reduced the ciclosporin blood level by 24%. An associated improvement in renal function, indicated by an increase in glomerular filtration rate of 17%, was also seen and may have been associated with reduced ciclosporin levels.[4] In a placebo-controlled study in 56 kidney transplant patients taking ciclosporin with vitamin C 1 g daily and vitamin E 300 mg daily, trough ciclosporin levels were

decreased in the group given vitamins, when compared with the placebo group (14 micrograms/L decrease compared with 10 micrograms/L increase, respectively, from baseline values). A reduction in serum creatinine was also seen.[5] Similarly, in a retrospective study of 22 heart transplant patients, vitamin E 400 units twice daily with vitamin C 500 mg twice daily taken at the same time as ciclosporin, decreased trough ciclosporin levels by about 28%. The reduction in levels was more marked in the 6 patients taking the *Sandimmun* preparation than in the 16 patients taking the *Neoral* preparation, but the difference was not statistically significant (42% versus 25%).[6]

Mechanism

Unknown. The formulation of the vitamin E and of the ciclosporin appears to affect the interaction, suggesting that reduction in levels occurs as a result of altered absorption.

Importance and management

The clinical significance of these studies is unclear, and there appear to be no published case reports of any adverse effects due to this interaction. However, in some patients, changes in ciclosporin levels may significantly affect immunosuppression, and dose modification may be required. If vitamin E and C are used in transplant patients taking ciclosporin, ciclosporin levels should be well monitored. In addition, it may be prudent to question patients about their intake of vitamin supplements before starting or when taking ciclosporin, particularly if a sudden or unexplained reduction in stable ciclosporin levels occurs. More study is needed, particularly with regard to the concurrent use of standard, commercially available multivitamin preparations, which generally contain much lower doses of vitamin C and E than described here.

Corticosteroids + Aminoglutethimide

The effects of dexamethasone, but not hydrocortisone, can be reduced or abolished by aminoglutethimide.

Clinical evidence

(a) Dexamethasone

In a study in 6 patients, aminoglutethimide 500 to 750 mg daily reduced the half-life of dexamethasone 1 mg from 264 to 120 minutes.[1] In another 22 patients it was found that larger doses of dexamethasone (1.5 to 3 mg daily) compensated for the increased dexamethasone metabolism caused by aminoglutethimide and complete adrenal suppression was achieved over a prolonged period.[1] Another study found a fourfold increase in dexamethasone clearance in 10 patients taking aminoglutethimide 1 g daily.[2]

A patient, dependent on dexamethasone due to brain oedema caused by a tumour, deteriorated rapidly, with headache and lethargy, when aminoglutethimide was also given. The problem was solved by withdrawing the aminoglutethimide and temporarily increasing the dexamethasone dosage from 6 to 16 mg daily.[3]

(b) Hydrocortisone

One study found that aminoglutethimide did not affect the response to hydrocortisone, and that hydrocortisone 40 mg was adequate replacement therapy in patients taking aminoglutethimide 1 g daily. In this study, aminoglutethimide did not affect the half-life of ^{3}H-cortisol, which suggests that it does not affect hydrocortisone metabolism.[2] Hydrocortisone 30 mg daily is normally adequate replacement in patients taking aminoglutethimide.[4]

Mechanism

Aminoglutethimide is an enzyme inducer and it seems likely that it interacts with dexamethasone by increasing its hepatic metabolism and clearance, thereby reducing its effects.[5]

Importance and management

Information is limited but the interaction between dexamethasone and aminoglutethimide is established. The reduction in the serum corticosteroid levels can be enough to reduce or even abolish the effects of corticosteroid replacement therapy,[1] or to cause the loss of control of a disease condition.[3] This has been successfully accommodated by increasing the dosage of the dexamethasone. Hydrocortisone is routinely used with aminoglutethimide as replacement therapy, and would seem to be a suitable alternative to dexamethasone, where clinically appropriate. Other synthetic corticosteroids are predicted to interact in the same way as dexamethasone, but this needs confirmation.

Corticosteroids + Antacids

The absorption of prednisone, and probably prednisolone, can be reduced by large doses of aluminium/magnesium hydroxide antacids; small doses of antacid do not appear to interact. Dexamethasone absorption is reduced by magnesium trisilicate.

Clinical evidence

(a) Dexamethasone

In 6 healthy subjects, **magnesium trisilicate** 5 g in 100 mL of water considerably reduced the bioavailability of a single 1-mg oral dose of dexamethasone. Using the urinary excretion of 11-hydroxycorticosteroids as a measure, the reduction in bioavailability was about 75%.[1]

(b) Prednisolone

A study in 8 healthy subjects given a single 20-mg dose of prednisolone found that 30 mL of **Magnesium Trisilicate Mixture BP** or *Aludrox* (**aluminium hydroxide gel**) caused small changes in peak prednisolone levels and absorption, but these did not reach statistical significance. However, one subject given **magnesium trisilicate** had considerably reduced prednisolone levels.[2] **Aluminium phosphate** has also been found not to affect prednisolone absorption.[3,4]

(c) Prednisone

In a study in 5 patients and 2 healthy subjects, *Gastrogel* (**aluminium/magnesium hydroxide** and **magnesium trisilicate**) 20 mL had no significant effect on the serum levels, half-life or AUC of prednisone 10 or 20 mg.[5] In contrast, another study in healthy subjects and patients given 60 mL of *Aldrox* or *Melox* (both containing **aluminium/magnesium hydroxide**) found that the bioavailability of prednisone 10 mg was reduced by 30% on average, and even by 40% in some individuals.[6]

Mechanism

The reduction in dexamethasone absorption is attributed to adsorption onto the surface of the magnesium trisilicate.[1,7]

Importance and management

Information seems to be limited to these studies. The indication is that large doses of some antacids can reduce the bioavailability of corticosteroids, but small doses do not, although this needs confirmation. One man-

ufacturer of dexamethasone suggests that the doses of antacid should be spaced as far as possible from the dexamethasone dose,[8] while another suggests an interval of at least 2 hours.[9] In other similar antacid interactions 2 to 3 hours is usually sufficient. The manufacturer of **deflazacort** also suggests an interval of at least 2 hours between giving deflazacort and an antacid.[10] Concurrent use should be monitored to confirm that the therapeutic response is adequate. Information about the interaction of other corticosteroids and antacids is lacking.

Corticosteroids + Antithyroid drugs

Prednisolone clearance is increased by the use of carbimazole or thiamazole.

Clinical evidence

A comparative study was conducted in three groups of euthyroid women:

Group 1 – eight women taking **levothyroxine** with **thiamazole** 2.5 mg daily or **carbimazole** 5 mg daily for Graves' ophthalmology,

Group 2 – six women taking **levothyroxine** who had undergone subtotal thyroidectomy for Graves' disease, and

Group 3 – six healthy women.

It was found that the clearance of a 540-microgram/kg dose of intravenous **prednisolone** in those in group 1 was much greater than in groups 2 and 3 (0.37, 0.24 and 0.2 L/h.kg, respectively). After 6 hours the plasma **prednisolone** levels in group 1 were only about 10% of those in the healthy women (group 3) and were undetectable after 8 hours, whereas total and unbound **prednisolone** levels were much higher and measurable over the 10 hour study period in those women who had not taken **thiamazole** or **carbimazole**.[1] In another group of previously hyperthyroid patients, now euthyroid because of **carbimazole** treatment, the total **prednisolone** clearance was 0.4 L/hour.[1]

Mechanism

Not established. It seems possible that thiamazole and carbimazole increase the metabolism of prednisolone by the liver microsomal enzymes, thereby increasing its clearance.

Importance and management

Direct information seems to be limited to this study, although the authors point out that there is a clinical impression that higher doses of prednisolone are needed in patients with Graves' disease. Be alert for the need to use higher doses of prednisolone in patients taking either thiamazole or carbimazole. Also note that a hypothyroid state may increase corticosteroid effects, and thus corticosteroids are cautioned in hypothyroid patients.

Corticosteroids + Aprepitant

In the short term, aprepitant (and therefore fosaprepitant) increases the plasma levels of dexamethasone and methylprednisolone.

Clinical evidence

(a) Dexamethasone

In a crossover study in 20 healthy subjects, aprepitant 125 mg on day one and 80 mg on days 2 to 5, given with a standard dexamethasone regimen (20 mg on day one, and 8 mg on days 2 to 5) increased the dexamethasone AUC 2.2-fold. When the same dose of aprepitant was given with a reduced-dose dexamethasone regimen (12 mg on day one, and 4 mg on days 2 to 5), the AUC of dexamethasone was similar to that seen with the standard dexamethasone regimen given alone. All regimens in this study also included intravenous ondansetron 32 mg, given on day one.[1]

(b) Methylprednisolone

In a crossover study in 10 healthy subjects, aprepitant 125 mg on day one and 80 mg on days 2 and 3, given with a methylprednisolone regimen (125 mg intravenously on day one, and 40 mg orally on days 2 and 3), increased the AUC of methylprednisolone 1.3-fold on day one and 2.5-fold on day 3.[1]

Mechanism

Aprepitant is a moderate inhibitor of the cytochrome P450 isoenzyme CYP3A4, and probably raises levels of these corticosteroids in the short term, by inhibiting their metabolism via CYP3A4. However, aprepitant is also a mild inducer of CYP3A4 with a transient effect that may only become apparent after the end of treatment with aprepitant. The maximal effect is seen 3 to 5 days after stopping treatment and is clinically insignificant within 2 weeks, see 'Benzodiazepines + Aprepitant', p.840.

Importance and management

An established interaction of clinical importance. The manufacturers[2,3] recommend that the usual dose of dexamethasone should be reduced by about 50% when given with aprepitant (although note that the dose given in the manufacturer's dexamethasone/aprepitant antiemetic regimen accounts for the interaction). The manufacturers also recommend that the usual dose of intravenous methylprednisolone should be reduced by approximately 25%, and the usual oral dose by approximately 50%, when given with aprepitant. However, the manufacturer[2] also notes that during continuous treatment with methylprednisolone, corticosteroid levels may be expected to *decrease* at later time points within 2 weeks of starting aprepitant and the effect is expected to be greater if methylprednisolone is given orally rather than intravenously.

Fosaprepitant is a prodrug of aprepitant, and therefore similar precautions are appropriate in the presence of these corticosteroids.

Corticosteroids + Azathioprine

In a study in 11 subjects, a single dose of azathioprine did not appear to affect the pharmacokinetics of prednisolone given as a single oral dose of prednisone.[1]

1. Frey FJ, Lozada F, Guentert T, Frey BM. A single dose of azathioprine does not affect the pharmacokinetics of prednisolone following oral prednisone. *Eur J Clin Pharmacol* (1981) 19, 209–12.

Corticosteroids + Azoles; Itraconazole

There is some evidence to suggest that itraconazole can increase the levels and/or effects of inhaled budesonide, fluticasone, the active metabolite of ciclesonide, deflazacort, dexamethasone and methylprednisolone, and, to a lesser extent, prednisolone and prednisone. A few case reports describe the development of secondary Cushing's syndrome in patients taking itraconazole with budesonide, fluticasone or deflazacort.

Clinical evidence

(a) Budesonide

A 70-year-old patient receiving long-term treatment for asthma, which included inhaled budesonide 1.2 to 1.6 mg daily, developed Cushing's syndrome after taking itraconazole 200 mg twice daily for 8 weeks for a fungal infection of the skin and subcutaneous tissues. Corticosteroid levels may already have been increased as the patient was also taking 'diltiazem', (p.1261), with the effects becoming more pronounced after starting itraconazole. Budesonide and itraconazole were discontinued but she subsequently required long-term oral hydrocortisone for secondary adrenal insufficiency.[1]

Two other reports describe the development of Cushing's syndrome in patients with cystic fibrosis given inhaled budesonide, and then itraconazole for bronchopulmonary aspergillosis.[2] One patient was also taking clarithromycin, which may have contributed to the increased budesonide effects (see 'Corticosteroids + Macrolides', p.1264). The other patient was a 4-year-old boy who developed Cushing's syndrome 2 weeks after starting to take itraconazole 200 mg daily and inhaled budesonide 400 micrograms daily.[3]

In a double-blind, randomised, crossover study, 10 healthy subjects were given 1 mg of inhaled budesonide over a period of 2 minutes after taking itraconazole 200 mg daily for 5 days. The AUC of budesonide was increased 4.2-fold by the itraconazole, and the plasma cortisol levels of the patients were suppressed, indicating an increased budesonide effect.[4] Another study compared the results of the ACTH (tetracosactide) test in 25 patients taking itraconazole 400 to 600 mg daily and high-dose inhaled budesonide 800 micrograms to 1.6 mg daily with patients receiving either drug alone. Adrenal insufficiency was detected in 44% of those taking both drugs, but in none of the patients taking itraconazole or budesonide alone.[5]

(b) Ciclesonide

The manufacturer notes that giving itraconazole with ciclesonide may increase the exposure to the active metabolite of ciclesonide (seen with ketoconazole) and that the risk of systemic adverse effects of corticosteroids may be increased.[6]

(c) Deflazacort

A patient with cystic fibrosis taking deflazacort 15 mg daily developed Cushing's syndrome within 2 months of starting to take itraconazole 200 mg twice daily. The patient recovered within 4 months of stopping the itraconazole and reducing the dose of deflazacort to 12 mg daily.[7]

(d) Dexamethasone

A study in 8 healthy subjects found that itraconazole 200 mg daily for 4 days increased the AUC, peak plasma level, and elimination half-life of a single 4.5-mg dose of dexamethasone 3.7-fold, 1.7-fold, and 2.8-fold, respectively. In another phase of the study itraconazole decreased the systemic clearance of intravenous dexamethasone 5 mg by 68% and increased the AUC and elimination half-life 3.3-fold and 3.2-fold, respectively. The adrenal-suppressant effects of dexamethasone were enhanced by itraconazole.[8]

(e) Fluticasone

A case report describes profound adrenal suppression with secondary Cushing's syndrome in a patient with cystic fibrosis given itraconazole 200 mg twice daily and low-dose inhaled fluticasone 250 micrograms daily.[9] Another report describes a patient with asthma who had been taking inhaled fluticasone 1 to 1.5 mg twice daily for 2 years who developed secondary Cushing's syndrome and adrenal suppression 6 weeks after starting to take itraconazole (initially 100 mg daily then 200 mg daily).[10]

(f) Methylprednisolone

A study in 14 healthy subjects found that itraconazole 400 mg for one day and then 200 mg daily for the next 3 days, increased the AUC of a single 48-mg dose of methylprednisolone more than 2.5-fold.[11] Other studies in healthy subjects have found that itraconazole decreases the clearance, and increases the elimination half-life and AUC of both oral and intravenous methylprednisolone. Enhanced adrenal suppression also occurred.[12,13]

A man with a lung transplant taking methylprednisolone, ciclosporin and azathioprine was given itraconazole 200 mg twice daily to treat a suspected *Aspergillus fumigatus* infection. Three weeks later signs of corticosteroid toxicity developed, namely myopathy (confirmed by electromyography) and diabetes mellitus. Ten days after stopping the itraconazole the muscle force had improved and the daily dose of insulin had decreased from 120 units to 20 units.[14]

(g) Prednisolone or Prednisone

Six patients with allergic bronchopulmonary aspergillosis (3 with underlying cystic fibrosis and 3 with severe asthma) were given itraconazole 200 mg twice daily for one to 6 months. Four of the patients, who were also taking systemic prednisone, were able to reduce the corticosteroid dosage by 44% (from 43 mg daily to 24 mg daily) without any clinical deterioration.[15] Another study in healthy subjects found no clinically significant pharmacokinetic interaction between itraconazole (400 mg on day one then 200 mg daily for 3 days) and a single 60-mg dose of prednisone.[11]

A study in 10 healthy subjects found that itraconazole 200 mg daily for 4 days increased the AUC of a single 20-mg oral dose of prednisolone by 24%, but this was considered to be of limited clinical significance.[16]

Mechanism

It seems probable that itraconazole inhibits the metabolism of these corticosteroids by the cytochrome P450 isoenzyme CYP3A4 in the liver leading to higher levels and therefore increased effects. The active metabolite of ciclesonide is also metabolised by CYP3A4.[6] Prednisolone is less likely than methylprednisolone to interact with CYP3A4 inhibitors.[16]

Importance and management

These interactions appear to be established. There is currently too little data to assess the incidence, but it would be prudent to monitor the outcome of giving itraconazole with deflazacort, dexamethasone or methylprednisolone, being alert for the need to reduce the steroid dosage. The manufacturer of ciclesonide suggests that the concurrent use of itraconazole should be avoided unless the benefits outweigh the risks.[6]

Adrenal function should also be monitored in patients receiving inhaled budesonide or fluticasone given itraconazole, as Cushing's syndrome has been reported in a few patients during concurrent use. The manufacturer of budesonide suggests avoiding the concurrent use of itraconazole, but if this is not possible, the time interval between giving the interacting drugs should be as long as possible and a reduction in the dose of budesonide should also be considered.[17] Similarly, the manufacturer of fluticasone recommends caution, and, if possible, the avoidance of long-term treatment with itraconazole.[18]

Itraconazole appears to interact with prednisone and prednisolone to a lesser extent, but the effects may still be clinically important in some patients; consider this interaction as a possible cause if corticosteroid adverse effects develop. Information about other corticosteroids is lacking but good monitoring for increased systemic effects seems advisable as most are metabolised, at least in part, by CYP3A4.

Corticosteroids + Azoles; Ketoconazole

Ketoconazole reduces the metabolism and clearance of methylprednisolone. Ketoconazole may increase levels of the active metabolite of ciclesonide. Ketoconazole modestly increases the systemic effect of inhaled budesonide and possibly fluticasone, and markedly increases the AUC of oral budesonide. The situation with prednisone and prednisolone is uncertain: studies have shown some moderate pharmacokinetic effects, but this does not appear to alter the action of either drug.

Clinical evidence

(a) Budesonide

In a study, 16 healthy subjects were given a single 1-mg inhaled dose of budesonide after taking ketoconazole 200 mg daily for 2 days. Plasma cortisol levels and urinary cortisol excretion were used as a measure of how much budesonide was absorbed systemically. Ketoconazole was found to cause a 37% decrease in the $AUC_{0\text{-}24}$ of cortisol, which suggests an increase in systemic budesonide levels.[1]

Another study, in 8 healthy subjects, found that the AUC of a single 3-mg oral dose of budesonide was increased 6.5-fold when it was given with the last dose of ketoconazole 200 mg daily for 4 days. When budesonide was given 12 hours before the last dose of ketoconazole, the AUC was increased 3.8-fold.[2]

(b) Ciclesonide

The manufacturer notes that, in an interaction study, the use of ketoconazole with ciclesonide increased the exposure to the active metabolite of ciclesonide approximately 3.5-fold and that there is an increased risk of systemic adverse effects of corticosteroids.[3]

(c) Fluticasone

In a study, 16 healthy subjects were given a single 500-microgram inhaled dose of fluticasone after taking ketoconazole 200 mg daily for 2 days. Plasma cortisol levels and urinary cortisol excretion were used as a measure of how much fluticasone was absorbed systemically, and it was found that ketoconazole had no effect on fluticasone absorption.[1] However, the manufacturer of fluticasone cites a study in which the exposure to fluticasone was increased by 150% by ketoconazole, which resulted in reductions in plasma cortisol levels.[4]

(d) Methylprednisolone

In 6 healthy subjects ketoconazole 200 mg daily for 6 days increased the mean AUC of a single 20-mg intravenous dose of methylprednisolone by 135% and decreased its clearance by 60%. The 24-hour cortisol AUC was reduced by 44%.[5] These findings were confirmed in another study by the same group of workers.[6]

(e) Prednisolone or Prednisone

In 10 healthy subjects ketoconazole 200 mg daily for 6 to 7 days caused a 50% rise in the levels of both total and unbound prednisolone, following a dose of either oral prednisone (which is metabolised to prednisolone) or intravenous prednisolone.[7] In contrast, two other studies found that ketoconazole 200 mg daily for 6 days did not affect either the pharmacokinetics or the pharmacodynamics of prednisolone, as measured by the suppressive effects on serum cortisol, blood basophil and helper T-lymphocyte values of prednisolone.[8,9]

Mechanism

Ketoconazole inhibits the cytochrome P450 isoenzyme CYP3A4 in the intestinal wall and liver so that the metabolism of some corticosteroids is reduced and therefore their levels increase. The active metabolite of ciclesonide is also metabolised by CYP3A4,[3] and it may therefore be similarly affected.

Importance and management

The interaction between methylprednisolone and ketoconazole appears to be established and clinically important. A 50% reduction in the dose of methylprednisolone was recommended by the authors of one study.[6] It has been pointed out that increased corticosteroid serum levels have an increased immunosuppressive effect, which may be undesirable in those with a fungal infection needing treatment with ketoconazole.[7] The situation with prednisone and prednisolone is as yet uncertain,[10,11] and more study is needed.

The study using inhaled budesonide indicates that ketoconazole increases the systemic effect of inhaled budesonide. Some manufacturers[12,13] recommend that, if the combination cannot be avoided, the interval between giving the two drugs should be as great as possible; a reduction in the dose of budesonide should also be considered. In addition, a significant interaction may occur with oral budesonide; the effects of ketoconazole on budesonide appear to be reduced by about half by separating the administration of the two drugs by 12 hours.[2] One manufacturer suggests reducing the oral budesonide dose if adverse effects occur.[14]

The situation with inhaled fluticasone is less clear, with one study finding an effect and another finding no effect. The manufacturer of fluticasone suggests that caution is warranted and, where possible, long-term concurrent use should be avoided.[4] Similarly, the manufacturer of ciclesonide suggests that it should not be used with ketoconazole unless the benefits outweigh the risks.[3]

It would seem prudent to bear this possible interaction in mind if ketoconazole is added to treatment with any systemic or inhaled corticosteroid. Patients should be warned to be alert for any evidence of increased corticosteroid effects (such as moon face, weight gain, hyperglycaemia) and to seek medical advice if these occur.

Corticosteroids + Azoles; Voriconazole

Voriconazole increases plasma levels of prednisolone but not to a clinically significant extent. A case report notes that voriconazole appears not to interact with oral hydrocortisone.

Clinical evidence

In healthy subjects, voriconazole 200 mg twice daily for 30 days increased the maximum plasma levels and AUC of a single 60-mg dose of **prednisolone** by 11% and 34%, respectively.[1,2]

A patient who developed Cushing's syndrome and secondary adrenal insufficiency during treatment with itraconazole and inhaled budesonide was given oral **hydrocortisone** replacement. The patient was then also

given voriconazole 200 mg twice daily for 3 months without any apparent effects on the **hydrocortisone**.[3]

Mechanism

Voriconazole is an inhibitor of the cytochrome P450 isoenzyme CYP3A4, but its inhibitory effects are much less than those of itraconazole.[3] Therefore voriconazole is less likely than 'itraconazole', (p.1257), or 'ketoconazole', (p.1259) to affect the pharmacokinetics of the corticosteroids, many of which are metabolised, at least in part, by CYP3A4.

Importance and management

No dose adjustment of the corticosteroid is said to be necessary if voriconazole is given with prednisolone,[1,2] and this also appears to be the case if voriconazole is given with hydrocortisone.[3] The effects of voriconazole on other corticosteroids does not appear to have been studied.

Corticosteroids + Barbiturates

The therapeutic effects of systemic dexamethasone, methylprednisolone, prednisone and prednisolone are decreased by phenobarbital. Other barbiturates, including primidone, and some other corticosteroids probably interact similarly.

Clinical evidence

(a) Dexamethasone

A 14-year-old girl with congenital adrenal hyperplasia taking dexamethasone rapidly became over-treated (weight gain, signs of hypercortisolism) when **primidone** 250 mg twice daily was withdrawn over a month. Satisfactory control was only achieved when the dexamethasone dosage was reduced threefold.[1] A reduction in the effects of dexamethasone has been described when another patient with congenital adrenal hyperplasia was given **primidone** for petit mal seizures.[2] A patient with pemphigus vulgaris failed to respond to large doses of corticosteroids including **prednisolone** 100 mg daily or dexamethasone 30 mg daily when he was given **phenobarbital** and phenytoin. Dramatic improvement occurred following gradual discontinuation of the antiepileptic drugs.[3]

(b) Methylprednisolone

Phenobarbital increased the clearance of intravenous methylprednisolone in asthmatic children by 209%, but had no significant effect on the bioavailability of oral methylprednisolone.[4]

(c) Prednisolone

Phenobarbital increased the clearance of intravenous prednisolone in asthmatic children by 41%, but had no significant effect on the bioavailability of oral prednisolone.[4] Another study, in renal transplant patients, found that prednisolone elimination is increased by **phenobarbital**.[5]

Nine patients with rheumatoid arthritis taking prednisolone 8 to 15 mg daily had strong evidence of clinical deterioration (worsening joint tenderness, pain, morning stiffness, fall in grip strength) when they took **phenobarbital** for 2 weeks (plasma levels 0 to 86.2 micromol/L). The prednisolone half-life fell by 25%.[6]

For mention of a patient with pemphigus vulgaris, who was unresponsive to prednisolone following antiepileptic treatment including phenobarbital, see under *Dexamethasone*, above.

(d) Prednisone

In a group of 75 children with kidney transplants taking azathioprine and prednisone, the incidence of graft failure was increased in 11 epileptic children taking **phenobarbital** 60 to 120 mg daily. Two of the 11 children were also taking phenytoin 100 mg daily.[7] Three prednisone-dependent patients with bronchial asthma taking prednisone 10 to 40 mg daily had a marked worsening of their symptoms within a few days of starting to take **phenobarbital** 120 mg daily. There was a deterioration in pulmonary function tests (FEV_1, degree of bronchospasm) and a rise in eosinophil counts, all of which improved when the **phenobarbital** was stopped. The prednisone clearance was increased by the **phenobarbital**.[8] In contrast, the prednisone requirements of asthmatic children were unaltered when they took a compound preparation containing **phenobarbital** 24 mg daily.[9]

Mechanism

Phenobarbital is a recognised potent liver enzyme inducer that increases the metabolism of corticosteroids, thereby reducing their effects. Pharmacokinetic studies have shown that phenobarbital reduces the half-lives of these corticosteroids and increases their clearances by 40 to 209%.[4,8,10] Primidone interacts in a similar way because it is metabolised in the body to phenobarbital.[1]

Importance and management

The interaction between the corticosteroids and phenobarbital is well documented, well established and clinically important. Concurrent use need not be avoided but the outcome should be monitored. Increase the corticosteroid dosage as necessary. The extent of the increase is variable, but dexamethasone,[8] **hydrocortisone**,[11] methylprednisolone,[4,10] prednisone[7,8] and prednisolone[4,6] are all known to be affected. Prednisolone is less affected than methylprednisolone and may therefore be preferred in some situations. Be alert for the same interaction with other corticosteroids and other barbiturates, which also are enzyme-inducers, although direct evidence seems to be lacking. The dexamethasone adrenal suppression test may be expected to be unreliable in those taking phenobarbital, just as it is with phenytoin, another potent enzyme-inducer. See 'Corticosteroids + Phenytoin', p.1267.

Corticosteroids + Bile-acid binding resins

Colestyramine and possibly colestipol reduce the absorption of oral hydrocortisone. Some other corticosteroids may possibly be affected, although colestyramine does not appear to affect prednisolone absorption.

Clinical evidence

(a) Colestyramine

In 10 healthy subjects, colestyramine 4 g reduced the AUC of a 50-mg oral dose of **hydrocortisone** by 43%. Peak **hydrocortisone** levels were reduced and delayed (by about 50 minutes).[1] Two of the subjects were given both 4 g and 8 g of colestyramine, and their AUCs were reduced by 47% and 59% by the 4-g dose and by 97% and 86% by the 8-g dose.[1]

In contrast, an 8-g dose of colestyramine did not affect the bioavailability of **prednisolone** in 2 patients receiving long-term **prednisolone**.[2]

(b) Colestipol

A man with hypopituitarism taking **hydrocortisone** 20 mg each morning and 10 mg each evening became lethargic, ataxic, and developed headaches (all signs of **hydrocortisone** insufficiency) within 4 days of starting to take colestipol 15 g three times daily for hypercholesterolaemia. He responded rapidly when given intravenous **hydrocortisone** 100 mg, and was discharged with the colestipol replaced by a statin.[3]

Mechanism

It seems that hydrocortisone can become bound to colestyramine or colestipol in the gut, thereby reducing its absorption.[1,4]

Importance and management

Information is limited, but the interactions of colestipol and colestyramine with hydrocortisone appear to be established (they are consistent with the interactions of both of these bile-acid resins with other drugs). Separate the administration of the drugs as much as possible to minimise admixture in the gut, although the authors of one report warn that this may not necessarily avoid this interaction because their data show that the colestyramine may remain in the gut for a considerable time.[1] The usual recommendation is to give other drugs one hour before or 4 to 6 hours after taking colestyramine, and one hour before or 4 hours after taking colestipol. Monitor the effects and increase the hydrocortisone dosage, or use an alternative to colestyramine, if necessary. Some manufacturers of other corticosteroids including **budesonide** and **dexamethasone** have suggested that colestyramine may potentially reduce the absorption of the corticosteroid,[5,6] and it would therefore be prudent to separate administration. One manufacturer advises taking oral budesonide and colestyramine at least 2 hours apart.[5] Prednisolone may be a non-interacting alternative, but the evidence for this is extremely limited.

Corticosteroids + Carbamazepine

The clearance of dexamethasone, methylprednisolone, prednisolone, and probably some other corticosteroids, can be increased in patients taking carbamazepine. The results of the dexamethasone suppression test may be invalid in those taking carbamazepine.

Clinical evidence

(a) Dexamethasone

A study in 8 healthy subjects found that, in the presence of carbamazepine 800 mg daily, the dosage of dexamethasone needed to suppress cortisol secretion (as part of the dexamethasone adrenal suppression test) was increased two- to fourfold.[1] A further study found that it took 2 to 13 days for false-positive results to occur after carbamazepine was started, and 3 to 12 days to recover when the carbamazepine was stopped.[2] A report describes two patients suspected of having Cushing's syndrome because the overnight suppression test with dexamethasone 1 mg had not suppressed their cortisol levels. Further investigation found no clinical evidence of Cushing's syndrome and the false-positive test results were attributed to the fact that both patients were taking carbamazepine 400 mg three times daily at the time of the test. The test was repeated in one of the patients 3 weeks after carbamazepine was stopped and it indicated normal cortisol suppression.[3]

(b) Prednisolone

A study in 8 patients receiving long-term treatment with carbamazepine found that the elimination half-life of prednisolone was about 45 minutes shorter, and its clearance was 42% higher, than in 9 healthy subjects not taking carbamazepine.[4]

A study in asthmatic children found that carbamazepine increased the clearance of intravenous prednisolone by 79% and increased the clearance of intravenous **methylprednisolone** by 342%.[5] A patient taking carbamazepine and valproate required high-dose prednisolone (20 to 60 mg daily) for polymyalgia rheumatica. It was noted that when carbamazepine was discontinued her response to prednisolone improved, allowing the dose to be reduced to 20 mg then 10 mg daily.[6]

Mechanism

Carbamazepine induces liver enzymes, which results in the increased metabolism of the corticosteroids.

Importance and management

Information is limited but the interaction appears to be established. Patients taking carbamazepine are likely to need increased doses of dexamethasone, methylprednisolone or prednisolone. Prednisolone is less affected than methylprednisolone and may therefore be preferred in some situations. The same interaction seems likely with other corticosteroids but more study is needed to confirm this. Note that **hydrocortisone** and **prednisone** are affected by another potent enzyme inducer, phenobarbital (see 'Corticosteroids + Barbiturates', p.1260), and would therefore also be expected to interact with carbamazepine.

Corticosteroids + Diltiazem

Diltiazem increases the AUC of intravenous and oral methylprednisolone, and the metabolism of oral prednisone is also reduced by diltiazem.

Clinical evidence

In a study, 5 healthy subjects were given diltiazem 180 mg daily for 4 days, with and without *intravenous* **methylprednisolone** 300 micrograms/kg (based on ideal body-weight) on day 5. Diltiazem increased the AUC of **methylprednisolone** by 50%, prolonged its half-life by 37% and reduced the **methylprednisolone** clearance by 33%. Although the morning cortisol concentration was only 12% of that during the placebo phase, overall the suppressive effects of **methylprednisolone** on cortisol excretion were unchanged.[1] Another similar study in which patients were given diltiazem and a single 16-mg oral dose of **methylprednisolone** found much larger effects: the AUC of **methylprednisolone** was increased 2.6-fold, and the morning cortisol excretion was only 12% of that in the absence of diltiazem,[2] suggesting an enhanced effect.

Another study in healthy subjects found that diltiazem 180 mg daily for 3 days inhibited the metabolism of a single 15-mg oral dose of **prednisone**; the AUC of **prednisolone** (the major active metabolite of prednisone) was increased by 21%.[3]

Mechanism

Diltiazem is a moderate inhibitor of the cytochrome P450 isoenzyme CYP3A4. As methylprednisolone is mainly metabolised by CYP3A4, any inhibition of its activity would be expected to raise the corticosteroid levels.[1,2] Prednisolone is less dependent on CYP3A4 for metabolism, and is therefore more modestly affected. It has been suggested that P-glycoprotein may also play a role in the interaction with methylprednisolone.[1,2] Inhibition of intestinal/hepatic CYP3A4 may increase the oral bioavailability of methylprednisolone, which could contribute to the pharmacokinetic differences seen in the interaction when methylprednisolone is given orally rather than intravenously.

Importance and management

Information about the interaction between diltiazem and methylprednisolone seems limited to these two studies, but the effect of concurrent use is clear. However, the clinical significance of the raised methylprednisolone levels has not been established. Monitoring for an increase in the

adverse effects of methylprednisolone, as suggested by one of the authors, seems a prudent measure.[1] Similarly, prednisone/prednisolone bioavailability might possibly be affected by diltiazem but the effect is modest, and possibly not clinically relevant.

Corticosteroids + Diuretics; Potassium-depleting

Both corticosteroids and the loop or thiazide diuretics can cause potassium loss, severe depletion is therefore possible if they are used together.

Clinical evidence, mechanism, importance and management

There seem to be no formal clinical studies about the extent of the additive potassium depletion that can occur when potassium-depleting diuretics and corticosteroids are given together, but an exaggeration of the potassium loss undoubtedly occurs (e.g. seen with **hydrocortisone** and **furosemide**[1]). One study looking at hypokalaemia with potassium-depleting diuretics found that corticosteroids were a significant risk factor for hypokalaemic events; 20% of patients taking a potassium-depleting diuretic developed hypokalaemia, whereas 31% of patients taking a potassium-depleting diuretic and a corticosteroid developed hypokalaemia.[2] Hypokalaemia in patients taking potassium-depleting diuretics should be corrected before a corticosteroid is started. Concurrent use should be well monitored and the potassium intake increased as appropriate to balance this loss.

The greatest potassium loss occurs with the naturally occurring corticosteroids such as **cortisone** and **hydrocortisone**. **Corticotropin** (**ACTH**), which is a pituitary hormone, and **tetracosactrin** (a synthetic polypeptide) stimulate corticosteroid secretion by the adrenal cortex and can thereby indirectly cause potassium loss. **Fludrocortisone** also causes potassium loss. The synthetic corticosteroids (glucocorticoids) have a less marked potassium-depleting effect and are therefore less likely to cause problems. These include **betamethasone**, **dexamethasone**, **prednisolone**, **prednisone** and **triamcinolone**.

The potassium-depleting diuretics (i.e. **loop diuretics** or **thiazide** and related diuretics) are listed in 'Table 26.1', (p.1121). **Acetazolamide**, a weak diuretic, has also been predicted to cause hypokalaemia in the presence of corticosteroids. However, hypokalaemia seen with **acetazolamide** is rarely clinically significant, and therefore any risk is lower.

Corticosteroids + Ephedrine

Ephedrine increases the clearance of dexamethasone.

Clinical evidence, mechanism, importance and management

Nine asthmatic patients had a 40% increase in the clearance and a similar reduction in the half-life of **dexamethasone** when they were given ephedrine 100 mg daily for 3 weeks.[1] This would be expected to reduce the overall effects of **dexamethasone**, but this requires confirmation. Be alert for any evidence that the **dexamethasone** effects are reduced if both drugs are given; an increase in the dexamethasone dose might be necessary. It is not clear whether other corticosteroids behave similarly.

1. Brooks SM, Sholiton LJ, Werk EE, Altenau P. The effects of ephedrine and theophylline on dexamethasone metabolism in bronchial asthma. *J Clin Pharmacol* (1977) 17, 308–18.

Corticosteroids + Fluoxetine

Fluoxetine does not affect the pharmacokinetics of prednisolone or its effects on cortisol suppression.

Clinical evidence, mechanism, importance and management

In healthy subjects, fluoxetine 20 mg daily for 5 days then 60 mg daily for 9 days did not significantly affect the pharmacokinetics of a single 40-mg dose of **prednisolone succinate**, given as an intravenous bolus, or the duration of cortisol suppression in response to the **prednisolone**.[1] Although fluoxetine has some inhibitory effect on the cytochrome P450 isoenzyme CYP3A4, and thus may inhibit the metabolism of corticosteroids that are CYP3A4 substrates, its effects are weak and not usually clinically relevant. Furthermore, **prednisolone** is only partly metabolised by this route.[2] No clinically important interaction is likely if **prednisolone** and fluoxetine are given concurrently. The situation with other corticosteroids that may be more likely to interact (e.g. **methylprednisolone**, which is mainly metabolised by CYP3A4) is not known.

Corticosteroids + Grapefruit juice

Grapefruit juice moderately increases the plasma levels of budesonide and methylprednisolone. Grapefruit juice does not affect the pharmacokinetics of prednisolone or prednisone.

Clinical evidence, mechanism, importance and management

(a) Budesonide

In a study in 8 healthy subjects giving budesonide (*Entocort EC*) capsules with concentrated grapefruit juice resulted in a twofold increase in the bioavailability of budesonide, compared with enteric-coated budesonide alone. Similar results were obtained with a plain capsule formulation, but the clearance, volume of distribution and half-life of budesonide given intravenously were not altered by grapefruit juice. These results suggest that grapefruit juice increases the systemic availability of budesonide capsules due to inhibition of intestinal CYP3A4 activity.[1] One of the manufacturers of budesonide therefore advises that regular ingestion of grapefruit or grapefruit juice should be avoided in connection with budesonide administration.[2] Another manufacturer of oral and rectal budesonide also recommends avoidance of concurrent use.[3,4]

(b) Methylprednisolone

In a crossover study, 10 healthy subjects were given either double-strength grapefruit juice 200 mL, or water, three times daily for 2 days. On day 3, grapefruit juice 200 mL or water was given with, 30 minutes and 90 minutes after a single 16-mg dose of methylprednisolone. Grapefruit juice increased the AUC and peak plasma level of methylprednisolone by 75% and 27%, respectively. The time to reach peak levels was increased from 2 to 3 hours and the elimination half-life was increased by 35%. Plasma cortisol levels after methylprednisolone was given with grapefruit juice or water were not significantly different, although grapefruit juice slightly decreased plasma cortisol levels before the morning dose of methylprednisolone. As the effects on plasma cortisol levels were slight, this interaction is unlikely to be of clinical significance in most patients, although the authors note that in some sensitive subjects large amounts of grapefruit juice might enhance the effects of oral methylprednisolone.[5]

(c) Prednisolone or Prednisone

A study in 12 kidney transplant patients taking ciclosporin and corticosteroids found that grapefruit juice, given every 3 hours for 30 hours, increased ciclosporin levels, but had no significant effect on the AUC of prednisolone or prednisone It was concluded that grapefruit juice does not affect the metabolism of prednisolone or prednisone.[6] No special precautions are therefore needed if patients drink grapefruit juice while taking these corticosteroids.

Corticosteroids + H_2-receptor antagonists

Cimetidine does not appear to interact with budesonide, dexamethasone prednisolone, or prednisone, and ranitidine does not interact with prednisone.

Clinical evidence, mechanism, importance and management

A double-blind crossover study in 9 healthy subjects found that **cimetidine** 300 mg every 6 hours or **ranitidine** 150 mg twice daily for 4 days did not significantly alter the pharmacokinetics of prednisolone after a single 40-mg oral dose of **prednisone**.[1] **Prednisone** is a pro-drug, which must be converted to prednisolone within the body to become active.

Another double-blind, crossover study found that **cimetidine** 1 g daily only caused minor changes in plasma **prednisolone** levels following a 10-mg dose of enteric-coated **prednisolone**.[2] Similarly, **cimetidine** has been reported to have a slight but clinically insignificant effect on the pharmacokinetics of oral **budesonide**.[3] Another study found that **cimetidine** 600 mg twice daily for 7 days had no effect on the pharmacokinetics of a single 8-mg intravenous dose of **dexamethasone sodium phosphate**.[4]

Dosage adjustments therefore seem unlikely to be necessary if any of these corticosteroids are given with cimetidine or other H_2-receptor antagonists.

Drugs such as cimetidine, which inhibit the cytochrome P450 isoenzyme CYP3A4, might be expected to decrease the rate of metabolism of corticosteroids, such as **methylprednisolone**, that are largely metabolised by this route. However, information appears to be lacking, and cimetidine has only weak to modest effects on this isoenzyme. Therefore no clinically significant interaction is anticipated.

Corticosteroids + Hormonal contraceptives or Sex hormones

The serum levels of cloprednol, methylprednisolone, prednisolone, prednisone, and possibly other corticosteroids are increased by combined hormonal contraceptives. In theory, both the therapeutic and toxic effects would be expected to be increased, but in practice it is uncertain whether these changes are important. Total serum cortisol levels may also be increased by hormonal contraceptives. Fluocortolone and oral budesonide levels were not affected by oral contraceptives. Prasterone did not affect the pharmacokinetics of prednisone or the effects of its metabolite, prednisolone, on cortisol secretion. Progesterone appears not to affect the metabolism of prednisolone.

Clinical evidence

(a) Hormonal contraceptives

1. Budesonide. The plasma levels of oral budesonide 4.5 mg daily for 7 days, and cortisol suppression were no different in 20 women taking an oral contraceptive (**ethinylestradiol**/**desogestrel**) when compared with 20 women not taking an oral contraceptive.[1]

2. Cloprednol. The clearance of cloprednol 20 mg was decreased by about one-third in 7 women taking an oral contraceptive (**ethinylestradiol**/**norethisterone**), when compared with women not taking an oral contraceptive.[2]

3. Corticotropin. In a study in 11 healthy women who were not taking hormonal contraceptives, the mean basal concentration of total serum cortisol was 454 nanomol/L, but when the women took combined hormonal contraceptives orally for 3 months the cortisol level increased to 861 nanomol/L. After a low-dose (1 microgram) corticotropin (ACTH) test, using **tetracosactide** (*Synacthen*), the mean serum cortisol level at 30 minutes increased to 652 nanomol/L and 1374 nanomol/L before and after hormonal contraceptive use, respectively. The basal plasma concentration of corticotropin also increased from 17.2 to 38.2 nanograms/L after hormonal contraceptive use. However, the basal and corticotropin-stimulated salivary cortisol was not significantly different between the baseline period and the hormonal contraceptive period.[3]

4. Fluocortolone. A study in 7 women found that the pharmacokinetics of fluocortolone 20 mg were unaffected by an oral contraceptive (**ethinylestradiol**/**norethisterone**).[4]

5. Methylprednisolone. A study in two groups of 6 patients found that the clearance of methylprednisolone was decreased to about half in the group taking oral contraceptives (**ethinylestradiol/levonorgestrel**), when compared with the group not taking oral contraceptives. The oral contraceptive group were less sensitive to the suppressive effects of methylprednisolone on the secretion of cortisol, and had more suppression of basophils, but no changes in the T-helper cell response patterns.[5]

6. Prednisolone. In a placebo-controlled study, 20 healthy women took an oral contraceptive (**ethinylestradiol**/**desogestrel** 30/150 micrograms) for at least 4 months before being given prednisolone 20 mg daily for 7 days. The prednisolone AUC and steady-state levels were 2.3-fold higher, when compared with those in 20 women not taking oral contraceptives.[1] Several other studies have found similar results, with the prednisolone AUC increasing 1.6- to 6-fold,[6,7] and the clearance reducing by about 35 to 85% in the presence of oral contraceptives containing **ethinylestradiol** or **mestranol** and various progestogens such as **levonorgestrel**, **norgestrel** and **norethisterone**.[6-11] Similarly, a 2.3-fold increase in the AUC of prednisolone and a 45% decrease in its clearance was seen when **prednisone** was given to 10 women (9 taking an oral combined hormonal contraceptive and one taking ethinylestradiol).[12]

(b) Prasterone

In a study in 14 healthy women, prasterone 200 mg daily for one menstrual cycle (approximately 28 days) did not affect the pharmacokinetics of a single 20-mg dose of **prednisone** or its inhibition of cortisol secretion.[13]

(c) Progesterone

Intravenous and oral **prednisolone** were given to 6 post-menopausal women before and after they took progesterone 5 mg for 2 months. The pharmacokinetics of **prednisolone** were not significantly altered by progesterone.[14]

Mechanism

Not fully understood. The possibilities include a change in the metabolism of the corticosteroids, or in their binding to serum proteins.[12] The absence of an interaction with progesterone suggests that the oestrogenic component of the oral contraceptive is possibly responsible for any interaction.[14] Endogenous and synthetic oestrogens appear to cause an increase in the plasma concentration of cortisol binding globulin, which results in an elevation of the total cortisol level.[3]

Importance and management

It is established that the pharmacokinetics of some corticosteroids are affected by combined hormonal contraceptives, but the clinical importance of any such changes is not known. The therapeutic and adverse effects would be expected to be increased but there appear to be no clinical reports of adverse reactions arising from concurrent use. In fact the authors of one study[5] concluded that women can be dosed similarly with methylprednisolone irrespective of contraceptive use.

However, until more is known it would be prudent to bear this interaction in mind when using any corticosteroid and combined hormonal contraceptive together. Only prednisone, prednisolone, cloprednol and methylprednisolone have been reported to interact although some other corticosteroids possibly behave similarly, the exceptions apparently being fluocortolone and oral budesonide.

Total serum cortisol levels may be increased by hormonal contracep-

tives, but the unbound fraction of cortisol appears to be unaffected.[3] Progesterone appears not to interact with prednisolone.

Corticosteroids + Liquorice

Liquorice can delay the clearance of prednisolone and hydrocortisone. Dexamethasone may attenuate the mineralocorticoid effects of glycyrrhizin. Liquorice, if given in large quantities with corticosteroids, may cause additive hypokalaemia.

Clinical evidence, mechanism, importance and management

Liquorice has a great number of active compounds of different classes that act in different ways. The most important constituent is usually considered to be glycyrrhizin (glycyrrhizic or glycyrrhizinic acid).

(a) Dexamethasone

In a parallel group study, 6 patients were given **glycyrrhizin** 225 mg daily for 7 days, and 6 patients were given the same dose of **glycyrrhizin** and dexamethasone 1.5 mg daily for 7 days. The mineralocorticoid effects of **glycyrrhizin** were significantly reduced by dexamethasone; cortisol plasma concentrations and urinary excretions were reduced by up to 70%.[1]

(b) Hydrocortisone

Glycyrrhizin slightly increased the AUC of cortisol by 14% in 4 patients with adrenocorticol insufficiency taking oral hydrocortisone 20 to 40 mg daily. Note that **glycyrrhizin** had no effect on endogenous cortisol levels in 7 control subjects without adrenal insufficiency.[2] In a study in 23 healthy subjects, topical **glycyrrhetinic acid** markedly potentiated the activity of topical hydrocortisone, as assessed by cutaneous vasoconstrictor effect.[3]

(c) Prednisolone

A study in 6 healthy subjects found that after taking four 50-mg oral doses of **glycyrrhizin** at 8-hourly intervals, followed by a bolus injection of prednisolone hemisuccinate 96 micrograms/kg, the AUC of total prednisolone was increased by 50% and the AUC of free prednisolone was increased by 55%.[4] This confirms previous findings with **glycyrrhizin** 200 mg given by intravenous infusion.[5]

Glycyrrhizin slightly increased the AUC of prednisolone by about 16 to 20% in 12 patients who had been taking oral prednisolone 10 to 30 mg daily for at least 3 months.[2]

Mechanism

Inhibition of 11 β-hydroxysteroid dehydrogenase by glycyrrhetinic acid may slightly delay the clearance of hydrocortisone and prednisolone and thereby enhance their effects. However, note that whether a mineralocorticoid or glucocorticoid is a substrate for this enzyme system depends on its chemical structure. Therefore, it cannot be assumed that liquorice will inhibit the inactivation of all corticosteroids.

Dexamethasone appears to attenuate the mineralocorticoid effects of glycyrrhizin because it suppresses endogenous cortisol secretion (causes adrenal suppression). Other corticosteroids would be expected to interact similarly if given in adrenal-suppressant doses.

Deglycyrrhizinated liquorice would not have these effects.

Importance and Management

The clinical importance of these observations is uncertain. Doses of corticosteroids sufficient to cause adrenal suppression would be expected to reduce the mineralocorticoid activity of liquorice, but mineralocorticoid activity might still occur. Glycyrrhizin (an active constituent of liquorice) and its metabolite glycyrrhetinic acid slightly increased the plasma levels of hydrocortisone and prednisolone and markedly potentiated the cutaneous effects of hydrocortisone. This suggests that liquorice will slightly potentiate the effects of these steroids. However, this might not apply to other corticosteroids (see *Mechanism*, above). Nevertheless, it might be prudent to monitor the concurrent use of liquorice and corticosteroids, especially if liquorice ingestion is prolonged or if large doses are taken, as additive effects on water and sodium retention, and potassium depletion may occur.

Note that several manufacturers of corticosteroids comment that the hypokalaemic effects of **carbenoxolone**, a synthetic derivative of glycyrrhizic acid, may be enhanced by corticosteroids.

Corticosteroids + Macrolides

Troleandomycin and, to a lesser extent, clarithromycin and erythromycin can reduce the clearance of methylprednisolone, thereby increasing both its therapeutic and adverse effects; azithromycin does not appear to affect the pharmacokinetics of methylprednisolone. A patient receiving long-term clarithromycin developed Cushing's syndrome after using inhaled budesonide. There appears to be no pharmacokinetic interaction between erythromycin and inhaled ciclesonide or fluticasone. Similarly, prednisolone appears not to be affected by macrolides, except possibly in those patients also taking enzyme-inducers such as phenobarbital. Isolated case reports describe the development of acute mania and psychosis in two patients, apparently due to an interaction between prednisone and clarithromycin.

Clinical evidence

(a) Budesonide

A 40-year-old woman with cystic fibrosis given **clarithromycin** 500 mg twice daily for 4 years for a *Mycobacterium abscessus* infection developed Cushing's syndrome with adrenal suppression 6 weeks after starting to use inhaled budesonide 400 micrograms daily. A slow rise in morning free cortisol levels was found 4 weeks after stopping budesonide. She died 8 weeks later of severe respiratory failure.[1]

(b) Ciclesonide

In a crossover study, healthy subjects were given a single 500-mg dose of **erythromycin** and inhaled ciclesonide 640 micrograms, alone or together. Concurrent use did not alter the pharmacokinetics of either drug.[2]

(c) Fluticasone

In a multiple-dose study, giving **erythromycin** 333 mg three times daily did not affect the pharmacokinetics of inhaled fluticasone propionate 500 micrograms twice daily.[3]

(d) Methylprednisolone

1. Azithromycin. A review by the manufacturers briefly mentions that azithromycin does not alter the pharmacokinetics of methylprednisolone.[4]

2. Clarithromycin. A study in 6 asthmatic patients found that clarithromycin 500 mg twice daily for 9 days reduced the clearance of a single dose of methylprednisolone by 65% and resulted in significantly higher plasma methylprednisolone levels.[5]

3. Erythromycin. A study in 9 asthmatic patients aged 9 to 18 years found that after taking erythromycin 250 mg four times daily for a week, the clearance of methylprednisolone was decreased by 46% (range 28 to 61%) and the half-life was increased by 47%, from 2.3 to 3.5 hours.[6]

4. Troleandomycin. A pharmacokinetic study in 4 children and 6 adult corticosteroid-dependent asthmatics found that troleandomycin 14 mg/kg daily for one week increased the half-life of methylprednisolone by 88%, from 2.46 to 4.63 hours, and reduced the total body clearance by 64%. All 10 had cushingoid symptoms (cushingoid faces and weight gain), which resolved when the methylprednisolone dosage was reduced, without any loss in the control of the asthma.[7] Another study found that the dose of methylprednisolone could be reduced by 50% in the presence of troleandomycin, without loss of disease control.[8] Other studies have found similar effects.[9-14] However, a randomised, placebo-controlled, 2-year study found that although troleandomycin modestly reduced the required dose of methylprednisolone, this did not reduce corticosteroid-related adverse effects.[14] A case report describes a fatal varicella infection attributed to the potentiation of steroid effects by troleandomycin.[15]

(e) Prednisolone or Prednisone

1. Clarithromycin. A 30-year-old woman with no history of mental illness was treated for acute sinusitis with prednisone 20 mg daily for 2 days, followed by 40 mg daily for a further 2 days and clarithromycin 1 g daily. After 5 days she stopped taking both drugs (for unknown reasons), but a further 5 days later she was hospitalised with acute mania (disorganised thoughts and behaviour, pressured speech, increased energy, reduced need for sleep and labile effect). She spontaneously recovered after a further 5 days and had no evidence of psychiatric illness 4 months later.[16] A 50-year-old man with emphysema was given prednisone 20 mg daily to improve dyspnoea. After about 2 weeks he was also given clarithromycin 500 mg twice daily for purulent bronchitis. Shortly afterwards his family noticed psychiatric symptoms characterised by paranoia, delusions and what was described as dangerous behaviour. He recovered following treatment with low-dose olanzapine, a gradual reduction of the prednisone dosage and discontinuation of the clarithromycin. An interaction was suspected as the patient had previously received prednisone on a number of occasions without the development of psychosis.[17]

A study in 6 asthmatic patients found that clarithromycin 500 mg twice daily for 9 days had no significant effect on prednisone pharmacokinetics.[5]

2. Troleandomycin. A study found that prednisolone clearance was not affected by troleandomycin in 3 patients, but was reduced by about 50% by troleandomycin in one patient who was also taking **phenobarbital**, which is an enzyme inducer.[9]

Mechanism

The available evidence suggests that clarithromycin, erythromycin and troleandomycin can inhibit the metabolism of methylprednisolone. The volume of distribution is also decreased.[6,7,9,18] Clarithromycin may inhibit the metabolism of budesonide.[1]

Importance and management

Information about the clarithromycin or erythromycin interactions with methylprednisolone is much more limited than with the interaction between troleandomycin and methylprednisolone, but they all appear to be established and of clinical importance. The effect should be taken into account during concurrent use and appropriate dosage reductions made to avoid the development of corticosteroid adverse effects. The authors of one study[7] suggest that this reduction should be empirical, based primarily on clinical symptoms. Another group found that a 68% reduction in methylprednisolone dosage was possible within 2 weeks.[11] Troleandomycin appears to have a greater effect than erythromycin or clarithromycin.

Prednisolone seems not to interact with troleandomycin and may be a non-interacting alternative to methylprednisolone, except possibly in those taking enzyme-inducers (e.g. phenobarbital). Nevertheless, one manufacturer of prednisolone advises caution with the concurrent use of CYP3A4 inhibitors including troleandomycin and says that dosages of the corticosteroid may need to be decreased.[19] The available evidence suggests that potent CYP3A4 inhibitors (such as troleandomycin) present the greatest risk.

The evidence for the interaction leading to psychosis between prednisone and clarithromycin is limited and its general importance is uncertain, but prescribers should be aware of the reports of psychosis if both drugs are used together. Note that psychosis is a rare adverse effect of high-dose corticosteroids given alone.

One case report indicates that clarithromycin may enhance the effects of inhaled budesonide and although the authors suggest that prolonged use of clarithromycin and the terminal condition of the patient may have been factors, they advise close monitoring if the combination is used.[1] One manufacturer of budesonide advises that potent inhibitors of CYP3A4 (they name clarithromycin) should be avoided.[20] However, given the evidence available, this seems a very cautious approach.

Some other manufacturers of corticosteroids, including **dexamethasone** and **hydrocortisone** have also mentioned the potential for increased plasma concentrations of corticosteroids with macrolides such as erythromycin. In general the concurrent use of these corticosteroids and CYP3A4-inhibiting macrolides need not be avoided, but it would seem prudent to monitor for corticosteroid adverse effects and suspect an interaction if symptoms occur. In most cases the interaction should be manageable by reducing the dose of the corticosteroid until the macrolide is withdrawn.

Corticosteroids + Mifepristone

The UK manufacturer of mifepristone says that, due to the antiglucocorticoid activity of mifepristone, the efficacy of long-term corticosteroids (including inhaled corticosteroids) may be decreased during the 3 to 4 days following intake of mifepristone.[1] Patients taking corticosteroids should be monitored during this time, and consideration given to increasing the corticosteroid dose. However, the US manufacturer contraindicates the use of

mifepristone in patients receiving long-term corticosteroid therapy.[2]

Corticosteroids + Nefazodone

Nefazodone inhibits the metabolism of methylprednisolone and prolongs its effects on cortisol suppression.

Clinical evidence

In healthy subjects, nefazodone (initial dose of 100 mg, increased to 150 mg, then 200 mg, twice daily, for a total of 9 days) increased the AUC of a single 600-microgram/kg intravenous dose of **methylprednisolone** twofold and increased its half-life from 2.3 to 3.3 hours. **Methylprednisolone** clearance was decreased by about 50%. The duration of cortisol suppression after **methylprednisolone** alone was 23.3 hours, which increased to more than 32 hours when nefazodone was also given.[1]

Mechanism

Nefazodone probably inhibits the metabolism of methylprednisolone by the cytochrome P450 isoenzyme CYP3A4.[1]

Importance and management

At clinically relevant doses nefazodone decreases methylprednisolone clearance and significantly prolongs methylprednisolone-induced cortisol suppression. Care is recommended during concurrent use.[1] Note that many other corticosteroids are metabolised, at least in part, by the same route as methylprednisolone, and may therefore also be expected to interact to some extent, although this needs confirmation. Note that nefazodone has been generally withdrawn from the market because of adverse hepatic effects.

Corticosteroids + NNRTIs

Delavirdine may increase the levels of dexamethasone and possibly other corticosteroid, whereas the plasma levels of dexamethasone, prednisolone, and possibly other corticosteroids, may be decreased by efavirenz or nevirapine.
Dexamethasone may decrease the plasma levels of delavirdine and etravirine, and prednisone may increase the incidence and severity of rash associated with the use of nevirapine.

Clinical evidence, mechanism, importance and management

(a) Delavirdine

The manufacturer of delavirdine says that it should be used with caution with **dexamethasone** because delavirdine may be less effective due to decreased plasma concentrations.[1] This is presumably because delavirdine is primarily metabolised by the cytochrome P450 isoenzyme CYP3A4,[1] which is said to be induced by **dexamethasone**.[2] However, evidence of **dexamethasone** having clinically relevant interactions as a result of this mechanism is generally lacking. The levels of **dexamethasone** may possibly be increased by delavirdine, due to inhibition of CYP3A4.[2] There appears to be little information about other corticosteroids and delavirdine, but many corticosteroids (particularly **methylprednisolone**) are metabolised, at least in part, by CYP3A4 and therefore their levels may also be raised to some extent by delavirdine. Be alert for increased corticosteroid adverse effects.

(b) Efavirenz or Nevirapine

Systemic **dexamethasone** levels may be decreased by efavirenz or nevirapine due to induction of CYP3A4,[2] by which dexamethasone is metabolised.

A study in HIV-positive subjects given a single 20-mg dose of **prednisone**, found that efavirenz, as part of antiretroviral medication, decreased the AUC of **prednisolone** by about 20%, when compared with similar patients who were not taking antiretrovirals; however, this was not statistically significant. When the patients taking efavirenz were compared with patients receiving lopinavir boosted with ritonavir there was a 40% reduction in the AUC of **prednisolone**. This indicates that **prednisolone** concentrations may fluctuate widely when HIV-positive individuals established on efavirenz change to lopinavir/ritonavir or *vice versa*.[3]

Corticosteroids may be used to treat rash associated with efavirenz,[4] however, the manufacturers of nevirapine warn that **prednisone** 40 mg daily for the first 14 days of nevirapine use has not been shown to reduce the incidence of nevirapine-associated rash and may be associated with an increase in incidence and severity of rash during the first 6 weeks of nevirapine use.[5,6] The US manufacturer therefore states that the use of **prednisone** to prevent nevirapine-associated rash is not recommended.[6]

There appears to be little information about other corticosteroids and efavirenz of nevirapine, but many corticosteroids (particularly **methylprednisolone**) are metabolised, at least in part, by CYP3A4. Dosage increases of the corticosteroid may possibly be needed if efavirenz or nevirapine are started, stopped, or the doses changed.

(c) Etravirine

The manufacturer of etravirine says that it should be used with caution with **dexamethasone** because etravirine may be less effective due to decreased plasma concentrations. They advise that alternatives to dexamethasone should be considered if possible, particularly for long-term use.[7] This is presumably because etravirine is metabolised by the cytochrome P450 isoenzyme CYP3A4,[1] which is said to be induced by **dexamethasone**.[2] However, evidence of **dexamethasone** having clinically relevant interactions as a result of this mechanism is generally lacking.

Corticosteroids + NSAIDs

Corticosteroids or NSAIDs alone may be risk factors for gastrointestinal bleeding and ulceration. The concurrent use of NSAIDs and corticosteroids increases the risk of gastrointestinal bleeding and probably ulceration.
Ibuprofen, indometacin and naproxen may increase the levels of free prednisolone, and the plasma levels of diclofenac are modestly increased by triamcinolone. Dexamethasone and prednisone do not appear to affect the levels of oxyphenbutazone.

Clinical evidence, mechanism, importance and management

(a) Gastrointestinal bleeding and ulceration

A retrospective study of about 20 000 patients who had taken corticosteroids found that the incidence of upper gastrointestinal bleeding resulting in hospitalisation was very low in outpatients taking corticosteroids for dermatitis and asthma. Bleeding occurred in only 45 (0.23%) of the patients. However, the risk of bleeding was increased if the patients were also taking aspirin or other NSAIDs (incidence rate of 5.1 per 10 000 person-months, compared with 2.2 per 10 000 person-months in those who did not take NSAIDs).[1] This is consistent with the results of another study in patients taking **prednisone** and **indometacin**.[2]

A case-control study reviewed 1415 patients aged 65 years or older, hospitalised between 1984 and 1986 for peptic ulcer or upper gastrointestinal haemorrhage of unknown cause, and 7063 control patients. The relative risk for the development of peptic ulcer disease was estimated to be 2 in those taking oral corticosteroids; however, for those corticosteroid users not receiving NSAIDs it was 1.1 and the estimated risk was only increased in those taking corticosteroids with NSAIDs (relative

risk 4.4). It was estimated that patients taking corticosteroids with NSAIDs have an approximately 15-fold greater risk for peptic ulcer disease than patients taking neither drug.[3]

Another study compared 1121 patients aged 60 years or over who were admitted to hospital with bleeding peptic ulcers, with 989 control patients, to investigate factors other than NSAIDs that may have contributed to the risk of bleeding.[4] The risk (calculated as odds ratio) was about threefold greater for the use of corticosteroids alone, but when corticosteroids were used with NSAIDs, the risk was ninefold greater.[4]

NSAIDs alone increase the risk of gastrointestinal adverse effects.[5-8] Most patients with NSAID-associated ulcers are elderly: this is because there is a greater prevalence of ulcer disease in the elderly, and they are more likely to be taking NSAIDs and to be sensitive to them.[7] A history of ulcer disease is a further risk factor.[7] Corticosteroids alone are reported not to be a risk factor in some studies,[1,9] while other studies found they were a risk factor for gastrointestinal adverse effects.[4,10] However, several studies have found that the risk of gastrointestinal adverse effects is increased by the combined use of corticosteroids and NSAIDs[3,4,11,12] and caution with concurrent use has been suggested.[3] It may be prudent to consider the use of gastroprotection in patients taking NSAIDs and corticosteroids, especially if they are elderly.

(b) Pharmacokinetic interactions

A patient with rheumatoid arthritis taking **prednisolone** 5 to 10 mg daily with the intermittent use of an NSAID (aspirin 700 mg to 2.8 g daily, **ibuprofen** 400 mg to 1.2 g daily, or **naproxen** 250 to 500 mg daily), developed osteonecrosis of the upper third of the femoral head, which was attributed to increased free levels of **prednisolone** due to protein-binding displacement by the NSAID.[13] A study in 11 patients with stable rheumatoid disease regularly taking a corticosteroid found that **indometacin** 75 mg or **naproxen** 250 mg twice daily for 2 weeks did not alter the total plasma levels of a single 7.5-mg dose of **prednisolone** but the amount of unbound (free) **prednisolone** increased by 30 to 60%.[14] The probable reason for this effect is that these NSAIDs displace both administered and endogenous corticosteroids from their plasma protein binding sites. In a double-blind, crossover study 12 healthy subjects were given **rofecoxib** 250 mg daily or placebo for 14 days, with a single 30-mg dose of either intravenous **prednisolone** or oral **prednisone** on days 10 and 14. **Rofecoxib** did not affect the pharmacokinetics of the corticosteroids, even at a dose 10 times greater than that used clinically.[15]

In a double-blind, crossover study in healthy subjects given a single intramuscular dose of **diclofenac** 75 mg, the use of **triamcinolone** 40 mg increased the maximum plasma levels of **diclofenac** by 24%. This was possibly due to an increased rate of absorption. Other pharmacokinetic parameters of **diclofenac** were not significantly changed.[16] In another study, neither **prednisone** 5 mg nor **dexamethasone** 1.5 mg daily were found to affect **oxyphenbutazone** levels.[17]

The majority of these pharmacokinetic interactions seem unlikely to be of clinical significance, but they may well contribute to the adverse effects of both drugs, particularly the corticosteroids. No particular action appears to be necessary to account for these pharmacokinetic effects.

Corticosteroids + Phenytoin

The therapeutic effects of dexamethasone, fludrocortisone, methylprednisolone, prednisolone, prednisone, and probably other corticosteroids, can be markedly reduced by phenytoin. One study suggested that dexamethasone may modestly increase serum phenytoin levels, but another study and two case reports of patients with brain metastases suggest that a *decrease* can occur. The results of the dexamethasone adrenal suppression test may prove to be unreliable in those taking phenytoin.

Clinical evidence

Several studies suggest that phenytoin may affect the half-life and clearance of a number of corticosteroids. These are shown in 'Table 29.2', (below). Other information regarding specific corticosteroids is given in the sections below.

Table 29.2 A comparison of the effects of phenytoin on the pharmacokinetics of different corticosteroids (after Petereit and colleagues[1])

Corticosteroid	*Daily dosage of phenytoin (mg)*	*Half-life without phenytoin (minutes)*	*Decreased half-life with phenytoin (%)*	*Increased mean clearance rate with phenytoin (%)*	*Refs*
Dexamethasone	300	250	51	140	2
Hydrocortisone	300 to 400	60 to 90	15	25	3
Methylprednisolone	300	165	56	130	4
Prednisolone	300	190 to 240	45	77	3
Prednisone	Prednisolone is the biologically active metabolite of prednisone so that the values for prednisone and prednisolone should be similar				5

(a) Dexamethasone

1. Dexamethasone levels/response. A comparative pharmacokinetic study in 6 neurological or neurosurgical patients taking oral dexamethasone and phenytoin found that the average amount of dexamethasone that reached the general circulation was a quarter of that observed in 9 other patients taking dexamethasone alone (mean oral bioavailability fractions of 0.21 and 0.84, respectively).[1] Another report describes patients who needed increased doses of dexamethasone while taking phenytoin,[2] and a patient with pemphigus vulgaris failed to respond to large doses of corticosteroids including **prednisolone** 100 mg daily or dexamethasone 30 mg daily when he took phenytoin and phenobarbital. Dramatic improvement occurred following gradual discontinuation of the antiepileptic drugs.[3]

A study in 7 patients found that phenytoin 300 to 400 mg daily reduced the plasma cortisol levels in response to dexamethasone from 220 to 190 microgram/L, compared with a mean reduction from 180 to 40 microgram/L in the absence of phenytoin.[4] Other studies confirmed that, in patients taking long-term phenytoin, plasma cortisol and urinary 17-hydroxycorticosteroid levels were suppressed far less than might be expected with small doses of dexamethasone (500 micrograms every 6 hours for 8 doses), but with larger doses (2 mg every 6 hours for 8 doses) suppression was normal.[5] However, one case describes a patient in whom even 16 mg of dexamethasone failed to cause cortisol depression while she was taking phenytoin, but when she was re-tested in the absence of phenytoin only 1 mg of dexamethasone was needed to elicit a response.[6]

Phenytoin levels. A study into epilepsy prophylaxis post-trauma found that the serum phenytoin levels in those taking dexamethasone 16 to 150 mg (mean 63.6 mg) were 40% higher than in those taking phenytoin alone (17.3 micrograms/mL compared with 12.5 micrograms/mL). The phenytoin was given as a loading dose of 11 mg/kg intravenously and then 13 mg/kg intramuscularly.[7] Conversely, a retrospective study of 40 patient records (diagnosis unspecified) indicated that dexamethasone reduced serum phenytoin levels: the serum phenytoin levels of 6 patients receiving fixed doses of phenytoin were halved by dexamethasone.[8] Another report describes a patient with brain metastases who required over 8 mg/kg of phenytoin (600 mg) to achieve therapeutic phenytoin levels in the presence of dexamethasone 16 mg. When the dexamethasone was increased to 28 mg daily he experienced seizures, and an increase in his phenytoin dose from 600 mg to 1 g only resulted in an increase in his levels from 13.9 to 16.4 micrograms/mL.[9] Another patient, also with a brain metastasis, needed a large dose of phenytoin (greater than 10 mg/kg) while taking dexamethasone. He had an almost fourfold rise in serum phenytoin levels when dexamethasone was stopped.[10]

(b) Other corticosteroids

The **fludrocortisone** dosages of two patients required 4-fold and 10- to 20-fold increases, respectively, in the presence of phenytoin.[11]

Renal allograft survival is decreased in patients taking **prednisone** and phenytoin, due (it is believed) to a reduction in the immunosuppressant effects of the corticosteroid.[12] For mention of a patient with pemphigus vulgaris who did not respond to corticosteroids including **prednisolone** when he was also treated with drugs including phenytoin, see under *Dexamethasone*, above.

Mechanism

Phenytoin is a potent liver enzyme inducer that increases the metabolism of the corticosteroids so that they are cleared from the body more quickly, reducing both their therapeutic and adrenal suppressant effects.

Importance and management

The fall in serum corticosteroid levels is established and of clinical importance in systemic treatment, but it seems unlikely to affect the response to steroids given topically or by inhalation, intra-articular injection or enema.[13] The interaction can be accommodated in several ways:

- Increase the corticosteroid dosage proportionately to the increase in clearance (see 'Table 29.2', (p.1267)). With prednisolone an average increase of 100% (range 58 to 260% in 5 subjects) proved effective.[13] A fourfold increase may be necessary with dexamethasone,[1] and much greater increases have been required with fludrocortisone.[11]
- Exchange the corticosteroid for another that is less affected (see 'Table 29.2', (p.1267)). A comparative study in children found that **methylprednisolone** was more affected than prednisolone.[14] In another case the exchange of dexamethasone 16 mg daily for prednisone 100 mg daily was successful.[15]
- Exchange the phenytoin for another antiepileptic: barbiturates (including primidone[16]) and carbamazepine, are also enzyme-inducers, but valproate is a possible non-interacting alternative,[2] where clinically appropriate. However, remember that corticosteroids should only be given to epileptics with care and good monitoring because of the risk that they will exacerbate the disease condition.

The effects of phenytoin on the dexamethasone adrenal suppression test can apparently be accommodated by using larger than usual doses of dexamethasone (2 mg every 6 hours for 8 doses)[5] or by an overnight test using 50 mg of hydrocortisone.[17]

The reports on the changes in serum phenytoin levels are inconsistent (both increases and decreases have been seen). The effects of concurrent use should be closely monitored.

Corticosteroids + Protease inhibitors

Several cases of Cushing's syndrome have been seen in patients using inhaled or intranasal fluticasone when ritonavir was also given. In healthy subjects given fluticasone propionate intranasally, ritonavir increased fluticasone propionate plasma concentrations several hundred fold, resulting in markedly reduced serum cortisol concentrations. Ritonavir may reduce the clearance of prednisone, prednisolone and some other corticosteroids. Ritonavir and nelfinavir may increase levels of the active metabolite of ciclesonide. Dexamethasone may reduce the levels of indinavir, saquinavir and possibly darunavir.

Clinical evidence

(a) Fluticasone

Case reports of adverse effect. An HIV-positive 32-year-old man who had been using intranasal fluticasone 200 micrograms twice daily for 3 years for allergic rhinitis, developed a cushingoid face and gained 6.5 kg in weight within 5 months of starting to take **ritonavir**, zidovudine and lamivudine.[1] Another HIV-positive man receiving inhaled beclometasone 400 to 800 micrograms daily for asthma and intranasal fluticasone 800 micrograms daily for allergic rhinitis was also given **ritonavir**, **saquinavir**, stavudine and nevirapine, after which he developed mild cushingoid facial changes. Both patients had high plasma levels of fluticasone. The problems resolved when the fluticasone was withdrawn. A third HIV-positive patient receiving inhaled beclometasone and intranasal fluticasone as well as **ritonavir**, zidovudine and lamivudine, had increased fluticasone levels but no signs of Cushing's syndrome.[1]

A further 6 HIV-positive patients taking protease inhibitors, including low

doses of **ritonavir**, and with HIV-lipodystrophy developed symptomatic Cushing's syndrome when given inhaled fluticasone. All had adrenal suppression, and after withdrawal of fluticasone, 3 patients required oral corticosteroids for several months. Exacerbation of pre-existing diabetes mellitus occurred in one patient and 4 patients had osteoporosis (1 with fractures). Diagnosis was made more difficult by the lipodystrophy masking the Cushingoid features.[2] Another report describes exacerbation of AIDS-associated Kaposi sarcoma together with iatrogenic Cushing syndrome in a patient receiving **ritonavir**-boosted **atazanavir** and fluticasone. Discontinuation of the fluticasone resulted in resolution of the cutaneous Kaposi sarcoma.[3]

There are reports of at least 12 other patients, including 4 children or adolescents,[4-6] who have developed Cushing's syndrome within 2 to 5 months of using regimens of inhaled[4-12] or intranasal[13] fluticasone, with **ritonavir**,[6,13] and the following ritonavir-boosted protease inhibitors: **amprenavir**,[7,11] **atazanavir**,[12] **indinavir**,[11] **lopinavir**,[4,5,9] **saquinavir**,[8] or **lopinavir** with **saquinavir**.[10] The interaction was confirmed in one patient by replacing the **ritonavir** with nevirapine for 3 weeks and then restarting the **ritonavir**.[13]

2. Pharmacokinetic studies. In a crossover study in 18 healthy subjects, fluticasone propionate nasal spray 200 micrograms was given daily for 7 days. Plasma fluticasone propionate levels were undetectable in most subjects, and when they were detectable, maximum levels averaged 11.9 picograms/mL. After the addition of **ritonavir** 100 mg twice daily for 7 days, the maximum plasma levels of fluticasone propionate increased to 318 picograms/mL and the AUC increased approximately 370-fold. The serum cortisol AUC decreased by 86%.[14]

(b) Prednisolone or Prednisone

A study in healthy subjects found that the AUC of a single 20-mg dose of prednisone, given before and on days 4 and 14 of a 14.5 day course of **ritonavir** 200 mg twice daily, was increased by about 30% by the **ritonavir**. The apparent oral clearance of prednisolone was reduced from 8.84 L/hour to 6.45 L/hour and 6.88 L/hour on days 4 and 14, respectively.[15] A further study in HIV-positive subjects found that **lopinavir**/**ritonavir** increased the AUC of a single 20-mg dose of prednisolone compared with the AUC in subjects not receiving antiretroviral medications, although this was not statistically significant.[16]

Mechanism

Ritonavir, and all protease inhibitors, inhibit the cytochrome P450 isoenzyme CYP3A4 to varying degrees. Fluticasone is metabolised by this isoenzyme and therefore the protease inhibitors cause its plasma levels to rise. The active metabolite of ciclesonide is also metabolised by CYP3A4,[17] and is therefore similarly affected. Prednisolone is less dependent on CYP3A4 for metabolism, and is therefore only modestly affected.

Importance and management

The interaction between ritonavir and **fluticasone** appears to be established and clinically important. The incidence is not known, but any patient using these two drugs should be very well monitored for any signs of corticosteroid overdose. The problem may take months to manifest itself. It has been suggested that if an inhaled corticosteroid is required by a patient taking ritonavir, a corticosteroid that is not a substrate for CYP3A4 (e.g. beclometasone)[18] or one with less systemic availability should be given at the lowest effective dose.[19] The manufacturers of fluticasone inhaler[14,20] and nasal spray[21,22] advise against their concurrent use with ritonavir unless the potential benefit is considered to outweigh the risk of systemic corticosteroid adverse effects; similar advice has been given by the manufacturers of protease inhibitors boosted with ritonavir.

Ritonavir may increase the levels of **prednisone** and **prednisolone** and some manufacturers of **betamethasone**,[23] **budesonide**,[24] **ciclesonide**,[17] or **dexamethasone**[25,26] predict a similar interaction. As a result, concurrent use is not generally recommended due to the increased risk of systemic adverse effects of corticosteroids, but if the combination is essential careful monitoring would be prudent. The need for dosage reduction of the corticosteroid should be borne in mind. Note that, of the protease inhibitors, **nelfinavir**, like ritonavir, is a highly potent inhibitor of CYP3A4, and therefore similar precautions to those advised with ritonavir would seem prudent if nelfinavir is given with one of these corticosteroids. Other protease inhibitors have less effect on CYP3A4, but some monitoring would still seem appropriate, particularly as low-dose ritonavir is often used with these protease inhibitors as a pharmacological booster.

The manufacturers of **dexamethasone** note that it is a modest inducer of CYP3A4 and state that it may reduce the plasma levels of indinavir or saquinavir.[26] Similar warnings are given by the manufacturer of **darunavir**.[18] The clinical outcome of this predicted effect is unknown, but until more is known, it would seem prudent to monitor antiviral efficacy if these combinations are used.

Corticosteroids + Proton pump inhibitors

Lansoprazole appears to have no effect on the pharmacokinetics of prednisolone following a single dose of prednisone. Omeprazole has no effect on oral budesonide or prednisone pharmacokinetics in healthy subjects, but an isolated and unexplained report describes a reduction in the effects of prednisone in a patient taking omeprazole.

Clinical evidence, mechanism, importance and management

(a) Lansoprazole

A placebo-controlled, randomised study in 18 healthy subjects found that lansoprazole 30 mg daily had no effect on the absorption of a single 40-mg oral dose of **prednisone**. Furthermore, the biotransformation of prednisone to **prednisolone**, and the pharmacokinetics of prednisolone were not affected.[1]

(b) Omeprazole

A placebo-controlled, randomised study in 18 healthy subjects found that omeprazole 40 mg daily had no effect on the pharmacokinetics of **prednisolone** after a single 40-mg dose of **prednisone**.[1] This contrasts with an isolated and unexplained report of a patient suffering from pemphigus who was given **prednisone** 1 mg/kg daily with, a week later, ranitidine 200 mg daily for a gastric ulcer. Four weeks later, when the skin lesions were well controlled, it was decided to replace the ranitidine with omeprazole 40 mg daily. Within 4 days the skin lesions began to worsen progressively, although the **prednisone** dosage remained unchanged. After 3 weeks it was decided to stop the omeprazole and restart the ranitidine because an adverse interaction between the **prednisone** and the omeprazole was suspected. Within about a week, the skin condition had begun to improve.[2] The suggested explanation for the interaction is that the omeprazole inhibited the liver enzyme (11β-hydroxylase) that normally converts **prednisone** into its active form (prednisolone) resulting in inadequate treatment of the pemphigus.[2]

A placebo-controlled, randomised study in 11 healthy subjects found that omeprazole 20 mg daily for 5 days had no effect on the pharmacokinetics of a single 9-mg dose of **budesonide** (*Entocort CR* capsules).[3]

It would seem that adverse interactions between oral **budesonide** or **prednisone** and omeprazole are unlikely, but the isolated case should be borne in mind in the event of an unexpected response to treatment.

Corticosteroids + Rifampicin (Rifampin)

The effects of systemic cortisone, dexamethasone, fludrocortisone, hydrocortisone, methylprednisolone, prednisone and prednisolone can be markedly reduced by rifampicin, but aldosterone appears not to be affected. Rifabutin and rifapentine are predicted to interact similarly, all be it to a lesser extent.

Clinical evidence

(a) Aldosterone

In 7 patients with Addison's disease due to tuberculosis, there were no changes in the pharmacokinetics of intravenous aldosterone after they were also given rifampicin 600 mg daily for 6 days.[1]

(b) Cortisone and Fludrocortisone

A patient with Addison's disease taking cortisone and fludrocortisone had typical signs of corticosteroid overdosage when the rifampicin he was taking was replaced by ethambutol,[2] suggesting that the rifampicin had reduced the levels of these corticosteroids. Another Addisonian patient needed an increase in her dosage of cortisone from 37.5 mg daily to 50 mg daily, and fludrocortisone 100 micrograms daily, when rifampicin 450 mg daily was started.[3] A patient had an Addisonian crisis when rifampicin was added to treatment with **dexamethasone** and fludrocortisone.[4]

(c) Dexamethasone

Rifampicin markedly increases the clearance of dexamethasone.[5,6] A patient had an Addisonian crisis when rifampicin was added to treatment with dexamethasone and **fludrocortisone**.[4]

(d) Hydrocortisone

A metabolic study in an Addisonian patient taking hydrocortisone found that rifampicin shortened its half-life and reduced its AUC.[7]

(e) Other corticosteroids

A child with nephrotic syndrome taking **prednisolone**, and accidentally given a BCG vaccine, was given rifampicin and isoniazid to prevent possible dissemination of the vaccine. When the nephrotic condition did not respond, the prednisolone dosage was raised from 2 to 3 mg/kg daily without any evidence of corticosteroid overdosage. Later when the rifampicin and isoniazid were withdrawn, remission of the nephrotic condition was achieved with the original dosage of prednisolone.[8] A number of other reports describe a reduction in the response to **prednisone**, **prednisolone** or **methylprednisolone** in patients given rifampicin.[4,9-17] Pharmacokinetic studies in patients have shown that the AUC of **prednisolone** is reduced by about 60% by rifampicin, and its half-life is decreased by 40% to 60%.[11,15,18]

Mechanism

Rifampicin is a potent liver enzyme inducer, which increases the metabolism of the corticosteroids by the liver,[10] thereby decreasing their levels and reducing their effects.

Importance and management

The interactions between the corticosteroids and rifampicin are established, well documented and clinically important. The need to increase the dosages of cortisone, dexamethasone, fludrocortisone, hydrocortisone, methylprednisolone, prednisolone and prednisone should be expected if rifampicin is given. It has been suggested that as an initial adjustment the dosage of prednisolone should be increased two- to threefold, and reduced proportionately if the rifampicin is withdrawn.[10,11,18,19] In the case of prednisolone the interaction develops maximally by 14 days and disappears about 14 days after withdrawal of the rifampicin.[20]

There seems to be no direct information about corticosteroids other than those mentioned here, but be alert for them to be similarly affected. Systemic corticosteroids are usually considered as contraindicated, or only to be used with great care, in patients with active or quiescent tuberculosis.

It is not clear whether any of the topically applied corticosteroids will interact with rifampicin, but any clinically significant interaction would be expected to be very rare.

There does not seem to be any information regarding the other rifamycins, **rifabutin** (a weak enzyme inducer) and **rifapentine** (a moderate enzyme inducer). However, the UK manufacturers and the CSM in the UK warn that rifabutin may possibly reduce the effects of a number of drugs,[21,22] including corticosteroids,[21] and therefore some caution is probably prudent.

Corticosteroids + Somatropin

Corticosteroid doses may possibly require increasing if somatropin is also given. Corticosteroid replacement therapy may attenuate the growth promoting effects of somatropin.

Clinical evidence, mechanism, importance and management

One manufacturer of somatropin says that it inhibits 11β-hydroxysteroid dehydrogenase type 1 (11βHSD-1) in adipose and hepatic tissue and may affect the metabolism of cortisol and cortisone.[1] Limited *in vitro*[2] and *in vivo*[3] data also indicate that somatropin may be an inducer of cytochrome P450 isoenzymes and that it may increase the clearance of drugs that are metabolised by CYP3A4 enzymes, including a number of corticosteroids.[1-4] The clinical significance of this is unknown, but careful monitoring is advisable. Somatropin has been reported to induce a modest reduction of serum cortisol levels in growth hormone deficient patients receiving adrenal substitution treatment.[2] Therefore, patients receiving corticosteroid replacement therapy may require an increase in their maintenance or stress doses of corticosteroid if they are given somatropin;[1,2] this may be especially true for patients taking **cortisone acetate** and **prednisone** since conversion of these drugs to their biologically active metabolites is dependent on the activity of the 11βHSD-1 enzyme.[1]

In addition, glucocorticoid therapy may attenuate the growth promoting effects of somatropin.[1,2,4] Therefore, glucocorticoid replacement therapy should be carefully adjusted in patients with growth hormone and glucocorticoid deficiency to avoid both hypoadrenalism and an inhibitory effect on growth.[1]

Corticosteroids + St John's wort (*Hypericum perforatum*)

St John's wort does not appear to affect the pharmacokinetics of prednisone or its metabolite, prednisolone.

Clinical evidence

In a pharmacokinetic study, 8 healthy subjects were given a single 20-mg oral dose of **prednisone** before, and at the end, of a 28-day course of St John's wort 300 mg three times daily. The pharmacokinetics of **prednisone**, and its metabolite **prednisolone**, were not significantly affected by St John's wort. The St John's wort extract was standardised to contain hypericin 0.3% and a minimum of 4% hyperforin.[1]

Mechanism

It was thought that St John's wort, a known inducer of the cytochrome P450 isoenzyme CYP3A4, would increase the metabolism of prednisone and prednisolone and reduce their levels. While prednisone and prednisolone are substrates of CYP3A4, it is not a major metabolic pathway as they have been shown to be only modestly affected by potent CYP3A4 inhibitors in healthy subjects.

Importance and management

St John's wort does not appear to induce the metabolism of a single dose of prednisone, or its metabolite prednisolone, in healthy subjects; however, further study is needed to clarify significance of this in patients receiving long-term prednisone.

1. Bell EC, Ravis WR, Chan HM, Lin Y-J. Lack of pharmacokinetic interaction between St. John's wort and prednisone. *Ann Pharmacother* (2007) 41, 1819–24.

Corticosteroids + Sucralfate

Sucralfate does not appear to affect the pharmacokinetics of prednisone to a clinically relevant extent.

Clinical evidence, mechanism, importance and management

In 12 healthy subjects, sucralfate 1 g every 6 hours had no significant effect on the pharmacokinetics of a single 20-mg dose of **prednisone**; however, the peak plasma levels were delayed by about 45 minutes when the drugs were given at the same time, but not when the sucralfate was given 2 hours after the **prednisone**.[1] No particular precautions are likely to be needed in patients given both drugs. Information about other corticosteroids is lacking.

Corticosteroids + Tobacco

The pharmacokinetics of dexamethasone, prednisone and prednisolone do not appear to be affected by smoking. Cigarette smoking in asthma is associated with a reduced sensitivity to corticosteroids.

Clinical evidence, mechanism, importance and management

Studies have shown that cigarette smoking impairs the efficacy of inhaled corticosteroids,[1-4] including **beclometasone,**[1,2] **budesonide**[3] and **fluticasone**.[4] One study showed that smokers with mild persistent asthma were insensitive to the therapeutic effect of low-doses of inhaled corticosteroids, although some benefit was observed with high-doses of inhaled corticosteroids.[2] However, another study found that neither lung function nor eosinophil markers changed in smokers, even when high doses of inhaled corticosteroids were given.[3]

Active smoking also impairs the therapeutic response to short-term oral corticosteroids in chronic asthma. In a study in asthmatic patients, **prednisolone** 40 mg daily for 14 days significantly improved FEV_1 in patients who had never smoked, but had no effect on smokers, when compared with placebo.[5] Ex-smokers who had stopped smoking for more than one year showed a trend towards improvement in asthma control after **prednisolone** treatment.[5] However, in another study there was no change in airway corticosteroid responses in patients who had only stopped smoking for 6 weeks, although baseline lung function had improved.[6]

In addition, the insensitivity to corticosteroids in smokers with asthma appears to affect tissue sites other than the airways; the cutaneous vasoconstrictor response to topical **beclometasone** is reduced in smokers with asthma, when compared with patients with asthma who have never smoked.[7] In a study in asthmatic patients who smoked, the vasoconstrictor response to topical **beclometasone** improved in those who had stopped smoking for 6 weeks, compared with those who continued to smoke.[6]

A study involving 18 healthy subjects, half of whom were smokers, found that smoking had no overall effect on the pharmacokinetics of oral or intravenous **dexamethasone**, oral **prednisone**, or intravenous **prednisolone**.[8]

Cigarette smoking is an important factor associated with corticosteroid resistance in asthmatics. The mechanism behind the reduced sensitivity to corticosteroids in smokers is not fully understood, but may possibly be due to increased oxidative stress resulting in reduced histone deacetylase activity, airway inflammation, and/or impaired glucocorticoid receptor function. There is some evidence that smoking cessation may at least partially restore corticosteroid responsiveness.[9-11] These findings reinforce the need for those with airways disease, including asthma, to give up smoking tobacco.

Corticosteroids + Vaccines

Patients who are immunised with live vaccines while receiving immunosuppressive doses of corticosteroids may develop generalised, possibly life-threatening, infections. Corticosteroids may attenuate the response to vaccination.

Clinical evidence, mechanism, importance and management

The use of corticosteroids can reduce the number of circulating lymphocytes and suppress the normal immune response, so that concurrent immunisation with live vaccines can lead to generalised infection. It has been suggested that **prednisone** in doses of greater than 10 to 15 mg daily will suppress the immune response, whereas doses of up to 40 to 60 mg on alternate days probably will not,[1] although this is debated.

A patient with lymphosarcoma and hypogammaglobulinaemia, taking **prednisone** 15 mg daily, developed a generalised vaccinial infection when she was given **smallpox vaccine**.[2] A fatal vaccinial infection developed following **smallpox vaccination** in another patient taking **cortisone**.[3] This type of problem can be controlled with immunoglobulin to give cover against a general infection while immunity develops, and this has been successfully used in steroid-dependent patients needing **smallpox vaccination**.[4]

The principles applied to **smallpox** may be generally applicable to other live attenuated vaccines (e.g. **measles**, **mumps**, **rubella**, **poliomyelitis**, **BCG**), but no studies seem to have been done to establish what is safe.[1]

It is generally accepted that patients taking immunosuppressants should not be given live vaccines. Problems with topical or inhaled steroids in normal dosages seem unlikely because the amounts absorbed are relatively small.[1] However, this needs confirmation. The UK Department of Health contraindicates the use of live vaccines in all patients receiving systemic high-dose steroids, until at least 3 months after treatment has been stopped.[5] This includes children who receive **prednisolone**, orally or rectally, at a daily dose (or its equivalent) of 2 mg/kg per day for at least one week, or 1 mg/kg per day for one month. For adults, immunosuppression should be considered in those who receive at least 40 mg of **prednisolone** per day for more than one week.

Note that immunosuppression caused by corticosteroids may also attenuate the response to other vaccines. In one study patients given a higher dose of **prednisolone** per kg had a reduced antibody response to **influenza vaccine**, and those given a daily dose had a reduced response, when compared with those given an alternate day schedule.[6] Consider also 'Immunosuppressants + Vaccines', p.1276.

Corticosteroids + Zileuton

No clinically relevant pharmacokinetic interaction occurs between prednisone and zileuton.

Clinical evidence, mechanism, importance and management

In a randomised, crossover study, 16 healthy subjects were given zileuton 600 mg every 6 hours for a week, with either a 40-mg dose of **prednisone** or placebo on day 6. The pharmacokinetics of both drugs were slightly altered but this was not considered to be clinically relevant. The half-life of **prednisolone** (derived from **prednisone**) increased from 2.8 to 2.9 hours, while the zileuton AUC and the time to achieve maximum serum levels were decreased by 13% and 26%, respectively. It was concluded that concurrent use carries a minimal risk of a clinically important pharmacokinetic interaction.[1] No special precautions would appear to be needed if both drugs are given.

1. Awni WM, Cavanaugh JH, Tzeng T-B, Witt G, Granneman GR, Dubé LM. Pharmacokinetic interactions between zileuton and prednisone. *Clin Pharmacokinet* (1995) 29 (Suppl 2), 105–111.

Corticosteroids; Dexamethasone + Asparaginase

Recent treatment with asparaginase may reduce dexamethasone clearance.

Clinical evidence, mechanism, importance and management

A study in 214 children with acute lymphoblastic leukaemia found that there was considerable inter- and intrapatient variability in the pharmacokinetics of dexamethasone 8 mg/m^2 daily on days 1 and 8 of an 8-day re-induction course of dexamethasone: more than a tenfold variability in systemic exposure to the drug was found. Much of the variability in dexamethasone clearance was accounted for by variability in serum albumin concentrations, which in turn were affected by the intensity of previous asparaginase treatment. Hypoalbuminaemia, a biomarker of asparaginase activity, was associated with a low dexamethasone apparent clearance, whilst higher apparent clearance of dexamethasone was associated with a greater serum albumin concentration and also with younger children (who tended to be treated in the low-risk group).[1] The authors of the report suggest that this interaction may be, at least in part, responsible for the variability in response to dexamethasone in this patient group. More study is needed.

Corticosteroids; Dexamethasone + Caffeine

The results of the dexamethasone suppression test can be falsified by the acute ingestion of caffeine but long-term caffeine use does not appear to have an effect.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study, 22 healthy subjects and 6 depressed patients were given a single 480-mg dose of caffeine at 2 pm, following a single 1-mg dose of dexamethasone given at 11 pm the previous evening. Caffeine significantly increased the cortisol levels following the dexamethasone dose: cortisol levels taken at 4 pm were about 146 nanomol/L with caffeine, compared with about 64 nanomol/L with placebo.[1] Thus the equivalent of about 4 to 5 cups of coffee may effectively falsify the results of the dexamethasone suppression test. However, in a study in 121 patients with depression, there was no correlation between long-term low to high intake of caffeine (6 mg to 2.3 g daily) and cortisol levels at 8 am, 4 pm or 11 pm on the day after a 1-mg dose of dexamethasone was given (at 11 pm the previous evening). It was suggested that long-term caffeine intake produces tolerance to the effects of acute caffeine on the hypothalamic-pituitary adrenal (HPA) axis.[2]

2. Lee MA, Flegel P, Cameron OG, Greden JF. Chronic caffeine consumption and the dexamethasone suppression test in depression. *Psychiatry Res* (1988) 24, 61–5.

Corticosteroids; Dexamethasone + Valspodar

Dexamethasone does not affect the pharmacokinetics of valspodar. Valspodar modestly increases the AUC of dexamethasone.

Clinical evidence, mechanism, importance and management

In a crossover study, healthy fasting subjects were given single doses of dexamethasone 8 mg and valspodar 400 mg either alone or together. Dexamethasone had no effect on the pharmacokinetics of valspodar. The AUC of dexamethasone was increased by 24% by valspodar. This change is modest and therefore dosage alterations are probably not required if concurrent use is of a short duration.[1]

1. Kovarik JM, Purba HS, Pongowski M, Gerbeau C, Humbert H, Mueller EA. Pharmacokinetics of dexamethasone and valspodar, a P-glycoprotein (*mdr1*) modulator: implications for coadministration. *Pharmacotherapy* (1998) 18, 1230–6.

Etanercept + Methotrexate

Methotrexate does not appear to alter the pharmacokinetics of etanercept.

Clinical evidence, mechanism, importance and management

A double-blind study in 98 patients with rheumatoid arthritis receiving subcutaneous etanercept 25 mg twice weekly, or etanercept with oral methotrexate (median weekly dose of 20 mg) found that the pharmacokinetics of etanercept were not altered by methotrexate.[1] No particular precautions or dosage adjustments appear to be necessary on concurrent use.

1. Zhou H, Mayer PR, Wajdula J, Fatenejad S. Unaltered etanercept pharmacokinetics with concurrent methotrexate in patients with rheumatoid arthritis. *J Clin Pharmacol* (2004) 44, 1235–43.

Etanercept + Miscellaneous

A higher incidence of malignancies has been reported in patients with Wegener's granulomatosis when given both cyclophosphamide and etanercept. A reduced neutrophil count may occur in patients taking etanercept with sulfasalazine. No interactions have been found when etanercept was given with salicylates other than sulfasalazine, corticosteroids, or NSAIDs.

Clinical evidence, mechanism, importance and management

(a) Cyclophosphamide

The US manufacturer says that etanercept is not recommended in patients receiving cyclophosphamide. They state that in a study in patients with Wegener's granulomatosis, the addition of etanercept to standard treatment, including cyclophosphamide, was associated with a higher incidence of non-cutaneous solid malignancies.[1]

(b) Sulfasalazine

A study in patients taking sulfasalazine found that when etanercept was also given, patients had a decrease in neutrophil counts, when compared to other groups of patients receiving either drug alone. The clinical significance of this finding is not known.[1,2]

(c) Other drugs

The UK manufacturer notes that no interactions have been found when etanercept was given with **corticosteroids**, **salicylates** (except *sulfasalazine*, see above), **NSAIDs** or other analgesics.[2]

2. Enbrel (Etanercept). Wyeth Pharmaceuticals. UK Summary of product characteristics, May 2009.

Everolimus + Calcium-channel blockers

Increased levels of both everolimus and verapamil can occur on concurrent use. Diltiazem might be expected to increase everolimus levels, although there was no clear evidence of an interaction in a population model. In this model, there was also no evidence of an interaction with amlodipine, isradipine or nifedipine.

Clinical evidence

A study in 16 healthy subjects given a single 2-mg dose of everolimus before and on day 2 of a 6-day course of **verapamil** 80 mg three times daily found that verapamil increased the AUC and peak blood level of everolimus 3.5-fold and 2.3-fold, respectively. Everolimus also increased the plasma levels of verapamil 2.3-fold.[1]

In a pharmacokinetic modelling study, the difference in everolimus clearance in 5 patients taking **verapamil** was not statistically significant. In addition, there was no clear evidence of an effect on everolimus clearance for **diltiazem** in 22 patients or the dihydropyridines, **amlodipine**, **isradipine**, or **nifedipine** in 267 patients.[2] These suggested findings require confirmation.

Mechanism

Verapamil is an inhibitor of the cytochrome P450 isoenzyme CYP3A4, the isoenzyme primarily involved in the metabolism of everolimus, and also inhibits P-glycoprotein, a transporter for which everolimus is a substrate. Therefore concurrent use raises everolimus levels. It is not known exactly why verapamil levels are raised. Diltiazem is also an inhibitor of the cytochrome P450 isoenzyme CYP3A4 and so might be expected to interact similarly, although the modelling study cited did not find any effect. Further study is needed.

Importance and management

If verapamil is given with everolimus, it would seem prudent to monitor everolimus blood levels as well as monitor for adverse effects due to verapamil, such as hypotension, flushing and oedema, and adjust the dose of both drugs as needed. The UK manufacturer recommends that, in patients given everolimus for renal cell carcinoma and also taking verapamil or diltiazem, an everolimus dose reduction from 10 mg daily to 5 mg daily or 5 mg on alternate days should be considered. However, they state that this dose decrease is a prediction and therefore good monitoring is still required.[3] Note that the US manufacturer advises avoiding the concurrent use of both of these calcium-channel blockers.[4]

One manufacturer[5] also lists **nicardipine**, but note that the degree of inhibition of CYP3A4 is less than that of diltiazem and verapamil.

Amlodipine, isradipine, and nifedipine do not appear to interact with everolimus, although this ideally needs confirmation in formal pharmacokinetic studies.

Everolimus + Ciclosporin

Ciclosporin increases the AUC of everolimus. Although everolimus appears to have no relevant effects on ciclosporin levels, concurrent use might potentiate ciclosporin-induced renal toxicity.

Clinical evidence

(a) Effects on ciclosporin

In a phase I pharmacokinetic study in 7 patients stable taking ciclosporin, there was no change in ciclosporin pharmacokinetics when they were given a single-dose of everolimus ranging from 0.25 to 15 mg.[1] Similarly, in a placebo-controlled study in 54 kidney transplant patients taking ciclosporin (93% also taking prednisone), everolimus 0.75 to 10 mg daily in single or divided doses had no consistent, clinically relevant effect on ciclosporin levels in 44 patients when compared with the 10 patients given placebo. However, because of wide interpatient variability, there is a possibility that an interaction could occur in some patients.[2] Another study in 101 kidney transplant patients taking ciclosporin and prednisone with everolimus 0.5 to 2 mg twice daily for one year also found no evidence that everolimus affected ciclosporin pharmacokinetics.[3]

(b) Effects on everolimus

The possibility of a drug interaction was assessed in a crossover study in 24 healthy subjects who were given a single 2-mg dose of everolimus, alone and with single doses of ciclosporin, either *Neoral* (microemulsion) 175 mg or *Sandimmun* (corn oil suspension) 300 mg. *Neoral* increased the peak levels and AUC of everolimus by 82% and 168%, respectively. *Sandimmun* did not affect the peak levels of everolimus but increased its AUC by 74%.[4]

In a pharmacokinetic study in 6 heart transplant recipients taking everolimus, trough concentrations of everolimus were almost halved from 4.2 micrograms/L to 2.3 micrograms/L when ciclosporin was stopped and tacrolimus was started. The AUC of everolimus was similarly decreased by about 50% and its maximum level was decreased by 35%.[5]

Mechanism

Not fully understood. Ciclosporin is a modest inhibitor of the cytochrome P450 isoenzyme CYP3A4 and of P-glycoprotein, of which everolimus is a substrate. Why the *Neoral* formulation had a greater effect than the *Sandimmun* formulation is unclear.

Importance and management

Information on the effects of ciclosporin on the pharmacokinetics of everolimus appear to be limited; however, the studies suggest that ciclosporin may increase everolimus levels to a clinically relevant extent. Therefore, it would be prudent to monitor everolimus levels with concurrent use of these drugs, and adjust the everolimus dose as necessary. The UK manufacturer recommends that, in patients given everolimus for renal cell carcinoma and also taking ciclosporin, an everolimus dose reduction from 10 mg daily, to 5 mg daily or 5 mg on alternate days, should be considered. However, they state that this dose decrease is a prediction and therefore good monitoring is still required.[6] Bear in mind that one study found that the *Neoral* formulation may have a greater effect than the *Sandimmun* formulation.

It would appear that, in general, everolimus has no clinically significant effects on the pharmacokinetics of ciclosporin. However, one manufacturer cautions that everolimus may potentiate the renal toxicity of ciclosporin. They recommend that renal function should be monitored, and that reduction of the ciclosporin dose should be considered in patients with raised serum creatinine. They say that, in renal transplantation, everolimus should not be used long term with full doses of ciclosporin.[7]

Everolimus + Food

A high-fat meal slightly reduces the exposure to everolimus.

Clinical evidence

In a single-dose study in 24 healthy subjects, giving everolimus 2 mg tablets with a high-fat breakfast reduced the maximum everolimus level by 60% and delayed the time to maximum level by about 1.25 hours when compared with the fasting state.[1] However, the everolimus AUC was reduced by just 16%. Similarly, in a study in 6 transplant patients taking ciclosporin and everolimus 2.5 mg daily, giving everolimus with a high-fat meal reduced the maximum level and AUC of everolimus by 53% and 21%, respectively, without altering the trough level.[1]

Mechanism

Unknown.

Importance and management

The available evidence suggests that food has little effect on the exposure to everolimus. Nevertheless, the UK manufacturer recommends that everolimus is taken consistently either with or without food, to minimise variability.[2]

1. Kovarik JM, Hartmann S, Figueiredo J, Rordorf C, Golor G, Lison A, Budde K, Neumayer HH. Effect of food on everolimus absorption: quantification in healthy subjects and a confirmatory screening in patients with renal transplants. *Pharmacotherapy* (2002) 22, 154–9.
2. Afinitor (Everolimus). Novartis Pharmaceuticals UK Ltd. UK Summary of product characteristics, October 2009.

Everolimus + Ketoconazole and other CYP3A4 inhibitors

Ketoconazole, a potent inhibitor of CYP3A4, very markedly increases everolimus levels. A report describes reduced everolimus clearance in a patient also given itraconazole, and another patient was treated with a markedly reduced everolimus dose while receiving voriconazole. Other inhibitors of CYP3A4 and/or P-glycoprotein are predicted to increase everolimus levels.

Clinical evidence

In a study, 12 healthy subjects were given a single 1-mg dose of everolimus on day 4 of an 8-day course of **ketoconazole** 200 mg twice daily. Ketoconazole increased the AUC, peak blood level and half-life of everolimus by 15-fold, 3.9-fold, and 1.9 fold, respectively.[1]

Similarly, in a pharmacokinetic modelling study, a patient taking **itraconazole** with everolimus, ciclosporin and prednisone had a 74% lower everolimus clearance. However, everolimus clearance was reduced by a non-significant 7% in 16 patients who were also taking **fluconazole**.[2] In one severely-ill patient receiving intravenous **fluconazole**, the authors stated that everolimus was started at about a 50 to 75% lower dose than usual (0.75 mg twice daily), and this maintained everolimus levels within the desired range.[3] However, note that the starting dose of 0.75 mg twice daily used in this study is the recommended initial dose in kidney and heart transplant patients.[4] When fluconazole was switched to **voriconazole**, the everolimus dose was reduced to just 0.25 mg daily, with everolimus levels remaining within the therapeutic range, although the concentration-dose ratio suggested that 0.25 mg twice daily might have been more appropriate.[3]

Mechanism

Everolimus, a derivative of sirolimus, is a substrate for the cytochrome P450 isoenzyme CYP3A4 and P-glycoprotein. The azole antifungals inhibit CYP3A4, to varying degrees (consider 'azole antifungals', (p.233)), and therefore inhibit everolimus metabolism.

Importance and management

The pharmacokinetic interaction with ketoconazole was very marked, and likely to be clinically important. One group recommends that, given the magnitude of the interaction, ketoconazole should be avoided if possible in patients taking everolimus.[5] The manufacturers also advise avoiding the concurrent use of ketoconazole; and also itraconazole, **posaconazole** and voriconazole.[6,7] If these azoles must be given with everolimus, patients should have their everolimus levels monitored closely and the dose reduced as necessary.

On the basis of the interaction with the azoles and its likely mechanism, the manufacturers predict that other moderate or potent CYP3A4 and/or P-glycoprotein inhibitors will interact similarly. They name **aprepitant**, **delavirdine**, **fluconazole**, **grapefruit juice**, **nefazodone**, the protease inhibitors **amprenavir**, **atazanavir**, **darunavir**, **fosamprenavir**, **indinavir**, **nelfinavir**, **ritonavir** and **saquinavir**.[6,7] The US manufacturers suggest that the concurrent use of everolimus and moderate or potent CYP3A4 inhibitors should be avoided. The UK manufacturers similarly

advise that potent CYP3A4 inhibitors should be avoided, but suggest that some moderate inhibitors (they name **amprenavir**, **fosamprenavir**, and **fluconazole**) can be used with monitoring and an appropriate dose reduction. They recommend an everolimus dose reduction from 10 mg daily to 5 mg daily or 5 mg on alternate days should be considered in patients with renal cell carcinoma; but note that this dose decrease is a prediction.[7] Remember to readjust the everolimus dose if needed when these drugs are stopped.

For further information about the CYP3A4 inhibitors clarithromycin, erythromycin, and telithromycin, see also 'Everolimus + Macrolides', below, and for diltiazem and verapamil, see 'Everolimus + Calcium-channel blockers', p.1273.

Everolimus + Macrolides

Erythromycin increased everolimus levels in one study. Other macrolides probably interact similarly.

Clinical evidence

In a study, 16 healthy subjects were given a single 4-mg dose of everolimus before and on day 5 of a 9-day course of **erythromycin** 500 mg three times daily. The peak blood levels and AUC of everolimus were increased twofold and 4.4-fold, respectively, and its half-life was prolonged by 39%.[1] In a pharmacokinetic modelling study, 9 patients were identified who had received a macrolide antibacterial. Those patients receiving **erythromycin** had a 22% lower clearance of everolimus, and those receiving **azithromycin** had an 18% lower clearance.[2]

Mechanism

Erythromycin probably inhibits the metabolism of everolimus by the cytochrome P450 isoenzyme CYP3A4, of which it is a moderate inhibitor. Everolimus is also a substrate for P-glycoprotein, and various macrolides (such as erythromycin, clarithromycin and possibly azithromycin) are inhibitors of this drug transporter.

Importance and management

The interaction of everolimus with erythromycin is likely to be clinically relevant. The authors recommend that appropriate everolimus dose reductions based on frequently monitored blood levels should be made when patients are given erythromycin.[1] The UK manufacturer recommends that, in patients taking everolimus for renal cell carcinoma and also given erythromycin, an everolimus dose reduction from 10 mg daily, to 5 mg daily or 5 mg on alternate days, should be considered. However, they state that this dose decrease is a prediction and therefore good monitoring is still required.[3] Note that the US manufacturer advises avoiding the concurrent use of erythromycin.[4]

Other macrolides that inhibit CYP3A4 and/or P-glycoprotein would be expected to interact similarly, although the extent of any effect may vary. Therefore if concurrent use with everolimus is considered necessary, everolimus levels should also be closely monitored and the dose adjusted as required. Note that the manufacturers advise avoiding the concurrent use of **clarithromycin** and **telithromycin**.[3,4]

4. Afinitor (Everolimus). Novartis. US Prescribing information, March 2009.

Everolimus + Rifampicin (Rifampin) and other CYP3A4 inducers

Rifampicin (a CYP3A4 and P-glycoprotein inducer) markedly reduces the bioavailability and increases the clearance of everolimus. Other inducers of CYP3A4 and P-glycoprotein are predicted to interact similarly.

Clinical evidence

In a study, 12 healthy subjects were given a single 4-mg dose of everolimus before and after taking rifampicin 600 mg daily for 7 days. Rifampicin increased the clearance of everolimus by 172%, and decreased its AUC and peak blood levels by 63% and 58%, respectively, although there was a large inter-individual variation in the AUC.[1]

Mechanism

Everolimus is metabolised by the cytochrome P450 isoenzyme CYP3A4 and is a substrate for P-glycoprotein, therefore induction of both CYP3A4 and P-glycoprotein by rifampicin may increase the metabolism and reduced the bioavailability of everolimus.

Importance and management

The interaction between everolimus and rifampicin is likely to be clinically important, and may lead to treatment failure. If concurrent use is necessary, it would be prudent to increase the dose of everolimus and monitor levels very closely. One group has suggested a two- to threefold increase in everolimus dose when used with rifampicin.[2] The US manufacturer predicts that **rifabutin** will interact similarly.[3] However, note that rifabutin is a less potent enzyme inducer than rifampicin, so would not be expected to reduce everolimus bioavailability to the same extent.

On the basis of the interaction with rifampicin the manufacturers advise avoiding concurrent use with potent CYP3A4 inducers: they name **carbamazepine**, **phenytoin** (and therefore probably **fosphenytoin**), **phenobarbital** (and therefore probably **primidone**),[3,4] **efavirenz**, **nevirapine**, and **St John's wort**.[4] However, if concurrent use is necessary, everolimus levels should be closely monitored and adjusted as necessary. The manufacturers recommend that, in patients given everolimus for renal cell carcinoma, an everolimus dose increase from 10 mg daily to 20 mg daily, in steps of 5 mg (starting on day 4 of concurrent use), should be considered. However, they state that this dose increase is a prediction and therefore good monitoring is still required.[3,4] Remember to adjust the everolimus dose when rifampicin, rifabutin or other CYP3A4 inducers are stopped.

The US manufacturer[3] also lists **dexamethasone** as a potent CYP3A4 inducer; however, note that clinically significant interactions with dexamethasone as a result of this mechanism appear to be rare.

For a list of CYP3A4 inducers, see 'Table 1.4', (p.6). What should be remembered is that the extent of the inducing effects of these drugs is not identical, so that very marked effects like those observed with rifampicin may not occur; nevertheless the interaction may still be clinically important.

Everolimus + Tacrolimus

No significant pharmacokinetic interaction appears to occur between everolimus and tacrolimus.

Clinical evidence

(a) Effect on everolimus

In one study, 8 transplant patients taking tacrolimus were changed from mycophenolate to everolimus 1.5 mg twice daily. After everolimus had been taken for 10 days the tacrolimus dose was halved. There was no difference in the pharmacokinetics of everolimus between the full-dose tacrolimus and half-dose tacrolimus periods (trough level 3.3 nanograms/mL compared with 3 nanograms/mL). In addition, the everolimus trough level and AUC were about 2.5-fold lower than in a previous study of patients taking the same dose of everolimus with ciclosporin, which is known to increase everolimus levels.[1] In another study, trough concentrations of everolimus were almost halved (from 4.2 to 2.3 nanograms/mL) when ciclosporin was stopped and tacrolimus was started in 6 heart transplant recipients taking everolimus. The AUC of everolimus was similarly decreased by about 50% and its maximum level was decreased by 35%.[2]

(b) Effect on tacrolimus

In a study in 8 transplant patients taking tacrolimus, there was no statistically significant change in the tacrolimus trough level (7.9 nanograms/mL compared with 8.4 nanograms/mL) and its AUC when mycophenolate was replaced with everolimus 1.5 mg twice a day.[1] Similarly, there was no change in tacrolimus pharmacokinetics in 6 transplant patients taking tacrolimus when azathioprine was replaced with everolimus 1.5 mg twice daily.[2]

Mechanism

None.

Importance and management

The limited available data suggest that there is no clinically significant pharmacokinetic interaction between tacrolimus and everolimus. The consequence of this is that higher everolimus doses are likely to be required in patients taking tacrolimus than in those patients taking ciclosporin. For further discussion on the effect of ciclosporin on everolimus levels, see 'Everolimus + Ciclosporin', p.1273.

Immunosuppressants + Vaccines

The body's immune response is suppressed by immunosuppressants such as ciclosporin, mycophenolate, sirolimus, and tacrolimus. The antibody response to vaccines may be reduced, although even partial protection may be of benefit. In general, the use of live attenuated vaccines is considered contraindicated because of the possible risk of generalised infection. Inactivated vaccines may be used.

Clinical evidence

(a) Diphtheria, tetanus, and inactivated polio vaccines

In a case-control review, organ transplant recipients taking immunosuppressants, tetanus vaccines[1,2] and inactivated polio vaccines[1] produced protective antibody titres. The response to diphtheria vaccine was lower than in healthy controls[1] and the antibody titre had fallen below the protective level by 12 months in 38% of patients in one study,[1] and 24% in another.[2] Note that live polio vaccines are not recommended in immunosuppressed patients (see *Live vaccines*, below).

(b) Hepatitis vaccines

The antibody response to **hepatitis B vaccine** is generally poor in patients taking immunosuppressants after organ transplantation,[3,4] although one research group reported a sustained antibody response in half of their patients,[5] and an overall 85% seroconversion rate was seen in one study in children (aged between 4 and 16 years).[6] In this latter study,[6] children receiving **ciclosporin** monotherapy had a higher seroconversion rate (100%) than those receiving **ciclosporin** and **corticosteroids** (84%) and those receiving **ciclosporin**, **azathioprine**, and **corticosteroids** (66%). The antibody response to **hepatitis A vaccine** in patients taking immunosuppressants after organ transplantation is variable,[7-9] and declines quicker than in healthy controls.[9] In kidney transplant recipients, there is some evidence that the response is inversely related to the number of immunosuppressant drugs.[8]

(c) Influenza vaccine

A number of studies have been published on the efficacy of influenza vaccination in organ transplant recipients taking immunosuppressants. Many have found a reduction in the proportion of patients developing a protective antibody titre compared with healthy control subjects,[10,11] whereas some have found no reduction.[12] A few studies have looked at the effects of individual drugs in the immunosuppressive regimen. In one comparative study in 59 kidney transplant patients, 21 patients taking **ciclosporin** and **prednisone** had a significantly lower immune response to influenza vaccine (inactivated trivalent) than 38 patients taking **azathioprine** and **prednisone** or 29 healthy subjects taking no drugs. All of the immune response measurements were reduced by 20 to 30% in those taking **ciclosporin**.[13] In another study, 13 patients taking **mycophenolate**, **ciclosporin**, and **prednisolone** had a marked reduction in antibody response to influenza vaccine, when compared with 25 patients taking **ciclosporin**, **azathioprine** and **prednisolone**.[14] In yet another study, patients taking **ciclosporin** had lower antibody responses when compared with patients taking **tacrolimus**.[15] Confirmation of the practical importance of the reduced antibody titre in some patients is described in a case report of a heart transplant patient taking **ciclosporin** who did not respond to influenza vaccination while taking **ciclosporin** and **prednisone**. He had two episodes of influenza, one serologically confirmed, and it was later shown that vaccination had not resulted in seroconversion.[16] Similarly, a patient taking **tacrolimus** after a liver transplant developed influenza A myocarditis despite prophylactic vaccination.[17]

(d) Live vaccines

The use of live vaccines in patients receiving corticosteroids has caused generalised infection, see 'Corticosteroids + Vaccines', p.1272. Similarly, the use of live vaccines in patients taking other immunosuppressants is not recommended: probably as a consequence of this there are few published reports about the use of live vaccines with immunosuppressants. One study found that **measles vaccine** was effective in 7 of 18 children under 3 years old after liver transplantation, and that there were no complications directly attributable to the vaccine.[18]

(e) Measles, mumps and rubella vaccines

A small study in 10 children with juvenile idiopathic arthritis found that low-dose methotrexate or methotrexate with **etanercept** 400 micrograms/kg twice weekly for at least 6 months before measles, mumps and rubella (MMR) revaccination did not interfere significantly with the immune response to revaccination, when compared with healthy children. Neither vaccine failure nor occurrence of overt measles, mumps and rubella or secondary severe infections was observed within 6 months of MMR revaccination. However, further studies are needed to provide a safety basis for the use of MMR vaccine in juvenile idiopathic arthritis.[19]

(f) Pneumococcal vaccines

Good responses to pneumococcal vaccines have been seen in patients taking immunosuppressant drugs after organ transplantation,[10,20] but protective antibody titres may not persist as long as in healthy subjects.[21]

Mechanism

Immunosuppression by these drugs diminishes the ability of the body to respond immunologically both to transplants and to vaccination.

Importance and management

These are established and clinically important interactions. The UK Department of Health[22] recommends that live vaccines should not be used in the following individuals:

- Patients who have received a solid organ transplant and are currently on immunosuppressive treatment.
- Patients who have received a bone marrow transplant, until at least 12 months after finishing all immunosuppressive treatment. Patients may lose their antibodies against most diseases and should be considered for re-immunisation under specialist supervision.

- Patients taking other immunosuppressive drugs such as ciclosporin, methotrexate, cyclophosphamide, leflunomide, and cytokine inhibitors [presumably including etanercept] should not be given live vaccines during or for up to 6 months after treatment has stopped.

They recommend that immunosuppressed patients be given inactivated vaccines in accordance with national recommendations, bearing in mind that they may not achieve as good an antibody response.
They say that, in individuals about to start immunosuppressive treatments, inactivated vaccines should ideally be given at least 2 weeks before immunosuppressive therapy is started, and in the case of live vaccines, a longer period before immunosuppression commences may be desirable.
The proportion of patients developing protective antibody titres to vaccines is often reduced in patients taking immunosuppressants. Nevertheless, for many vaccines, the reduced response seen is still considered clinically useful, and, for example, in the case of kidney transplant patients,[22] and in patients who are immunosuppressed (either by drugs or disease), influenza vaccination is actively recommended.[22] Pneumococcal vaccine should also be given to these patients. If a vaccine is given, it may be prudent to monitor the response, so that alternative prophylactic measures can be considered where it is considered inadequate. For influenza vaccine, one suggestion is that if patients remain unprotected after a single vaccination and a booster dose, amantadine 200 mg daily should be given during an influenza epidemic. It will protect against influenza A but not B infection.[16] Note that, even where effective antibody titres are produced, these may not persist as long as in healthy subjects, and more frequent booster doses may be required.

Leflunomide + Infliximab

An isolated report describes a delayed hypersensitivity reaction in a boy receiving leflunomide and infliximab. However, one study suggests that concurrent use does not increase the rate of adverse effects.

Clinical evidence, mechanism, importance and management

In a 30-week study, 72 patients with active rheumatoid arthritis who had received oral leflunomide for at least 16 weeks were given infliximab 3 mg/kg intravenously at weeks 0, 2, 6, 14, and 22. Serious adverse events occurred in 16 patients (22%), but the combination did not appear to increase the rate of toxicities or result in unexpected adverse events.[1] However, a 17-year-old boy with refractory psoriatic arthritis developed a unique cutaneous hypersensitivity reaction, manifesting as a vasculitic-like skin rash, after he had been receiving infliximab and leflunomide for 9 months. The rash cleared within 2 months of discontinuing treatment.[2] The general relevance of this isolated case is unclear.

Leflunomide + Itraconazole

A case of fatal fulminant hepatic failure has been reported in a patient taking leflunomide and itraconazole.

Clinical evidence, mechanism, importance and management

A 68-year-old woman who had been taking leflunomide 10 mg daily for about 4 months started taking itraconazole 300 mg daily for a fungal infection. About one month later her leflunomide dose was increased to 20 mg daily, and liver function tests were normal. The following month, she developed abdominal pain, vomiting, and weakness. Despite symptomatic treatment and washout with colestyramine, fatal fulminant hepatic failure occurred. The authors of the report attribute the reaction to additive hepatotoxicity between the leflunomide and itraconazole.[1] This interaction serves to highlight the cautions about the use of leflunomide with other hepatotoxic drugs, see *Alcohol* under 'Leflunomide + Miscellaneous', p.1278, and 'Leflunomide + Methotrexate', below.

Leflunomide + Methotrexate

Methotrexate may increase leflunomide hepatotoxicity and haematotoxicity.

Clinical evidence, mechanism, importance and management

No pharmacokinetic interaction was seen in patients taking methotrexate (mean dose 17.2 mg per week) with leflunomide (100 mg daily for 2 days as a loading dose followed by 10 to 20 mg daily).[1] However, elevated liver enzyme levels have been seen following concurrent use.[2,3] By March 2001, the EMEA was aware of 129 cases of serious hepatic reactions in patients taking leflunomide, and 78% of these were in patients also taking other hepatotoxic medications. In patients with elevated liver function tests, 58% were also taking methotrexate and/or NSAIDs.[4]

Pancytopenia has also been associated with the use of leflunomide with methotrexate.[5,6] The Australian Adverse Drug Reactions Advisory Committee (ADRAC) received 11 reports of pancytopenia associated with the use of leflunomide during its first 31 months of marketing and in 9 of these cases, the patients were also taking methotrexate. In 2 cases, methotrexate was added to leflunomide and in the other 7 cases methotrexate use preceded leflunomide use. In 5 of these cases methotrexate had been taken in weekly doses for a mean of 336 weeks (range 103 to 650 weeks) without the development of pancytopenia; however, when leflunomide was added the blood dyscrasia developed within 6 to 78 weeks. Of the total 394 re-

ports describing any type of adverse reaction associated with leflunomide over the 31-month study period, 128 reports (32.5%) also recorded methotrexate being taken concurrently.[6] Another report describes 5 cases of severe pancytopenia occurring within 23 days to 4 years of starting leflunomide and methotrexate.[7]

Due to the possible risks of additive or synergistic liver toxicity or haematotoxicity, particularly when used long-term, the UK manufacturer says that the concurrent use of methotrexate is not advisable.[2] The US manufacturer says that if concurrent use is undertaken, long-term monitoring should be increased to monthly intervals.[3] Close liver enzyme and haematological monitoring is also recommended if switching between these drugs, and colestyramine or activated charcoal washout is recommended as it may decrease the risk of toxicity when switching from leflunomide to methotrexate.[2,3]

Leflunomide + Miscellaneous

The serum levels of the active metabolite of leflunomide are reduced by activated charcoal and colestyramine. The concurrent use of alcohol may increase the risk of hepatotoxicity, although limited alcohol consumption appears to have little effect on liver enzyme values in patients taking leflunomide. The manufacturers predict interactions between leflunomide and phenytoin or tolbutamide, and advise caution with rifampicin (rifampin) as it may increase leflunomide metabolite levels. Concurrent use with other DMARDs (other than methotrexate) has not been studied, but is not recommended by the manufacturer. No clinically relevant interaction occurs with cimetidine, corticosteroids or NSAIDs.

Clinical evidence, mechanism, importance and management

(a) Alcohol

The UK manufacturer says that because of the potential for additive hepatotoxic effects, it is recommended that alcohol should be avoided by patients taking leflunomide.[1] However, one study suggested that self-reported alcohol consumption had no significant influence on ALT levels in rheumatoid arthritis patients taking leflunomide[2] and the British Society for Rheumatology guidelines recommend that patients taking leflunomide should be asked to limit alcohol intake to 4 to 8 units a week.[3]

(b) Charcoal or Colestyramine

Studies in healthy subjects found that colestyramine 8 g three times daily for 24 hours reduced the plasma levels of the active metabolite of leflunomide (A771726) by 40% after 24 hours and by 49 to 65% after 48 hours.[1,4]

Treatment with activated charcoal 50 g every 6 hours for 24 hours, either orally or by nasogastric tube, reduced A771726 levels by 37% after 24 hours and by 48% after 48 hours.[1,4]

These drugs are thought to bind with A771726 in the gut, reducing plasma levels by a gastrointestinal dialysis mechanism and/or by interrupting the enterohepatic cycle.[1] Patients should therefore not be given either colestyramine or activated charcoal with leflunomide, unless the intention is to remove the leflunomide,[1] for example following overdosage or when switching from leflunomide to another DMARD (see *DMARDs*, below), or where there is any other good reason to clear leflunomide from the body more quickly.[1,4]

(c) Cimetidine

The manufacturers say that no clinically significant interaction occurs between leflunomide and cimetidine.[1,4]

(d) Corticosteroids

The manufacturers say that corticosteroids may continue to be used if leflunomide is given.[1,4]

(e) CYP2C9 substrates

The manufacturers advise caution if leflunomide is given with **phenytoin** or **tolbutamide**.[1] The reason is that the active metabolite of leflunomide (A771726) has been shown by *in vitro* studies to be an inhibitor of the cytochrome P450 isoenzyme CYP2C9, which is concerned with the metabolism of these two drugs. If this inhibition were to occur *in vivo* it could possibly lead to a decrease in their metabolism and an increase in their toxicity. Although so far there appear to be no clinical reports of an interaction, the manufacturers made a similar prediction with warfarin, another CYP2C9 substrate, which has, in isolated cases, been borne out in practice, see 'Coumarins + Leflunomide', p.475.

(f) DMARDs

The manufacturers say that the concurrent use of leflunomide and other DMARDs (they list **azathioprine**, **chloroquine**, **hydroxychloroquine**, intramuscular or oral **gold** and **penicillamine**) has not yet been studied,[1,4] but the UK manufacturer says that combined use is not advisable because of the increased risk of serious adverse reactions (haemo- or hepatotoxicity).[1] As the active metabolite of leflunomide has a long half-life of 1 to 4 weeks, a washout with colestyramine or activated charcoal is recommended and the manufacturers say that this may decrease the risk of toxicity if patients are to be given other DMARDs.[1,4]

See also 'Leflunomide + Methotrexate', p.1277.

(g) NSAIDs

Leflunomide inhibits the activity of the cytochrome P450 isoenzyme CYP2C9 *in vitro* and might therefore be expected to increase the serum levels of NSAIDs that are metabolised by this isoenzyme. In addition, the metabolite of leflunomide (A771726) is extensively bound to protein and may displace other highly protein-bound drugs. Leflunomide displaced **diclofenac** and **ibuprofen** *in vitro*, but the effect was not considered to be clinically relevant.[1] The manufacturers say that no safety problems were seen in clinical studies with leflunomide and NSAIDs. No special precautions would seem to be needed if any of these or any other NSAID drugs are given concurrently with leflunomide.[1]

(h) Rifampicin (Rifampin)

When a single dose of leflunomide was given to subjects after taking multiple-dose rifampicin, the peak levels of the active metabolite of leflunomide (A771726) were increased by 40% but the AUC was unchanged.[1,4] There would seem to be no reason for avoiding concurrent use, but the US manufacturer advises caution as metabolite levels may build up over time.[4] It may be prudent to increase the frequency of leflunomide monitoring if these two drugs are used together.

Leflunomide + Tegafur with Uracil

A case of peripheral neuropathy has been reported in a patient taking leflunomide and tegafur with uracil.

Clinical evidence, mechanism, importance and management

A 75-year-old man with rectal cancer was given a 28-day course of tegafur 200 mg three times daily (with uracil) and calcium folinate 30 mg daily. Treatment was withheld because of an episode of minor duodenal bleeding and 3 months later he was given leflunomide 100 mg daily for 3 days followed by 20 mg daily to treat rheumatoid arthritis. A further two courses of tegafur and uracil (separated by 7 days) were given because of tumour progression, after which the patient had increasing numbness of the lower extremities, diagnosed as polyneuropathy. He also had severe diar-

rhoea and hand-foot syndrome. These symptoms had not occurred when tegafur and uracil had been given without leflunomide, and hence an interaction was suspected.

Tegafur is a prodrug of fluorouracil, which is given with uracil to prevent fluorouracil degradation (by inhibiting dihydropyrimidine dehydrogenase). Both tegafur with uracil and leflunomide may cause neurotoxicity and therefore the effects seen may have occurred as a result of simple additive toxicity. The authors suggested that leflunomide may increase fluorouracil toxicity by increasing its conversion to fluorouracil monophosphate, or by enhancing the effect of uracil by additional inhibition of dihydropyrimidine dehydrogenase.[1] This is an isolated case and its general importance is unclear.

1. Kopp H-G, Kanz L, Hartmann JT, Moerike K. Leflunomide and peripheral neuropathy: a potential interaction between uracil/tegafur and leflunomide. *Clin Pharmacol Ther* (2005) 78, 89–90.

Monoclonal antibodies + Azathioprine or Mercaptopurine

Infliximab may increase serum levels of azathioprine metabolites, and giving azathioprine and mercaptopurine with infliximab may be associated with higher trough levels of infliximab. Adalimumab clearance is not affected by azathioprine or mercaptopurine and basiliximab clearance is only modestly affected by azathioprine.
A rare T-cell lymphoma has been reported in adolescents and young adults given infliximab and azathioprine or mercaptopurine and serious infection may be associated with the use of natalizumab and azathioprine or mercaptopurine.

Clinical evidence, mechanism, importance and management

(a) Adalimumab

In a study of the pharmacokinetics of adalimumab, the concurrent use of either azathioprine (36 patients) or mercaptopurine (23 patients) slightly lowered or had no impact on adalimumab clearance.[1]

(b) Basiliximab

Azathioprine, added to regimens including basiliximab, ciclosporin microemulsion and corticosteroids reduced the clearance of basiliximab by 22%.[2-4] However, the use of basiliximab in triple regimens with azathioprine did not increase adverse effects or infections.[2,3] No dose adjustment is considered necessary if basiliximab is added to triple-immunosuppression regimens including ciclosporin, corticosteroids and azathioprine.[3,4]

(c) Infliximab

In 32 patients with Crohn's disease taking azathioprine (mean dose 2.81 mg/kg) and with stable levels of 6-tioguanine nucleotides (the active metabolites of azathioprine), an infusion of infliximab 5 mg/kg over 2 hours resulted in a significant increase in 6-tioguanine nucleotide levels in 21 patients after 1 to 3 weeks, when compared with pre-infusion levels. The leucocyte count was significantly decreased and mean corpuscular volume increased. Significant increases in 6-tioguanine nucleotides were associated with good tolerance and a favourable response to infliximab. These changes were transient even in patients who received two additional infusions of infliximab over the following 6 weeks: levels returned to normal 3 months after the first infusion.[5]

The manufacturers state that rare post-marketing cases of an aggressive and usually fatal hepatosplenic T-cell lymphoma have been reported in adolescent and young adult patients with Crohn's disease who were given infliximab. All cases occurred in patients also receiving azathioprine or mercaptopurine, either with or immediately before the use of infliximab. A causal relationship is unclear.[6,7] Up until October 2006, the Adverse Event Reporting System (AERS) database of the FDA in the US had received 8 case reports of hepatosplenic T-cell lymphoma associated with infliximab use in young patients being treated for Crohn's disease or ulcerative colitis; all had received concurrent azathioprine and/or mercaptopurine.[8] Further study has suggested that, in patients with Crohn's disease, continuing azathioprine or mercaptopurine with infliximab beyond 6 months offers no clear benefit over infliximab monotherapy, but is associated with a higher median infliximab trough level and decreased C-reactive protein level.[9]

No dosage adjustments appear to be necessary with the concurrent use of azathioprine or mercaptopurine, but the long-term benefits of treatment need further study.

(d) Natalizumab

In clinical studies in patients with Crohn's disease, the concurrent use of natalizumab with long-term mercaptopurine and azathioprine did not result in an increase in overall infections, when compared with natalizumab alone.[10] Nevertheless, in patients with Crohn's disease the manufacturer states that natalizumab should not be used in combination with azathioprine or mercaptopurine, because of the potential for increased risk of progressive multifocal leukoencephalopathy and other infections.[10]

Monoclonal antibodies + Cytochrome P450 substrates

Although the manufacturers of golimumab and tocilizumab predict that they may interact with substrates of the cytochrome P450 isoenzyme system there appears to be no clinical data to confirm this.

Clinical evidence, mechanism, importance and management

(a) Golimumab

The manufacturer notes that golimumab, a tumour necrosis factor antibody, is expected to reverse the suppression of cytochrome P450 isoenzymes caused by tumour necrosis factor-alpha. They therefore advise that patients taking drugs metabolised cytochrome P450 that have a narrow therapeutic window (they name **ciclosporin**, **theophylline** and **warfarin**) should be monitored when golimumab is started or stopped, as they may require a dosage increase to ensure efficacy.[1] At present there appears to be no *in vitro* or clinical data to confirm these predicted interactions. Furthermore, other tumour necrosis factor antibodies, such as infliximab, do not appear to have these effects in practice.

(b) Tocilizumab

Tocilizumab, an interleukin-6 inhibitor, can reverse the suppression of cytochrome P450 isoenzymes caused by interleukin. *In vitro* studies have shown that tocilizumab can reverse this effect on the cytochrome P450 isoenzymes CYP1A2, CYP2C9, CYP2C19, and CYP3A4, and that levels of these isoenzymes may return to normal values and their metabolic capacity may increase. The manufacturer therefore advises that patients taking drugs metabolised by these isoenzymes (they name **theophylline** (CYP1A2), **warfarin** (CYP2C9), **phenytoin** (CYP2C19), **atorvastatin**, **benzodiazepines** [e.g. midazolam], **calcium-channel blockers**, and **ciclosporin** (CYP3A4)) should be monitored as they may require a dosage increase to ensure efficacy. At present there appears to be no clinical data to confirm these predictions; however, until more is known, it would be

prudent to consider the possibility of an interaction if clinical symptoms suggest that the levels of these drugs have been reduced. Note that as tocilizumab has a long half-life, any clinically relevant effect on cytochrome P450 isoenzymes will persist for up to several weeks after it has been stopped.[2]

2. RoActemra (Tocilizumab). Roche Registration Ltd. Summary of product characteristics, January 2009.

Monoclonal antibodies + Methotrexate

The clearance of adalimumab may be decreased by methotrexate. Concurrent use may decrease antibody formation and result in elevations in liver enzymes. The concurrent use of methotrexate with natalizumab is predicted to increase the risk of developing infections, some of which may be severe. Several other monoclonal antibodies do not appear to interact with methotrexate, and some are specifically licensed for concurrent use.

Clinical evidence, mechanism, importance and management

(a) Adalimumab

In 45 patients with rheumatoid arthritis taking stable doses of methotrexate for at least 3 months, the mean clearance of a single intravenous dose of adalimumab was decreased by approximately 22%, when compared with 89 similar patients who did not receive methotrexate.[1] Another study found that giving adalimumab to patients taking methotrexate had no statistically significant effect on the pharmacokinetics of methotrexate.[2] No dose adjustment of either adalimumab or methotrexate is considered necessary when they are given concurrently.[3]

The manufacturers say that giving adalimumab in the absence of methotrexate resulted in increased formation of antibodies, increased clearance and reduced efficacy of adalimumab.[3,4] Elevations in liver enzymes have been observed with adalimumab alone, but appear to be more frequent in patients who have received both adalimumab and methotrexate.[3,4] It may therefore be prudent to increase the frequency of liver enzyme monitoring if both drugs are given.

(b) Rituximab

A study in 38 patients with highly active rheumatoid arthritis found that the pharmacokinetics of rituximab were not altered by the concurrent use of methotrexate.[5]

(c) Tocilizumab

The manufacturer reports that a single 10 mg/kg dose of tocilizumab had no clinically relevant effect on the overall exposure to methotrexate (given weekly at a dose of 10 to 25 mg weekly). They also state that, in population pharmacokinetic analyses, methotrexate had no significant effect on the clearance of tocilizumab. Therefore, no dose adjustments appear to be necessary should tocilizumab be given with weekly methotrexate. Note that it is licensed for concurrent use with methotrexate.[6]

(d) Other monoclonal antibodies

Although specific interaction studies appear to be lacking certolizumab pegol[7] and golimumab[8] have been safely given with methotrexate in clinical studies. Note that certolizumab pegol and golimumab are specifically licensed for use with methotrexate.

In clinical studies, the concurrent use of natalizumab with methotrexate did not increase the risk of infection when compared with natalizumab alone. However, the US manufacturer specifically advises against the concurrent use of natalizumab with methotrexate due to the risk of progressive multifocal leukoencephalopathy (a viral infection that can lead to severe disability and death) and other infections, which have been associated with the use of natalizumab in immunosuppressed patients.[9]

Monoclonal antibodies + Miscellaneous

Monoclonal antibodies appear to increase the risk of infection in patients receiving drugs that are known to alter immune function (e.g. antineoplastics, immunosuppressants). They may also increase the risk of malignancy in predisposed individuals (e.g. tobacco smokers).

Clinical evidence, mechanism, importance and management

For a list of drugs that are not expected to interact with monoclonal antibodies, see 'Table 29.3', (p.1281).

(a) Antineoplastics

A study in 37 patients with highly active rheumatoid arthritis found that the pharmacokinetics of **rituximab** were not altered by the concurrent use of **cyclophosphamide**.[1]

The UK manufacturer of **natalizumab** contraindicates the concurrent use of immunosuppressant drugs, or other drugs that modulate the immune response, due to the increased risk of opportunistic infections, particularly progressive multifocal leukoencephalopathy (PML). They specifically name **cyclophosphamide** and **mitoxantrone**.[2] However, PML has developed in 2 patients taking **natalizumab** as monotherapy[3] and the US manufacturer says that the number of cases is too low to suggest that concurrent use of immunosuppressant drugs increases the risk of PML. Nevertheless, they suggest that concurrent use should be avoided wherever possible.[4] See also 'Monoclonal antibodies + Methotrexate', above, and 'Monoclonal antibodies + Azathioprine or Mercaptopurine', p.1279.

(b) Corticosteroids

In clinical studies in patients with multiple sclerosis, short courses of corticosteroids were not associated with an increased rate of infection and therefore can be used in combination with **natalizumab**.[2,4] Furthermore, in clinical studies in patients with Crohn's disease, the concurrent use of natalizumab with long-term corticosteroids did not result in an increase in overall infections, when compared with **natalizumab** alone.[4] Nevertheless, it has been advised that care should be taken with patients who have previously received immunosuppressants, to allow sufficient time for immune function recovery to occur.[2,5]

(c) Glatiramer acetate

The UK manufacturer of **natalizumab** contraindicates its concurrent use with the immunomodulator glatiramer acetate,[2] because of the potential for an increase in the risk of infections.

(d) Muromonab-CD3

The manufacturers of **basiliximab** say that patients in phase 3 studies received **basiliximab** with muromonab-CD3 for episodes of rejection, with no increase in adverse events or infections. Human antimurine antibody responses were reported in 2 of 138 patients receiving basiliximab and 4 of 34 patients receiving both **basiliximab** and muromonab-CD3. Therefore, the manufacturers say that if **basiliximab** has been given, muromonab-CD3 or other murine antilymphocytic antibody preparations can still subsequently be given.[6,7]

In a clinical study in heart transplant patients taking ciclosporin, mycophenolate mofetil, and corticosteroids, the use of **daclizumab** was associated with an increase in infection-related deaths. Furthermore, concurrent use of another antilymphocyte (such as muromonab-CD3 or antithymocyte immunoglobulin) appeared to be associated with a higher incidence of fatal infection: 8 of 40 patients died, compared with 2 of 37 who received an antilymphocyte and placebo. The manufacturer suggested that the concurrent use of **daclizumab** with another antilymphocyte antibody in patients receiving intensive immunosuppression may be a factor leading to fatal infection.[8] Caution may be warranted.

Table 29.3 Drugs that are not expected to interact with monoclonal antibodies as listed by the manufacturers

	Adalimumab[1]	*Basiliximab*[2,3]	*Infliximab*[4,5]	*Tocilizumab*[6]
Aminosalicylates	May be continued during treatment with adalimumab.		Infliximab levels unaffected by baseline aminosalicylate use.	
Analgesics		No increase in adverse effects with unspecified analgesics.	Infliximab clearance not affected by NSAIDs (population pharmacokinetic data).	Tocilizumab clearance not affected by NSAIDs (population pharmacokinetic data).
Antibacterials		No increase in adverse effects with unspecified antibacterials.	Infliximab levels unaffected by baseline ciprofloxacin or metronidazole use.	
Antifungals		No increase in adverse effects with unspecified antifungals.		
Antivirals		No increase in adverse effects with unspecified antivirals.		
Beta blockers		No increase in adverse effects with unspecified beta blockers.		
Calcium-channel blockers		No increase in adverse effects with unspecified calcium-channel blockers.		
Corticosteroids	May be continued during treatment with adalimumab.		Infliximab levels unaffected by baseline prednisolone use.	Tocilizumab clearance not affected (population pharmacokinetic data).
Diuretics		No increase in adverse effects with unspecified diuretics.		
Proton pump inhibitors			Infliximab clearance not affected by omeprazole (population pharmacokinetic data).

(e) Mycophenolate

Mycophenolate mofetil, added to regimens including **basiliximab**, ciclosporin microemulsion and corticosteroids, reduced the clearance of **basiliximab** by 51%.[6,7,9] However, the use of basiliximab in triple regimens with mycophenolate did not increase adverse effects or infections.[6,7] No dose adjustment is considered necessary if **basiliximab** is added to triple-immunosuppression regimens including ciclosporin, corticosteroids and mycophenolate mofetil.[7,9]

A study in 75 renal transplant recipients given immunosuppressants, including mycophenolate mofetil, found that **daclizumab** had no effect on the pharmacokinetics of its active metabolite, mycophenolic acid. The pharmacokinetics of **daclizumab** were comparable with historical data, suggesting that mycophenolate mofetil did not affect the clearance of **daclizumab**. The addition of **daclizumab** to immunosuppressant treatment including mycophenolate mofetil did not appear to result in any increase in adverse events.[10] However, in one clinical study in heart transplant patients taking ciclosporin, mycophenolate mofetil, and corticosteroids, the use of **daclizumab** was associated with an increase in infection-related deaths.[8]

(f) Tobacco

In a study in patients with moderate to severe chronic obstructive pulmonary disease (COPD), more malignancies were reported in patients given **infliximab** than in control patients: all patients had a history of heavy smoking. The manufacturer suggests caution when considering the use of **infliximab** in patients with an increased risk for malignancy due to heavy smoking.[11] Furthermore, because of these findings, the manufacturer of **adalimumab** suggests caution in patients with COPD, as well as in patients with increased risk for malignancy due to heavy smoking.[12] Note that both **infliximab** and **adalimumab** are both tumour necrosis factor antibodies.

Monoclonal antibodies + Tumour necrosis factor antagonists

The use of tumour necrosis factor antagonists with monoclonal antibodies can increase the incidence of neutropenia and severe infections.

Clinical evidence, mechanism, importance and management

A short-term study in patients with active Crohn's disease receiving **infliximab**, found that addition of **natalizumab** did not result in any significant safety concerns and the proportion of patients who experienced adverse effects associated with infection was comparable with patients who received infliximab alone.[1]

Despite one study suggesting safe effective use, it is generally recommended that the concurrent use of tumour necrosis factor antagonists should be avoided with monoclonal antibodies, because of the increased risk of neutropenia and severe infections.

Safety and tolerability of concurrent natalizumab treatment for patients with Crohn's disease not in remission while receiving infliximab. *Inflamm Bowel Dis* (2007) 13, 2–11.

Monoclonal antibodies + Vaccines

Live vaccines should not be given to patients receiving monoclonal antibodies.

Clinical evidence, mechanism, importance and management

In general, there is little experience of the concurrent use of live vaccines with monoclonal antibodies. Therefore, many manufacturers of monoclonal antibodies (such as **adalimumab**, **certolizumab**, **golimumab**, **infliximab**, **tocilizumab**) recommend that live vaccines are not given to patients receiving a monoclonal antibody, because of the risk of generalised infection. Information about the use of other vaccines with monoclonal antibodies is similarly sparse. The manufacturer of **adalimumab** reports that, in a study in 226 patients with rheumatoid arthritis, the antibody response to **pneumococcal vaccine** and **influenza trivalent vaccine** did not differ between patients given adalimumab and patients given placebo.[1] Similarly, in a study in patients, **golimumab** had no significant effect on the response to **pneumococcal vaccine**. The fact that patients who also received methotrexate had a lower response to vaccination acted as a positive control.[2] The manufacturers advise that vaccines, other than live vaccines, may be given to patients receiving **adalimumab**[1] or **golimumab**.[2] However, it is also recommended that, if possible, patients with juvenile idiopathic arthritis are brought up-to-date with all standard scheduled immunisations before starting **adalimumab**.[1]

2. Simponi (Golimumab). Centocor Ortho Biotech Inc. US Prescribing information, April 2009.

Monoclonal antibodies; Muromonab-CD3 + Indometacin

One report suggested that indometacin may possibly increase the incidence of encephalopathy and psychosis in patients given muromonab-CD3.

Clinical evidence, mechanism, importance and management

A study of patient records found that 4 out of a total of 55 kidney transplant patients (7.3%) given muromonab-CD3 and indometacin 50 mg orally or rectally every 6 to 8 hours for 48 to 72 hours developed serious encephalopathy and psychosis, compared with only 2 out of 173 patients (1.2%) who had received muromonab-CD3 without indometacin.[1]

This appears to be an isolated report, and its general significance is unknown. Indometacin has been used to reduce the adverse effects of muromonab-CD3, and in one analysis, concurrent use was associated with reduced fever, headache, and gastrointestinal disturbances.[2] Muromonab-CD3 alone is associated with encephalopathy and other CNS adverse effects, and the manufacturer warns that patients should be closely monitored for these effects.[3]

3. Orthoclone OKT3 (Muromonab-CD3). Ortho Biotech. US Prescribing information, November 2004.

Monoclonal antibodies; Natalizumab + Interferon beta

Two cases of progressive multifocal leukoencephalopathy occurred in patients receiving natalizumab with interferon beta. Concurrent use does not cause a clinically relevant change in the pharmacokinetics of either drug.

Clinical evidence, mechanism, importance and management

In a study in 38 patients with multiple sclerosis who were receiving interferon beta-1a 30 micrograms weekly, 15 patients were given a single 3-mg/kg dose of natalizumab and 21 patients were given a single 6-mg/kg dose of natalizumab. There was no significant change in the pharmacokinetics of interferon beta, although there were large variations in interferon beta levels between patients. Using historical control data interferon beta did not cause a clinically significant increase in the exposure to natalizumab 6 mg, when compared with natalizumab alone.[1]

Two cases of progressive multifocal leukoencephalopathy (PML) occurred in patients with relapsing multiple sclerosis who were receiving natalizumab with interferon beta-1a.[2] The use of natalizumab has been associated with an increased risk of PML[3,4] but no causal link has been confirmed with the concurrent use interferon beta; however, the UK manufacturer contraindicates the use of natalizumab with beta interferons.[3]

Mycophenolate + Aciclovir and related drugs

The concurrent use of aciclovir or ganciclovir and mycophenolate mofetil does not appear to significantly affect the pharmacokinetics of either drug. There are reports of neutropenia in patients taking mycophenolate with valaciclovir, ganciclovir or valganciclovir.

Clinical evidence, mechanism, importance and management

(a) Aciclovir or Valaciclovir

In a crossover study, healthy subjects were given a single-dose of oral aciclovir 800 mg and mycophenolate mofetil 1 g, both together and alone. The renal clearances of both drugs were not significantly altered by concurrent use. The AUC of aciclovir was increased by about 17% (not statistically significant), that of mycophenolic acid was increased by about 9% (not significant), and that of the glucuronide metabolite of mycophenolate was increased by about 9%. It was concluded that none of these changes was likely to be clinically significant.[1,2] In another single-dose study in healthy subjects, a 31% increase in the AUC of aciclovir was seen when it was given with mycophenolate mofetil: there were no changes to mycophenolic acid pharmacokinetics. The concurrent use of valaciclovir 2 g with mycophenolate mofetil 1 g did not alter aciclovir pharmacokinetics, and the only change in mycophenolate pharmacokinetics was a 12% decrease in AUC of its glucuronide metabolite.[3] None of these changes are likely to be clinically important in patients with normal renal function. The manufacturers of mycophenolate state that, in renal impairment there may be competition for tubular secretion, and that further increases in the concentrations of both aciclovir and mycophenolate may occur.[4,5]

A case report describes a kidney transplant patient taking, amongst other drugs, mycophenolate mofetil 1 g twice daily, who developed neutropenia after starting valaciclovir 6 g daily for prophylactic treatment of a cytomegalovirus infection after successful treatment with ganciclovir. The neutropenia resolved on stopping the valaciclovir. The authors suggested that mycophenolate may increase the haematotoxic effect of valaciclovir especially at high doses.[6] Neutropenia is a rare adverse effect of valaciclovir alone. Bear the possibility of an interaction in mind should neutropenia occur with the combination.

(b) Ganciclovir or Valganciclovir

A crossover study in 12 transplant patients found no pharmacokinetic interaction between a single 1.5-g oral dose of mycophenolate mofetil and intravenous ganciclovir 5 mg/kg, but the renal clearance of ganciclovir was slightly reduced, by 12%.[7] However, the manufacturers predict that, due to competition for renal tubular secretion, the concurrent use of these two drugs may result in increases in ganciclovir levels and in the levels of the inactive metabolite of mycophenolate. They suggest careful monitoring in patients with renal impairment given both drugs.[4,5] These cautions are also applied to the ganciclovir prodrug, valganciclovir.[4,5]

Five cases of neutrophil dysplasia in transplant patients appeared to be related to the concurrent use of ganciclovir and mycophenolate, rather than to the use of mycophenolate alone.[8] In three retrospective analyses, the use of valganciclovir with mycophenolate appeared to be associated with an increased risk of myelotoxicity.[9-11] In one study, there was some evidence that this more frequent with higher dose valganciclovir (900 mg versus 450 mg daily).[11] This emphasises the need for caution with concurrent use. The UK manufacturer of valganciclovir says that as both mycophenolate mofetil and ganciclovir have the potential to cause neutropenia and leucopenia, patients should be monitored for additive toxicity.[12]

Mycophenolate + Allopurinol

No clinically relevant interactions have been seen between mycophenolate mofetil and allopurinol.

Clinical evidence, mechanism, importance and management

A study in 5 kidney transplant patients with gouty arthritis, who were switched from azathioprine to mycophenolate mofetil 2 g daily (to avoid the risk of an interaction between azathioprine and allopurinol), found that no adverse effects occurred when they were given allopurinol 100 or 200 mg daily. On average, 10 weeks after the switch had taken place, uricaemia had fallen by 21%, mean serum creatinine levels were only slightly raised (by 12%,) and white cell counts were unchanged.[1] Another study in 19 kidney transplant patients taking mycophenolate 2 g daily, ciclosporin and prednisolone also found a significant reduction in uricaemia without any adverse effects on white cell count, after allopurinol 100 mg daily was also taken for 60 days.[2]

No special precautions would therefore seem necessary if allopurinol is used with mycophenolate, although the authors of both studies suggest that long-term randomised studies are needed to confirm safety.

Mycophenolate + Antacids

An aluminium/magnesium hydroxide antacid modestly reduced the absorption of mycophenolate in two studies.

Clinical evidence, mechanism, importance and management

In a study in 10 patients, 10 mL of an **aluminium/magnesium hydroxide** antacid (*Maalox TC*) taken four times daily with a single 2-g dose of mycophenolate mofetil (*Cellcept*), reduced the AUC of mycophenolic acid (the active form of the drug) by 17% and its maximum plasma concentration by 38%.[1] Similarly, the manufacturer of mycophenolate sodium (*Myfortic*) noted that a single 30-mL dose of an **aluminium/magnesium hydroxide** antacid reduced the AUC and maximum level of mycophenolic acid by about 37% and 25%, respectively.[2,3]

The clinical significance of this reduction has not been assessed, but the reductions seen in the *Myfortic* study in particular could well be clinically important. The US manufacturer of *Cellcept* says that **aluminium/magnesium** antacids can be used in patients taking mycophenolate, but that they should not be given simultaneously.[4] With many other (but not all) antacid interactions, a 2-hour separation is usually sufficient to avoid an interaction. Similarly, the US manufacturer of *Myfortic* also advises against simultaneous administration.[3] The UK manufacturer of *Myfortic* says that aluminium-magnesium containing antacids may be used intermittently for the treatment of occasional dyspepsia. However their long-term daily use with *Myfortic* is not recommended due to the potential for decreased mycophenolic acid exposure and reduced efficacy.[2] It would seem prudent to check that the immunosuppressant effects of mycophenolate remain adequate in the presence of this or any other antacid.

Mycophenolate + Antibacterials

Amoxicillin with clavulanic acid, ciprofloxacin, the combination of norfloxacin with metronidazole, and a selective bowel decontamination regimen of nystatin, tobramycin and cefuroxime have all modestly reduced mycophenolate bioavailability. No interaction appears to occur between mycophenolate and co-trimoxazole.

Clinical evidence

(a) Co-trimoxazole (Sulfamethoxazole with Trimethoprim)

In a study in healthy subjects,[1] co-trimoxazole 960 mg twice daily for 10 days had no effect on the AUC or maximum level of mycophenolic acid, when a single-dose of mycophenolate mofetil 1.5 g was given on day 8.

(a) Metronidazole

A study in 9 healthy subjects found that metronidazole 500 mg three times daily for 5 days reduced the AUC of a single 1-g oral dose of mycophenolate mofetil, given 2 hours after metronidazole on day 4, by 19%. The AUC of the glucuronide metabolite was also reduced, by 27%. When norfloxacin 400 mg twice daily was also given, the AUC of mycophenolate and its glucuronide metabolite were reduced by 33% and 41%, respectively.[2]

(b) Penicillins

In a study in kidney transplant patients taking mycophenolate, mycophenolic acid trough levels were monitored in patients receiving **amoxicillin** with **clavulanic acid** 375 mg three times daily for 7 days (20 patients) or for 14 days or more (17 patients). In both groups the trough mycophenolic acid levels were about 50% lower 3 days after starting the antibacterial, and they were still at this level on day 7. Three days after stopping the antibacterial in the 7-day group, the trough levels had returned to baseline. On day 14 in the longer-term group, the trough levels had *risen*, and were just 19% lower than baseline.[3]

(c) Quinolones

A study in 11 healthy subjects found that **norfloxacin** 400 mg twice daily reduced the AUC of a single 1-g oral dose of mycophenolate mofetil, given 2 hours after the antibacterial on day 4, by 10%. The AUC of the glucuronide metabolite was also reduced by 10%. When metronidazole 400 mg twice daily was also given, the AUC of mycophenolate and its glucuronide metabolite were reduced by 33% and 41%, respectively.[2]

In a study in kidney transplant patients taking mycophenolate, mycophenolic acid trough levels were monitored in patients receiving **ciprofloxacin** 500 mg twice daily for 7 days (24 patients) or for 14 days or more (21 patients). In both groups the trough levels were about 35 to 40% lower 3 days after starting **ciprofloxacin**, and they were still at this level on day 7. Three days after stopping **ciprofloxacin** in the 7-day group, the trough levels had returned to baseline. On day 14 in the longer-term group, the trough levels had *risen*, and were just 17% lower than baseline.[3]

(d) Rifampicin (Rifampin)

For the effect of rifampicin on the pharmacokinetics of mycophenolate, see 'Mycophenolate + Rifampicin (Rifampin)', p.1287.

(e) Selective bowel decontamination

Six liver transplant patients were given a regimen for selective bowel decontamination for 21 days after the transplant, which consisted of **nystatin**, **tobramycin** and **cefuroxime** and also received mycophenolate mofetil 1 g twice daily. The AUC of mycophenolic acid was measured when the patients were taking the antibacterials (one measurement between day 17 and 20, at which time mycophenolate had been given for at least 10 days) and then again after stopping the antibacterials (one measurement between day 23 and 29). The AUC was 31% lower while taking the antibacterials, although this did not reach statistical significance. However, the reduction in $AUC_{6\text{-}12}$ of 57% was statistically significant.[4]

Mechanism

Mycophenolic acid is metabolised to the glucuronide conjugate, which is excreted in bile and urine. Gut bacteria that express the beta-glucuronidase enzyme (mostly Gram-negative anaerobes) cleave the glucuronide conjugate allowing free mycophenolic acid to be reabsorbed (enterohepatic recirculation). Antibacterials that decimate gut bacteria can reduce this enterohepatic recirculation leading to lower levels of mycophenolic acid.[2,3] However, the effect may lessen over time as the bowel flora recover even with continued use of the antibacterial.[3]

Importance and management

The available evidence suggests that antibacterials that can decimate gut bacteria might reduce levels of mycophenolic acid by up to one-third or one-half. In the study assessing the time course of this effect during an antibacterial course, the effect was rapid, occurring within 3 days of starting the antibacterial and recovering within 3 days of stopping it. Also, interestingly, the effect lessened with continued use of the antibacterial beyond 7 days.

The clinical relevance of these reductions has not been assessed. One manufacturer considers that a change in the dose of mycophenolate should not normally be necessary, in the absence of clinical evidence of graft dysfunction, if amoxicillin with clavulanic acid or ciprofloxacin are also given. However, close clinical monitoring is advisable during the concurrent use of the antibacterial, and shortly after it is stopped.[5] The available evidence suggests that this advice should be applied to any antibacterial that affects gut flora. Note that the US manufacturer considers that the combination of metronidazole and norfloxacin should not be used with mycophenolate mofetil.[1]

Mycophenolate + Azathioprine

The manufacturers of mycophenolate have recommended that it should not be given with azathioprine because they say that concurrent use has not been studied,[1-4] and as both drugs inhibit purine metabolism,[4] they have the potential to cause bone marrow suppression.[1]

Mycophenolate + Ciclosporin or Tacrolimus

Ciclosporin reduces the levels of mycophenolic acid. Tacrolimus may increase mycophenolic acid levels in some patient groups.

Clinical evidence

(a) Mycophenolate with Ciclosporin or Tacrolimus

A study in 78 kidney transplant patients taking corticosteroids with mycophenolate 1 g two or three times daily, and also taking either ciclosporin (68 patients) or tacrolimus (10 patients), found lower trough levels of the active metabolite, mycophenolic acid, and higher levels of the glucuronide metabolite in patients taking ciclosporin during the first 3 months post-transplant, when compared with those taking tacrolimus. Of interest, of the 11 patients that changed from ciclosporin to tacrolimus during the study, 5 patients subsequently required mycophenolate dose reductions because of adverse effects.[1] Another study found that despite a higher dose of mycophenolate, patients also taking ciclosporin had a 50% lower trough mycophenolic acid level when compared with those taking mycophenolate with tacrolimus.[2] Other studies have found similar results.[3-5] In another study, 12 stable kidney transplant patients taking ciclosporin (*Neoral*) were given enteric-coated mycophenolate sodium (*Mycofortic*) 720 mg twice daily for 14 days. After pharmacokinetic assessment, they were then changed over to tacrolimus with the same dose and formulation of mycophenolate sodium. This study found that when tacrolimus was given the mycophenolic acid AUC was 20% greater than when ciclosporin was taken, but maximum concentration of mycophenolic acid was 24% greater with ciclosporin than with tacrolimus.[6] However, a study in 22 kidney transplant patients taking mycophenolate found that neither ciclosporin (13 patients) nor tacrolimus (9 patients) affected the plasma levels of mycophenolic acid. Levels of the glucuronide metabolite were increased by ciclosporin but not tacrolimus.[7] The manufacturers report that in one study in kidney transplant patients receiving ciclosporin and mycophenolate mofetil, the AUC of mycophenolic acid was increased by about 30% when ciclosporin was replaced by tacrolimus.[8]

(b) Mycophenolate with Ciclosporin

There are reports that the trough levels of the active metabolite of mycophenolate, mycophenolic acid, may be reduced in the presence of ciclosporin.[9] In a study, 52 kidney transplant patients were given mycophenolate mofetil 1 g twice daily with ciclosporin and prednisone. Six months after transplantation 19 patients continued triple therapy, 19 discontinued ciclosporin and 14 discontinued prednisone. Three months later, patients in whom ciclosporin had been discontinued had higher trough mycophenolic acid levels compared with the other groups of patients. Discontinuing ciclosporin resulted in almost a doubling of mycophenolic acid trough levels.[10] Other studies note similar effects on mycophenolic acid levels in adult[11] and paediatric patients.[12]

A study in 33 children taking ciclosporin with prednisolone and 15 children additionally taking mycophenolate mofetil found that the ciclosporin levels 2 hours after the ciclosporin dose, was significantly reduced in those patients taking mycophenolate.[13] Another study in children found similar results.[14]

(c) Mycophenolate with Tacrolimus

A study in stable kidney transplant patients taking tacrolimus long-term found that the addition of mycophenolate mofetil resulted in a increase in the tacrolimus AUC, but this was not considered significant.[15] Another

study in kidney transplant patients found no change in tacrolimus levels when mycophenolate was given.[8] However, a 20% increase in tacrolimus levels has been reported in a study in liver transplant patients given mycophenolate 1.5 g twice daily.[8]

Mechanism

Mycophenolate is hydrolysed to its active drug, mycophenolic acid. This then undergoes glucuronidation by glucuronosyltransferases (UGT) to form an inactive glucuronide metabolite. This metabolite is then either excreted in urine or undergoes enterohepatic recirculation, where it is converted back into the active form, mycophenolic acid. Ciclosporin is thought to inhibit the enterohepatic conversion of the glucuronide metabolite back to the active metabolite, mycophenolic acid, leading to lower levels of mycophenolic acid.[8]

Tacrolimus may inhibit UGT which metabolises mycophenolic acid to the glucuronide metabolite,[1,7] and may also interfere with the enterohepatic recycling of the glucuronide metabolite.[8]

Importance and management

The addition of mycophenolate to ciclosporin has been found to reduce the incidence of rejection episodes in kidney transplant patients[16] and it is licensed for concurrent use.[8] From the studies above, ciclosporin appears to reduce the levels of the active metabolite, mycophenolic acid, and increase the levels of the glucuronide metabolite (which is associated with mycophenolate adverse effects). The UK manufacturers point out that as efficacy studies were conducted in patients taking ciclosporin, mycophenolate and corticosteroids, the finding that ciclosporin reduces the mycophenolic acid AUC by 19 to 38% does not affect the recommended dose requirements.[8] They also state that ciclosporin pharmacokinetics are not affected by mycophenolate.[8,17] However, this is in contrast to the studies in children reported above.[13,14] It has also been observed that the use of triple therapy with corticosteroids, ciclosporin and mycophenolate mofetil rather than with azathioprine makes it possible to use a lower dose of ciclosporin.[18] However, other studies have noted that adjusting ciclosporin doses affects mycophenolic acid levels, and therefore the overall effect on immunosuppression needs careful monitoring.[12]

The significance of the reported increases in mycophenolic acid levels with concurrent tacrolimus is not clear, and the manufacturers note that the benefit of concurrent use with tacrolimus has not been established.[8,17] There are also inherent problems in interpretation of the results of studies comparing ciclosporin or tacrolimus with mycophenolate.[2,4,19,20] It has been suggested that the changes in mycophenolic acid trough levels are because tacrolimus increases mycophenolic acid levels;[4] however, another interpretation may be that the differences in mycophenolic acid trough levels and AUCs seen are because ciclosporin decreases mycophenolic acid exposure.[19]

Patients taking either ciclosporin or tacrolimus with mycophenolate should have their immunosuppressive response closely monitored, particularly if changing from ciclosporin to tacrolimus or *vice versa*, and dose adjustment of mycophenolate should be considered if patients develop mycophenolate-related adverse effects (such as diarrhoea, vomiting and leucopenia) on switching from ciclosporin to tacrolimus.

Mycophenolate + Colestyramine

Colestyramine modestly reduces the AUC of mycophenolic acid after administration of mycophenolate.

Clinical evidence

In a study in healthy subjects, colestyramine 4 g three times daily for 4 days reduced the AUC of mycophenolic acid by 37% (range 10 to 61%) after they took a single 1.5-g oral dose of mycophenolate mofetil one hour after the first colestyramine dose on day 2.[1-3] There was no difference in the maximum level, and the main difference was a reduction in mycophenolic acid levels from 6 hours onwards.[3]

Mechanism

Mycophenolic acid is metabolised to the glucuronide conjugate, which is excreted in bile and urine. Gut bacteria cleave the glucuronide conjugate allowing free mycophenolic acid to be reabsorbed (enterohepatic recirculation). Colestyramine appears to reduce the enterohepatic recirculation of mycophenolate.[3]

Importance and management

The clinical importance of the reduction in mycophenolic acid levels has not been assessed; however, enterohepatic recirculation of mycophenolic acid varies widely between individuals,[3] and therefore this interaction may well be significant in some patients. If colestyramine is considered essential, it would seem prudent to confirm that the immunosuppressant effects of mycophenolate remain adequate. Separating the administration of colestyramine and mycophenolate is not likely to eliminate this interaction. Note that the US manufacturers of mycophenolate advise avoiding the concurrent use of colestyramine[2,4] and other drugs that bind to bile acids, such as **bile-acid binding resins** or oral **activated charcoal**.[4]

Mycophenolate + Corticosteroids

One study suggests that methylprednisolone might modestly decrease mycophenolate levels, but a similar study suggests that

it does not. In another study, prednisone did not alter mycophenolate levels.

Clinical evidence, mechanism, importance and management

(a) Methylprednisolone

In a study in kidney transplant patients taking mycophenolate, ciclosporin and methylprednisolone, the dose-normalised mycophenolic acid AUC was 35% lower in the first month when patients were receiving higher doses of methylprednisolone (about 16 mg daily) than at 6 months when lower maintenance doses of methylprednisolone (8 mg daily) were being used. In addition, plasma levels of the glucuronide metabolite were 2.7-fold higher in the first month than at 6 months. Moreover, in those patients in whom methylprednisolone was tapered and discontinued, there was a 56% and 31% increase in trough levels and AUC of mycophenolic acid, respectively. This difference was apparent even when controlling for 'ciclosporin', (p.1284), exposure.[1]

In contrast, in another very similar study, the authors reported that methylprednisolone dose or withdrawal had no effect on mycophenolic acid trough concentrations or AUC.[2]

(b) Prednisone

In a study in patients taking triple therapy (mycophenolate, ciclosporin and prednisone), trough mycophenolate acid levels did not differ between 19 patients who continued this therapy and 14 patients who discontinued prednisone.[3]

Mechanism

Corticosteroids might induce the glucuronidation of mycophenolic acid, thereby decreasing its levels.[1]

Importance and management

It is unclear from these studies whether corticosteroids can alter mycophenolate levels, but the extent was modest in the one study that did find a decrease, and probably of limited clinical relevance. The combination is in general clinical use.

Mycophenolate + Food

Food had no effect on the extent of absorption of mycophenolate mofetil or mycophenolate sodium, but markedly delayed absorption with mycophenolate sodium.

Clinical evidence, mechanism, importance and management

(a) Mycophenolate mofetil

In a study in 10 rheumatoid arthritis patients, there was no difference in the AUC of mycophenolic acid when a single 2-g dose of mycophenolate mofetil (*Cellcept*) was given in the fasting state or immediately after a high-fat breakfast. The time to maximum level was delayed from one to two hours and there was a slight 24% reduction in the maximum level, suggesting some delay in absorption. There was also a slight 14% increase in the AUC of the glucuronide metabolite.[1] Similarly, the manufacturers report that, in a further study in kidney transplant patients, there was no change in extent of absorption (AUC), but there was a more marked 40% reduction in maximum levels.[2,3] It is doubtful if this is clinically relevant, but note that the US manufacturer recommends that mycophenolate mofetil is taken on an empty stomach. They say that, in stable kidney transplant patients, mycophenolate mofetil can be taken with food if necessary.[2]

(b) Mycophenolate sodium

The manufacturer reports that no difference was seen in the AUC of mycophenolic acid when a single dose of mycophenolate sodium (*Myfortic*) was given in the fasting state or immediately after a high-fat meal. However, there was a 33% decrease in the maximum concentration and a 5-hour delay in the time to maximum level suggesting significant delay in absorption.[4,5] Some patients had a time to maximum level of greater than 15 hours, which can lead to an absorption overlap from one dose interval to the next.[4] Because of this, the UK manufacturer recommends that patients take mycophenolate sodium consistently, either with or without food.[4] However, the US manufacturer advises that, to avoid the variability in absorption between doses, mycophenolate sodium (*Myfortic*) should be taken on an empty stomach, one hour before or 2 hours after food intake.[5]

5. Myfortic (Mycophenolate sodium). Novartis. US Prescribing information, October 2009.

Mycophenolate + Iron compounds

Most studies have found that oral iron has no significant effect on the absorption of mycophenolate mofetil.

Clinical evidence, mechanism, importance and management

In the first study of the effect of iron on mycophenolate levels, a single 1050-mg dose of sustained-release **ferrous sulfate** (210 mg of elemental iron; *Fero-Gradumet*) reduced the AUC and maximum levels of mycophenolic acid by more than 90% when given at the same time as a single 1-g dose of mycophenolate mofetil in 7 healthy fasting subjects.[1] However, this finding was not replicated in an identical study in which 16 healthy fasting subjects were given a single 1-g dose of mycophenolate mofetil with sustained-release **ferrous sulfate** (210 mg elemental iron; *Ferro-Gradumet*). There was no change in the AUC of mycophenolic acid.[2]

Moreover, three studies in kidney transplant patients taking mycophenolate have also not identified an interaction.[3-5] In one study in 10 kidney transplant patients taking mycophenolate mofetil 1 g daily, a single 105-mg dose of elemental iron (as **ferrous sulfate** in *Ferro-Gradumet*) had no effect on the absorption of mycophenolate in the fasted state, either when given at the same time, or 4 hours apart.[3] Similarly, another study in 40 kidney transplant patients found that two sustained-release tablets of **ferrous sulfate** (*Ferrogradumet*) daily, given either at the same time or 4 hours after the morning dose of mycophenolate (for 5 days after kidney transplantation), had no significant effect on the absorption of mycophenolate 1 g twice daily, when compared with patients not given an iron supplement. In addition, the groups appeared comparable in terms of incidence of rejection and adverse effects, although the study was not big enough to properly assess this.[4] A further study in 5 transplant patients, found no change in the mycophenolic acid AUC when slow-release **ferrous sulfate** was given daily for 7 days, either at the same time as the morning dose of mycophenolate mofetil or 2 hours afterwards. With a **polysaccharide iron complex**, the mean mycophenolic acid AUC was modestly increased by 22% when it was given 2 hours after mycophenolate mofetil, with no change when given at the same time.[5]

The reason why the first study had such a different finding to all the others is unknown, but it has been suggested that there may have been a problem with the assay.[2]

On balance, it would appear that oral iron compounds do not alter the pharmacokinetics of mycophenolate, and that no special precautions are required if an iron supplement is needed in a patient taking mycophenolate.

Mycophenolate + Methotrexate

A study in patients with rheumatoid arthritis found that the concurrent use of methotrexate and mycophenolate mofetil was well tolerated and there were no pharmacokinetic interactions.[1] There would appear to be no need for dose adjustments if both drugs are given for rheumatoid arthritis.

1. Yocum D, Kremer J, Blackburn W, Caldwell J, Furst D, Nunez M, Zuzga J, Zeig S, Gutierrez M, Merrill J, Dumont E, B Leishman. Cellcept® (mycophenolate mofetil - MMF) and methotrexate (MTX) safety and pharmacokinetic (PK) interaction study in rheumatoid arthritis patients. *Arthritis Rheum* (1999) 42 (9 Suppl), S83.

Mycophenolate + Polycarbophil calcium

Polycarbophil calcium reduced the bioavailability of mycophenolate in one study in healthy subjects.

Clinical evidence, mechanism, importance and management

A study in 5 healthy subjects given a single 1-g dose of mycophenolate alone or with polycarbophil calcium 2.4 g found that the AUC and peak serum levels of mycophenolic acid were reduced by about 51% and 69%, respectively. The authors suggest that this interaction was probably the result of reduced absorption due to chelate-complex formation between mycophenolate and the calcium ions, which they also demonstrated in an *in vitro* study. It was concluded that mycophenolate and polycarbophil calcium should not be taken at the same time.[1] A suitable interval was not specified, but a separation of 2 hours has been suggested with antacids, which may interact by a similar mechanism (see 'Mycophenolate + Antacids', p.1283). Further study is needed, especially as this study used the same assay method as that in a study with iron, the validity of which has been questioned.

1. Kato R, Ooi K, Ikura-Morii M, Tsuchishita Y, Hashimoto H, Yoshimura H, Uenishi K, Kawai M, Tanaka K, Ueno K. Impairment of mycophenolate mofetil absorption by calcium polycarbophil. *J Clin Pharmacol* (2002) 42, 1275–80.

Mycophenolate + Probenecid

Probenecid might increase mycophenolic acid levels.

Clinical evidence, mechanism, importance and management

In *animals*, probenecid increased the AUC of mycophenolic acid twofold and the AUC of its glucuronide metabolite threefold.[1] This was thought to be because probenecid competitively inhibits the renal excretion of the glucuronide metabolite of mycophenolate.[1] However, as there appear to be no clinical reports of an interaction, the clinical significance of this is unclear. Further study is needed.

1. CellCept (Mycophenolate mofetil). Roche Laboratories Inc. US Prescribing information, October 2009.

Mycophenolate + Proton pump inhibitors

Lansoprazole, but not rabeprazole, might modestly reduce mycophenolic acid levels.

Clinical evidence, mechanism, importance and management

In a retrospective study in 22 kidney transplant patients taking mycophenolate mofetil and tacrolimus, **lansoprazole** 30 mg daily reduced the dose-adjusted maximum level and trough level of mycophenolic acid by 32% and 45%, respectively, when compared with a control group of 22 patients not taking a proton pump inhibitor. The dose-adjusted AUC was 25% lower, but this was not statistically significant. The interaction tended to be greater in intermediate CYP2C19 metabolisers than in extensive metabolisers (i.e. the interaction was greater in those with lower levels of this isoenzyme).[1] In the same study, there was no difference in mycophenolic acid pharmacokinetics between 17 patients taking **rabeprazole** 10 mg daily and the control group.[1]

The exact mechanism for this interaction and the differences seen is uncertain it may be related to gastric pH and therefore the differing acid-suppressant effects of the doses studied. It is unclear if the modest differences in mycophenolic acid levels reported with **lansoprazole** are of clinical relevance and a controlled study is needed to confirm these results. Until more is known, it would seem prudent to bear the possibility of an interaction in mind in patients taking **lansoprazole**.

Mycophenolate + Rifampicin (Rifampin)

In a controlled study, rifampicin slightly reduced the levels of mycophenolic acid (the active metabolite of mycophenolate) and markedly increased the levels of the acyl-glucuronide metabolite, which may be associated with mycophenolate adverse effects. One case report describes markedly increased mycophenolate dose requirements in a patient taking rifampicin.

Clinical evidence

A heart-lung transplant patient taking tacrolimus 7 mg twice daily and mycophenolate mofetil 1 g twice daily was given rifampicin 600 mg daily, pyrazinamide 1 g daily, isoniazid 300 mg daily and pyridoxine 250 mg weekly for a suspected mycobacterial infection. As expected, the tacrolimus dose needed to be substantially increased when rifampicin was started, and the rifampicin dose was reduced to 450 mg daily to try to minimise the interaction. However, the mycophenolate mofetil dose also needed to be increased threefold to 6 g daily without achieving an adequate level (target trough plasma level of 2.5 micrograms/mL). Rifampicin was then stopped and the patient continued taking isoniazid and pyrazinamide. Pharmacokinetic analysis of mycophenolate before and 13 days after rifampicin was stopped, found that the dose-corrected trough level of mycophenolic acid increased 18-fold and the $AUC_{0\text{-}12}$ increased threefold after stopping rifampicin.[1]

However, a subsequent study by the same authors in 8 kidney transplant patients taking mycophenolate 750 mg to 1 g twice daily found that rifampicin 600 mg daily for 8 days decreased the $AUC_{0\text{-}12}$ and peak levels of mycophenolic acid by just 18% and 19%, respectively. The $AUC_{0\text{-}12}$ of the inactive 7-*O*-glucuronide metabolite was increased by 34%, and the $AUC_{0\text{-}12}$ and peak levels of the acyl-glucuronide metabolite were significantly increased by 193% and 121%, respectively. The acyl-glucuronide metabolite has been associated with an increase in mycophenolate adverse effects, but this was not seen in this study.[2]

Mechanism

The exact mechanism of this interaction is unknown. Mycophenolate is a prodrug and is metabolised to its active form, mycophenolic acid, which undergoes glucuronidation by glucuronosyltransferases (UGTs) in the liver, kidney and intestine to its inactive 7-*O*-glucuronide metabolite. The authors of these reports suggest that rifampicin induces intestinal, kidney and liver glucuronidation of mycophenolic acid by UGT and reduces its enterohepatic recirculation and absorption.[1,2]

Importance and management

These appear to be the only reports of an interaction between rifampicin and mycophenolate. However, the effects of reduced mycophenolic acid levels could be significant in terms of acute graft rejection. Also the increases in the levels of the acyl-glucuronide metabolite could put the patient at greater risk of adverse effects, although as mentioned, this was not seen in these studies. Mycophenolate should be monitored closely during the concurrent use of rifampicin and the dose adjusted as required, both on starting or stopping rifampicin. For a discussion of the effects of antibacterials on mycophenolate via an effect on gut bacteria, see 'Mycophenolate + Antibacterials', p.1283.

Mycophenolate + Sevelamer

The short-term use of sevelamer moderately reduces mycophenolic acid levels.

Clinical evidence, mechanism, importance and management

In a pharmacokinetic study, 3 adult and 6 paediatric kidney transplant patients taking mycophenolate and ciclosporin were given sevelamer (at the same time), either as a single 1.6-g dose in the adults, or a single 1.2-g dose in the children, or for 4 days (same dose given three times daily). The average age of the children was 12 years. The single dose of sevelamer reduced the AUC of mycophenolic acid by 25%, and multiple-dosing of sevelamer reduced its AUC by 30%. The interaction was thought to be due to sevelamer reducing the absorption of mycophenolate.[1] The UK manufacturer notes that no graft rejection occurred in this study.[2]

The clinical significance of this modest interaction is unclear. However, until more is known, it would seem prudent to monitor mycophenolic acid levels in any patient given sevelamer. The UK manufacturer[2] of mycophenolate mofetil recommends that drugs for which a reduction in bioavailability could be clinically important, should be taken at least one hour before or three hours after taking sevelamer. One US manufacturer advises taking mycophenolate 2 hours before sevelamer.[3]

Further study is required with longer-term administration and to evaluate if separation of doses is an effective way of reducing the interaction.

Mycophenolate + Sirolimus

Higher levels of mycophenolic acid have been seen in kidney transplant patients taking mycophenolate with sirolimus when compared with similar patients taking mycophenolate with ciclosporin.

Clinical evidence

A study in 12 kidney transplant patients taking mycophenolate 1 g twice daily at the same time as sirolimus (dose adjusted to attain therapeutic trough blood levels of 10 to 15 nanograms/mL) for 30 days found that the $AUC_{0\text{-}9}$ of the active metabolite of mycophenolate, mycophenolic acid, was 50% higher in the sirolimus-treated group when compared with a similar group of 19 patients taking ciclosporin instead of sirolimus.[1] Similarly, in a study in 13 kidney transplant patients taking mycophenolate 1 g twice daily with sirolimus (trough blood levels of 10 to 20 nanograms/mL), the mycophenolic acid trough levels and AUC were significantly higher in patients taking sirolimus, compared with a similar group of 17 patients given ciclosporin, although peak mycophenolic acid levels were similar. Mycophenolate dose reductions were required in 2 patients in the first month, another 3 patients in the second month and 6 patients in the third month (total of 11 patients), compared with the ciclosporin group where only 5 patients needed mycophenolate dose reductions. A higher incidence of leucopenia at months one and 2 after transplantation was reported in patients taking sirolimus, rather than ciclosporin, with mycophenolate.[2]

Another study in 11 kidney transplant patients taking low-dose mycophenolate 500 mg twice daily with low-dose sirolimus (mean dose of between 3.6 to 4.3 mg daily adjusted to achieve a trough blood level of 5 to 10 nanograms/mL) found that the sirolimus-based regimen had a 4.4-fold higher dose-adjusted mycophenolic acid trough level than those found in another similar group of 10 patients taking a ciclosporin-based regimen.[3]

Yet another study in 15 kidney transplant patients taking mycophenolate with sirolimus looked at the effects of sirolimus on mycophenolate dose regimens of 500 mg, 750 mg, and 1 g twice daily and compared them with the effects of ciclosporin on mycophenolate 1 g twice daily in 12 similar patients. They found that mycophenolate 750 mg twice daily with sirolimus produced a comparable $AUC_{0\text{-}12}$ and trough mycophenolic acid levels to mycophenolate 1 g twice daily with ciclosporin.[4] Another study also found that exposure to mycophenolic acid was about 70 to 100% higher in 30 patients given sirolimus than in 15 given ciclosporin, and exposure to the glucuronide metabolite was lower. Moreover, biopsy proven rejection was higher in the sirolimus group (40% versus 13.3%).[5]

Mechanism, importance and management

Ciclosporin is known to inhibit the metabolism of mycophenolate, producing lower levels of mycophenolic acid, see 'Mycophenolate + Ciclosporin or Tacrolimus', p.1284. Whether sirolimus specifically raises mycophenolic acid levels compared with mycophenolate taken on its own is unclear; however, raised mycophenolic acid levels have been associated with an increased risk of adverse effects.[1-3] The authors of one of the studies suggest that the mycophenolate dose should be reduced from 1 g to 750 mg twice daily in patients taking sirolimus, as this produced comparable mycophenolic acid levels to the recommended dose of mycophenolate 1 g twice daily with ciclosporin.[4]

However, until further information is available, patients taking mycophenolate and changed from ciclosporin to sirolimus should be closely monitored for mycophenolate adverse effects (such as diarrhoea, vomiting and leucopenia), and the dose of mycophenolate reduced accordingly.

Mycophenolate + St John's wort (*Hypericum perforatum*)

St John's wort does not appear to alter the pharmacokinetics of mycophenolate.

Clinical evidence

In a pharmacokinetic study, 8 stable kidney transplant patients taking mycophenolate 1 to 2 g daily and tacrolimus were given 600 mg of St John's wort extract (*Jarsin 300*) daily for 14 days. The levels of mycophenolic acid, the main metabolite of mycophenolate, were measured before St John's wort was started, on day 14, and two weeks after St John's wort was stopped. The pharmacokinetics of mycophenolic acid were unchanged throughout the study, and no dosage adjustments were needed in any of the 8 patients.[1]

Mechanism

No mechanism. St John's wort is an inducer of the cytochrome P450 isoenzyme CYP3A4, and P-glycoprotein. As mycophenolate is not significantly metabolised or transported by these routes, an interaction would not be expected.

Importance and management

St John's wort does not appear to affect the pharmacokinetics of mycophenolate and therefore no additional precautions seem necessary on concurrent use.

1. Mai I, Störmer E, Bauer S, Krüger H, Budde K, Roots I. Impact of St John's wort treatment on the pharmacokinetics of tacrolimus and mycophenolic acid in renal transplant patients. *Nephrol Dial Transplant* (2003) 18, 819–22.

Mycophenolate + Voriconazole

Voriconazole does not alter the pharmacokinetics of mycophenolate.

Clinical evidence, mechanism, importance and management

In a study, voriconazole had no effect on the pharmacokinetics of a single 1-g dose of mycophenolate.[1] Similarly, the AUC, trough levels and maximum levels of mycophenolic acid did not change in a kidney transplant patient 7 days after stopping a 3-month course of voriconazole.[2] Mycophenolate is not metabolised by the cytochrome P450 system and is not a substrate for P-glycoprotein, so would not be expected to be affected by drugs that affect this isoenzyme and drug transporter, such as voriconazole.

No pharmacokinetic interaction occurs, so no dose adjustment of mycophenolate should be necessary on concurrent use.

Sirolimus and related drugs + ACE inhibitors or Angiotensin II receptor antagonists

Angioedema has been reported in patients taking everolimus, sirolimus or temsirolimus with ACE inhibitors.

Clinical evidence

(a) Everolimus

One report described 6 cases of tongue angioedema in 114 patients given everolimus, all of whom were taking an ACE inhibitor (**enalapril**, **ramipril**) or angiotensin II receptor antagonists (**losartan**). All 6 required hospitalisation. In 5 patients, concurrent use was continued and there had been no recurrences (15 to 126 days follow-up). One patient had two recurrences (day 42 and 67) and everolimus was discontinued.[1] Two other similar cases were briefly mentioned in a consensus conference report.[2] The manufacturer of everolimus lists angioneurotic oedema as a common adverse reaction, which predominantly occurs in patients also receiving an ACE inhibitor.[3]

(b) Sirolimus

A study in 52 kidney transplant patients taking sirolimus 2 to 5 mg daily with **ramipril** 2.5 to 5 mg daily found that 5 of these patients developed non-life threatening tongue oedema within one month of starting **ramipril**. All of these patients had taken **ramipril** before their transplant without any adverse effects or signs of angioedema. The tongue oedema resolved within 2 weeks of stopping ramipril. The authors noted that at that time all 5 patients were taking sirolimus 5 mg daily and ramipril 5 mg daily, with their sirolimus levels in the higher end of the range between 16 and 20 nanograms/mL. Three months after their transplant, when sirolimus had been stabilised at a lower dose of 2 to 4 mg daily, resulting in blood levels of 8 to 12 nanograms/mL, ramipril was restarted at 2.5 mg daily with no adverse effects.[4]

A kidney transplant patient taking sirolimus 9 mg daily developed non-pitting oedema of the eyelid, cheek and lips when he started to take **ramipril** (dose not specified).[5] Another kidney transplant patient who had taken **enalapril** 2.5 mg daily for 2 months developed erythematous skin lesions with non-pitting oedema of the neck, face and chest 9 days after she was switched from tacrolimus to sirolimus 2 mg daily. Symptoms resolved in both patients when the ACE inhibitor was stopped and corticosteroid therapy was increased.[5]

(c) Temsirolimus

The manufacturers of temsirolimus note that angioneurotic oedema-type reactions (including delayed reactions occurring 2 months following initiation of therapy[6]) have been observed in some patients who were given temsirolimus with ACE inhibitors.[6,7]

Mechanism

ACE inhibitors alone can cause angioedema, and this has also been reported for sirolimus (rarely[8]) and everolimus (common with ACE inhibitors[3]). It is therefore possible that the risk of angioedema might be increased by the concurrent use of ACE inhibitors. Although angioedema is not specifically listed as an adverse effect of temsirolimus, facial oedema is common, and as temsirolimus is a pro-drug of sirolimus, the risk of angioedema cannot be ruled out.[6,7]

Importance and management

These reports suggest that it would be prudent to be more alert to the possibility of angioedema when either starting an ACE inhibitor in a patient already taking everolimus, sirolimus or temsirolimus or when starting these immunosuppressants in a patient taking an ACE inhibitor. The effect may be dose-related, with higher doses of both drugs potentially posing a greater risk.

Sirolimus or Tacrolimus + Amiodarone

A case report describes increased sirolimus and tacrolimus levels in a paediatric patient and another case report describes markedly elevated tacrolimus levels in an adult, both associated with the concurrent use of amiodarone.

Clinical evidence

A 2-year-old heart transplant patient taking tacrolimus 20 micrograms/kg daily was given amiodarone to control ventricular arrhythmias. Her tacrolimus trough levels were reported as within the target range of 8 to 10 micrograms/L on both day one and day 3 after starting amiodarone. She was then switched from tacrolimus to sirolimus 60 micrograms/kg daily, increased to 120 micrograms/kg after 2 days, with tacrolimus continued until therapeutic sirolimus levels were achieved. The sirolimus levels and tacrolimus levels 9 days after starting amiodarone were found to be 53 micrograms/L and 13 micrograms/L, respectively. Subsequent sirolimus doses were put on hold and tacrolimus was stopped. The sirolimus levels were raised for a further 14 days. Sirolimus was restarted at a lower dose (30 micrograms/kg daily) but the levels remained above 10 micrograms/L and the sirolimus dose was reduced further to 20 micrograms/kg daily.[1]

A 73-year-old kidney transplant patient, who had been taking ciclosporin and amiodarone long-term, had the ciclosporin switched to tacrolimus 7 mg daily. About 3 months later he was found to have a markedly raised tacrolimus level of 63 nanograms/mL. The tacrolimus dose was reduced to 2 mg daily, with a resulting level of 12.9 nanograms/mL.[2]

Mechanism

The elevated levels of tacrolimus and sirolimus were attributed to an interaction with amiodarone, which can inhibit the cytochrome P450 isoenzyme CYP3A4, and affect P-glycoprotein, which have effects on the metabolism and clearance of sirolimus and tacrolimus.[1]

Importance and management

The authors of the first report advise that, because of the long half-life of sirolimus, and the difficulty in reducing elevated levels quickly, prescribers should consider reducing sirolimus and tacrolimus doses before starting amiodarone[1] rather than waiting for the interaction to occur. They also advise more frequent monitoring of sirolimus and tacrolimus levels if amiodarone is also given. Although there are limited data, given that a similar interaction has been reported with ciclosporin (see 'Ciclosporin + Amio-

darone', p.1214), which is metabolised in a similar way to sirolimus and tacrolimus, this would seem prudent.

Sirolimus + Azoles

Sirolimus levels are very markedly raised by ketoconazole, posaconazole and voriconazole. Itraconazole appears to interact similarly. Two case reports suggest that fluconazole can markedly raise sirolimus levels. Clotrimazole and miconazole oral gel are predicted to interact similarly.

Clinical evidence

(a) Fluconazole

A kidney transplant patient taking sirolimus was given fluconazole 200 mg daily for oesophageal candidiasis. As an interaction was anticipated, the sirolimus dose was reduced from 4 to 3 mg daily. After 4 days the sirolimus level had risen from about 10 micrograms/L to 22.8 micrograms/L. The dose of sirolimus was then reduced to 2 mg daily, but by the seventh day of fluconazole use the sirolimus level had reached 35 micrograms/L, after which they began to fall. The patient then had a hyperkalaemic arrest and died.[1] The sirolimus levels of another kidney transplant patient were raised almost fivefold about 3 weeks after she started to take fluconazole.[2]

(b) Itraconazole

A heart transplant patient needed only half of his normal sirolimus dose to maintain about the same trough levels when he took itraconazole 400 mg daily for a year.[2] A kidney transplant patient taking sirolimus 5 mg daily was given an initial dose of itraconazole 600 mg daily on post-transplant day 10 followed by 400 mg daily. The sirolimus trough level was subtherapeutic at 6.8 nanograms/mL one day after starting itraconazole so the sirolimus dose was increased to 10 mg daily. However, the sirolimus level then increased rapidly and reached a level of 82.5 nanograms/mL 6 days later.[3] A haematopoietic stem cell transplant patient taking itraconazole 200 mg twice daily was changed from tacrolimus to sirolimus 7 mg daily. The sirolimus dose was reduced to 5 mg daily 6 days later because the sirolimus level was 17.5 nanograms/mL (therapeutic range 5 to 15 nanograms/mL). As the sirolimus level was found to be 35.6 nanograms/mL two days later sirolimus was stopped until the level had fallen back to the therapeutic range. Sirolimus was subsequently restarted, with the dose adjusted to between 0.5 mg and 2 mg daily according to levels.[4]

(c) Ketoconazole

A pharmacokinetic study in 23 healthy subjects found that while taking ketoconazole 200 mg daily for 10 days, the maximum serum levels and AUC of a single 5-mg dose of sirolimus were increased 4.3-fold and 10.9-fold, respectively.[5] In a study in 6 kidney transplant patients, ciclosporin was stopped because of toxicity or rejection episodes, and sirolimus was started. The subjects were given about a 75 to 87% lower than recommended dose of sirolimus (250 to 500 micrograms daily) along with ketoconazole 100 to 200 mg daily, adjusted to maintain sirolimus levels within the therapeutic range. The serum creatinine levels of the patients improved and reduced from 230 micromol/L to 194 micromol/L.[6]

(d) Posaconazole

In a study in healthy subjects, posaconazole 400 mg given orally twice daily for 16 days increased the maximum serum levels and AUC of a single 2-mg dose of sirolimus about 6.7-fold and 8.9-fold, respectively.[7]

(e) Voriconazole

The manufacturers report that voriconazole 400 mg twice daily for one day, then 200 mg twice daily for 8 days, markedly raised the maximum serum levels and AUC of a single 2-mg dose of sirolimus about 7-fold and 11-fold, respectively.[8,9] In a retrospective study of allogeneic haematopoietic stem cell transplant patients, 11 patients were found to have received both sirolimus and voriconazole for a median of 33 days (range, 3 to 100 days). Three patients had increased trough sirolimus levels of between 10 and 19 nanograms/mL and serious toxicity occurred in 2 of them. The other 8 patients had their sirolimus dose reduced by 90% when voriconazole was started, in anticipation of the interaction, and in these patients, trough sirolimus levels were similar to those before voriconazole was started: no significant toxicity from either drug occurred.[10] A patient taking sirolimus, who had markedly raised sirolimus levels with itraconazole, was given voriconazole, and the sirolimus dose was decreased from 1.5 mg daily to 0.5 mg daily in anticipation of a similar interaction. The sirolimus trough level was 6.4 nanograms/mL (about the patients' usual range) two days after starting voriconazole.[4]

A case report describes a heart transplant patient who was given two doses of voriconazole 400 mg then 200 mg twice daily for 16 days. When sirolimus was started a dose of 1 mg gave a sirolimus trough level of 12.8 nanograms/mL, but after the voriconazole was stopped a dose of 3 mg only gave trough sirolimus levels of 7.4 nanograms/mL.[2] Voriconazole has been reported to markedly raise sirolimus levels in a number of other patients.[2,11]

Mechanism

Ketoconazole, itraconazole, posaconazole and voriconazole are potent inhibitors of the cytochrome P450 isoenzyme CYP3A4, the isoenzyme that is at least partly responsible for the metabolism of sirolimus.[9] Therefore these azoles probably cause raised sirolimus levels by inhibiting its metabolism. Fluconazole and miconazole also inhibit CYP3A4, but are less potent than ketoconazole. Hence sirolimus levels rise when fluconazole is given, but the rise is not as great as that seen with ketoconazole. Sirolimus is also a substrate for P-glycoprotein and, as azole antifungals may inhibit intestinal P-glycoprotein, this may also contribute to the interaction by increasing the oral bioavailability of sirolimus.[3]

Importance and management

The interactions between the azole antifungals and sirolimus are established and of clinical importance. The rises in sirolimus levels caused by **voriconazole** might be too large to be easily accommodated by reducing the dose of the sirolimus, although one study found that an initial empiric reduction in sirolimus dose by 90% at the start of treatment with voriconazole was adequate. However, more study is required to confirm the safety of such regimens.[10] Note that the concurrent use of sirolimus is contraindicated by the manufacturers of **voriconazole**,[8,12] and not recommended by the manufacturers of sirolimus.[9,13]

The rises in sirolimus levels with **ketoconazole** and **posaconazole** are of a similar magnitude to those seen with voriconazole, and, although data are more limited, **itraconazole** also appears to interact to the same extent. If these azoles are required in a patient taking sirolimus, a pre-emptive sirolimus dose reduction would appear to be prudent, and trough sirolimus levels should be very closely monitored both during use and after they are stopped. About an 80% reduction in sirolimus dose was used in one study with ketoconazole.[6] However, note that the manufacturers of sirolimus say that concurrent use of sirolimus with ketoconazole, and itraconazole is not recommended.[9,13] Similar advice is also given by the manufacturers of **posaconazole**.[7,14] If the combination is unavoidable, the UK manufacturers advise aiming for trough sirolimus levels in the upper part of the therapeutic range. This is because there is a change in the disposition of sirolimus which means that lower levels, even within the therapeutic range, may be subtherapeutic.[7]

Fluconazole, although a weaker inhibitor of CYP3A4 than ketoconazole, voriconazole or itraconazole, has been reported to interact in two cases. **Clotrimazole**[9,13] (presumably systemic clotrimazole) may also interact similarly. Sirolimus plasma levels should be closely monitored during treatment with and following the withdrawal of both of these antifungals.

There appear to be no reports of an interaction between **miconazole** and sirolimus. However, a large proportion of miconazole oral gel (both prescription and non-prescription doses) may be swallowed and therefore adequate systemic absorption may occur to produce an interaction. The manufacturers of miconazole oral gel recommend close monitoring and possible dose reduction of sirolimus if both drugs are given.[15] An interaction with intravaginal miconazole would not normally be expected because its systemic absorption is usually very low (less than 2%).[16]

Sirolimus + Calcium-channel blockers

Sirolimus modestly raised verapamil levels, but did not appear to affect diltiazem levels. Diltiazem and verapamil raise sirolimus levels. Nicardipine is predicted to interact similarly. Nifedipine appears not to interact with sirolimus.

Clinical evidence

(a) Diltiazem

A randomised, crossover study in 18 healthy subjects found that a single 120-mg oral dose of diltiazem increased the AUC and the maximum serum levels of a single 10-mg oral dose of sirolimus by 60% and 43%, respectively. The pharmacokinetics of diltiazem and its metabolites were unchanged.[1] Similarly, in a study in 76 patients given sirolimus 2 mg daily alone for 28 days then with diltiazem 180 mg daily after coronary stenting, blood levels of sirolimus were increased by 50%, from 6.2 nanograms/mL to 9.3 nanograms/mL.[2]

(b) Nifedipine

In a study comparing 16 patients taking nifedipine and sirolimus with 10 patients taking sirolimus alone, there were no significant differences in sirolimus pharmacokinetics between the two groups.[3] Similarly, in a study in healthy subjects, there was no pharmacokinetic interaction between nifedipine and sirolimus.[4]

(c) Verapamil

In 26 healthy subjects, the concurrent use of sirolimus oral solution 2 g daily and verapamil 180 mg every 12 hours to steady-state resulted in an increase in the sirolimus maximum levels and AUC of 2.3-fold and 2.2-fold, respectively. In addition, there was a 50% increase in the maximum levels and AUC of the active *S*-verapamil isomer.[5,6]

Mechanism

Diltiazem and verapamil inhibit the cytochrome P450 isoenzyme CYP3A4 in the intestinal wall and liver, which is the primary route of sirolimus metabolism. Verapamil may also inhibit P-glycoprotein activity, which leads to increased sirolimus absorption. It is not known why verapamil levels were raised. Nifedipine is not an inhibitor of CYP3A4 or P-glycoprotein.

Importance and management

The pharmacokinetic interactions between sirolimus and diltiazem or verapamil would appear to be established. The manufacturers recommend whole blood monitoring and a possible sirolimus dose reduction (based on sirolimus levels) if diltiazem or verapamil are used concurrently.[5,6] The clinical relevance of the modest increase in verapamil levels is uncertain, but bear it in mind in the event of an increase in adverse effects due to verapamil, such as hypotension, flushing and oedema. The manufacturers note that other calcium-channel blockers that inhibit CYP3A4 might interact similarly, and they specifically name **nicardipine**,[5,6] although note that other calcium-channel blockers do not usually act as CYP3A4 inhibitors.

Sirolimus + Ciclosporin

Ciclosporin markedly raises sirolimus levels, and this effect is approximately halved if sirolimus is given at least 4 hours after ciclosporin. Concurrent use for longer than 3 to 4 months possibly increases renal toxicity, and should be used with caution only when the benefits outweigh the risks. Sirolimus does not appear to alter blood ciclosporin levels in the short-term.

Clinical evidence

(a) Effects on ciclosporin

In a placebo-controlled study in kidney transplant patients, when sirolimus was added to a regimen including ciclosporin and a corticosteroid for 2 weeks, the steady-state ciclosporin levels remained unchanged. Blood pressure, glomerular filtration rate, creatinine levels, triglyceride levels and liver enzymes (ALT, AST) were unchanged.[1] Similarly, in a 2-week pharmacokinetic study in 40 kidney transplant patients, sirolimus 0.5 to 6.5 mg/m^2 given twice daily did not affect the pharmacokinetics of ciclosporin 75 to 400 mg twice daily. The patients were also taking prednisone.[2] In a related study in kidney transplant patients, a single dose of sirolimus had no effect on ciclosporin pharmacokinetics.[3] Similarly, in another study in healthy subjects, single doses of sirolimus did not affect the pharmacokinetics of a single dose of ciclosporin (*Neoral*) when given either at the same time or 4 hours apart.[4]

Nevertheless, the US manufacturer notes that in kidney transplant patients taking ciclosporin (*Neoral*) and sirolimus (taken 4 hours after ciclosporin) over a 6-month period, the oral clearance of ciclosporin was decreased, and lower doses of ciclosporin were needed to maintain therapeutic levels.[5]

In contrast, there is an isolated report of a kidney transplant patient who had a marked rise in ciclosporin levels shortly after starting sirolimus 2 mg daily. Within 2 weeks of starting the sirolimus, she was readmitted to hospital with signs of ciclosporin toxicity, including raised creatinine and urea, high blood pressure, and increased ciclosporin level (536 nanograms/mL). The ciclosporin dose was reduced from 400 to 300 mg daily, sirolimus was continued, and her ciclosporin level fell to 276 nanograms/mL. The sirolimus levels remained at 5.2 to 10.6 nanograms/mL, within the therapeutic range.[6]

(b) Effects on sirolimus

In a single-dose study in healthy subjects, ciclosporin (*Neoral*) given 4 hours before sirolimus increased the maximum serum levels of sirolimus by 40% and increased its AUC by 80%. When the drugs were given at the same time, the effect was even greater, with a 2.2-fold increase in maximum sirolimus level and 3.3-fold increase in the AUC.[4] This study confirmed the findings of a previous multiple-dose study in kidney transplant recipients,[7] and similar results have been seen in another study (40% increase when sirolimus was given 6 hours after ciclosporin).[8] When sirolimus was taken at the same time or 2 hours after ciclosporin, the AUC of sirolimus was increased by 183% and 141%, respectively, but when sirolimus was given 2 hours before the ciclosporin there was no effect on its AUC or peak plasma levels.[9] The US manufacturer of sirolimus also presents data showing that ciclosporin oral solution (*Sandimmune*) given at the same time as sirolimus, increased sirolimus trough levels by 67 to 86% in 150 patients with psoriasis.[5]

(c) Renal toxicity

The manufacturers note that, in clinical studies in patients with kidney transplants, the concurrent use of ciclosporin and sirolimus for more than 6 months and up to 36 months was associated with an increase in serum creatinine and a decrease in glomerular filtration rate when compared with patients treated with ciclosporin and placebo.[5,9] The difference in glomerular filtration rate was about 5.5 mL/minute (10%) at 12 and 36 months.[5] In patients in whom ciclosporin was successfully withdrawn, glomerular filtration rates were higher than in those maintained on ciclosporin.[5,9]

Mechanism

It appears that ciclosporin inhibits the metabolism of sirolimus by the cytochrome P450 isoenzyme CYP3A4 in the gut and liver leading to increased sirolimus levels[4,5,9] and inhibits P-glycoprotein leading to increased sirolimus absorption. There is some experimental evidence to suggest that sirolimus may increase ciclosporin renal toxicity by increasing intracellular ciclosporin levels in the renal epithelial cells by inhibiting P-glycoprotein.[10]

Importance and management

The effect of ciclosporin on sirolimus levels is an established interaction. The manufacturers recommend that, to minimise the interaction, sirolimus should be given 4 hours after microemulsion ciclosporin, and consistently, either with or without food.[5,9] Despite this, it may still be necessary to reduce the sirolimus dose,[4] and blood levels of sirolimus should be monitored and the dose adjusted to maintain levels of 4 to 12 nanograms/mL.[9] Renal function should be closely monitored, and if serum creatinine levels increase, discontinuation of sirolimus or ciclosporin should be considered.[5] Moreover, the manufacturers do not recommend continued use of the combination long-term,because higher serum creatinine levels and lower glomerular filtration rates have been seen.[5,9] Ciclosporin should be gradually discontinued over 4 to 8 weeks increasing the sirolimus dose to obtain higher trough sirolimus levels of 12 to 20 nanograms/mL.[9] In general, the sirolimus dose will need to be raised fourfold to take into account the absence of the interaction (twofold increase) and the need for increased immunosuppression (twofold increase).[9]

The UK manufacturer does not recommend the use of sirolimus in high-risk patients (e.g. those with renal impairment, markers of rejection of multi-organ transplants) as insufficient numbers of this type of patient were studied.[9] However, the US manufacturer states that it may be used in combination with ciclosporin in high-risk patients for up to one year.

The concurrent use of both drugs increases the risk of developing calcineurin inhibitor-induced haemolytic uraemic syndrome, thrombotic thrombocytopenic purpura, and thrombotic microangiopathy.[5,9] An increased risk of hepatic artery thrombosis, leading to graft loss and/or death in most cases, has also been seen in clinical studies in *de novo* liver transplant patients taking sirolimus with ciclosporin, and the manufacturers do not recommend using sirolimus in liver or lung transplant patients as safety and effectiveness have not been proven.[5,9]

Sirolimus + Corticosteroids

Intravenous methylprednisolone appears to have no effect on trough sirolimus levels. Sirolimus slightly increased prednisolone levels (derived from prednisone).

Clinical evidence, mechanism, importance and management

(a) Methylprednisolone

When 14 patients taking sirolimus (and also taking either azathioprine or mycophenolate) were given methylprednisolone as a daily intravenous bolus for one to 5 days (total dose of between 500 mg and 3 g) the sirolimus trough concentrations were not significantly altered.[1] No sirolimus dose adjustment appears to be necessary on concurrent use.[1]

(b) Prednisolone or Prednisone

In a study in kidney transplant patients taking ciclosporin and prednisone 5 to 20 mg daily, only minor to moderate changes occurred in the pharmacokinetics of the metabolite, prednisolone, when sirolimus 6 to 13 mg/m^2 daily was given for 2 weeks.[2] The maximum plasma prednisolone levels were raised by 14%, and the AUC was raised by 18%. The clinical relevance of these findings is uncertain, but they are likely to be minor.

2. Jusko WJ, Ferron GM, SM Mis, Kahan BD, Zimmerman JJ. Pharmacokinetics of prednisolone during administration of sirolimus in patients with renal transplants. *J Clin Pharmacol* (1996) 36, 1100–6.

Sirolimus + Co-trimoxazole

A single dose of co-trimoxazole did not alter sirolimus levels in one study.

Clinical evidence, mechanism, importance and management

In a study in 15 kidney transplant patients who had started sirolimus one week previously, there was no change in the AUC and maximum level of sirolimus after the first daily dose of oral co-trimoxazole (sulfamethoxazole with trimethoprim) 480 mg when compared with the day before.[1] There was also no change in serum creatinine levels between these two days, although a slight mean 4.3% increase was seen in 9 of the 15 patients on the following day.

The evidence suggests that co-trimoxazole does not have a marked effect on the pharmacokinetics of sirolimus and that no sirolimus dose adjustment is likely to be needed with concurrent use. However, the authors note that it does not rule out the possibility that longer-term concurrent use might lead to increases in sirolimus levels, particularly if renal function is impaired leading to co-trimoxazole accumulation.[1]

1. Böttiger Y, Brattström C, Bäckman L, Claesson K, Burke JT. Trimethoprim-sulphamethoxazole does not affect the pharmacokinetics of sirolimus in renal transplant recipients. *Br J Clin Pharmacol* (2005) 60, 566–9.

Sirolimus + Food

A high-fat meal modestly increased the exposure to sirolimus in one study.

Clinical evidence

In a single-dose study in healthy subjects, giving a non-aqueous solution of sirolimus with a high-fat breakfast reduced the maximum sirolimus level by 34%, delayed the time to maximum level by about 2 hours, and increased the AUC by 34%, when compared with the fasting state. There was no change in the elimination half-life of sirolimus.[1] In a similar study using sirolimus tablets, the maximum level and AUC of sirolimus were increased by 65% and 23%, respectively, by a high-fat meal.[2] The extent of this interaction was considered minor when compared with the large variability in sirolimus levels between subjects.[1] Nevertheless, the manu-

facturer recommends that sirolimus solution or tablets should be taken consistently either with or without food, to minimise variability.[2,3]

3. Rapamune (Sirolimus). Wyeth Pharmaceuticals Inc. US Prescribing information, November 2009.

Sirolimus + Macrolides

Erythromycin markedly increased sirolimus levels in healthy subjects, and there is a report of two patients who had large elevations in their sirolimus levels when they were given erythromycin. Similarly, there is a case report of clarithromycin causing a marked increase in sirolimus levels and renal impairment. Many other macrolides are expected to interact similarly.

Clinical evidence

(a) Clarithromycin

A kidney transplant patient taking sirolimus 2 mg daily and with stable but poor renal function (creatinine clearance 14 mL/minute) was given clarithromycin 250 mg twice daily for a week. At the end of the week, her trough sirolimus level was found to have risen markedly by 8.4-fold (from 6.2 to 52.2 nanograms/mL) and there was a sharp fall in her creatinine clearance to 6.8 mL/minute. Sirolimus was temporarily stopped until trough levels fell to low normal (8 days), and the creatinine clearance gradually improved.[1]

(b) Erythromycin

The manufacturers report that, in 24 healthy subjects, the concurrent use of erythromycin 800 mg three times daily with sirolimus oral solution 2 mg daily resulted in a significant increase in the peak blood levels and AUC of sirolimus, of 4.2- and 4.4-fold, respectively. The peak plasma levels and AUC of erythromycin were also increased, by 60% and 70%, respectively.[2,3]

A case report describes 2 patients taking sirolimus who were also given erythromycin 1 g three times daily for suspected Legionella pneumonia. Despite marked reductions in the sirolimus dose (actual reductions not stated), the sirolimus levels of both patients rose fivefold.[4]

Mechanism

Erythromycin and clarithromycin are inhibitors of the cytochrome P450 isoenzyme CYP3A4, which is the main enzyme responsible for the metabolism of sirolimus, and are also said to be inhibitors of P-glycoprotein, which is involved in the transport of sirolimus. Therefore they probably inhibited the metabolism of sirolimus and increased its bioavailability, causing the levels to rise. The mechanism behind sirolimus increasing erythromycin levels is uncertain.

Importance and management

The pharmacokinetic interaction leading to an increase in sirolimus levels would appear to be established and of clinical importance. Single-dose sirolimus also raised **erythromycin** levels, and although the increase seen is probably of little clinical relevance, further study is needed to see if a greater effect occurs on repeated use. The manufacturers of sirolimus differ in their recommendations for erythromycin use: in the US it is advised that erythromycin is avoided,[3] whereas in the UK the advice is to monitor sirolimus levels and decrease the dose of both drugs as appropriate.[2] In both countries, the advice is to avoid the use of **clarithromycin** and also **telithromycin** in patients taking sirolimus.[2,3] The manufacturers of sirolimus also name **troleandomycin** as a moderate inhibitor of CYP3A4, which may possibly interact.[2,3] However, note that troleandomycin tends to be a more potent inhibitor of CYP3A4 than clarithromycin. On the basis of the available data, if any macrolide is considered essential in a patient taking sirolimus, it would be prudent to decrease the sirolimus dose and closely monitor levels.

Sirolimus and related drugs + Miscellaneous

Cimetidine is predicted to increase levels of everolimus, sirolimus and temsirolimus, and grapefruit juice might also interact. No pharmacokinetic interaction appears to occur between sirolimus and aciclovir, digoxin or glibenclamide (glyburide). It has been suggested that cisapride, danazol, etravirine, metoclopramide and bromocriptine might interact with everolimus and sirolimus. Temsirolimus is a prodrug of sirolimus, and may therefore be expected to share some of its interactions.

Clinical evidence, mechanism, importance and management

(a) Aciclovir

In a study in healthy subjects, there was no pharmacokinetic interaction between aciclovir and sirolimus.[1]

(b) Digoxin

In a study in healthy subjects, there was no pharmacokinetic interaction between digoxin and sirolimus.[1]

(d) Glibenclamide (Glyburide)

In a study in healthy subjects, there was no pharmacokinetic interaction between glibenclamide and sirolimus.[1]

(e) Grapefruit juice

Grapefruit juice inhibits CYP3A4 (potentially raising sirolimus levels), and so the manufacturers recommend that concurrent use should be avoided.[2,3]

(f) NNRTIs

The manufacturer of **etravirine** predicts that it will induce the metabolism of sirolimus by the cytochrome P450 isoenzyme CYP3A4 and thus reduce sirolimus levels. However, note that etravirine is only a weak inducer of this isoenzyme.[4] The manufacturer advises caution on concurrent use and, until more is known, close monitoring of sirolimus levels would seem prudent. Until the extent of any interaction is established, similar caution may be appropriate if etravirine is given with **everolimus** and **temsirolimus**.

(g) Prokinetic drugs

The manufacturers of sirolimus note that **cisapride** and **metoclopramide** may increase sirolimus levels, although there do not appear to be any published reports of this interaction.[2,3] The manufacturer of **everolimus** also lists **cisapride** and **metoclopramide** as potentially interacting.[5]

(h) Other drugs

The manufacturers of **everolimus** and sirolimus list **bromocriptine**, **cimetidine**, and **danazol** as drugs that might increase sirolimus levels,[2,3,5] on the basis of these drugs being moderate or weak inhibitors of the cytochrome P450 isoenzyme CYP3A4.[2,5] However a significant interaction with **bromocriptine** would not generally be expected as it is not usually considered to be a clinically relevant CYP3A4 inhibitor. The UK manufacturer of **temsirolimus** contraindicates **cimetidine** on the basis that it is a potent inhibitor of CYP3A4.[6] However, **cimetidine** is a moderate non-specific inhibitor of cytochrome P450, and would be expected to cause only a minor interaction via this mechanism. Some caution might therefore be appropriate with cimetidine if it is given with sirolimus, **everolimus** or **temsirolimus**.

Sirolimus + Phenytoin

Two case reports describe increased sirolimus dose requirements in the presence of phenytoin.

Clinical evidence

An 11-year-old girl with a kidney transplant taking phenytoin started taking sirolimus 30 micrograms/kg twice daily following an episode of acute rejection. The dose of sirolimus was increased tenfold over the next few weeks in an attempt to achieve the target trough level of 10 to 20 nanograms/mL, and two further episodes of acute rejection occurred. About one month after the sirolimus had been started, tacrolimus was added, and her phenytoin was stopped. Over the next few weeks her sirolimus level rose to about 40 nanograms/mL. The patient subsequently recovered.[1]

A 62-year-old woman started taking phenytoin 100 mg twice daily because she developed a seizure disorder following a liver transplant. At this time she was taking ciclosporin, but it was decided to start sirolimus because of neurological complications. The initial sirolimus dose of 5 mg daily produced subtherapeutic sirolimus levels. She was subsequently stabilised taking sirolimus 15 mg daily, with trough levels of less than 5 nanograms/mL. Phenytoin was stopped, and about 5 days later her trough sirolimus level was found to be around 15 to 20 nanograms/mL. After a further 5 days, the sirolimus dose was reduced to 10 mg daily.[2]

Mechanism

Sirolimus is extensively metabolised by the cytochrome P450 isoenzyme CYP3A4 in the intestinal wall and is a substrate for P-glycoprotein. Phenytoin and other antiepileptics that induce the activity of this isoenzyme and transporter protein would be expected to lower sirolimus levels.

Importance and management

These appear to be the only reports of an interaction between sirolimus and phenytoin, but they are consistent with the way both drugs are known to interact. It would therefore seem prudent to closely monitor sirolimus levels in any patient in whom phenytoin is started or withdrawn, and to adjust the sirolimus dose as necessary.

Sirolimus + Protease inhibitors

Nelfinavir markedly increased the levels of sirolimus in one patient. Other protease inhibitors are predicted interact similarly.

Clinical evidence, mechanism, importance and management

An HIV-positive, liver transplant patient taking sirolimus 5 mg daily was given **nelfinavir** 250 mg twice daily (one-fifth of the normal dose), lamivudine and zidovudine. Three weeks later, because of a reduced full blood count, her sirolimus blood levels were checked, and found to be 24.7 nanograms/mL. Her sirolimus dose was reduced to 3 mg daily and then 2 mg daily and her levels rechecked 5 days later. The trough sirolimus level was found to be 4.6 nanograms/mL, which was almost fivefold higher than the trough levels of 3 control patients taking sirolimus 5 to 7 mg daily but not taking nelfinavir. The peak level and AUC of sirolimus were also much higher in the patient taking nelfinavir.[1]

The manufacturers point out that sirolimus is extensively metabolised by the cytochrome P450 isoenzyme CYP3A4 and cleared by P-glycoprotein, so drugs such as the protease inhibitors, which inhibit the activity of this isoenzyme and drug transporter may raise sirolimus levels.[2,3] On the basis of the interaction with ketoconazole (see 'Sirolimus + Azoles', p.1290), they advise against the concurrent use of potent inhibitors of CYP3A4.[2,3] This would generally be expected to include the protease inhibitors (ritonavir is the most potent CYP3A4 inhibitor known). However, the UK manufacturer of sirolimus[3] lists the protease inhibitors as moderate or weak inhibitors of CYP3A4. The US manufacturer[2] suggests that the protease inhibitors (they specifically name **indinavir** and **ritonavir**) may significantly increase in sirolimus levels, and suggest that if both drugs are given it would be prudent to very closely monitor sirolimus levels and adjust the dose of sirolimus as necessary.

Sirolimus + Repaglinide

Repaglinide does not appear to alter sirolimus levels.

Clinical evidence, mechanism, importance and management

In a study in kidney transplant patients stabilised on immunosuppressants, the concurrent use of repaglinide in the 5 patients taking sirolimus did not appear to cause any significant changes in sirolimus blood levels and no sirolimus dose changes were required on starting repaglinide 1 to 3 mg daily (mostly as monotherapy but a few patients were also given either metformin or rosiglitazone).[1] It would appear from the limited data from this observational study, that a significant pharmacokinetic interaction between sirolimus and repaglinide does not occur, however this ideally needs confirmation in a pharmacokinetic study.

Sirolimus + Rifampicin (Rifampin) and other CYP3A4 inducers

Rifampicin (a potent CYP3A4 inducer) markedly decreases sirolimus levels. Rifabutin and rifapentine are predicted to interact similarly, although to a lesser extent. Other CYP3A4 inducers are also predicted to interact similarly.

Clinical evidence

A clinical study in 14 healthy subjects found that **rifampicin** 600 mg daily for 6 days increased the clearance of a single 10-mg oral dose of sirolimus 5.5-fold, and reduced the AUC and maximum serum levels of sirolimus by 82% and 71%, respectively.[1,2]

Mechanism

Sirolimus is extensively metabolised by the cytochrome P450 isoenzyme CYP3A4 in the intestinal wall and liver, and is also a substrate for the drug transporter protein P-glycoprotein: drugs such as rifampicin that induce the activity of this isoenzyme and drug transporter would be expected to lower sirolimus levels.[1,2]

Importance and management

This interaction is likely to result in markedly reduced sirolimus trough levels and efficacy. The manufacturers say that concurrent use is not recommended, and that alternatives to rifampicin should be used.[1,2] **Rifabutin**[1,2] and **rifapentine**[2] are predicted to also lower sirolimus levels, but this will probably be to a lesser extent than with rifampicin. Nevertheless, the concurrent use of **rifabutin** is also not recommended.[1,2]

On the basis of the interaction with rifampicin, the manufacturers state that the concurrent use of potent CYP3A4 inducers should be avoided, and cautions the use of other CYP3A4 inducers.[1,2] They specifically mention **St John's wort**, **carbamazepine**, phenytoin and **phenobarbital** (see 'Sirolimus + Phenytoin', above, for case reports of this interaction). It would certainly be prudent to monitor sirolimus levels closely if any of these drugs are used concurrently. What should be remembered is that the extent of the inducing effects of these drugs is not identical, so that very marked effects like those observed with rifampicin may not occur; never-

theless the interaction may still be clinically important. For a list of CYP3A4 inducers, see 'Table 1.4', (p.6).

Tacrolimus + ACE inhibitors or Angiotensin II receptor antagonists

Candesartan and losartan do not appear to affect the pharmacokinetics of tacrolimus, although concurrent use may increase the risk of hyperkalaemia.

Clinical evidence

A study in 12 kidney transplant patients taking tacrolimus twice daily for 12 days with **candesartan** (2 mg daily for 3 days, then 4 mg daily for 3 days, and then 16 mg daily for 3 days) found that the pharmacokinetics of tacrolimus were unchanged. Renal function remained stable and unchanged, and no adverse effects were reported.[1] Another study in a group of 21 kidney transplant patients taking tacrolimus found no significant change in serum creatinine or the levels of tacrolimus when they also took **candesartan** 4 to 12 mg daily for one year. Serum potassium levels were reported to have increased by an average of 0.34 mmol/L, although it is unclear from the study if this was specifically in the tacrolimus group or also included another group taking candesartan and ciclosporin.[2]

A study in kidney transplant patients taking tacrolimus and given **losartan** 50 mg daily for 12 weeks (some receiving 100 mg daily from week 8) for hypertension found no significant changes in the tacrolimus levels. Transient hyperkalaemia occurred in 4 of the 67 patients.[3]

Mechanism

Both ACE inhibitors and angiotensin II receptor antagonists can raise potassium levels, and this effect might be additive with that of tacrolimus.

Importance and management

No pharmacokinetic interaction is anticipated. However, as tacrolimus may cause nephrotoxicity and hyperkalaemia, bear in mind the possibility of additive effects if ACE inhibitors or angiotensin II receptor antagonists are also given.

Tacrolimus + Antacids

Aluminium/magnesium hydroxide caused a minor increase in tacrolimus levels in one study. There is some evidence to suggest that sodium bicarbonate may possibly reduce the tacrolimus levels.

Clinical evidence

(a) Aluminium/magnesium antacids

In an early *in vitro* study, **aluminium hydroxide** gel and **magnesium oxide** caused a significant reduction in tacrolimus concentrations due to pH-mediated degradation, leading to the suggestion that the administration of antacids and tacrolimus should be separated until data from clinical studies became available.[1] However, in a crossover study in healthy subjects, a single dose of **aluminium/magnesium hydroxide** slightly *increased* the mean AUC of tacrolimus by 21% and decreased the mean peak level of tacrolimus by 10%.[2] Moreover, a retrospective study in 18 kidney transplant patients found that the concurrent use of antacid medications (H_2-receptor antagonists, **magnesium oxide**, sodium bicarbonate or proton pump inhibitors) did not reduce tacrolimus blood levels and no patients required a tacrolimus dose increase,[3] although interpretation of this study is limited by the broad range of drugs considered together.

(b) Sodium bicarbonate

A review very briefly states that widely variable trough plasma tacrolimus levels have been seen in patients taking sodium bicarbonate close to the time when the tacrolimus was given, and that the use of sodium bicarbonate results in lower blood levels of tacrolimus. No details were given.[4] It was suggested that their administration should be separated by at least 2 hours[4] However, a retrospective study in 18 renal transplant patients found that the concurrent use of antacid medications (H_2-receptor antagonists, magnesium oxide, sodium bicarbonate or proton pump inhibitors) did not reduce tacrolimus blood levels and no patient required a tacrolimus dose increase,[3] although interpretation of this study is limited by the broad range of drugs considered together.

Mechanism

Unknown.

Importance and management

More study is needed to confirm and assess the extent and clinical importance of these interactions, but the best available evidence suggests that aluminium/magnesium hydroxide might cause a minor increase in tacrolimus levels, which is probably unlikely to be clinically relevant. Nevertheless, it would seem prudent to bear this in mind if tacrolimus is given with any antacids, and be alert for the need to separate the doses by at least 2 hours.

Tacrolimus + Antiepileptics; Enzyme-inducing

An isolated report describes an increase in phenytoin levels attributed to the use of tacrolimus. Phenytoin decreased tacrolimus levels in three cases, and has been used to reduce tacrolimus levels after an overdose. Phenobarbital has also been used for this purpose. Carbamazepine is predicted to interact similarly.

Clinical evidence

(a) Phenobarbital

In a 4-month-old liver transplant recipient with tacrolimus toxicity, intravenous phenobarbital 5 mg/kg was used to try to increase the tacrolimus clearance. The half-life of tacrolimus was calculated as 70 to 235 hours before phenobarbital administration, and 13 to 30 hours during phenobarbital administration.[1] Two other infants were similarly treated, resulting in about three to fivefold decreases in the tacrolimus half-life.[2]

(b) Phenytoin

1. Phenytoin levels. A kidney transplant patient taking phenytoin 500 and 600 mg on alternate days (and also taking azathioprine, bumetanide, digoxin, diltiazem, heparin, insulin and prednisone) had his immunosuppressant changed from ciclosporin, to tacrolimus 14 to 16 mg daily. About 7 weeks later he presented to hospital because of a fainting episode and his phenytoin levels were found to have risen from 18.4 micrograms/mL to 36.2 micrograms/mL. The phenytoin was temporarily stopped until his serum levels had fallen, and he was then discharged on a reduced phenytoin dose of 400 and 500 mg on alternate days with no further problems.[3] The presumption is that the fainting episode was due to the raised serum phenytoin levels.

2. Tacrolimus levels. In one kidney transplant patient taking phenytoin, tacrolimus 250 micrograms/kg daily was needed to give a blood level of 9 nanograms/mL. Three months later phenytoin was gradually stopped, with gradual tapering of the tacrolimus dose. The patient was eventually stabilised with a tacrolimus dose of 160 micrograms/kg daily giving a blood level of 11 nanograms/mL.[4] Similarly, two other cases of about two- to threefold increases in tacrolimus requirements while taking pheny-

toin 200 mg daily and decreased requirements on stopping have been reported.[5] In another patient, variable tacrolimus doses and levels were seen in the post-transplant period while taking phenytoin, and phenytoin was eventually tapered and replaced with oxcarbazepine.[6]
Another report describes the use of an intravenous phenytoin infusion to treat acute tacrolimus overdoses in 2 patients, with the aim of enhancing tacrolimus metabolism.[7]

Mechanism

Tacrolimus is extensively metabolised by the cytochrome P450 isoenzyme CYP3A4, and phenytoin and phenobarbital are known inducers of this system, and are therefore predicted to decrease tacrolimus levels. In the case of raised phenytoin levels, it was suggested that tacrolimus might have inhibited the metabolism of phenytoin, although other factors may have had some part to play.[3]

Importance and management

Information is limited, but based on the known metabolism of these drugs it would be prudent to monitor tacrolimus levels in all patients given phenytoin or phenobarbital. The manufacturers suggest that **carbamazepine** will interact similarly.[8,9] It would certainly be prudent to monitor tacrolimus levels closely if any of the enzyme-inducing antiepileptics (including the prodrug of phenytoin, **fosphenytoin**; and **primidone**, which is metabolised to phenobarbital) are used concurrently.

Similarly, until more is known, based on the single case of phenytoin toxicity, it may also be advisable to monitor phenytoin levels in patients taking tacrolimus.

Tacrolimus + Azoles

The azole antifungals increase tacrolimus levels, to varying degrees, and tacrolimus dose reductions may be needed. There is some evidence (using fluconazole and ketoconazole) that the levels of tacrolimus after intravenous administration are less affected by the azoles. In theory it is possible that miconazole oral gel may also interact with tacrolimus.

Clinical evidence

(a) Clotrimazole

In a study in 35 kidney transplant patients taking tacrolimus 150 micrograms/kg twice daily, patients were randomised to receive either clotrimazole lozenges 10 mg three times daily (17 patients) or nystatin oral suspension (control group, 18 patients). Clotrimazole markedly increased tacrolimus trough blood levels from a mean of about 15 nanograms/mL up to 53 nanograms/mL at day 5, whereas tacrolimus levels were not affected by nystatin. By day 7, patients in the clotrimazole group were found to require significantly lower tacrolimus doses than those in the nystatin group.[1] In a further pharmacokinetic study by this research group, in 6 patients, a 5-day course of clotrimazole lozenges markedly increased the AUC and trough levels of tacrolimus about 2.5-fold.[2]

Similarly, in a liver transplant patient the trough plasma levels of tacrolimus 6 mg daily rose from 3.5 nanograms/mL to 5.6 nanograms/mL within a day of clotrimazole 10 mg four times daily being started, and reached more than 9 nanograms/mL within 8 days. Later studies and rechallenge confirmed that clotrimazole was responsible for the rise in tacrolimus levels. The tacrolimus AUC was nearly doubled.[3]

(b) Fluconazole

1. Oral tacrolimus. Twenty organ transplant patients (11 liver, 6 kidney, 2 heart and one bone marrow) taking tacrolimus were also given fluconazole 100 or 200 mg daily for various fungal infections. On day one the median plasma trough levels of those given fluconazole 100 mg rose by 40%, and in those taking 200 mg it rose 3.1-fold. The dose of tacrolimus was reduced to accommodate this rise: the median dose reduction was 56% (range 0 to 88%). The highest tacrolimus level was seen within 3 days. A pharmacokinetic study in one patient found that when fluconazole 100 mg daily was stopped, the tacrolimus AUC fell by about 60%.[4] In two other studies, patients given fluconazole required a reduction of 40% or 47% (increased to 65% at 3 months) in tacrolimus dose to achieve similar trough levels.[5,6]
Other studies in adult[7] and paediatric patients[8] and individual case reports[9,10] have confirmed that tacrolimus levels are increased by oral fluconazole, increasing the risk of nephrotoxicity.[8-10] A bone-marrow transplant patient taking tacrolimus and given fluconazole for oral candidiasis experienced headache and was found to have glycosuria, increased serum creatinine and Pelger-Huet anomaly of granulocytes, which disappeared after tacrolimus was discontinued. The effects were thought to be due to tacrolimus toxicity due to an interaction with fluconazole.[11] In yet another study in patients receiving oral tacrolimus, both oral and intravenous fluconazole appeared to increase tacrolimus trough levels to a similar extent,[12] but other studies suggest that an interaction with intravenous tacrolimus may be smaller than with oral tacrolimus, see *Intravenous tacrolimus*, below.

2. Intravenous tacrolimus. When intravenous tacrolimus was given with intravenous fluconazole 400 mg, the steady-state levels of tacrolimus were only slightly increased (by about 16%), which was considered to be clinically unimportant.[13] In a retrospective study in patients receiving intravenous tacrolimus, the tacrolimus blood level rose slightly (from 17.4 nanograms/mL to 18.8 nanograms/mL) when they were switched from intravenous to oral fluconazole.[14]

(c) Itraconazole

A study in 40 lung transplant patients taking tacrolimus with prophylactic itraconazole 200 mg twice daily for 6 months found that when itraconazole was stopped the mean tacrolimus dose needed to maintain therapeutic levels increased by 76% (to 5.74 mg daily). The adverse effects and rejection rate were not affected by itraconazole.[15] Similar findings were reported in two other studies in heart and lung transplant patients, who required about one-third of the tacrolimus dose while taking itraconazole.[16,17]

Various cases of this interaction have also been reported. The trough blood levels of tacrolimus in a heart-lung transplant patient increased threefold (from 16 to 57 nanograms/mL) and serum creatinine levels also rose after she was given itraconazole 200 mg daily.[18] A kidney transplant patient taking tacrolimus 6 mg daily was given itraconazole 100 mg twice daily for a urinary candida infection. Within a day, the tacrolimus trough levels increased from 12.6 nanograms/mL to 21 nanograms/mL and the tacrolimus dose needed to be progressively reduced to 3 mg daily. Four days after the itraconazole was discontinued tacrolimus had to be progressively increased back to its initial dose.[19] The interaction has been reported in three other transplant recipients.[17,20-22] Similarly, in a study in 9 patients, intravenous itraconazole 200 mg twice daily for 2 days then 200 mg daily caused a mean 83% increase in the levels of *intravenous* tacrolimus.[23]

(d) Ketoconazole

In a kidney transplant patient taking tacrolimus and prednisone, the addition of ketoconazole 200 mg daily resulted in an increase in tacrolimus blood levels from 11.1 nanograms/mL to 27.9 nanograms/mL, despite a 45% decrease in the dose of tacrolimus. Eventually the dose of tacrolimus had to be reduced by 80% to keep the levels within the therapeutic range. Tacrolimus levels decreased to 5.8 nanograms/mL within a week of discontinuing ketoconazole and so the dose was raised.[24] Similarly, in a study in 11 kidney transplant patients taking tacrolimus, the concurrent use of ketoconazole 87 mg daily allowed a reduction in the tacrolimus dose of about 75 to 80%.[25] In another similar study, a reduction in the tacrolimus dose of about 50% was needed with ketoconazole 100 mg daily.[26] A pharmacokinetic study in 6 healthy subjects found that ketoconazole 200 mg orally at bedtime for 12 days increased the bioavailability of a single 100-microgram/kg dose of oral tacrolimus from 14% to 30%.[27] The man-

ufacturer notes that the clearance of *intravenous* tacrolimus was not significantly changed by ketoconazole, although it was highly variable between patients.[28]

(e) Posaconazole

In a study in healthy subjects, the peak blood level and AUC of a single 50 microgram/kg dose of tacrolimus were increased by 2.2-fold and 4.6-fold, respectively, when posaconazole 400 mg twice daily was given for 7 days.[29]

In another report, increased tacrolimus levels occurred in just 2 of 10 transplant patients given posaconazole 800 mg daily, occurring after 17 days and 39 days of concurrent use. One of these patients had acute renal impairment.[30] The manufacturer notes that, in clinical efficacy studies, clinically important interactions with tacrolimus, resulting in hospitalisation and/or posaconazole discontinuation, were reported.[31]

(f) Voriconazole

A small study comparing the tacrolimus levels of two patients, one taking voriconazole 200 mg twice daily and the other taking placebo, found that the tacrolimus levels were nearly tenfold higher in the patient taking voriconazole. This was originally designed as a larger study, but the study was stopped after the finding in these initial two subjects.[32] Another study in 14 healthy subjects found that voriconazole 400 mg twice daily on day one, then 200 mg twice daily for 6 days increased the AUC and maximum plasma levels of a single 100 microgram/kg dose of tacrolimus 3.2-fold and 2.3-fold, respectively.[33]

A liver transplant patient taking tacrolimus was hospitalised with multiple complaints, and was found to have a high tacrolimus level. Tacrolimus was withheld and later restarted at 3 mg daily and then gradually reduced to 1.5 mg daily. When voriconazole 400 mg twice daily was started, the tacrolimus dose was reduced by one-third to 0.5 mg daily, but eventually needed to be reduced to 0.15 mg daily (a 90% reduction in the overall dose) as a result of rising tacrolimus levels.[34] A kidney transplant patient taking tacrolimus 2 mg daily had an increase in tacrolimus levels from less than 12 nanograms/mL to 25 nanograms/mL when voriconazole 4 mg/kg twice daily was added. His renal function also worsened. The tacrolimus dose was eventually reduced to 0.5 mg on alternate days, with an improvement in his renal function.[35] Another similar case has been reported.[36] A case of thrombotic microangiopathy and severe leukoencephalopathy was attributed to tacrolimus toxicity in a patient who had no tacrolimus dose reduction when given voriconazole.[37]

Painful neuromuscular disorders occurred in 9 of 27 patients taking tacrolimus who were also treated with voriconazole. Tacrolimus levels were maintained within the therapeutic range. At the time of onset of the symptoms, trough voriconazole levels were higher than in the patients without symptoms. Patients completely recovered when voriconazole was stopped. It was suggested that tacrolimus triggered voriconazole neurotoxicity, and that this does not appear to occur if voriconazole doses are adjusted to maintain voriconazole trough levels below 1.5 mg/mL.[38]

Mechanism

Fluconazole, itraconazole, ketoconazole, posaconazole and voriconazole inhibit the metabolism of tacrolimus by the gut wall and/or liver by the cytochrome P450 isoenzyme CYP3A4, and/or inhibit the activity of P-glycoprotein so that more tacrolimus is absorbed.[13,19,27,32] Intravenous tacrolimus is less affected as it does not undergo first-pass metabolism in the gut,[13]

Importance and management

The evidence suggests that all azoles can markedly raise tacrolimus levels. The interaction between tacrolimus and **fluconazole** is established, clinically important and can develop rapidly (within 3 days). Fluconazole generally only inhibits CYP3A4 at high doses (greater than 200 mg daily), and the authors of one of the reports say that up to 200 mg of oral fluconazole daily can be used safely and effectively provided that the tacrolimus dose is reduced by half;[4] however, note that clinically relevant, although less dramatic rises, do occur with lower fluconazole doses. Concurrent use should be closely monitored and the tacrolimus dose adjusted as required. One study specifically examining dose adjustments suggested that fluconazole can be safely used if 60% of the original tacrolimus dose is given.[5] If tacrolimus is given intravenously, no clinically important interaction appears to occur.[13]

The interactions of tacrolimus with **itraconazole** and **ketoconazole** also appear to be established, and the UK manufacturer of tacrolimus states that nearly all patients will require tacrolimus dose reductions when given these drugs.[39]

The manufacturers of **posaconazole** recommend that the tacrolimus dose is initially reduced (they suggest by about two-thirds) in patients given posaconazole, with further dose adjustments made as required on the basis of close monitoring of tacrolimus levels both during concurrent use and after the antifungal is stopped.[40] Similarly, the manufacturers of **voriconazole** advise reducing the tacrolimus dose by two-thirds when starting voriconazole, closely monitoring tacrolimus levels throughout, and increasing the tacrolimus dose in response to levels obtained when voriconazole is stopped.[41,42] Note that, greater reductions in the dose of tacrolimus may be needed in some patients.[32,34] However, the authors of one review state that pre-emptive tacrolimus dose reductions when starting azoles are not standard practice among transplant clinicians, because of the concern of an increased risk of rejection[43] (due to subtherapeutic tacrolimus levels). Whatever is done, close monitoring is necessary.

Information about oral **clotrimazole** is more limited, but on the basis of the case report and studies cited it would be prudent to monitor tacrolimus levels, and adjust the dose as necessary. No interaction would generally be expected with clotrimazole used topically (e.g. pessaries or cream), as the systemic absorption is usually low.

In vitro studies with human liver microsomes have shown that **miconazole**[44] also inhibits liver and small intestine microsomes that metabolise tacrolimus and it seems possible that it may interact like fluconazole but this needs confirmation. There appear to be no clinical reports of an interaction between miconazole and tacrolimus. However, a large proportion of miconazole oral gel (both prescription and non-prescription doses) may be swallowed and therefore adequate systemic absorption may occur to produce an interaction. The manufacturer of miconazole oral gel recommends close monitoring and a possible dose reduction of tacrolimus if both drugs are given concurrently.[45] An interaction with intravaginal miconazole would not normally be expected because its systemic absorption is usually very low (less than 2%) in healthy women of child-bearing age.[46] No interaction would be expected if miconazole is applied to the skin.

Remember to readjust the dose of tacrolimus when the azole antifungal is stopped.

Tacrolimus + Basiliximab

Basiliximab increases tacrolimus levels and adverse effects.

Clinical evidence, mechanism, importance and management

A study in 12 adult kidney transplant patients found that trough tacrolimus levels on day 3 were increased by 63% in patients also given basiliximab, and in 50% of these patients this was associated with the development of acute tubular necrosis. By day 30, tacrolimus trough levels showed a downward trend in the group receiving basiliximab, despite similar dose requirements to those on day 10. Tacrolimus dose requirements were lower in the group receiving basiliximab throughout the 60-day study period, when compared with the control group.[1] Dose reductions were not considered necessary by the authors, but close monitoring was recommended.[1]

Tacrolimus + Calcium-channel blockers

Nifedipine may cause a moderate rise in tacrolimus levels and also appears to be kidney protective. Marked rises in tacrolimus levels have been reported in a few cases with diltiazem, although one study found no interaction. There is an isolated case of increased levels with felodipine. Nicardipine, verapamil, and possibly nilvadipine, are predicted to interact similarly.

Clinical evidence

(a) Diltiazem

A liver transplant patient taking tacrolimus 8 mg twice daily had an increase in his tacrolimus trough blood levels from 12.9 nanograms/mL to 55 nanograms/mL within 3 days of starting diltiazem (initially 5 to 10 mg/hour intravenously for one day, then 30 mg orally every 8 hours). The patient became delirious, confused and agitated. Both drugs were stopped, and over the next 3 days his mental state improved and his tacrolimus levels fell to 6.7 nanograms/mL. Tacrolimus was then restarted, gradually increasing to a dose of 5 mg twice daily, which produced levels of 9 to 10 nanograms/mL.[1] Another report briefly mentions that one kidney transplant patient with acute tacrolimus nephrotoxicity required a 66% tacrolimus dose reduction after starting diltiazem.[2] Diltiazem was thought to have contributed to a case of very high tacrolimus levels in a patient also taking 'protease inhibitors', (p.1305), but ritonavir alone could equally well have been responsible.

Similarly, a study in 2 liver and 2 kidney transplant patients found that diltiazem increased the AUC of tacrolimus. In the kidney transplant patients the increase appeared to be dose-related; a 20 mg dose of diltiazem caused a 26% and 67% rise, while a 180 mg dose caused a 48% and 177%, rise in each patient, respectively. The liver transplant patients did not have any alteration in the AUC of tacrolimus until they were given higher doses of diltiazem; one patient had an 18% rise following a 120 mg dose, the other a 22% rise following a 180 mg dose.[3]

However, in a study in liver transplant patients given tacrolimus, there was no difference in the required tacrolimus dose at day 3, day 7, month one and month 3 between 7 patients also given modified-release diltiazem 90 mg daily when compared with 7 patients not given diltiazem.[4] The authors of the other study[3] suggested that this lack of effect may have been because only 90 mg of diltiazem was used.

(b) Felodipine

A 13-year-old boy taking tacrolimus 4 mg twice daily was given felodipine 2.5 mg daily 15 days after receiving a kidney transplant. Two weeks later his tacrolimus level was reported as greater than 30 nanograms/mL (previous levels ranged from 10.6 to 20 nanograms/mL), and despite a reduction in the dose of tacrolimus to 3 mg twice daily, a subsequent tacrolimus level was 53.9 nanograms/mL. He was eventually stabilised at the original tacrolimus levels with tacrolimus 500 micrograms twice daily. When felodipine was stopped several months later, his tacrolimus dose needed to be raised to maintain therapeutic levels.[5]

(c) Nifedipine

A one-year retrospective study of two groups of liver transplant patients found that in the 22 patients taking nifedipine 30 or 60 mg daily there was a 55% increase in the tacrolimus blood levels after one month. By 6 months the tacrolimus dose had been reduced by a total of 25.5% in the nifedipine group and by 12 months by 31.4% when compared with the group not taking nifedipine. The nifedipine group also had improved renal function (lowered serum creatinine).[6]

Mechanism

Diltiazem and verapamil are established moderate inhibitors of the cytochrome P450 isoenzyme CYP3A4, and verapamil is known to also inhibit P-glycoprotein. Tacrolimus is a substrate for this isoenzyme and transporter protein, and diltiazem and verapamil would therefore be expected to reduce the metabolism and clearance of tacrolimus leading to increased blood levels. Nifedipine and felodipine are not known to act as inhibitors of drug metabolism, and the reasons for the potential interactions described are unclear. However, an early *in vitro* study using human liver microsomes did find inhibition of tacrolimus metab-

olism by nifedipine and nilvadipine,[7] although there is some doubt about the clinical relevance of these findings.

Importance and management

Information about an interaction between tacrolimus and **diltiazem** is limited. However, given that diltiazem is known to affect one of the main routes of tacrolimus metabolism and that marked rises in tacrolimus levels have been seen in some patients, it would seem wise to closely monitor tacrolimus levels when this drug is started or stopped. **Verapamil** would also be expected to interact with tacrolimus (see *Mechanism*) and the manufacturers of tacrolimus state that interactions have been reported.[8,9] Similar precautions to those advised for diltiazem would be prudent with concurrent use.

Limited evidence from one retrospective study suggests that **nifedipine** might interact with tacrolimus. However, the increase seems slow, and it seems likely that any decrease in the dose requirements of tacrolimus will be detected by routine monitoring.

There is only one isolated case report with **felodipine**, and no interaction is established; however, some manufacturers of felodipine advise monitoring tacrolimus levels if felodipine is given and a dose adjustment as required.[10,11] Published information about other calcium-channel blockers appears to be lacking, but the manufacturers of tacrolimus[8,9] say that interactions have occurred with **nicardipine**, and the UK manufacturer additionally suggests that **nilvadipine** may interact similarly, based on *in vitro* data.[9]

Tacrolimus + Chloramphenicol

A marked rise in tacrolimus trough levels has been reported in several patients who were given systemic chloramphenicol.

Clinical evidence

A retrospective study identified 3 patients taking tacrolimus who had received a total of 5 courses of intravenous chloramphenicol, each lasting for at least 12 days. Tacrolimus trough blood levels were doubled by day 2, and had risen by 207% at their peak, on day 6. The tacrolimus dose had been decreased by about one-third by day 12, and the tacrolimus levels returned to around the baseline value.[1]

An adolescent patient with a kidney transplant developed toxic tacrolimus levels on the second day of starting chloramphenicol for a vancomycin-resistant enterococcal infection. The tacrolimus dose had to be reduced by 83% to achieve safe serum levels, and it was found that the dose-adjusted tacrolimus AUC was 7.5-fold greater in the presence of chloramphenicol.[2] Another report describes a similar interaction in a liver transplant patient taking tacrolimus 4 mg twice daily. The patient was given intravenous chloramphenicol, but at the unintentionally high dose of 1850 mg every 6 hours. After about 3 days the patient complained of lethargy, fatigue, headaches and tremors, so both drugs were stopped. His tacrolimus trough level had increased from a range of 9 to 11 nanograms/mL to more than 60 nanograms/mL. Seven days after chloramphenicol had been stopped his tacrolimus level was 8.2 nanograms/mL and his symptoms had resolved.[3] Another case report in a kidney-pancreas transplant patient taking tacrolimus 4 mg twice daily found that the addition of oral chloramphenicol 750 mg four times daily increased the tacrolimus trough blood level to more than 30 micrograms/L within 3 days. After 10 days, the dose of tacrolimus was reduced to 1.5 mg twice daily and the tacrolimus level fell to between 18 and 25 micrograms/L. Chloramphenicol was stopped 5 days later and the tacrolimus dose was increased to 3 mg twice daily. However, the tacrolimus level fell to below 5 micrograms/L for several days leading to an episode of acute organ rejection. The tacrolimus level then returned to within the therapeutic range and the patient stabilised.[4]

Mechanism

The authors suggest that chloramphenicol increased tacrolimus levels by rapidly inhibiting its metabolism.[2]

Importance and management

These appear to be the only reports of this interaction, but it is expected to be an interaction of general importance. It would be prudent to monitor the outcome closely if systemic chloramphenicol is given to any patient taking tacrolimus, being alert for the need to reduce the tacrolimus dose. It seems doubtful if a clinically relevant interaction will occur with topical chloramphenicol because the dose and systemic absorption are small, but this needs confirmation.

Tacrolimus + Ciclosporin

The manufacturers say that tacrolimus and ciclosporin should not be used concurrently because of the increased risk of nephrotoxicity.

Clinical evidence, mechanism, importance and management

One study found that, in patients with normal bilirubin levels, the half-life of ciclosporin was prolonged from a range of 6 to 15 hours up to 26 to 74 hours, and the ciclosporin serum levels, measured by a fluorescent polarisation immunoassay, were raised by tacrolimus.[1] On the other hand another study found no changes in the pharmacokinetics of ciclosporin, as measured by HPLC, in patients given tacrolimus, but creatinine levels were almost doubled (suggesting kidney damage),[2] which confirmed a previous report suggesting that severe renal impairment may develop when both drugs are given.[3] Tacrolimus levels may also be raised by ciclosporin.[4]

The manufacturers of tacrolimus say that it should not be given with ciclosporin because of the risk of additive/synergistic nephrotoxicity, and, if ciclosporin is being replaced by tacrolimus, 12 to 24 hours should elapse between stopping one drug and starting the other. If ciclosporin levels are raised, the introduction of tacrolimus should be further delayed.[4,5]

Tacrolimus + Cinacalcet

In a controlled study, cinacalcet had little effect on the pharmacokinetics of tacrolimus. However, a case report describes a marked fall in tacrolimus levels in a patient who started to take cinacalcet.

Clinical evidence

In a pharmacokinetic study in 6 kidney transplant patients taking tacrolimus, cinacalcet 30 mg daily for 7 days had minimal effects on the pharmacokinetics of tacrolimus. There was an average 14% reduction in the AUC of tacrolimus, with no change in the trough level and no change in the renal function.[1]

In clinical studies, no change in tacrolimus dose was needed in 5 patients when they were given cinacalcet, 30 mg daily then titrated to effect, for 6 months.[2,3]

However, there is one case report of a woman taking tacrolimus 4 mg twice daily who had a marked fall in tacrolimus levels (from 6.3 to 2.6 micrograms/L) one week after starting to take cinacalcet 30 mg daily. Increasing the dose of tacrolimus to 6 mg twice daily led to levels within the therapeutic range. Because of a rise in serum creatinine, cinacalcet was withdrawn and her tacrolimus levels rose from 6.6 micrograms/L to 8 micrograms/L. No further tacrolimus dose adjustment was required.[4]

Mechanism

The reason for the slight reduction in tacrolimus exposure in the pharmacokinetic study is unknown. Whether the marked reduction in the case report was actually due to cinacalcet, and the mechanism for this effect, is unknown. Cinacalcet is not an inhibitor of the cytochrome P450 isoenzyme CYP3A4, by which tacrolimus is principally metabolised and therefore this mechanism is not involved.

Importance and management

The minor reduction in tacrolimus levels in the pharmacokinetic study are unlikely to be clinically relevant, and this seems to be borne out in the few patients in clinical studies taking tacrolimus who were given cinacalcet for 6 months. However, the case report of a marked reduction in levels introduces a note of caution. Until further clinical experience is gained, it would be prudent to monitor tacrolimus levels more closely with concurrent use.

Tacrolimus + Corticosteroids

The concurrent use of tacrolimus and corticosteroids is very common but some evidence suggests that methylprednisolone may alter tacrolimus pharmacokinetics. Prednisone appears to reduce the levels of tacrolimus.

Clinical evidence, mechanism, importance and management

A review of early studies of tacrolimus stated that serum levels were said to have been increased on 10 occasions, decreased on 5 occasions, and unaltered on 2 occasions by **methylprednisolone**.[1]

In a randomised study conducted over 3 months, 31 patients receiving tacrolimus, mycophenolate and daclizumab were compared with 34 patients receiving tacrolimus, mycophenolate and **prednisone**. Higher tacrolimus doses were required to maintain therapeutic tacrolimus levels in the **prednisone** group. This reached a maximum after one month, when a 30% larger tacrolimus dose was necessary.[2] A further study found that patients taking higher doses of **prednisone** (more than 0.25 mg/kg daily) also needed larger doses of tacrolimus to maintain therapeutic trough blood levels. The authors considered that this was possibly due to induction of the cytochrome P450 isoenzyme CYP3A4 by **prednisone** and recommended that tacrolimus levels be closely monitored and adjusted according to any changes in corticosteroid dose.[3]

The concurrent use of tacrolimus and corticosteroids common and advantageous but be alert for any evidence of altered tacrolimus effects.

Tacrolimus + Danazol

An isolated report describes an increase in tacrolimus levels in a patient given danazol.

Clinical evidence, mechanism, importance and management

In a kidney transplant patient, the trough serum levels of tacrolimus 10 mg daily rose from 0.7 nanograms/mL to 2.7 nanograms/mL within 4 days of danazol 400 mg to 1.2 g daily being started. Despite a reduction in the danazol dose to 600 mg and then 400 mg daily, her tacrolimus levels and serum creatinine remained high for one month until the danazol was withdrawn.[1]

The reason for this effect is not known, but the authors suggest that danazol possibly inhibits the metabolism (demethylation and hydroxylation) of tacrolimus by the liver so that it is cleared from the body more slowly.[1]

Although this is an isolated case, it seems possible that it will be of general significance (compare 'Ciclosporin + Danazol', p.1236). Monitor the effects of concurrent use in any patient, reducing the tacrolimus dose as necessary.

Tacrolimus + Echinocandins

Caspofungin slightly decreases tacrolimus levels. Anidulafungin and micafungin do not appear to affect tacrolimus pharmacokinetics, and tacrolimus does not affect the pharmacokinetics of anidulafungin, caspofungin, or micafungin.

Clinical evidence, mechanism, importance and management

(a) Anidulafungin

Thirty-five healthy subjects were given a single 5-mg oral dose of tacrolimus 3 days before and on day 10 of a course of intravenous anidulafungin (200 mg loading dose and then 100 mg daily). Anidulafungin did not have any significant effects on the pharmacokinetics of tacrolimus and no serious adverse effects were reported. The pharmacokinetics of anidulafungin were not affected by tacrolimus.[1] No additional monitoring would seem to be required with this combination; however, bear in mind that the study above was a single-dose study in healthy subjects. Ideally, more study is required in patients taking long-term tacrolimus.

(b) Caspofungin

The preliminary results of one study in healthy subjects suggest that caspofungin reduces the AUC of tacrolimus by a modest 20%,[2] and reduces the trough tacrolimus levels by 26%.[3] Tacrolimus did not alter the pharmacokinetics of caspofungin.[2] However, in another study in 17 transplant patients taking tacrolimus, just 3 required a tacrolimus dose adjustment (no details given) when also given caspofungin.[4] In a small retrospective study of liver transplant patients, the concurrent use of tacrolimus and caspofungin did not appear to be associated with elevations of liver enzymes.[5]

The manufacturers of caspofungin advise that standard monitoring of tacrolimus levels should be undertaken if caspofungin is given, and the tacrolimus dose should be adjusted as appropriate.[3,6]

(c) Micafungin

Twenty-six healthy subjects were given single 5-mg doses of tacrolimus alone, after intravenous micafungin 100 mg, and one day after intravenous micafungin 100 mg daily for 5 days. The pharmacokinetics of tacrolimus were not affected by micafungin, and single-dose tacrolimus had no effects on the pharmacokinetics of micafungin.[7] Similarly, in a clinical study of patients given micafungin, there was no difference in micafungin blood levels, bilirubin or creatinine clearance between 7 patients taking tac-

rolimus (14 samples) and 22 patients not taking tacrolimus (26 samples).[8] No additional monitoring would seem to be required with this combination.

Tacrolimus + Food

Food decreases the rate and extent of tacrolimus absorption.

Clinical evidence

In a single-dose study in healthy subjects, giving tacrolimus capsules with a high-fat breakfast reduced the maximum tacrolimus level by 77%, delayed the time to maximum level by about 5 hours, and decreased the AUC by 33%, when compared with the fasting state. There was no change in the elimination half-life.[1] Slightly less marked findings were noted with a low-fat, high carbohydrate breakfast (65% and 26% reductions in maximum level and AUC, respectively, and about a 2 hour delay in time to maximum level.[1]

In another study in healthy subjects, taking tacrolimus 1.5 hours after a meal resulted in the same reduction in the AUC as when it was given immediately after a meal (39%), but the decrease in maximum level was slightly less (63% versus 71%).[2]

The manufacturers report that, in a study in 11 liver transplant patients, taking tacrolimus 15 minutes after a high-fat breakfast resulted in a 27% decrease in the AUC and 50% decrease in maximum levels when compared with the fasted state.[2,3] However, the effect was less pronounced in a study in kidney transplant patients given tacrolimus immediately after a continental breakfast, the AUC of tacrolimus was reduced by 2 to 12% and its maximum level was reduced by 15 to 38%.[3]

Mechanism

Unknown.

Importance and management

The extent of this interaction is likely to be clinically relevant.[1] The UK manufacturer advises that tacrolimus is taken on an empty stomach at least one hour before or 2 to 3 hours after a meal to optimise absorption.[3]

Tacrolimus + Grapefruit and other fruit juices

Grapefruit juice can markedly increase the levels of tacrolimus. Pomelo may interact similarly. An isolated case describes an increase in tacrolimus levels in a patient eating grapefruit marmalade.

Clinical evidence

(a) Grapefruit juice

Eight liver transplant patients were given 12 oz (about 360 mL) of grapefruit juice twice daily, which they drank within 45 minutes of taking their dose of tacrolimus. After one week it was found that their 12-hour trough, and one-hour and 4-hours post-dose tacrolimus levels were raised by 300%, 195%, and 400%, respectively. Two patients had headaches, one had diarrhoea and one had an increased creatinine level that reversed, but none developed irreversible toxicity. Two of the patients continued to drink the grapefruit juice and it was possible to halve their tacrolimus dose.[1] Similarly, 6 kidney transplant patients had their dose of tacrolimus reduced by an average of 40% after drinking 100 mL of grapefruit juice daily for 5 days.[2]

A hospitalised liver transplant patient was advised to drink grapefruit juice in an effort to increase her tacrolimus trough blood levels, which were subtherapeutic (below 5 nanograms/mL) despite a dose of tacrolimus 10 mg daily. She drank 250 mL of grapefruit juice four times over 3 days during which time the tacrolimus level did not increase. However, one week after she stopped the grapefruit juice the tacrolimus level was found to have increased to 37 nanograms/mL.[3]

(b) Other grapefruit products

A 52-year-old man with a liver transplant, stabilised on tacrolimus 3 mg twice daily, began to feel anxious and febrile with continued trembling and blurred vision. Within 5 days he deteriorated and developed severe left chest pain. His tacrolimus whole blood level was found to be markedly raised to 55.4 micrograms/L from a previous therapeutic level (between 8 and 13 micrograms/L), and he had renal impairment (serum creatinine of 174 micromols/L). It transpired that during the week preceding the onset of symptoms he had eaten more than 1.5 kg of a home-made marmalade, which was made with more than 50% grapefruit.

(c) Pomelo

A case report describes a kidney transplant patient taking tacrolimus whose tacrolimus level rose from a range of 8 to 10 nanograms/mL up to 25.2 nanograms/mL after he ate about 100 g of pomelo (*Citrus grandis*, a fruit related to grapefruit).[4]

Mechanism

Grapefruit juice inhibits the activity of the cytochrome P450 isoenzyme CYP3A4, mainly in the gut wall. Tacrolimus is primarily metabolised by CYP3A4 and so its bioavailability rises. Pomelo is related to grapefruit and therefore potentially interacts by the same mechanism. *In vitro*, pomelo juice and grapefruit juice extracts inhibited the cytochrome P450 isoenzyme CYP3A4, and had a lesser effect on P-glycoprotein (pomelo weaker than grapefruit).[5] However, the reason for the delayed rise in tacrolimus levels in the liver transplant patient is unclear.[3]

Importance and management

In practical terms the authors of the first report suggest that this interaction means that the dose of tacrolimus can possibly be reduced (to save money) although there is a clear need to monitor the effects closely not only because of the inter-individual factors affecting tacrolimus dosing but also because of the difficulties of standardising grapefruit juice.[1] However, the manufacturers of tacrolimus suggest that the combination should be avoided.[6,7] This would appear prudent. Patients should be informed of the potential risk of this interaction.

The case report with grapefruit marmalade appears to be isolated. As such, it requires confirmation by further study. Note that in this case, the patient consumed an unusually large amount of marmalade (estimated 14 dessert spoonfuls (15 g) daily). More modest consumption (a spoonful of about 15 g daily) would appear unlikely to interact.

Tacrolimus + H_2-receptor antagonists

Cimetidine might slightly increase tacrolimus levels, but famotidine and ranitidine do not appear to interact.

Clinical evidence

(a) Cimetidine

In a retrospective study in 48 kidney transplant patients, patients switched from cimetidine 400 mg daily to omeprazole 20 mg daily had a 15% decrease in their dose to weight-normalised tacrolimus trough levels.[1]

(b) Famotidine

In a transplant patient taking tacrolimus 8 mg daily with lansoprazole, tacrolimus levels of 12 to 15.4 nanograms/mL were achieved. However, when lansoprazole was replaced by famotidine, the tacrolimus levels were reduced to 8 nanograms/mL.[2,3] Another similar case has been reported.[4] In another patient, a slight decrease in tacrolimus levels (from a range of 8.3 to 8.5 nanograms/mL down to a range of 6.2 to 8.4 nanograms/mL) was seen when rabeprazole was switched to famotidine.[3]

(c) Ranitidine

In one case report, a marked increase in tacrolimus levels occurred when ranitidine was switched to omeprazole.[5]

Mechanism

Cimetidine is a known minor inhibitor of various cytochrome P450 isoenzymes, and so might be expected to slightly increase tacrolimus levels. The *decreased* tacrolimus levels in one study when stopping cimetidine and starting omeprazole would seem to support this suggestion (although the authors concluded that omeprazole may have induced tacrolimus metabolism, but this would be unexpected for omeprazole, see 'Tacrolimus + Proton pump inhibitors', p.1306). Other H_2-receptor antagonists do not inhibit any cytochrome P450 isoenzymes.

Importance and management

There is very little information available regarding an interaction between tacrolimus and the H_2-receptor antagonists. Cimetidine might slightly increase tacrolimus levels, although this may be of little general relevance. Other H_2-receptor antagonists are not expected to interact to a clinically relevant extent. The studies above found that when a proton pump inhibitor was substituted with ranitidine or famotidine, the increased tacrolimus levels caused by the proton pump inhibitor were not sustained by the H_2-receptor antagonist, supporting this predicted lack of an interaction. For more information on the modest interaction of the proton pump inhibitors with tacrolimus, see 'Tacrolimus + Proton pump inhibitors', p.1306.

Sirolimus or Tacrolimus + Imatinib

Imatinib modestly increases tacrolimus levels and is predicted to increase sirolimus levels.

Clinical evidence, mechanism, importance and management

One study, in patients with leukaemia who had undergone stem cell transplantation, found that the levels of tacrolimus were increased by 25 to 33% within 72 hours of starting imatinib. An empiric tacrolimus dose reduction of 25% at the start of imatinib treatment was found to prevent further serum level fluctuations.[1]

Imatinib is an inhibitor of the cytochrome P450 isoenzyme CYP3A4, and it would therefore be expected to increase the levels of immunosuppressants metabolised in this way (such as ciclosporin, tacrolimus and sirolimus.[2] P-glycoprotein might also be involved.

Although data is limited, based on the likely mechanism and increase in levels reported when imatinib was taken with other CYP3A4 substrates (such as simvastatin, see 'Statins + Imatinib', p.1337), it would be prudent to monitor tacrolimus, **ciclosporin** and sirolimus levels on starting or stopping imatinib.

Tacrolimus + Macrolides

Patients have had marked increases in tacrolimus levels accompanied by evidence of renal toxicity when they were also given erythromycin. The same interaction has been seen in patients given clarithromycin, and is predicted with josamycin and troleandomycin. One case report describes an increase in tacrolimus levels when azithromycin was given.

Clinical evidence

(a) Azithromycin

One report briefly describes a patient taking tacrolimus following a bone marrow transplant who took a 10-day course of azithromycin (dose not stated) without any significant alteration in his serum creatinine or trough tacrolimus levels.[1] However, in another case report, a patient who had been given intravenous tacrolimus 20 micrograms/kg had an increase in tacrolimus levels from a range of 15.8 to 17.5 nanograms/mL to greater than 30 nanograms/mL 3 days after azithromycin 500 mg daily was started.[2]

(b) Clarithromycin

A woman with a kidney transplant taking tacrolimus, prednisone and azathioprine was given clarithromycin 500 mg twice daily for 4 days, then 250 mg daily to treat a severe *Mycoplasma pneumoniae* infection. Despite a 64% reduction in the dose of the tacrolimus, the trough tacrolimus concentrations rose sharply, from 2.8 nanograms/mL to 36.1 nanograms/mL by day 6 and creatinine levels increased from 309 micromol/L to 442 micromol/L. The tacrolimus dose was further reduced and then stopped, and not restarted until clarithromycin treatment was completed.[3] In another 2 kidney transplant patients, tacrolimus levels increased by 146% and 131%, following 9 doses of clarithromycin 250 mg. Creatinine levels increased by 91% and 30%, respectively.[4] Similarly, the tacrolimus levels of a bone marrow transplant patient rose from below 1.1 nanograms/mL to 10.1 nanograms/mL after he took clarithromycin 500 mg twice daily for about 4 days.[1] A similar increase in tacrolimus levels has been reported in a heart transplant patient, despite an initial 33% reduction in the tacrolimus dose in anticipation of the interaction,[5] and in another kidney transplant patient.[6]

(c) Erythromycin

A liver transplant patient taking tacrolimus 6 mg twice daily for one year had a marked rise in serum tacrolimus levels from about 1.4 nanomol/L to 6.5 nanomol/L when intravenous ampicillin with sulbactam 3 g every 6 hours and oral erythromycin 250 mg every 6 hours were given for 4 days to treat pneumonia. Renal toxicity, demonstrated by increased blood urea and creatinine levels also occurred. Erythromycin was stopped, and the next day tacrolimus was also stopped. Over the next week the tacrolimus plasma levels, creatinine levels, and blood urea nitrogen fell.[7] A kidney transplant patient had an increase in his plasma tacrolimus levels from 1.3 nanograms/mL to 8.5 nanograms/mL 4 days after starting erythromycin 400 mg four times daily. His serum creatinine levels almost doubled.[8] A man with a kidney transplant had a sixfold rise in tacrolimus blood levels when he took erythromycin.[9] Another similar case has been described.[10] Two children aged 3 and 7 years also had rises in tacrolimus

blood levels, which were accompanied by renal toxicity when erythromycin was added.[11]

Mechanism

The macrolides inhibit tacrolimus metabolism by the cytochrome P450 subfamily CYP3A and inhibit its transport by P-glycoprotein. Azithromycin is less likely to interact with tacrolimus because it does not inhibit this subfamily,[12] although, as it might inhibit P-glycoprotein, an interaction cannot be entirely ruled out.

Importance and management

Direct information about an interaction between tacrolimus and the macrolides seems to be limited to these case reports. However, what is known is in line with the way both tacrolimus and these macrolides are known to interact with other drugs. It would therefore be prudent to closely monitor the effects of adding clarithromycin or erythromycin in any patient, being alert for the need to reduce the tacrolimus dose to avoid nephrotoxicity. Remember to reduce the tacrolimus dose when the macrolide is stopped. Most other macrolides would also be expected to interact, although they do not all behave identically. The manufacturers of tacrolimus name **josamycin**[13] and **troleandomycin**.[13,14] Note that troleandomycin is considered to be a more potent inhibitor of CYP3A4 than erythromycin, and may produce a greater increase in tacrolimus levels. Similar precautions would also be prudent with **telithromycin**.[15]

Azithromycin would appear less likely to interact, but the case report of increased tacrolimus levels should be borne in mind.

Tacrolimus + Metoclopramide

In an isolated case, metoclopramide may have increased tacrolimus levels, resulting in tacrolimus toxicity and acute renal failure.

Clinical evidence, mechanism, importance and management

A case report describes a liver transplant patient taking tacrolimus up to 28 mg twice daily (and several other drugs), whose subtherapeutic tacrolimus levels were increased when she took metoclopramide for gastric dysmotility (initially 10 mg four times daily, then 20 mg four times daily). Her tacrolimus trough levels increased from less than 2 nanograms/mL to greater than 30 nanograms/mL within 5 to 6 days, and she developed tremor, weakness, nausea, vomiting, diarrhoea and acute renal failure. The authors considered that the increase in tacrolimus levels was due to metoclopramide, possibly due to its effects in increasing gut motility and hence, tacrolimus absorption. However, several other factors may have contributed, such as diarrhoea and the use of cimetidine and ketoconazole, both of which can inhibit the metabolism of tacrolimus and increase its levels.[1]

This appears to be the only reported case of tacrolimus toxicity with metoclopramide, and because of the number of complicating factors, it is by no means established. Its general significance is unclear.

1. Prescott WA, Callahan BL, Park JM. Tacrolimus toxicity associated with concomitant metoclopramide therapy. *Pharmacotherapy* (2004) 24, 532–7.

Tacrolimus + Metronidazole

Two case reports describe increases in tacrolimus levels in patients also given metronidazole.

Clinical evidence

A kidney transplant patient taking tacrolimus 3 mg twice daily had a three-fold increase in his tacrolimus levels when he was given metronidazole 500 mg four times daily for 14 days. His trough level increased from 9.2 nanograms/mL to 26.3 nanograms/mL within 4 days of starting the metronidazole, requiring a tacrolimus dose reduction to 1 mg twice daily. Five days after stopping the metronidazole his trough level had returned to 9.2 nanograms/mL and his dose was increased back up to 2 mg twice daily.[1] A similar increase in tacrolimus trough levels was seen in a kidney transplant patient taking tacrolimus 3 mg in the morning and 2 mg at night. His tacrolimus level rose from 9 nanograms/mL to nearly 18 nanograms/mL when he started taking metronidazole 400 mg three times daily for a *C. difficile* infection. The tacrolimus dose was reduced to 1 mg twice daily and the tacrolimus level fell to 8.1 nanograms/mL. When the metronidazole was stopped, his tacrolimus level decreased further, to 5.2 nanograms/mL, and his tacrolimus dose needed to be increased to 2 mg twice daily.[2]

Mechanism

Unknown. It was suggested that metronidazole might be a weak inhibitor of the cytochrome P450 isoenzyme CYP3A4 or an inhibitor of P-glycoprotein.[1] As tacrolimus is metabolised by CYP3A4 and is also a substrate for P-glycoprotein, one or both of these mechanisms may be involved in this interaction.

Importance and management

These two cases appear to be the only reports of a possible interaction between tacrolimus and metronidazole. There is insufficient evidence to advocate monitoring in every patient given the combination, but it would be prudent to at least bear this interaction in mind if using metronidazole in patients taking tacrolimus.

Tacrolimus + Miscellaneous

The manufacturers advise caution on the concurrent use of tacrolimus with anticoagulants, antidiabetics, nephrotoxic and neurotoxic drugs, and also with various drugs that might alter tacrolimus metabolism.

Clinical evidence, mechanism, importance and management

(a) Isoniazid

The UK manufacturer of tacrolimus states that isoniazid has the potential to decrease tacrolimus levels.[1] However, note that there is little to suggest that isoniazid has any enzyme-inducing effects.

(b) Neurotoxicity or nephrotoxicity

The manufacturers of tacrolimus predict that there may be additive neuro- or nephrotoxicity on the concurrent use of **aciclovir**,[1] **aminoglycosides**,[1,2] **co-trimoxazole**,[1] **ganciclovir**,[1] **gyrase inhibitors**,[1] **NSAIDs**[1] (see 'Tacrolimus + NSAIDs', p.1304) or vancomycin.[1] They also note that nephrotoxicity has been seen when **amphotericin B** was given with tacrolimus.[1]

(c) Protein-binding interactions

Because tacrolimus is extensively bound to plasma proteins, the UK manufacturer mentions the possibility of protein-binding interactions with oral

anticoagulants or **antidiabetics**,[1] but this has largely been discredited as a mechanism, see 'Protein-binding interactions', (p.3).

(d) Other drugs

On the basis of *in vitro* studies, the UK manufacturer of tacrolimus suggests that **bromocriptine**, **dapsone**, **ergotamine**, **lidocaine**, **midazolam**, **quinidine** and **tamoxifen** might inhibit tacrolimus metabolism.[1] The US manufacturer mentions **bromocriptine** may increase tacrolimus levels.[2] These predictions are as yet unconfirmed, and note that these drugs are not generally considered to be associated with clinically significant interactions by inhibition of the cytochrome P450 isoenzyme CYP3A4, which is the main isoenzyme involved in tacrolimus metabolism.

Tacrolimus + NNRTIs

Limited evidence from case reports suggests that efavirenz increases tacrolimus clearance. Nevirapine possibly has less effect. Etravirine is predicted to interact similarly, whereas delavirdine is predicted to decrease tacrolimus clearance.

Clinical evidence

(a) Efavirenz

A kidney transplant patient taking efavirenz 600 mg daily and two nucleoside analogues needed a much larger than expected tacrolimus dose of 24 mg daily to maintain a tacrolimus level of 12.5 nanograms/mL.[1,2] In another study in 4 transplant patients taking stable doses of tacrolimus and various other drugs including fluconazole, the addition of efavirenz and two nucleoside analogues had little effect on the required dose of tacrolimus, but the calculated oral clearance of tacrolimus was almost doubled. In two of these patients for whom a detailed pharmacokinetic analysis was available, one had a 51% decrease in tacrolimus trough level (from 16.1 to 7.9 nanograms/mL) and the other just a 12% decrease in the tacrolimus trough level.[3]

(b) Nevirapine

One case report mentions that a liver transplant patient taking nevirapine and dual nucleoside analogues was maintained on tacrolimus 1 mg daily.[4] In another report, two kidney transplant patients taking nevirapine and dual nucleoside analogues were maintained on tacrolimus 4 mg daily.[1,2]

(c) NNRTIs with protease inhibitors

Adding an NNRTI (efavirenz or nevirapine) to a protease inhibitor required a modest 40% increase in the tacrolimus dose to 1 mg, and a big decrease in the dosing interval (every 12 hours instead of once every 80 hours).[5]

Mechanism

Efavirenz, etravirine and nevirapine generally act as inducers of the cytochrome P450 isoenzyme CYP3A4 by which tacrolimus is metabolised (although note that etravirine is only a weak inducer[6]). As such, they would be expected to decrease tacrolimus levels. The effect of efavirenz in one study may have been attenuated by fluconazole (which may inhibit CYP3A4). NNRTIs slightly attenuated the effect of protease inhibitors on tacrolimus metabolism.

Note that delavirdine *inhibits* CYP3A4 and is predicted to *increase* tacrolimus levels.[7]

Importance and management

There is some evidence that efavirenz increases the clearance of tacrolimus and increases the required dose, whereas there is limited evidence that nevirapine has little effect on the required dose. However, until further data becomes available, it would seem prudent to closely monitor tacrolimus levels in any patient given efavirenz or nevirapine, because of the possibility they may decrease tacrolimus levels. The effect of etravirine on tacrolimus metabolism has not been studied. The manufacturer[6] predicts that it will decrease tacrolimus levels; however, this is likely to be to a lesser degree than efavirenz or nevirapine.

In contrast, delavirdine is predicted to increase tacrolimus levels and so may require tacrolimus dose reductions. Until further information is available, it would be prudent to monitor tacrolimus levels closely in patients also given delavirdine.

Tacrolimus + NSAIDs

Two liver transplant patients taking tacrolimus developed acute renal failure after also taking ibuprofen. However, the concurrent use of an NSAID use did not appear to be a contributor to tacrolimus renal toxicity in a study in rheumatoid arthritis patients.

Clinical evidence

Two patients with liver transplants taking tacrolimus developed acute but reversible renal failure, one after taking four **ibuprofen** tablets (strength not stated) and the other after taking three 400-mg tablets of **ibuprofen** taken over 24 hours. Both had stable renal function before taking **ibuprofen**.[1]

However, in another study of the use of tacrolimus in patients with rheumatoid arthritis, the concurrent use of an NSAID use did not appear to influence the renal toxicity of tacrolimus. In this study, increases in creatinine levels of 40% or more above baseline occurred in 9% of patients receiving tacrolimus 1 mg daily, 19% of patients receiving 3 mg daily, and 28% of patients receiving 5 mg daily, and required tacrolimus discontinuation in 2 patients taking 3 mg daily and 7 patients taking 5 mg daily. Stable NSAID therapy (specific drugs not stated) was used in 68 to 81% of patients. The frequency of NSAID use was not higher in patients who developed creatinine elevations, nor was it higher in those who discontinued tacrolimus because of creatinine elevations (about half of the patients who discontinued tacrolimus were taking NSAIDs).[2]

Mechanism

NSAIDs are known to inhibit prostaglandin synthesis and as a result may decrease renal blood flow, which in certain circumstances can lead to renal failure. Renal impairment is more likely to occur in the presence of renal vasoconstrictors. Tacrolimus is known to cause renal vasoconstriction and thus the combined effects of ibuprofen and tacrolimus may have led to acute renal failure. Both patients also had a degree of liver impairment, which the authors suggest may have potentiated the toxicity of tacrolimus with ibuprofen.[1]

Importance and management

Renal impairment with tacrolimus is well known and renal function should be routinely monitored. Whether NSAIDs can contribute to this is uncertain. However, the risk of renal impairment may be increased by other nephrotoxic drugs, and the UK manufacturer lists NSAIDs in this category.[3] Some caution would seem appropriate with concurrent use, taking into account the usual precautions for both NSAIDs and tacrolimus in renal impairment.

Tacrolimus + Nystatin

Nystatin oral suspension did not alter tacrolimus levels in one study.

Clinical evidence, mechanism, importance and management

In a study, 18 kidney transplant patients taking tacrolimus 150 micrograms/kg twice daily were given nystatin oral suspension 5 mL four times daily for the prophylaxis of oral thrush immediately following transplantation. Tacrolimus levels measured on days 1, 3, 5 and 7 were not affected by the use of nystatin.[1] It would appear that nystatin has no significant affect on the absorption of tacrolimus, and therefore no tacrolimus dose adjustment would appear to be necessary on concurrent use.

Tacrolimus + Orlistat

In patients adhering to recommended dietary fat intake, orlistat does not appear to significantly affect the pharmacokinetics of tacrolimus, although small dose adjustments may be needed in some patients.

Clinical evidence, mechanism, importance and management

In a study in 12 liver transplant patients taking tacrolimus with orlistat 120 mg three times daily for 6 months, there was no statistically significant difference in the tacrolimus dose or trough-level to daily-dose ratio at any time point. However, 4 patients required a reduction and 2 required an increase in their tacrolimus dose, although these adjustments were only minor dose changes. No elevations in liver enzymes were seen and no episodes of rejection occurred. No diarrhoea was reported by the patients in this study, which suggests that the patients adhered well to the dietary advice regarding fat intake. In this study, patients took their morning tacrolimus dose 30 minutes before orlistat, and then ate breakfast after a further 30 minutes. In the evening the patients took orlistat 30 minutes before dinner, and took their evening dose of tacrolimus 2 hours later.[1] The authors concluded that orlistat could be safely used in patients taking tacrolimus provided that tacrolimus levels are carefully monitored. They do however caution that there is a possibility that transplant patients who do not follow dietary fat advice and develop diarrhoea or steatorrhoea when taking orlistat may need a more marked adjustment of their tacrolimus dose.[1]

Tacrolimus + Phosphodiesterase type-5 inhibitors

Sildenafil does not affect the pharmacokinetics of tacrolimus. The levels of sildenafil were reported to be higher in patients taking tacrolimus than in healthy subjects. A marked blood pressure drop occurred when both drugs were given in one study, and two patients required modification of their antihypertensives in another. Vardenafil does not appear to affect tacrolimus levels.

Clinical evidence

(a) Sildenafil

In 10 men with erectile dysfunction taking tacrolimus after a kidney transplant, a single 50-mg dose of sildenafil did not affect the pharmacokinetics of tacrolimus. When the pharmacokinetics of sildenafil were compared with those quoted by the manufacturer for healthy subjects, it was found that the maximum plasma concentration and AUC of sildenafil were increased by 44% and 90%, respectively, in patients taking tacrolimus. The AUC of the sildenafil metabolite was also raised. Apart from the pharmacokinetic effects, it was noted that the mean blood pressure dropped by 27/20 mmHg after sildenafil was given.[1] A subsequent study by the same authors in 9 men with erectile dysfunction taking tacrolimus after a kidney transplant, found that sildenafil 25 mg daily for 9 days had no significant effects on the trough levels or half-life of tacrolimus. Mean arterial blood pressure was reduced (by 1 to 7 mmHg, but this was not statistically significant), and 2 patients required a reduction in dose of their antihypertensives.[2]

Another study in 4 patients taking tacrolimus found that sildenafil 50 or 100 mg did not affect tacrolimus trough levels.[3]

(b) Vardenafil

In a study in kidney transplant patients, vardenafil 10 or 20 mg (maximum frequency of once in 24 hours) in repeated doses during a 4-week period had no effect on the levels or required dose of tacrolimus, and no change in renal function was reported.[4]

Mechanism

There are several possible reasons for the apparent increase in sildenafil levels in transplant patients other than a direct effect of tacrolimus. The pharmacokinetic data quoted by the manufacturer are from healthy subjects, not patients, and the patients in the study were taking a multitude of other drugs, some of which could have affected sildenafil.

Importance and management

It would appear that sildenafil does not affect tacrolimus levels; however, given the reduction in blood pressure seen in two studies,[1,2] it may be prudent to start patients on a 25-mg dose of sildenafil, as the authors of this study advise, and increase the dose according to efficacy and tolerability. Vardenafil also does not appear to affect tacrolimus levels, but the effects on blood pressure do not appear to have been studied.

Tacrolimus + Potassium-sparing diuretics

The concurrent use of tacrolimus and potassium-sparing diuretics may cause hyperkalaemia.

Clinical evidence, mechanism, importance and management

Tacrolimus alone can cause hyperkalaemia, especially if renal function is impaired, and the risk might be additive with potassium-sparing drugs. Because of this, the manufacturers suggest that tacrolimus should not be used with potassium-sparing diuretics,[1,2] such as **amiloride**, **triamterene**, and **spironolactone**.[2] **Eplerenone** may also cause hyperkalaemia, and similar precaution would seem appropriate. It would be prudent to closely monitor potassium levels and renal function if the concurrent use of any of these diuretics is considered essential.

Tacrolimus + Protease inhibitors

Protease inhibitors markedly inhibit the metabolism of tacrolimus and increase its levels. The available evidence suggests the effect is most apparent with ritonavir-boosted regimens.

Clinical evidence

In transplant patients taking tacrolimus and started on a protease inhibitor-based regimen, the tacrolimus dose was reduced by 80% (to 700 micrograms) and the dosing interval markedly increased to just once every 80 hours. This effect was attenuated somewhat when 'NNRTIs', (p.1304), were additionally given.[1] In another case series, the average

tacrolimus dose was 1 to 3 mg *weekly* in patients taking a protease inhibitor (mostly nelfinavir).[2] Another report briefly mentions that 4 HIV-positive kidney transplant patients taking a protease inhibitor (not specified) required a dramatic tacrolimus dose reduction, and 3 of them needed a change from a protease inhibitor to an NNRTI.[3]

(a) Fosamprenavir

Four transplant patients needed an average threefold increase in the dose of tacrolimus (from about 290 to 880 micrograms daily) when their protease inhibitor was changed from **nelfinavir** to fosamprenavir.[4]

(b) Nelfinavir

An HIV-positive patient, with hepatitis C following a liver transplant, was given stavudine, lamivudine, and nelfinavir 500 mg three times daily. Tacrolimus 6 mg daily was started postoperatively, but high blood levels were observed and the dose was reduced over the next 3 months to a maintenance dose of 500 micrograms *weekly*, which achieved levels of 7 to 25.9 nanograms/mL.[5] In one case series, the required dose of tacrolimus varied between 500 micrograms once every 5 days and 1 mg every other day in 4 patients taking nelfinavir-based antiretroviral regimens.[6,7] Similar decreased tacrolimus dose requirements have been noted in other patients given nelfinavir (500 micrograms every 3 days[8] or weekly[9] or a 75 to 93% reduction in daily dose[10]).

A brief report describes petit mal seizures brought on by high tacrolimus levels, which were thought to be due to an interaction with nelfinavir.[11] One report mentions a patient who developed acute cellular rejection progressing to chronic rejection due to low tacrolimus levels when nelfinavir was stopped without an increase in the tacrolimus dose.[2]

(c) Ritonavir-boosted protease inhibitors

1. Lopinavir. A liver transplant patient taking tacrolimus 5 mg twice daily (to give a tacrolimus trough blood level of 10.6 nanograms/mL) had a large increase in tacrolimus levels to 78.5 nanograms/mL when ritonavir-boosted lopinavir was started, despite a tacrolimus dose reduction to 6 mg daily. Tacrolimus neurotoxicity developed, but no nephrotoxicity was seen. The patient was eventually stabilised taking tacrolimus 500 micrograms *weekly* while taking ritonavir-boosted lopinavir.[9] Two other patients taking ritonavir-boosted lopinavir developed raised tacrolimus levels and were eventually stabilised on tacrolimus doses of 500 micrograms to 1 mg weekly.[9,12] A further patient was unable to tolerate tacrolimus with ritonavir-boosted lopinavir and was switched to nelfinavir.[9] In seven liver transplant patients taking tacrolimus, the tacrolimus dose needed to be reduced by 99% (to about 20 to 250 micrograms daily) when ritonavir-boosted lopinavir was started. Maintenance doses of tacrolimus in these patients varied from 500 micrograms to 1.5 mg, given between once weekly and just once every 25 days.[10]

2. Saquinavir. A case report describes an HIV-positive patient taking ritonavir-boosted saquinavir 100/800 mg twice daily who developed a very high tacrolimus level (200 micrograms/L) 5 days after starting tacrolimus 5 mg twice daily after a kidney transplant. The tacrolimus dose was reduced tenfold to 500 micrograms twice daily, and by 15 months post-transplant he was stabilised on just 500 micrograms *weekly*.[13] In another case, a patient had a tacrolimus level of 10.9 nanograms/mL while taking tacrolimus 4 mg twice daily without antiretrovirals. When he was given ritonavir-boosted saquinavir, a reduced dose of tacrolimus 1 mg twice daily resulted in tacrolimus levels in excess of 120 nanograms/mL, with severe and prolonged toxicity.[8]

Mechanism

All protease inhibitors are, to varying degrees, potent inhibitors of the cytochrome P450 isoenzyme CYP3A4, by which tacrolimus is metabolised. It therefore seems likely that the protease inhibitors reduced tacrolimus metabolism resulting in the extremely high levels seen. The protease inhibitors also inhibit P-glycoprotein, of which tacrolimus is a substrate. It has been suggested that this could lead to increased levels of unmetabolised tacrolimus in the bile which may be reabsorbed through the enterohepatic circulation system, thus further increasing tacrolimus levels.[9]

Importance and management

An established and clinically important interaction. When protease inhibitors, particularly ritonavir, are given to patients taking tacrolimus, a marked reduction in the dose of tacrolimus is required, with close and frequent monitoring of tacrolimus levels. One centre found that the average tacrolimus dose needed was just 1 mg to 3 mg *weekly* in patients taking a protease inhibitor-based HAART regimen (mostly nelfinavir).[2] In another centre, the average tacrolimus dose required was 700 micrograms every 80 hours (3.3 days).[1] In yet another centre, in patients specifically taking ritonavir-boosted lopinavir, the required tacrolimus dose was just 0.5 to 1.5 mg given between once *weekly* and just once every 25 days.[10] The effect of fosamprenavir appears to be less than that of nelfinavir.[4]

Tacrolimus + Proton pump inhibitors

Lansoprazole may increase tacrolimus levels, and the extent of the interaction might depend on the metaboliser status of the patient. Pantoprazole and omeprazole are predicted to interact similarly, although there is some evidence of a lack of interaction for both these drugs. Rabeprazole does not appear to have a clinically significant effect on tacrolimus levels.

Clinical evidence

(a) Lansoprazole

A 57-year-old woman taking tacrolimus following a kidney transplant started taking lansoprazole 30 mg daily 19 days after her transplant because of a peptic ulcer. After 3 days her tacrolimus trough level rose from a range of 16.3 to 17.6 nanograms/mL up to 26.7 nanograms/mL. The tacrolimus dose was reduced, and levels of 12 to 15.4 nanograms/mL were achieved. When lansoprazole was replaced by famotidine, the tacrolimus levels reduced to 8 nanograms/mL[1,2] Two other very similar cases have been reported in Japanese transplant patients,[3,4] and in all these cases the patients were CYP2C19 poor metabolisers (those lacking or deficient in this isoenzyme).

In a pharmacokinetic study in 19 healthy Japanese subjects, lansoprazole 30 mg daily for 4 days increased the $AUC_{0\text{-}8}$ of tacrolimus by 48% and decreased its clearance by 31% when a single 2-mg dose of tacrolimus was given with the lansoprazole on day 4. When divided by CYP2C19 metaboliser status, the increase in AUC was 52% greater in the 11 intermediate or poor metabolisers, than in the 8 extensive metabolisers (that is, those with normal levels of this isoenzyme), although there was wide variability between subjects.[5] However, in another study in 40 transplant patients taking tacrolimus and lansoprazole 30 mg daily, the degree of the interaction appeared to be influenced more by CYP3A5 genetic polymorphisms than CYP2C19 genetic polymorphisms.[6]

(b) Omeprazole

In a study in 51 kidney transplant patients taking tacrolimus and omeprazole 20 mg daily for 6 months after transplantation, there was no differ-

ence in the tacrolimus level to dose ratio in the 3 months before stopping omeprazole and the 3 months after stopping omeprazole.[7] However, a retrospective study in 48 kidney transplant patients found that when patients switched from cimetidine 400 mg daily to omeprazole 20 mg daily there was a 15% decrease in the dose to weight-normalised tacrolimus trough levels.[8]

In contrast, a case report of a 13-year-old transplant patient, describes a marked increase in tacrolimus trough levels (from around 10 nanograms/mL up to 28 nanograms/mL) and an increase in serum creatinine when omeprazole 20 mg daily was started, both of which resolved on stopping the omeprazole. This patient was not a CYP2C19 poor metaboliser.[9] Another similar case is reported (genetic status unknown).[10]

(c) Pantoprazole

A study in 6 transplant patients taking tacrolimus found that pantoprazole 40 mg daily for 5 days did not significantly affect the trough levels of tacrolimus.[11]

(d) Rabeprazole

One patient who had a rise in tacrolimus levels while taking lansoprazole was later given rabeprazole 10 mg daily without any alteration in tacrolimus levels.[1,2] Two other reports also describe a lack of interaction between rabeprazole and tacrolimus.[4,10] Another report describes a patient who had no significant alteration in tacrolimus levels when rabeprazole 10 mg daily was started and stopped.[2]

In a pharmacokinetic study in 15 healthy Japanese subjects, rabeprazole 10 mg daily for 4 days slightly increased the AUC_{0-8} of tacrolimus by 18% when a single-dose of tacrolimus 2 mg was given with the rabeprazole on day 4, but this change was not statistically significant.[5]

Mechanism

Uncertain. In some of the cases and one study, the interaction with lansoprazole was greatest in patients with decreased activity of the cytochrome P450 isoenzyme CYP2C19, by which lansoprazole (and also esomeprazole, omeprazole and pantoprazole) is mainly metabolised. When levels of this isoenzyme are low, lansoprazole levels are much higher, and it has been suggested that this might be sufficient to inhibit tacrolimus metabolism by CYP3A4 and/or affect transport by P-glycoprotein (which is inhibited to some extent by all the proton pump inhibitors).[5] If this is the mechanism, then **esomeprazole**, omeprazole and **pantoprazole** would be expected to interact similarly. Nevertheless, one study suggested that CYP3A5 metaboliser status was more important than CYP2C19 metaboliser status or P-glycoprotein.[6] Rabeprazole is principally metabolised non-enzymatically and seems less likely to interact,[1,2,5] although one study found no difference between rabeprazole and lansoprazole.[6]

The *decreased* tacrolimus levels in one study with omeprazole was thought to be due to induction of CYP3A4 by omeprazole,[8] but may have been more to do with stopping the cimetidine (a known enzyme inhibitor) than an effect of omeprazole. Further study is required.

Importance and management

The incidence of the interaction between tacrolimus and lansoprazole is unknown. There is some evidence that it is most likely in those with decreased CYP2C19 activity,[5] although not all evidence supports this.[6,9] As metaboliser status is rarely known, it is not possible to predict which patients would be affected. No interaction was seen in the one study with pantoprazole or one study with omeprazole, although there are a couple of case reports with omeprazole. Some evidence suggests that rabeprazole is less likely to interact and may be a suitable alternative, but not all evidence supports this. Further detailed pharmacokinetic study is required for all proton pump inhibitors. Until more is known, bear the possibility of an interaction in mind and give consideration to increasing the monitoring of tacrolimus levels when any of these drugs are started or stopped, taking into account the significance of a potential increase in levels to the individual patient.

Tacrolimus + Quinolones

Levofloxacin modestly increased the bioavailability of tacrolimus in one study.

Clinical evidence, mechanism, importance and management

A study in 5 kidney transplant patients found that **levofloxacin** 500 mg twice daily for 5 days increased the AUC_{0-12} of tacrolimus by about 27%.[1] The authors concluded that levofloxacin inhibits the metabolism of tacrolimus, but levofloxacin is not a known inhibitor of the principal mechanisms of tacrolimus elimination (the cytochrome P450 isoenzyme CYP3A4 and P-glycoprotein).

The one available study suggests that a modest increase in tacrolimus levels might occur in patients given levofloxacin, but this is probably not likely to be clinically relevant for a short course of the antibacterial. Nevertheless, the authors of this study suggest that close monitoring would be appropriate if tacrolimus is given with levofloxacin.[1] Further study is needed.

Tacrolimus + Quinupristin/Dalfopristin

Quinupristin/dalfopristin may modestly increase tacrolimus levels. There is limited evidence suggesting that tacrolimus might increase the risk of myalgia and/or arthralgia occurring with quinupristin/dalfopristin.

Clinical evidence

The manufacturer states that the concurrent use of quinupristin/dalfopristin has been reported to increase the trough levels of tacrolimus by 15%.[1]

In an analysis of myalgia and/or arthralgia occurring with quinupristin/dalfopristin in cancer patients, the use of tacrolimus within the month preceding treatment was associated with a higher risk. Seven (35%) of the patients experiencing myalgia and/or arthralgia had received tacrolimus compared with 4 (11%) of those not experiencing myalgia and/or arthralgia.[2]

Mechanism

Quinupristin/dalfopristin is an inhibitor of the cytochrome P450 isoenzyme CYP3A4, the main isoenzyme involved in the metabolism of tacrolimus.[1,3] Concurrent use therefore leads to decreased tacrolimus metabolism and increased levels. Myalgia and/or arthralgia are common in patients receiving quinupristin/dalfopristin and their aetiology is uncertain. It was suggested that tacrolimus-induced impairment in biliary function/cholestasis might predispose patients to develop myalgia and/or arthralgia with quinupristin/dalfopristin.[2]

Importance and management

Although the increase in trough tacrolimus levels with quinupristin/dalfopristin is modest, it might be prudent to monitor tacrolimus levels more closely during concurrent use.[1,3] Bear in mind the possibility that tacrolimus use might increase the risk of myalgia and/or arthralgia with quinupristin/dalfopristin. The US manufacturer of quinupristin/dalfopristin notes that improvement has been noted in some patients with this adverse effect when the dose frequency has been extended.[3]

Tacrolimus + Repaglinide

Repaglinide does not appear to alter tacrolimus levels.

Clinical evidence, mechanism, importance and management

In a study in kidney transplant patients stabilised on immunosuppressants, the concurrent use of repaglinide in the 14 patients taking tacrolimus did not appear to cause any significant changes in tacrolimus blood levels and no tacrolimus dose changes were required on starting repaglinide 1 to 3 mg daily (mostly as monotherapy but a few patients were also given either metformin or rosiglitazone).[1] It would appear from the limited data from this observational study, that a significant pharmacokinetic interaction between tacrolimus and repaglinide does not occur; however, this ideally needs confirmation in a pharmacokinetic study.

Tacrolimus + Rifamycins

A number of liver transplant patients have needed markedly increased tacrolimus doses when rifampicin (rifampin) was added. A pharmacokinetic study found that rifampicin increases the clearance and decreases the bioavailability of intravenous and oral tacrolimus. One case report demonstrates that rifabutin does not interact to the same extent as rifampicin (rifampin).

Clinical evidence

(a) Rifabutin

A renal transplant patient developed low tacrolimus levels (3.7 to 5.5 nanograms/mL) despite an increase in dose from 16 to 60 mg daily while taking rifampicin 600 mg daily. When the rifabutin was substituted for rifampicin, the tacrolimus doses were gradually reduced to 20 mg daily with serum levels between 10 and 15 nanograms/mL.[1]

(b) Rifampicin (Rifampin)

The trough tacrolimus blood levels of a 10-year-old boy with a liver transplant fell from 10 nanograms/mL to unmeasurable levels within 2 days of rifampicin 150 mg twice daily being started. His tacrolimus dose was therefore doubled from 4 to 8 mg twice daily. When rifampicin was later stopped, the tacrolimus dose had to be reduced to 3 mg twice daily to keep the blood levels in the region of 10 nanograms/mL.[2]

Various other similar cases have been reported.[1,3-7] In one of these, a tenfold increase in the tacrolimus dose was needed to keep trough blood levels within the target range when rifampicin was started. However, despite levels within the acceptable range, a biopsy showed suspected tacrolimus nephrotoxicity, which was considered to be possibly due to the cumulative tacrolimus dose, or to high levels of tacrolimus metabolites (which were not measured).[5] In another case, a decrease in tacrolimus levels from 9.2 nanograms/mL to 1.4 nanograms/mL occurred just 2 days after starting rifampicin. Rifampicin was stopped and replaced by pyrazinamide, with a gradual return to the baseline tacrolimus level.[6] In yet another case, the effect of rifampicin was so potent that the use of either 'fluconazole', (p.1296), or 'clarithromycin', (p.1302), both known inhibitors of tacrolimus metabolism, did not increase tacrolimus levels.[7]

A study in 6 healthy subjects supports the findings of these case reports. In the study, rifampicin 600 mg daily for 18 days markedly decreased the AUC of tacrolimus after both oral and intravenous administration (by 68% and 35%, respectively). The oral bioavailability of tacrolimus was halved.[8]

Mechanism

This interaction is thought to occur because rifampicin (rifampin), a known enzyme inducer, increases the metabolism of tacrolimus by the cytochrome P450 isoenzyme CYP3A4 in the liver and small bowel, and induces P-glycoprotein, so that tacrolimus is cleared more rapidly. Rifabutin is a less potent enzyme inducer than rifampicin, and therefore has less effect on tacrolimus metabolism.

Importance and management

An established and clinically important interaction. Anticipate the need to increase the dose of tacrolimus, sometimes markedly, if rifampicin (rifampin) is also given. Note that if the interaction is not managed well in patients given tacrolimus post-transplant, there is a risk of transplant rejection.

The one case report with rifabutin suggests that any interaction with tacrolimus is much less marked than with rifampicin. Nevertheless, until the situation is clearer, it would be prudent to closely monitor concurrent use with other rifamycins (for example, **rifapentine** is a moderate CYP3A4 inducer), being alert for the need to increase the tacrolimus dose.

Tacrolimus + Schisandra

Schisandra greatly increases tacrolimus levels and its adverse effects.

Clinical evidence

In a pharmacokinetic study, 12 healthy subjects were given an extract of *Schisandra sphenanthera* (containing 33.75 mg schizandrin) twice daily for 14 days, with a single 2-mg oral dose of tacrolimus on day 14. The extract of *Schisandra sphenanthera* increased the AUC and maximum plasma concentrations of tacrolimus by 164% and 227%, respectively, but did not alter its half-life. Six of the 12 subjects experienced indigestion, and burning hands and feet, one hour after both medicines were given. These symptoms resolved over 10 hours.[1]

Mechanism

Not established. P-glycoprotein is involved in the intestinal absorption of tacrolimus. It is therefore possible that the inhibition of P-glycoprotein by schizandrin, and possibly other related compounds, may have resulted in increased absorption of tacrolimus. The authors also suggest that the metabolism of tacrolimus, which is a substrate of the cytochrome P450 isoenzyme CYP3A4, may have been inhibited by schisandra. However, one *animal* study suggests that this effect on CYP3A4 may not be clinically relevant.[2]

Importance and management

An interaction between schisandra and tacrolimus seems fairly well established, although the mechanism is not fully established. Concurrent use

appears to result in a large rise in tacrolimus levels, accompanied by an increase in tacrolimus adverse effects. If the use of both medicines is considered desirable it would seem prudent to monitor the outcome of concurrent use closely, adjusting the tacrolimus dose as necessary. It is important to note that, although the schisandra product used in the study was standardised for schizandrin content, this constituent has not been established as the cause of the interaction. Therefore the extent of the interaction may vary between different schisandra products, and different batches of the same schisandra product. This may make this interaction difficult to standardise for, and therefore it may be prudent to avoid concurrent use where tacrolimus blood levels are critical, such as in organ transplantation.

Tacrolimus + Sevelamer

Sevelamer may reduce the absorption of tacrolimus.

Clinical evidence, mechanism, importance and management

A kidney transplant patient had a progressive reduction in his tacrolimus levels requiring an increase in his tacrolimus dose after he started to take sevelamer 800 mg three times daily. A pharmacokinetic study in the same patient found that the peak tacrolimus level was increased from 9.9 nanograms/mL to 13.1 nanograms/mL, and the AUC_{0-7} was increased 2.4-fold, three days after sevelamer was stopped.[1] Sevelamer can bind with drugs in the gut and prevent their absorption, and this may have lead to the reduction in tacrolimus levels seen.

This appears to be the only case report of an interaction between these two drugs, but sevelamer has been seen to have similar effects on the absorption of a number of other drugs. It is recommended that any drug for which a reduction in the bioavailability may be clinically significant (the UK manufacturer specifically names tacrolimus[2]) should be taken at least one hour before or 3 hours after sevelamer, or their concentrations should be monitored.[2,3] Tacrolimus levels should be closely monitored and the dose adjusted as needed if concurrent use is required or if sevelamer is stopped.

3. Renagel (Sevelamer hydrochloride). Genzyme. US Prescribing information, November 2007.

Tacrolimus + Sirolimus

No pharmacokinetic interaction occurred between tacrolimus and sirolimus in healthy subjects, but there is clinical evidence that sirolimus may modestly reduce tacrolimus blood levels. Tacrolimus does not appear to alter sirolimus levels.

Clinical evidence and mechanism

A single-dose study in 28 healthy subjects found that, compared with either drug alone, there was no pharmacokinetic interaction between sirolimus and tacrolimus when they were given either at the same time or 4 hours apart.[1] A study in 18 liver transplant and 7 kidney-pancreas transplant patients taking tacrolimus and sirolimus found no difference in the pharmacokinetics of either drug when the drugs were taken either simultaneously or 4 hours apart. No nephrotoxicity was seen.[2]

However, subsequent studies have found decreases in tacrolimus levels due to the concurrent use of sirolimus. A study in 7 children with kidney transplants taking tacrolimus and prednisone found that the addition of sirolimus to treat chronic allograft nephropathy resulted in a decrease in dose-normalised tacrolimus trough blood levels from 0.14 kg/L, to 0.1 kg/L on day 3 and to 0.08 kg/L on day 28. All patients required a tacrolimus dose increase, with a mean increase of about 70% (range 22 to 245%) in order to keep the tacrolimus blood levels above 3 nanograms/mL. This was thought to be due to a reduction in the bioavailability of tacrolimus rather than increased excretion.[3] Another study in 28 kidney transplant patients taking tacrolimus and given sirolimus 500 micrograms, 1 mg, or 2 mg daily also found an initial reduction in the tacrolimus level with the first dose. The tacrolimus levels recovered, but a trend towards reduced tacrolimus levels was seen with continued dosing. Tacrolimus did not appear to alter sirolimus levels, when compared with previous data in studies with sirolimus alone.[4] The US manufacturer of tacrolimus includes a study in which use of tacrolimus and sirolimus (2 or 5 mg daily) in stable kidney transplant patients decreased the AUC and trough level of tacrolimus by about 30% relative to tacrolimus alone. With a lower dose of 1 mg of sirolimus daily, the tacrolimus AUC and trough level decreased by about 3% and 11%, respectively.[5]

A study in 16 adult kidney transplant patients taking tacrolimus and fixed-dose sirolimus 500 micrograms or 2 mg daily found a significant, dose-dependent increase in the AUC of tacrolimus of 16% and 31%, respectively, and an increase in the peak levels of tacrolimus of 19% and 33%, respectively, when sirolimus was stopped.[6]

A retrospective study in adult kidney transplant patients taking tacrolimus and sirolimus found that concurrent use may be associated with extensive tubular cell injury and a unique form of cast nephropathy.[7]

The manufacturers of sirolimus note that clinical studies in *de novo* liver transplant patients have found an increased risk of hepatic artery thrombosis when tacrolimus is also given,[8,9] and in the US concurrent use is not recommended in this patient group.[9] The US manufacturer of sirolimus also notes that a study in *de novo* liver transplant patients found an increased risk of graft loss and mortality in patients also taking tacrolimus.[9]

Moreover, the US manufacturer of tacrolimus notes that the use of full-dose tacrolimus with sirolimus 2 mg daily in heart transplant recipients was associated with increased risk of wound healing complications, impaired renal function, and post-transplant insulin-dependent diabetes mellitus, and is not recommended.[5]

Importance and management

The controlled pharmacokinetic study shows that no interaction appears to occur; however, there is clinical evidence of increased tacrolimus dose requirements on starting sirolimus. As both tacrolimus and sirolimus are given as individualised doses based on target blood levels, any change in required dose on concurrent use should be identified with routine monitoring.

Note that, the US manufacturer of tacrolimus actually recommends avoiding use with sirolimus on the basis of questions regarding safety and efficacy of the combination.[5]

Tacrolimus + SSRIs and related antidepressants

Marked increases in tacrolimus levels and toxicity were observed when three patients were also given nefazodone. Fluvoxamine is predicted to increase tacrolimus levels. Paroxetine and sertraline may not interact with tacrolimus, but the situation is not clear.

Clinical evidence

A kidney transplant patient taking tacrolimus 5 mg daily developed delirium and renal failure 4 weeks after starting to take **nefazodone** 150 mg daily. The tacrolimus levels had been 9.4 nanograms/mL some 3 months earlier when he was taking tacrolimus 6 mg daily, but in the presence of **nefazodone** the tacrolimus level increased to 46.4 nanograms/mL with a tacrolimus dose of 5 mg daily and his serum creatinine had doubled. Within 2 days of the tacrolimus dose being reduced to 3 mg daily, the tacrolimus level had fallen to 29.6 nanograms/mL. **Nefazodone** was then

replaced by **paroxetine** 20 mg daily. After 3 days the tacrolimus dose was increased to 5 mg daily and satisfactory levels of 12.4 nanograms/mL were achieved.[1]

A kidney transplant patient taking prednisone, azathioprine and tacrolimus 5 mg daily for 2 years experienced headache, confusion and 'grey areas' in her vision within one week of starting **nefazodone** 50 mg twice daily in place of **sertraline**. Her serum creatinine had risen from 132 micromol/L to 195 micromol/L and her trough tacrolimus level was greater than 30 nanograms/mL. **Nefazodone** was replaced by **sertraline**, and tacrolimus was withheld for 4 days. Signs of tacrolimus-induced neurotoxicity disappeared within 36 hours, and the serum creatinine and tacrolimus levels returned to the levels seen before **nefazodone** was started within 2 weeks.[2]

Another patient developed raised liver enzymes and raised tacrolimus levels after taking **nefazodone** and tacrolimus for 2 weeks. When the **nefazodone** was stopped his liver enzymes normalised over the next 5 days, and his tacrolimus levels fell from 23 nanograms/mL to 9.5 nanograms/mL over 10 days.[3]

Mechanism

Tacrolimus is metabolised by the cytochrome P450 isoenzyme CYP3A4, which is inhibited by nefazodone. Concurrent use therefore results in increased levels of tacrolimus. Paroxetine and sertraline do not have significant effects on CYP3A4 and are therefore not expected to interact with tacrolimus.

Importance and management

Information appears to be limited but what is known indicates that tacrolimus levels or at least signs of tacrolimus toxicity should be well monitored if nefazodone is also given. In view of the narrow therapeutic index of tacrolimus, it may be advisable to avoid nefazodone. Note that nefazodone has generally been withdrawn due to adverse hepatic effects.

Fluvoxamine is a minor to moderate inhibitor of CYP3A4[4] and so theoretically could affect the metabolism of tacrolimus. Close monitoring of tacrolimus levels would therefore be prudent. Paroxetine and sertraline and possibly other SSRIs may be suitable alternative antidepressants, but the evidence is sparse, so additional monitoring may still be warranted.[1] Further study on the use of antidepressants with tacrolimus is needed.

Tacrolimus + St John's wort (*Hypericum perforatum*)

St John's wort decreases tacrolimus levels.

Clinical evidence

In a clinical study, 10 healthy subjects were given a single 100-microgram/kg dose of tacrolimus alone, or after they took St John's wort 300 mg three times daily for 14 days. On average St John's wort decreased the maximum blood level of tacrolimus by 65% and decreased its AUC by 32%. However, the decrease in AUC ranged from 15 to 64%, with one patient having a 31% *increase* in AUC.[1] Similar results have been found in a study in 10 kidney transplant patients given St John's wort (*Jarsin300*) 600 mg daily for 2 weeks. In order to achieve target levels, the tacrolimus dose was increased in all patients, from a median of 4.5 mg daily to 8 mg daily. Two weeks after stopping St John's wort, tacrolimus doses were reduced to a median of 6.5 mg daily, and then to the original dose of 4.5 mg daily after about 4 weeks.[2]

A case report describes a 65-year-old patient taking tacrolimus following a kidney transplant. The patient started to take St John's wort (*Neuroplant*) 600 mg daily, and after one month the tacrolimus trough blood levels had dropped from a range of 6 to 10 nanograms/mL down to 1.6 nanograms/mL, with an unexpected improvement in creatinine levels. When the St John's wort was stopped, tacrolimus levels and creatinine returned to the previous range. Subsequently a lower target range of tacrolimus was set.[3]

Mechanism

St John's wort induces the cytochrome P450 isoenzyme CYP3A4 and affects the transporter protein P-glycoprotein. CYP3A4 and P-glycoprotein are involved in the metabolism and clearance of tacrolimus, so an increase in their effects would be expected to result in a decrease in tacrolimus levels.[1,3]

Importance and management

Although the evidence currently seems limited to these reports the interaction between tacrolimus and St John's wort has been predicted from the pharmacokinetics of these two drugs. Given the unpredictability of the interaction (and the variability in content of St John's wort products) it would seem prudent to avoid St John's wort in transplant patients, and possibly other types of patient taking tacrolimus. If St John's wort is started or stopped, monitor tacrolimus levels and adjust the dose accordingly.

Tacrolimus + Theophylline

An isolated report suggests that theophylline may increase tacrolimus levels.

Clinical evidence

A kidney transplant patient taking tacrolimus 7 mg daily was given theophylline 600 mg daily to treat post-transplant erythrocytosis. After one month serum creatinine levels increased from 110 micromol/L to 145 micromol/L and the tacrolimus trough blood level increased to 16 nanograms/mL, from a range of 5 to 15 nanograms/mL. The theophylline dose was reduced to 300 mg daily on 4 days of each week and one month later the serum creatinine was 175 micromol/L and the trough tacrolimus level was 48.5 nanograms/mL. Theophylline was discontinued and the renal function and trough tacrolimus levels rapidly returned to normal. The pharmacokinetics of tacrolimus were later assessed in the same patient. Theophylline 125 mg daily for 4 days was associated with an almost fivefold increase in the AUC of tacrolimus and an increase in the peak tacrolimus blood levels from 19.3 nanograms/mL to 37.4 nanograms/mL, without significant alterations in renal function on this occasion.[1]

Mechanism

Unclear. An *in vitro* study found that tacrolimus and theophylline each exhibited a negligible effect on the metabolism of the other drug.[2] However, the authors of the case report suggest that theophylline levels in their patient could have been sufficient to inhibit the cytochrome P450 isoenzyme-mediated metabolism of tacrolimus,[1] but note that there is no direct evidence to suggest that theophylline acts this way.

Importance and management

Direct information regarding an increase in tacrolimus levels caused by an interaction with theophylline seems to be limited to this single case report. The authors concluded that low-dose theophylline may be given to transplant patients with erythrocytosis provided that tacrolimus levels are closely monitored.[1] However, this interaction is unconfirmed and of uncertain clinical significance. There is insufficient evidence to recommend increased monitoring in every patient, but be aware of the potential for an interaction in the case of an unexpected response to treatment.

Temsirolimus + Ketoconazole and other CYP3A4 inhibitors

Ketoconazole (a potent CYP3A4 inhibitor) markedly increases the levels of temsirolimus and its active metabolite, sirolimus. Other potent CYP3A4 inhibitors are expected to interact similarly.

Clinical evidence

To determine the effect of ketoconazole on the pharmacokinetics of temsirolimus, 14 healthy subjects were given a single 5-mg intravenous dose of temsirolimus alone, or 2 hours after the first dose of ketoconazole 400 mg daily for 7 days. There was no significant change in the pharmacokinetics of temsirolimus, but the maximum plasma level and AUC of the active metabolite, sirolimus, were increased 2.2-fold and 3.2-fold, respectively.[1] In a study of *oral* temsirolimus (not the clinically used route of administration), ketoconazole 200 mg daily for 10 days increased the AUC of temsirolimus 2 mg given on day 5 sevenfold and increased that of the sirolimus metabolite ninefold.[2]

Mechanism

Ketoconazole is a potent inhibitor of the cytochrome P450 isoenzyme CYP3A4 and P-glycoprotein. Temsirolimus is metabolised by CYP3A4 to sirolimus, which is the major metabolite after intravenous administration, and is equipotent to temsirolimus.[3] Sirolimus is itself also metabolised by CYP3A4, and appears to be more sensitive to CYP3A4 inhibition than temsirolimus. Both sirolimus and temsirolimus are also substrates of P-glycoprotein. Ketoconazole had a much greater effect on oral temsirolimus than intravenous temsirolimus suggesting that intravenous administration bypasses significant gastrointestinal metabolism.

Importance and management

Although the evidence is limited, based on the likely mechanisms and large increases seen in the studies above, an interaction between ketoconazole and temsirolimus would appear to be established. As all of the azoles inhibit CYP3A4 to various degrees, see 'azole antifungals', (p.233), they would be expected to interact similarly. Note that the intravenous study used a very low dose of temsirolimus, and it is possible that increased exposure to sirolimus with the clinically recommended doses of intravenous temsirolimus would give rise to greater increases in toxicity. The authors suggest reducing the temsirolimus dose by half if they are also given potent inhibitors of CYP3A4. They also advise, that if the CYP3A4 inhibitor is stopped, a one week washout period should be allowed before increasing temsirolimus back up to the original dose.[1] The manufacturers of temsirolimus predict that other potent inhibitors of CYP3A4 (they name ketoconazole, **itraconazole**, **voriconazole**, **atazanavir**, **indinavir**, **nelfinavir**, **ritonavir**, **saquinavir**, **telithromycin**, and **nefazodone**) will interact similarly.[3,4] However, the UK manufacturer advises avoiding concurrent use, whereas the US manufacturer suggests considering halving the temsirolimus dose.[4]

The UK manufacturer[3] also suggests that the concurrent use of temsirolimus and moderate inhibitors of CYP3A4 (they name **aprepitant** [and therefore probably **fosaprepitant** should be considered], **fluconazole**, **amiodarone**, **erythromycin**, **diltiazem**, **verapamil**, **fluvoxamine**, and **grapefruit juice**) should be used with caution in patients taking temsirolimus 25 mg [weekly], and should be avoided in patients taking doses of greater than 25 mg weekly. Note that grapefruit juice may have little effect, as the main interactions of grapefruit juice are with orally administered drugs, and temsirolimus bypasses gastrointestinal metabolism because it is used intravenously. Also note that aprepitant has a mild *inducing* effect on CYP3A4, which usually occurs 3 to 5 days after it has been stopped, and fluvoxamine is generally considered to have weak effects on CYP3A4. Both manufacturers also mention **clarithromycin** as a potentially interacting drug, but in the US it is considered to be a potent CYP3A4 inhibitor, whereas in the UK it is considered to be a moderate CYP3A4 inhibitor.

Temsirolimus + Rifampicin (Rifampin) and other CYP3A4 inducers

Rifampicin, phenytoin and carbamazepine (all potent CYP3A4 inducers) markedly reduce levels of the active metabolite of temsirolimus, sirolimus, after administration of intravenous temsirolimus. Other potent CYP3A4 inducers are expected to interact similarly.

Clinical evidence

(a) Antiepileptics

In a study in patients with malignant gliomas, the maximum tolerated dose of intravenous temsirolimus was 250 mg in patients taking enzyme-inducing antiepileptics compared with 170 mg in patients taking non-enzyme-inducing antiepileptics. The sum of the AUC of temsirolimus and sirolimus was 50% lower in the patients taking enzyme-inducing antiepileptics, despite taking a higher temsirolimus dose. At comparable doses, the AUC for temsirolimus did not differ between the groups, but that for sirolimus was 53% lower in the enzyme-inducing antiepileptic group. The majority of the patients in the enzyme-inducing antiepileptics group were taking **phenytoin** (47%): other drugs used being **carbamazepine**, **oxcarbazepine**, **fosphenytoin**, **phenobarbital** and **primidone**.[1]

In another similar study, the AUC of sirolimus was 43% lower in 11 patients receiving **carbamazepine** or **phenytoin** than in 14 patients not receiving enzyme inducers. The AUC of temsirolimus was 15% lower (not statistically significant).[2]

(b) Rifampicin

In a study in healthy subjects, a single dose of oral or intravenous temsirolimus was given on the sixth day of rifampicin 600 mg daily for 14 days. With *intravenous* temsirolimus, rifampicin reduced the maximum plasma level and AUC of sirolimus by 65% and 56%, respectively, but had no effect on the pharmacokinetics of temsirolimus. With *oral* temsirolimus, rifampicin had a similar effect on sirolimus pharmacokinetics (63% and 60% reduction in maximum level and AUC, respectively) and also reduced the temsirolimus maximum level and AUC, by 41% and 30%, respectively.[2]

Mechanism

Rifampicin and some antiepileptics (carbamazepine, phenytoin, phenobarbital, primidone) are potent inducers of the cytochrome P450 isoenzyme CYP3A4 and P-glycoprotein. Temsirolimus is metabolised by CYP3A4 to sirolimus, which is the major metabolite after intravenous administration, and is equipotent to temsirolimus.[3] Sirolimus is itself metabolised by CYP3A4, and appears to be more sensitive to CYP3A4 induction than temsirolimus. Both sirolimus and temsirolimus are also substrates of P-glycoprotein. Rifampicin had a much greater effect on oral temsirolimus than intravenous, suggesting that intravenous administration bypasses significant gastrointestinal metabolism.

Importance and management

The reductions seen in the levels of the active metabolite of temsirolimus after intravenous administration (the usual clinical route) with the enzyme-inducing antiepileptics or rifampicin are less than after oral temsirolimus, but could well be clinically important. The manufacturers advise avoiding other drugs that are potent inducers of CYP3A4 and they name **carbamazepine**, **phenobarbital**, **phenytoin** and **rifampicin**.[3,4] It would seem prudent to also apply this to **primidone**, which is metabolised to phenobarbital, and **fosphenytoin**, which is a prodrug of phenytoin. In the UK, in patients given temsirolimus for renal cell cancer, they recommend avoidance only if the CYP3A4 inducer is continued beyond an initial 5 to 7 days. However, for patients given temsirolimus for mantle cell lymphoma, concurrent use is not recommended because of the higher dose of temsirolimus used for this condition.[3] The US manufacturer additionally lists **rifabutin** and **dexamethasone**. However, note that clinically significant interactions with dexamethasone as a result of this mechanism

appear to be rare. If treatment with a CYP3A4 inducer is essential, the US manufacturer recommends that the dose of temsirolimus in patients with renal cell cancer should be doubled while the CYP3A4 inducer is being taken and readjusted when the inducer is stopped.[4]

It is also recommended that **St John's wort** is avoided by patients taking temsirolimus.[3,4] For a list of CYP3A4 inducers, see 'Table 1.4', (p.6). What should be remembered is that the extent of the inducing effects of these drugs is not identical, so that marked effects like those observed with rifampicin may not occur; nevertheless the interaction may still be clinically important.

Temsirolimus + Sunitinib

Unexpected dose-limiting toxicity was seen in a phase I study in which temsirolimus was given with sunitinib.

Clinical evidence, mechanism, importance and management

In a phase I study, two of the first 3 patients who received treatment with intravenous temsirolimus 15 mg weekly and oral sunitinib 25 mg daily for 19 to 21 days of a 4 week course, experienced dose-limiting toxicities (including erythematous rash, thrombocytopenia, gout and cellulitis requiring hospitalisation).[1] The study was terminated early because of the toxicity seen at these low starting doses of both drugs. This specific regimen should not be used.

30

Lipid regulating drugs

This section is concerned with the drugs that are used for dyslipidaemias (i.e. disturbed levels of lipids in the blood). In the very broadest of terms (and ideally) they lower the blood levels of cholesterol and low-density lipoprotein (LDL), and raise those of high-density lipoprotein (HDL). Such drugs include the statins (more properly known as HMG-CoA (hydroxymethylglutaryl-coenzyme A) reductase inhibitors), fibrates, ezetimibe, bile-acid binding resins (e.g. colestipol, colestyramine) and nicotinic acid (niacin) and related drugs. These are listed in 'Table 30.1', (below). Bile acids (e.g. ursodeoxycholic acid), which affect cholesterol levels in the bile are also included in this chapter. Where lipid regulating drugs or bile acids affect other drugs, the interactions are covered elsewhere.

Table 30.1 Lipid-regulating drugs

Group	*Drugs*
Bile-acid binding resins	Colesevelam, Colestilan, Colestipol, Colestyramine
Fibrates	Bezafibrate, Ciprofibrate, Clofibrate, Fenofibrate, Gemfibrozil
Statins	Atorvastatin, Fluvastatin, Lovastatin, Pitavastatin, Pravastatin, Rosuvastatin, Simvastatin
Miscellaneous	Acipimox, Ezetimibe, Nicotinic acid, Omega-3 marine triglycerides

(a) Statins

1. Muscle and liver toxicity. Statins are generally well tolerated, but have two major but relatively uncommon adverse effects. They raise liver enzymes, and can cause skeletal muscle disorders (e.g. myalgia, myopathy and rhabdomyolysis). Rhabdomyolysis is a syndrome resulting from skeletal muscle injury, which results in the release of the enzyme creatine kinase (among other things) into the circulation. Creatine kinase (CK) is also known as creatine phosphokinase (CPK). Both terms are used throughout the text, the choice being dependent on the term used in the source quoted. Reports of muscle disorders associated with statins have not always been consistent in their definitions, although the generally accepted definition of myopathy is myalgia (muscle pain or soreness), weakness, and/or cramps plus a CK level greater than 10 times the upper limit of normal; rhabdomyolysis has been defined as a CK level of greater than 10,000 units/L or a CK level greater than 10 times the upper level or normal with worsening renal function and/or a requirement for medical intervention with intravenous hydration.[1] As well as elevated creatine kinase levels, signs and symptoms of rhabdomyolysis include muscle pain and weakness and reddish-brown urine (myoglobinuria).[2]

Just how statins cause muscle disorders is as yet unclear, although it is thought to be connected to elevated statin levels[3] and may vary with individual statins, due to lipophilicity and pharmacokinetic differences. Similarly, elevated hepatic transaminases are dose dependent, although progression to liver failure is exceedingly rare.[4] Any pharmacokinetic interaction that results in a marked rise in statin levels is therefore to be regarded seriously.

One of the ways blood statin levels can become elevated is if the interacting drug inhibits the metabolism of the statin, with the result that it is cleared from the body more slowly and it begins to accumulate (see pharmacokinetics below). The overall risk of myopathy with the statins at standard therapeutic doses is quite low and commonly quoted as 0.01 to 0.1%, although in clinical studies involving patients taking statins muscle symptoms have been reported to occur in 1.5 to 3% of patients.[1] A further report[5] puts the incidence of mild myopathies with a statin alone as up to 7%, whilst another observational study found mild to moderate muscular symptoms occurred in 10.5% of patients given a high dose of a statin.[6] However, it has been estimated that for every 15 million prescriptions there is only one occurrence of severe muscle damage.[7] The incidence seems to rise markedly if other interacting drugs are being taken concurrently. Thus a literature review of published reports for the period 1985 to 2000 found 15 cases of rhabdomyolysis with statins alone, but 54 cases when then statin was given with other drugs.[3] Other patient-related risk factors for myopathy include:[4]

- advanced age (especially greater than 70 to 80 years),
- frailty,
- multisystem disease (e.g. chronic renal impairment, especially due to diabetes),
- perioperative periods,
- hypothyroidism,
- alcohol abuse,
- female sex.

In order to reduce the risk of myopathy the CSM in the UK have advised that statins should be used with care in patients who are at increased risk of this adverse effect. Among other risk factors, they mention the concurrent use of fibrates (such as 'gemfibrozil', (p.1332)), 'ciclosporin', (p.1326), 'macrolides', (p.1337), 'azoles', (p.1321), and 'protease inhibitors', (p.1341). They also recommend that patients should be made aware of the risks of myopathy and rhabdomyolysis, and asked to promptly report muscle pain, tenderness, or weakness, especially if this is accompanied by malaise, fever, or dark urine.[8] The American College of Cardiology/American Heart Association/National Heart, Lung and Blood Institute (ACC/AHA/NHLBI) Clinical Advisory on Statins[4] and the National Lipid Association Safety Assessment Task Force[1] give some important safety recommendations, which are useful in the context of interactions:

- Routine monitoring of creatine kinase is of little value in the absence of clinical symptoms.
- If a patient has intolerable muscle symptoms or a creatine kinase value 10 times the upper limit of normal, and is symptomatic, statin treatment should be immediately discontinued.
- If a patient has symptoms of muscle pain with a creatine kinase of up to 10 times the upper limit of normal they should be monitored closely. Statin therapy may be continued at the same or reduced doses and symptoms and creatine kinase levels may be used as the clinical guide to stop or continue treatment.
- If progressive creatine kinase elevations occur consider a dose reduction or temporary discontinuation of the statin.
- Liver transaminase levels should be obtained during routine general evaluation of patients being considered for statin therapy.
- Liver enzyme values of up to 3 times the upper limit of normal do not represent a contraindication to treatment but patients should be carefully monitored.

2. Pharmacokinetics. Lovastatin and simvastatin are extensively metabolised by the cytochrome P450 isoenzyme CYP3A4 so that drugs that can inhibit this enzyme can cause marked rises in blood statin levels. Atorvas-

tatin is also metabolised by CYP3A4, but to a lesser extent than lovastatin or simvastatin. Some of the statins are not metabolised by this isoenzyme so they interact differently. Fluvastatin is metabolised primarily by CYP2C9 (with a minor contribution from other isoenzymes, including CYP3A4), only 10% of rosuvastatin is metabolised, and the isoenzymes involved appear to be CYP2C9 and CYP2C19, while the cytochrome P450 system does not appear to be significantly involved in the metabolism of pravastatin or pitavastatin.[9,10]

Hepatic uptake and biliary excretion are also important in statin elimination, and multiple uptake transporters including the organic anion transporting polypeptide (OATP) 1B1 (also known as OATP-C, OATP2, and LST-1) play an important role in the clearance of statins; atorvastatin, pitavastatin, pravastatin and rosuvastatin have all been reported to be OATP1B1 substrates.[10] The statins are also P-glycoprotein substrates, and may therefore interact due to competition for this carrier, generally resulting in altered oral bioavailability.[9] However, *in vitro* study has suggested that, due to the low affinity of atorvastatin and simvastatin for P-glycoprotein this is unlikely to be a clinically significant cause of statin drug interactions.[11] Some metabolites of atorvastatin, lovastatin and simvastatin have been shown to inhibit P-glycoprotein, while fluvastatin and pravastatin seem to have little effect.[12] There appears to be no data on the effect of rosuvastatin on P-glycoprotein.[13]

(b) Bile-acid binding resins

Bile-acid binding resins lower cholesterol by binding with bile acids in the gastrointestinal tract to form an insoluble complex that is excreted in the faeces. This predisposes them to interactions by binding with other drugs in the same way as they do with bile acids, which prevents absorption or local action of the affected drug. A new bile-acid binding resin, colesevelam, is supposed to be devoid of clinically significant drug-binding interactions.[14]

(c) Ezetimibe

Ezetimibe is a cholesterol absorption inhibitor, and, as this term suggests, it (and the major metabolite), ezetimibe glucuronide, impair the intestinal absorption of cholesterol, both from the diet and biliary cholesterol.[15] The absorption of other fats is not affected. Ezetimibe has not been found to have significant effects on cytochrome P450, suggesting it is unlikely to interact by this mechanism.

(d) Fibrates

Fibrates are protein-bound drugs that are metabolised by the cytochrome P450 isoenzyme CYP3A4. They are not generally recognised as inhibitors of this enzyme. Although protein binding contributes to their interactions, this mechanism alone does not usually lead to serious interactions. This leaves their mechanism of interaction largely unexplained, although it has been suggested that they may act as inhibitors of glucuronidation.[16] Fibrates do not all share the same pharmacokinetic interactions, for example gemfibrozil inhibits CYP2C8 as well as OATP1B1, and seems to increase the plasma levels of most statins, whereas bezafibrate and fenofibrate have less effect on statin bioavailability.[17] As with the statins (see above), fibrates are also recognised as causing myopathies, and the risk of this appears to be greatly increased when they are given with statins, see 'Statins + Fibrates', p.1332.

(e) Nicotinic acid (Niacin)

Nicotinic acid has little effect on the cytochrome P450 isoenzyme system and is therefore unlikely to result in significant pharmacokinetic interactions. It may possibly increase the risk of myopathies when given with statins, see 'Statins + Nicotinic acid (Niacin)', p.1339. Also note that although no interaction has been shown with **acipimox**, the manufacturer recommends caution with drugs that interact with nicotinic acid.[18] This is because nicotinic acid is an analogue of **acipimox**, and so may share its interactions.

Acipimox + Colestyramine

Colestyramine does not appear to significantly affect the pharmacokinetics of acipimox.

Clinical evidence, mechanism, importance and management

A randomised, crossover study, in 7 healthy subjects given acipimox 150 mg with three 4-g doses of colestyramine (taken concurrently, and then 8 and 16 hours later), found that the pharmacokinetics of acipimox were slightly but not significantly altered by colestyramine.[1] There would seem to be no good reason for avoiding concurrent use.

Colestyramine + Food

A study in 10 patients with type IIA hyperlipoproteinaemia found that the efficacy of colestyramine in controlling total cholesterol and low density lipoprotein levels was unaltered whether the colestyramine was taken with or before meals.[1]

1. Sirtori M, Pazzucconi F, Gianfranceschi G, Sirtori CR. Efficacy of cholestyramine does not vary when taken before or during meals. *Atherosclerosis* (1991) 88, 249–52.

Ezetimibe + Antacids

The bioavailability of ezetimibe does not appear to be affected to a clinically significant extent by aluminium/magnesium hydroxide-containing antacids.

Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects found that giving ezetimibe 10 mg with 20 mL of an **aluminium**/**magnesium** [hydroxide]-containing antacid (*Supralox*) did not affect the AUC of ezetimibe or conjugated ezetimibe metabolites, although the mean maximum plasma concentration of total ezetimibe (ezetimibe plus conjugated ezetimibe) decreased by about 30% and the time to maximum plasma concentration of ezetimibe increased from 1.5 to 3 hours.[1] However, these changes would not be expected to be clinically relevant and therefore ezetimibe may be given without regard to the timing of aluminium/magnesium hydroxide-containing antacids.

Ezetimibe + Antiretrovirals

In one study ezetimibe did not appear to interact with HAART including lopinavir and nevirapine.

Clinical evidence, mechanism, importance and management

In a study, 19 HIV-positive patients (18 on stable HAART) who had poorly controlled antiretroviral-associated dyslipidaemia despite the use of pravastatin 20 mg daily, were also given ezetimibe 10 mg daily. After 6, 12, or 24 weeks of concurrent use, there were significant declines in LDL-cholesterol levels, compared to baseline values, irrespective of antiretroviral type (protease inhibitor or NNRTI). No differences were observed in **lopinavir** or **nevirapine** minimum plasma levels measured just before and 12 weeks after ezetimibe introduction. The addition of ezetimibe appeared to be well tolerated.[1] This study suggests that these antiretrovirals do not alter the efficacy of ezetimibe: concurrent use appears to be beneficial.

Ezetimibe + Bile-acid binding resins

Colestyramine reduces ezetimibe exposure.

Clinical evidence, mechanism, importance and management

In a study, 8 otherwise healthy hypercholesterolaemic subjects were given colestyramine 4 g twice daily with ezetimibe 10 mg daily for 14 days. Concurrent use decreased the AUC of total ezetimibe (ezetimibe plus glucuronide metabolite) by 56%.[1] The manufacturers suggest that this interaction may reduce the expected additive effects of ezetimibe and colestyramine on LDL-cholesterol reduction, and recommend that ezetimibe should be taken at least 2 hours before or 4 hours after bile-acid binding resins.[2,3] Note that ezetimibe undergoes enterohepatic recirculation, so separating administration may not fully resolve this interaction.

Ezetimibe + Ciclosporin

The levels of ezetimibe may be greatly increased by ciclosporin. Ezetimibe may have a small effect on ciclosporin levels.

Clinical evidence, mechanism, importance and management

(a) Effect on ciclosporin

A randomised, crossover study in 12 healthy subjects found that ezetimibe 20 mg daily for 8 days increased the AUC of a single 100-mg dose of ciclosporin by 15%. The authors noted that it would be difficult to determine the outcome of long-term concurrent use, but the modest effect seen suggested that caution was necessary if the combination was given.[1] However, a 15% increase in the AUC of a narrow therapeutic index drug like ciclosporin is not usually considered to be clinically significant. Furthermore, an efficacy study noted that in 16 renal transplant patients the addition of ezetimibe 10 mg daily had no effect on ciclosporin levels.[2] Nevertheless, the manufacturers of ezetimibe recommend monitoring ciclosporin levels in patients given ezetimibe.[3,4]

(b) Effect on ezetimibe

In one study, 8 stable renal transplant patients taking ciclosporin were given a single 10-mg dose of ezetimibe. When compared with other data from healthy control subjects, the AUC of ezetimibe was found to be 3.4-fold higher in the patients taking ciclosporin.[5]

A case report describes a heart transplant patient taking ciclosporin 100 mg twice daily with atorvastatin 40 mg daily. As his LDL-cholesterol was inadequately lowered by the atorvastatin, and greater doses had not been tolerated due to elevated creatine kinase levels, ezetimibe 10 mg daily was added. His LDL-cholesterol then decreased from 126 mg/dL to 51 mg/dL (target less than 100 mg/dL), and so his dose of ezetimibe was decreased to 5 mg daily.[6] The authors of this case report note that only about 50% of heart transplant patients are able to achieve LDL-cholesterol of less than 100 mg/dL and attribute the effects seen in their patient to an interaction. However, the validity of any interaction has been debated,[7,8] and an efficacy study in which renal transplant patients taking ciclosporin and a statin were given ezetimibe 10 mg daily noted an enhanced but not excessive effect on lipids.[2]

A further patient, with severe renal impairment taking multiple drugs including ciclosporin, had a 12-fold increase in the AUC of ezetimibe.[5]

Therefore, it seems that ciclosporin can greatly raise ezetimibe levels, possibly resulting in an increased effect on lipid reduction. If concurrent use is necessary, until the effects of concurrent treatment are better established, it would seem prudent to monitor the effects on lipid levels, anticipating the need to reduce the dosage of ezetimibe. The authors of the case report cited suggest that, in patients taking ciclosporin, ezetimibe should be started at a dose of 5 mg daily or less, with careful monitoring if the dose is increased.[8]

Ezetimibe + Cimetidine

In a study in 12 healthy subjects, cimetidine 400 mg twice daily for 7 days caused a small increase in the peak plasma level and AUC of ezetimibe 10 mg daily, but the overall bioavailability was not affected to a clinically significant extent. The combination was well tolerated.[1] No dosage adjustments therefore seem necessary on concurrent use.

1. Krishna G, Kosoglou T, Ezzet F, Pember L, Statkevich P, Boutros T, Maxwell SE, Basso L, Batra VK. Effect of cimetidine on the pharmacokinetics of ezetimibe. *AAPS PharmSci* (2001) 3; 3.

Ezetimibe + Food

The bioavailability of ezetimibe does not appear to be affected to a clinically significant extent by food.

Clinical evidence, mechanism, importance and management

A study in 18 healthy subjects found that the AUC of a single 10-mg dose of ezetimibe was not significantly affected by a high-fat or non-fat meal, when compared with the fasting state. The maximum plasma concentration of ezetimibe was increased by about 40% by the high-fat meal and slightly reduced by the non-fat meal, but these changes were not considered to be clinically significant due to the considerable overlap in the data. Ezetimibe can therefore be given without regard to meals.[1]

Ezetimibe + Rifampicin (Rifampin)

Single-doses of rifampicin increase ezetimibe levels without altering its effects on sterols, whereas multiple doses of rifampicin decrease ezetimibe levels and almost totally abolish its effects.

Clinical evidence

In a single-dose study investigating the disposition of ezetimibe, 8 healthy subjects were given ezetimibe 20 mg with rifampicin 600 mg. Rifampicin increased the ezetimibe maximum serum levels about 2.5-fold, without affecting the AUC. The maximum serum levels of ezetimibe glucuronide (the major active metabolite of ezetimibe) were similarly increased, and its AUC was also increased, about twofold. The sterol-lowering effects of ezetimibe were also more rapid in the presence of rifampicin, but the overall effect was unchanged, possibly because ezetimibe and its glucuronide were excreted more rapidly.[1] In another study by the same researchers, subjects were given rifampicin 600 mg daily for 8 days, with a single 20-mg dose of ezetimibe given 12 hours after the last dose of rifampicin. Both the AUC and maximum serum levels of ezetimibe and its glucuronide were *decreased* (AUC decreased by more than 50%) and the effect of ezetimibe on sterols was almost completely abolished.[2]

Mechanism

The raised ezetimibe levels seen in the single-dose study are thought to occur because rifampicin enhances the absorption of ezetimibe, probably by inhibiting intestinal P-glycoprotein, and another transporter protein, MRP2. However, inhibition of MRP2 appears to reduce enterohepatic circulation, which is needed for the long duration of ezetimibe effects, and therefore shortens the sterol-lowering effects of ezetimibe.[1] It seems likely that the balance of these factors is altered when rifampicin is given in multiple doses, which leads to a reduction in the effects of ezetimibe. Other factors are possibly also involved.[2]

Importance and management

Information about the interaction between ezetimibe and rifampicin appears to be limited to these studies, which were primarily designed to investigate ezetimibe disposition. However, it seems likely that the effects of ezetimibe will be reduced in patients who are also given multiple doses of rifampicin. If both drugs are given it would be prudent to closely monitor the effects on lipid levels.

Fibrates + Bile-acid binding resins

Colestyramine does not alter the pharmacokinetics of clofibrate when both drugs are given at the same time. Similarly colestipol does not alter the pharmacokinetics of clofibrate or fenofibrate, and colesevelam does not alter the pharmacokinetics of fenofibrate. Colestipol can reduce the absorption of gemfibrozil if both drugs are given at the same time, but not if they are given 2 hours apart. A similar interaction may occur between bezafibrate and colestyramine.

Clinical evidence, mechanism, importance and management

(a) Bezafibrate

The manufacturer of bezafibrate recommends that there should be a 2-hour interval between giving an ion-exchange resin [such as **colestyramine**] and bezafibrate, as the absorption of bezafibrate may otherwise be impaired.[1]

(b) Clofibrate

In a study in 24 healthy subjects **colestipol** 10 g daily did not alter the pharmacokinetics of clofibrate 500 mg daily, when both drugs were given at the same time, for 6 days.[2] In a study in 6 patients **colestyramine** 4 g four times daily had no effect on the fasting plasma levels, urinary and faecal excretion, or the half-life of clofibrate 1 g twice daily. In this study, the morning and evening doses of **colestyramine** were taken at the same time as the clofibrate.[3]

(c) Fenofibrate

In a 6-day study in 6 healthy subjects the pharmacokinetics of fenofibrate were not altered to a clinically relevant extent, when **colestipol** 10 g daily was given at the same time as fenofibrate 200 mg in the morning, and **colestipol** 5 g daily was given at the same time as fenofibrate 100 mg in the evening.[4] In a randomised, crossover study 27 healthy subjects took fenofibrate 160 mg with **colesevelam** 3.75 g, four hours before **colesevelam**, or alone. **Colesevelam** caused some slight changes in the pharmacokinetics of fenofibrate when both drugs were given at the same time but this was not considered to be clinically significant.[5]

(d) Gemfibrozil

A study in 10 patients with raised serum cholesterol and triglyceride levels found that if gemfibrozil 600 mg was given alone, 2 hours before or 2 hours after **colestipol** 5 g, the AUCs of gemfibrozil were similar. However, when both drugs were given at the same time, the AUC of gemfibrozil was reduced by about one-third.[6] Another study found that giving gemfibrozil at the same time as **colestipol** enhanced the LDL-lowering effects of both drugs, but tended to mitigate the HDL-raising effects of the gemfibrozil.[7] Combined use is effective, but information is very limited about the clinical importance of the reduction in gemfibrozil bioavailabil-

ity. However, the interaction can be avoided by separating the administration of the two drugs by at least 2 hours.

Fibrates + Colchicine

Case reports suggest that the concurrent use of fibrates and colchicine can result in rhabdomyolysis or neuromyopathy.

Clinical evidence

A 40-year-old man with chronic hepatitis and nephrotic syndrome, who had been taking colchicine 500 micrograms three times daily uneventfully for 2 to 3 years, started taking **gemfibrozil** 600 mg twice daily. About one month later he presented with muscle pain and dark brown urine, and had an elevated serum creatine kinase level of 3 559 units/L, and he was diagnosed as having rhabdomyolysis. Both drugs were stopped, and he recovered over the following 9 days.[1] Another case report describes neuromyopathy (creatine kinase level 15 084 units/L), in a patient who had been taking **bezafibrate** 400 mg daily with colchicine 3 mg daily for 14 days.[2] This patient was known to have renal impairment.

Mechanism

Colchicine alone can, rarely, cause myopathy. However, it is more common in those given colchicine long term (as in the case with gemfibrozil), in high dose, or in the presence or renal impairment (as in the case with bezafibrate).[2] As the fibrates can also, rarely, cause myopathy, an additive or synergistic effect seems possible.

Importance and management

Although information seems limited to these two cases, the effects seen are known to be associated with both colchicine and the fibrates, so an interaction, all be it rare, seems to be established. It would be prudent to suspect this interaction in any patient presenting with muscle pain or a raised creatine kinase level. The section on 'muscle toxicity', (p.1313), discusses risk factors for myopathy and it would seem prudent to be aware of these when prescribing the combination, as both patients in the cases above had other risk factors for rhabdomyolysis.

Fibrates + Diuretics

Treatment with clofibrate in patients with nephrotic syndrome receiving furosemide has sometimes led to marked diuresis with severe and disabling adverse muscular effects. An isolated report describes rhabdomyolysis in a patient taking bezafibrate and furosemide.

Clinical evidence

(a) Bezafibrate

An isolated report attributed a case of acute renal failure and rhabdomyolysis to treatment with bezafibrate 400 mg daily and **furosemide** 25 mg on alternate days.[1]

(b) Clofibrate

Three patients with hyperlipoproteinaemia secondary to nephrotic syndrome, taking **furosemide** 80 to 500 mg daily, developed severe muscle pain, low lumbar backache, stiffness, and general malaise with pronounced diuresis within 3 days of starting to take clofibrate 1 to 2 g daily. Similarly, a patient taking **bendroflumethiazide** 10 mg daily developed adverse muscle effects within 3 days of starting to take clofibrate 2 g daily. Of these 4 patients, 3 had documented raised serum transaminases or creatine phosphokinase, and 3 were also taking **spironolactone** 75 or 100 mg daily.

Two other patients had raised levels of serum transaminases or creatine phosphokinase while taking clofibrate with **furosemide**.

Further study in 4 of the 6 patients discussed above and 4 healthy controls, found that free serum clofibrate was markedly higher in the patients, and this correlated with low serum albumin. Urinary clofibrate excretion was markedly delayed.[2]

Mechanism

Not understood. The marked diuresis may have been due to competition and displacement of the furosemide by the clofibrate from its plasma protein binding sites. Clofibrate occasionally causes muscle toxicity, which could have been exacerbated by the urinary loss of sodium and potassium and the increase in the half-life of clofibrate. The reason for the rhabdomyolysis attributed to bezafibrate and furosemide is unknown.

Importance and management

The clinical documentation for an interaction between diuretics and fibrates seems to be limited to these reports. In the case of clofibrate and furosemide it appears to be a combination of a drug-drug interaction, with or without a drug-disease interaction (clofibrate with nephrotic syndrome). The authors of one report[2] suggest that serum proteins and renal function should be checked before giving clofibrate to any patient. If serum albumin is low, the total daily dosage of clofibrate should not exceed 500 mg for each 1 g per 100 mL of the albumin concentration. However, note that this guidance is old. The general importance of the isolated case of rhabdomyolysis with bezafibrate and furosemide is expected to be small.

Fibrates + Ezetimibe

Fenofibrate and gemfibrozil may increase ezetimibe levels, but ezetimibe does not alter fenofibrate or gemfibrozil pharmacokinetics. The concurrent use of ezetimibe and a fibrate may increase cholesterol excretion into the bile, which increases the risk of gallstone formation.

Clinical evidence

(a) Fenofibrate

In a randomised, crossover study, 18 healthy subjects were given ezetimibe 10 mg daily with fenofibrate 145 mg daily for 10 days, or either drug alone. Ezetimibe did not affect the AUC of fenofibrate, but fenofibrate increased the total AUC of ezetimibe and ezetimibe-glucuronide by 50%.[1] In a randomised, placebo-controlled study, 32 otherwise healthy patients with hypercholesterolaemia were given fenofibrate 200 mg daily, ezetimibe 10 mg daily, both drugs in combination, or placebo daily; each for 14 days. The combination was well tolerated, and resulted in an increased reduction in LDL-cholesterol than that achieved by either ezetimibe or fenofibrate alone. Concurrent use had no effect on the pharmacokinetics of fenofibrate, whereas the AUCs of ezetimibe and its glucuronide metabolite were increased by about 50%.[2] A further efficacy and safety study, in 172 patients with mixed hyperlipidaemia taking ezetimibe 10 mg daily with fenofibrate 160 mg daily for 12 weeks, found that the concurrent use of fenofibrate with ezetimibe did not seem to influence the adverse effects beyond those noted with fenofibrate alone and no cases of rhabdomyolysis or myopathy were recorded. However, both drugs were discontinued in one patient because of cholelithiasis, which was managed with a cholecystectomy.[3] In a 48-week extension phase of this study, the combination of fenofibrate and ezetimibe was well tolerated and more efficacious than fenofibrate alone.[4]

(b) Gemfibrozil

In a randomised, crossover study, 12 healthy subjects were given ezetimibe 10 mg daily with gemfibrozil 600 mg twice daily for 7 days, or either drug alone. Ezetimibe did not affect the AUC of gemfibrozil, but gemfibrozil increased the total AUC of ezetimibe and ezetimibe glucuronide by about 70%.[5]

Mechanism, importance and management

Despite these seemingly favourable results, the manufacturers of ezetimibe state that the safety of combined use with fibrates is not yet established[6,7] and the US manufacturer further says that the concurrent use of ezetimibe and fibrates (other than fenofibrate) is not recommended.[7] This is because both fibrates and ezetimibe may increase cholesterol excretion into the bile, which could promote the production of gallstones.[6,7] The manufacturers recommend that if gallstones or gall bladder disease is suspected in a patient receiving ezetimibe and fenofibrate then the combination should be discontinued.[6,7]

Fibrates + Nifedipine

It has been suggested that three cases of rhabdomyolysis occurred because of an interaction between bezafibrate and nifedipine, but it seems more likely that the dose of bezafibrate was too high.

Clinical evidence, mechanism, importance and management

Rhabdomyolysis developed in 4 of 5 patients undergoing CAPD, who were given **bezafibrate** 200 to 400 mg daily for raised cholesterol and triglyceride levels. Of these, 2 patients were also taking nifedipine, and one patient was also taking nifedipine and lovastatin. Raised creatine kinase levels developed within 8 to 16 days of concurrent use, and resolved within 48 hours of stopping the **bezafibrate**. The authors suggest that nifedipine may have competed with **bezafibrate** for metabolism by the cytochrome P450 isoenzyme CYP3A4. They therefore say that patients with renal failure needing a fibrate should avoid taking CYP3A4 substrates.[1] However, note that there appear to be no interactions reported for bezafibrate as a result of CYP3A4 inhibition. Furthermore, the recommended dose for **bezafibrate** in dialysis patients is 200 mg every 72 hours.[2] It therefore appears likely that the high dose, and not an interaction, was responsible for the rhabdomyolysis.

Fibrates + Probenecid

Plasma clofibrate levels can be approximately doubled by probenecid.

Clinical evidence, mechanism, importance and management

A pharmacokinetic study in 4 healthy subjects taking clofibrate 500 mg every 12 hours found that probenecid 500 mg every 6 hours for 7 days almost doubled the steady-state clofibric acid levels, from 72 mg/L to 129 mg/L, and raised the free clofibric acid levels from 2.5 mg/L to 9.1 mg/L. The suggested reason is that probenecid reduces the renal and metabolic clearance of clofibrate by inhibiting its conjugation with glucuronic acid.[1] The clinical importance of this interaction is uncertain, but it may be prudent to be alert for increased clofibrate adverse effects (e.g. gastrointestinal disturbances, headache, fatigue) and review treatment if these become a problem. There appears to be no information about other fibrates and probenecid.

1. Veenendaal JR, Brooks PM, Meffin PJ. Probenecid-clofibrate interaction. *Clin Pharmacol Ther* (1981) 29, 351–8.

Fibrates + Rifampicin (Rifampin)

Limited evidence suggests that rifampicin can reduce the plasma levels of the active metabolite of clofibrate. In contrast, rifampicin does not appear to affect gemfibrozil pharmacokinetics.

Clinical evidence, mechanism, importance and management

(a) Clofibrate

In a study in 5 healthy subjects, the steady-state plasma levels of the active metabolite of clofibrate, chlorophenoxyisobutyric acid (CIPB), was reduced by 35% after they took rifampicin 600 mg daily for 7 days.[1] This reduction in CIPB levels appears to occur because its metabolism by the liver and/or the kidneys is increased.[1] On the basis of this study it would seem prudent to monitor serum lipid levels of patients taking clofibrate if rifampicin is added, and to increase the clofibrate dosage if necessary. More study is needed to establish this interaction.

(b) Gemfibrozil

In a study in 10 healthy subjects, rifampicin 600 mg daily for 6 days did not significantly affect the pharmacokinetics of gemfibrozil 600 mg.[2] No dosage adjustment therefore seems necessary if both drugs are given.

Fibrates; Ciprofibrate + Ibuprofen

An isolated report describes a patient taking ciprofibrate who developed acute renal failure and rhabdomyolysis, which was, in part, attributed to the use of ibuprofen.

Clinical evidence, mechanism, importance and management

A 29-year-old man with type M hyperlipidaemia[1] who had been taking ciprofibrate for 6 months (current dose 200 mg daily) began to take ibuprofen 200 mg and then 400 mg daily for a painful heel. The pain became general, his urine turned 'muddy', he complained of having a 'stiff body'. After a dose of a contrast medium he developed acute renal failure. His serum creatinine concentration was found to be 647 micromol/L and his creatine kinase was 13 740 units/L. He subsequently made a full recovery (treatment not stated).

The reasons for this reaction are not known, but the authors of the report postulate that the ibuprofen displaced the ciprofibrate from its binding sites, thereby turning a safe dose into a toxic one.[1] However, it should be said that this mechanism of interaction is rarely important on its own, so it seems likely that some other factors may have contributed to what happened. The authors also note that, during the time this patient was treated, the recommended dose of ciprofibrate was reduced from 200 mg daily to 100 mg daily, due to a high incidence of rhabdomyolysis.

This is an isolated case, and an interaction is by no means established. It therefore seems unlikely to be of general relevance.

Fibrates; Clofibrate + Hormonal contraceptives

Combined hormonal contraceptives increase the clearance of clofibrate but the significance of this is unclear.

Clinical evidence, mechanism, importance and management

A comparative study in men, women, and women taking oral combined hormonal contraceptives found that the clearance of clofibrate was increased by 48% in those taking combined oral contraceptives, apparently due to an increase in clofibrate glucuronidation.[1] Another study found that oral combined hormonal contraceptives increased the excretion of clofibric acid glucuronide (the pharmacologically active form of clofibrate) by 25%.[2] None of these studies addressed the question of whether concurrent use significantly reduces clofibrate efficacy, but it would seem prudent to be aware that increases in blood lipid levels could be possible.

2. Liu H-F, Magdalou J, Nicolas A, Lafaurie C, Siest G. Oral contraceptives stimulate the excretion of clofibric acid glucuronide in women and female rats. *Gen Pharmacol* (1991) 22, 393–7.

Fibrates; Fenofibrate + Donepezil

Dropped head syndrome occurred in a patient given donepezil and fenofibrate.

Clinical evidence, mechanism, importance and management

A 77-year-old patient who had been taking fenofibrate for 10 years presented with a dropped head 6 months after starting to also take donepezil. Clinical examination showed muscle weakness and pain with swallowing difficulties, and serum muscle enzymes were increased. Donepezil and fenofibrate were discontinued and the symptoms disappeared with slow normalisation of creatine kinase. It was suggested that this effect occurred because both drugs have a potential action on muscle fibres through different mechanisms.[1]

This appears to be an isolated case report and its general relevance is unknown.

Fibrates; Gemfibrozil + Antacids

Aluminium-containing antacids can reduce the absorption of gemfibrozil.

Clinical evidence, mechanism, importance and management

A study in patients with kidney and liver disease found that the concurrent use of antacids (**aluminium hydroxide**, **aluminium magnesium silica hydrate**) reduced the maximum plasma levels of gemfibrozil by about 50 to 70%, and reduced its AUC by about 30 to 60%. The precise values are not given in the text. The reasons for these reductions are not known, but it was suggested that the gemfibrozil is adsorbed onto the antacids in the gut. The authors recommend that gemfibrozil is given 1 to 2 hours before antacids.[1] More study is needed to confirm these findings.

1. Knauf H, Kölle EU, Mutschler E. Gemfibrozil absorption and elimination in kidney and liver disease. *Klin Wochenschr* (1990) 68, 692–8.

Fibrates; Gemfibrozil + Interferon alfa

An isolated report describes severe gastrointestinal symptoms and raised liver enzymes potentially due to an interaction between interferon alfa and gemfibrozil.

Clinical evidence

A 43-year-old man receiving interferon alfa-2b and a melanoma vaccine (melanoma theraccine) for malignant melanoma was given gemfibrozil 600 mg twice daily for interferon-induced hypertriglyceridaemia. About one month later, he developed severe gastrointestinal symptoms, consisting of nausea and decreased appetite, and raised liver enzymes. The dose of gemfibrozil was reduced to 300 mg daily and, 3 weeks later, his symptoms and liver enzyme levels had significantly improved. The patient had been receiving the same dose of interferon alfa for 6 months without any adverse effects.

Mechanism

Unknown. The adverse effects seen are known to occur with both gemfibrozil and interferon alfa alone, so it was suggested that what occurred was due to the additive effects of both drugs. However, an effect of gemfibrozil alone, and an interaction involving the melanoma vaccine was not ruled out. Furthermore, the potential for a pharmacokinetic interaction was not examined.[1]

Importance and management

Evidence for an interaction between interferon alfa and gemfibrozil appears to be limited to this case report, and is not established. Nevertheless, as gastrointestinal adverse effects and raised liver enzymes are known adverse effects of both drugs it would be prudent to use some caution if both drugs are given. It seems likely that any interaction would be detected by routine monitoring associated with the use of interferon alfa, but consider increasing the frequency of monitoring in stabilised patients if gemfibrozil is started.

1. Wong S-F, Jakowatz JG, Taheri R. Potential drug-drug interaction between interferon alfa-2b and gemfibrozil in a patient with malignant melanoma. *Clin Ther* (2005) 27, 1942–8.

Fibrates; Gemfibrozil + Psyllium

When 10 healthy subjects took gemfibrozil 600 mg with, or 2 hours after, psyllium 3 g in 240 mL of water, the AUC of gemfibrozil was reduced by about 10%.[1] This reduction is almost certainly too small to be clinically significant. Note that the name psyllium may cover several *Plantago* species including *Plantago ovata*, also known as ispaghula.

Nicotinic acid (Niacin) + Aspirin

Aspirin reduces the flushing reaction that often occurs with nicotinic acid, but there is some evidence that it can also increase nicotinic acid plasma levels.

Clinical evidence, mechanism, importance and management

Nicotinic acid (a 70 to 100 micrograms/kg per minute infusion over 6 hours) was given to 6 healthy subjects. Two hours after the infusion was started, oral aspirin 1 g was also given. The plasma nicotinic acid levels rose markedly, and its clearance was reduced by 30 to 54%.[1] It was thought that the salicylate competes with nicotinic acid for metabolism by glycine conjugation in the liver so that the clearance of nicotinic acid is reduced, resulting in a rise in its levels. The clinical importance of this effect when aspirin is given to reduce the annoying nicotinic acid flushing reaction[2] is not known. However, as nicotinic acid is titrated upwards, according to efficacy and tolerability, any increase in its levels caused by aspirin is probably naturally accounted for.

2. Jungnickel PW, Maloley PA, Vander Tuin EL, Peddicord TE, Campbell JR. Effect of two aspirin pretreatment regimens on niacin-induced cutaneous reactions. *J Gen Intern Med* (1997) 12, 591–6.

Nicotinic acid (Niacin) + Nicotine

An isolated report describes an unpleasant flushing reaction that developed when a woman taking nicotinic acid started to use nicotine transdermal patches.

Clinical evidence, mechanism, importance and management

A case report describes a woman who had taken nicotinic acid 250 mg twice daily for 3 years without problems, as well as nifedipine, ranitidine, colestyramine and ferrous sulfate. Following laryngectomy for cancer of the larynx, she restarted all of the drugs except the colestyramine and began to use nicotine transdermal patches 21 mg daily to try to give up

smoking. On several occasions, shortly after taking the nicotinic acid, she developed unpleasant flushing episodes lasting about 30 minutes. No further episodes developed when the nicotinic acid was stopped.[1] The reasons are not understood, but flushing is a very common adverse effect of nicotinic acid, and it would seem that in this case the nicotine patch may have been responsible for its emergence. A comment on this report suggests that this reaction may possibly have an immunological basis.[2] Either way, this reaction is more unpleasant than serious.

Statins + ACE inhibitors

In general the statins do not appear to interact adversely with the ACE inhibitors. An isolated report describes severe hyperkalaemia in a diabetic given lisinopril with lovastatin, and acute pancreatitis has been attributed to the use of lisinopril with atorvastatin.

Clinical evidence, mechanism, importance and management

Retrospective analysis of clinical study data found no evidence that the safety or efficacy of **fluvastatin** was altered by the use of unspecified ACE inhibitors.[1] Another retrospective analysis of clinical study data found no evidence that the safety of **lovastatin** was altered by the use of unspecified ACE inhibitors in 142 patients.[2] Likewise, another study found that the addition of **lovastatin** 20 mg daily to **lisinopril** therapy, for 6 weeks, was well tolerated and there was a substantial reduction in serum cholesterol levels without any clinically relevant effect on the antihypertensive efficacy of lisinopril.[3] However, one study in 70 patients taking **enalapril** or **lisinopril** found that the addition of **lovastatin** or **pravastatin** caused a greater reduction in blood pressure compared with ACE inhibitor alone.[4] A study in healthy subjects found that **simvastatin** had no effect on the pharmacokinetics or ACE-inhibitory effects of **ramipril** or its metabolites.[5] Similarly, no evidence of clinically important adverse interactions was found when **moexipril** was used with **cholesterol-lowering drugs** [not specifically named].[6] An isolated report describes a type I diabetic (receiving insulin) with hypertension and hyperlipidaemia who developed myositis and severe hyperkalaemia (serum potassium 8.4 mmol/L) when given **lovastatin** 20 to 40 mg daily with **lisinopril** 50 mg daily. His serum potassium returned to about 5.5 mmol/L after the **lovastatin** was stopped and the dosage of **lisinopril** lowered (to 20 mg daily). About 3 months later, the patient resumed taking the **lovastatin**, but after only 2 doses he again had severe myositis and hyperkalaemia, which resolved after the **lovastatin** was discontinued. The reason seemed to be a combination of the potassium-sparing effects of the **lisinopril**, the release of intracellular potassium into the blood stream associated with the myositis caused by the **lovastatin**, and a predisposition to hyperkalaemia due to the diabetes and mild renal impairment.[7] Another case report describes the development of acute pancreatitis in a patient who had been taking **lisinopril** 10 mg daily with **atorvastatin** 20 mg daily for 9 months. No other cause for the pancreatitis was identified, and both drugs alone have, rarely, been associated with the development of pancreatitis.[8] These are unusual cases and, given the widespread concurrent use of drugs from these classes they seem unlikely to be of general importance. No special precautions would seem to be necessary if ACE inhibitors are given with statins.

Statins + Amiodarone

There is some evidence of a high incidence of myopathy when amiodarone is given with high doses of simvastatin or possibly atorvastatin. Cases of myopathy and rhabdomyolysis have been reported in patients taking amiodarone and a statin.

Clinical evidence

The manufacturers of **simvastatin** note that in an ongoing unpublished clinical study, myopathy (clinically significant muscle pain with a creatine kinase concentration at least 10 times the upper limit of normal[1]) has been reported in 6% of patients receiving simvastatin 80 mg daily with amiodarone.[2,3] There is some evidence from reports to the FDA in the US that the concurrent use of **simvastatin** (or **atorvastatin**) with amiodarone is associated with a higher incidence of muscle toxicity than **pravastatin** with amiodarone. The percentage of reports of muscle, liver, pancreas, and bone marrow toxicity associated with the concurrent use of statins and amiodarone was 1% for **simvastatin**, 0.7% for **atorvastatin**, and 0.4% for **pravastatin**.[4]

A study in 12 healthy subjects found that amiodarone 400 mg daily for 3 days significantly increased the bioavailability of a single 40-mg dose of **simvastatin**; the mean AUC of simvastatin and simvastatin acid were increased by 73% and 78%, respectively. However, amiodarone had no clinically relevant effect on the pharmacokinetics of a single 40-mg dose of **pravastatin**.[5]

A 63-year-old man with diabetes developed diffuse muscle pain with generalised muscular weakness 4 weeks after starting to take **simvastatin** 40 mg daily, and about 2 weeks after starting to take amiodarone (1 g daily for 10 days, then 200 mg daily thereafter). There was a marked increase in creatine kinase, which normalised after stopping both drugs.[6] A 77-year-old man taking multiple medications including amiodarone 100 mg daily and **simvastatin** 20 mg daily, developed increasing lower-extremity pain and darkening of his urine 3 weeks after his simvastatin dose was increased to 40 mg daily. He was diagnosed with rhabdomyolysis secondary to **simvastatin** use,[7] although a later comment suggested that amiodarone could have contributed.[8] Two other cases of rhabdomyolysis in patients taking amiodarone with **simvastatin**[9,10] (one involving clarithromycin)[10] have also been reported. One of these patients had pneumonia,[10] and the other diabetes,[9] both of which have been suggested as risk factors for rhabdomyolysis. Another case report describes rhabdomyolysis in a 72-year-old HIV-positive man taking amiodarone who began taking **simvastatin** 80 mg daily about 3 weeks before his symptoms started. He was also taking atazanavir and delavirdine, so it is difficult to directly attribute this reaction to an interaction with amiodarone.[11]

Asymptomatic elevated serum transaminase levels, which were attributed to an interaction between **rosuvastatin** and amiodarone, have also been reported in a 73-year-old woman with diabetes and hypothyroidism who had recently undergone surgery.[12] However, diabetes, hypothyroidism and the peri-operative period are all associated with an increased risk of myopathy, so this case may not have occurred as a result of an interaction.

Mechanism

Amiodarone is an inhibitor of various cytochrome P450 isoenzymes. Whether it inhibits the metabolism of simvastatin and other extensively-metabolised statins, and thereby increases the risk of muscle toxicity, is not known. Amiodarone alone may sometimes cause myopathy.

Importance and management

An interaction between simvastatin and amiodarone appears to be established. Some manufacturers recommend that the dose of simvastatin should not exceed 20 mg daily in patients also taking amiodarone, unless the clinical benefit is likely to outweigh the increased risk of myopathy and rhabdomyolysis.[2,3] **Lovastatin** is metabolised in the same way as simvastatin, and shares many of its interactions: the manufacturer of lovastatin suggests a maximum dose of 40 mg daily in the presence of amiodarone.[13] Atorvastatin is also metabolised (at least in part) by CYP3A4 inhibitors and the UK manufacturer of atorvastatin suggests that, although interaction studies have not been conducted, amiodarone may possibly result in increased exposure to atorvastatin; lipid levels should be monitored to ensure that the lowest dose necessary of atorvastatin is used.[14]

As a general rule, any patient given simvastatin, lovastatin or atorvastatin should be told to report any signs of myopathy and possible rhabdomyolysis (i.e. otherwise unexplained muscle pain, tenderness or weakness or dark coloured urine). If myopathy does occur, the statin should be stopped immediately. See also 'muscle toxicity', (p.1313), for further guidance on monitoring and risk factors for muscle toxicity.

Rosuvastatin and pravastatin undergo limited metabolism by the cytochrome P450 isoenzyme system and are therefore considered less likely to interact.

Statins + Angiotensin II receptor antagonists

Irbesartan, telmisartan and valsartan appear not to alter the pharmacokinetics of simvastatin, simvastatin does not significantly affect the pharmacokinetics of valsartan, fluvastatin does not alter the pharmacokinetics of losartan or its active metabolite, and olmesartan appears not to interact with pravastatin.

Clinical evidence, mechanism, importance and management

(a) Fluvastatin

In a crossover study, 12 healthy subjects were given **losartan** 50 mg in the morning for 7 days, followed by fluvastatin 40 mg at bedtime for 7 days, and then both drugs together for another 7 days. It was found that the steady-state pharmacokinetics of **losartan** and its active metabolite, E-3174, were not significantly altered by fluvastatin.[1] The findings of this study indicate that a clinically relevant pharmacokinetic interaction is unlikely, and no **losartan** dose adjustment is required on combined use.

(b) Pravastatin

The manufacturer of **olmesartan** states that it has no clinically relevant interaction with pravastatin in healthy subjects.[2]

(c) Simvastatin

A study in 12 healthy subjects found that **irbesartan** 300 mg had no significant effect on the pharmacokinetics of a single 50-mg dose of simvastatin, or its metabolite simvastatin acid, and the combination was well tolerated.[3] No clinically relevant interaction was noted when **telmisartan** was given with simvastatin.[4] In a randomised study, 18 healthy subjects were given **valsartan** 160 mg daily with simvastatin 40 mg daily for 7 days. Although some changes occurred in the pharmacokinetics of both drugs these were small and not considered to be clinically relevant.[5]

Statins + Antacids

Aluminium/magnesium hydroxide antacids cause a moderate reduction in the bioavailability of atorvastatin, pravastatin, and rosuvastatin, but the lipid-lowering efficacy of atorvastatin and pravastatin is not affected.

Clinical evidence, mechanism, importance and management

In a multiple-dose study, 18 patients were given **atorvastatin** 10 mg daily for 15 days with 30 mL of an **aluminium/magnesium hydroxide** antacid *(Maalox TC)* four times daily for a further 17 days. The maximum serum levels and AUC of **atorvastatin** were reduced by 34%, and the absorption rate was also reduced by the antacid. However, the LDL-cholesterol reduction remained the same.[1] In another study, giving an **aluminium/magnesium hydroxide** antacid *(Maalox TC)* 15 mL four times daily, one hour before a single 20-mg dose of **pravastatin**, reduced the bioavailability of **pravastatin** by 28%. This change was less than that seen with food, which did not alter **pravastatin** efficacy.[2] There is therefore no need to avoid the concurrent use of **aluminium/magnesium hydroxide** antacids, nor does the dosage of **atorvastatin** or **pravastatin** need to be raised.

In a randomised study, 14 healthy subjects were given a single 20-mL dose of an **aluminium/magnesium hydroxide** antacid (*Maalox*); either with, or 2 hours after, a single 40-mg dose of **rosuvastatin**. The antacid reduced the AUC of **rosuvastatin** by 54% when given simultaneously, and by 22% when given 2 hours after the **rosuvastatin**.[3] On this basis, the authors concluded that antacids should be given at least 2 hours after **rosuvastatin**, which seems prudent advice.

3. Martin PD, Schneck DW, Dane AL, Warwick MJ. The effect of a combination antacid preparation containing aluminium hydroxide and magnesium hydroxide on rosuvastatin pharmacokinetics. Curr Med Res Opin (2008) 24, 1231–5.

Statins + Aspirin

Aspirin 324 mg did not significantly affect the pharmacokinetics of a single 20-mg dose of pravastatin.[1] In a study in 73 patients, the addition of atorvastatin or pravastatin did not interfere with the anti-aggregatory effect of aspirin (with clopidogrel).[2] An isolated report describes acute pancreatitis possibly associated with the long-term use of aspirin 100 mg daily and atorvastatin 40 mg daily.[3] This is not expected to be of general relevance.

1. ER Squibb. A report on the effect of nicotinic acid alone and in the presence of aspirin on the bioavailability of SQ 31,000 in healthy male subjects. Data on file (Protocol No 27, 201-6), 1987.

Statins + Azoles

Fluconazole modestly increases the levels of fluvastatin, slightly increases the levels of rosuvastatin, but does not affect pravastatin levels. Miconazole would be expected to interact similarly.
Itraconazole causes a marked rise in the serum levels of atorvastatin, lovastatin and simvastatin, a minimal to modest rise in pravastatin levels, but no change in fluvastatin or rosuvastatin

levels. Ketoconazole, posaconazole and voriconazole would be expected to interact similarly.
Case reports describe rhabdomyolysis associated with the use of statins and azoles.

Clinical evidence

(a) Atorvastatin

A case report describes a 76-year-old man taking multiple medications, including long-term **fluconazole** 150 mg daily had his treatment with pravastatin 80 mg daily changed to atorvastatin 40 mg daily due to a lack of response. Within one week he began to feel tired, and 3 weeks later he was admitted to hospital with dyspnoea, myopathy, rhabdomyolysis and renal failure. Although both drugs were stopped he later died of multi-organ failure. The authors considered an interaction between atorvastatin and **fluconazole** as the most likely explanation for the rhabdomyolysis.[1]

Ten healthy subjects were given **itraconazole** 200 mg daily for 5 days with a single 40-mg dose of atorvastatin on day 4. The **itraconazole** increased the AUC of atorvastatin acid and atorvastatin lactone fourfold and threefold, respectively, and increased their half-lives threefold and twofold, respectively. The AUC values of active and total HMG-CoA reductase inhibitors were increased by 60% and 70%, respectively.[2] Raised atorvastatin levels have been seen in other studies with itraconazole.[3,4]

In a review of the FDA spontaneous reports of statin-associated rhabdomyolysis covering the period November 1997 to March 2000, an azole antifungal was potentially implicated in 2 cases of rhabdomyolysis involving atorvastatin.[5]

(b) Fluvastatin

A randomised study in 12 healthy subjects found that **fluconazole** (400 mg on day 1 followed by 200 mg daily for 3 days) increased the AUC of a single 40-mg dose of fluvastatin by 84% and increased its maximum plasma level by 44%. The pharmacokinetics of the **fluconazole** were unaffected.[6] In a similar study, **itraconazole** 100 mg daily for 4 days did not significantly affect the pharmacokinetics of fluvastatin, apart from a small increase in its half-life.[7]

(c) Lovastatin

In a placebo-controlled, crossover study, 12 healthy subjects were given **itraconazole** 200 mg daily for 4 days with a single 40-mg oral dose of lovastatin on day 4. On average the peak plasma concentration and the 24-hour AUC of the lovastatin were increased more than 20-fold. The peak plasma concentration of the active metabolite of lovastatin, lovastatin acid, was increased 13-fold (range 10 to 23-fold) and its AUC was increased 20-fold. The creatine kinase activity of one subject increased 10-fold, but in the other 11 subjects it remained unchanged.[8] Another study also found similar pharmacokinetic changes.[7] Two reports describe rhabdomyolysis in patients taking lovastatin and **itraconazole**,[8,9] which, in one case, developed after 2 weeks of concurrent use.[9]

Another patient who had received lovastatin for several years was diagnosed with hepatitis and rhabdomyolysis about 4 weeks after **ketoconazole** 400 mg three times daily was started.[10]

In a review of the FDA spontaneous reports of statin-associated rhabdomyolysis covering the period November 1997 to March 2000, an azole antifungal was potentially implicated in 6 cases of rhabdomyolysis involving lovastatin.[5]

(d) Pravastatin

A randomised, double-blind study in 12 healthy subjects found that **fluconazole** (400 mg on day 1 followed by 200 mg daily for 3 days) had no significant effect on the pharmacokinetics of a single 40-mg dose of pravastatin.[6]

In a study in 10 healthy subjects, the AUC of a single 40-mg dose of pravastatin was increased by 71% by **itraconazole** 200 mg daily for 4 days, although this did not reach statistical significance.[11] In a similar study, the same dosage of **itraconazole** caused a modest 51% increase in the AUC of pravastatin.[3] In contrast, one study in 104 subjects found that **itraconazole** had no effect on pravastatin pharmacokinetics.[4]

(e) Rosuvastatin

In a study in 14 healthy subjects, **fluconazole** 200 mg daily for 11 days increased the AUC and maximum plasma concentration of a single 80-mg dose of rosuvastatin (given on day 8) by 14% and 9%, respectively. The proportion of circulating active HMG-CoA reductase inhibitors was not affected by **fluconazole**.[12] In similar studies by the same workers, **itraconazole**[13] and **ketoconazole**[14] also had no clinically significant effect on the levels of rosuvastatin.

(f) Simvastatin

An 83-year-old man who had been taking multiple medications including simvastatin 40 mg daily for 2 years was given **fluconazole** 400 mg daily as part of a prophylactic regimen against chemotherapy-induced neutropenic sepsis. After one week he developed generalised muscle weakness and was found to have brown urine and an elevated serum creatine kinase. His medication was stopped, and he was treated with hydration and diuretics, after which his symptoms resolved.[15] A similar case of rhabdomyolysis has been reported in another taking patient simvastatin and **fluconazole**.[16]

In a two-phase crossover study, 10 healthy subjects were given **itraconazole** 200 mg daily or a placebo for 4 days, with a single 40-mg dose of simvastatin on day 4. The peak serum levels of total simvastatin acid (simvastatin acid plus simvastatin lactone) were increased 17-fold and the AUC was increased 19-fold. The maximum serum levels and the AUC of total HMG-CoA reductase inhibitors increased about 3-fold and 5-fold, respectively.[11] Five case reports describe rhabdomyolysis in patients taking simvastatin and **itraconazole**.[17-21] Symptoms started within 2 to 3 weeks of concurrent use.[17,18] Four of these cases were complicated by the presence of ciclosporin, which may also cause rhabdomyolysis with simvastatin (see 'Statins + Ciclosporin', p.1326). Gemfibrozil was also taken in one of these cases.[21] An otherwise healthy subject with hypercholesterolaemia also had an increase in simvastatin serum levels, from 0.5 to 6.5 nanogram/mL within a day of starting **itraconazole** 200 mg daily.[18]

Five cases of rhabdomyolysis have been reported in patients taking simvastatin, which developed between 7 days and 4 weeks after starting **ketoconazole**.[22-25]

In a review of the FDA spontaneous reports of statin-associated rhabdomyolysis covering the period November 1997 to March 2000, an azole antifungal was potentially implicated in 4 cases of rhabdomyolysis involving simvastatin.[5]

Mechanism

Fluconazole (and **miconazole**) inhibits the cytochrome P450 isoenzymes CYP2C9 and has moderate inhibitory effects on CYP3A4, whereas itraconazole and ketoconazole are potent inhibitors of CYP3A4. Consequently they interact differently with the various statins depending on which isoenzymes are involved in the metabolism of the statins in question: this has been shown in several studies.[3,6,7] The more dependent the statin is on metabolism by an isoenzyme, the greater its interaction in the presence of an inhibitor of this isoenzyme. Thus, itraconazole has a greater effect on simvastatin than atorvastatin, and has less effect on fluvastatin than fluconazole. See 'Lipid regulating drugs', (p.1313), for further discussion on the metabolism of the statins, and 'azole antifungals', (p.233), for the enzyme-inhibitory effects of the azoles. Raised statin levels are known to be associated with the development of myopathy and rhabdomyolysis.

Importance and management

An established interaction of clinical importance, which differs depending on the drug pair used. The differing risks and management of the various drug pairs are discussed below. See also 'muscle toxicity', (p.1313), for further guidance on monitoring, and risk factors for muscle toxicity.

1. Lovastatin or Simvastatin. The very marked increases in levels of lovastatin and simvastatin that can occur considerably increase the risk of severe muscle damage and therefore the use of these statins with **itraconazole** or **ketoconazole** should be avoided. If a short course of an azole antifungal is considered essential, the manufacturers suggest temporary withdrawal of the statin.[26-28] The manufacturers of **voriconazole** predict that it will interact similarly, but they suggest that a dose adjustment [reduction] of the statin should be considered during concurrent use.[29,30] Similarly the US manufacturer of **posaconazole** suggests a dose reduction of lovastatin and simvastatin,[31] whereas the UK manufacturer contraindicates concurrent use.[32] **Fluconazole**, particularly in high dose (greater than 200 mg daily), and **miconazole** (including the oral gel, which can be absorbed sufficiently to have enzyme-inhibitory effects), have the potential to interact similarly, but probably to a lesser extent. Nevertheless, cases of rhabdomyolysis have been reported with fluconazole and therefore it would be prudent to monitor for muscle toxicity. Note that the UK manufacturers of miconazole oral gel contraindicate concurrent use.[33]

2. Atorvastatin. Although the increase in the levels of atorvastatin are not as great as those with lovastatin or simvastatin, they are still marked, and concurrent use of an azole antifungal with atorvastatin should only be undertaken if the benefits outweigh the risks.[34] Lower doses of atorvastatin,[34,35] or alternatively (for short courses of **itraconazole** or **ketoconazole**) a temporary suspension of treatment with atorvastatin may be considered.[35] The UK manufacturer of atorvastatin says that in the case of itraconazole (and therefore probably ketoconazole), the maintenance dose of atorvastatin should not exceed 40 mg daily.[35] As a general rule, any patient given atorvastatin with an azole should be told to report any signs of myopathy and possible rhabdomyolysis (i.e. otherwise unexplained muscle pain, tenderness or weakness or dark coloured urine). If myopathy does occur, the statin should be stopped immediately. Note that the US manufacturer of **posaconazole**[31] and the manufacturers of **voriconazole**[29,30] suggest considering a dosage reduction of statins metabolised via CYP3A4, such as atorvastatin, although the UK manufacturer of posaconazole[32] contraindicates concurrent use.

Fluconazole, particularly in high dose (greater than 200 mg daily), and **miconazole** (including the oral gel, which can be absorbed sufficiently to have enzyme-inhibitory effects), have the potential to interact similarly, but probably to a lesser extent. Nevertheless, a case of rhabdomyolysis has been reported with fluconazole and therefore it would be prudent to monitor for muscle toxicity.

3. Fluvastatin. The clinical relevance of the modest changes in fluvastatin levels with **fluconazole** is unclear. Note that in a review of the FDA spontaneous reports of statin-associated rhabdomyolysis for the period November 1997 to March 2000, azole antifungals were not identified as a potentially interacting drug in any of the reports for fluvastatin.[5] However, fluconazole, **miconazole** (and to some extent **voriconazole**) are inhibitors of CYP2C9 by which fluvastatin is metabolised and so a degree of caution seems warranted. Therefore, any patient given fluvastatin and one of these azoles (including miconazole in preparations such as the oral gel, which is can be absorbed in sufficient quantities to have enzyme-inhibitory effects) should be told to report any signs of myopathy and possible rhabdomyolysis (i.e. otherwise unexplained muscle pain, tenderness or weakness or dark coloured urine). If myopathy does occur, the statin should be stopped immediately. Other azoles would not be expected to interact.

4. Pravastatin. The clinical relevance of the modest changes in pravastatin levels with different azole antifungals seems likely to be small, and a clinically significant interaction would not be expected. Note that in a review of the FDA spontaneous reports of statin-associated rhabdomyolysis for the period November 1997 to March 2000, azole antifungals were not identified as a potentially interacting drug in any of the reports for pravastatin.[5]

5. Rosuvastatin. The small increase in rosuvastatin levels with fluconazole is not considered to be clinically relevant. Other azoles would not be expected to interact.

Statins + Beta blockers

Propranolol does not cause any clinically relevant changes to the pharmacokinetics of fluvastatin, lovastatin or pravastatin. The concurrent use of simvastatin and talinolol does not affect the pharmacokinetics of either drug. In clinical studies, the safety and efficacy of statins were not altered by the concurrent use of beta blockers as a class.

Clinical evidence, mechanism, importance and management

In a study in 24 healthy subjects, the pharmacokinetics of a single 40-mg dose of **fluvastatin** was not affected by the concurrent use of **propranolol** 40 mg every 12 hours for 3 days.[1] Similarly, the same dose of **propranolol** caused less than an 18% reduction in the AUC of **lovastatin** 20 mg and its metabolites, and modestly reduced the AUC of **pravastatin** 20 mg and its metabolites by 16 to 23%.[2] These changes are small and unlikely to be clinically relevant. In another study in healthy subjects the pharmacokinetics of **simvastatin** and **talinolol** were not affected during the concurrent use of these drugs.[3]

Retrospective analysis of clinical study data found no evidence that the safety or efficacy of **fluvastatin** was altered by the use of beta blockers (unspecified).[4] Similarly, in another analysis, there was no evidence that the safety or efficacy of **lovastatin** was altered by cardioselective beta blockers (primarily **atenolol**, **metoprolol** and **labetalol**) or non-selective beta blockers (primarily **propranolol**, **nadolol** and **timolol**).[5]

No special precautions would seem to be necessary if beta blockers are given concurrently with statins.

Statins + Bile-acid binding resins

Although colestyramine and colestipol reduce plasma fluvastatin and pravastatin levels, the overall total lipid-lowering effect is increased by concurrent use. Colestipol appears to interact with atorvastatin similarly. Colesevelam appears not to interact with atorvastatin, lovastatin or simvastatin.

Clinical evidence

(a) Atorvastatin

A study in which atorvastatin 40 mg daily and **colestipol** 10 mg twice daily were given concurrently found that although the serum levels of atorvastatin were reduced by about 25%, the total reduction in the LDL-cholesterol levels was greater than when each drug was given alone.[1,2]

(b) Fluvastatin

In a study in 19 healthy subjects, **colestyramine** 8 g given at the same time as fluvastatin 20 mg decreased the AUC and the maximum plasma levels of fluvastatin by 89% and 96%, respectively. When the fluvastatin was given 2 hours after the **colestyramine**, the AUC and the maximum plasma levels of fluvastatin were reduced by just over 50%.[3] In another study in 20 healthy subjects, the AUC and maximum plasma levels of fluvastatin were reduced by 51% and 82%, respectively, when fluvastatin was taken 4 hours after **colestyramine** 8 g and a meal.[3]

Despite these marked reductions in fluvastatin bioavailability, other studies in large numbers of hypercholesterolaemic patients have found that the concurrent use of **colestyramine** and fluvastatin actually has additive lipid-lowering effects.[3,4] In the first of these studies, fluvastatin was given 4 hours after **colestyramine**,[3] but the other study did not indicate whether or not doses were separated.[4]

(c) Lovastatin

A crossover study in 22 healthy subjects found that the pharmacokinetics of lovastatin 20 mg given with a meal were not significantly affected when **colesevelam** 2.25 g was given at the same time.[5]

(d) Pravastatin

In a randomised study, 33 patients with primary hypercholesterolaemia were given pravastatin 5, 10, or 20 mg twice daily before their morning and evening meals for 4 weeks, and then for a further 4 weeks they also took **colestyramine** 24 g daily. The **colestyramine** was taken at least an hour after the pravastatin. Despite the fact that **colestyramine** reduced the bioavailability of pravastatin by 18 to 49%, the reduction in blood lipid levels was enhanced by concurrent use.[6] A related study in 18 subjects found that **colestyramine** reduced the bioavailability of pravastatin by about 40% when given at the same time, but only small and clinically insignificant pharmacokinetic changes occurred when the pravastatin was given one hour before, or 4 hours after the **colestyramine**.[7] Similarly, a multicentre study in 311 patients found that the combined use of pravastatin 40 mg daily and **colestyramine** 12 g daily was highly effective in the treatment of hypercholesterolaemia. The **colestyramine** was taken at least one hour after the pravastatin.[8]

In a study in 18 subjects, **colestipol** reduced the bioavailability of pravastatin by about 50%, but no reduction in bioavailability was seen when pravastatin was given 1 hour before **colestipol** and a meal.[7]

Mechanism

It seems probable that these bile-acid binding resins bind with statins in the gut and thereby reduce the amount of statin available for absorption.

Importance and management

The interactions of colestipol and colestyramine with the statins are established but of only relatively minor importance. Although colestipol modestly decreased atorvastatin bioavailability it appears that atorvastatin may be used with bile acid-binding resins for additive effect. Similarly, despite the reduction in the bioavailability of pravastatin caused by colestyramine or colestipol, the overall lipid-lowering effect is increased by concurrent use.[6,8] The effects of the interaction can be minimised by separating their administration as described above. This can be achieved by taking the colestyramine or colestipol with meals, and the pravastatin at bedtime. Likewise, any interaction between fluvastatin and colestyramine can be minimised by taking fluvastatin at least one hour before or 4 hours after colestyramine.

There would appear to be no reason for avoiding concurrent use of lovastatin and colesevelam. The manufacturer of colesevelam says that its concurrent use with atorvastatin, lovastatin or simvastatin in clinical studies shows that colesevelam can be dosed at the same time as the statin.[9]

Statins + Bosentan

Bosentan modestly reduces the AUC of simvastatin and its active metabolite, which could lead to a reduction in simvastatin efficacy. Other statins metabolised by the same route as simvastatin may be similarly affected.

Clinical evidence

In a three-way, crossover study, 9 healthy subjects were given either bosentan 125 mg twice daily for 5.5 days, simvastatin 40 mg daily for 6 days, or both treatments together. Simvastatin had no effect on the pharmacokinetics of bosentan, but bosentan reduced the AUC of simvastatin and its β-hydroxyacid metabolite by 34% and 46%, respectively.[1]

Mechanism

Bosentan is known to be a mild inducer of the cytochrome P450 isoenzyme CYP3A4, which is involved in the metabolism of simvastatin. Induction of simvastatin metabolism may have led to the reduced levels seen.

Importance and management

Evidence is limited to this study, but the interaction found is in line with the way both drugs are known to interact. A 40% reduction in the AUC of simvastatin is potentially clinically significant. If bosentan and simvastatin are used concurrently it would seem prudent to monitor the outcome to ensure that simvastatin is effective. Other statins metabolised by the same route as simvastatin (that is, predominantly by CYP3A4) are likely to interact similarly, and the same precautions described for simvastatin would seem appropriate. See 'Lipid regulating drugs', (p.1313), for more information on the metabolism of the statins. **Atorvastatin** seems unlikely to be affected to the same extent, but bear this interaction in mind if lipid-lowering targets are not met.

1. Dingemanse J, Schaarschmidt D, van Giersbergen PLM. Investigation of the mutual pharmacokinetic interactions between bosentan, a dual endothelin receptor antagonist, and simvastatin. *Clin Pharmacokinet* (2003) 42, 293–301.

Statins + Calcium-channel blockers

Marked rises in statin plasma levels have been seen when lovastatin or simvastatin were given with diltiazem, and when simvastatin was given with verapamil. Isolated cases of rhabdomyolysis have occurred as a result of these interactions. However, overall, it seems that problems with combinations of statins and calcium-channel blockers (particularly the dihydropyridine-type) are rare, especially if the lowest possible dose of statin is used.

Clinical evidence

(a) Atorvastatin

1. Amlodipine. One manufacturer reports that amlodipine 10 mg increased the AUC of an 80-mg dose of atorvastatin by 18%,[1] which would not be expected to be clinically relevant. A randomised study involving 1660 patients with hypertension and dyslipidaemia, found that various combinations of amlodipine 5 or 10 mg, atorvastatin 10, 20, 40, or 80 mg or placebo, for 8 weeks, were well tolerated and without adverse pharmacodynamic interaction. Atorvastatin did not modify the effect of amlodipine on systolic blood pressure, and amlodipine did not adversely affect the overall lipid-lowering capacity of atorvastatin. In addition, all treatments were well tolerated and the occurrence of adverse effects or laboratory abnormalities was similar in patients given both drugs and patients receiving either amlodipine or atorvastatin alone.[2]

2. Diltiazem. One manufacturer reports that diltiazem 240 mg increased the AUC of a 40-mg dose of atorvastatin by 51%.[1] A 60-year-old man taking atorvastatin 20 mg daily developed rhabdomyolysis 3 weeks after diltiazem was started.[3] Another similar case has also been reported.[4]

3. Verapamil. A study in 12 healthy subjects found that atorvastatin increased the AUC of verapamil by 43%.[5]

(b) Fluvastatin

A retrospective study of the effects of antihypertensives on the efficacy of fluvastatin found that the concurrent use of unspecified calcium-channel blockers did not significantly affect the safety or lipid-lowering effects of fluvastatin, although there was a trend towards enhanced lowering of triglycerides.[6]

(c) Lovastatin

A retrospective study of the effects of lovastatin and antihypertensive medication found that when calcium-channel blockers (**diltiazem**, **nifedipine** or **verapamil**) were used in combination with lovastatin there was an additional 3 to 5% lowering in the LDL-cholesterol, which was of marginal significance.[7] Another study found that the use of lovastatin 20 mg daily with **nifedipine** for 6 weeks was well tolerated and there was a substantial reduction in serum cholesterol levels without any impact on the antihypertensive efficacy of nifedipine.[8]

Pharmacokinetic studies have shown that oral **diltiazem** increases the AUC and maximum serum levels of lovastatin about fourfold.[9,10] In another study, in 12 healthy subjects, lovastatin 20 mg and **isradipine** 5 mg were given alone or together for 5 days. **Isradipine** reduced the AUC of lovastatin by 40%, in males but not females.[11]

(d) Pravastatin

A study in 10 healthy subjects found that sustained-release **diltiazem** 120 mg twice daily had no effect on the pharmacokinetics of a single 20-mg dose of pravastatin.[9] Similarly, a study in 15 healthy subjects found that extended-release **verapamil** 480 mg daily for 3 days did not affect the pharmacokinetics of pravastatin 40 mg daily.[12]

(e) Simvastatin

1. Amlodipine. In a study in 8 patients taking simvastatin 5 mg daily, the addition of amlodipine 5 mg daily for 4 weeks increased the maximum levels and AUC of simvastatin by a modest 40% and 30%, respectively, without affecting the lipid profiles of the patients.[13]

2. Diltiazem. In a study, 10 healthy subjects were given sustained-release diltiazem 120 mg twice daily for 2 weeks followed by a single 20-mg dose of simvastatin. Diltiazem caused about a fivefold increase in the simvastatin AUC, a fourfold increase in its maximum serum levels, and a 2.5-fold increase in its half-life.[14] A further study in 11 subjects found that the concurrent use of simvastatin 5 mg daily and diltiazem 30 mg three times daily resulted in a twofold increase in the AUC and maximum plasma level of simvastatin acid (the active metabolite of simvastatin), and a 20% decrease in the AUC and maximum plasma level of diltiazem.[15]

The clinical relevance of the diltiazem interaction has been demonstrated in a 53-year-old man, who developed rhabdomyolysis 3 months after diltiazem 30 mg four times daily was added to established treatment with simvastatin 40 mg daily. Both drugs were discontinued and he recovered over the following 10 days.[16] Other similar cases have also been reported.[4,17,18]

3. Lacidipine. In a randomised, crossover study, simvastatin 40 mg daily was given for 8 days, with or without lacidipine 4 mg daily. Lacidipine raised the AUC of simvastatin by 35%.[19]

4. Verapamil. A study in which 12 subjects were given verapamil 80 mg three times daily, found a 4.6-fold increase in the AUC of simvastatin and a 2.8-fold increase in the AUC of simvastatin acid (the active metabolite of simvastatin). In addition, there was a 2.6-fold increase in the maximum serum levels of simvastatin, and about a twofold increase in its half-life.[20] Similarly, a study in 12 healthy subjects found that extended-release verapamil 480 mg daily for 3 days caused a fivefold increase in the maximum serum levels of simvastatin 40 mg, and about a fourfold increase in its AUC.[12]

The clinical relevance of the verapamil interaction has been demonstrated in a 63-year-old man, who developed rhabdomyolysis about 1 month after extended-release verapamil 240 mg daily was added to established treatment with simvastatin 40 mg daily and ciclosporin. Verapamil and simvastatin were discontinued and he recovered over the following 14 days.[21]

Mechanism

Diltiazem and verapamil inhibit the cytochrome P450 isoenzyme CYP3A4, which is responsible for the metabolism of lovastatin, simvastatin and to an extent, atorvastatin. Therefore concurrent use of these drugs results in an increase in the levels of the statin. One study found that oral, but not intravenous diltiazem interacts, suggesting that it is CYP3A4 in the gut wall that is the site of the interaction.[22] Isradipine and lovastatin are both metabolised by CYP3A4, and therefore the modest interaction may have occurred as a result of competition for metabolism. A similar mechanism probably accounts for the modest interaction between simvastatin and lacidipine or amlodipine. Note that fluvastatin, pravastatin and **rosuvastatin** are not significantly metabolised by CYP3A4 and so are less likely to interact with diltiazem or verapamil. See 'Lipid regulating drugs', (p.1313), and 'Calcium-channel blockers', (p.1025), for more information about the way these groups of drugs are metabolised.

Importance and management

Interactions between the statins and calcium-channel blockers are established, but the effects are not usually clinically relevant. Even with those pairs of drugs where the increases in plasma levels are quite large (such as when simvastatin is given with diltiazem or verapamil) problems seem to be very rare. Indeed an analysis of the 4S study and the Heart Protection Study (which used maximum simvastatin doses of 40 mg) found no evidence that the concurrent use of a calcium-channel blocker increases the risk of myopathy.[23] However, with higher doses of simvastatin, the risk of myopathy is increased with concurrent verapamil and possibly diltiazem: the incidence of myopathy with an 80-mg dose of simvastatin appears to be doubled by verapamil and diltiazem, but is still low, at 1%.[24] Therefore, although concurrent use need not be avoided, it has been suggested that treatment with a statin metabolised by CYP3A4 (see 'statins', (p.1313)) in a patient taking diltiazem or verapamil should be at the lowest possible dose; in patients already taking statins, the dose of the statin may need to be considerably reduced.[20]

The manufacturers of simvastatin and lovastatin recommend the following dose restrictions:

- maximum dose of 40 mg of simvastatin in the presence of diltiazem,[24]
- maximum dose of 20 mg of simvastatin in the presence of verapamil,[24,25]
- maximum dose of 40 mg of lovastatin in the presence of verapamil.[26]

Fluvastatin, pravastatin and rosuvastatin appear less likely to interact with diltiazem or verapamil. See also 'muscle toxicity', (p.1313), for further guidance on monitoring and risk factors for muscle toxicity.

Statins + Carbamazepine

Carbamazepine dramatically reduces simvastatin levels. Other statins metabolised in the same way as simvastatin may be similarly affected.

Clinical evidence

In a randomised, crossover study, 12 healthy subjects were given carbamazepine 200 mg daily for 2 days, then 300 mg twice daily for 12 days, with a single 80-mg dose of **simvastatin** 12 hours after the last dose of carbamazepine. The AUC and maximum serum levels of **simvastatin** were reduced by 75% and 68%, respectively, and the AUC and maximum serum levels of simvastatin acid (the active metabolite of **simvastatin**) were reduced by 82% and 69%, respectively.[1]

Mechanism

Carbamazepine is a known potent inducer of the cytochrome P450 isoenzyme CYP3A4 by which simvastatin is metabolised. Carbamazepine therefore increases simvastatin metabolism, leading to reduced levels.

Importance and management

Although this appears to be the only study, the effects of concurrent use are consistent with both the way carbamazepine interacts with many other CYP3A4 substrates and the way simvastatin interacts with other CYP3A4 inducers. The effects of simvastatin are likely to be greatly reduced with concurrent use and a dose increase seems likely to be necessary. Monitor concurrent use to check simvastatin is effective. Statins metabolised by the same route as simvastatin may also have their levels reduced, at least modestly. In contrast, it seems unlikely that other statins that are not metabolised by CYP3A4, will interact, and they may therefore be preferable. However, this needs confirmation. See 'statins', (p.1313), for more information on the metabolism of the various statins.

Statins + Ciclosporin

Ciclosporin can cause marked rises in the plasma levels of atorvastatin, fluvastatin, lovastatin, pravastatin, rosuvastatin, and simvastatin, and for some of the statins this has led to the development of serious myopathy (rhabdomyolysis) and renal failure. The plasma levels of ciclosporin appear not to be affected by fluvastatin, lovastatin, pravastatin, or rosuvastatin, but some moderate changes in ciclosporin levels have been seen when atorvastatin or simvastatin were given.

Clinical evidence

(a) Atorvastatin

1. Effect on ciclosporin. In a study of 10 patients taking ciclosporin following a kidney transplant, 4 had increases in their trough ciclosporin levels of between 26 and 54% when atorvastatin 10 mg was added, necessitating a dosage reduction of ciclosporin. No changes were seen in 6 other patients, and the incidence of adverse effects was no greater than in a control transplant group not given atorvastatin.[1] When atorvastatin 10 mg daily was given to 21 renal transplant patients taking ciclosporin, the maximum serum levels of ciclosporin generally decreased (by a mean of 13.5%). However, 4 patients needed a *decrease* in their ciclosporin dose and one patient needed an increase.[2] A follow-up study suggested that atorvastatin does not, on average, affect ciclosporin pharmacokinetics in renal transplant patients, although the influence of atorvastatin on the ratio between ciclosporin and a major metabolite (AM9) showed large interindividual variability.[3] Another study suggested that atorvastatin causes a negligible increase in ciclosporin levels in liver transplant patients.[4]

2. Effect on atorvastatin. In an open study the concurrent use of atorvastatin 10 mg daily with ciclosporin resulted in a more than sevenfold increase in atorvastatin levels (data calculated from figures), when compared with historical controls not taking ciclosporin.[2] A further analysis of this study has been reported elsewhere,[5] suggesting that ciclosporin may cause an 8.7-fold increase in the AUC of atorvastatin acid. A pharmacokinetic study in 13 healthy subjects found that the short-term use of ciclosporin (2 doses 12 hours apart) increased the AUC of atorvastatin acid 15-fold.[6]
A case of rhabdomyolysis has been described in a woman who took atorvastatin 10 mg daily and ciclosporin for 2 months. She had also been taking modified-release diltiazem 240 mg daily.[7] In a review of the FDA spontaneous reports of statin-associated rhabdomyolysis covering the period November 1997 to March 2000, ciclosporin was potentially implicated in 5 cases of rhabdomyolysis involving atorvastatin.[8]

(b) Fluvastatin

1. Effect on ciclosporin. When fluvastatin 20 mg daily was given to 16 patients taking ciclosporin 21 to 103 months after renal transplantation, no significant changes were seen in their ciclosporin levels.[9,10] Similar results were seen in other studies, one using fluvastatin 20 mg twice daily,[11] and one in 17 renal transplant recipients taking extended-release fluvastatin 80 mg daily.[12]

2. Effect on fluvastatin. In a double-blind study, 52 heart transplant patients taking ciclosporin were randomised to receive fluvastatin 40 mg daily for 1 year, or placebo. Fluvastatin had a positive effect on lipid profiles, and, although creatine phosphokinase levels rose, the maximum reached was 4.5 times normal, which did not require cessation of the fluvastatin and normalised without intervention. There was no increase in the reported rate of myalgia, and no patients developed rhabdomyolysis.[13]
In 20 renal transplant patients taking ciclosporin, the AUC and maximum serum concentration of fluvastatin 20 mg daily were found to be about 94% and 30% higher, respectively, than in historical control patients not taking ciclosporin.[14] Results from another study in renal transplant patients taking ciclosporin and fluvastatin 80 mg found a twofold increase in fluvastatin exposure, when compared with historical data.[12] Similarly, the AUC and maximum serum concentration of fluvastatin 40 mg daily for 4 weeks were threefold and sixfold greater in heart transplant patients taking ciclosporin than in healthy subjects not given ciclosporin.[15] One study reported 2 patients with mild myalgia without creatine phosphokinase rises, and a patient with elevated creatine phosphokinase without myalgia, when fluvastatin 20 mg daily was given with ciclosporin.[14] Further studies suggest that concurrent use does not affect creatine phosphokinase or result in additional adverse effects.[9-11]

(c) Lovastatin

1. Effect on ciclosporin. Ciclosporin and creatine phosphokinase levels were not significantly changed in 6 renal transplant patients taking ciclosporin and lovastatin (10 mg for 8 weeks, then 20 mg for 12 weeks).[16] Similar results were found in another study.[17]

2. Effect on lovastatin. In 6 patients taking ciclosporin the plasma levels of lovastatin 10 to 20 mg daily were about the same as those seen in healthy subjects taking lovastatin 40 mg alone (i.e. the levels were increased up to fourfold by ciclosporin).[16] In another study in 21 renal transplant patients taking ciclosporin, the maximum serum levels and AUC of lovastatin 20 mg daily were 40 and 47% higher, respectively, after 28 days of concurrent use than on day 1 (suggesting accumulation) and were estimated to be 20-fold higher than values reported in healthy subjects not taking ciclosporin.[18] A further study found that the AUC of lovastatin was five times greater in patients taking ciclosporin than in patients not taking ciclosporin, irrespective of whether the patients had received a transplant or were receiving other immunosuppressants.[19]

There are at least 9 documented cases of rhabdomyolysis, often resulting in acute renal failure, in patients taking ciclosporin and lovastatin.[20-24] In each of these cases the patient was taking lovastatin 40 to 80 mg daily. Several other studies suggest that this interaction may be dose-related. In one study, 15 patients taking ciclosporin were given lovastatin 20 mg daily without problem, but 4 of 5 other patients, who were given lovastatin 40 to 80 mg, daily developed rhabdomyolysis, which was associated with renal failure in two of them.[25] In a further study 24 patients were given lovastatin 10 or 20 mg daily in addition to ciclosporin. Of the 12 receiving the 20-mg dose, 7 developed either myalgia and muscle weakness or raised creatine phosphokinase levels, but only one patient from the 10-mg group did.[26] The incidence of myopathies with lovastatin is about 0.1 to 0.2%,[18] but in the presence of ciclosporin the incidence is said to be as high as 30%.[27]

(d) Pravastatin

1. Effect on ciclosporin. Several studies have shown no significant change in ciclosporin levels in patients also taking pravastatin.[18,28,29]

2. Effect on pravastatin. A study in 19 paediatric and adolescent cardiac transplant patients (mean age 12.1 years) found that triple immunosuppressant therapy (17 patients taking ciclosporin) raised the maximum levels and AUC of pravastatin 10 mg daily for 8 weeks by about eightfold and tenfold, respectively, when compared with control subjects not receiving immunosuppressants. There was extremely large intersubject variation in the pravastatin AUC and maximum levels.[30] Similar results have been found in other studies in adults.[31,32] Although a study in patients taking ciclosporin found that the AUC of pravastatin 20 mg daily did not differ between day 1 and day 28 of therapy (suggesting no accumulation), the AUC values were estimated to be five to sevenfold higher than in patients not taking ciclosporin.[18]

A report describes asymptomatic rhabdomyolysis in a heart transplant patient taking ciclosporin, who had taken pravastatin 40 mg daily for more than 3 years.[33] In a review of the FDA spontaneous reports of statin-associated rhabdomyolysis covering the period November 1997 to March 2000, ciclosporin was potentially implicated in 2 cases of rhabdomyolysis involving pravastatin.[8]

Several studies have shown no rises in creatine phosphokinase levels,[28,34,35] and no increase in adverse effects[18,34,36] when pravastatin in doses of 10 to 40 mg daily was given with ciclosporin.

(e) Rosuvastatin

In an open-label study 10 stable heart transplant patients taking ciclosporin were given rosuvastatin 10 mg daily for 10 days. When compared to healthy historical controls, the rosuvastatin maximum levels and $AUC_{0\text{-}24}$ were found to have been increased by 10.6-fold and 7.1-fold, respectively. Rosuvastatin had little effect on ciclosporin levels.[37]

(f) Simvastatin

1. Effect on ciclosporin. A study found that the ciclosporin levels of 12 renal transplant patients fell from 334 to 235 micrograms/L after simvastatin 5 to 15 mg daily was added.[38] A retrospective study by the same authors confirmed these results in 12 patients.[38] In contrast, a single-dose pharmacokinetic study suggested that simvastatin increases the maximum levels and AUC of ciclosporin by a modest 8% and 13%, respectively.[39] Another study reported no significant change in ciclosporin levels over a period of 9 months in patients also taking simvastatin 10 mg daily, and no clinical signs of myopathy were observed.[29]

2. Effect on simvastatin. A group of 20 heart transplant patients were given simvastatin 10 mg daily and ciclosporin over a period of 4 months. The plasma levels of simvastatin acid were at least 6 times higher in 7 patients taking ciclosporin than in 7 control patients not taking ciclosporin. Significant changes in ALT levels and creatine kinase were seen, but the combination was well tolerated.[40] Another study, comparing 5 renal transplant patients taking ciclosporin and simvastatin 20 mg daily with 5 renal transplant patients not given ciclosporin, found that the AUC and maximum serum levels of simvastatin were 2.5-fold and 2-fold greater, respectively, in the patients taking ciclosporin.[41] In a third study, low-dose simvastatin 10 mg daily was well tolerated over 8 months in heart transplant patients receiving ciclosporin.[42]

There are at least 6 documented cases of rhabdomyolysis,[43-47] one of which was fatal,[44] in patients given ciclosporin and simvastatin. A further case of rhabdomyolysis occurred in a patient taking ciclosporin and amlodipine about 2 months after his statin was changed from atorvastatin 20 mg daily to simvastatin 40 mg daily.[48] Yet another case has been reported in a patient who had received ciclosporin and a statin (fluvastatin then pravastatin) for several years. Onset of muscle pain occurred about 2 months after simvastatin was substituted for pravastatin and 2 weeks after verapamil was added to his treatment : the effect was attributed to multiple drug interactions[49] (see also 'Statins + Calcium-channel blockers', p.1324). In a review of the FDA spontaneous reports of statin-associated rhabdomyolysis covering the period November 1997 to March 2000, ciclosporin was potentially implicated in 31 cases of rhabdomyolysis involving simvastatin.[8]

Mechanism

Complex and not fully understood. Ciclosporin appears to cause an increased systemic exposure to statins regardless of their main route of metabolism. However, the more marked rises in statin levels and/or toxicity (rhabdomyolysis) may occur because ciclosporin and some statins (e.g. lovastatin and simvastatin) compete for the same metabolising enzyme, the cytochrome P450 isoenzyme CYP3A4. The extent of the interaction seems to depend on the relative affinities of the different statins for this isoenzyme, and also on whether they can be metabolised by alternative pathways. P-glycoprotein and other transporter proteins such as the organic anion transporting polypeptide (OATP) 1B1 also have a part to play, especially in the raised statin levels seen with atorvastatin, and rosuvastatin. See 'Lipid regulating drugs', (p.1313), for more information about the metabolism of the statins.

Importance and management

The interacting effect of ciclosporin on the statins is well documented, well established and clinically important. Concurrent use need not be avoided but it should be very well monitored, a precautionary recommendation being to start (or reduce) the statin to the lowest daily dose appropriate to the patient's condition.[50,51]

For patients taking ciclosporin, the manufacturers of **atorvastatin**[52,53] and **simvastatin**[54,55] suggest that the statin dose should not exceed 10 mg daily, and the manufacturer of **lovastatin**[50] suggests its dose should not exceed 20 mg daily. The UK manufacturer of **pravastatin** suggests a starting dose of 20 mg.[51] The US manufacturer of **rosuvastatin** states that the dose of rosuvastatin should be limited to 5 mg daily,[56] whereas the UK manufacturer contraindicates concurrent use.[57]

Any patient given ciclosporin with a statin should be told to report any signs of myopathy and possible rhabdomyolysis (i.e. otherwise unexplained muscle pain, tenderness or weakness or dark coloured urine). If myopathy does occur, withdrawing the statin has been shown to resolve the symptoms. See also 'muscle toxicity', (p.1313), for further guidance on monitoring and risk factors for muscle toxicity.

Alterations in ciclosporin levels with the statins are generally small and seem likely to be identified by routine ciclosporin monitoring. However, note that, of the statins, simvastatin, and possibly atorvastatin have somewhat larger effects, and an increase in the frequency of ciclosporin monitoring may be desirable if these statins are used.

Statins + Cilostazol

Cilostazol may increase the plasma levels of lovastatin (and therefore probably simvastatin).

Clinical evidence

In a study in 13 healthy subjects, a single 80-mg oral dose of **lovastatin** was given before, and then on the final day of a 7-day treatment period with cilostazol 100 mg twice daily. The AUCs of **lovastatin** and its beta-hydroxy acid metabolite were increased by about 60% and 70%, respectively, by cilostazol, but the maximum plasma levels were unaffected.[1] At the end of this study (day 9), 12 subjects were given **lovastatin** 80 mg with a larger 150-mg dose of cilostazol. It was found that the maximum level and the AUC of the **lovastatin** metabolite were increased about twofold, suggesting that larger cilostazol doses may have a greater effect.[1] Lovastatin decreased the absorption of cilostazol by about 15%, but this was not considered to be clinically relevant.[1]

Mechanism

Lovastatin is metabolised by the cytochrome P450 isoenzyme CYP3A4 and it would appear that cilostazol can modestly inhibit this enzyme. **Simvastatin** is metabolised by the same route as lovastatin, and may therefore be expected to interact similarly.

Importance and management

Evidence for an interaction between cilostazol and lovastatin appears to be limited to this one study. The increases in lovastatin levels described here are much lower than those seen with moderate CYP3A4 inhibitors (e.g. see 'Statins + Calcium-channel blockers', p.1324) but the authors of the study still suggest that the dose of lovastatin may need to be reduced if cilostazol is also taken. This appears over-cautious. However, it may be prudent to remind patients to report any signs of myopathy and possible rhabdomyolysis (i.e. otherwise unexplained muscle pain, tenderness or weakness or dark coloured urine), especially if other risk factors are present. Similar advice should probably be given with concurrent use of cilostazol and simvastatin. If myopathy does occur, the statin should be

stopped immediately. See also 'muscle toxicity', (p.1313), for further guidance on monitoring, and risk factors for muscle toxicity.

Statins + Colchicine

Several case reports describe myopathy or rhabdomyolysis in patients given colchicine with atorvastatin, fluvastatin, pravastatin or simvastatin. It seems possible that this interaction could occur with colchicine and any statin.

Clinical evidence

(a) Atorvastatin

A 45-year-old man with nephrotic syndrome who had been taking colchicine 1.5 mg daily for 3 years without adverse effects, began to experience lower extremity weakness, muscle pain and gait instability about 2 weeks after he started taking atorvastatin 10 mg daily. Two weeks later rhabdomyolysis was diagnosed, with acute renal failure and an elevated creatine kinase level of more than fifty times the reference values. After withdrawal of colchicine and atorvastatin, his creatine kinase levels and muscle strength improved, but he then developed septic shock as a result of hospital-acquired pneumonia and died.[1]

(b) Fluvastatin

A 70-year-old man who had been taking fluvastatin 80 mg daily for 2 years started taking colchicine 1.5 mg daily for an attack of gouty arthritis. Within 3 days he felt nauseous and began to develop muscle pains and weakness. On admission to hospital he was found to have acute renal failure and a raised creatine kinase, and was diagnosed with rhabdomyolysis. Both drugs were stopped and he recovered over 19 days. He was eventually restabilised on fluvastatin without incident.[2]

(c) Pravastatin

A 65-year-old woman who had been taking pravastatin 20 mg daily for 6 years was given colchicine 1.5 mg daily for an episode of gout. Within 20 days she had developed muscle weakness in the legs and had a slightly raised creatine kinase. A diagnosis of myopathy was made and so both the colchicine and pravastatin were stopped. The weakness resolved over the following week. The colchicine was subsequently given alone, and myopathy did not occur.[3]

(d) Simvastatin

A 70-year-old man with chronic renal failure who had been taking simvastatin (dose not stated) for 2 years was given colchicine 500 micrograms twice daily for gout. Within 2 weeks he developed muscle weakness, which was diagnosed as myopathy. Both drugs were stopped and the symptoms resolved.[4] Another report describes rhabdomyolysis in a 61-year-old woman with mild renal impairment taking simvastatin 40 mg daily, who was also taking colchicine 600 micrograms twice daily. Two weeks later, the simvastatin dose was doubled to 80 mg daily. About one week after this, the patient began to experience increasing muscle weakness in her lower extremities, progressing to an inability to stand up or walk; on admission to hospital her creatine kinase levels were substantially increased. Both drugs were discontinued and within 2 weeks the muscle weakness had resolved and the creatine kinase levels had returned to the expected range. Simvastatin was restarted at 80 mg daily and allopurinol initiated; 6 months later, she was asymptomatic with normal creatine kinase levels.[5] A further report describes a similar case of rhabdomyolysis in a 79-year-old man with mild, chronic renal impairment after he had taken simvastatin 40 mg daily and colchicine (initially 600 micrograms daily, increased to twice daily after 4 days).[6]

Mechanism

It has been suggested that the interaction between colchicine and simvastatin or atorvastatin could occur due to competition for metabolism by the cytochrome P450 isoenzyme CYP3A4.[1,4,5] However, as the interaction has also been seen with fluvastatin and pravastatin, which are not metabolised in this way, this seems unlikely to be the full explanation. P-glycoprotein has also been implicated.[1,3] Colchicine alone can, rarely, cause myopathy. However, it is more common in those given colchicine long term, in high dose, or in the presence of renal impairment.[3] As the statins can also cause myopathy, an additive or synergistic effect seems possible.[2]

Importance and management

Although this interaction is rare, it is serious. Given the evidence available it seems likely to occur with all statins, although this has not been clearly demonstrated. All patients taking statins should be warned about the symptoms of myopathy and told to report muscle pain or weakness. It would be prudent to reinforce this advice if they are given colchicine. See also 'muscle toxicity', (p.1313), for further guidance on monitoring and risk factors for muscle toxicity.

Statins + Danazol

Severe rhabdomyolysis and myoglobinuria developed in a man taking lovastatin about two months after danazol was added. Other reports describe similar interactions with danazol in another patient taking lovastatin and a man taking simvastatin.

Clinical evidence

(a) Lovastatin

A 72-year-old man taking atenolol, aspirin, dipyridamole and lovastatin 20 mg twice daily was admitted to hospital after complaining of myalgia over the last 12 days, and brown urine over the last 5 days. He was diagnosed with severe rhabdomyolysis and myoglobinuria. About 2 months previously he had started taking danazol 200 mg three times daily and prednisone, and one month previously he had received a 10-day course of doxycycline 100 mg twice daily. The aspirin and lovastatin were stopped (danazol was stopped 4 days before admission and the doxycycline was stopped 5 days before the onset of symptoms), and all the symptoms resolved. Laboratory tests were normal within 2 weeks.[1] A similar case has been reported in a woman with end-stage renal disease, who was given danazol 600 mg daily, with the addition of lovastatin 40 mg daily, 5 weeks before admission. The authors note that both drugs had been previously tolerated when given alone, but it should be noted that the lovastatin had been given in a lower dose of 20 mg daily.[2]

(b) Simvastatin

A 68-year-old man who had been taking simvastatin 40 mg daily long-term without problem developed rhabdomyolysis (progressive muscle pain and weakness, tea-coloured urine, renal impairment, and a raised creatine phosphokinase) within 3 weeks of starting to take danazol 200 mg three times daily. He was given haemodialysis and subsequently recovered.

Mechanism

It has been suggested that danazol was hepatotoxic, which led to decreased lovastatin metabolism, or that the danazol had a direct toxic effect on the muscles.[1] However, it has also been suggested that danazol is an inhibitor of the cytochrome P450 isoenzyme CYP3A4 by which simvastatin and lovastatin are metabolised. This could result in raised statin levels, and therefore myopathy and rhabdomyolysis.[1,3] This seems a more likely explanation for the effects seen, but this suggestion needs confirmation.

Importance and management

These appear to be the only reports of this apparent interaction, but the pharmacokinetic basis of the interaction seems to be established. The benefits of combining lovastatin or simvastatin with danazol should be weighed against the potential risks and low doses should be used. The US manufacturer of lovastatin[4] suggests that the dose should be started at

10 mg daily, and should not exceed 20 mg daily in the presence of danazol. Similarly, the US manufacturer[5] of simvastatin suggests that the dose should be started at 5 mg daily, and both manufacturers state that the simvastatin dose should not exceed 10 mg daily in the presence of danazol.[5,6] It would seem prudent to monitor for symptoms of myopathy and tell patients to report any unexplained muscle pain, tenderness or weakness. The authors of the lovastatin report[1] point out that, as in this case, severe lovastatin muscle toxicity may be very slow to develop. See also 'muscle toxicity', (p.1313), for further guidance on monitoring, and risk factors for muscle toxicity.

The statins that are not significantly metabolised by CYP3A4 (**fluvastatin**, **pravastatin**, **rosuvastatin**) are not expected to interact.

Statins + Dipeptidylpeptidase-4 inhibitors

Saxagliptin, sitagliptin and vildagliptin do not alter the pharmacokinetics of simvastatin. Sitagliptin use was considered a possible contributing factor to two cases of statin-induced rhabdomyolysis (one with lovastatin and one with simvastatin). Simvastatin does not alter the pharmacokinetics of saxagliptin or vildagliptin.

Clinical evidence

(a) Saxagliptin

In a study in 23 healthy subjects, when saxagliptin 10 mg daily and **simvastatin** 40 mg daily were given together for 4 days there was no change in the pharmacokinetics of **simvastatin**, when compared with **simvastatin** alone. In addition, there was no change in the AUC of saxagliptin, and just a minor 21% increase in the saxagliptin maximum level, when compared with saxagliptin alone.[1]

(b) Sitagliptin

In a study in 12 healthy subjects, sitagliptin 200 mg daily for 5 days did not alter the pharmacokinetics of simvastatin acid or simvastatin lactone when a single 20-mg dose of **simvastatin** was given on day 5. In addition, there was no alteration in plasma inhibition of HMG-CoA reductase.[2]

Two cases of possible interactions have been reported.[3,4] In one, a 76-year-old man with chronic renal impairment and numerous other medical conditions was admitted with rhabdomyolysis and acute renal failure. His medications included antihypertensives, amiodarone, **simvastatin**, ezetimibe and sitagliptin. Four months previously, his simvastatin dose had been increased from 40 to 80 mg daily and ezetimibe 10 mg daily added. Six weeks previously, he had started sitagliptin 50 mg daily, increased to 100 mg daily 3 weeks later. Various medications were stopped including sitagliptin, simvastatin and ezetimibe, and he made a full recovery. He was later given **lovastatin** 10 mg daily.[3] In another case, a 75-year-old woman with normal renal function who had been taking **lovastatin** 40 mg daily for 12 years and diltiazem 240 mg daily (last dose adjustment 10 months previously) presented with weakness and was diagnosed with rhabdomyolysis secondary to statin use. Nineteen days earlier she had started sitagliptin 100 mg daily and after 14 days this was replaced with glimepiride 1 mg daily. A statin was not restarted.[4]

(c) Vildagliptin

In a study in 24 healthy subjects, there was no change in the pharmacokinetics of vildagliptin, **simvastatin** or its active metabolite, compared with either drug given alone, when vildagliptin 100 mg daily and **simvastatin** 80 mg daily were given together for 7 days.[5]

Mechanism

Saxagliptin, sitagliptin and vildagliptin do not affect the cytochrome P450 isoenzyme CYP3A4, by which simvastatin is principally metabolised, therefore no pharmacokinetic interaction was anticipated, and the controlled studies available confirm this. In the case of rhabdomyolysis with simvastatin, it was suggested that too high a dose of sitagliptin for the degree of renal impairment possibly contributed to renal impairment, which reduced simvastatin clearance.[3] However, it is also possible that the effect was due to using too high a dose of simvastatin with amiodarone.[6] In the second case with lovastatin, diltiazem could have caused this interaction, but the authors discounted this on the basis of the time frame since the diltiazem dose increase.[4] For more information on the interactions of amiodarone and diltiazem with the statins, see 'Statins + Amiodarone', p.1320, and 'Statins + Calcium-channel blockers', p.1324.

Importance and management

It appears that saxagliptin, sitagliptin and vildagliptin have no effect on the pharmacokinetics of simvastatin, and no interaction as a result of altered levels would therefore be expected. However, two possible cases of rhabdomyolysis with sitagliptin and a statin have been reported. One case could equally well have been caused by other factors, but another explanation for the other case is less clear. These cases are insufficient evidence to issue a general caution, but bear them in mind in the event of an unexpected response to treatment.

Statins + Distigmine

A case report describes rhabdomyolysis associated with the use of pravastatin and distigmine.

Clinical evidence, mechanism, importance and management

An isolated report describes a 70-year-old woman taking **pravastatin**, colestyramine and distigmine 10 mg daily who was admitted to hospital with symptoms including reduced urine output and muscle weakness. She was found to have a creatine kinase level of 4,069 units/L (reference range 45 to 163 units/L) and was diagnosed with rhabdomyolysis, which was thought to have been due to the pravastatin and colestyramine. These drugs were discontinued immediately, but 2 days later the patient's creatine kinase level remained elevated, and so the distigmine was also discontinued. After 3 days the creatine kinase levels had fallen, and had returned to the expected range after a further 8 days.[1] The authors of the report attributed the rhabdomyolysis to distigmine, with a possible contribution from pravastatin, based on the fall in the CK levels after its discontinuation, and recommend caution if distigmine is given with any statin. However, the patient had seemingly taken both drugs uneventfully for more than 18 months, distigmine is not normally associated with myopathy, it is unknown whether the creatine kinase levels would have dropped without the withdrawal of the distigmine, and the dose of pravastatin was not stated. Therefore an interaction is far from established. The current evidence is too slim to warrant any action if both drugs are taken.

Statins + Diuretics

In clinical studies, the safety and efficacy of statins were not altered by the concurrent use of diuretics. Reversible diabetes mellitus developed in a woman taking cyclothiazide with triamterene when she was also given pravastatin. No clinically relevant pharmacokinetic interaction occurs between simvastatin and eplerenone.

Clinical evidence, mechanism, importance and management

(a) Lovastatin

Retrospective analysis of clinical study data[1] found no evidence that the safety or efficacy of lovastatin was altered by the use of **potassium-sparing diuretics** (hydrochlorothiazide with **triamterene** or **amiloride**), or **thiazide diuretics** (mostly **hydrochlorothiazide**). Another retrospective study of 19 patients found that the addition of lovastatin to diuretic treatment caused an initial 30% fall in total serum cholesterol levels for one month, followed by a rise of about 20%. In a further 13 patients, the addition of diuretic treatment to lovastatin caused a 20% fall in total serum cholesterol for one month followed by a 20% rise back to baseline values. The diuretics used were **furosemide** (16 patients), **triamterene** with **hydrochlorothiazide** (7), **hydrochlorothiazide** (8), **indapamide** (1). The fall and subsequent rise in serum cholesterol levels occurred in all of the patients except just the one taking **indapamide**.[2] The reason for this initial fall in cholesterol, particularly when the diuretic was added to the statin, is unknown, and the findings of this study are difficult to interpret.

(b) Pravastatin

A 63-year-old woman who had been taking **cyclothiazide** with **triamterene**, and acebutolol, for 4 years, developed polyuria and polydipsia, which gradually worsened, within 3 weeks of starting to take pravastatin 20 mg daily. After another 4 months she was hospitalised with hyperglycaemia, which was treated with insulin and later glibenclamide (glyburide). The **cyclothiazide** with **triamterene** and pravastatin were stopped and gradually the diabetic symptoms began to abate. Five weeks after admission she was discharged without the need for any antidiabetic treatment with the diabetes fully resolved.[3] The detailed reasons for this reaction are not understood, but it would seem that the pravastatin increased the potential of the thiazide diuretic to raise blood glucose levels to the point where frank diabetes developed. This is an isolated case and its general importance is likely to be small. Indeed, a study involving dyslipidaemic, hypertensive patients found that captopril, **hydrochlorothiazide** and pravastatin were effective and well tolerated by the 128 patients taking this combination, and there was no significant change in glucose levels.[4]

(c) Simvastatin

In 18 healthy subjects simvastatin 40 mg daily had no effect on the pharmacokinetics of **eplerenone** 100 mg daily. The maximum level and AUC of simvastatin were decreased by 32% and 14%, respectively, but this was not considered to be clinically relevant.[2]

(d) Other statins

Retrospective analysis of clinical study data found no evidence that the safety or efficacy of **fluvastatin** was altered by the use of unspecified **diuretics**.[5]

The bulk of the evidence suggests no special precautions are necessary if diuretics are given concurrently with statins.

Statins + Everolimus

In a single-dose study in healthy subjects, everolimus did not cause a clinically relevant alteration in the pharmacokinetics or HMG-CoA reductase activity of atorvastatin or pravastatin. Everolimus pharmacokinetics were unaltered by the statins.[1] Dosage adjustments therefore seem unlikely to be necessary on concurrent use.

Statins + Ezetimibe

Ezetimibe does not appear to have adverse pharmacokinetic interactions with atorvastatin, fluvastatin, lovastatin, pitavastatin, rosuvastatin or simvastatin. However, some evidence suggests that concurrent use may increase the risk of myopathy.

Clinical evidence

(a) Atorvastatin

In a three-arm study, patients were given atorvastatin 80 mg daily, atorvastatin 80 mg daily with ezetimibe 10 mg daily, or atorvastatin 40 mg daily with ezetimibe 10 mg daily. No difference in adverse events was noted between each of the three groups and there were no significant elevations in creatine kinase. No cases of myopathy or rhabdomyolysis occurred, and the combination was well tolerated.[1] Similarly, an efficacy study found that ezetimibe did not worsen statin intolerance or toxicity in 628 patients with hypercholesterolaemia who were taking atorvastatin.[2] However, a case report describes a 43-year-old man taking atorvastatin 80 mg daily who developed severe muscle pain with elevated creatine kinase levels 3 weeks after he started taking ezetimibe 10 mg daily. Symptoms resolved when both drugs were withdrawn and he later restarted the atorvastatin without problems.[3] Other similar cases have also been reported, in patients taking ezetimibe 10 mg daily and atorvastatin 40 mg or 80 mg daily.[4,5]

(b) Fluvastatin

In a randomised study 32 otherwise healthy subjects with hypercholesterolaemia were given either ezetimibe 10 mg daily, fluvastatin 20 mg daily or both drugs in combination for 14 days. The pharmacokinetics of ezetimibe were not significantly affected by fluvastatin, but ezetimibe appeared to modestly decrease fluvastatin bioavailability: this was not considered to be clinically significant. The combination was well tolerated, with no evidence of increased incidence of adverse effects, and an enhanced lowering of LDL-cholesterol was noted, which was considered to be clinically favourable.[6] Similarly, another study in 199 patients with a history of muscle-related adverse effects with other statins, found that fluvastatin alone or in combination with ezetimibe were well tolerated for 12 weeks: the incidence of muscle-related adverse effects were 24%, 17%, and 14% in patients who received ezetimibe 10 mg daily, prolonged-release fluvastatin 80 mg daily, or both drugs, respectively.[7] However, a case report describes a 52-year-old man taking fluvastatin 80 mg daily who developed elevated creatine kinase levels 8 weeks after ezetimibe 10 mg daily was added. His creatine kinase levels returned to normal 4 weeks after the ezetimibe was withdrawn.[3]

(c) Lovastatin

In a randomised, crossover study, 18 healthy subjects were given either ezetimibe 10 mg daily, lovastatin 20 mg daily or both drugs in combination for 7 days. The combination was well tolerated, and no significant pharmacokinetic interaction was noted.[8]

(d) Pitavastatin

A review of ezetimibe[9] cites an unpublished study in which 18 healthy subjects were given ezetimibe 10 mg and pitavastatin 2 mg, alone and together. Concurrent use did not affect the pharmacokinetics of either drug.

(e) Rosuvastatin

In a placebo-controlled study 12 otherwise healthy subjects with hypercholesterolaemia were given ezetimibe 10 mg daily with rosuvastatin 10 mg daily for 14 days. The combination was well tolerated (no significant changes in liver enzymes or creatine phosphokinase noted), the pharmacokinetics of both drugs were not significantly changed, and an enhanced lowering of LDL-cholesterol was noted, which was considered to be clinically favourable.[10]

(f) Simvastatin

In a three-arm study, patients were given simvastatin 80 mg daily, simvastatin 80 mg daily with ezetimibe 10 mg daily, or simvastatin 40 mg daily with ezetimibe 10 mg daily. No difference in adverse events was noted between each of the 3 groups and there were no significant elevations in creatine kinase. No cases of myopathy or rhabdomyolysis occurred, and the combination was well tolerated.[1] Another study in patients with primary hypercholesterolaemia found a similar safety profile between simvastatin 10, 20, 40 or 80 mg daily taken as monotherapy (560 subjects) or in combination with ezetimibe 10 mg daily (544 subjects) for up to

6 months.[11] A further observational study in 25 heart transplant recipients (all of whom were receiving ciclosporin) found that ezetimibe 10 mg daily combined with simvastatin 10 or 20 mg daily was well tolerated.[12] A retrospective analysis of 17 studies found that overall, muscle related adverse effects, including myopathy, were no more common in patients taking ezetimibe with simvastatin than in those taking simvastatin alone. The incidence of myopathy was 0.08% (2 of 2563) in those taking simvastatin alone and 0.04% (2 of 4558) in those taking ezetimibe with simvastatin. However, these findings should be interpreted with caution as the studies were not specifically designed to detect muscle toxicity. In addition, many patients were excluded if they had other medical conditions, such as renal impairment, or if they were taking other potentially interacting medication.[13] In another study, ezetimibe 0.25 mg, 1 mg or 10 mg daily had no effect on the pharmacokinetics of simvastatin 10 mg daily, when both drugs were given for 14 days. In addition, 10 and 20-mg doses of simvastatin were well tolerated in combination with ezetimibe.[14]

(g) Unnamed statins

The manufacturers of ezetimibe note that, in controlled clinical studies, the incidence of consecutive elevations (3 or more times the upper limit of normal) in hepatic transaminase levels was 1.3% for patients taking a statin with ezetimibe and 0.4% for patients taking statins alone. These elevations in transaminases were generally asymptomatic, and resolved spontaneously, either with continued treatment or after the drugs were stopped.[15,16] Creatine phosphokinase levels greater than 10 times the upper limit of normal were reported in 1 of 917 (0.1%) patients given ezetimibe and a statin, 4 of 1674 (0.2%) patients given ezetimibe alone, and 4 of 929 (0.4%) patients given a statin alone.[15,16]

Mechanism, importance and management

The available evidence suggests that on the whole the concurrent use of a statin with ezetimibe does not result in a change in the pharmacokinetics of either drug. However, there is some evidence to suggest that, rarely, concurrent use may increase the risk of myopathy. Therefore any patient taking a statin who is also given ezetimibe should be told to report any signs of myopathy and possible rhabdomyolysis (i.e. otherwise unexplained muscle pain, tenderness or weakness or dark coloured urine). See also 'muscle toxicity', (p.1313), for further guidance on monitoring, and risk factors for muscle toxicity. Note that a combination preparation containing simvastatin and ezetimibe is widely available.

Statins + Fibrates

The plasma levels of lovastatin, simvastatin, atorvastatin, pitavastatin and pravastatin are increased by gemfibrozil, the levels of fluvastatin are increased by bezafibrate, and the levels of pravastatin are increased by fenofibrate. Both statins and fibrates are known to cause rhabdomyolysis, and their concurrent use increases the risk of this reaction, especially if plasma levels of the statin are also raised.

Clinical evidence

A. Bezafibrate

(a) Fluvastatin

In one study bezafibrate 200 mg three times daily increased the AUC and maximum levels of fluvastatin 20 mg daily by about 50 to 60%. Bezafibrate pharmacokinetics were not affected.[1]

(b) Lovastatin

In a study in 11 healthy subjects the pharmacokinetics of a single 40-mg dose of lovastatin were not altered by bezafibrate 400 mg daily for 3 days.[2]

B. Ciprofibrate

The manufacturer of fluvastatin reports that the concurrent use of ciprofibrate has no effect on the bioavailability of fluvastatin.[1]

C. Fenofibrate

(a) Atorvastatin

A 58-year-old man who had been taking atorvastatin 10 mg daily for 4 months developed rhabdomyolysis-induced acute renal failure one month after starting to take fenofibrate 200 mg daily. He recovered within a month, after treatment with diuretics and haemodialysis.[3]

(b) Fluvastatin

A single-dose study in 24 healthy subjects found that there was no significant pharmacokinetic interaction between fenofibrate 160 mg and fluvastatin 40 mg. Fenofibrate increased the AUC of fluvastatin by about 15%, but fluvastatin had little effect on fenofibric acid exposure.[4]

(c) Pitavastatin

In a crossover study in 24 healthy subjects, fenofibrate 160 mg daily increased the AUC of pitavastatin 4 mg by 18%, without affecting its maximum levels.[5]

(d) Pravastatin

A single-dose study in 23 healthy subjects found that the concurrent use of pravastatin 40 mg and fenofibrate 201 mg had no effect on the pharmacokinetics of either drug, but a moderate increase in the formation of a non-toxic pravastatin metabolite was seen. This was not thought to be clinically important.[6] In a multiple-dose study, pravastatin 40 mg daily was given to 23 healthy subjects with fenofibrate 160 mg daily. Fenofibrate increased the maximum levels and AUC of pravastatin by about 40% and 30%, respectively. Similar increases were seen for the main pravastatin metabolite. The combination was well tolerated, and the increases were considered to be modest.[7] However, a case report describes a patient taking fenofibrate 300 mg daily, who developed rhabdomyolysis after starting to take pravastatin 10 mg daily.[8] In another report, a 56-year-old woman who had taken pravastatin 20 mg daily for 12 years, developed severe rhabdomyolysis-induced acute renal failure about 2 months after starting to take fenofibrate 200 mg daily. She recovered in about 2 weeks after treatment with diuretics and haemodialysis.[3]

(e) Rosuvastatin

In a study in 14 healthy subjects, fenofibrate 67 mg three times daily and rosuvastatin 10 mg daily for 7 days resulted in only minor changes in fenofibric acid and rosuvastatin exposure, when compared with either drug given alone.[9] However, a 68-year-old man taking rosuvastatin 10 mg daily developed myopathy about 3 weeks after fenofibrate 160 mg was added. Rhabdomyolysis was diagnosed and both drugs were stopped, resulting in marked clinical improvement within 24 hours.[10]

(f) Simvastatin

In a randomised, crossover study 25 healthy subjects were given simvastatin 80 mg daily with fenofibrate 160 mg daily for 7 days. The phar-

macokinetics of both drugs and their main metabolites (as assessed in 12 subjects) were unchanged by concurrent use. All 25 subjects were assessed for safety, and the combination was found to be well tolerated.[11] Similarly, an 18-week, multicentre study (the SAFARI trial) investigated the efficacy and tolerability of simvastatin 20 mg and fenofibrate 160 mg daily. In the 411 patients who received both drugs concurrently, no drug-related serious adverse events were observed and there were no instances of clinical myopathy or severe abnormalities in liver function.[12] One manufacturer of simvastatin says that when simvastatin and fenofibrate are given concurrently, there is no evidence that the risk of myopathy exceeds the sum of the individual risks of each drug.[13] However, one 70-year-old man with diabetes and hypothyroidism, who was taking medication including simvastatin 40 mg, developed bilateral leg myalgia 2 weeks after fenofibrate 160 mg was started. Two weeks later he was found to have raised creatinine and creatine phosphokinase (CPK) levels and rhabdomyolysis was diagnosed. The fenofibrate and simvastatin were discontinued and, with hydration, the myalgia resolved; his creatinine levels returned to baseline over the next week and serum CPK returned to baseline within 4 weeks.[14]

D. Gemfibrozil

(a) Atorvastatin

A pharmacokinetic study in 10 healthy subjects found that gemfibrozil 600 mg twice daily increased the AUC of atorvastatin and its metabolites by 24% and 30 to 80%, respectively, which was considered a moderate increase.[15] A 43-year-old woman with multiple medical problems was taking gemfibrozil 600 mg twice daily. After a recurrent attack of pancreatitis, atorvastatin 10 mg and glibenclamide (glyburide) 2.5 mg, both twice daily, were added. About 3 weeks later she developed brown and turbid urine (suggesting urinary myoglobin), creatine kinase levels of 4633 units/L and had myalgia: she was diagnosed as having rhabdomyolysis. Her serum creatine kinase levels rapidly fell when the atorvastatin and gemfibrozil were withdrawn.[16]

In a case series of 10 patients taking a statin who experienced myopathy and presented for muscle biopsy, one patient taking gemfibrozil developed gradual onset of weakness over a 3-month period after his dose of atorvastatin was increased from 10 mg to 20 mg.[17]

(b) Fluvastatin

In a randomised, crossover study, 15 patients were given fluvastatin 20 mg and gemfibrozil 600 mg twice daily. The pharmacokinetics of both gemfibrozil and fluvastatin were unchanged by concurrent use and no significant adverse effects were noted.[18] However, a case report describes serious hepatocellular injury, and rhabdomyolysis causing acute renal failure, in a patient one month after she started to take fluvastatin 80 mg daily and gemfibrozil 1.2 g daily; she was not using any other medications.[19]

(c) Lovastatin

In a pharmacokinetic study, 11 healthy subjects were given gemfibrozil 1.2 g daily for 3 days, with a single 40-mg dose of lovastatin on day 3. The AUC and maximum plasma level of lovastatin acid (a metabolite) were nearly threefold greater in the presence of gemfibrozil.[2]

By 1990 the FDA had documented 12 case reports of severe myopathy or rhabdomyolysis associated with the concurrent use of lovastatin and gemfibrozil. The mean serum creatine kinase levels of the patients reached 15 250 units/L. Four of those tested had myoglobinuria and five had acute renal failure.[20] Other cases of rhabdomyolysis associated with the concurrent use of these drugs have been reported,[21-26] five involving renal failure.[21-23,25] A review of the concurrent use of a statin and a fibrate identified additional cases of rhabdomyolysis involving gemfibrozil and lovastatin, mainly with lovastatin doses of 40 mg daily and above.[27] Further cases of rhabdomyolysis have been seen in patients taking lovastatin and gemfibrozil, with ciclosporin,[28] or niacin.[29]

Many reports suggest there is insufficient benefit to warrant combining lovastatin and gemfibrozil,[20,30] although in contrast, some describe apparently safe and effective concurrent use under very well controlled conditions,[31-33] although muscle symptoms and/or elevated creatine phosphokinase levels, without rhabdomyolysis, were seen in up to 9% of cases.

(d) Pitavastatin

In a crossover study in 24 healthy subjects, the concurrent use of pitavastatin 4 mg daily and gemfibrozil 600 mg twice daily increased the AUC and maximum level of pitavastatin by 45% and 31%, respectively.[5]

(e) Pravastatin

In a study in 18 healthy subjects gemfibrozil 600 mg caused no clinically significant changes in the bioavailability of a single 20-mg dose of pravastatin.[34] However, another study using pravastatin 40 mg found that the AUC and maximum levels of pravastatin were increased roughly twofold by gemfibrozil.[35] A 12-week study with pravastatin 40 mg daily and gemfibrozil 600 mg twice daily found that marked abnormalities in creatine kinase concentrations (four times the pretreatment values) occurred in 1 of 71 patients taking pravastatin alone, 1 of 73 patients taking placebo, 2 of 72 patients taking gemfibrozil alone, and 4 of 75 patients taking gemfibrozil with pravastatin. The differences between treatments were not statistically significant. Two patients taking gemfibrozil with pravastatin had these drugs withdrawn because of asymptomatic creatine kinase elevations. Severe myopathy or rhabdomyolysis was not seen in any patient, although 14 patients had musculoskeletal pain, but in most cases this was not considered to be related to treatment.[36]

(f) Rosuvastatin

In a randomised, crossover study, 20 healthy subjects were given gemfibrozil 600 mg twice daily for 7 days, with a single 80-mg dose of rosuvastatin on day 4. The AUC of rosuvastatin was increased by 88% (11 subjects assessed) and the maximum level of rosuvastatin was increased 2.21-fold. Three subjects had asymptomatic increases in ALT levels (less than 2.5 times upper limit of normal).[37]

(g) Simvastatin

A 62-year-old man with diabetes taking simvastatin 20 mg daily and gemfibrozil 600 mg daily (as well as acenocoumarol, glibenclamide (glyburide) and diclofenac) was hospitalised because of melaena, generalised myalgia, malaise and brown urine. Laboratory tests confirmed the diagnosis of rhabdomyolysis. He recovered when the simvastatin and gemfibrozil were stopped.[38] Another diabetic patient had been taking simvastatin and gemfibrozil 600 mg daily for two and a half years (as well as felodipine, indapamide, calcium carbonate, bumetanide, psyllium, acenocoumarol and insulin). She complained of tiredness, generalised myalgia and anuria 3 months after her dosage of simvastatin had been increased to 80 mg daily. Rhabdomyolysis with renal impairment were diagnosed and confirmed. She recovered when the simvastatin and gemfibrozil were stopped.[38] Four further cases of rhabdomyolysis have been reported in patients taking simvastatin, 3 weeks to 3 months after starting gemfibrozil.[39-42] One of these cases was fatal.[39]

A pharmacokinetic study found that when gemfibrozil was given with simvastatin the AUC of simvastatin acid (an active metabolite of simvastatin) was increased nearly threefold and the peak concentration was approximately doubled.[43]

In a case series of 10 patients taking a statin who experienced myopathy and presented for muscle biopsy, two patients taking gemfibrozil gradually developed myopathy while also taking simvastatin 80 mg daily.[17]

E. Unspecified Fibrates or Statins

In a review[44] of the FDA spontaneous reports of statin-associated rhabdomyolysis covering the period November 1997 to March 2000, fibrates (unspecified) were potentially implicated in 10 of 73 cases of rhabdomyolysis seen with **atorvastatin**, 4 of 10 with **fluvastatin**, 5 of 40 with **lovastatin**, 6 of 71 with **pravastatin**, and 33 of 215 with **simvastatin**. Another review using data from the adverse event reporting system of the FDA concluded that the concurrent use of **fenofibrate** with a statin results in fewer reports of rhabdomyolysis than the concurrent use of **gemfibrozil** and a statin (0.58 cases per million prescriptions and 8.6 cases per million prescriptions, respectively).[45]

Mechanism

Complex and not fully understood. Myopathy can occur with statins and fibrates alone and their effects may therefore be additive or synergistic. There is also evidence that some fibrates may inhibit the metabolism of the statins, but *not* by inhibiting the cytochrome P450 isoenzyme CYP3A4.[2,43] More recent study has shown that gemfibrozil may inhibit the glucuronidation of some of the statin metabolites, and that gemfibrozil and gemfibrozil glucuronide are inhibitors of some of the CYP2C isoenzymes e.g. CYP2C8.[46,47] Other evidence suggests that drug transporter proteins, such as the organic anion transporting polypeptide OATP1B1 (also known as OATP2 and OATP-C), may also be involved.[35,37,48,49] However, a pharmacokinetic interaction with statins does not appear to be a group effect of the fibrates, for example, bezafibrate does not affect the bioavailability of lovastatin.

Importance and management

There are many studies showing efficacious use of many pairs of statins and fibrates, and the overall incidence of myopathy with a statin and a fibrate has been put at 0.12%, although this may be an underestimate as many of the studies excluded patients with renal or liver impairment and thyroid dysfunction.[27] In addition, evaluation of the data is difficult as there has been no standard definition of myopathy. Another retrospective review of patients with myopathy suggested an incidence of 0.12% with statins alone and 0.22% with statins combined with an interacting drug, including fibrates.[50] A further study estimated that, compared with statin monotherapy, the concurrent use of a statin and a fibrate was associated with a 5.5-fold increase in the risk of rhabdomyolysis. In addition, the use of a statin with a fibrate increased the risk twofold when compared with a fibrate alone.[51] Therefore, the risks of these combinations are evident, at least for individual patients.

The pharmacokinetic interaction varies between the different statins and fibrates with gemfibrozil affecting the bioavailability of most statins (except fluvastatin), and other fibrates such as fenofibrate less likely to cause a pharmacokinetic interaction. In addition, individual fibrates have different safety profiles: for example, a review of adverse events submitted to the FDA over a 5-year period suggested that fenofibrate had a higher rate of liver-related adverse effects than gemfibrozil and gemfibrozil had a higher rate of muscle-related adverse effects than fenofibrate.[52] Therefore, individual combinations of statins and fibrates are associated with different levels of risk.

General recommendations. In general, concurrent use of a stain and a fibrate should only be undertaken if the benefits of treatment outweigh the risks. Monitoring of creatine kinase has been suggested in patients taking a statin with a fibrate, but this will not necessarily identify all cases of developing rhabdomyolysis. As a general rule, any patient given a statin and a fibrate should be told to report any signs of myopathy and possible rhabdomyolysis (i.e. otherwise unexplained muscle pain, tenderness or weakness or dark coloured urine). If myopathy does occur, the statin should be stopped immediately. See also 'muscle toxicity', (p.1313), for further guidance on monitoring and risk factors for muscle toxicity.

Simvastatin and Lovastatin. The interactions of lovastatin and simvastatin with fibrates, particularly **gemfibrozil**, are established and clinically important. The FDA discourage the concurrent use of lovastatin with gemfibrozil in any patient, but suggest that it should be completely avoided in patients with compromised liver or renal function.[20] The manufacturers of lovastatin and simvastatin recommend that combined use with gemfibrozil should generally be avoided, but if the benefits are considered to outweigh the risks, a low dose of the statin should be used. In the presence of gemfibrozil, the maximum generally recommended dose for lovastatin is 20 mg and for simvastatin is 10 mg.[13,53,54] For **other fibrates**, the manufacturers recommend caution, and similarly suggest that if the benefits are considered to outweigh the risks, a low dose of the statin should be used: the same maximum statin doses are generally recommended,[13,53] although **fenofibrate** has been excluded from this recommendation for simvastatin.[13] Note that the manufacturer of **bezafibrate** contraindicates the use of a statin if a number of conditions considered to be risk factors for myopathy (such as renal impairment and hypothyroidism) are present.[55]

Atorvastatin. If the concurrent use of atorvastatin and a fibrate is unavoidable, the manufacturers suggest that lower doses of atorvastatin should be considered; in the UK a starting dose of 10 mg is specifically mentioned.[56,57] Note that the manufacturer of **bezafibrate** contraindicates the use of a statin if a number of conditions considered to be risk factors for myopathy (such as renal impairment and hypothyroidism) are present.[55]

Rosuvastatin. The manufacturers of rosuvastatin also suggest that combination with **gemfibrozil** should be avoided, but if the benefits outweigh the risks, the US manufacturer recommends a maximum dose of 10 mg of rosuvastatin.[58] Further, the UK manufacturer recommends starting with a 5-mg dose of rosuvastatin, and contraindicates the 40-mg dose, in any patient taking a fibrate.[59] Note that the manufacturer of **bezafibrate** contraindicates the use of a statin if a number of conditions considered to be risk factors for myopathy (such as renal impairment and hypothyroidism) are present.[55]

Other statins. The manufacturer of **bezafibrate** contraindicates the use of a statin if a number of conditions considered to be risk factors for myopathy (such as renal impairment and hypothyroidism) are present.[55]

Statins + Fibre or Pectin

Pectin and oat bran can reduce the cholesterol-lowering effects of lovastatin.

Clinical evidence, mechanism, importance and management

The serum LDL-cholesterol levels of 3 patients taking lovastatin 80 mg daily showed a marked 42% rise from 4.48 mmol/L to 6.36 mmol/L when they were also given pectin 15 g daily. One patient had a 59% rise in LDL-cholesterol.[1] Two other patients taking lovastatin had a rise in LDL-cholesterol from 5.03 mmol/L to 6.54 mmol/L when they were also given **oat bran** 50 to 100 g daily. One patient had a 41% rise in LDL-cholesterol.[1] When the pectin and **oat bran** were stopped, the serum levels of the LDL-cholesterol fell.

It is presumed that both pectin and **oat bran** reduced the absorption of lovastatin from the gut.[1] Evidence is still very limited but if patients are adding these fibres to their diets it would seem prudent to separate the ingestion of lovastatin by as much as possible. The effect of these fibres on other statins does not appear to have been studied.

1. Richter WO, Jacob BG, Schwandt P. Interaction between fibre and lovastatin. *Lancet* (1991) 338, 706.

Statins + Fusidic acid

Rhabdomyolysis has been described in patients given atorvastatin or simvastatin with fusidic acid.

Clinical evidence, mechanism, importance and management

A 66-year-old man with a renal transplant and diabetes, taking various drugs, was given **atorvastatin** 10 mg daily for hyperlipidaemia. Six weeks later, because of a resistant infection, clindamycin and ciprofloxacin were discontinued and fusidic acid 1.5 g daily was started. At this time serum creatine kinase was 54 units/L. Two weeks later the patient was admitted with progressive muscle weakness and pain in both legs. His serum creatine kinase was 3550 units/L, and he also had raised myoglobin levels. Both continued to rise for 5 days after the **atorvastatin** and fusidic acid were stopped, and then gradually returned to normal over one week. Serum levels of both fusidic acid and **atorvastatin** were higher than expected, and it was considered that an interaction was likely.[1]

A 78-year-old woman who had been taking **simvastatin** 10 mg daily for 10 months, developed rhabdomyolysis 15 days after starting to take fusidic acid. She recovered after stopping both drugs.[2] Another case of rhabdomyolysis and acute renal failure occurred postoperatively in a 71-year-old man taking multiple drugs including fusidic acid and **simvastatin** 40 mg daily. He recovered after withdrawal of the simvastatin.[3] Other cases of rhabdomyolysis, following the use of fusidic acid with **atorvastatin** or **simvastatin** have also been reported.[4,5] This includes a case where simvastatin was originally considered to be interacting with tacrolimus rather than fusidic acid, see 'Statins + Tacrolimus', p.1344.

The clinical significance of this possible interaction is unclear. It would seem wise to remind patients taking either **atorvastatin** or **simvastatin** with fusidic acid to be on the look out for the symptoms of myopathy and rhabdomyolysis (i.e. otherwise unexplained muscle pain, tenderness or weakness or dark coloured urine). If myopathy does occur, the statin should be stopped immediately. See also 'muscle toxicity', (p.1313), for further guidance on monitoring, and risk factors for muscle toxicity.

Statins + Grapefruit and other fruit juices

Large amounts of grapefruit juice markedly increase the plasma levels of lovastatin and simvastatin, and also increase the plasma levels of atorvastatin. Pitavastatin and pravastatin seem not to interact. The clinical significance of the possible effects of pomegranate juice on rosuvastatin, and orange juice on pravastatin are unclear.

Clinical evidence

(a) Atorvastatin

Twelve healthy subjects were given 200 mL of double-strength grapefruit juice three times daily for 5 days. On day 3 they were given a single 40-mg dose of atorvastatin with the grapefruit juice then two more 200-mL doses of grapefruit juice, one after 30 minutes and the other after 90 minutes. The $AUC_{0\text{-}72}$ of atorvastatin acid and total HMG-CoA reductase inhibitors were increased 2.5-fold and by 50%, respectively.[1] Other studies, using 250 mL of single-strength grapefruit three times a day, have found broadly similar increases in atorvastatin levels.[2,3] In contrast, the manufacturers report that one 240-mL glass of grapefruit juice has a more modest effect, causing an increase of only 37% in the AUC of atorvastatin.[4]

(b) Lovastatin

Ten healthy subjects were given 200 mL of double-strength grapefruit juice three times daily for 3 days. On day 3 they took lovastatin 80 mg with 200 mL of grapefruit juice, then two more 200-mL doses of grapefruit juice, one after 30 minutes and the other after 90 minutes. The mean peak serum levels of the lovastatin and its active metabolite, lovastatin acid, were increased 12-fold and fourfold, respectively, and the mean AUCs were increased 15-fold and fivefold, respectively.[5] However, another study in which lovastatin 40 mg was given the evening after single-strength grapefruit juice was taken with breakfast found that the AUC and maximum serum level of lovastatin were approximately doubled, and the AUC and maximum serum level of lovastatin acid were only increased by 60%.[6] It has been suggested that if the grapefruit juice had been given at the same time as the lovastatin in the latter study[6] then much greater increases in the AUC and maximum serum levels would have been found.[7]

(c) Pitavastatin

A study in 8 healthy Japanese men found that 250 mL of single-strength grapefruit juice three times daily for 4 days had a minimal effect on the pharmacokinetics of a single dose of pitavastatin 4 mg given on day 4. The AUC of pitavastatin acid was increased by 13% and the change in the maximum plasma concentration was negligible.[2]

(d) Pravastatin

Grapefruit juice did not significantly affect the pharmacokinetics of a single 40-mg dose of pravastatin. In this study, 200 mL of double-strength grapefruit juice was given three times daily for 2 days, and then on the third day 200 mL was given with the pravastatin and again after 30 and

90 minutes.[1] A further study using 10 mg of pravastatin similarly found that grapefruit juice did not significantly affect pravastatin pharmacokinetics.[3]

In a study in 14 healthy subjects a total of 800 mL of **orange juice**, was given over about 3 hours, starting 15 minutes before a 10-mg dose of pravastatin. **Orange juice** increased the $AUC_{0\text{-}4}$ of pravastatin by a modest 50%, without affecting the maximum pravastatin levels.[8]

(e) Rosuvastatin

A case report describes a 48-year-old man taking ezetimibe 10 mg daily, and rosuvastatin 5 mg on alternate days, who developed rhabdomyolysis within 3 weeks of starting to drink 200 mL of **pomegranate juice** twice weekly. Although the patient had been stable taking ezetimibe with rosuvastatin for 15 months he had a history of myopathy with statins and had an elevated creatine kinase before statin treatment was started.[9]

(f) Simvastatin

Ten healthy subjects were given 200 mL of double-strength grapefruit juice three times daily for 2 days. On day 3 they took 60 mg of simvastatin with 200 mL of grapefruit juice, then two more 200-mL doses of grapefruit juice, one after 30 minutes and the other after 90 minutes. The mean peak serum levels of the simvastatin and simvastatin acid were increased ninefold and sevenfold, respectively, and the mean AUCs were increased 16-fold and sevenfold, respectively.[10] In a further study by the same research group, when simvastatin was given 24 hours after the last dose of grapefruit juice (same dosage regimen as the previous study) the effect was only 10% of that observed during concurrent use, and had disappeared within 3 to 7 days.[11] However, the manufacturers of simvastatin note that drinking 240 mL of standard grapefruit juice in the morning and taking simvastatin in the evening increased the exposure to simvastatin by 90%.[12] Another study found as little as 200 mL of grapefruit juice daily for 3 days could increase the maximum levels of a single 40-mg dose of simvastatin taken on day 3, and its metabolite, simvastatin acid, up to about fourfold.[13]

A case report describes rhabdomyolysis in a patient taking simvastatin 80 mg daily (dose increased 6 months before presentation), which occurred 4 days after she started to eat one fresh grapefruit a day.[14]

Mechanism

It seems that some components of the grapefruit juice (including furanocoumarin derivatives and flavonoids such as naringenin), inhibit the activity of the cytochrome P450 isoenzyme CYP3A4 in the gut wall, thereby reducing the metabolism of the affected statins as they are absorbed, and allowing more to pass into the body. See 'Lipid regulating drugs', (p.1313), for more information about the metabolism of the statins.

Importance and management

Information about the interaction of statins and grapefruit juice seems to be mainly limited to pharmacokinetic reports (i.e. few adverse case reports) but they are consistent with the way other CYP3A4 inhibitors interact with the statins. Large increases in the serum levels of **lovastatin** and **simvastatin** are potentially hazardous because elevated statin levels carry the risk of toxicity (muscle damage and the possible development of rhabdomyolysis). As even small quantities of grapefruit juice taken in the morning can significantly affect simvastatin levels the UK manufacturer says that concurrent use should generally be avoided.[15] In the US the manufacturers suggest that intake of grapefruit juice should be restricted to less than one quart [roughly 1 litre] daily.[12,16] See also 'muscle toxicity', (p.1313), for further guidance on monitoring and risk factors for muscle toxicity.

The modest increase in **atorvastatin** levels when taken with usual doses of grapefruit juice seems less likely to be clinically relevant, but the UK manufacturer suggests that large quantities (not defined) are not recommended.[4] In general, the occasional glass of grapefruit juice would not appear to be a problem. **Pitavastatin** and **pravastatin** seem not to interact. Information about other statins appears to be lacking, but no interaction would be expected with **fluvastatin** or **rosuvastatin**, as these statins are not significantly metabolised by CYP3A4.

The interaction of **pomegranate juice** with rosuvastatin and ezetimibe seems to be limited to one case report, which is clouded by other possible contributory factors. Furthermore, although pomegranate juice has been shown to inhibit CYP3A4,[9] rosuvastatin is not metabolised by this route. Although it is possible that other mechanisms may be responsible, no firm conclusions can be drawn from this case.

The interaction of pravastatin with **orange juice** would be expected to be of little clinical significance in most patients, but this needs confirmation.

Statins + H_2-receptor antagonists or Proton pump inhibitors

No clinically significant interaction usually appears to occur between cimetidine and atorvastatin, fluvastatin, or pravastatin; between ranitidine and fluvastatin; or between omeprazole and fluvastatin.

Clinical evidence, mechanism, importance and management

(a) Atorvastatin

In a crossover study, 12 healthy subjects were given atorvastatin for 15 days with and without **cimetidine** 300 mg four times daily. **Cimetidine** had no effect on the maximum serum levels or AUC of atorvastatin. **Cimetidine** had little effect on the lipid-lowering ability of atorvastatin, except that the reduction in triglycerides was slightly less, but this difference was considered to be of little clinical significance.[1] There would appear to be no reason for avoiding concurrent use.

Esomeprazole has been implicated in a case of rhabdomyolysis involving atorvastatin and clarithromycin. See 'Statins + Macrolides', p.1337.

(b) Fluvastatin

The manufacturers of fluvastatin say that its bioavailability is increased by **cimetidine**, **omeprazole**, and **ranitidine** (AUC increased by 24 to 33%[2]), but they say that this is of no clinical relevance.[3] No dose adjustments would seem to be necessary on concurrent use.

(c) Pravastatin

Cimetidine 300 mg four times daily for 3 days increased the bioavailability of a single 20-mg dose of pravastatin by 58%. The dose of pravastatin was given on day 3, one hour after the first dose of **cimetidine**.[4] However, the manufacturers say that it is unlikely that the changes caused by **cimetidine** will affect the clinical efficacy of pravastatin.[4]

Statins + Imatinib

Imatinib raises simvastatin serum levels, increasing the risk of toxicity. It seems likely that statins metabolised in the same way as simvastatin may also be similarly affected.

Clinical evidence, mechanism, importance and management

In a single-dose study, 20 patients with chronic myeloid leukaemia were given **simvastatin** 40 mg before and on the last day of a 7-day course of imatinib 400 mg daily. Imatinib increased the maximum serum levels of **simvastatin** twofold and the AUC threefold. The authors conclude that caution is warranted if **simvastatin** and imatinib are taken concurrently.[1]

Imatinib inhibits the cytochrome P450 isoenzyme CYP3A4,[1] by which **simvastatin** is metabolised. It therefore seems likely that **lovastatin** will be similarly affected, and **atorvastatin** may be affected to some extent. These rises increase the risk of statin toxicity (myopathy and rhabdomyolysis).

As a general rule, any patient given imatinib with **simvastatin** (or **lovastatin**, and probably **atorvastatin**) should be told to report any signs of myopathy and possible rhabdomyolysis (i.e. otherwise unexplained muscle pain, tenderness or weakness or dark coloured urine). If myopathy does occur, the statin should be stopped immediately. See also 'muscle toxicity', (p.1313), for further guidance on monitoring, and risk factors for muscle toxicity.

Effects of imatinib mesylate (STI517, Glivec) on the pharmacokinetics of simvastatin, a cytochrome P450 3A4 substrate, in patients with chronic myeloid leukaemia. *Br J Cancer* (2003) 89, 1855–9.

Statins + Macrolides

Cases of acute rhabdomyolysis have been reported between lovastatin and azithromycin, clarithromycin, or erythromycin and between simvastatin and clarithromycin or roxithromycin. Macrolide antibacterials have also been potentially implicated in cases of rhabdomyolysis with atorvastatin and pravastatin. Pharmacokinetic studies suggest that many macrolides increase the levels of atorvastatin, lovastatin and simvastatin.

Clinical evidence

(a) Azithromycin

1. Atorvastatin. In a randomised study, two groups of 12 healthy subjects were given atorvastatin 10 mg daily for 8 days with azithromycin 500 mg daily or placebo for the final 3 days. When the azithromycin group were compared with the placebo group no change in atorvastatin pharmacokinetics were noted.[1]

2. Lovastatin. A 51-year-old man who had been taking lovastatin 40 mg daily for 5 years developed muscle aches and fever one day after finishing a 5-day course of azithromycin 250 mg daily. His creatine phosphokinase levels were elevated and he was diagnosed as having rhabdomyolysis. This patient was also taking colestyramine, diltiazem, doxazosin, glibenclamide (glyburide), 'thyroid', allopurinol, naproxen, prednisone, loratadine and inhaled beclometasone.[2]

(b) Clarithromycin

1. Atorvastatin. In a randomised study, two groups of 12 healthy subjects were given atorvastatin 10 mg daily for 8 days with clarithromycin 500 mg twice daily or placebo for the final 3 days. When the clarithromycin group were compared with the placebo group the atorvastatin AUC was 82% higher and the maximum serum levels 50% higher.[1] In another randomised study, 15 healthy subjects were given atorvastatin 80 mg daily with clarithromycin 500 mg twice daily for 8 days. Clarithromycin increased the AUC of atorvastatin fourfold.[3]

Two case reports describe rhabdomyolysis in patients taking atorvastatin with clarithromycin,[4,5] although both of these cases were complicated by the presence of other drugs (efavirenz/lopinavir/ritonavir,[5] **esomeprazole**[4]) which may also have contributed to the interaction.

2. Lovastatin. A 76-year-old woman who had been taking lovastatin 40 mg daily for 5 years developed muscle pain and weakness 2 days after completing a 10-day course of clarithromycin 500 mg twice daily. Later, when hospitalised, she was found to have elevated creatine phosphokinase levels and was diagnosed as having acute rhabdomyolysis.[2] Another case report describes rhabdomyolysis in a patient taking lovastatin and clarithromycin. This patient was also taking gemfibrozil, which may have played a part in the interaction.[6]

3. Pravastatin. In a randomised study, 15 healthy subjects were given pravastatin 40 mg daily with clarithromycin 500 mg twice daily for 8 days. Clarithromycin increased the AUC of pravastatin twofold.[3]

4. Simvastatin. A preliminary report of a pharmacokinetic study suggests that clarithromycin 500 mg twice daily for 7 days can cause an eightfold increase in the AUC and maximum levels of a single 40-mg dose of simvastatin.[7] In a randomised study, 15 healthy subjects were given simvastatin 40 mg daily with clarithromycin 500 mg twice daily for 8 days. Clarithromycin increased the AUC of simvastatin tenfold.[3]

A case report describes a 64-year-old man with multiple pathologies, including renal impairment, developed rhabdomyolysis 3 weeks after clarithromycin was added to his treatment, which included simvastatin 80 mg daily.[8] Other reports describe 5 further cases of rhabdomyolysis in patients taking simvastatin,[9-13] which in some cases occurred within days of the clarithromycin being started. In 3 of these cases the patients were also taking amiodarone,[11] or ciclosporin,[10,12] which may also have had some part to play in the reaction.

(c) Erythromycin

1. Atorvastatin. In a study, 12 healthy subjects were given a single 10-mg dose of atorvastatin on day 7 of an 11-day course of erythromycin 500 mg four times daily. The maximum serum levels of atorvastatin were raised by 38% and the AUC was raised by 33% by the erythromycin.[14]

2. Fluvastatin. The manufacturer reports a study in which the steady-state plasma levels of fluvastatin 40 mg daily were not affected by a single 500-mg dose of erythromycin.[15]

3. Lovastatin. A man taking lovastatin 20 mg three times daily, diltiazem, allopurinol and aspirin developed progressive weakness and diffuse myalgia after taking erythromycin 500 mg every 6 hours for 13 days. When admitted to hospital his creatine kinase level was high (35 200 units/L) and his urine was reddish-brown. The rhabdomyolysis was treated by stopping the lovastatin, and by giving furosemide with vigorous intravenous hydration.[16] A woman who had been taking lovastatin for 7 years developed multiple organ toxicity (rhabdomyolysis, acute renal failure, pancreatitis, livedo reticularis and raised aminotransferase levels) when erythromycin was added.[17] Four other cases of rhabdomyolysis attributed to an interaction between lovastatin and erythromycin have been reported,[17-19] although it should be noted that one of these patients[18] was also taking ciclosporin, which may have contributed to the effects seen.

In a study, 6 healthy subjects were given lovastatin 40 mg daily for 14 days, with erythromycin 500 mg three times daily for the last 7 days. The erythromycin caused the maximum serum levels and AUC of lovastatin to rise more than fivefold.[20]

4. Pravastatin. In a study, 6 healthy subjects were given pravastatin 40 mg daily for 14 days, with erythromycin 500 mg three times daily for the last 7 days. The pharmacokinetics of the pravastatin remained unchanged.[20] However, in another study, erythromycin caused a 70% increase in the AUC and a 2.2-fold increase in the maximum level of pravastatin.[21]

5. Rosuvastatin. In a study in 11 healthy subjects, erythromycin 500 mg four times daily for 7 days did not raise the levels of a single 80-mg dose of rosuvastatin. In fact, rosuvastatin levels were slightly lowered, although this was not considered to be of clinical relevance if short-term courses of erythromycin are used.[22]

6. Simvastatin. An 83-year-old man receiving multiple medication, who had been taking simvastatin 80 mg daily for at least 5 years, developed rhabdomyolysis about 2 weeks after he completed a 14-day course of erythromycin 500 mg four times daily (given intravenously for 2 days then orally for 10 days) for atypical pneumonia.[13]

A study in which 12 subjects were given erythromycin 500 mg three times daily, found a 6.2-fold increase in the AUC of a single 40-mg dose of simvastatin, and a 3.4-fold increase in its maximum serum levels. The major active metabolite, simvastatin acid, was similarly affected.[23]

(d) Roxithromycin

1. Lovastatin. In a randomised, crossover study, 12 healthy subjects were given lovastatin 80 mg either alone or following 5 days of pre-treatment with roxithromycin 300 mg four times daily. Roxithromycin increased the

maximum level and AUC of lovastatin acid by 38% and 42%, respectively, and decreased the maximum level and AUC of lovastatin lactone by a similar amount.[24]

2. Simvastatin. A 73-year-old woman, who had been stable for 6 months while taking a combination of gemfibrozil 600 mg twice daily, simvastatin 80 mg daily and diltiazem, developed muscular weakness and myalgia 7 days after starting roxithromycin. All drugs were stopped, and initially she developed myoglobinuria and had a further elevation in her creatine kinase level, but this normalised over the following 18 days. She was discharged after 6 weeks, by which time she had regained full strength.[25]

(e) Telithromycin

In a randomised, crossover study, 14 healthy subjects were given telithromycin 800 mg daily for 5 days, with a single 40-mg dose of **simvastatin** either with, or 12 hours after, the last dose of telithromycin. Although separating administration decreased the effect of telithromycin on **simvastatin** levels by over 50%, the AUC and maximum serum levels of **simvastatin** were still raised 4-fold and 3.4-fold, respectively.[26]

(f) Unspecified macrolides

In a review of the FDA spontaneous reports of statin-associated rhabdomyolysis covering the period November 1997 to March 2000, macrolide antibacterials (unspecified) were potentially implicated in 13 of 73 cases of rhabdomyolysis seen with **atorvastatin**, 11 of 40 with **lovastatin**, 6 of 71 with **pravastatin**, and 10 of 215 with **simvastatin**.[27]

Mechanism

Most macrolides inhibit the cytochrome P450 isoenzyme CYP3A4, by which lovastatin, simvastatin and, to some extent, atorvastatin are metabolised. Hence the concurrent use of a macrolide raises the levels of these statins, leading in some instances to toxicity (myopathy and rhabdomyolysis). No interaction would be expected with pravastatin because it is not metabolised by CYP3A4, (although a moderate effect has been found with clarithromycin but it is possible that another mechanism may be responsible), no interaction would be expected with rosuvastatin as it is minimally metabolised, and no interaction would be expected with azithromycin (and possibly **dirithromycin** and **spiramycin**) as these macrolides not appear to inhibit CYP3A4 to any great extent. See 'Lipid regulating drugs', (p.1313), for a more detailed discussion of statin metabolism.

Importance and management

Information about the interactions between statins and macrolide antibacterials seems to be limited to the reports cited here. In general it appears that the macrolides raise the levels of statins metabolised by CYP3A4 (i.e. atorvastatin, lovastatin and simvastatin), but not all patients are affected. One study found a large interpatient variation in results,[23] which may account for this. It should be noted that the manufacturers of **lovastatin** and **simvastatin** contraindicate the concurrent use of these drugs with clarithromycin, erythromycin or telithromycin, and that the statin must be temporarily withdrawn if these antibacterials are required.[28-30]

The risk is smaller with atorvastatin, but as the cases illustrate adverse interactions are possible. The manufacturers of **atorvastatin** therefore recommend that concurrent use with clarithromycin or erythromycin should only be undertaken if the benefits outweigh the risks and that lower doses of atorvastatin should be considered.[31,32] The manufacturers of atorvastatin also suggest that the maintenance dose of atorvastatin should not exceed 20 mg daily if clarithromycin is also given or alternatively (for short courses of antibiotic) a temporary suspension of treatment with atorvastatin may be considered.[31,32] Note that the manufacturer of telithromycin specifically contraindicates atorvastatin.[33]

Pravastatin, **rosuvastatin** and **fluvastatin** are not significantly metabolised by CYP3A4, and so would not be expected to interact with macrolides via this mechanism, but potential cases have been identified with pravastatin.

To be on the safe side, any patient taking pravastatin who is given a macrolide (except probably azithromycin, dirithromycin or spiramycin) should be warned to be alert for any signs of myopathy (i.e. otherwise unexplained muscle pain, tenderness or weakness or dark coloured urine). If myopathy does occur, the statin should be stopped immediately. See also 'muscle toxicity', (p.1313), for further guidance on monitoring, and risk factors for muscle toxicity.

Statins + Nefazodone

Nefazodone has been implicated in cases of muscle toxicity and rhabdomyolysis in patients taking simvastatin, lovastatin, and possibly pravastatin.

Clinical evidence

(a) Lovastatin

In a review of the FDA spontaneous reports of statin-associated rhabdomyolysis, covering the period November 1997 to March 2000, nefazodone was potentially implicated in 2 cases of rhabdomyolysis involving lovastatin.[1]

(b) Pravastatin

A 74-year-old man taking atenolol, aspirin and pravastatin had his treatment with citalopram replaced by nefazodone 50 mg twice daily. Because the possibility of an interaction was suspected, his plasma creatine kinase levels were monitored and were found to be 877 units/L (reference range 0 to 190 units/L) at 36 hours. Lactate dehydrogenase, aspartate aminotransferase and alanine aminotransferase were all slightly elevated and

this was interpreted as indicating muscle toxicity. The nefazodone was withdrawn and although creatine kinase levels were falling they were still above the normal range when the pravastatin was withdrawn 14 days later. Pravastatin was subsequently re-introduced, and then venlafaxine 75 mg twice daily was added without problems.[2] However, the diagnosis of muscle toxicity has been questioned, and, because pravastatin levels were not measured, the possibility of an interaction has also been questioned.[3]

(c) Simvastatin

A 44-year-old man who had uneventfully taken simvastatin 40 mg daily for 19 weeks developed 'tea-coloured' urine, initially misdiagnosed as a urinary tract infection, a month after starting to take nefazodone 100 mg twice daily. A month later he was also complaining of severe myalgias of the thighs and calves, and was found to have muscle weakness and tenderness. Laboratory tests confirmed a diagnosis of rhabdomyolysis and myositis. He was asymptomatic within 3 weeks of stopping both drugs, and remained problem-free 5 weeks after restarting simvastatin 40 mg daily.[4] A further case of rhabdomyolysis has been reported in a 72-year-old man taking simvastatin. Symptoms developed 6 weeks after nefazodone was initiated (2 weeks after a dose increment). He recovered with rehydration after the nefazodone was stopped.[5] Other similar cases have also been reported,[6,7] and a review of the FDA spontaneous reports of statin-associated rhabdomyolysis, covering the period November 1997 to March 2000, nefazodone was potentially implicated in 2 cases of rhabdomyolysis involving simvastatin.[1]

Mechanism

Uncertain. The suggestion is that nefazodone (an inhibitor of the cytochrome P450 isoenzyme CYP3A4, an enzyme involved in the metabolism of simvastatin) caused a marked increase in the serum levels of simvastatin with accompanying toxicity.[4] The same mechanism might also account for the interaction with lovastatin, but the explanation for the case with pravastatin is less clear. See, 'Lipid regulating drugs', (p.1313), for a more detailed discussion of statin metabolism.

Importance and management

Information about interactions between nefazodone and the statins seems to be limited to these reports, but they are in line with the way lovastatin, simvastatin and **atorvastatin** are known to interact with other drugs. The manufacturers of lovastatin and simvastatin either advise avoiding or contraindicate the combination.[8-10] Some caution is probably prudent with atorvastatin, as it is also metabolised by CYP3A4, and a dose reduction should be considered. Patients given atorvastatin with nefazodone should be told to report any signs of myopathy and possible rhabdomyolysis (i.e. otherwise unexplained muscle pain, tenderness or weakness or dark coloured urine). If myopathy does occur, the statin should be stopped immediately. See also 'muscle toxicity', (p.1313), for further guidance on monitoring, and risk factors for muscle toxicity.

Other statins seem unlikely to interact. Note that in 2003 nefazodone was withdrawn in many countries due to cases of liver toxicity.

Statins + Nicotinic acid (Niacin)

The risk of muscle toxicity may possibly be increased in patients taking a statin with nicotinic acid, but there appear to be only isolated reports of rhabdomyolysis in patients given these drugs.

Clinical evidence

(a) Lovastatin

A 43-year-old man taking lovastatin 40 mg twice daily developed rhabdomyolysis, which was attributed to the addition of nicotinic acid, titrated up to 2.5 g daily.[1] A similar reaction occurred in a 54-year-old man taking lovastatin 120 mg daily and nicotinic acid 3 g daily,[2] as well as in a 53-year-old man with a heart transplant taking multiple medications including ciclosporin, nicotinic acid 1.5 g daily and lovastatin 40 mg twice daily.[3] Myositis has also been briefly reported in a patient taking lovastatin and nicotinic acid.[1]

A combined preparation of lovastatin/nicotinic acid is marketed (*Advicor*, USA), and in a 52-week study investigating efficacy and tolerability, none of the 814 patients experienced drug-induced myopathy (myalgia and elevated creatine kinase levels greater than 10 times the upper limit of normal), although 7 patients were withdrawn from the study due to elevated creatine kinase levels.[4] A similar study reported that the risk of adverse events with extended-release nicotinic acid/lovastatin did not exceed the risks associated with the individual drug components; discontinuation of treatment due to muscle ache occurred in 2 of 57 patients (4%) taking nicotinic acid 1 g/lovastatin 20 mg, in 0 of 57 patients taking nicotinic acid 2 g/lovastatin 40 mg, in 1 of 61 patients (2%) taking nicotinic acid alone, and in 4 of 61 patients (7%) taking lovastatin alone.[5] Furthermore, a review of the use of extended-release niacin with lovastatin found that myalgia, which was reported in 3% of patients, tended to be associated with higher initial doses of statins.[6] In a review of the FDA spontaneous reports of statin-associated rhabdomyolysis covering the period November 1997 to March 2000, nicotinic acid was identified as a potentially interacting drug in 1 of 40 cases for lovastatin.[7] However, a later study using the FDA adverse event reporting system (1999 to March 2005) found no evidence of a clinically significant adverse drug interaction between extended-release nicotinic acid and lovastatin, and the rate of serious adverse event reports associated with the combination was similar to that of lovastatin or extended-release nicotinic acid alone.[8]

(b) Other statins

In contrast to the use of lovastatin, there do not appear to be any published reports of myopathy occurring with nicotinic acid and any other statin. Indeed, the manufacturers of **fluvastatin**[9] and **pravastatin**[10] report clinical studies in which nicotinic acid was given with pravastatin and myopathy was not observed. Furthermore, nicotinic acid does not alter the bioavailability of **fluvastatin**[11] or **pravastatin**.[12] The HDL-atherosclerosis treatment study (HATS) found that patients taking **simvastatin** (mean dose 13 mg daily) with nicotinic acid (mean dose 2.4 g daily) for 3 years had similar adverse effects and abnormal laboratory findings, when compared with patients who received placebo: symptoms of fatigue, nausea and/or muscle aches occurred in 9% versus 5% of patients, and creatine phosphokinase levels greater than twice the upper limit of normal occurred in 3% versus 4% of patients, respectively.[13]

In a review of the FDA spontaneous reports of statin-associated rhabdomyolysis covering the period November 1997 to March 2000, nicotinic acid was identified as a potentially interacting drug in 2 of 215 cases for **simvastatin** and 1 of 71 cases for **pravastatin**. Nicotinic acid was not identified as an interacting drug in any reports for **atorvastatin** or **fluvastatin**.[7]

Mechanism

Unknown. Additive muscle toxicity has been suggested.

Importance and management

The reports describing an adverse interaction between nicotinic acid and a statin are isolated and it is by no means certain that nicotinic acid contributed to what happened. For example, in one case, ciclosporin may have been a contributory factor (consider also 'Statins + Ciclosporin', p.1326) and myopathy is known to occur with lovastatin alone,[14] with a reported incidence of 0.1%. Furthermore, in a report covering recommendations to healthcare professionals regarding the safety of nicotinic acid, it was proposed that, on the basis of almost two decades of clinical evidence, the use of nicotinic acid with a statin does not potentiate statin-related myopathic reactions. In addition, it was suggested that isolated case reports of myopathy, including rhabdomyolysis, with the concurrent use of nicotinic acid and a statin might have been related to other drug interactions or possibly hepatic toxicity from earlier forms of nicotinic acid with subsequent

decreased hepatic extraction of statins and increased peripheral blood statin levels.[15]

Nevertheless, the manufacturer of lovastatin recommends a maximum dose of 20 mg in patients taking nicotinic acid in doses of 1 g or more daily.[16] Similarly the UK manufacturer of simvastatin recommends a maximum dose of 10 mg in patients taking nicotinic acid in doses of 1 g or more daily.[17] The manufacturers of atorvastatin[18,19] and rosuvastatin[20] also suggest that the lowest statin dose should be used, or a statin dose reduction considered. Patients should be told to report otherwise unexplained muscle pain, tenderness or weakness or dark coloured urine). See also 'muscle toxicity', (p.1313), for further guidance on monitoring, and risk factors for muscle toxicity.

Statins + NNRTIs

Delavirdine is expected to raise the levels of atorvastatin, fluvastatin, simvastatin and lovastatin. This expectation is supported by a case of rhabdomyolysis, which developed in a patient taking atorvastatin and delavirdine. Efavirenz (and possibly nevirapine) *lower* the levels of atorvastatin, simvastatin, and pravastatin. Etravirine lowers atorvastatin levels and is predicted to lower simvastatin and lovastatin levels. Etravirine is also predicted to raise fluvastatin levels.

Clinical evidence, mechanism, importance and management

(a) Delavirdine

An isolated case report describes a 63-year-old HIV-positive man, who had been taking **atorvastatin** 20 mg daily with indinavir, lamivudine and stavudine, and who was admitted to hospital 2 months after indinavir was replaced with delavirdine. He had a one-month history of malaise, muscle pain, vomiting, and dark urine. Laboratory tests confirmed a diagnosis of rhabdomyolysis, and he was found to have acute renal failure. All drugs were withheld, and he gradually recovered over the following month. It was suggested that delavirdine inhibited the metabolism of **atorvastatin**,[1] probably by the cytochrome P450 isoenzyme CYP3A4. The manufacturer of delavirdine reports that it may be expected to increase the plasma levels of **atorvastatin**. They advise caution, due to the risk of rhabdomyolysis, and suggest using the lowest possible dose of **atorvastatin** with careful monitoring.[2] See 'muscle toxicity', (p.1313), for further guidance on monitoring, and risk factors for muscle toxicity. The same advice is given for **fluvastatin**,[2] which is metabolised by the cytochrome P450 isoenzyme CYP2C9, which delavirdine is known to inhibit.

Simvastatin and **lovastatin** are metabolised in a similar way to **atorvastatin**, and would therefore be expected to interact to a similar, if not greater magnitude. Indeed, a case report describes rhabdomyolysis in a patient taking **simvastatin**, delavirdine, atazanavir and amiodarone, see 'Statins + Protease inhibitors', p.1341.

The manufacturer of delavirdine recommends that it should not be used concurrently with either **simvastatin** or **lovastatin**.[2]

(b) Efavirenz

In an open-label study, 42 healthy subjects were given efavirenz 600 mg daily for 11 days, with **atorvastatin** 10 mg daily, **simvastatin** 40 mg daily, or **pravastatin** 40 mg daily for the last 2 days. Efavirenz reduced the AUC of **simvastatin** and its active metabolites by about 45 to 55%, reduced the AUC of **atorvastatin** and its active metabolites by 35 to 45%, and reduced the AUC of **pravastatin** by about 40%. The pharmacokinetics of efavirenz were not changed. Decreases in LDL-cholesterol were attenuated when efavirenz was given with **simvastatin**.[3] The changes with **atorvastatin** and **simvastatin** were expected, as efavirenz induces the cytochrome P450 isoenzyme CYP3A4, by which **simvastatin**, and to an extent **atorvastatin** are metabolised. The authors note that similar results would be expected with **nevirapine**, which also induces CYP3A4. The reasons for the reduction in the **pravastatin** AUC are less clear, as it is not metabolised by CYP3A4.[3]

It would seem prudent to monitor the lipid-profile of patients taking efavirenz and any of these statins, although bear in mind that NNRTIs are often used with 'protease inhibitors', (p.1341), which dramatically raise the levels of some statins.

(c) Etravirine

The manufacturers report a study in which 16 healthy subjects were given **atorvastatin** 40 mg daily with etravirine. Etravirine pharmacokinetics were unaffected, but the AUC of **atorvastatin** was modestly decreased, by 37%, and the AUC of its hydroxy metabolite was modestly raised, by 27%.[4,5] These effects probably occur because etravirine induces the cytochrome P450 isoenzyme CYP3A4 by which **atorvastatin** is metabolised. The manufacturers reasonably predict that the levels of other statins metabolised by CYP3A4 (i.e. **lovastatin** and **simvastatin**) may be similarly affected.[4,5]

Etravirine is also an inhibitor of the cytochrome P450 isoenzyme CYP2C9 by which **fluvastatin** is metabolised. The manufacturers therefore predict that **fluvastatin** levels may be raised by etravirine.[4,5]

The manufacturers recommend monitoring the concurrent use of etravirine and any of these statins, and adjusting the dose according to clinical response. The US manufacturers predict that **rosuvastatin** will not interact; however the UK manufacturers suggest that an interaction is possible. This seems highly unlikely, as less than 10% of **rosuvastatin** is metabolised. No interaction is expected between etravirine and **pravastatin**. Therefore these **pravastatin** or **rosuvastatin** may prove to be suitable alternatives.

Statins + Orlistat

Orlistat has no clinically relevant effect on the pharmacokinetics of atorvastatin, pravastatin or simvastatin.

Clinical evidence, mechanism, importance and management

(a) Atorvastatin

In a randomised study, 32 healthy subjects were given atorvastatin 20 mg daily for 6 days, with or without orlistat 120 mg three times daily for 6 days. Orlistat had no significant effect on the pharmacokinetics of atorvastatin.[1]

(b) Pravastatin

In a placebo-controlled, crossover study in 24 subjects with mild hypercholesterolaemia, orlistat 120 mg three times daily was reported to have no effect on the pharmacokinetics, or lipid-lowering effects, of pravastatin 40 mg daily, when both drugs were given for 6 days.[2]

A review includes brief details of a comparative study in two groups of healthy subjects given pravastatin, either with orlistat or placebo. After 10 days there was no significant difference in the pravastatin AUC between the groups, but the maximum serum concentration did show a tendency to be higher in the orlistat group.[3]

(c) Simvastatin

In a placebo-controlled, randomised study in 29 healthy subjects orlistat 120 mg three times daily had no effect on the pharmacokinetics of simvastatin 40 mg daily.[4]

Statins + Phenytoin

A number of isolated case reports describe a reduced cholesterol-lowering effect of simvastatin, fluvastatin and atorvastatin in patients taking phenytoin. The concurrent use of phenytoin and fluvastatin modestly raises the levels of both drugs.

Clinical evidence

A 50-year-old woman taking **simvastatin** 10 mg daily had her antiepileptic medication changed from sodium valproate to phenytoin 325 mg daily. Over the following 3 months her total cholesterol rose from 9.4 mmol/L to 15.99 mmol/L. The dose of **simvastatin** was gradually increased to 40 mg daily without a significant effect on her cholesterol levels. Despite further changes (to **fluvastatin** 40 mg daily, then to **atorvastatin** 80 mg daily) her cholesterol level remained above 10 mmol/L. Finally phenytoin was discontinued and her cholesterol dropped to 6.24 mmol/L with **atorvastatin** 80 mg daily.[1] Similarly, a 78-year-old woman, who had been stable on multiple drugs including **simvastatin** 40 mg and phenytoin 300 mg daily for several years, was admitted to hospital after she inadvertently omitted her diuretic and mistakenly took extra phenytoin for a week: her phenytoin levels and also her cholesterol levels were found to be raised. The phenytoin was withheld and the cholesterol levels decreased gradually along with the reduction in phenytoin levels.[2] A further case describes a 61-year-old man taking long-term phenytoin and phenobarbital who had a lack of significant improvement in lipid profiles while taking **atorvastatin** 40 mg for 8 weeks then 80 mg daily, even with the addition of ezetimibe 10 mg daily and nicotinic acid (niacin), titrated up to 2 g daily. His phenytoin was discontinued and 2 months later his LDL-cholesterol levels had decreased by about 50%.[3]

The addition of modified-release phenytoin 300 mg daily to **fluvastatin** 40 mg daily increased the maximum levels and AUC of **fluvastatin** by 27% and 40%, respectively, and increased the maximum levels and AUC of phenytoin by 5% and 20%, respectively.[4]

Mechanism

It seems possible that phenytoin induced the metabolism of simvastatin and atorvastatin by the cytochrome P450 isoenzyme CYP3A4, so that they were cleared from the body more quickly and were therefore less effective. The increase in fluvastatin levels and phenytoin levels seen in the study probably occurs because both drugs are metabolised by the cytochrome P450 isoenzyme CYP2C9.

Importance and management

Evidence of an interaction between phenytoin and atorvastatin or simvastatin currently appears to be limited to these few reports and their general significance remains unclear. However, if lipid levels remain significantly elevated in a patient taking phenytoin, it might be worth considering switching to a statin that is not significantly metabolised by the cytochrome P450 enzyme system (see 'statins', (p.1313)).

There is a small risk that the concurrent use of fluvastatin and phenytoin could result in myopathy. Patients should be told to report any signs of myopathy and possible rhabdomyolysis (i.e. otherwise unexplained muscle pain, tenderness or weakness or dark coloured urine). If myopathy does occur, the statin should be stopped immediately. See also 'muscle toxicity', (p.1313), for further guidance on monitoring, and risk factors for muscle toxicity. The alteration in phenytoin levels caused by fluvastatin seems unlikely to be clinically significant, although the manufacturer of fluvastatin cautiously recommends monitoring phenytoin when fluvastatin is started or the dose is altered.[4]

Statins + Phosphodiesterase type-5 inhibitors

A man taking simvastatin developed symptoms of rhabdomyolysis after taking a single dose of sildenafil. The pharmacokinetics of atorvastatin and sildenafil do not appear to be altered by concurrent use, and tadalafil does not alter lovastatin pharmacokinetics.

Clinical evidence

(a) Sildenafil

A 76-year-old man who had been taking **simvastatin** 10 mg daily for 3 years, presented at a clinic with a 3-day history of severe and unexplained muscle aches, particularly in the lower part of his legs and feet. The problem had started within 10 hours of taking a single 50-mg dose of sildenafil. When examined he showed no muscle tenderness or swelling but his creatine phosphokinase level was slightly raised (406 units/L). There was also a mild elevation of blood urea nitrogen and an increase in creatinine and potassium levels. A tentative diagnosis of rhabdomyolysis was made, there being no other obvious identifiable cause for the myalgia. Both **simvastatin** and sildenafil were stopped, and he made a full recovery.[1] A study in 24 healthy subjects found that the pharmacokinetics of sildenafil (single 100-mg dose) and **atorvastatin** (10 mg daily for 7 days) were unchanged by concurrent use.[2]

(b) Tadalafil

In a study in 16 healthy subjects, tadalafil 20 mg daily for 14 days did not affect the pharmacokinetics of a 40-mg dose of **lovastatin**.[3]

Mechanism, importance and management

The reasons for this possible interaction are not known. This is as yet an isolated case, and no broad generalisations can be based on such slim evidence. Based on this evidence no further precautions currently seem necessary.

Statins + Protease inhibitors

The levels of simvastatin and/or atorvastatin are markedly increased by darunavir, lopinavir, saquinavir and tipranavir (all boosted with ritonavir), or nelfinavir alone. Several cases of rhabdomyolysis have been attributed to this interaction. Lovastatin would be expected to interact similarly. Rosuvastatin appears to be moderately affected by protease inhibitors, and pravastatin is usually only modestly affected, although there can be large inter-

individual variations. There do not appear to be any reports of interactions with fluvastatin and protease inhibitors.

Clinical evidence

(a) Atazanavir

A 72-year-old HIV-positive man with coronary artery disease taking multiple medications including atazanavir 400 mg daily and delavirdine 600 mg twice daily presented with muscle pain, fatigue and dark orange urine. He had been taking atorvastatin 40 mg daily for 2 years without any adverse effects, but 27 days earlier had been switched to **simvastatin** 80 mg daily. Furthermore, amiodarone had also been started 19 days earlier. The patient was diagnosed with rhabdomyolysis and acute renal failure probably due to an interaction between simvastatin and atazanavir and/or amiodarone,[1] see also 'Statins + Amiodarone', p.1320. Note that delavirdine may also increase simvastatin plasma levels, see 'Statins + NNRTIs', p.1340.

(b) Darunavir with Ritonavir

In a study, ritonavir-boosted darunavir 100/300 mg twice daily increased the AUC and minimum levels of **atorvastatin** 10 mg daily by three- to fourfold. Ritonavir-boosted darunavir 100/600 mg twice daily increased the AUC of a single 40-mg dose of **pravastatin** fivefold in some patients, although the majority of patients experienced no increase.[2,3]

(c) Indinavir

In a non-randomised study, patients receiving HAART were given **pravastatin** or **fluvastatin**. Neither of the statins altered the pharmacokinetics of indinavir, the combination was well tolerated, and no increase in adverse events was seen.[4]

(d) Lopinavir with Ritonavir

In a study, 24 healthy subjects were given either **atorvastatin** 20 mg daily or **pravastatin** 20 mg daily for 4 days during a 14-day course of lopinavir/ritonavir 400/100 mg twice daily. The maximum serum levels and AUC of **atorvastatin** were increased 4.7- to 5.9-fold and the maximum serum levels and AUC of **pravastatin** were only increased by about 30%. **Atorvastatin** and **pravastatin** had no effect on the pharmacokinetics of lopinavir or ritonavir.[5] A study in 22 HIV-positive patients found that lopinavir/ritonavir concentrations were not affected by **rosuvastatin** 10 to 40 mg daily over a 12-week period, but rosuvastatin levels appeared to be increased by about 60%, when compared with data from healthy subjects.[6] Another study in 15 healthy subjects found that lopinavir/ritonavir 400/100 mg twice daily increased the AUC and maximum plasma concentration of **rosuvastatin** 20 mg daily twofold and fivefold, respectively.[7]

(e) Nelfinavir

In an open label study, 31 healthy subjects were given either **atorvastatin** 10 mg daily or **simvastatin** 20 mg daily for 28 days, with nelfinavir 1.25 g twice daily for the last 14 days. Nelfinavir increased the maximum serum levels and AUC of **atorvastatin** approximately twofold and the maximum serum levels and AUC of **simvastatin** approximately sixfold. No significant adverse effects, or any signs of rhabdomyolysis were noted throughout the study.[8]

One study found that nelfinavir 750 mg three times daily increased the maximum serum levels and AUC of **pravastatin** 40 mg daily by 29% and 35%, respectively, and increased the maximum serum levels and AUC of **atorvastatin** 40 mg daily by 32% and 209%, respectively.[9] A further study, in which 14 healthy subjects took nelfinavir 1.25 g twice daily for 12 days, with **pravastatin** 40 mg daily for the final 4 days, found that the AUC of **pravastatin** ranged from a decrease of 65% to an increase of 11%, and the maximum serum levels ranged from a decrease of 77% to an increase of 154%.[10]

In another study, 14 healthy subjects were given nelfinavir 1.25 g twice daily for 18 days, with **pravastatin** 40 mg daily for the last 4 days. No significant change was noted in the pharmacokinetics of nelfinavir, nor of its major metabolite.[11]

A case report describes a 70-year-old HIV-positive man taking nelfinavir who developed rhabdomyolysis and died, about 3 weeks after being given **simvastatin** 80 mg daily. He had previously tolerated both **pravastatin** 40 mg daily and **simvastatin** 10 mg daily.[12]

(f) Ritonavir

A 51-year-old woman was admitted to hospital with a 4-day history of muscular aches and weakness. Among other drugs, she had been taking zidovudine, lamivudine, indinavir, and **simvastatin** for 2 years. Ritonavir 100 mg twice daily had been added to her usual regimen 2 weeks previously. The rhabdomyolysis was therefore attributed to an interaction between ritonavir and **simvastatin**.[13] Another similar case has also been reported.[14] See also (b) and (d) above and (g) and (h) below for interactions of ritonavir combined with other protease inhibitors.

(g) Saquinavir with Ritonavir

Ritonavir 300 mg twice daily and saquinavir 400 mg twice daily were given to healthy subjects for 3 days, after which the dose was increased to ritonavir 400 mg twice daily and saquinavir 400 mg twice daily for a further 11 days. On the last 4 days **atorvastatin**, **pravastatin**, or **simvastatin** (all 40 mg daily) were also given. The mean **pravastatin** AUC was approximately halved (13 subjects), the mean **atorvastatin** AUC was increased approximately fourfold (14 subjects) and the mean **simvastatin** acid AUC was increased approximately 32-fold (14 subjects). No cases of rhabdomyolysis were noted.[11]

(h) Tipranavir with Ritonavir

Tipranavir with ritonavir has been found to increase the plasma levels of a single dose of **atorvastatin** by eight- to tenfold. The pharmacokinetics of tipranavir are not affected by **atorvastatin**.[15] The manufacturer of tipranavir says that the plasma levels of both tipranavir and **rosuvastatin** are increased when rosuvastatin and ritonavir-boosted tipranavir are given concurrently.[16]

(i) Unnamed antiretrovirals

A study found that although **rosuvastatin** 10 or 20 mg was effective in lowering lipid parameters in HIV-positive patients (84% taking protease inhibitors), the lipid changes were smaller than those found in subjects not infected with HIV.[17]

Mechanism

Many protease inhibitors, especially ritonavir, are known to be potent inhibitors of the cytochrome P450 isoenzyme CYP3A4. The levels of statins metabolised by this isoenzyme (notably simvastatin, lovastatin and to some extent atorvastatin) are therefore increased. See 'Lipid regulating drugs', (p.1313) for information on the metabolism of the individual statins. The exact mechanism of the interaction with rosuvastatin is unknown, but may be the result of transporter inhibition. Fluvastatin and pravastatin are less likely to be affected by protease inhibitors because they are not significantly metabolised by CYP3A4, or any of the other isoenzymes that ritonavir can inhibit.

Importance and management

The interactions of the protease inhibitors and simvastatin appear to be established by the pharmacokinetic studies cited here, and supported by a few case reports. It is generally recommended that **simvastatin** and **lovastatin**, which is similarly metabolised, should be avoided in patients taking protease inhibitors.

The interactions of **atorvastatin** with protease inhibitors are also established. Concurrent use should only be undertaken if the benefits outweigh the risks and atorvastatin should be used in low doses (e.g. 10 mg) with care; the US manufacturer says that in the presence of a ritonavir-boosted protease inhibitor, for doses of atorvastatin exceeding 20 mg, appropriate clinical assessment is recommended to ensure the lowest dose necessary is used.[18]

The US manufacturer of **rosuvastatin** states that the dose should be limited to 10 mg daily in patients taking lopinavir/ritonavir.[19] However, the UK manufacturer of rosuvastatin says that the concurrent use of protease inhibitors is not recommended.[20]

Pravastatin, **fluvastatin** or low-dose atorvastatin have been recommended as first-line agents in HIV-positive patients receiving protease inhibitors.[21] Pravastatin and fluvastatin can probably be used without dose adjustments with most protease inhibitors, but monitoring is needed to confirm this as one study with nelfinavir and pravastatin[10] suggested a trend towards *reduced* pravastatin efficacy, while a small number of patients had *increased* pravastatin levels when they were given darunavir. Until more is known, it would seem prudent to initiate the concurrent use of pravastatin and a protease inhibitor at the lowest dose of pravastatin.

As a general rule, any patient given a statin and a protease inhibitor should be told to report any signs of myopathy and possible rhabdomyolysis (i.e. otherwise unexplained muscle pain, tenderness or weakness or dark coloured urine). If myopathy does occur, the statin should be stopped

immediately. See also 'muscle toxicity', (p.1313), for further guidance on monitoring, and risk factors for muscle toxicity.

Statins + Ranolazine

Ranolazine may increase the levels of simvastatin. Other statins that are similarly metabolised may also be affected.

Clinical evidence

In an open-label study, simvastatin 80 mg daily was given with ranolazine 1 g twice daily for 4 days. Simvastatin had no effect on the pharmacokinetics of ranolazine, but ranolazine increased the maximum plasma levels of simvastatin and its active metabolites by up to about twofold and increased its AUC by 40 to 60%.[1]

Mechanism

Simvastatin is a substrate of the cytochrome P450 isoenzyme CYP3A4, of which ranolazine is a moderate inhibitor. Concurrent use can therefore increase the levels of simvastatin and its active metabolite. Note that, **lovastatin** is also predominantly metabolised by CYP3A4 and **atorvastatin** is metabolised, in part, by CYP3A4.

Importance and management

Evidence for an interaction between the statins and ranolazine appears to be limited to this one study, but an interaction appears to be established. The increased simvastatin levels seen appear to be modest; however, they may be clinically significant in some patients. All patients taking statins should be warned about the symptoms of myopathy and told to report muscle pain or weakness. It would be prudent to reinforce this advice to patients given simvastatin or lovastatin, and possibly atorvastatin, if they are given ranolazine.

Statins + Rifampicin (Rifampin)

Rifampicin lowers the serum levels of atorvastatin, fluvastatin, pravastatin, and simvastatin, and may increase or decrease the levels of rosuvastatin in some subjects.

Clinical evidence

It was briefly mentioned in a review by the manufacturer of **fluvastatin** that rifampicin reduced the AUC and the maximum serum levels of **fluvastatin** by 51% and 59%, respectively. No further study details were given.[1] In a randomised, crossover study in 10 healthy subjects, 5 days of pretreatment with rifampicin 600 mg daily reduced the AUCs of **simvastatin** and simvastatin acid by 87% and 93%, respectively.[2] A study of the same design with a 40-mg dose of **atorvastatin** found that rifampicin decreased the AUC of **atorvastatin** by 80% and decreased the AUCs of its two active metabolites by 43% and 81%, respectively. There was considerable intersubject variation in these values.[3] In a further study by the same authors, this time with **pravastatin** 40 mg, it was found that rifampicin reduced the AUC of **pravastatin** by 31%, but again there were large interindividual differences in the results, with some subjects having an *increase* in AUC.[4]

In a randomised, placebo-controlled study, 18 healthy subjects were given rifampicin 450 mg daily for 6 days, with a single 20-mg dose of **rosuvastatin** on day 7. The mean AUC of **rosuvastatin** was not altered by rifampicin; however, 3 subjects had an increase in the AUC of **rosuvastatin** of more than 50% and 3 subjects had an decrease in the AUC of **rosuvastatin** of more than 50%.[5]

Mechanism

Rifampicin is a known inducer of cytochrome P450 isoenzymes, including CYP3A4 and CYP2C9 by which a number of the statins are metabolised (see 'statins', (p.1313)). Rifampicin also has effects on drug transporter proteins (OATP, P-glycoprotein) and it seems possible that this may account for its interaction with statins that are not greatly metabolised by the cytochrome P450 enzyme system.

Importance and management

Evidence appears to be limited to the pharmacokinetic studies cited, which do not assess the clinical relevance of the pharmacokinetic interactions seen between rifampicin and a number of the statins. Nevertheless an interaction appears to be established. It might therefore be necessary to increase the dosage of atorvastatin, fluvastatin, simvastatin, and possibly pravastatin in some subjects, if rifampicin is given concurrently, but the efficacy of this approach needs confirmation.

The situation with rosuvastatin is less clear. Until more is known it would seem prudent to be alert both for the need to increase the rosuvastatin dose or an increase in rosuvastatin adverse effects if rifampicin is also given.

Statins + Risperidone

A schizophrenic patient taking risperidone developed rhabdomyolysis when simvastatin was added.

Clinical evidence

A 22-year-old patient with schizophrenia taking risperidone 4 mg daily and clonazepam 2 mg daily for about 4 weeks started taking **simvastatin** 10 mg daily. After about 5 days later he experienced pain in his right ankle and heel, which increased in severity and spread proximally, accompanied by swelling and a rash over the affected area. In addition, his creatine phosphokinase levels were dramatically raised (12, 408 units/L). The simvastatin was discontinued and rhabdomyolysis associated with an acute compartment syndrome was diagnosed, requiring emergency surgery.

Mechanism

It was suggested that the risperidone might have reduced the metabolism of the simvastatin by the cytochrome P450 system, causing increased plasma concentration of the statin and resulting in muscle injury. However, simvastatin is metabolised by CYP3A4 and risperidone via CYP2D6, and to a lesser extent CYP3A4, and risperidone is not known to directly inhibit CYP3A4. Nevertheless, risperidone might compete with simvastatin for this isoenzyme, and this may become clinically relevant in a patient who is lacking or totally deficient in CYP2D6, when CYP3A4 would become more important in the metabolism of risperidone.[1]

Importance and management

Evidence for an interaction between simvastatin and risperidone is limited to this case report. As the patient did not receive simvastatin alone, an interaction is not established. Nevertheless, the authors advise caution regarding the selection of statins that are metabolised via CYP3A4 in patients taking risperidone, and suggest that statins that are not significantly metabolised by cytochrome P450 may be a safer alternative (see 'statins', (p.1313), for a further discussion of statin metabolism). However, it seems somewhat premature to take precautions in all patients based on this isolated case report.

Statins + St John's wort (*Hypericum perforatum*)

St John's wort modestly decreases the plasma level of simvastatin and may reduce the lipid-lowering effects of atorvastatin. An isolated report also unexpectedly suggests that rosuvastatin may also interact. St John's wort does not appear to affect the pharmacokinetics of pravastatin.

Clinical evidence

In a placebo-controlled, crossover study, 16 healthy subjects took St John's wort 300 mg three times daily for 14 days. On day 14 **simvastatin** 10 mg was given to 8 subjects and **pravastatin** 20 mg was given to the other 8 subjects. St John's wort did not affect the plasma concentration of **pravastatin**, but it tended to reduce the **simvastatin** AUC and significantly reduced the AUC of its active metabolite, simvastatin hydroxy acid, by 62%.[1]

In a crossover study in 24 patients with hypercholesterolaemia taking long-term **simvastatin** 10 to 40 mg daily (an average dose of 20.8 mg daily), St John's wort (*Movina*) 300 mg twice daily for 4 weeks, significantly raised the levels of total cholesterol from 4.56 mmol/L (pre-treatment) to 5.08 mmol/L and LDL-cholesterol from 2.30 mmol/L to 2.72 mmol/L. The authors equate the magnitude of the increased LDL-cholesterol levels to a halving of the effects of **simvastatin**.[2]

In a similar study by the same authors, 16 patients with hypercholesterolaemia taking long-term **atorvastatin** 10 to 40 mg daily (an average dose of 14.4 mg daily), were given St John's wort (*Movina*) 300 mg twice daily for 4 weeks. St John's wort significantly raised the levels of total cholesterol from 4.76 mmol/L (pre-treatment) to 5.1 mmol/L and LDL-cholesterol from 2.39 mmol/L to 2.66 mmol/L. The levels of **atorvastatin** were not measured in this study. The authors equate the magnitude of the increased LDL-cholesterol levels to a loss of a third of the effects of **atorvastatin**. No adverse effects were reported.[3]

A case report describes a 59-year-old man who was taking **rosuvastatin** 10 mg daily with satisfactory lipid levels. Six months later, a routine blood test indicated that his total cholesterol had risen from 4.27 mmol/L to 6.1 mmol/L. On questioning he said that he had been taking a supplement containing St John's wort 600 mg daily. He stopped taking the supplement, and 4 months later his cholesterol levels had reduced to about the former level.[4]

Mechanism

The reason for this interaction is unknown. St John's wort may reduce the levels of simvastatin and its metabolite by inducing the cytochrome P450 isoenzyme CYP3A4 or by having some effect on P-glycoprotein. Rosuvastatin does not appear to be a P-glycoprotein substrate; the authors of the study suggest that CYP2C9 and CYP2C19 may have been involved, but as rosuvastatin is less than 10% metabolised this seems unlikely.

Importance and management

Although the evidence is limited, it appears that St John's wort may reduce the efficacy of atorvastatin and simvastatin, which may result in a clinically relevant increase in total cholesterol and LDL-cholesterol levels, depending on the patients baseline result and medical history. It may be prudent to consider an interaction if lipid-lowering targets are not met, and advise the patient to stop taking St John's wort or adjust the dose of statin, as needed.

No significant interaction would be expected with pravastatin as it is not primarily metabolised by CYP3A4, and this was demonstrated in the study above. Similarly, no significant interaction would be expected with rosuvastatin, but the case report adds a note of caution.

Statins + Tacrolimus

An isolated case report attributes rhabdomyolysis to an interaction between tacrolimus and simvastatin. Tacrolimus does not appear to affect atorvastatin pharmacokinetics.

Clinical evidence, mechanism, importance and management

A pharmacokinetic study in 13 healthy subjects found that the short-term use of tacrolimus (2 doses 12 hours apart) did not affect the pharmacokinetics of **atorvastatin**.[1]

A 51-year-old woman, who was taking tacrolimus after a kidney transplant, started taking **simvastatin** 10 mg daily following a stroke. After 5 months, the dose was increased to 20 mg daily, and fusidic acid was started for osteomyelitis. Muscle pain developed 2 weeks later, and after a further 3 weeks she was admitted to hospital, when her creatine kinase level was found to be 24 000 units/mL (normal range 10 to 70 units/mL) and she had renal impairment. The **simvastatin** and fusidic acid were immediately stopped and the patient recovered over the following 2 weeks. She was later treated with a combination of **fluvastatin**, tacrolimus and fusidic acid without incident, leading the authors to suspect that the rhabdomyolysis was caused by an interaction between **simvastatin** and tacrolimus.[2] However, note that fusidic acid, has been implicated in a number of cases of rhabdomyolysis with statins, including simvastatin, see 'Statins + Fusidic acid', p.1335, many of which were only reported subsequent to this case. It therefore now seems more likely that the reaction seen in this case was actually an interaction between fusidic acid and simvastatin.

Statins + Vaccines

A study suggests that influenza vaccination does not precipitate myopathy in patients taking statins, although one possible case

has been reported. Atorvastatin does not appear to affect the antibody response to hepatitis A vaccination.

Clinical evidence, mechanism, importance and management

An isolated report describes a patient who had uneventfully taken cerivastatin and bezafibrate for 2 months, who developed rhabdomyolysis after being given an **influenza vaccine**. The patient developed diffuse myalgia within 24 hours of the vaccination. Initially he attributed the myalgia to the vaccination, but he developed increasing muscular weakness, which rendered him unable to get out of bed 3 days post vaccination.[1] In contrast, in a study in 98 outpatients receiving **influenza vaccination**, there was no indication that **influenza vaccine** caused clinical or laboratory evidence of myopathy in patients taking statins. Only 2 patients experienced myopathy (one of 52 taking statins and one of 46 controls). Creatine phosphokinase levels were measured in all the patients, before and after vaccination: no significant differences were identified.[2] Considering the number of patients taking statins who also receive influenza vaccination, there seems to be little evidence to suggest there is a problem.

Statins appear to have immunomodulatory properties, but **atorvastatin** was reported to have no effect on the antibody response to **hepatitis A vaccine** in healthy young subjects.[3]

On the whole the evidence suggests that no interaction occurs with statins and influenza or hepatitis A vaccines. The case report involving cerivastatin and influenza vaccine seems unlikely to be of general significance: an interaction between cerivastatin and bezafibrate (which sometimes takes some months to develop, see 'Statins + Fibrates', p.1332) cannot be ruled out; and cerivastatin alone is known to be associated with severe myopathy, an adverse effect that led to its general withdrawal from the market.

Statins + Vitamin E substances

Supplementation with antioxidants including vitamin E appears to reduce the beneficial effect of statins on HDL-cholesterol. However, one study suggests that alpha-tocopherol alone may not adversely affect HDL-cholesterol.

Clinical evidence, mechanism, importance and management

In a coronary artery disease intervention study over 12 months, patients taking antioxidants (vitamin E, **vitamin C**, **betacarotene** and **selenium**) in combination with **simvastatin** and nicotinic acid (niacin) were found to have a smaller increase in HDL–cholesterol when compared with those receiving the statin and nicotinic acid alone.[1] Similarly, in a 3-year, placebo-controlled, study (The HDL-Atherosclerosis Treatment Study; HATS) involving 160 patients, the protective increase in HDL2 cholesterol found in patients taking **simvastatin** and nicotinic acid was attenuated by the concurrent use of antioxidants (**betacarotene**, **selenium**, **vitamin C** and vitamin E). Coronary artery stenosis *progressed* by 3.9% with placebo, 1.8% with antioxidants, and 0.7% with **simvastatin**, nicotinic acid and antioxidants, and *regressed* by 0.4% with simvastatin and nicotinic acid alone. Thus the benefit of regression of coronary stenosis seen with **simvastatin** and nicotinic acid was lost when antioxidants were also given.[2] A further placebo-controlled study found that vitamin E supplementation (equivalent to *d*-α-tocopherol 268 mg daily) for 8 weeks did not affect total or LDL-cholesterol levels in hypercholesterolaemic patients taking **lovastatin** or **simvastatin**. There was a small decrease in HDL-cholesterol levels during vitamin E supplementation, which was not sufficient to change the ratio of total cholesterol to HDL–cholesterol (a measure of cardiac risk) and was not sustained.[3] However, another study concluded that high-dose *d*-alpha-tocopherol for 2 years in patients with coronary artery disease taking concurrent statin therapy did not affect HDL-cholesterol.[4]

The available evidence suggests that some types of antioxidant use may decrease the response to statins, but the use of vitamin E alone may not have this effect. More study is needed to confirm to suitability of different types and doses of antioxidant supplementation.

Statins; Atorvastatin + Sirolimus

A case report describes a patient who developed elevated sirolimus levels after atorvastatin was started.

Clinical evidence, mechanism, importance and management

A case report describes a patient who had undergone a pancreatic islet transplant and who had been stable taking sirolimus 8 to 11 mg daily for 5 months. A routine lipid evaluation at 6 months found raised cholesterol and triglyceride levels, and so atorvastatin was started. Six weeks later the trough sirolimus level was 20.5 nanograms/mL (target 7 to 10 nanograms/mL) and so the sirolimus dose was reduced. Further reductions were subsequently needed, and 3 months after the atorvastatin was started the sirolimus dose had been halved.[1] The authors suggested that the atorvastatin competed with sirolimus for metabolism by the cytochrome P40 isoenzyme CYP3A4, which resulted in reduced sirolimus metabolism and the elevated levels seen.[1] However, alone, competition for the same route of metabolism rarely seems to result in a clinically relevant elevation in the levels of either drug. This case report seems to be the only evidence of an interaction and so its general significance is unknown, it seems likely to be small.

1. Barshes NR, Goodpastor SE, Goss JA, DeBakey ME. Sirolimus-atorvastatin drug interaction in the pancreatic islet transplant recipient. *Transplantation* (2003) 76, 1649–50.

Statins; Pravastatin + Mianserin

An isolated report describes rhabdomyolysis attributed to the long-term concurrent use of pravastatin and mianserin, triggered by a cold.

Clinical evidence, mechanism, importance and management

An isolated report describes a 72-year-old woman taking pravastatin 20 mg daily and mianserin 10 mg daily for 2 years, who was hospitalised because of weakness in her legs that began 2 days previously, shortly after she developed a cold. She could stand, but was unable to walk unaided. Laboratory data revealed evidence of increased serum enzymes, all of which suggested rhabdomyolysis. Within a week of stopping the pravastatin the leg weakness had disappeared and all of the laboratory results had returned to normal. The authors of the report attributed the toxicity to the long-term use of both drugs, ageing and the development of a cold.[1] However, what part these factors and/or the presence of mianserin actually played in the development of this toxicity is not known. It seems unlikely that this case is of general significance.

1. Takei A, Chiba S. Rhabdomyolysis associated with pravastatin treatment for major depression. *Psychiatry Clin Neurosci* (1999) 53, 539.

Statins; Pravastatin + Probucol

In a study in 20 healthy subjects, probucol 500 mg did not cause any clinically significant changes in the bioavailability of a single 20-mg dose of pravastatin.[1]

1. ER Squibb. A report on the bioavailability of pravastatin in the presence and absence of gemfibrozil or probucol in healthy male subjects. Data on file (Protocol No 27, 201-18), 1988.

Statins; Simvastatin + Fish oils

In a randomised, crossover study in 23 subjects, omega-3-acid ethyl esters (*Omacor*) 4 g daily did not significantly affect the pharmacokinetics of simvastatin 80 mg daily when both drugs were given together for 14 days. The combination was also well tolerated.[1] No dosage adjustments would appear to be necessary on concurrent use.

1. McKenney JM, Swearingen D, Di Spirito M, Doyle R, Pantaleon C, Kling D, Shalwitz RA. Study of the pharmacokinetic interaction between simvastatin and prescription omega-3-acid ethyl esters. *J Clin Pharmacol* (2006) 46, 785–91.

Ursodeoxycholic acid (Ursodiol) + Bile-acid binding resins

The absorption of ursodeoxycholic acid can be more than halved by the simultaneous dosing of colestilan or colestyramine, and its efficacy might be reduced.

Clinical evidence

(a) Colestilan

Following a test meal with an overnight fast, 5 healthy subjects were given 200 mg of ursodeoxycholic acid alone or with 1.5 g of colestilan granules. It was found that the ursodeoxycholic acid serum levels at 30 minutes were reduced by more than 50% by colestilan in 4 out of the 5 subjects; the mean ursodeoxycholic acid level was decreased from 9.2 micromol/L to 3.4 micromol/L.[1]

(b) Colestyramine

In a study in 5 healthy subjects the simultaneous administration of colestyramine 4 g daily with ursodeoxycholic acid reduced the fasting serum levels of ursodeoxycholic acid by about 60%. Separating administration by 5 hours tended to diminish the reduction in ursodeoxycholic acid levels (serum levels reduced by less than 40%).[2]

Mechanism

It seems likely that the bile-acid binding resins bind with ursodeoxycholic acid (a bile acid) in the intestine and thereby reduce its absorption.

Importance and management

The interactions of colestilan and colestyramine with ursodeoxycholic acid would appear to be established, and are probably clinically important. One UK manufacturer of ursodeoxycholic acid actually advises that **colestipol** and colestyramine should be avoided, as they may limit its effectiveness.[3] Note that it is usually recommended that other drugs are given 1 hour before or 4 to 6 hours after colestyramine, and 1 hour before or 4 hours after colestipol. However, the authors of the reports recommend that, in order to reduce the effects of this interaction, administration of ursodeoxycholic acid and the bile-acid binding resin should be separated,[1,2] by at least 2 hours.[1]

3. Urdox (Ursodeoxycholic acid). Wockhardt UK Ltd. UK Summary of product characteristics, March 2008.

Ursodeoxycholic acid (Ursodiol) + Miscellaneous

Antacids are expected to decrease ursodeoxycholic acid absorption. The concurrent use of fibrates is predicted to decrease the efficacy of ursodeoxycholic acid.

Clinical evidence, mechanism, importance and management

(a) Antacids

Some antacids have been shown to adsorb bile acids *in vitro* and some manufacturers of ursodeoxycholic acid[1-3] suggest that these antacids (a number of manufacturers specifically mention aluminium-based antacids) may be expected to interfere with absorption in the same manner as bile-acid binding resins (see 'Ursodeoxycholic acid (Ursodiol) + Bile-acid binding resins', p.1346). One manufacturer advises that antacids should be avoided when ursodeoxycholic acid is given, as they may reduce efficacy.[4] However, most absorption interactions with antacids can be managed by separating administration (2 to 3 hours is usually sufficient).

(b) Fibrates

The manufacturers of ursodeoxycholic acid[1-4] recommend that it should not be taken with certain blood cholesterol-lowering agents (some name clofibrate), which may counteract its effectiveness by increasing cholesterol elimination in the bile and thus encourage gallstone formation. Note that, all fibrates increase cholesterol elimination, and may therefore be expected to interact similarly.

Ursodeoxycholic acid (Ursodiol) + Oestrogens

Ursodeoxycholic acid does not affect the bioavailability of ethinylestradiol. However, oestrogens are predicted to decrease the effectiveness of ursodeoxycholic acid.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study, 8 healthy women were given an oral hormonal contraceptive (**ethinylestradiol**/gestodene 30/75 micrograms daily) with ursodeoxycholic acid 8 to 10 mg/kg daily for 21 days. Ursodeoxycholic acid was found not to affect the bioavailability of **ethinylestradiol**. Mean serum triglyceride levels increased from 58.3 mg/dL at the start of the study, to 91.4 mg/dL and 88.6 mg/dL, during **ethinylestradiol** treatment with placebo and ursodeoxycholic acid, respectively.[1]

The study indicates that contraceptive efficacy would not be affected by ursodeoxycholic acid, although further study is required to evaluate the combination in patients with cholestatic liver disease, as there is some evidence to suggest that these patients may metabolise bile salt acids differently.[1] In addition, some manufacturers of ursodeoxycholic acid recommend that drugs such as **oestrogens**, which increase cholesterol elimination in the bile and gallstone formation, should not be taken with ursodeoxycholic acid[2,3] as they may reduce its effectiveness.[4]

Lithium

Lithium is used in the management of mania, bipolar disorder (formerly manic depression) and recurrent depressive illnesses. The dose of lithium is adjusted to give therapeutic serum concentrations of 0.4 to 1 mmol/L, although it should be noted that this is the range used in the UK, and other ranges have been quoted.

Lithium is given under close supervision with regular **monitoring** of serum concentrations because there is a narrow margin between therapeutic concentrations and those that are toxic. Initially weekly monitoring is advised, dropping to every 3 months for those on stable regimens. It is usual to take serum lithium samples about 10 to 12 hours after the last oral dose.

Adverse effects that are not usually considered serious include nausea, weakness, fine tremor, mild polydipsia and polyuria. If serum concentrations rise into the 1.5 to 2 mmol/L range, toxicity usually occurs, and may present as lethargy, drowsiness, coarse hand tremor, lack of coordination, muscular weakness, increased nausea and vomiting, or diarrhoea. Higher levels result in neurotoxicity, which manifests as ataxia, giddiness, tinnitus, confusion, dysarthria, muscle twitching, nystagmus, and even coma or seizures. Cardiovascular symptoms may also develop and include ECG changes and circulatory problems, and there may be a worsening of polyuria.[1-3] Lithium levels of over 2 mmol/L can be extremely dangerous and therefore require urgent attention. Chronic lithium toxicity has been reported to have a 9% mortality, whilst acute toxicity has a 25% mortality.[4] However, patients with chronic lithium toxicity are more likely to experience severe symptoms at lower serum lithium levels. Concurrent medications, older age and prior neurological illness may increase the susceptibility to lithium toxicity.[5]

In addition to the effects described above, lithium can induce diabetes insipidus and hypothyroidism in some patients, and is contraindicated in those with renal or cardiac insufficiency.

Just how lithium exerts its beneficial effects is not known, but it may compete with sodium ions in various parts of the body, and it alters the electrolyte composition of body fluids.

Interactions

Many of the interactions involving lithium occur because of altered serum lithium concentrations. Lithium is mainly excreted by the kidney; it undergoes glomerular filtration and then tubular reabsorption, and competes with sodium for this process. Therefore, drugs that affect renal excretion (e.g. thiazides, see 'Lithium + Diuretics; Thiazide and related', p.1357) or electrolyte balance (e.g. sodium compounds, see 'Lithium + Sodium compounds', p.1364) are likely to interact. Drug interactions may be an important cause of lithium neurotoxicity occurring when serum lithium levels are within the therapeutic range.[6] This tends to occur with centrally active drugs, including many antipsychotics (see. 'Antipsychotics + Lithium', p.834), carbamazepine (see 'Lithium + Carbamazepine', p.1354), and a number of antidepressants (see 'Lithium + SSRIs', p.1365, and 'Lithium + Tricyclic and related antidepressants', p.1367). Most of the interactions involving lithium are discussed in this section but a few are found elsewhere in this publication. Virtually all of the reports are concerned with the carbonate, but sometimes lithium is given as the acetate, aspartate, chloride, citrate, gluconate, orotate or sulfate instead. There is no reason to believe that these lithium compounds will interact any differently to lithium carbonate.

Lithium + ACE inhibitors

ACE inhibitors can raise lithium levels, and in some individuals two- to fourfold increases have been recorded. Cases of lithium toxicity have been reported in patients given captopril, enalapril or lisinopril (and possibly perindopril). One analysis found an increased relative risk for lithium toxicity requiring hospitalisation in elderly patients newly started on an ACE inhibitor.

Clinical evidence

An analysis of 10 615 elderly patients receiving lithium found that 413 (3.9%) were admitted to hospital at least once for lithium toxicity during a 10-year study period. The prescriptions for any ACE inhibitor (not specifically named) were compared between these 413 hospitalised patients and 1651 control patients. For any use of ACE inhibitor (63 cases and 110 controls) there was an increased relative risk of hospitalisation for lithium toxicity of 1.6. When patients who had started taking an ACE inhibitor within the last month were evaluated (14 cases and 5 controls), a dramatically increased risk of lithium toxicity was found (relative risk 7.6).[1]

Studies and case reports of the interaction between lithium and specific named ACE inhibitors are outlined in the subsections below.

(a) Captopril

A patient taking lithium carbonate developed a serum lithium level of 2.35 mmol/L and toxicity (tremor, dysarthria, digestive problems) within 10 days of starting to take captopril 50 mg daily. He was restabilised on half his previous dose of lithium.[2] A retrospective study also reports a case of increased lithium levels with captopril (see under *Lisinopril*, below).

(b) Enalapril

A woman taking lithium carbonate developed signs of lithium toxicity (ataxia, dysarthria, tremor, confusion) within 2 to 3 weeks of starting to take enalapril 20 mg daily. After 5 weeks her plasma lithium levels had risen from 0.88 mmol/L to 3.3 mmol/L, and moderate renal impairment was noted.[3] No toxicity occurred when the enalapril was later replaced by nifedipine.[3] Lithium toxicity following the use of enalapril, and associated in some cases with a decrease in renal function, has been seen in another 5 patients,[4-8] and a reduced lithium dose was found adequate in another patient.[9] Enalapril 5 mg daily for 9 days had no effect on the mean serum lithium levels of 9 healthy male subjects. However, one subject had a 31% increase in lithium levels.[10]

A retrospective study also reports several cases of increased lithium levels with enalapril (see under *Lisinopril*, below).

(c) Lisinopril

A retrospective study of patient records identified 20 patients who were stabilised on lithium and then started taking an ACE inhibitor (13 given lisinopril, 6 enalapril and one captopril). Their serum lithium levels rose by an average of 35% (from 0.64 to 0.86 mmol/L) and there was a 26% decrease in lithium clearance. Signs and symptoms suggestive of toxicity (increased tremor, confusion, ataxia), necessitating a dose reduction or lithium withdrawal, developed in four (20%) of these patients. In 3 patients the development of the interaction was delayed for several weeks.[11]
A woman taking lithium developed lithium toxicity and a trough serum lithium level of 3 mmol/L within 3 weeks of stopping clonidine and starting lisinopril 20 mg daily.[12] Other reports similarly describe acute lithium toxicity in 5 patients when they were given lisinopril.[8,13-16] One of them was also taking verapamil,[15] which has also been shown to interact with lithium, but not usually to raise lithium levels (see 'Lithium + Calcium-channel blockers', p.1353), and one patient experienced an increase in lithium levels on changing from fosinopril to lisinopril.[16] A case report describes toxic lithium levels of 2.04 mmol/L, without any signs of lithium toxicity in a woman taking lithium 900 mg daily with lisinopril 10 mg daily. Her lithium levels fell to 1.45 mmol/L on reducing the lithium dose to 600 mg daily, but when she took this dose without lisinopril, her lithium levels were 0.86 mmol/L.[17]

(d) Perindopril

A patient taking lithium developed toxicity 3 months after starting to take perindopril and bendroflumethiazide,[18] which may also interact, see 'Lithium + Diuretics; Thiazide and related', p.1357.

Mechanism

Not fully understood. It has been suggested that as both ACE inhibitors and lithium cause sodium to be lost in the urine, and also ACE inhibitors reduce thirst stimulation, fluid depletion can occur. The normal compensatory reaction for fluid depletion is constriction of the efferent renal arterioles to maintain the glomerular filtration rate, but this mechanism is blocked by the ACE inhibitor. In addition, lithium and sodium ions are competitively reabsorbed, mainly in the proximal tubule, and with less sodium available, more lithium is retained. Consequently the renal excretion of lithium falls and toxicity develops.

Importance and management

The interaction between lithium and the ACE inhibitors is established and of clinical importance, although it seems that the incidence of adverse effects as a result of this interaction is probably small. It has been suggested that concurrent use should be avoided, or only undertaken with caution and close monitoring. However, although lithium levels can rise, this is not always of clinical importance, but it should be noted that the risk of lithium toxicity increases when other risk factors are also present.

Risk factors for increased lithium toxicity include: advanced age,[1,11] congestive heart failure,[10,12] renal impairment[7,12] and volume depletion.[6,12] Some consider these to be contraindications to the use of lithium.[7,12] Only captopril, enalapril, lisinopril (and possibly perindopril) have been reported to interact, but it seems likely, given the proposed mechanism, that this interaction will occur with any other ACE inhibitor. Therefore if any ACE inhibitor is added to established lithium treatment, monitor well for symptoms of lithium toxicity (see 'Lithium', (p.1347)) and consider measuring lithium levels more frequently. Be alert for the need to reduce the lithium dose (possibly by between one-third to one-half).[12,14] The development of the interaction may be delayed, so monitoring lithium levels every week[12] or every two weeks[11] for several weeks has been advised.

Lithium + Acetazolamide

There is some evidence that the excretion of lithium can be increased by the short-term use of acetazolamide. However, lithium toxicity has been seen in one patient given both drugs for a month.

Clinical evidence, mechanism, importance and management

A single-dose study in 6 subjects given lithium 600 mg ten hours before acetazolamide 500 or 750 mg found a 31% increase in the urinary excretion of lithium.[1] A case report describes a woman who was successfully treated for a lithium overdose with acetazolamide, intravenous fluids, sodium bicarbonate, potassium chloride and mannitol.[2]

Paradoxically, lithium toxicity occurred in another patient after a month of treatment with acetazolamide. Lithium levels rose from 0.8 to 5 mmol/L, although it should be noted that the later measurement was taken 8 hours post-dose.[3] See 'Lithium', (p.1347) for details of lithium monitoring.

Lithium + Aciclovir

An isolated case report describes lithium toxicity caused by high-dose intravenous aciclovir.

Clinical evidence, mechanism, importance and management

A 42-year-old woman taking lithium carbonate 450 mg twice daily developed signs of lithium toxicity 6 days after starting treatment with intravenous aciclovir 10 mg/kg, which was given every 8 hours for a severe herpes zoster infection following chemotherapy. Her serum lithium levels had risen over fourfold to 3.4 mmol/L. The reasons for this interaction are unknown but the authors of the report suggest that aciclovir may have inhibited the renal excretion of lithium.[1]

This appears to be the first and only report of this interaction, but it would now be prudent to monitor for symptoms of lithium toxicity (see *Interactions*, under 'Lithium', (p.1347)) and consider monitoring lithium levels if high-dose intravenous aciclovir is given to any patient. The report recommends measuring lithium levels every second or third day.[1] Oral aciclovir is predicted not to interact because of its low bioavailability, and no interaction would be expected with topical aciclovir as the plasma levels achieved by this route are minimal.

1. Sylvester RK, Leitch J, Granum C. Does acyclovir increase serum lithium levels? *Pharmacotherapy* (1996) 16, 466–8.

Lithium + Amisulpride

Amisulpride does not appear to affect the pharmacokinetics of lithium. However, lithium may increase the plasma levels of amisulpride.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study in 24 healthy subjects, lithium carbonate 500 mg twice daily was given for 7 days to obtain stable lithium serum levels, and then amisulpride 100 mg twice daily was added for a further 7 days. Amisulpride appeared to have no effect on lithium pharmacokinetics.[1] In a pharmacokinetic analysis of amisulpride levels in patients with schizophrenia or schizoaffective disorder, dose-corrected amisulpride plasma levels were 80% higher in 3 patients taking lithium than in 13 patients taking amisulpride alone.[2] In a further study by the same authors, 7 patients who had been taking amisulpride 250 to 1200 mg daily for between 9 and 110 days were given lithium carbonate 450 to 1125 mg daily. Dose-corrected plasma levels of amisulpride were increased by about 8 to 56% (mean 31%) by lithium, taken for between 3 and 73 days. There was a positive correlation between the duration of lithium treatment and the increase in amisulpride levels.[3]

Evidence for an interaction between amisulpride and lithium is limited, but it appears to be established. Although the mean increase in amisulpride levels would not be expected to be clinically significant, the authors of the study suggest that increases of up to 56% could result in increased adverse effects. It would therefore seem prudent to monitor concurrent use for amisulpride adverse effects (extrapyramidal effects, insomnia, constipation) and consider reducing the amisulpride dose if these become troublesome.

Lithium + Angiotensin II receptor antagonists

Case reports describe lithium toxicity in patients given candesartan, losartan, valsartan, and possibly irbesartan. Other angiotensin II receptor antagonists would be expected to interact similarly.

Clinical evidence

(a) Candesartan

A 58-year-old woman taking long-term lithium for depression (stable serum lithium levels between 0.6 and 0.7 mmol/L), and unnamed calcium-channel blockers for hypertension, was additionally given candesartan 16 mg daily. She was hospitalised 8 weeks later with a 10-day history of ataxia, increasing confusion, disorientation and agitation, and was found to have a serum lithium level of 3.25 mmol/L. She recovered completely when all the drugs were stopped. She was later restabilised on her original lithium dose with a change to urapidil for her hypertension.[1]

(b) Irbesartan

A report describes a 74-year-old woman with increased lithium levels of 2.3 mmol/L and symptoms of lithium toxicity, which were associated with the use of several drugs including irbesartan, lisinopril, escitalopram, levomepromazine, furosemide and spironolactone. It was suggested that these drugs could have delayed lithium excretion or worsened neurotoxic effects. An increase in the lisinopril dose and the addition of irbesartan several weeks before admission may have contributed to the lithium toxicity.[2]

(c) Losartan

An elderly woman taking lithium carbonate developed lithium toxicity (ataxia, dysarthria, and confusion) after starting to take losartan 50 mg daily. Her serum lithium levels rose from 0.63 mmol/L to 2 mmol/L over 5 weeks. The lithium and losartan were stopped and her symptoms had disappeared 2 days later. When lithium was restarted and the losartan was replaced by nicardipine, her lithium levels were restabilised at 0.77 mmol/L within 2 weeks.[3]

(d) Valsartan

A woman with a long history of bipolar disorder was treated with lithium carbonate (serum levels consistently at 0.9 mmol/L) and a number of other drugs (L-tryptophan, lorazepam, glibenclamide, conjugated oestrogens and ciprofloxacin). Two weeks before being hospitalised for a manic relapse she was additionally started taking valsartan 80 mg daily. While in hospital the ciprofloxacin was stopped, lorazepam was replaced by zopiclone, and quetiapine was added. On day 3 of her hospitalisation her serum lithium levels were 1.1 mmol/L and she became increasingly delirious, confused and ataxic over the next week. By day 11 her serum lithium levels had risen to 1.4 mmol/L. When an interaction was suspected, the valsartan was replaced by diltiazem. She later recovered and was stabilised on her original lithium carbonate dose with lithium levels of 0.8 mmol/L.[4] A second case describes a woman taking lithium 600 mg daily who experienced an increase in lithium serum levels to 1.72 mmol/L after she started to take valsartan 80 mg daily. She demonstrated signs of lithium toxicity including ataxia, limb rigidity and falls. Previously, her lithium levels had been stable between 0.62 and 0.87 mmol/L when she took lithium in doses of 900 mg to 1.2 g daily.[5]

Mechanism

Not fully understood. It could be that, as with the ACE inhibitors, angiotensin II receptor antagonists inhibit aldosterone secretion, resulting in increased sodium loss by the renal tubules. This causes lithium retention and thus an increase in lithium levels. However, angiotensin II receptor antagonists have less effect on aldosterone than the ACE inhibitors, making a clinically significant interaction less likely. *Animal* studies show that

ramipril,[6] but not losartan,[7] decreases the excretion of lithium by the kidney, which would support this idea.

Importance and management

Direct information about interactions between lithium and angiotensin II receptor antagonists seems to be limited to these reports, although the interaction has been predicted to occur with all drugs of this class. Such sparse evidence is not enough to recommend contraindicating the concurrent use of angiotensin II receptor antagonists with lithium, especially as an interaction is less likely than with the ACE inhibitors (see *Mechanism*, above), although some manufacturers do not recommend the combination. One report suggests weekly monitoring for the first month of concurrent use,[4] but any rise in serum lithium levels may be gradual so that toxicity might take as long as 3 to 7 weeks to develop fully. Be mindful that the lithium dose may need to be decreased.

Patients taking lithium should be aware of the symptoms of lithium toxicity and told to report them immediately should they occur. This should be reinforced when they are given angiotensin II receptor antagonists. As with ACE inhibitors (see 'Lithium + ACE inhibitors', p.1348), the risk of lithium toxicity would be expected to increase when risk factors such as advanced age, renal insufficiency, heart failure and volume depletion are also present.

Lithium + Antibacterials

A retrospective study of patients receiving long-term lithium found that concurrent medication, especially antibacterials, tended to be associated with a higher risk of elevated serum lithium levels.

Clinical evidence, mechanism, importance and management

A multicentre, retrospective study of patients receiving long-term lithium found 51 patients with elevated serum lithium levels (greater than or equal to 1.3 mmol/L) which was at least 50% greater than the previous serum level. Fifteen patients had taken potentially interacting medication and, of these, 7 patients had taken antibacterials (6 different unnamed antibacterials). It was suggested that the underlying infection, associated fever and poor fluid intake might have contributed to the elevated lithium levels in these patients rather than the use of the antibacterial *per se*.[1]

1. Wilting I, Movig KLL, Moolenaar M, Hekster YA, Brouwers JRBJ, Heerdink ER, Nolen WA, Egberts ACG. Drug-drug interactions as a determinant of elevated lithium serum levels in daily clinical practice. *Bipolar Disord* (2005) 7, 274–80.

Lithium + Antibacterials; Co-trimoxazole or Trimethoprim

Two reports describe lithium toxicity in three patients given co-trimoxazole; in two of these patients toxicity was paradoxically accompanied by a fall in lithium levels. A further report describes lithium toxicity accompanied by an increase in lithium levels in a patient given trimethoprim.

Clinical evidence, mechanism, importance and management

Two patients stabilised on lithium carbonate (serum level 0.75 mmol/L) had signs of lithium toxicity (tremor, fasciculations, muscular weakness, dysarthria, apathy) within a few days of being given co-trimoxazole (dose not stated), yet their serum lithium levels were found to have fallen to about 0.4 mmol/L. Within 48 hours of withdrawing the co-trimoxazole, the signs of toxicity had gone, and their serum lithium concentrations had returned to their former level.[1] Another report very briefly states that ataxia, tremor and diarrhoea developed in a patient taking lithium and timolol when co-trimoxazole was given.[2]

A 40-year-old woman taking lithium 1.2 g daily, experienced nausea, diarrhoea, malaise, difficulty concentrating, trembling, an uncertain gait and muscle spasms after trimethoprim 300 mg daily was started; her serum lithium levels appeared to be elevated. She made a good recovery following rehydration.[3]

The reasons for this interaction are not understood, although trimethoprim may affect the renal excretion of lithium.[3] The general importance of this interaction is uncertain. If concurrent use is undertaken it would clearly be prudent to monitor the clinical response, as it would appear that in this situation serum level monitoring might not always be a reliable guide to toxicity. Consider also 'Lithium + Antibacterials', above.

Lithium + Antibacterials; Linezolid

Two cases describe serotonin syndrome in patients taking linezolid and lithium, although in both cases other potentially interacting drugs were also taken.

Clinical evidence, mechanism, importance and management

A retrospective review of adverse events reported to the FDA in the US, identified 29 cases of serotonin syndrome involving linezolid. One patient had received lithium; their other medication included bupropion, sertraline and trazodone.[1] A case report also describes serotonin syndrome occurring in a 36-year-old woman after linezolid was added to her drug regimen, which also included lithium, venlafaxine, and imipramine.[2]

Although the use of linezolid was implicated in both of these cases, it is unclear what part lithium had to play, although cases of serotonin syndrome have been reported when lithium is taken with other drugs affecting serotonin, see 'Lithium + SSRIs', p.1365. However, in both of the cases cited above, other drugs were also taken which are known to result in serotonin syndrome with linezolid and therefore the general significance of these cases is unclear. For more information on serotonin syndrome, see under 'Additive or synergistic interactions', (p.9).

Lithium + Antibacterials; Metronidazole

The lithium levels of three patients rose, to toxic levels in two cases, after they took metronidazole. Renal impairment was also reported in two of these patients.

Clinical evidence, mechanism, importance and management

A 40-year-old woman taking lithium carbonate 1.8 g daily, levothyroxine 150 micrograms daily and propranolol 60 mg daily developed signs of lithium toxicity (ataxia, rigidity, poor cognitive function, impaired coordination) after completing a one-week course of metronidazole 500 mg twice daily. Her serum-lithium levels had risen by 46% (from 1.3 to 1.9 mmol/L).[1] Another report describes 2 patients whose serum-lithium levels rose by about 20% and 125%, 5 to 12 days, after they finished a one-week course of metronidazole 750 mg or 1 g daily, respectively, in divided doses.[2] A degree of renal impairment occurred during concurrent use and was still present 5 to 6 months later.[2] In contrast, one other patient is said to have taken both drugs together uneventfully.[1]

There seems to be no reason for avoiding concurrent use, but the outcome should be well monitored. Some have recommended that a reduction in the lithium dose should be considered, especially in patients maintained at relatively high serum lithium levels.[1,2] Patients taking lithium should be aware of the symptoms of lithium toxicity and told to report them immediately should they occur. This should be reinforced when they are given

metronidazole. The authors of one of the reports also recommend frequent analysis of creatinine and electrolyte levels and urine osmolality in order to detect any renal problems in patients taking this combination.[2] Consider also 'Lithium + Antibacterials', p.1350.

Lithium + Antibacterials; Quinolones

An isolated case of lithium toxicity has been reported in a patient taking lithium and levofloxacin. Another possible case has been reported with ciprofloxacin.

Clinical evidence, mechanism, importance and management

A 56-year-old man taking lithium carbonate 400 mg three times daily for a bipolar disorder was admitted to hospital with bronchitis. He was given **levofloxacin** 300 mg daily, and within 2 days was noted to have developed gait ataxia, dysarthria, coarse tremor, dizziness, vomiting, and confusion. Lithium toxicity was suspected, and because of the time course of the symptoms, an interaction with **levofloxacin** was considered responsible. Serum lithium levels were found to have risen from 0.89 mmol/L (measured 2 weeks previously) to 2.53 mmol/L, and a reduction in his renal function was noted. Both drugs were stopped and the patient recovered over the following 4 days. His lithium level was found to be 1.12 mmol/L at that time.[1]

The mechanism of this interaction between lithium and **levofloxacin** is unclear, and this appears to be the only report. However, it would seem prudent to bear this interaction in mind if a patient taking lithium is given **levofloxacin**. Patients taking lithium should be aware of the symptoms of lithium toxicity and told to report them immediately should they occur. This should be reinforced when they are given **levofloxacin**. For a report of lithium toxicity with raised lithium levels in a patient taking **ciprofloxacin** and nimesulide, which was attributed to the NSAID, see *Nimesulide*, under 'Lithium + NSAIDs', p.1360, and consider also 'Lithium + Antibacterials', p.1350.

Lithium + Antibacterials; Spectinomycin

An isolated case report describes a patient who developed lithium toxicity when given spectinomycin.

Clinical evidence, mechanism, importance and management

A woman developed lithium toxicity (tremor, nausea, vomiting, ataxia and dysarthria) when given spectinomycin injections (dose not stated) in addition to her long-term treatment with lithium.[1] Her serum-lithium levels had risen from a range of 0.8 to 1.1 mmol/L up to 3.2 mmol/L. Spectinomycin reduces urinary output, and so it was suggested that a reduced renal clearance of lithium led to these elevated levels. Information seems to be limited to this report, but it would seem prudent to bear this interaction in mind in any patient given both drugs.

Consider also 'Lithium + Antibacterials', p.1350.

Lithium + Antibacterials; Tetracyclines

The concurrent use of lithium and the tetracyclines is normally uneventful, but two isolated reports describe increased lithium levels and lithium toxicity, one in a woman taking tetracycline, and the other in a man taking doxycycline. An isolated case of pseudotumor cerebri occurred in one patient taking lithium and minocycline.

Clinical evidence

(a) Doxycycline

A man receiving long-term treatment with lithium carbonate became confused within a day of starting to take doxycycline 100 mg twice daily. By the end of a week he had developed symptoms of lithium toxicity (ataxia, dysarthria, worsened tremor, fatigue, etc.). His serum lithium levels had risen from a range of 0.8 to 1.1 mmol/L up to 1.8 mmol/L; his renal function remained normal. He recovered when the doxycycline was withdrawn.[1]

(b) Minocycline

A case report describes pseudotumor cerebri in an obese 15-year-old girl taking lithium, 4 months after she started taking minocycline 75 mg twice daily for acne.[2]

(c) Tetracycline

An isolated report describes a woman who had been taking lithium for 3 years, with serum levels within the range of 0.5 to 0.84 mmol/L. Within 2 days of starting to take a sustained-release form of tetracycline (*Tetrabid*) her serum lithium levels had risen to 1.7 mmol/L, and 2 days later they had further risen to 2.74 mmol/L. By then she had clear symptoms of lithium toxicity (slight drowsiness, slurring of the speech, fine tremor and thirst).[3] In contrast, 13 healthy subjects taking lithium carbonate 450 mg twice daily or 900 mg daily had a small 8% reduction in serum lithium levels (from 0.51 to 0.47 mmol/L) when they were given tetracycline 500 mg twice daily for 7 days.[4] The incidence of adverse reactions remained largely unchanged, except for a slight increase in CNS and gastrointestinal adverse effects.

Mechanism

Not understood. One suggested reason for increased serum lithium levels is that tetracycline (known to have nephrotoxic potential) may have adversely affected the renal clearance of lithium.[3]

Importance and management

These adverse interaction reports describing a possible interaction between lithium and the tetracyclines are isolated and unexplained. Two reports make the point that these drugs are commonly used for acne caused by lithium,[1,5] so any common interaction resulting in raised lithium levels would be expected to have come to light by now. The case of pseudotumor cerebri also appears rare, but note that the female gender, obesity, and minocycline use alone are risk factors for its development and so greater caution may be warranted in this type of patient.[2] The authors advise frequent enquiry about headaches and visual changes.

There would seem to be no reason for avoiding the concurrent use of lithium and tetracycline, doxycycline or minocycline, but be aware of the potential for a rare interaction. One manufacturer advises increased frequency of lithium level monitoring when a tetracycline is started or stopped.[6] Consider also 'Lithium + Antibacterials', p.1350.

Lithium + Aripiprazole

Lithium does not affect the pharmacokinetics of aripiprazole to a clinically significant extent. A case report describes neuroleptic malignant syndrome in a patient taking aripiprazole and lithium.

Clinical evidence, mechanism, importance and management

In a study, 7 healthy subjects were given aripiprazole 30 mg daily for 5 weeks, with lithium carbonate slow-release tablets 1.2 to 1.8 g daily (to give a plasma level of 1 to 1.4 mmol/L) during weeks 3 to 5. The AUC and maximum plasma concentrations of aripiprazole were increased by 15% and 19%, respectively.[1] Results from a routine therapeutic drug monitoring service suggest that aripiprazole levels are increased by 34% by lithium.[2]

Moderately severe neuroleptic malignant syndrome developed in a patient with bipolar disorder within 3 weeks of starting aripiprazole in a dose of 5 mg daily titrated slowly up to 15 mg twice daily and lithium which was increased to 600 mg twice daily. The patient improved over 4 days after aripiprazole was discontinued and lithium withheld and after a further 3 days lithium was restarted. The use of lithium may have increased the risk of this syndrome with aripiprazole.[3]

The concurrent use of lithium and aripiprazole modestly increases the plasma levels of both drugs, but these increases are not considered to be clinically significant. The case describing neuroleptic malignant syndrome is isolated, and as this effect can occur in response to one antipsychotic drug there would seem no need to take additional precautions if both aripiprazole and lithium are taken.

Lithium + Aspirin or other Salicylates

No clinically significant pharmacokinetic interaction appears to occur between aspirin, lysine aspirin or sodium salicylate and lithium.

Clinical evidence, mechanism, importance and management

In a steady-state study, 10 healthy women with average plasma lithium levels of 0.63 mmol/L had a slight 6% rise in their renal excretion of lithium when they were given aspirin 1 g four times daily for 7 days. However, no statistically significant alteration in lithium levels was found.[1]

No change in serum lithium levels was seen in 7 patients taking lithium when they were given aspirin 975 mg four times daily for 6 days.[2] Another report states that aspirin 600 mg four times daily had no effect on the absorption or renal excretion of single doses of lithium carbonate given to 6 healthy subjects.[3] Further reports describe no change in serum lithium levels with **lysine aspirin**,[4] intravenous aspirin,[5] or intravenous **sodium salicylate**.[5] However, lithium clearance was slightly reduced by 22% by intravenous **sodium salicylate**,[5] and a study in one healthy subject found a 32% increase in mean serum lithium levels (from 0.41 to 0.54 mmol/L) after 5 days' use of oral aspirin (975 mg four times daily for 2 days, then 650 mg four times daily for 3 days).[6]

Note that pyrexia, for which aspirin and other related drugs may be taken, can itself alter fluid and electrolyte balance and thereby cause elevated lithium levels.

Lithium + Baclofen

The hyperkinetic symptoms of two patients with Huntington's chorea were aggravated within a few days of starting to take lithium and baclofen.

Clinical evidence, mechanism, importance and management

A patient with Huntington's chorea, taking lithium and haloperidol, was also given baclofen, and another patient taking imipramine, clopenthixol, chlorpromazine and baclofen was also given lithium. Within a few days both patients had a severe aggravation of their hyperkinetic symptoms, which disappeared within 3 days of withdrawing the baclofen.[1] Other patients with Huntington's chorea had no major changes in their mental state or movement disorders when given up to 90 mg of baclofen daily,[2,3] which suggests that an interaction with lithium may have been the cause of the hyperkinesis in these two patients. On the basis of this very limited evidence it would seem prudent to monitor the effects of concurrent use and consider stopping one of the drugs if hyperkinesis develops.

Lithium + Benzodiazepines

Neurotoxicity and increased lithium levels were reported in several patients when clonazepam was given to patients taking lithium, and increased lithium levels have been described in one patient taking bromazepam. An isolated case of serious hypothermia has been reported during the concurrent use of lithium and diazepam. Alprazolam seems unlikely to cause a clinically important rise in lithium levels.

Clinical evidence, mechanism, importance and management

(a) Alprazolam

In 10 healthy subjects taking lithium carbonate 900 mg to 1.5 g daily, alprazolam 2 mg daily for 4 days slightly increased the steady-state AUC of lithium by about 8% and reduced its urinary recovery from 93.6% to 78.2%. It was suggested that these changes were unlikely to be clinically significant, but confirmation of this is needed.[1]

(b) Bromazepam

A case report describes a patient taking lithium carbonate 900 mg daily, whose lithium levels rose from 1.12 mmol/L to 1.4 mmol/L within 4 days of starting to take bromazepam 18 mg daily. His lithium dose was reduced to 500 mg daily, which resulted in his lithium level returning to its former value.[2]

(c) Clonazepam

A retrospective study of patient records revealed 5 patients with bipolar affective disorder, taking lithium carbonate 900 mg to 2.4 g daily, who had developed a reversible neurotoxic syndrome with ataxia, dysarthria, drowsiness and confusion when they were given clonazepam 2 to 16 mg daily. In one case the clonazepam was added to their antipsychotics (chlorpromazine, perphenazine, haloperidol) and in 4 cases the clonazepam replaced the antipsychotic treatment. In all cases the lithium levels rose, and in two of these cases they reached toxic levels. The authors of the report suggest that the neurotoxicity was caused either by the increase in lithium levels, or by synergistic toxicity; however, the use of antipsychotics may also have increased CNS sensitivity. It was recommended that lithium levels should be measured more frequently if clonazepam is added, and the effects of concurrent use well monitored.[3]

(d) Diazepam

A patient who was described as having profound mental retardation had occasional hypothermic episodes (below 35°C) while taking lithium and diazepam, but not while taking either drug alone. After taking lithium carbonate 1 g and diazepam 30 mg daily for 17 days, the patient's temperature fell from 35.4°C to 32°C over 2 hours, and she became comatose with reduced reflexes, dilated pupils, a systolic blood pressure of 40 to 60 mmHg, a pulse rate of 40 bpm and no piloerector response.[4] The reasons for this reaction are not known. This is an isolated case and therefore no general recommendations can be made. There seems to be no evidence of this adverse interaction with any of the other benzodiazepines.

Lithium + Caffeine

The heavy consumption of caffeine-containing drinks may cause a small to moderate reduction in serum lithium levels.

Clinical evidence

An early single-dose study found that the intake of xanthines such as caffeine caused an increase in lithium excretion.[1] In contrast, another single-dose study did not find any significant changes in the urinary clearance of lithium in 6 subjects given caffeine 200 mg four times daily compared with a caffeine-free control period.[2] However, a study in 11 psychiatric patients taking lithium 600 mg to 1.2 g daily who were also regular **coffee** drinkers (4 to 8 cups daily containing 70 to 120 mg of caffeine per cup), serum lithium levels rose by an average of 24% when the **coffee** was withdrawn, although the levels of 3 patients did not change.[3] These findings are consistent with another report of 2 patients with lithium-induced tremors that were aggravated when they stopped drinking large amounts of **coffee**. One of the patients had a 50% rise in lithium levels, and required a reduction in lithium dose from 1.5 g daily to 1.2 g daily.[4]

Mechanism

It is not clear exactly how caffeine affects the excretion of lithium by the renal tubules, but other xanthines have a similar effect (see 'Lithium + Theophylline', p.1366).

Importance and management

The weight of evidence suggests that, although there is no need for those taking lithium to avoid caffeine (from caffeine-containing herbs, coffee, tea, cola drinks etc.), they should stick to a moderate intake, and in cases where a reduction in caffeine intake is desirable, it should be withdrawn cautiously. This is particularly important in those whose serum lithium levels are already high, because of the risk of toxicity. When caffeine is withdrawn it may be necessary to reduce the dose of lithium. In addition, remember that there is a caffeine-withdrawal syndrome (headache and fatigue being the major symptoms) that might worsen some of the major psychiatric disorders (such as affective and schizophrenic disorders)[3] for which lithium is given.

Lithium + Calcitonin (Salcatonin)

A study in 4 women found that calcitonin caused a small reduction in serum lithium levels.

Clinical evidence

Prompted by the occasional observation of decreased serum lithium levels in outpatients receiving calcitonin, a study was undertaken in 4 women with bipolar depression. The patients, who had been taking lithium for 10 years, were also given salmon calcitonin 100 units subcutaneously for three consecutive days for postmenopausal osteoporosis. It was found that their serum lithium levels fell, on average, from 0.73 mmol/L to 0.59 mmol/L. The clearance of lithium in the urine was tested in 2 of the patients, and both had increases (9.8% and 16.2%).[1]

Mechanism

Not known. Increased renal excretion and possibly some reduced intestinal absorption of the lithium have been suggested by the authors of the report.[1]

Importance and management

Information seems to be limited to this study, which only lasted for 3 days. The study found only a small fall in serum lithium levels, and did not assess the effect on the control of depression. It seems unlikely that this interaction will be clinically important in most patients, but as some patients may be affected, monitor the outcome of concurrent use, and consider monitoring lithium levels if an interaction is suspected.

Lithium + Calcium-channel blockers

The concurrent use of lithium and verapamil can be uneventful, but neurotoxicity (ataxia, movement disorders, tremors) with unchanged lithium levels has been reported in a few patients. Reduced and increased lithium levels have also occurred with verapamil. An acute parkinsonian syndrome and marked psychosis has been seen in at least one patient taking lithium and diltiazem. Reduced lithium clearance, and one possible case of increased lithium levels have been reported with nifedipine.

Clinical evidence

(a) Diltiazem

A woman stable on lithium for several years developed marked psychosis and parkinsonism within a week of starting to take diltiazem 30 mg three times daily.[1] An acute parkinsonism syndrome developed in a 58-year-old man taking lithium and tiotixene within 4 days of starting 30 mg of diltiazem three times daily.[2] However, this report has been questioned as the symptoms may have been attributable to an adverse effect of the tiotixene, and, even if the lithium toxicity was genuine, it is thought to have been more likely due to recent increases in the lithium dose, or the patient's diuretic therapy than diltiazem.[3]

(b) Nifedipine

In a study of patients with essential hypertension, two doses of nifedipine 20 mg did not affect single-dose lithium clearance, but nifedipine 40 to 80 mg daily for 6 and 12 weeks was found to decrease single-dose lithium clearance by 30%.[4] A man, taking lithium carbonate 1.5 g daily with a level of 0.8 mmol/L, developed ataxia and dysarthria 7 days after starting nifedipine 30 mg daily for 48 hours, then 60 mg daily. His lithium dose was reduced by 40%, but his serum lithium level first increased to 1.1 mmol/L (about 2 weeks after starting the nifedipine), before restabilising at 0.9 mmol/L.[5] In contrast, a patient taking lithium, who developed dysarthria and ataxia after verapamil was added to her treatment (see *Verapamil*, below), was subsequently well controlled while taking lithium and nifedipine 40 mg daily.[6]

(c) Verapamil

A 42-year-old woman taking lithium carbonate 900 mg daily developed toxicity (nausea, vomiting, muscular weakness, ataxia and tinnitus) within 9 days of starting to take verapamil 80 mg three times daily. Her bipolar depressive disorder improved even though her serum lithium levels remained unchanged at 1.1 mmol/L. The toxicity disappeared within 48 hours of stopping the verapamil, but her disorder worsened. The same pattern was repeated when verapamil was restarted and then withdrawn.[7] Another 3 cases of movement disorders (including ataxia, tremors and choreoathetosis) resulting from the concurrent use of lithium and verapamil have also been reported,[6,8,9] two of which had documented unchanged serum lithium levels.[6,8] In one case the patient was restabilised by halving the dose of lithium.[8]

Conversely, a patient stable taking lithium 900 mg to 1.2 g daily for over 8 years had a marked fall in his serum lithium levels from about 1.04 mmol/L to 0.5 mmol/L when he was given verapamil 80 mg four times daily. He was restabilised on approximately double the dose of lithium.[10] Another patient had an increased lithium clearance when he took verapamil for 3 days, and he had a fall in his serum lithium levels, from 0.61 mmol/L to 0.53 mmol/L.[10]

In addition to unchanged or decreased lithium levels with verapamil, one manufacturer notes that increased lithium levels have occurred.[11]

Two cases of bradycardia have been reported when verapamil was added to lithium treatment; in one case the patient's heart rate returned to normal on stopping verapamil, in the other case the patient, who was also taking propranolol, developed asymptomatic class I atrioventricular ectopy and died following a myocardial infarction.[12]

Mechanism

Not understood. However, it has been suggested that calcium-channel blockers and lithium affect neurotransmitter production[1,2,9] (several pathways have been described), which results in CNS sensitivity. This produces movement disorders, which are said to mimic lithium toxicity. In most of the cases mentioned above, symptoms of toxicity were present at therapeutic lithium levels, which would support this suggested mechanism. It

is unclear whether the cases of bradycardia are attributable to an interaction between lithium and verapamil, or the effects of verapamil alone. The contribution of propranolol in the second case may also be significant, see 'Beta blockers + Calcium-channel blockers; Verapamil', p.1003.

Importance and management

The neurotoxic adverse reactions cited above for lithium and verapamil contrast with two other case reports describing uneventful concurrent use.[13,14] Variable reports of altered serum lithium levels have also occurred. This unpredictability emphasises the need to monitor the effects closely where it is thought appropriate to give lithium and verapamil. Only a couple of isolated reports of neurotoxicity have been reported with lithium and diltiazem, and their general relevance is uncertain, but bear them in mind in the event of an unexpected response to treatment. Some limited data suggest that nifedipine may slightly reduce lithium clearance, and the clinical relevance of this is also uncertain.

Lithium + Carbamazepine

Although the concurrent use of lithium and carbamazepine is beneficial in many patients, it may increase the risk of neurotoxicity. Sinus node dysfunction has also occurred in a few patients. An isolated report describes a patient who had a marked rise in lithium levels and lithium toxicity, which was apparently caused by carbamazepine-induced renal impairment.

Clinical evidence

(a) Neurotoxicity with normal drug levels

A patient taking lithium 1.8 g daily developed severe neurotoxicity (ataxia, truncal tremors, nystagmus, limb hyperreflexia, muscle fasciculation) within 3 days of starting to take carbamazepine 600 mg daily. Blood levels of both drugs remained within the therapeutic range. The symptoms resolved when each drug was withdrawn in turn, and recurred within 3 days of restarting concurrent treatment.[1] Five patients with rapid-cycling bipolar disorder developed similar neurotoxic symptoms (confusion, drowsiness, generalised weakness, lethargy, coarse tremor, hyperreflexia, cerebellar signs) when they were given lithium carbonate with carbamazepine (doses not stated). Plasma levels of both drugs remained within the accepted range.[2] Other reports describe adverse neurological effects during the concurrent use of lithium and carbamazepine, which were also not accompanied by significant changes in lithium levels,[3-7] although in one patient raised serum levels of both drugs were seen.[8] A systematic search through the Medline database, for reports of neurotoxic adverse effects in patients taking lithium at low therapeutic concentrations, found a total of 41 cases over approximately 30 years from 1966. Carbamazepine had been taken concurrently in 22% of these cases, in some instances with other potentially interacting drugs.[9] Another retrospective study of 46 patients with type I bipolar disorder found significant benefits of the long-term concurrent use of lithium and carbamazepine, compared with lithium (31 patients) or carbamazepine (15 patients) alone. However, rates of adverse effects increased 2.5-fold compared with monotherapy, and there were particular excesses of tremor and drowsiness.[10]

In other patients the concurrent use of lithium and carbamazepine was said to be well tolerated and beneficial,[11,12] but one report suggests that the doses may need to be carefully titrated to avoid adverse effects.[13]

(b) Sinus node dysfunction

A 9-year study in a psychiatric hospital found that, of 5 patients taking lithium who developed sinus node dysfunction, 4 were also taking carbamazepine.[14]

(c) Toxic lithium levels

An isolated case report describes carbamazepine-induced acute renal failure, which resulted in a 3.5-fold rise in lithium levels and lithium toxicity 3 weeks after carbamazepine was started.[15]

Mechanism

Not understood. A paper that plotted the serum levels of lithium and carbamazepine on a two-dimensional graph did not find any evidence of synergistic toxicity.[16] Sinus node dysfunction can be caused by either lithium or carbamazepine, but this is rare. However, the effects may possibly be additive.

Importance and management

The neurotoxic interaction between lithium and carbamazepine is established, but its incidence is not known. The incidence of severe neurotoxicity may be quite small, but increased mild adverse events such as tremor and drowsiness seem to be fairly common.[10] The authors of one paper suggest that the risk factors appear to be a history of neurotoxicity with lithium, and compromised medical or neurological function.[2] If concurrent use is undertaken, the outcome should be closely monitored. This is particularly important because neurotoxicity can develop even though the levels remain within the accepted therapeutic range. If severe neurotoxicity develops the lithium treatment should be discontinued promptly, whatever the lithium level.[9] The manufacturers of **oxcarbazepine**[17] predict that it may interact similarly, and therefore it would seem prudent to take similar precautions to those suggested for carbamazepine.

Lithium + Cisplatin

Isolated case reports describe either a fall or no alteration in lithium levels in patients given cisplatin. However, note that cisplatin-induced renal impairment may cause an increase in lithium levels.

Clinical evidence, mechanism, importance and management

The serum lithium levels of a woman taking lithium carbonate 300 mg four times daily fell, over a period of 2 days, from 1 mmol/L to 0.3 mmol/L, and from 0.8 mmol/L to 0.5 mmol/L, on two occasions when given cisplatin (100 mg/m^2 intravenously over 2 hours). To prevent cisplatin-induced renal toxicity, she was also given a fluid load over a total of 24 hours, which included one litre of sodium chloride 0.9% over 4 hours, one litre of mannitol 20% over 4 hours, and one litre of dextrose 5% in sodium chloride 0.9%. Serum lithium levels returned to normal at the end of 2 days. No change in the control of the psychotic symptoms was seen.[1] A man had a transient 64% decrease in serum lithium levels, without perceptible clinical consequences, during the first of four courses of cisplatin, bleomycin, and etoposide. The effect became less pronounced during the subsequent courses.[2] It is not clear whether the fall in serum lithium levels in these cases was due to increased renal clearance caused by the cisplatin or the sodium load, dilution from the fluid load, or a combination of all three factors.

In contrast, one patient had no clinically significant changes in her serum lithium levels when given cisplatin, but 2 months later her deteriorating renal function resulted in a rise in her serum lithium levels.[3]

None of these interactions was of great clinical importance, but the authors of the first report pointed out that some regimens of cisplatin involve the use of higher doses (40 mg/m^2 daily) with a sodium chloride 0.9% fluid load over 5 days, and under these circumstances it would be prudent to monitor the serum lithium levels carefully. Concurrent use should be monitored in all patients.

Lithium + Clozapine

A few patients given lithium carbonate and clozapine have experienced adverse reactions including myoclonus, neuroleptic malignant syndrome, seizures, delirium, and psychoses.

Clinical evidence

A review of the medical records of 44 patients taking clozapine and lithium identified 28 patients who had experienced an adverse effect, three of which were possibly associated with the drug combination. There were two reports of myoclonus and one of a grand mal seizure.[1] A retrospective study using both Medline and the spontaneous reporting system of the FDA in the US, over the period 1969 to 1994, identified 237 cases of severe neurotoxicity involving lithium, with 188 involving lithium with antipsychotics and of these, 6 involved clozapine.[2,3]

Four out of 10 patients taking lithium carbonate (mean dose of 1.4 g daily) and clozapine (mean maximum dose 900 mg daily) developed reversible neurological symptoms including involuntary jerking of the limbs and tongue, facial spasm, tremor, confusion, generalised weakness, stumbling gait, leaning and falling to the right. One of them also became delirious. Serum lithium levels remained unchanged, and the problems resolved when the lithium was stopped. Three of the four had a recurrence of the symptoms when rechallenged with the drug combination.[4]

A man with poorly controlled schizophrenia, taking clozapine 750 mg daily for 6 weeks, was given lithium, initially 900 mg and then subsequently 1.2 g daily. His serum lithium level was 0.86 mmol/L. Within one week he began to experience paroxysmal jerky movements of his upper and lower extremities lasting about 30 minutes. This myoclonus resolved when both drugs were stopped, and did not recur when clozapine was restarted alone.[5] Another patient taking lithium developed neuroleptic malignant syndrome (stiffness, rigidity, tachycardia, diaphoresis, hypertension) 3 to 4 weeks after clozapine was added. The symptoms disappeared within 2 to 3 days of stopping the clozapine.[6] An elderly man also developed neuroleptic malignant syndrome 3 days after starting to take clozapine 25 mg daily. He was also taking carbamazepine, and had stopped taking lithium 3 days earlier.[7] A number of other case reports describe adverse neurological effects in patients taking clozapine and lithium. These include neurotoxic symptoms (ataxia, coarse tremor, myoclonus, facial spasm, and increased deep tendon reflex) which developed after 3 days of concurrent use,[8] psychosis and raised lithium levels,[9] and two cases of seizures (one within 4 days of concurrent use).[10]

It has been suggested that lithium may help to protect patients from the adverse effects of clozapine, in particular agranulocytosis.[11] However, lithium is thought to have masked a clozapine-induced agranulocytosis in a 59-year-old woman who developed leucopenia and subsequently agranulocytosis after 40 days of treatment with lithium and clozapine.[12]

Mechanism

Not understood.

Importance and management

An interaction between clozapine and lithium appears to be established; however, not all patients are affected. It is not clear just why some patients develop a toxic reaction when given both drugs, and others do not, and it is also not clear which patients are at risk. One group of workers suggest that lithium levels of no more than 0.5 mmol/L may give therapeutic benefits while minimising adverse effects.[4]

The concurrent use of clozapine and lithium should therefore be well monitored for adverse effects, particularly for evidence of neuroleptic malignant syndrome, which appears to be the most common adverse effect reported. An interaction with clozapine leading to increased lithium levels is not established: there appears to be only one case report describing this effect.

Lithium + Corticosteroids

Corticosteroids may disturb electrolyte balance, which in theory could affect serum lithium levels, but there do not appear to be any reports of significant interactions. A case report suggests that lithium caused resistance to corticosteroid treatment in a patient with Addison's disease.

Clinical evidence, mechanism, importance and management

A patient with systemic lupus erythematosus suffering from steroid-induced depression and moderate renal impairment was given lithium 600 mg daily and her depression improved. However, serum lithium levels increased from 0.4 to 0.8 mmol/L within one week and the lithium treatment caused an exacerbation of a finger tremor. The lithium was discontinued and then restarted at 400 mg daily, resulting in serum levels of 0.4 mmol/L, which improved her depression and was associated with only a fine finger tremor. Three other patients with steroid-induced depression were also successfully treated with lithium.[1] One case describes a 29-year-old patient taking several drugs including **fludrocortisone** 150 micrograms daily and **hydrocortisone** 40 mg daily for Addison's disease and also taking lithium carbonate 1.2 g daily for bipolar disorder. He was admitted to hospital with an Addisonian crisis and a plasma sodium level of 117 mmol/L, but this normalised (to 130 mmol/L) within 48 hours of stopping his medication and treatment with intravenous **hydrocortisone** and hypertonic fluids. Lithium levels remained within the therapeutic range. Hyponatraemia developed a second time when treatment was re-

instated, and again, resolved within 48 hours after stopping lithium.[2]

Two UK manufacturers warn that drugs affecting electrolyte balance, such as corticosteroids, may alter lithium excretion and should therefore be avoided,[3,4] but other manufacturers do not appear to specifically mention this potential interaction. An early study in *rats* reported increased lithium clearance with **methylprednisolone**.[5] The available evidence is insufficient to recommend routine monitoring. However, it may be prudent to consider monitoring lithium effects in patients with renal impairment, or other conditions pre-disposing to lithium toxicity, taking levels if early symptoms suggest a potential problem.

Lithium + Diuretics; Loop

The concurrent use of lithium carbonate and furosemide can be safe and uneventful, but serious lithium toxicity has been described. Bumetanide interacts similarly. The risk of lithium toxicity with a loop diuretic is greatly increased during the first month of concurrent use.

Clinical evidence

An analysis of 10 615 elderly patients receiving lithium found that 413 patients (3.9%) were admitted to hospital at least once for lithium toxicity during a 10-year study period. The prescriptions for any loop diuretic (not specifically named) were compared between these 413 hospitalised patients and 1 651 control patients. For any use of a loop diuretic (54 cases and 71 controls) there was an increased relative risk of hospitalisation for lithium toxicity of 1.7. When patients who were newly started on a loop diuretic were analysed (12 cases and 6 controls), a dramatically increased risk of lithium toxicity within a month of initiating treatment was found (relative risk 5.5).[1] Reports relating to specific named loop diuretics are discussed below.

(a) Bumetanide

Bumetanide has been responsible for the development of lithium toxicity in 2 patients[2,3] one of whom was following a salt-restricted diet,[3] which has also been implicated in episodes of lithium toxicity, see 'Lithium + Sodium compounds', p.1364.

(b) Furosemide

Six healthy subjects stabilised on lithium carbonate 300 mg three times daily (mean serum levels 0.43 mmol/L) were given furosemide 40 mg daily for 14 days. Five experienced some minor adverse effects, probably attributable to the furosemide, without significant changes in serum lithium levels, but one subject experienced such a marked increase in the toxic effects of lithium that she withdrew from the study after taking both drugs for only 5 days. Her serum lithium levels were found to have risen from 0.44 mmol/L to 0.71 mmol/L.[4]

There are another 4 case reports of individual patients who experienced serious lithium toxicity or other adverse reactions when given lithium and furosemide.[5-8] One of the patients was also following a salt-restricted diet,[5] which has also been implicated in episodes of lithium toxicity, see 'Lithium + Sodium compounds', p.1364. In contrast, 6 patients who had been stabilised on lithium for over 6 years had no significant changes in their serum lithium levels over a 12-week period while taking furosemide 20 to 80 mg daily.[9] Other studies in healthy subjects also found no significant changes in lithium levels when furosemide 40 or 80 mg daily was given.[10,11]

Mechanism

Not fully understood. If and when a rise in serum lithium levels occurs, it may be related to the salt depletion that can accompany the use of furosemide (for a more detailed explanation see 'Lithium + Sodium compounds', p.1364). As with the thiazides (see 'Lithium + Diuretics; Thiazide and related', p.1357), such an interaction would take a few days to develop. This may explain why one study in subjects given a single dose of lithium did not find any effect of furosemide on the urinary excretion of lithium.[12]

Importance and management

Information about an interaction between loop diuretics and lithium seems to be limited to the reports cited. The incidence of this interaction is uncertain and its development unpredictable. It would be imprudent to give furosemide or bumetanide to patients stabilised on lithium unless the effects can be well monitored, because some patients may develop serious toxicity. Patients taking lithium should be aware of the symptoms of lithium toxicity (see 'Lithium', (p.1347)) and told to report them immediately should they occur. Consider increased monitoring of lithium levels in patients newly started on this combination.

Lithium + Diuretics; Potassium-sparing

There is evidence that the excretion of lithium can be increased by triamterene. In contrast, lithium levels may rise if spironolactone is used: eplerenone is predicted to interact similarly. Amiloride appears not to interact with lithium.

Clinical evidence and mechanism

(a) Amiloride

Amiloride has been found to have no significant effect on serum lithium levels when used in the treatment of lithium-induced polyuria.[1,2] Similarly, in a study to investigate the effect of amiloride on urine osmolality in 11 patients taking lithium, there was no change in the lithium plasma levels after they took amiloride 5 mg daily for 2 weeks, then 10 mg daily for 4 weeks.[3] One review briefly mentions a case report in which amiloride was successfully used as a replacement for bendroflumethiazide, which had caused lithium toxicity.[4] However, one manufacturer[5] suggests that, as a diuretic, amiloride reduces the renal clearance of lithium, thereby increasing the risk of lithium toxicity. There appears to be no evidence to confirm this alleged interaction.

(b) Spironolactone

One study found that spironolactone had no statistically significant effect on the excretion of lithium,[6] whereas in another report, the use of spironolactone 100 mg daily was accompanied by a rise in serum lithium levels from 0.63 mmol/L to 0.9 mmol/L. The levels continued to rise for several days after the spironolactone was stopped.[7]

(c) Triamterene

Triamterene, given to a patient taking lithium while following a salt-restricted diet, is said to have led to a strong lithium diuresis.[8] Similarly, triamterene increased lithium excretion in 8 healthy subjects.[9]

Importance and management

Amiloride, spironolactone and triamterene have been available for a very considerable time and it might have been expected that by now any serious adverse interactions with lithium would have emerged, but information is very sparse. None of the reports available gives a clear indication of the

outcome of concurrent use, but some monitoring would be a prudent precaution with any potassium-sparing diuretic. No interaction study has been undertaken with lithium and **eplerenone**.[10,11] The manufacturers suggest that lithium levels should be monitored frequently if eplerenone is also given,[10,11] although, in the UK, the manufacturer advises avoidance of the combination.[11] They state that this is because raised lithium levels have occurred with related drugs such as the ACE inhibitors and diuretics.

Patients taking lithium should be aware of the symptoms of lithium toxicity (see 'Lithium', (p.1347)) and told to report them immediately should they occur.

Lithium + Diuretics; Thiazide and related

Thiazide and related diuretics can cause a rapid rise in lithium levels, leading to toxicity unless the lithium dose is reduced appropriately.

Clinical evidence

A retrospective analysis of 10 615 elderly patients receiving lithium found that 413 (3.9%) were admitted to hospital at least once for lithium toxicity during a 10-year study period. The prescriptions for a thiazide-type diuretic were compared between these 413 hospitalised patients and 1 651 control patients. For any use of a thiazide diuretic (16 cases and 37 controls) there was a non-significant increased relative risk of 1.3 for hospitalisation due to lithium toxicity. When treatment for patients who were newly started on a thiazide diuretic was analysed (5 cases and 6 controls), the increased relative risk of toxicity was also non-significant (1.3). The authors considered that these findings suggest that the use of thiazide diuretics and lithium may not be as hazardous as previously thought. However, the authors also suggest that another explanation is that clinicians were aware of the potential interaction and so adjusted doses or observed patients more closely in the outpatient setting, thereby avoiding any hospitalisations for toxicity.[1]

Case reports and studies for named thiazide diuretics are outlined below.

(a) Bendroflumethiazide

A study in 22 patients, who had been taking either bendroflumethiazide 2.5 mg daily or hydroflumethiazide 25 mg daily for at least 2 months, found that these diuretics caused a 24% reduction in the urinary clearance of a single 600-mg dose of lithium carbonate.[2] There is also a case report of a roughly twofold increase in serum lithium levels,[3] and a case of lithium toxicity with a roughly threefold increase in serum lithium levels mentioned in a review article,[4] both after bendroflumethiazide was started in patients taking lithium. In a further case, lithium toxicity, with serum lithium levels of 4.28 mmol/L was detected 3 months after the addition of bendroflumethiazide.[5] However, this case was complicated by the presence of perindopril, which might also raise lithium levels, as has occurred with other ACE inhibitors, see 'Lithium + ACE inhibitors', p.1348.

In contrast to these reports, one single-dose study found that bendroflumethiazide 7.5 mg given 10 hours after lithium carbonate 600 mg had no effect on lithium clearance.[6] However, it seems unlikely that single-dose studies will detect an interaction (see *Mechanism* below).

(b) Chlorothiazide

A single 300-mg dose of lithium carbonate was given to 4 healthy subjects alone and following 7 days of treatment with chlorothiazide 500 mg daily. Lithium-plasma levels were increased and lithium clearance was decreased by about 26% following chlorothiazide treatment.[7]

Lithium toxicity developed in a patient taking lithium after she was given chlorothiazide, spironolactone and amiloride.[8] The lithium levels rose from 0.6 mmol/L to 2.2 mmol/L. A 54-year-old patient developed nephrogenic diabetes insipidus when she took lithium carbonate. The addition of chlorothiazide reduced her polyuria, but resulted in an elevation in her lithium level from 1.3 mmol/L to more than 2 mmol/L, with accompanying signs of toxicity. The patient was later successfully treated with chlorothiazide and a reduced dose of lithium.[9]

(c) Chlortalidone

A 58-year-old woman developed lithium toxicity within 10 days of starting chlortalidone (dose unknown).[10] Her lithium levels rose from 0.8 mmol/L to 3.7 mmol/L.

(d) Hydrochlorothiazide

In a placebo-controlled study, the serum lithium levels of 13 healthy subjects taking lithium 300 mg twice daily rose by 23% (from 0.3 to 0.37 mmol/L), when they were given hydrochlorothiazide 25 mg twice daily for 5 days.[11] Similar results were found in another small study.[12] In addition to these studies at least 6 cases of lithium toxicity have been seen when hydrochlorothiazide was given to patients taking lithium.[13-17] Hydrochlorothiazide was either given with amiloride,[13-15] spironolactone[16] or triamterene.[17] See also 'Lithium + Diuretics; Potassium-sparing', p.1356.

(e) Hydroflumethiazide

A study in 22 patients who had been taking either bendroflumethiazide 2.5 mg daily or hydroflumethiazide 25 mg daily for at least 2 months found that these diuretics caused a 24% reduction in the urinary clearance of a single 600-mg dose of lithium carbonate.[2]

(f) Indapamide

A 64-year-old man developed lithium toxicity one week after starting to take indapamide 5 mg daily.[18] His serum lithium level was 3.93 mmol/L.

Mechanism

Not fully understood. The interaction occurs even though the thiazides and related diuretics exert their major actions in the distal part of the kidney tubule whereas lithium is mainly reabsorbed in the proximal part. However, thiazide diuresis is accompanied by sodium loss which, within a few days, is compensated by retention of sodium, this time in the proximal part of the tubule. As both sodium and lithium ions are treated similarly, the increased reabsorption of sodium would include lithium as well, hence a significant and measurable reduction in its excretion.[5,19]

Importance and management

Established, well-documented and potentially serious interactions. The rise in serum lithium levels and the accompanying toxicity develops most commonly within about a week to 10 days,[4,7,9-11,13,17] although it has apparently been seen after 19 days[16] and even 3 months.[5] Not every patient necessarily develops a clinically important interaction, but it is not possible to predict which patients will be affected. The lack of serious cases of toxicity in the case-control study either suggests the interaction is rare, or that appropriate precautions are used when the combination is prescribed.[1]

Although only the diuretics named above have been implicated in this interaction, it seems likely that all thiazides and related diuretics will interact similarly. None of the thiazide or related diuretics should be given to patients taking lithium unless the serum lithium levels can be closely monitored and appropriate downward dose adjustments made. Patients taking lithium should be aware of the symptoms of lithium toxicity (see 'Lithium', (p.1347)) and told to report them immediately should they occur.

The concurrent use of lithium and thiazides, under controlled conditions, has been advocated for certain psychiatric conditions and for the control of lithium-induced nephrogenic diabetes insipidus. A successful case is described above.[9] It has been suggested that a 40 to 70% reduction in the lithium dose would be needed with doses of 0.5 to 1 g of chlorothiazide,[20,21] but it would seem sensible to base any dose adjustments on individual lithium levels.

Lithium + Gabapentin

Gabapentin did not alter the pharmacokinetics of single-dose lithium in patients with normal renal function.

Clinical evidence, mechanism, importance and management

In a double-blind study, 13 patients with normal renal function were given a single 600-mg dose of lithium, either with or without gabapentin at steady state. Gabapentin did not significantly alter the pharmacokinetics of the lithium, and no increase in adverse effects was noted on concurrent use. Ideally, longer-term studies are needed to confirm this lack of interaction, especially in patients with impaired renal function as both drugs are eliminated by renal excretion.[1] However, on the basis of the information from this report, no lithium dose adjustment would be expected to be necessary on concurrent use.

Lithium + Herbal medicines

A woman developed lithium toxicity after taking a herbal diuretic remedy. A brief report describes mania in a patient taking lithium who also took St John's wort.

Clinical evidence, mechanism, importance and management

(a) Herbal diuretics

A 26-year-old woman who had been taking lithium 900 mg twice daily for 5 months, with hydroxyzine, lorazepam, propranolol, risperidone and sertraline, came to an emergency clinic complaining of nausea, diarrhoea, unsteady gait, tremor, nystagmus and drowsiness (all symptoms of lithium toxicity). Her lithium level, which had previously been stable at 1.1 mmol/L was found to be 4.5 mmol/L. For the past 2 to 3 weeks she had been taking a non-prescription **herbal diuretic** containing **corn silk**, ***Equisetum hyemale***, **juniper**, **ovate buchu**, **parsley** and **bearberry**, all of which are believed to have diuretic actions. The other ingredients were bromelain, paprika, potassium and vitamin B_6.[1]

The most likely explanation for what happened is that the **herbal diuretic** caused the lithium toxicity. It is impossible to know which herb or combination of herbs actually caused the toxicity, or how, but this case once again emphasises that herbal remedies are not risk-free just because they are natural. It also underscores the need for patients to avoid self-medication without first seeking informed advice and supervision if they are taking potentially hazardous drugs like lithium.

(b) St John's wort (Hypericum perforatum)

A search of Health Canada's database of spontaneous adverse reactions identified one case in which St John's wort was suspected of inducing mania in a patient also taking lithium.[2] The reasons for this effect are unknown, although it seems likely that the symptoms could be due to the effects of both lithium and St John's wort on serotonin. No further details were given of this case.

Lithium + Iodides

The hypothyroid and goitrogenic effects of lithium carbonate and iodides may be additive if they are given concurrently.

Clinical evidence

A man with normal thyroid function showed evidence of hypothyroidism after 3 weeks of treatment with lithium carbonate 750 mg to 1.5 g daily. After two further weeks, during which he was also given **potassium iodide**, the hypothyroidism became even more marked, but resolved completely within 2 weeks of the withdrawal of both drugs. This patient was studied before the potential risk of hypothyroidism with iodine was well recognised.[1] Another report also describes a case of hypothyroidism associated with the use of lithium carbonate and **potassium iodide**.[2]

In a study of the possible effects of iodide intake on thyroid function in 10 patients receiving lithium, 3 to 5 weeks of **potassium iodide** caused hypothyroidism in 2 patients and hyperthyroidism in one. Little effect on thyroid function was seen in 5 control patients given **potassium iodide** without lithium.[3] A case of hypothyroidism involving lithium and a product containing **isopropamide iodide** with haloperidol (*Vesalium*) has also been reported.[4,5]

Mechanism

Lithium accumulates in the thyroid gland and blocks the release of the thyroid hormones by thyroid-stimulating hormone, and can therefore cause clinical hypothyroidism.[1,6-13] The prevalence of hypothyroidism may be higher in women, in middle age,[13] and in countries with a higher level of nutritional iodine.[14] Potassium iodide temporarily prevents the production of thyroid hormones but, as time goes on, synthesis recommences. Thus, both lithium and iodide ions can depress the production or release of the hormones and therefore have additive hypothyroid effects.

Importance and management

The pharmacological interaction of altered thyroid function with lithium and iodides would appear to be established. However, the clinical use of iodides is now very limited (mostly to the pre-operative treatment of thyrotoxicosis). It is therefore unlikely that iodides will be used in patients taking lithium. However, note that patients taking lithium are advised against the regular use of some preparations of povidone iodine, such as sprays that may be used as disinfectants for minor wounds.[15] Where countries are adopting iodization programmes to prevent iodine deficiency, there may be an increased risk of clinical hypothyroidism in patients taking lithium.[14] Lithium-induced hypothyroidism can be treated with levothyroxine replacement.

Lithium + Ispaghula (Psyllium)

In an isolated case, the withdrawal of ispaghula husk resulted in an increase in lithium levels. Psyllium slightly reduced the absorption of lithium in a study in healthy subjects.

Clinical evidence

A 47-year-old woman who had recently started taking lithium was found to have a blood lithium level of 0.4 mmol/L five days after an increment in her lithium dose and whilst also taking one teaspoonful of ispaghula husk twice daily. The ispaghula husk was stopped 3 days later and lithium levels measured 4 days later were found to be 0.76 mmol/L.[1] A study in 6 healthy subjects similarly found that the absorption of lithium (as measured by the urinary excretion) was reduced by about 14% by psyllium.[2]

Mechanism

Not understood. One idea is that the absorption of the lithium from the gut is reduced by psyllium and ispaghula.[1,2]

Importance and management

Information is very limited and the general importance of this interaction is uncertain, but it would seem prudent to bear this interaction in mind in patients taking lithium who are given ispaghula or psyllium preparations. If an interaction is suspected consider monitoring lithium levels and separating the administration of the two drugs by at least an hour, or use an alternative laxative.

Lithium + Lamotrigine

Lamotrigine does not appear to cause a clinically significant alteration in lithium levels. Delirium has been reported in one patient taking both drugs.

Clinical evidence, mechanism, importance and management

In a randomised, two-period, crossover study, 20 healthy men were given 2 g of anhydrous lithium gluconate (9.8 mmol of lithium) every 12 hours for 11 doses, either with or without lamotrigine 100 mg daily. It was found that the serum lithium levels were decreased by about 8% by lamotrigine, but these small changes were not considered to be clinically relevant.[1]

A 2002 review of the few published reports on the use of lithium with lamotrigine suggested that concurrent use appears to be well tolerated.[2] However, one woman taking lithium who had been taking lamotrigine 50 mg for 4 weeks, experienced delirium when the dose of lamotrigine was increased to 150 mg daily. The symptoms disappeared when the lamotrigine dose was reduced to 100 mg daily.[3] It is not clear whether these effects were directly caused by the concurrent use of lithium and lamotrigine. However; the author of the review considered that if cognitive adverse effects occur, it might be worth considering a reduction in the dose of either or both drugs.[2]

Lithium + Mazindol

An isolated report describes a case of lithium toxicity, which was attributed to the concurrent use of mazindol.

Clinical evidence, mechanism, importance and management

A bipolar depressive woman, stabilised on lithium carbonate, had signs of lithium toxicity (sluggishness, ataxia) within 3 days of starting to take mazindol 2 mg daily. After 9 days she developed twitching, limb rigidity and muscle fasciculation, and was both dehydrated and stuporose. Her serum lithium levels were found to have risen from a range of 0.4 to 1.3 mmol/L up to 3.2 mmol/L. The mazindol was stopped, and she recovered over the next 48 hours whilst being rehydrated.[1] It is not known whether this was a direct interaction between the two drugs, but the authors suggest that the anorectic effect of mazindol led to this toxicity [i.e. the reduced intake of sodium and water caused a reduction in the renal excretion of lithium]. There seem to be no other reports of interactions between lithium and other anorectic drugs confirming this possibility.

This is an isolated case and its general importance is uncertain, but bear it in mind in the case of an unexpected response to treatment. Note that stimulants such as mazindol are no longer generally recommended as appetite suppressants.[2]

2. Sweetman SC, ed. Martindale: The complete drug reference. 36th ed. London: Pharmaceutical Press; 2009. p. 2149.

Lithium + Methyldopa

Symptoms of lithium toxicity, not always associated with raised lithium levels, have been described in four patients and four healthy subjects when they were also given methyldopa.

Clinical evidence

A woman with manic depression, taking lithium carbonate 900 mg daily was hospitalised for signs of manic decompensation and her lithium dose was increased to 1.8 g daily. When she was also given methyldopa 1 g daily for hypertension, she developed signs of lithium toxicity (blurred vision, hand tremors, mild diarrhoea, confusion, and slurred speech), even though her serum lithium levels were within the range of 0.5 to 0.7 mmol/L. The methyldopa was then stopped and the lithium carbonate dose reduced to 1.5 g daily. Ten days later the lithium level was 1.4 mmol/L, and the lithium dose was decreased to 900 mg daily.[1] Later the author of this report demonstrated this interaction on himself.[2] He took lithium carbonate 150 mg four times daily for a week (lithium level 0.5 mmol/L), and then added methyldopa 250 mg every 8 hours. Within 2 days, signs of lithium toxicity had clearly developed, and the following day his lithium level had increased to 0.8 mmol/L. He then stopped the methyldopa, and about 36 hours later his lithium level was 0.7 mmol/L.

There are three other cases of patients who took methyldopa with lithium, and developed symptoms of lithium toxicity. In one of these cases the patient had lithium levels within the normal therapeutic range,[3] but in the other two the lithium levels increased to 1.5 mmol/L and 1.87 mmol/L.[4,5] A small study in 3 healthy subjects also found that the concurrent use of lithium and methyldopa resulted in increased confusion, sedation and dysphoria.[6]

Mechanism

Not understood. Both a central effect and an effect on renal excretion have been proposed.[3-5]

Importance and management

Information appears to be limited to the reports cited, but the interaction would seem to be established. If both drugs are given then the effects should be closely monitored. Serum lithium measurements may be unreliable because symptoms of toxicity can occur even though the levels remain within the normally accepted therapeutic range.

Lithium + Mirtazapine

No pharmacokinetic or pharmacodynamic interactions appeared to occur between lithium and mirtazapine in one study in healthy subjects.

Clinical evidence, mechanism, importance and management

In a randomised, double-blind, crossover study, 12 healthy subjects were given lithium carbonate 600 mg daily or placebo for 10 days, with a single 30-mg dose of mirtazapine on day 10. The pharmacokinetics of both mirtazapine and lithium were unaltered by concurrent use. In addition, no pharmacodynamic changes, as studied by psychometric testing, were identified.[1] The UK manufacturer of mirtazapine warns of the potential for serotonin syndrome in patients also taking lithium.[2] There do not appear to be any reports of this reaction with lithium and mirtazapine, but consider also 'Lithium + SSRIs', p.1365, and 'Lithium + Venlafaxine', p.1368.

2. Zispin (Mirtazapine). Organon Laboratories Ltd. UK Summary of product characteristics, February 2009.

Lithium + Nefazodone

No pharmacokinetic interaction appears to occur between lithium and nefazodone.

Clinical evidence, mechanism, importance and management

In a study in 12 healthy subjects, nefazodone 200 mg twice daily was given alone for 5 days. After a washout period, lithium was given for 11 days, in escalating doses from 250 mg twice daily to 500 mg twice daily. When therapeutic steady-state lithium levels were achieved nefazodone 200 mg twice daily was added for 5 days. The pharmacokinetics of both nefazodone and lithium were unaltered by concurrent use, although there were some small changes in the pharmacokinetics of the nefazodone metabolites. However, as concurrent use was well tolerated, no dose adjustments were considered necessary on concurrent use.[1]

Lithium + NSAIDs

NSAIDs may increase lithium levels leading to toxicity, but there is great variability between different NSAIDs and also between individuals taking the same NSAID. For example, studies have found that celecoxib causes a modest 17% increase in lithium levels, yet case reports describe increases of up to 344%. Similar effects occur with other NSAIDs, and it seems likely that all NSAIDs will interact similarly. However, note that sulindac seems unique in that it is the only NSAID that has also been reported to cause a decrease in lithium levels.

Clinical evidence

A retrospective analysis of 10 615 elderly patients receiving lithium found that 413 (3.9%) were admitted to hospital at least once for lithium toxicity during a 10-year study period. The prescriptions for any NSAID were compared between these 413 hospitalised patients and 1 651 control patients. For any use of an NSAID (63 cases and 187 controls) there was no increased relative risk of hospitalisation for lithium toxicity (relative risk 1.1). Similarly, when patients who were newly started on an NSAID were analysed (4 cases and 17 controls), there was still no increased risk (relative risk 0.6). The authors considered that these findings suggest that the use of NSAIDs and lithium may not be as hazardous as previously thought, although they do suggest that another explanation could be that clinicians were aware of the potential interaction and so adjusted doses or observed patients more closely in the outpatient setting, thereby avoiding any hospitalisations for toxicity.[1]

Case reports and studies about individual, named NSAIDs are outlined in the following subsections, and 'Table 31.1', (p.1361) summarises the effects of NSAIDs on lithium concentrations.

(a) Celecoxib

A 58-year-old woman, with a stable serum lithium level of between 0.5 and 0.9 mmol/L, developed renal impairment associated with severe lithium toxicity, within 5 days of starting to take celecoxib 400 mg twice daily. Her lithium level was 4 mmol/L. Of note, and a possible contributory factor, was the presence of ibuprofen, which she had taken with her lithium for several years without incident.[2]

In addition to 3 of the cases in 'Table 31.1', (p.1361), in January 2003, a review of the Adverse Event Reporting System database of the FDA in the US found 2 cases of increased lithium levels and symptoms of lithium toxicity in patients who also took celecoxib.[3]

(b) Flurbiprofen

A woman who was taking lithium carbonate 600 mg twice daily, with serum levels of 0.5 to 0.9 mmol/L, started to take flurbiprofen 200 mg daily. Within 4 days she became sleepy, hypotensive, and experienced nausea and vomiting, and tremor. Her serum lithium level had risen to 1.3 mmol/L. Seven days after stopping all treatment her lithium level had fallen to 0.5 mmol/L.[4]

(c) Ibuprofen

Three patients stabilised on lithium, with plasma levels of 0.7 to 0.9 mmol/L, were given ibuprofen 1.2 or 2.4 g daily for 7 days. The serum lithium levels of one patient rose from 0.8 to 1 mmol/L and he experienced nausea and drowsiness. The two other patients, including the one taking the 1.2-g ibuprofen dose, did not show this interaction.[5]

Three other case reports describe patients with symptoms of lithium toxicity that occurred within one to 7 days of them starting to take ibuprofen 1.2 g daily.[6-8] In another case, episodes of unsteadiness and tremor associated with raised lithium levels were attributed to varying use of prescribed ibuprofen 400 mg three times daily.[9]

(d) Indometacin

A case report describes lithium toxicity in a man given indometacin 50 mg every 6 hours. Three days after he started the indometacin his serum creatinine was raised, and 9 days later he had symptoms of lithium toxicity and was found to have a lithium level of 3.5 mmol/L. It was suggested that the indometacin caused renal impairment, which led to lithium retention and toxicity.[10] A study in 7 healthy subjects given a 200-mmol and 40-mmol sodium diet found that indometacin 50 mg three times daily for 4 doses increased mean plasma concentrations of a single 400-mg dose of lithium carbonate by 20% and 26%, respectively. Indometacin reduced lithium clearance by 16% and 28%, and fractional renal lithium reabsorption increased from 71% to 75% and from 75% to 81% during the high- and low-sodium diets, respectively.[11]

(e) Ketorolac

An 80-year-old man taking haloperidol, procyclidine, clonazepam, aspirin, digoxin and lithium (serum lithium levels between 0.5 and 0.7 mmol/L) was additionally given indometacin 100 mg daily for arthritis, which was replaced, after 13 days, by ketorolac 30 mg daily. The next day his serum lithium level was 0.9 mmol/L and 6 days later 1.1 mmol/L. Subsequently the patient developed severe nausea and vomiting, and both drugs were stopped.[12]

(f) Mefenamic acid

Acute lithium toxicity, accompanied by a sharp deterioration in renal function, was seen in a patient taking lithium carbonate with mefenamic acid 500 mg three times daily for 2 weeks. Withdrawal of the drugs and subsequent rechallenge confirmed this interaction.[13] Another case of toxicity was seen in a patient taking lithium who was given mefenamic acid. Her renal function was impaired when the lithium was started, but it had been stable for about 6 months before the NSAID was added.[14] A brief report also mentions another case of this interaction.[15]

(g) Niflumic acid

An isolated report describes lithium toxicity in a woman who took niflumic acid (said to be three capsules daily) for 7 days with the addition of

Table 31.1 Summary of the effects of NSAIDs on lithium levels

NSAID	*Dose*	*Subjects*	*Increase in lithium levels*	*Time to symptoms or increase in levels*	*Refs*
Celecoxib	200 to 800 mg daily	4 cases	56 to 248%	10 days to 10 weeks	1, 2
	200 mg twice daily	Study in healthy subjects	17%		3, 4
Diclofenac	75 mg daily	Case	86%	25 days	5
	50 mg three times daily	Study in 5 healthy subjects	26%	7 to 10 days	6
Flurbiprofen	200 mg twice daily	Case	44 to 160%	4 days	7
	100 mg twice daily	Placebo-controlled study in 11 otherwise healthy subjects with bipolar disorder	19%	7 days	8
Ibuprofen	1.6 to 1.8 g daily in divided doses	Studies in 11 healthy subjects and 9 subjects with bipolar disorder	12 to 67%	6 to 9 days	9, 10
Indometacin	150 mg daily	Studies in 9 healthy subjects and 6 subjects with bipolar disorder	30 to 61%	6 to 10 days	11-13
Ketoprofen	400 mg daily	Case	About 90%	3 weeks	14
Ketorolac	60 mg daily	Case	50%	3 weeks	15
	40 mg daily	Study in 5 healthy subjects	29%	5 days	16
Lornoxicam	4 mg twice daily	Study in 12 healthy subjects	20% (61% in one subject)	7 days	17
Meloxicam	15 mg daily	Study in 16 healthy subjects	21%	14 days	18
Naproxen	220 or 250 mg three times daily	Study in 9 healthy subjects and 7 bipolar or schizoaffective disorder	0 to 42%	5 to 6 days	19, 20
Phenylbutazone	750 mg daily (suppositories)	Case	106%	36 hours	21
	100 mg three times daily	Study in 5 subjects with bipolar disorder	0 to 15%	6 days	22
Piroxicam	20 mg daily	2 cases	130 to 235%	1 to 2 months	23, 24
Rofecoxib	Not stated or 25 mg once or twice daily	7 cases	58 to 448%	6 days to about 3 months	2, 25
	50 mg [daily]	Study in 10 healthy subjects	Unstated rise in 9 subjects, of these 3 were withdrawn early with levels of 1.26 mmol/L or more	Up to 5 days	26

aspirin 1.5 g daily after 5 days. Her serum lithium levels rose from 0.8 mmol/L to 1.6 mmol/L.[16]

(h) Nimesulide

A 42-year-old woman taking lithium was given nimesulide 100 mg and ciprofloxacin 250 mg, both twice daily, for flank pain and dysuria. After 72 hours, she developed symptoms of lithium toxicity and the dose of lithium was reduced. After 98 hours she had vomiting, ataxia, and oliguria, and lithium levels were found to be 3.23 mmol/L (previous level 1.08 mmol/L) and her serum creatinine was raised.[17]

(i) Oxyphenbutazone

In an apparently isolated case, a 49-year-old woman is reported to have developed nausea and vomiting associated with a rise in lithium levels following the addition of oxyphenbutazone suppositories 500 mg daily. She responded well to a reduction in the lithium dose.[18]

(j) Parecoxib

The manufacturer of parecoxib says that valdecoxib, the main active metabolite of parecoxib, has been shown to cause decreases in the clearance of lithium (serum clearance reduced by 25%, renal clearance reduced by 30%), resulting in a 34% increase in exposure.[19]

(k) Piroxicam

A 56-year-old woman, taking lithium for over 9 years, with levels usually between 0.8 and 1 mmol/L, experienced lithium toxicity (unsteadiness, trembling, confusion) and was admitted to hospital on three occasions after taking piroxicam. Her serum levels on two occasions had risen to 2.7 mmol/L and 1.6 mmol/L, although in the latter instance the lithium had been withdrawn the day before the levels were taken. In a subsequent study her serum lithium levels rose from 1 mmol/L to 1.5 mmol/L after she took piroxicam 20 mg daily.[20] Two other case reports describe lithium toxicity, which occurred 4 weeks and 4 months after piroxicam was started.[21,22]

(l) Rofecoxib

A 73-year-old man, with lithium levels of between 0.6 and 0.9 mmol/L for the past 13 years, developed symptoms of lithium toxicity (serum lithium level 1.5 mmol/L) within 9 days of starting to take rofecoxib 12.5 mg daily. An interaction was strongly suspected. However, it should be noted that the patient had required his lithium dose to be successively decreased over the 13 years to maintain his lithium levels within the desired range. Captopril 6.25 mg daily had also been started during this time,[23] although it is unclear whether it had a part to play either in the lithium dose reduction or the development of an interaction. In addition to 6 of the cases in 'Table 31.1', (p.1361), in January 2003, a review of the Adverse Event Reporting System database of the FDA in the US found 7 cases of increased serum lithium concentrations after the addition of rofecoxib.[3]

(m) Sulindac

1. Lithium levels reduced. A patient stabilised on lithium had a marked fall in serum lithium levels from 0.65 mmol/L to 0.39 mmol/L after 2 weeks of the concurrent use of sulindac 100 mg twice daily. Her serum lithium levels gradually climbed over the next 6 weeks to 0.71 mmol/L and restabilised without any change in the dose of either lithium or sulindac. She needed amitriptyline for depression while the lithium levels were low, but bouts of depression had not been uncommon, even when lithium levels were stable.[24] The serum lithium levels of another patient were approximately halved a week after his dose of sulindac was doubled to 200 mg twice daily. He continued taking both drugs, but a higher dose of lithium was needed.[24]

2. Lithium levels unaffected. Two small studies (in a total of 10 patients)[25,26] and a case report[27] found that serum lithium levels were unaffected by the use of sulindac.

3. Lithium levels increased. Two patients developed increased serum lithium levels, apparently due to the use of sulindac.[28] In one case the lithium levels rose from 1 mmol/L to 2 mmol/L after 19 days of treatment with sulindac 150 mg twice daily, and symptoms of toxicity were seen. The levels fell to 0.8 mmol/L within 5 days of stopping the sulindac. The other patient had a rise from 0.9 mmol/L to 1.7 mmol/L within a week of adding sulindac 150 mg twice daily. The sulindac was continued and the lithium dose was reduced from 1.8 g daily to 1.5 g daily. The serum lithium levels fell and were 1.2 mmol/L at 37 days and 1 mmol/L at 70 days. No symptoms of lithium toxicity occurred.[28]

(n) Tiaprofenic acid

A 79-year-old woman taking lithium (as well as fosinopril, nifedipine, oxazepam and haloperidol) had a rise in her trough serum lithium levels from 0.36 mmol/L to 0.57 mmol/L within 3 days of starting to take tiaprofenic acid 200 mg three times daily. The serum lithium levels had risen to 0.65 mmol/L by the next day and, despite halving the lithium dose, were found to be 0.69 mmol/L five days later. These rises were attributed to an interaction with the tiaprofenic acid exacerbated by the fosinopril,[29] see 'Lithium + ACE inhibitors', p.1348.

Mechanism

Not understood. It has been suggested that the interacting NSAIDs inhibit the synthesis of the renal prostaglandins (PGE_2) so that the renal blood flow is reduced, thereby reducing the renal excretion of the lithium. In addition, reduced renal PGE_2 levels may be associated with increased reabsorption of sodium and lithium. However, this fails to explain why aspirin, which blocks renal prostaglandin synthesis by 65 to 70%, does not usually affect serum lithium levels, see 'Lithium + Aspirin or other Salicylates', p.1352.

Importance and management

The interaction between NSAIDs and lithium is well established, although the incidence is unknown. The increase in serum lithium levels appears to vary between the different NSAIDs and also between individuals taking the same NSAID (see 'Table 31.1', (p.1361)). Factors such as advanced age, impaired renal function, decreased sodium intake, volume depletion, renal artery stenosis, and heart failure increase the risk.

The documentation of these interactions is variable and limited, and although only some NSAIDs have been shown to interact, it seems likely that they will all interact to a greater or lesser extent. What is known indicates that most NSAIDs should be avoided, especially if other risk factors are present, unless serum lithium levels can be very well monitored (initially every few days) and the dose reduced appropriately. The effects of sulindac appear to be unpredictable (serum levels raised, lowered or unchanged) so that good monitoring is still necessary.

Patients taking lithium should be aware of the symptoms of lithium toxicity (see 'Lithium', (p.1347)) and told to report them immediately should they occur. This should be reinforced when they are given an NSAID. The situation with regards to single doses of NSAIDs is less clear. As many cases have demonstrated a rise in lithium levels within a matter of days, those buying non-prescription NSAIDs should be advised to only intermittently self-medicate with NSAIDs (i.e. very short-term use), or preferably to use a non-interacting alternative, such as paracetamol, see 'Lithium + Paracetamol (Acetaminophen)', p.1363. The same advice regarding an awareness of lithium toxicity should be reinforced. If any of the pre-disposing conditions that increase the risk of toxicity are present it may be safer to avoid concurrent use unless monitoring can be undertaken.

Lithium + Olanzapine

Several case reports suggest that some patients taking olanzapine and lithium may develop adverse reactions (neuroleptic malignant syndrome or serotonin syndrome, encephalopathy, priapism) without raised serum lithium levels. One study found no pharmacokinetic interaction between the drugs, but another analysis suggested that lithium may reduce olanzapine plasma levels.

Clinical evidence, mechanism, importance and management

A 16-year-old boy taking lithium 1.2 g daily, with a therapeutic serum lithium level, developed neuroleptic malignant syndrome (generalised rigidity, urinary retention, fever, tachycardia) about 2 weeks after his olanzapine dose was increased from 10 to 20 mg daily. Both drugs were stopped, and the symptoms resolved over 8 days. He had previously taken olanzapine and lithium separately without problem.[1]

A 59-year-old man who had been diagnosed with encephalopathy and confusion while taking a combination of carbamazepine, haloperidol and lithium (at a level within the therapeutic range), developed similar symptoms when he was later given lithium with olanzapine.[2] Another elderly patient who had taken lithium for 7 years, developed severe delirium and extrapyramidal symptoms after the addition of olanzapine. Serum lithium levels were found to be 3 mmol/L.[3] The serotonin syndrome developed in a woman with bipolar affective disorder taking lithium and citalopram after olanzapine was also given. She became increasingly irritable 3 months after starting the combination and one month later (4 days after increasing the dose of olanzapine from 15 to 20 mg and stopping the citalopram) she became severely agitated, confused and was sweating profusely with hyperreflexia, tremor and a low-grade fever. The symptoms resolved on cessation of her medication.[4] Citalopram may have contributed to this reaction, as the serotonin syndrome has been reported with the concurrent use of 'lithium and SSRIs', (p.1365).

A case of non-ketotic hyperosmolar syndrome has been reported in a non-diabetic patient taking olanzapine, lithium and valproic acid. Symptoms began only 5 days after the olanzapine was started.[5] Priapism, which was reversed by surgical detumescence, occurred when a 30-year-old man took olanzapine with lithium.[6]

In an open-label study, 12 healthy subjects took a single 32.4-mmol dose of lithium with olanzapine 10 mg, and after a washout period, olanzapine 10 mg daily for 8 days, with a single 32.4-mmol dose of lithium on the last day. No pharmacokinetic interactions were detected.[7] However, an analysis of olanzapine levels in schizophrenic patients found that the concurrent use of lithium was associated with lower olanzapine plasma levels.[8]

The case reports detailed above suggest that some patients taking olanzapine and lithium may develop a pharmacodynamic interaction. Concurrent use of lithium and olanzapine need not be avoided but be aware that there is some risk of developing adverse reactions to the combination. The presence of other serotonergic drugs (e.g. antidepressants such as SSRIs) or dopamine antagonists (e.g. antipsychotics such as haloperidol) is likely to increase the risk of an interaction.

Lithium + Paracetamol (Acetaminophen)

Paracetamol appears not to alter lithium levels.

Clinical evidence, mechanism, importance and management

A study in 9 healthy subjects given lithium carbonate 300 mg every 12 hours to achieve steady state, followed by the addition of 650 mg of paracetamol every 6 hours for 5 days, found no evidence that paracetamol increased serum lithium levels. Six subjects had no change in lithium levels, one subject had a 0.1 mmol/L decrease, and two had a 0.1 mmol/L increase.[1] One patient whose serum lithium level doubled while taking rofecoxib was later given paracetamol without any problems.[2] No precautions seem necessary on concurrent use.

Lithium + Phenytoin

Symptoms of lithium toxicity (sometimes with unchanged lithium levels) have been seen in a few patients taking lithium and phenytoin, although the interaction has not been clearly demonstrated.

Clinical evidence, mechanism, importance and management

A patient with a history of depression and convulsions was given increasing doses of lithium carbonate and phenytoin over a period of about 4 years. Although the serum levels of both drugs remained within the therapeutic range, he eventually began to develop symptoms of lithium toxicity (thirst, polyuria, polydipsia and tremor) that disappeared when the lithium was stopped. Later, when lithium was restarted, the symptoms returned, this time abating when the phenytoin was replaced by carbamazepine. The patient then claimed that he felt normal for the first time in years.[1] Another report describes symptoms of lithium toxicity in a patient with lithium levels within the therapeutic range. This patient was also taking phenytoin.[2]

In a further case[3] a man taking phenytoin became ataxic within 3 days of starting to take lithium. He had no other toxic symptoms and his serum lithium level was 2 mmol/L. However, as he only ever took lithium in the presence of phenytoin, it is not possible to say whether the effects were as a result of an interaction, or whether toxic levels would have occurred with the lithium alone. Another similar case has also been reported.[4]

Information seems to be limited to these reports and none of them presents a clear picture of the role of phenytoin in the reactions

described.[1-4] The interaction is not well established. Patients taking lithium should be aware of the symptoms of lithium toxicity and told to report them immediately should they occur. This should be reinforced when they are given phenytoin. Increased serum lithium monitoring does not appear to be of value in this situation as the interaction occurred in patients with lithium levels within the normally accepted range.

Lithium + Propranolol

One study suggests that propranolol may decrease the clearance of lithium. An isolated report describes a patient taking lithium who developed marked bradycardia after he took propranolol 30 mg daily.

Clinical evidence, mechanism, importance and management

A study in lithium-treated patients with manic depression found that the clearance of lithium was about 20% lower in 23 patients also taking propranolol than in 292 similar patients taking lithium alone.[1] However, the clinical effects of this difference were not evaluated, so the significance of this finding is unclear. A 70-year-old man who had been stable on lithium for 16 years was started on propranolol 30 mg daily for lithium-induced tremor. Six weeks later he was hospitalised because of vomiting, dizziness, headache and a fainting episode. His pulse rate was 35 to 40 bpm and his serum lithium level was 0.3 mmol/L. When later discharged taking lithium without propranolol his pulse rate had risen to a range of 64 to 80 bpm.[2]

The authors of the case report attribute the bradycardia to an interaction with lithium, as the low dose of propranolol was considered unlikely to cause bradycardia alone. They also point out that both drugs affect the movement of calcium across cell membranes, which could account for the decreased contraction rate of the heart muscle, and thus bradycardia in this patient. They suggest careful monitoring in elderly patients with atherosclerotic cardiovascular problems.[2]

The general importance of this interaction, if it is such, is uncertain, but it seems possible with all beta blockers because they can all cause bradycardia. However, as beta blockers are used to treat lithium-induced tremor, any serious problem would be expected to have come to light by now.

Lithium + Quetiapine

Quetiapine does not appear to affect serum lithium levels in one study, and concurrent use did not increase the incidence of extrapyramidal symptoms in another study. An isolated report describes the development of delirium in a patient given quetiapine and lithium.

Clinical evidence, mechanism, importance and management

A patient with a long history of schizoaffective disorder stopped his medication and 2 months later developed psychosis, mood instability and psychomotor agitation. He was given an initial dose of quetiapine 50 mg daily which was increased over 7 days to 700 mg daily. He became sedated but as he was still experiencing mood fluctuations he was also given lithium carbonate 900 mg daily. Two days later he became confused, disorientated with cloudy consciousness and had short-term memory disturbances, visual hallucinations and agitation. The lithium serum level was 0.6 mmol/L. Quetiapine and lithium were stopped. He was treated with diazepam and the delirium gradually resolved. It was noted that lithium may induce delirium when given in combination with other drugs and that it may occur when lithium levels are within the therapeutic range.[1]

The steady-state serum lithium levels of 10 patients with schizophrenia, schizoaffective or bipolar disorder were studied before, during, and after the concurrent use of quetiapine 250 mg three times daily. Quetiapine increased the AUC and maximum serum levels of lithium by 12% and 4.5%, respectively, but this was not statistically significant. Concurrent use was well tolerated.[2]

A randomised, placebo-controlled study found that the incidence of extrapyramidal symptoms in patients receiving quetiapine with lithium was similar to that in patients receiving placebo with lithium.[3]

Although the studies suggest no special precautions would appear to be necessary on concurrent use, the isolated case report of delirium should be borne in mind if this combination is used.

Lithium + Risperidone

There appears to be no pharmacokinetic interaction between risperidone and lithium, although a number of case reports describe adverse effects (e.g. extrapyramidal symptoms) when both drugs are given.

Clinical evidence, mechanism, importance and management

In a study 13 patients were given lithium and a conventional antipsychotic for at least 5 days on days 1 and 2 of the study. On study day 3, the patients were given lithium and risperidone 1 mg twice daily. The risperidone dose was increased to 2 mg twice daily on day 4 and then to 3 mg twice daily on days 5 to 9. The steady-state pharmacokinetics of lithium were not affected by the switch to risperidone and the plasma levels of risperidone and 9-hydroxyrisperidone were comparable to historical levels in subjects taking risperidone alone.[1]

A case report describes a 42-year-old woman taking lithium 800 mg daily who developed extrapyramidal adverse effects of the mouth after risperidone was started. Three days after her risperidone dose had reached 5 mg daily, she experienced an abrupt onset of abnormal peri-oral movements. Her serum lithium level was 0.7 mmol/L. Symptoms resolved after intravenous promethazine was given.[2] Another case report describes a non-diabetic patient, who developed diabetic ketoacidosis 2 years after starting treatment with risperidone and lithium. During this acute illness he also experienced neuroleptic malignant syndrome and a myocardial infarction. The authors considered the combination of these two drugs was a causative factor, as the patient was able to continue taking lithium alone with no recurrence of this condition, or the need for antidiabetic medication.[3] In a further case, a man taking lithium developed somnolence, confusion, delirium, fever and a rise in creatinine phosphokinase levels when risperidone was given.[4]

The study suggests that dose adjustments are unlikely to be necessary in patients given lithium and risperidone. The case reports serve as a reminder to be alert for adverse effects if both drugs are given.

Lithium + Sodium compounds

The ingestion of marked amounts of sodium can prevent the establishment or maintenance of adequate lithium levels. Conversely, dietary salt restriction can cause lithium levels to rise to toxic concentrations if the lithium dose is not reduced appropriately.

Clinical evidence

(a) Lithium response reduced by the ingestion of sodium

A 35-year-old man who started to take lithium carbonate 250 mg four times a day, had a serum lithium level of 0.5 mmol/L by the following

morning. When the dose frequency was progressively increased to five, and later six times daily, his serum lithium levels did not exceed 0.6 mmol/L because, unknown to his doctor, he was also taking **sodium bicarbonate**. The patient's wife said he had been taking "**Soda Bic**" for years but since he started taking lithium he had been "shovelling it in". When the **sodium bicarbonate** was stopped, relatively stable serum lithium levels of 0.8 mmol/L were achieved with the initial dose of lithium carbonate.[1]

An investigation to find out why a number of inpatients were unable either to reach or maintain adequate therapeutic serum lithium levels over a period of 2 months, revealed that a clinic nurse had been giving the patients *Efferdex*, a product containing about 50% **sodium bicarbonate**, because the patients complained of nausea. The reduction in the expected serum lithium levels was as much as 40% in some cases.[2]

Other studies confirm that the serum lithium levels can fall, and the effectiveness of treatment can lessen, if the intake of sodium is increased.[3-6]

(b) Lithium response increased by sodium restriction

The serum lithium levels of 4 patients rose more rapidly and achieved a higher peak when salt was restricted to less than 10 mmol of sodium per day compared with the situation when the patients took a **dietary salt supplement**.[7]

Mechanism

The situation is complex and not fully established, but the mechanism can be broadly described in simplistic terms. Sodium balance is controlled by the kidney; if the serum sodium is low the kidney can reabsorb more sodium to maintain the balance. The kidney excretes and reabsorbs both lithium and sodium, but it does not appear to clearly distinguish between lithium and sodium ions. Therefore, if a patient taking lithium restricts sodium intake, the kidney may reabsorb both sodium and lithium, causing a rise in serum lithium levels. A corresponding decrease in lithium levels can occur when sodium intake is supplemented.[8,9]

Importance and management

Well established and clinically important interactions. The establishment and maintenance of therapeutic serum lithium levels can be jeopardised if the intake of sodium is altered. Warn patients not to take non-prescription antacids or urinary alkalinisers without first seeking informed advice. Sodium bicarbonate comes in various guises and disguises e.g. *Alka-Seltzer* (55.8%), *Andrews Salts* (22.6%), *Eno* (46.4%), *Jaap's Health Salts* (21.3%), *Peptac* (28.8%). Substantial amounts of sodium also occur in some **urinary alkalinising agents** (e.g. *Citralka*, *Citravescent*).[10] There are many similar preparations available throughout the world. An antacid containing **aluminium**/**magnesium hydroxide** with simeticone has been found to have no effect on the bioavailability of lithium carbonate,[11] so that antacids of this type would appear to be safer alternatives.

Patients already stabilised on lithium should not begin to limit their intake of salt unless their serum lithium levels can be monitored and suitable dose adjustments made, because their lithium levels can rise quite rapidly.

Lithium + SSRIs

The concurrent use of lithium and SSRIs can be advantageous and uneventful, but various kinds of neurotoxicities have occurred. Isolated reports describe the development of symptoms similar to those of serotonin syndrome in patients taking lithium and fluoxetine, fluvoxamine, paroxetine and possibly citalopram. In addition, increases and decreases in serum lithium levels have been seen with fluoxetine.

Clinical evidence

(a) Citalopram

In a study in 8 healthy subjects, no pharmacokinetic changes were seen when lithium 30 mmol/day (as lithium sulfate 1.98 g daily) was added to citalopram 40 mg daily.[1] Another study, in 24 patients who had previously not responded to citalopram alone, found that the concurrent use of citalopram 40 or 60 mg and lithium carbonate 800 mg daily was effective and did not increase adverse effects.[2] For a report describing serotonin syndrome in a patient with bipolar affective disorder taking lithium, citalopram and olanzapine, see 'Lithium + Olanzapine', p.1363.

(b) Fluoxetine

A woman with bipolar affective disorder, successfully maintained for 20 years on lithium carbonate 1.2 g daily, developed stiffness of her arms and legs, dizziness, unsteadiness in walking and speech difficulties within a few days of starting fluoxetine 20 mg daily. Her serum lithium levels had risen from a range of 0.75 to 1.15 mmol/L up to 1.7 mmol/L. The lithium dose was reduced to 900 mg daily and the fluoxetine withdrawn. Within 7 days, the toxic symptoms had disappeared and the lithium levels had fallen to 0.9 mmol/L.[3] Two other patients had increases in serum lithium levels of about 45% and 70% (but no lithium toxicity) about a month after starting fluoxetine 20 mg daily or 40 mg daily, respectively. The problem resolved when the lithium dose was reduced by 40% and 30%, respectively, and in the second case, the fluoxetine was withdrawn. Both patients also developed mania, either after readjustment of the lithium dose or during concurrent use.[4]

In contrast, a study in 10 healthy subjects who took a single 32.4-mmol dose of lithium acetate alone, with a single 60-mg dose of fluoxetine, or with fluoxetine 60 mg after pretreatment with fluoxetine 20 mg three times daily for 7 days, found no significant changes in the distribution or elimination of lithium. Lithium levels were lower in the first 4 hours after it was taken with the single dose of fluoxetine than when it was taken alone or at fluoxetine steady-state, but all levels remained within the therapeutic range.[5] The US manufacturer of fluoxetine[6] says that the concurrent use of these two drugs has resulted in both increased and decreased serum lithium concentrations.

Toxicity (confusion, ataxia, coarse tremor, incoordination, movement disorders, fever) was seen in a patient when lithium was added to treatment with fluoxetine, although the serum lithium levels remained within the therapeutic range.[7] A woman taking clonazepam who started taking fluoxetine 20 mg then 40 mg daily, developed tremor and ataxia 6 days after lithium carbonate 100 mg increased to 400 mg daily was added. The problems resolved when the lithium and fluoxetine were withdrawn.[8] Extrapyramidal adverse effects and ataxia were seen in one patient taking lithium and fluoxetine, and dystonia occurred in another patient who was also taking carbamazepine, captopril and trimipramine.[9] The development of serotonin syndrome is also reported to have occurred in 2 patients taking lithium and fluoxetine.[10,11] Heat stroke developed in a man taking lithium and fluoxetine, attributed to synergistic impairment of his temperature regulatory system by the two drugs.[12] Absence seizures occurred in another patient given both drugs.[13]

(c) Fluvoxamine

A woman taking fluvoxamine became somnolent within a day of starting to take lithium. The lithium level 20 hours after the last dose was 0.2 mmol/L. She recovered when both drugs were stopped and she was discharged taking lithium alone. The excessive somnolence was considered to have been possibly caused by increased serotonin levels caused by this drug combination.[14] A woman taking long-term lithium started taking fluvoxamine 50 mg daily, increased to 200 mg daily over 10 days. She gradually developed tremor, difficulties in making fine hand movements, impaired motor co-ordination and hyperreflexia. Serum lithium levels remained therapeutic throughout. The reaction was interpreted as a mild form of serotonin syndrome.[15]

By 1989, the CSM in the UK had received 19 reports of adverse reactions when fluvoxamine was given with lithium (5 reports of convulsions and one of hyperpyrexia).[16]

In contrast to these reports, a study in 6 patients found that lithium (dosed to achieve plasma levels of 0.3 to 0.65 mmol/L) and fluvoxamine 100 to 150 mg daily (for between 3 and 23 weeks) was safe and effective, and no

adverse interaction of any kind occurred.[17] Another study in 6 depressed patients found that lithium did not affect the pharmacokinetics of fluvoxamine 100 mg daily and concurrent use was more effective than fluvoxamine alone.[18] It would seem therefore that concurrent use can be valuable, but there is a clear need to monitor the outcome so that any problems can be quickly identified.

(d) Paroxetine

A study in 14 patients taking lithium found that tremor increased significantly when paroxetine 20 to 40 mg daily was added. The greatest increments occurred approximately 3 weeks after concurrent use was started, but tremor activity was still significantly greater than baseline after 6 weeks. No patient discontinued treatment because of the increase in tremor.[19]

A 59-year-old woman with a long-standing bipolar disorder who had taken paroxetine 10 mg increased to 30 mg daily for 3 weeks, developed symptoms suggestive of serotonin syndrome (shivering, tremor of her arms and legs, flushed face, agitation, and some impairment of mental focussing) after lithium 400 mg daily was added.[20] Her serum lithium and paroxetine levels were found to be 0.63 mmol/L and 690 nanograms/mL, respectively (the latter being sixfold higher than the upper levels seen in other patients). The paroxetine dose was reduced to 10 mg daily, which decreased the paroxetine serum levels to 390 nanograms/mL, whereupon she became symptom-free and her depression was relieved. It is not clear whether this reaction was due to an interaction as she never took the higher dose of paroxetine in the absence of lithium.

There is a report of seizures, unsteady gait and blurred speech in a patient with bipolar disorder and cystic fibrosis taking lithium and paroxetine; both drugs were discontinued. However, this patient was abusing oxycodone and clonazepam and was also taking a variety of anti-asthma medications (salbutamol, salmeterol, budesonide, montelukast and cromoglicate), so the exact cause of the seizures is unclear.[21]

(e) Sertraline

In a randomised, placebo-controlled study, 16 healthy subjects were given lithium 600 mg twice daily for 9 days. On day 8, half of the subjects received two 100-mg doses of sertraline 8 hours apart, while the other half received placebo. Sertraline caused reduced steady-state lithium levels by 1.4%, and increased the renal excretion of lithium, but neither of these changes was statistically significant. However, there was a high incidence of adverse effects (mainly tremor and nausea) on concurrent use: tremor occurred in 7 out of the 8 taking sertraline, whereas no adverse effects were reported in the placebo group.[22]

Severe priapism occurred in a patient taking lithium carbonate 600 mg daily within 2 weeks of having the dose of sertraline increased from 50 to 100 mg daily. It was not clear whether this was purely a reaction to the increased sertraline dose, although it was suggested that the effect may have been due to the serotonergic effects of both drugs.[23]

Mechanism

Not fully understood although it seems likely that many of the symptoms could be due to the effects of both lithium and SSRIs on serotonin.

Importance and management

The concurrent use of lithium and an SSRI can be uneventful. A review of the safety of the concurrent use of lithium and the SSRIs identified 503 subjects who had received the combination without any evidence of serious adverse events.[24] However, occasionally and unpredictably adverse reactions develop, but the precise incidence is not known. If lithium is used in conjunction with an SSRI be alert for any evidence of toxicity. The symptoms may include tremor, dysarthria, ataxia, confusion, and many other symptoms of serotonin syndrome (see also *Serotonin syndrome*, under 'Additive or synergistic interactions', (p.9)). Heat stroke has also been seen and the serum lithium levels may rise. It would clearly be prudent to monitor concurrent use carefully.

Lithium + Theophylline

Lithium levels are moderately reduced by 20 to 30% by the concurrent use of theophylline, which may cause patients to relapse.

Clinical evidence

The serum lithium levels of 10 healthy subjects taking lithium carbonate 900 mg daily fell by 20 to 30%, and the urinary clearance increased by 30%, when they were given theophylline (*Theo-dur*). Steady-state theophylline levels of 5.4 to 12.7 micrograms/mL were achieved, and it was noted that higher theophylline levels were strongly correlated with increased lithium clearance.[1] This study has been reported in brief elsewhere.[2]

A man taking theophylline was diagnosed with a bipolar disorder and started taking lithium while in hospital for an exacerbation of COPD. When the dose of theophylline was raised, because of a worsening in his condition, his lithium dose also had to be increased to control the emergence of manic symptoms. He received a maximum theophylline dose of 1.5 g daily, during which time he needed 2.7 g of lithium daily. When the theophylline was stopped, he only needed around 1.5 g of lithium daily to control his manic symptoms.[3] Two studies support the evidence from these cases, with the finding that lithium excretion is increased by about 50% by aminophylline or theophylline.[4,5]

Mechanism

Uncertain. Theophylline has an effect on the renal clearance of lithium.

Importance and management

Information is very limited but the interaction between aminophylline or theophylline and lithium appears to be established. Depressive and manic relapses may occur if the dose of lithium is not raised appropriately when these drugs are given. Serum lithium levels should be monitored if theophylline or aminophylline is stopped, started, or if the dose is altered.

Lithium + Topiramate

Two isolated reports describe elevated lithium levels and evidence of toxicity in patients also taking topiramate. No important pharmacokinetic interaction has been seen in healthy subjects.

Clinical evidence, mechanism, importance and management

A 42-year-old woman with type II bipolar disorder started taking lithium carbonate 1.5 g and topiramate 500 mg daily, resulting in a steady-state trough serum lithium level of 0.5 mmol/L after 10 days. She was also started taking citalopram 10 mg daily. The patient raised the topiramate dose to 800 mg daily in an attempt to lose weight, and 5 weeks later began to complain of severe anorexia, nausea, fatigue and impaired concentration. She had managed to lose 35 lb (almost 16 kg) of weight she had gained whilst taking a previous drug combination. When examined she was lethargic, with tremors, nystagmus, bradycardia and memory loss. Her trough serum lithium level had risen by 180% to 1.4 mmol/L. The symptoms disappeared over 4 days when the lithium was stopped. Two months later she was stabilised once again on lithium carbonate 1.2 g and topiramate 500 mg daily, with a steady-state serum lithium level of 0.5 mmol/L.[1]

Another report describes a case of increased lithium levels and toxicity (worsening concentration, confusion, lethargy) after topiramate was given to a patient taking lithium. The lithium was stopped and then restarted at half the original dose, which produced therapeutic lithium levels of 0.67 mmol/L. In addition, while maintaining the dose of lithium at 450 mg daily, further increases in the topiramate dose from 75 to 125 mg daily over 4 weeks resulted in parallel elevations of lithium levels (from 0.67 to 0.92 mmol/L).[2]

However, a review of the pharmacokinetic interactions of topiramate reported a study that had found that there was little pharmacokinetic interaction with lithium when topiramate (50 mg twice daily titrated to 100 mg twice daily) was given to 12 healthy subjects receiving lithium carbonate 300 mg two or three times daily [dosing frequency unclear]. The AUC of lithium was about 18% lower and the clearance 22% higher. When compared with historical data, the clearance of topiramate appeared to be lower in the presence of lithium.[3]

The reasons for these reactions are not known, but topiramate is mainly eliminated by renal excretion and high doses of topiramate may competitively interfere with lithium excretion.[1] Similarly, lithium may affect topiramate clearance.[3] Some of the toxicity could have been due to the adverse effects of either drug, with the weight loss in the first case possibly disturbing the sodium excretion, which could have affected the loss of lithium in the urine.

These cases highlight the possible risk of elevated serum lithium levels especially if high doses of topiramate are used. Patients taking lithium should be aware of the symptoms of lithium toxicity and told to report them immediately should they occur. This should be reinforced when they are given topiramate. The authors of two reports suggest that lithium levels should be monitored in patients newly started on this combination and the dose of topiramate and/or lithium carefully adjusted to minimise adverse effects.[4,5]

Lithium + Tricyclic and related antidepressants

The concurrent use of a tricyclic antidepressant and lithium can be successful in some patients, but others may develop adverse effects, a few of them severe. Cases of neurotoxicity, serotonin syndrome, and neuroleptic malignant syndrome have been reported.

Clinical evidence

A study in 14 treatment-resistant depressed patients aged between 61 and 82 years found that 7 patients had complete improvement and 3 patients had partial improvement, 3 to 21 days after lithium was added to treatment with the tricyclic or related antidepressants. Lithium adverse effects occurred in 6 patients; 4 of whom stopped lithium as a result. One of them was successfully restarted at a lower dose. Tremor was the most frequent adverse effect, and reversible neurotoxicity with a stroke-like syndrome was the most severe. The antidepressants used were **amitriptyline**, **doxepin**, **maprotiline** and **trazodone**.[1]

A meta-analysis of 9 studies on the acute treatment of unipolar or bipolar depression indicated that the concurrent use of a mood stabiliser (lithium in 6 studies) and a tricyclic antidepressant was associated with an increased risk of switches into (hypo)mania, when compared with a mood stabiliser alone. It was suggested that monotherapy with a mood stabiliser should be tried to see if it is effective, before adding an antidepressant. Tricyclics were considered to be second-line antidepressants, with SSRIs the preferred choice.[2]

Reports relating to specific tricyclics are outlined below.

(a) Amitriptyline

A study in 17 lithium-maintained patients found that tremor increased significantly when amitriptyline 75 to 150 mg daily was added. The greatest increments occurred within approximately 3 weeks of starting concurrent use, but tremor activity was still significantly greater than baseline after 6 weeks. No patient discontinued treatment because of the increase in tremor.[3] Seizures occurred in a patient taking amitriptyline 300 mg daily, 13 days after lithium carbonate 300 mg three times daily was started. After recovery, concurrent use was resumed, but further seizures occurred 10 days later. Her lithium levels were 0.9 mmol/L three days before this second episode. She later took amitriptyline 500 mg daily without adverse effect.[4] Another patient developed neuroleptic malignant syndrome after one week of treatment with lithium carbonate 300 mg and amitriptyline 25 mg, both three times daily. The patient had also received chlorpromazine for one week, just before the concurrent use of lithium and amitriptyline was started.[5] No pharmacokinetic interaction was found in 10 therapy-resistant patients with major depression who were given amitriptyline and lithium for 4 weeks.[6]

(b) Amoxapine

An analysis of the spontaneous reporting system of the FDA in the US identified one case of neurotoxicity involving the use of amoxapine and lithium.[7]

(c) Clomipramine

A depressed man taking clomipramine 175 mg, levomepromazine 25 mg and flunitrazepam 2 mg daily, started taking lithium 600 mg daily. About one week later, after his dose of lithium was raised to 1 g daily he developed serotonin syndrome (myoclonus, shivering, tremors, incoordination). Due to this reaction, and because his serum lithium levels were 1.6 mmol/L, the lithium was stopped. Serotonin syndrome then abated. The clomipramine dose was reduced, but some mild symptoms remained until the clomipramine was stopped. He responded well to lithium 600 mg daily alone, without developing serotonin syndrome.[8]

(d) Doxepin

A 64-year-old man developed periods of confusion and disorientation within 2 weeks of starting to take lithium 300 mg twice daily with doxepin 100 mg at bedtime. He was admitted to hospital because of urinary retention, and he was also lethargic and became confused, but despite the withdrawal of both drugs he developed a condition similar to neuroleptic malignant syndrome (fever, muscle rigidity, changes in consciousness, autonomic dysfunction), which was successfully treated with dantrolene.[9]

(e) Nortriptyline

A 65-year-old woman developed tremor, memory difficulties, disorganised thinking and auditory hallucinations when given lithium carbonate 300 mg twice daily (lithium level 0.82 mmol/L) and nortriptyline 50 mg daily. However, because she only ever received lithium with nortriptyline, the possibility that this was an effect of lithium alone cannot be excluded.[10]

Mechanism

Not fully understood. Tremor is a relatively frequent adverse effect of both lithium and antidepressants with serotonergic properties. It might be expected that the concurrent use of lithium (which is itself serotonergic) with such antidepressants will enhance not only efficacy, but also increase the incidence of adverse effects.[3] For more information about serotonin syndrome, see 'Additive or synergistic interactions', (p.9).

Importance and management

The concurrent use of lithium and tricyclics can be valuable, but the reports cited here clearly show the need to monitor the outcome closely so that any problems can be dealt with quickly. The incidence of these serious reactions is not known.

Lithium + Triptans

In two cases patients taking lithium developed symptoms suggestive of serotonin syndrome after taking sumatriptan.

Clinical evidence, mechanism, importance and management

A comprehensive literature search published in 1998 identified several cases of adverse events reported with **sumatriptan** and lithium, although in most cases other medications were also being taken. Two patients taking **sumatriptan** and lithium concurrently were identified with symptoms suggestive of serotonin syndrome, but the symptoms were mild to moderate and self-limiting. The number of patients taking lithium and **sumatriptan** was not stated, so the incidence of this effect is unknown.[1] The conclusion was reached that **sumatriptan** can be used cautiously in patients receiving lithium.[1] There seem to be no other reports of problems with lithium and triptans. However, note that, rarely, the use of lithium or triptans with other drugs has led to serotonin syndrome. For more information about serotonin syndrome, see under 'Additive or synergistic interactions', (p.9).

Lithium + Valproate

No clinically relevant adverse interaction appears to occur between lithium carbonate and valproate.

Clinical evidence, mechanism, importance and management

In a crossover study, 16 healthy subjects were given valproate (as valproate semisodium) or a placebo twice daily for 12 days, to which lithium carbonate 300 mg three times daily was added on days 6 to 10. The valproate serum levels and AUC rose slightly, while the serum lithium levels were unaltered. Adverse events did not change significantly. It was concluded that the concurrent use of these drugs is safe.[1] A review on the efficacy of the concurrent use of lithium and an antiepileptic in bipolar disorder lists several studies in which the combination of valproate (as valproate semisodium) and lithium was used. On the whole concurrent use was considered safe and well tolerated, although a few patients discontinued treatment due to adverse effects, which included gastrointestinal symptoms and raised liver transaminases. It was, however, difficult to know if these adverse effects were due to the individual drugs or the result of an interaction. Other adverse effects that have been reported on concurrent use include tremor, cognitive impairment and alopecia.[2]

Lithium + Venlafaxine

Symptoms similar to those of serotonin syndrome have developed in a few patients taking lithium with venlafaxine. No clinically significant pharmacokinetic interaction usually appears to occur between these two drugs.

Clinical evidence

In an open study of 13 patients with major depression who did not respond to a 4-week course of venlafaxine 300 mg daily, lithium was added and continued for 4 weeks. After 12 days of concurrent use, 2 patients experienced symptoms of hypomania, marked nausea and trembling (considered to be a moderate form of serotonin syndrome), and had to stop lithium. Their lithium plasma levels were within the therapeutic range (0.83 and 0.77 mmol/L on day 7). Lithium was well tolerated by most of the other patients, with trembling being the most frequent adverse effect (4 out of 11).[1]

A case report describes a 50-year-old woman who developed serotonin syndrome 45 days after starting to take lithium and venlafaxine (and within 10 days of the most recent dose increase of venlafaxine). Both drugs were immediately stopped and she recovered over the next 4 to 5 days. Plasma levels of venlafaxine, its metabolite *O*-desmethylvenlafaxine, and lithium had remained within the normal therapeutic ranges throughout. As she had previously experienced profound adverse effects with two different SSRIs, the authors concluded that the patient was unusually sensitive to serotonergic medication.[2] Another case report describes a 71-year-old woman who developed signs of serotonin syndrome a few days after dose increases of venlafaxine from 75 mg to 150 mg daily and lithium carbonate 400 mg to 600 mg daily. She had only been taking the combination for a few days in total when serotonin syndrome developed. Her lithium levels remained within the therapeutic range, but her venlafaxine levels were 239 micrograms/L, (reference range 10 to 200 micrograms/L). She recovered within 3 days of stopping treatment with venlafaxine and lithium. Subsequently, when taking venlafaxine alone, her levels were within the reference range.[3]

In a pharmacokinetic study, 12 healthy subjects were given a single 600-mg dose of lithium carbonate on day one and day 8, with venlafaxine 50 mg every 8 hours for 7 days from day 4. The renal clearance of venlafaxine was reduced by about 50% and that of its active metabolite, *O*-desmethylvenlafaxine, was reduced by 15%. Neither of these changes was considered to be clinically relevant, as the total clearance was not affected. The maximum serum levels of the lithium were increased by about 10%, and the time to reach this was reduced by about 30 minutes, but these changes would not be expected to be clinically relevant, and the other pharmacokinetic parameters of lithium were unchanged.[4]

Mechanism, importance and management

The general picture that emerges from these reports is that normally no clinically important pharmacokinetic interaction occurs if venlafaxine and lithium are used together, but in some rare cases, serotonin syndrome may occur. The reason for the raised venlafaxine levels seen in one of the cases is unclear.[3] There seems to be no good reason for avoiding concurrent use, but be aware that an interaction is possible and monitor the outcome carefully. For more information about serotonin syndrome, see under 'Additive or synergistic interactions', (p.9).

Lithium + Ziprasidone

Ziprasidone does not appear to alter the pharmacokinetics of lithium. However, a neuroleptic malignant syndrome occurred in one patient taking both drugs.

Clinical evidence, mechanism, importance and management

A randomised, placebo-controlled study in 25 healthy subjects taking lithium carbonate 450 mg twice daily for 15 days, found that ziprasidone 20 mg twice daily on days 9 to 11, followed by 40 mg twice daily on days 12 to 15, caused only a small increase in the steady-state serum-lithium levels (14% compared with 11% in the placebo group). A 5% reduction in renal clearance was seen in the ziprasidone group and a 9% reduction was seen in the placebo group. These differences were neither statistically nor clinically significant.[1]

A case report describes a patient taking lithium 450 mg twice daily, divalproex sodium, and a number of other drugs, who started to take ziprasidone 80 mg twice daily orally with intramuscular ziprasidone 20 mg as needed. He became somnolent, was unable to walk and follow commands. His respiratory rate was increased (28 breaths/minute), his blood pressure was decreased (68/40 mmHg), and his temperature was raised (39.4°C) and had a raised white cell count. He had a high urine output and an elevated lithium level of 2.07 mmol/L and so diabetes insipidus secondary to lithium was suspected. He was also diagnosed with neuroleptic malignant syndrome.[2] The authors note that both ziprasidone and lithium (particularly in toxicity) are associated with the neuroleptic malignant syndrome. Although a reaction to ziprasidone was suspected they note that in interaction with lithium cannot be excluded.[2]

This is an isolated case and an interaction is not established. As neuroleptic malignant syndrome can occur in response to one antipsychotic drug there would seem no need to take additional precautions if both ziprasidone and lithium are taken.

32

MAOIs

The intended target of the MAOIs (monoamine oxidase inhibitors) is monoamine oxidase within the brain, but monoamine oxidase is also found in other parts of the body. Particularly high concentrations occur in the gut and liver, where it acts as a protective detoxifying enzyme against tyramine and possibly other potentially hazardous amines, which exist in foods that have undergone bacterial degradation. There are at least two forms of monoamine oxidase: MAO-A metabolises (deaminates) noradrenaline (norepinephrine) and serotonin (5-HT), while MAO-B metabolises phenylethylamine. Substances like tyramine and dopamine are metabolised by both forms of MAO.

The older MAOIs (see 'Table 32.1', below) are non-selective or non-specific, and inhibit both isoenzymes A and B. They are irreversible and long acting, because the return of monoamine oxidase activity depends upon the regeneration of new enzymes. As a result their effects (both beneficial and adverse) can last for 2 to 3 weeks after they have been withdrawn. Tranylcypromine differs in being a more reversible inhibitor of MAO, so the onset and disappearance of its actions are quicker than the other non-selective MAOIs. However, its effects still last for a number of weeks after withdrawal (e.g. see 'MAOIs or RIMAs + Tyramine-rich foods', p.1395), so it is still effectively an irreversible inhibitor, and is usually classified as such. These non-selective MAOIs cause serious and potentially life-threatening hypertensive reactions if they are given with the sympathomimetics found in some proprietary 'cough and cold remedies', (p.1388), and with 'tyramine-rich foods', (p.1395), and 'drinks', (p.1393).

Some of the newer and more recently developed drugs with MAO inhibitory activity (see 'Table 32.1', below) interact to a lesser extent than the older MAOIs. This is because they are largely selective. One group of these selective inhibitors targets MAO-A, and are relatively rapidly reversible; inhibition of this enzyme is responsible for the antidepressant effect. These selective MAO-A inhibitors (moclobemide, toloxatone) have been given the acronym RIMAs (Reversible Inhibitors of Monoamine oxidase A). They leave MAO-B largely uninhibited so that there is still a metabolic pathway available for the breakdown of amines, such as tyramine, that can cause a rise in blood pressure. In practical terms this means that the amount of tyramine needed to cause a hypertensive crisis is about tenfold greater than with the non-selective MAOIs (see 'tyramine-rich foods', (p.1395)).

The other newer selective MAOIs that specifically inhibit MAO-B are ineffective for the treatment of depression and are mainly used for Parkinson's disease, and so are covered elsewhere, see 'Antiparkinsonian and related drugs', (p.784). In low doses they inhibit MAO-B, leaving MAO-A largely uninhibited. However, selegiline loses some of its selectivity at doses of more than 10 mg daily and will therefore be subject to the same interactions as the non-selective MAOIs. Rasagiline is another irreversible selective inhibitor of MAO-B used for Parkinson's disease.

Some other drugs covered elsewhere in this publication also have MAOI activity. Furazolidone is an antiprotozoal with MAOI activity. Linezolid is an oxazolidinone antibacterial with weak, reversible non-selective MAOI activity. Interactions typical of MAOIs might therefore occur with these drugs.

The product information issued by manufacturers frequently contains warnings about real and alleged interactions with MAOIs. Blackwell,[1] who has done much work on the interactions of the MAOIs, has rightly pointed out that the MAOIs are among the drugs that accumulate much myth and misinformation. He notes that the MAOIs have developed such a sinister reputation that manufacturers often issue a reflexive admonition to avoid the concurrent use of MAOIs with new drugs.

This means that many of the warnings about potential interactions with the MAOIs may lack a sound scientific basis. However, equally this does not mean that the proven serious life-threatening interactions that are associated with the MAOIs should be dismissed, and it should be noted that any drug with indirectly-acting sympathomimetic activity is likely to interact.

Table 32.1 Monoamine oxidase inhibitors (MAOIs)†

Irreversible non-selective MAO-inhibitors (MAO-A and MAO-B)	*Reversible Inhibitors of MAO-A (RIMAs)*	*Irreversible inhibitors of MAO-B**
Iproniazid	Brofaromine	Rasagiline
Isocarboxazid	Moclobemide	Selegiline
Mebanazine	Toloxatone	
Nialamide		
Phenelzine		
Tranylcypromine		

*MAO-B inhibitors are used in Parkinson's disease, so are covered elsewhere

†Furazolidone, a non-selective MAOI used as an antiprotozoal, and linezolid, a weak, reversible non-selective MAOI, used as an antibacterial, are covered elsewhere

MAOIs + Antihistamines

The alleged interaction between the MAOIs and antihistamines appears to be based on a single *animal* study, and is probably more theoretical than real. There appear to be some exceptions, based on the additional properties of some specific antihistamines (cyproheptadine and promethazine).

Clinical evidence, mechanism, importance and management

A number of lists, charts and books about adverse interactions suggest that potentially serious interactions can occur between the MAOIs and the antihistamines. This appears to be based on a study in *rabbits* from 1972, which showed that some antihistamines (notably alkylamine antihistamines such as **chlorphenamine**, **brompheniramine**, and also **diphenhydramine**) produced a fatal hyperpyrexia, thought to be due to serotonin potentiation, when given intravenously to **phenelzine** pretreated *rabbits*.[1] This reaction was considered to be similar to that seen with 'pethidine (meperidine)', (p.1381), or the 'tricyclics', (p.1391). However, in over 20 years since the publication of this data, the manufacturers of various antihistamines did not identify any clinical reports of adverse interactions attributed to the use of any antihistamine with an MAOI.[2-6] Nevertheless, the UK manufacturers of most of the sedating antihistamines (**alimemazine**, **brompheniramine**, **chlorphenamine**, **diphenhydramine**) state that MAOIs may intensify the antimuscarinic effect of antihistamines, and many contraindicate or caution concurrent use.[7-10] No such warning is given for non-sedating antihistamines. In fact, brompheniramine and chlorphenamine have been specifically mentioned by one author as being suitable for the management of rhinitis associated with the common cold in patients taking MAOIs.[11]

There would appear to be no good reason to avoid the concurrent use of sedating or non-sedating antihistamines and MAOIs, although note that there other properties should be considered: because cyproheptadine has specific serotonin antagonist properties, and promethazine is a phenothiazine, they may interact differently, see 'MAOIs or RIMAs + Antihistamines; Cyproheptadine', below, and 'MAOIs or RIMAs + Antipsychotics', below.

MAOIs or RIMAs + Antihistamines; Cyproheptadine

Isolated reports describe delayed hallucinations in a patient taking phenelzine and cyproheptadine, and the rapid re-emergence of depression when two other patients taking brofaromine or phenelzine were given cyproheptadine.

Clinical evidence

A woman who had responded well to **brofaromine** rapidly became depressed again when she took cyproheptadine. She had to be hospitalised due to suicidal ideation, but eventually she responded to treatment and she then took **brofaromine** with cyproheptadine for 6 months.[1] A man whose depression responded well to **phenelzine** 75 mg daily was given cyproheptadine 4 mg to treat associated sexual dysfunction and anorgasmia. Within 3 days of adding the cyproheptadine his depression returned, but the anorgasmia did not improve. When the cyproheptadine was stopped his depression was relieved.[2] Hallucinations developed in a woman taking **phenelzine** 2 months after cyproheptadine was started.[3]

Mechanism

Cyproheptadine is a serotonin antagonist. The reversal of the effects of the brofaromine was therefore attributed by the authors of one report[1] to the blockage of 5-HT (serotonin) receptors by cyproheptadine (brofaromine has both MAO-A inhibitory and 5-HT uptake inhibitory properties).

Cyproheptadine also appears to block the activity of serotonin reuptake inhibitors (see 'SSRIs + Cyproheptadine', p.1482).

Importance and management

Information seems to be limited to these reports but it would be prudent to be alert for a reduction in efficacy or an adverse response if cyproheptadine is given with any MAOI or RIMA. The manufacturer of cyproheptadine actually contraindicates concurrent use with MAOIs.[4] However, there appears to be no reason why cyproheptadine cannot be used to treat the serotonin syndrome occurring in a patient taking an MAOI.

The UK manufacturer of cyproheptadine also says that MAOIs prolong and intensify the antimuscarinic effects of antihistamines,[4] but there seems to be no clinical data to support this suggestion with cyproheptadine or any other antihistamine, see 'MAOIs + Antihistamines', above.

MAOIs + Antimuscarinics

No adverse interactions between the MAOIs and antimuscarinics have been reported, although the possibility has been suggested.

Clinical evidence, mechanism, importance and management

A hyperthermic reaction has been reported in some *animals* given **tranylcypromine** or **nialamide** with **procyclidine** or **benzatropine**. It was considered that this might be due to an exaggerated dopamine response.[1] However, there do not appear to be any reports of such an interaction occurring clinically. Nevertheless, the manufacturer of procyclidine,[2] and some manufacturers of irreversible non-selective MAOIs (isocarboxazid and phenelzine)[3,4] advise caution because of the possibility that the concurrent use of an antimuscarinic and an MAOI may lead to increased antimuscarinic effects. This is presumably because, in theory, inhibition of drug-metabolising enzymes by MAOIs may possibly enhance the effects of antimuscarinics.

MAOIs or RIMAs + Antipsychotics

The concurrent use of MAOIs and phenothiazines is usually safe and effective. However, rarely, cases of possible neuroleptic malignant syndrome or hyperpyrexia have been reported when MAOIs were given with chlorpromazine, levomepromazine or trifluoperazine. Some of these cases were fatal. Chlorpromazine has been successfully used for treatment of serotonin syndrome occurring with MAOIs and other drugs.
Moclobemide has been given with various antipsychotics without a significant interaction, although adverse effects were increased. However, one case describes a fatal overdose which was attributed to an interaction between moclobemide and perazine.

Clinical evidence

(a) MAOIs

MAOIs and phenothiazines have been safe and effective when used together in the treatment of psychiatric conditions, particularly in the form

of a preparation containing both **tranylcypromine** and **trifluoperazine**,[1-3] which is still marketed in some countries. There is also a report of the beneficial use of **tranylcypromine** with **chlorpromazine**.[4]

However, rarely, cases suggestive of neuroleptic malignant syndrome or similar have been reported. In one case, a 70-year-old woman taking **isocarboxazid** 10 mg daily and **chlorpromazine** 25 mg three times daily, suddenly developed dyspnoea, tachycardia, pyrexia, muscular rigidity, hypotension, and became comatose. Her condition initially improved over 24 hours, but she later died from acute renal failure as a result of rhabdomyolysis. Throughout the previous 2 years of inpatient care, the patient had received neuroleptics intermittently and had developed an unexplained toxic confusional state on 6 occasions, which suggested that neuroleptic malignant syndrome had a milder chronic course in this patient before the full acute syndrome developed.[5] In another case, a woman presented with symptoms of neuroleptic malignant syndrome one week after starting **tranylcypromine**/**trifluoperazine** 10/1 mg and immediately after doubling the dose. She was intubated and treated with dantrolene and intravenous sodium bicarbonate, and made a full recovery.[6] Interpretation of her case is complicated by the fact she had been previously taking imipramine, and was switched to tranylcypromine/trifluoperazine without a break (see also 'MAOIs or RIMAs + Tricyclic and related antidepressants', p.1391). One study mentions an unexplained fatality in a woman who suddenly developed hyperthermia and coma while taking **levomepromazine** and **pargyline**.[7] Another report briefly mentions a woman who developed fatal hyperthermia while taking **levomepromazine** and **tranylcypromine**,[8] and a fatality following the use of an unnamed MAOI/phenothiazine combination.[8] Note that **chlorpromazine**[9] has 5-HT antagonist activity, and has been successfully used in the treatment of severe serotonin syndrome occurring with 'MAOIs and tricyclic antidepressants', (p.1391).

One early reviewer stated that MAOIs increase the potency of phenothiazine derivatives such that their initial dose should be reduced by three-quarters. He briefly mentions a case of a patient taking long-term **perphenazine** who developed a Parkinson-like syndrome with extrapyramidal symptoms a few hours after starting an MAOI.[10] The US manufacturer notes that, based on the increased incidence of extrapyramidal effects reported with concurrent use of some MAOIs and phenothiazines, this possibility should be considered with **promethazine**,[11] whilst the UK manufacturer contraindicates the use of **promethazine** with MAOIs and for 14 days after stopping treatment with an MAOI.[12] Also note that it has been suggested that MAOIs may intensify the antimuscarinic effects of **promethazine** (a phenothiazine antihistamine),[12] but evidence for this is largely lacking (see 'MAOIs + Antihistamines', p.1371).

A report attributes 2 cases of fatal fulminant hepatitis to an interaction between **iproniazid** and **prochlorperazine**.[13]

A single report[14] describes a woman taking an MAOI who developed a severe occipital headache after taking 30 mL of a paediatric cough linctus. Initially this interaction was attributed to **promethazine**, but it is now known that the linctus in question contained phenylpropanolamine, which is much more likely to have been the cause.[15] See 'MAOIs or RIMAs + Sympathomimetics; Indirectly-acting', p.1388 for the interaction with phenylpropanolamine.

Four days after the withdrawal of **phenelzine** and **perphenazine**, a patient was given operative premedication of **droperidol** 20 mg and hyoscine 400 micrograms, orally. About 2 hours later he was observed to be pale, sweating profusely and slightly cyanosed, with a blood pressure of 75/60 mmHg and a pulse rate of 60 bpm. He was not excitable, and no changes in respiration were seen. The blood pressure gradually rose to 115/80 mmHg over the next 45 minutes, but did not return to his normal level of 160/100 mmHg for 36 hours. The same premedication was given 11 days later without any adverse effects.[16] The response was attributed to the residual effects of **phenelzine** treatment.

(b) RIMAs

The manufacturer of **moclobemide** noted that in 1992 there were data available from 110 patients given **moclobemide** 150 to 400 mg daily with various antipsychotics, namely **acepromazine**, **aceprometazine**, **alimemazine**, **bromperidol**, **chlorpromazine**, **chlorprothixene**, **clothiapine**, **clozapine**, **cyamemazine**, **flupenthixol**, **fluphenazine**, **fluspirilene**, **haloperidol**, **levomepromazine**, **penfluridol**, **pipamperone**, **prothipendyl**, **sulpiride**, **thioridazine**, or **zuclopenthixol**. There was no evidence of any clinically relevant interactions, but there was some evidence that hypotension, tachycardia, sleepiness, tremor and constipation were more common, suggesting synergistic adverse effects.[17] A fatal case of overdose with **moclobemide** and **perazine** was attributed to synergistic effects resulting in functional cardiovascular disorder.[18]

Mechanism

Neuroleptic malignant syndrome (NMS) is a rare condition associated with a reduction in dopamine activity in the brain, which has occurred with a wide variety of dopamine antagonists including the phenothiazines. It is unclear what role, if any, is played by the MAOIs in the few possible cases cited here. Note that MAOIs can cause the similar serotonin syndrome, and it is important to differentiate between the two conditions, especially since phenothiazines would aggravate NMS, but can successfully treat the serotonin syndrome.

Importance and management

No special precautions would normally seem to be necessary during the concurrent use of MAOIs and phenothiazines. However, bear in mind that serious, sometimes fatal, cases of neuroleptic malignant syndrome or hyperpyrexia have rarely occurred when an MAOI was given with chlorpromazine, levomepromazine or trifluoperazine. The role of the MAOI in these cases is unclear. Chlorpromazine has been used successfully to treat serotonin syndrome occurring with MAOIs and other serotonergic drugs, but note that it should be avoided if neuroleptic malignant syndrome is a possible diagnosis, or if the patient is hypotensive.

MAOIs + Barbiturates

Although the MAOIs can enhance and prolong the activity of barbiturates in *animals*, only a few isolated cases of adverse responses attributed to an interaction have been described.

Clinical evidence

One reviewer[1] briefly mentions that on three or four occasions patients taking an MAOI continued, without the prescriber's knowledge, to take their usual barbiturate hypnotic and thereby '…unknowingly raised their dose of barbiturate by five to ten times, and as a consequence barely managed to stagger through the day.' No details are given, so it is not known whether the serum barbiturate levels of these patients were measured, or whether the raised levels are only a surmise.

A patient taking **tranylcypromine** 10 mg three times daily was inadvertently given intramuscular **amobarbital sodium** 250 mg for sedation. Within an hour she became ataxic, and fell to the floor, repeatedly hitting her head. After complaining of nausea and dizziness the patient became semicomatose and remained in that state for a further 36 hours. To what extent the head trauma played a part is uncertain.[2]

A man taking **amobarbital sodium** 195 mg at night suffered severe headache, and became confused after also taking **phenelzine** 15 mg three times daily for 4 weeks. On admission to hospital he was comatose, and he had a temperature of 40°C, blood pressure of 150/90 mmHg, tachycardia, stertorous respiration, fixed dilated pupils, exaggerated tendon reflexes and extensor plantar responses. His condition deteriorated and he died 2 hours after admission.[3] Pathology suggested a rise in intracranial pressure was responsible. The authors attribute this response to the drugs, but do not rule out a possible contribution of alcohol.[3]

Mechanism

Not known. *Animal* studies[2,4] show that MAOIs prolong the activity of barbiturates, and that this is possibly because they inhibit the metabolism of barbiturates by a mechanism independent of MAO inhibition. Whether this occurs in man as well is uncertain.

Importance and management

The evidence for these interactions seems to be confined to a few unconfirmed anecdotal reports. There is no well-documented evidence showing that concurrent use should be avoided, although some caution is clearly appropriate. For mention of successful anaesthesia including the use of **thiopental** in patients taking MAOIs, see 'Anaesthetics, general + MAOIs and related drugs', p.112.

MAOIs or RIMAs + Benzodiazepines

Isolated cases of adverse reactions (chorea, severe headache, facial flushing, and severe oedema) attributed to interactions between phenelzine and chlordiazepoxide, clonazepam or nitrazepam, and between isocarboxazid and chlordiazepoxide have been described. Evidence from clinical studies suggests that there is no interaction between moclobemide and benzodiazepines, although one study found a slight progressive worsening in driving performance.

Clinical evidence and mechanism

(a) MAOIs

A patient who had been taking **phenelzine** 45 mg daily for 9 years developed a severe occipital headache after taking 500 micrograms of clonazepam. A similar but milder headache occurred the next night when she again took clonazepam 500 micrograms. No blood pressure measurements were taken.[1] Another report describes facial flushing in a patient taking clonazepam, which occurred after **phenelzine** was started, and which responded to a reduction in the clonazepam dose.[2]

A patient with depression responded well when given **phenelzine** 15 mg and chlordiazepoxide 10 mg three times a day, but 4 to 5 months later developed choreiform movements of moderate severity, and slight dysarthria. These symptoms subsided when both drugs were withdrawn.[3]

Two patients taking chlordiazepoxide and either **phenelzine** or **isocarboxazid** developed severe oedema, which was attributed to the use of the combination.[4,5]

A patient became unconscious and hyperreflexic, with a low blood pressure (100/60 mmHg), increased heart rate (100 bpm), and increased temperature (38.4°C) about 29 hours after taking an overdose of **phenelzine** and chlordiazepoxide.[6] Another report briefly mentions a case of prolonged coma lasting 3 days in a patient who overdosed with **phenelzine** and chlordiazepoxide.[7]

A patient taking **phenelzine** 30 mg twice daily started to take nitrazepam 5 mg at night and the dose was gradually increased to 15 mg at night over 2 months. He developed MAOI toxicity (excessive sweating, postural hypotension) within 10 days of increasing his dose of nitrazepam to 15 mg daily. Both drugs were stopped and he recovered after 3 days. The **phenelzine** was restarted 2 weeks later without problems. It was suggested that since the patient was a slow acetylator, metabolism of nitrazepam by *N*-acetyl transferase would have been decreased, which may have affected the metabolism of **phenelzine**, thereby increasing its levels.[8]

(b) RIMAs

A meta-analysis of 879 patients taking **moclobemide** is reported to have found that insomnia, restlessness, agitation and anxiety occurred twice as often in the 467 patients taking one or more benzodiazepines than in those not taking concurrent benzodiazepines. However, these adverse events were often already present when **moclobemide** was started, so it is suggested that the patient groups were probably different. Apart from this difference between the patient groups, there was no evidence of any relevant pharmacokinetic or pharmacodynamic interaction.[9] Another review briefly reported that no clinically relevant interaction was noted between **moclobemide** and benzodiazepines in clinical studies.[10]

Driving performance gradually worsened over 6 weeks in a double-blind study in depressed patients given **moclobemide** (22 subjects) or fluoxetine (19 subjects). Thirty-one patients were taking long-term benzodiazepines, and at the start of the study their driving was no different to the patients not taking benzodiazepines. In an attempt to suggest a possible reason for the worsening performance, various variables were assessed in a regression analysis. It was found that patients taking **moclobemide** who were also taking a benzodiazepine with nordiazepam among its metabolites (**clorazepate**, **prazepam**, **diazepam**, **cloxazolam**, **clotiazepam**) experienced a progressive worsening in their driving, whereas patients taking other benzodiazepines (**bromazepam**, **alprazolam**, **oxazepam**, **lorazepam**) tended to have no change in driving ability. It was tentatively suggested that **moclobemide** may have inhibited the metabolism of nordiazepam by the cytochrome P450 isoenzyme CYP2C19, so increasing the effect of the benzodiazepine, and worsening driving performance.[11]

Importance and management

The case reports of adverse interactions cited here appear to be isolated, and it is by no means certain that all the responses were in fact due to drug interactions. However, bear them in mind in the event of unexpected responses to treatment. No special precautions would normally be required during concurrent use, although a reminder that benzodiazepines may affect the performance of skilled tasks, such as driving, may be appropriate when a patient's medication is changed. Note that the manufacturer of moclobemide says that if depressed patients with excitation or agitation are first treated with moclobemide, a sedative, such as a benzodiazepine, should also be given for up to 2 to 3 weeks.[12] Further study is required to find out if there are any clinically important pharmacokinetic interactions between moclobemide and any of the benzodiazepines.

MAOIs or RIMAs + Beta blockers

Bradycardia has been reported in two patients taking nadolol or metoprolol with phenelzine. MAOIs commonly cause hypotension, and might reasonably be expected to have additive hypotensive effects with antihypertensive drugs, although this was not seen with phenelzine and atenolol in a study in normotensive patients. In one small study, the RIMA, moclobemide increased the hypotensive effect of metoprolol, but did not alter the effect of nifedipine or hydrochlorothiazide on blood pressure.

Clinical evidence, mechanism, importance and management

(a) MAOIs

It had been claimed[1] that MAOIs should be discontinued at least 2 weeks before starting **propranolol**, but studies in *animals*[2] using **mebanazine** as a representative MAOI failed to show any undesirable property of **propranolol** following the use of an MAOI. Bradycardia of 46 to 53 bpm has been described in two patients taking **nadolol** 40 mg or **metoprolol** 150 mg daily for hypertension within 8 to 11 days of starting **phenelzine** 60 mg daily. No noticeable adverse effects were seen, but the authors recommend careful monitoring, particularly in the elderly, who may tolerate bradycardia poorly.[3] MAOIs can cause symptomatic hypotension, and therefore additive blood pressure lowering effects with antihypertensive drugs might occur. However, in one small study in normotensive patients with migraine, 11 (33%) of patients had orthostatic hypotension when they were given **phenelzine** alone, but none of these had orthostatic hypotension when they were also given **atenolol**.[4] Nevertheless, it would be prudent to monitor blood pressure more closely in patients taking antihypertensives with MAOIs. Some UK manufacturers of beta blockers (namely **celiprolol** and **pindolol**) advise that the combination of beta blockers with MAOIs is not recommended,[5,6] even up to 14 days following discontinuation of the MAOI,[5] whilst the manufacturers of others (namely **acebutolol** and **bisoprolol**) suggest caution, on the grounds that significant hypertension may theoretically occur,[7,8] Some manufacturers also warn of the risk of hypotension,[7,9,10] and bradycardia.[10]

(b) RIMAs

A study in 5 hypertensive subjects taking **metoprolol** found that **moclobemide** 200 mg three times daily for 2 weeks increased the hypotensive effect of **metoprolol** (systolic 10 to 15 mmHg lower, diastolic 5 to 10 mmHg lower). However, no comparable effects were seen when **moclobemide** was given to 7 subjects taking **hydrochlorothiazide** or 6 subjects taking **nifedipine**. No orthostatic hypotension occurred with any of the drug combinations.[11] The reason for the differing effect with **metoprolol** is unknown, and further study is needed. Be aware that **moclobemide** may add to the effect of **metoprolol**, and consider increased monitoring if either drug is started or stopped.

MAOIs or RIMAs + Bupropion

Bupropion is contraindicated with MAOIs, although there is little clinical evidence of serious problems. Orthostatic hypotension occurred in a patient given bupropion and the MAO-B inhibitor selegiline.

Clinical evidence, mechanism, importance and management

In an uncontrolled study, 10 patients were treated for major affective disorder (8 unipolar, 2 bipolar) with bupropion in daily doses of 225 to 450 mg and an MAOI: **isocarboxazid** (1 patient), **phenelzine** (5), **tranylcypromine** (2), and the MAO-B inhibitor **selegiline** (2). Four were transferred from the MAOI to bupropion without any washout period, and the other 6 were given both drugs concurrently. No untoward cardiovascular events occurred, except for one patient taking bupropion and **selegiline**, who experienced orthostatic hypotension. Notable weight loss occurred in two others when they were transferred from the MAOI to bupropion.[1] A Medline search (1962 to 2003) and review of published literature found no documented reports of hypertensive crises or fatalities when a stimulant drug (including bupropion) was cautiously added to an MAOI, although orthostatic hypotension and elevated blood pressure were reported.[2] One case report describes intraoperative hypertension with bupropion and 'linezolid', (p.1468), which has MAOI activity.

The manufacturers of bupropion note that toxicity was seen in studies in *animals* when **phenelzine** and bupropion were given concurrently.[3] They contraindicate bupropion with MAOIs and recommend that at least 14 days should elapse between stopping irreversible MAOIs and starting bupropion.[3,4] This precaution would therefore apply particularly to the non-selective MAOIs (**phenelzine**, **tranylcypromine**, **isocarboxazid** etc.). For **moclobemide**, the manufacturers advise that a 24-hour washout period is sufficient before starting bupropion.[4]

MAOIs or RIMAs + Buspirone

Elevated blood pressure has been reported in four patients taking buspirone and either phenelzine or tranylcypromine. Buspirone may have contributed to a case of serotonin syndrome in a patient who took an overdose of moclobemide and clomipramine.

Clinical evidence, mechanism, importance and management

(a) MAOIs

Four cases of significant blood pressure elevation, which occurred during the use of buspirone and either **phenelzine** or **tranylcypromine**, have been reported to the Spontaneous Reporting System of the FDA in the US. One patient was a 75-year-old woman and the other 3 patients were men aged between 30 and 42 years. The report does not say how much the blood pressure rose, or how quickly, and no other details are given.[1] On the basis of this rather sparse information the manufacturers of buspirone[2,3] recommend that it should not be used concurrently with an MAOI.

(b) RIMAs

A severe case[4] of serotonin syndrome (including hyperthermia and muscle rigidity requiring mechanical ventilation) has been reported in a patient who took an overdose of **moclobemide**, clomipramine and buspirone, although what contribution the buspirone had to this reaction is unclear, as cases have been reported with clomipramine and moclobemide, see 'MAOIs or RIMAs + Tricyclic and related antidepressants', p.1391.

MAOIs + Caffeine or Choline theophyllinate

Isolated reports suggest that the CNS stimulant effects of caffeine may possibly be increased by the MAOIs. Another isolated report describes the development of tachycardia and apprehension in a patient taking phenelzine after she also took a cough syrup, containing choline theophyllinate.

Clinical evidence

(a) Caffeine

One reviewer briefly mentions that a patient who normally drank 10 or 12 cups of **coffee** daily, without adverse effects, experienced extreme jitteriness during treatment with an MAOI, which subsided when the **coffee** consumption was reduced to 2 or 3 cups a day. The same reaction was also said to have occurred in other patients taking MAOIs who drank **tea** or some of the **cola drinks**, which contain caffeine.[1] This reviewer also mentions another patient taking an MAOI who claimed that a single cup of **coffee** taken in the morning kept him jittery all day and up the entire night as

well, a reaction that occurred on three separate occasions.[1] In another report, a woman taking **phenelzine** experienced a severe headache with a slight blood pressure rise on two occasions after drinking **cola** containing 35 to 55 mg of caffeine.[2] Similarly, a brief mention is made of 2 patients taking **phenelzine** who experienced extreme restlessness, agitation, tremor, and insomnia after starting to drink large quantities of **diet cola**. This was attributed to an interaction between **phenelzine** and aspartame,[3] but could equally well be attributed to an interaction with caffeine, or indeed a reaction to caffeine alone. Caffeine and **theophylline** may have contributed to the serious reaction that occurred in a woman who took a *Do-Do* tablet (containing ephedrine, caffeine, theophylline) the day after discontinuing **phenelzine**.[4] For more information on the interactions of MAOIs and ephedrine, see 'MAOIs or RIMAs + Sympathomimetics; Indirectly-acting', p.1388.

(b) Choline theophyllinate

A woman with agoraphobia, taking **phenelzine** 45 mg daily, developed tachycardia, palpitations and apprehension lasting for about 4 hours after she had taken a cough syrup containing choline theophyllinate and guaifenesin. The symptoms recurred when she was again given the cough syrup, and yet again when given choline theophyllinate, but not when given guaifenesin.[5]

Mechanism

Unknown. Caffeine alone can cause headache, tachycardia, and jitteriness, and individuals vary in their susceptibility to these effects. The effects of caffeine, theophylline, and theobromine in *rats* were enhanced by MAOIs.[6]

Importance and management

Apart from these few reports, the literature appears to be otherwise silent about an interaction between the MAOIs and xanthines. Whether this reflects their mildness and unimportance, or their rarity, is not clear. There would seem to be no need for any special precautions in patients taking MAOIs who are given xanthine bronchodilators or consuming caffeine-containing beverages or pharmaceuticals, but bear these adverse reports in mind in the event of any unexpected response. Note that, some manufacturers of isocarboxazid, phenelzine and tranylcypromine recommend the avoidance of excessive amounts of tea and coffee,[7] or caffeine in any form.[8-10]

MAOIs + Cocaine

Some reports suggest that patients taking MAOIs may experience a severe headache if they abuse cocaine. Two isolated reports describe the delayed development of hyperpyrexia, and other symptoms including coma, agitation, muscle tremors and rigidity, after patients taking phenelzine or iproniazid were given a cocaine spray during surgery.

Clinical evidence, mechanism, importance and management

The use of cocaine is generally contraindicated in patients taking MAOIs[1-4] because it is expected to interact in the same way as 'indirectly-acting sympathomimetics', (p.1388). This is supported by a report of hypertensive reactions in 2 patients taking **phenelzine** who became drunk and used cocaine. Both experienced frightening reactions including headache, a rise in blood pressure, palpitations, and chest tightness. One required no treatment, and the other was treated with propranolol and diazepam.[5] Because this reaction was not considered as dangerous as expected, **phenelzine** has been tried as a deterrent to the abuse of cocaine: one uncontrolled study reports its use in 26 patients without mentioning any adverse reactions.[5] Another report mentions a man given **phenelzine** for cocaine abuse who experienced no reaction to the use of cocaine. He was then given **tranylcypromine**, and after 10 weeks risked sniffing cocaine, which did produce a severe occipital headache and nausea. However, after abstaining for another 10 weeks he again used cocaine, this time without any reaction.[6]

A man taking **phenelzine** 15 mg twice daily underwent vocal chord surgery. He was anaesthetised with thiopental, and later nitrous oxide and isoflurane 0.5% in oxygen. Muscle paralysis was produced with suxamethonium and gallamine. During the operation his vocal chords were sprayed with 1 mL of a 10% cocaine spray. He regained consciousness 30 minutes after the surgery and was returned to the ward, but a further 30 minutes later he was found unconscious, with generalised coarse tremors and marked muscle rigidity. His rectal temperature was 41.5°C. He was initially thought to have malignant hyperpyrexia and was treated accordingly with wet blankets, as well as with intravenous fluids and oxygen, and he largely recovered within 7 hours. However, later it seemed more likely that the reaction had been due to an adverse interaction between the **phenelzine** and cocaine, because he had been similarly and uneventfully treated with cocaine in the absence of **phenelzine** on two previous occasions.[7] In a similar case, a woman taking **iproniazid** had her trachea sprayed with 1 mL of 10% cocaine before intubation during surgery. She was also given pethidine 20 mg, and shortly after surgery became pyrexial, flushed, agitated and sweated profusely. She was treated with intravenous chlorpromazine.[8] In this case, the reaction could have been due to the pethidine alone (see 'MAOIs or RIMAs + Opioids; Pethidine (Meperidine)', p.1381), or both the cocaine and the pethidine. The reasons for these adverse reactions are not understood, but a delayed excitatory reaction due to increased 5-HT (serotonin) concentrations has been suggested.[7] The general importance of these cases is not known, but bear them in mind if cocaine is used by a patient taking an MAOI.

MAOIs or RIMAs + Dextromethorphan

Two fatal cases of hyperpyrexia and coma (symptoms similar to the serotonin syndrome) have occurred in patients taking phenelzine with dextromethorphan (in overdosage in one case). Three other serious but non-fatal reactions occurred in patients taking dextromethorphan with isocarboxazid or phenelzine. MAOIs should not be used with dextromethorphan. Moclobemide inhibits the metabolism of dextromethorphan, and isolated cases of severe CNS reactions have occurred with the combination: concurrent use is contraindicated.

Clinical evidence

(a) MAOIs

A woman taking **phenelzine** 15 mg four times daily complained of nausea and dizziness before collapsing, 30 minutes after drinking about 55 mL of a cough mixture containing dextromethorphan. She remained hyperpyrexic (42°C), hypotensive (systolic blood pressure below 70 mmHg) and unconscious for 4 hours, before she had a cardiac arrest and died.[1]

A 15-year-old girl taking **phenelzine** 15 mg three times daily (as well as thioridazine, procyclidine and metronidazole) took 13 capsules of *Romilar CF* (containing dextromethorphan hydrobromide 15 mg, phenindamine tartrate 6.25 mg, phenylephrine hydrochloride 5 mg and paracetamol (acetaminophen) 120 mg in each capsule). She became comatose, hyperpyrexic (about 39.4°C), had a blood pressure of 100/60 mmHg, a pulse of 160 bpm and later died of a cardiac arrest.[2] This case is complicated by the overdosage and multiplicity of drugs present, particularly the phenyle-

phrine. See 'MAOIs or RIMAs + Sympathomimetics; Phenylephrine', p.1390.

Three other case reports describe muscle spasms or rigidity, sweating, nausea or tremor in patients who took *Robitussin DM* (dextromethorphan hydrobromide 15 mg with guaifenesin 100 mg) with phenelzine or isocarboxazid.[3-5] One patient responded to 10 mg of intravenous diazepam and oral activated charcoal within 2 hours,[4] and the symptoms of another gradually resolved over 19 hours.[5]

In addition, the US manufacturer of **tranylcypromine** notes that the concurrent use of MAOIs and dextromethorphan has resulted in brief episodes of psychosis or bizarre behaviour.[6] Similarly, the US manufacturer of **phenelzine** mentions one case of drowsiness and bizarre behaviour when dextromethorphan lozenges were used by a patient taking phenelzine.[7]

(b) RIMAs

Moclobemide 300 mg twice daily for 9 days markedly reduced the *O*-demethylation of dextromethorphan (seven 20-mg doses given every 4 hours over 2 days), in 4 healthy subjects.[8] The manufacturer notes that isolated cases of severe CNS adverse reactions have been seen with the combination.[9] Concurrent use of dextromethorphan may have contributed to a fatality involving the illicit use of **moclobemide** and 'ecstasy', (p.1386).

Mechanism

It has been suggested[3-5] that the effects may be due to an increase in serotonin activity in the CNS. Symptoms similar to the serotonin syndrome (hyperpyrexia, dilated pupils, hyperexcitability and motor restlessness) have been seen in *rabbits* treated with dextromethorphan and **nialamide**, phenelzine or **pargyline**,[10] and also with MAOIs and 'pethidine (meperidine)', (p.1381). Moclobemide appears to inhibit the metabolism of dextromethorphan by the cytochrome P450 isoenzyme CYP2D6, and the combination may also cause adverse CNS effects, also possibly due to additive effects on serotonin. For more information about the serotonin syndrome, see 'Additive or synergistic interactions', (p.9).

Importance and management

Despite the very limited information available, the severity of the reactions indicates that patients taking MAOIs should avoid taking dextromethorphan: concurrent use is generally contraindicated. The manufacturer of moclobemide also contraindicates the concurrent use of dextromethorphan.[9] Patients should be warned that many cough preparations contain dextromethorphan.

MAOIs + Disulfiram

An isolated report describes delirium in a man taking lithium and disulfiram when the moclobemide he was also taking was replaced by tranylcypromine.

Clinical evidence, mechanism, importance and management

A man with disulfiram implants taking long-term lithium had his MAOI changed from **moclobemide** (dosage not stated) to **tranylcypromine** 10 mg twice daily. Within 2 days he became acutely delirious (agitated, disoriented, incoherent, visual hallucinations) and later subcomatose, with nystagmus and a downward gaze. He was successfully treated with haloperidol and promethazine, and recovered within 24 hours. No alcohol was detected in his blood, and serum **tranylcypromine** levels were below 50 micrograms/L, which was considered normal.[1]

The authors of this report attribute the reaction to an interaction between **tranylcypromine** and disulfiram. However, there would seem to be other possible explanations for this reaction. MAOIs have rarely been seen to interact adversely with 'lithium', (p.1378), and there also seems potential for an interaction between '**moclobemide** and **tranylcypromine**', (p.1378).

This seems to be the only report of an adverse reaction between disulfiram and an MAOI, so it is possible that this is just an idiosyncratic reaction. However, warnings about this drug combination, based on theoretical considerations and studies in *animals*, have previously been given, and **tranylcypromine** was considered to be the MAOI that presented the greatest risk.[2] Consequently, the US manufacturers of **tranylcypromine**[3] and **isocarboxazid**[4] recommend caution with the concurrent use of disulfiram. Note that this particular patient did not seem to have any problems while taking **moclobemide**, which is a RIMA.

MAOIs + Dopa-rich foods

A few reports describe a rapid and potentially life-threatening hypertensive reaction in patients taking MAOIs if they eat young broad bean pods, which contain dopa.

Clinical evidence

A 65-year-old hypertensive man taking **pargyline** had a severe headache and palpitations on two occasions after eating "whole, cooked, broad beans" (young broad bean pods). A controlled study in this man found that he had a rise in systolic blood pressure from 165 to 262 mmHg about 20 minutes after eating whole broad bean pods. The pods alone had the same effect, but the beans on their own had little effect. This rise in blood pressure was also seen in two other patients taking **pargyline**, and was reversed by intravenous phentolamine.

Two normotensive subjects taking pargyline 50 mg daily also had an increase in blood pressure (over 70 mmHg systolic in one subject) following the ingestion of bean pods.[1] Another case report describes a man taking **phenelzine** 15 mg three times daily who had a very severe headache after eating a meal including fresh, young, sliced, broad bean pods from his garden.[2] One other case has been briefly mentioned, although it was not known whether the broad beans were eaten with or without the pods.[3]

Mechanism

Broad bean (*Vicia faba*) pods contain dopa,[1] which is enzymatically converted in the body, firstly to dopamine and then to noradrenaline, both of which are normally broken down by monoamine oxidase. In the presence of an MAOI this breakdown is suppressed, which means that the total levels of dopamine and noradrenaline are increased. Precisely how this then leads to a sharp rise in blood pressure is not clear, but either dopamine or noradrenaline, or both, directly or indirectly stimulate the alpha-receptors of the cardiovascular system.

Importance and management

Although there are only a few cases of the interaction between the non-selective MAOIs (see 'Table 32.1', (p.1370) for a full list) and broad bean pods, the interaction would appear to be established: it is serious and potentially life-threatening. Patients should not eat young broad bean *pods* during treatment with any of these MAOIs, nor for a period of 2 to 3 weeks after their withdrawal. It should be noted that this prohibition does not apply to 'mature' broad beans (the seeds) removed from their pods, which is the more common way of eating broad beans.

MAOIs + Doxapram

No adverse interactions have been reported between the MAOIs and doxapram, although *animal* studies suggest that an increased pressor effect is theoretically possible.

Clinical evidence, mechanism, importance and management

The manufacturers note that *animal* studies have shown that the actions of doxapram may be potentiated by pretreatment with an MAOI,[1] and that the pressor effects of MAOIs and doxapram may be additive.[2] Based on this, they advise that concurrent use should be undertaken with great care.[1,2] To date, there appear to be no clinical reports of this interaction. Nevertheless, it may be prudent to consider blood pressure monitoring in patients given doxapram while taking an MAOI.

MAOIs + Ginseng

Case reports describe headache, insomnia and tremulousness, which was attributed to the concurrent use of ginseng and phenelzine.

Clinical evidence

A 64-year-old woman taking **phenelzine** [60 mg daily] developed headache, insomnia, and tremulousness after taking Natrol High, a product containing ginseng,[1,2] probably *Eleutherococcus senticosus* (Siberian ginseng). She had the same symptoms on another occasion after drinking a ginseng tea (type not stated), which she had used without problem before starting phenelzine.[1] Three years later, while taking **phenelzine** 45 mg daily, she experienced the same symptoms and an increase in depression 72 hours after starting to take ginseng capsules (type not stated) and a herbal tea.[2]

Another woman with depression taking ginseng (type not stated) and bee pollen experienced relief of her depression and became active and extremely optimistic when she started to take **phenelzine** 45 mg daily, but this was accompanied by insomnia, irritability, headaches and vague visual hallucinations. When the **phenelzine** was stopped and then re-started in the absence of the ginseng and bee pollen, her depression was not relieved.[3]

Mechanism

Uncertain. It seems unlikely that the bee pollen had any part to play. Note that the ginsengs have stimulant effects, and adverse effects include insomnia, nervousness, hypertension and euphoria.

Importance and management

Evidence is limited to three case reports, and the general importance of these poorly documented early cases is unclear. It may be that these cases could just represent idiosyncratic reactions, and not be due to an interaction. The data is therefore too limited to suggest any particular caution. Nevertheless, consider the possibility of an interaction in case of an unexpected response to treatment with phenelzine (or potentially any MAOI) in a patient taking any type of ginseng.

MAOIs or RIMAs + Levodopa

A rapid, serious and potentially life-threatening hypertensive reaction can occur in patients taking MAOIs if they are given levodopa. An interaction with levodopa given with carbidopa or benserazide is less likely. No serious hypertensive reaction has been reported to occur with moclobemide.

Clinical evidence

(a) MAOIs

A patient who had been taking **phenelzine** daily for 10 days was given 50 mg of oral levodopa. In just over an hour his blood pressure had risen from 135/90 mmHg to about 190/130 mmHg, and despite a 5 mg intravenous injection of phentolamine it continued to rise over the next 10 minutes to 200/135 mmHg, before falling after a further 4 mg injection of phentolamine. The following day the experiment was repeated with levodopa 25 mg, but no blood pressure changes were seen. Three weeks after **phenelzine** was withdrawn even 500 mg of levodopa had no hypertensive effect.[1]

Similar cases of severe, acute hypertension, accompanied in most instances by flushing, throbbing and pounding in the head, neck and chest, and light-headedness have been described in other case reports and studies in which levodopa was given with **pargyline**,[2] **nialamide**,[3] **tranylcypromine**,[4] **phenelzine**,[5] or **isocarboxazid**.[1]

A study in 4 normotensive patients with parkinsonism found that the combination of levodopa and **tranylcypromine** caused an increase in blood pressure, but this reaction was inhibited by carbidopa in 3 of the patients. In the remaining patient (who was also taking trihexyphenidyl) the pressor response with levodopa and tranylcypromine (mean increase in arterial blood pressure 40 mmHg) was only blunted by carbidopa (mean increase 20 mmHg).[6]

(b) RIMAs

A study in 12 healthy subjects given a single dose of levodopa/benserazide with **moclobemide** 200 mg twice daily found that nausea, vomiting and dizziness were increased, but no significant hypertensive reaction was seen.[7]

Mechanism

Not fully understood. Levodopa is enzymatically converted in the body, firstly to dopamine and then to noradrenaline, both of which are normally broken down by monoamine oxidase. In the presence of an MAOI this breakdown is suppressed, which means that the total levels of dopamine and noradrenaline are increased. Precisely how this then leads to a sharp rise in blood pressure is not clear, but either dopamine or noradrenaline, or both, directly or indirectly stimulate the alpha-receptors of the cardiovascular system. Dopa-decarboxylase inhibitors would be expected to minimise the interaction by decreasing the peripheral metabolism of the levodopa.

Importance and management

The interaction between the non-selective MAOIs (listed in 'Table 32.1', (p.1370)) and levodopa on its own is well documented, serious and potentially life-threatening. Patients should not be given levodopa on its own during treatment with any of these MAOIs, nor for a period of 2 to 3 weeks after their withdrawal. Note that this interaction is inhibited or decreased by the presence of dopa-decarboxylase inhibitors[6] such as carbidopa and benserazide (as in *Sinemet* and *Madopar*) so that a serious interaction is less likely to occur with these preparations. Nevertheless, the manufacturers continue to list the MAOIs among their contraindications.

No hypertensive effect appears to occur between levodopa/benserazide and moclobemide, but bear in mind that the incidence of adverse effects may be increased.

MAOIs or RIMAs + Lithium

Two cases of tardive dyskinesia have been described following the long-term use of tranylcypromine and lithium, which did not resolve when the MAOI was stopped. Limited evidence suggests that no problems occur when moclobemide is given with lithium.

Clinical evidence, mechanism, importance and management

(a) MAOIs

One report describes 2 patients with bipolar affective disorder who developed a buccolingual-masticatory syndrome after taking **tranylcypromine** 30 or 40 mg daily and lithium carbonate 900 mg or 1.2 g daily for 1.5 or 3 years. These symptoms did not resolve when the **tranylcypromine** was stopped. This reaction was attributed to dopamine receptor hypersensitivity.[1]

There appear to be no other reports suggesting that the combination of MAOIs and lithium is unsafe. However, there are a few reports of patients taking MAOIs and lithium who developed hyperpyrexia when given 'tryptophan', (p.1393). The role (if any) of lithium in these cases is unknown. Note that lithium has been used to augment antidepressants although most of the data relate to the use of tricyclics or SSRIs.[2] Any interaction seems to be rare, but bear these cases in mind in the event of any unexpected response to treatment with MAOIs and lithium.

(b) RIMAs

There was no evidence of any adverse interaction when **moclobemide** 150 to 675 mg daily was given for 3 to 52 weeks to 50 patients taking lithium.[3] Similarly, lithium augmentation was used in a small uncontrolled study in patients taking high-dose **moclobemide** without any evidence of important adverse effects.[4] No particular precautions would therefore seem necessary if both drugs are given.

MAOIs + MAOIs or RIMAs

Strokes, fatal reactions (possibly including serotonin syndrome), hypertensive reactions and CNS disturbances have been seen when one MAOI was abruptly replaced by another, when the two MAOIs were given together, or when there was an insufficient MAOI-free interval. A case of serotonin syndrome occurred in a patient who took an overdose of moclobemide and tranylcypromine.

Clinical evidence, mechanism, importance and management

(a) MAOIs with MAOIs

A patient who had been taking **isocarboxazid** for 3.5 weeks (starting at 10 mg daily and gradually increased to 30 mg daily) was switched to **tranylcypromine** 10 mg, starting the same day, followed by 10 mg three times daily on the following day. Later that night she complained of feeling 'funny', had difficulty in talking, developed a headache, was restless, flushed, sweating, had an elevated temperature of 39.5°C, and a pulse rate of 130 bpm. She died the following day.[1] Another patient, switched with-out a drug-free period, from **phenelzine** 75 mg daily (by tapering the dose by 15 mg daily until discontinued) to **tranylcypromine** (starting at 10 mg daily, increasing by 10 mg daily, until a dose of 20 mg twice daily was reached), suffered a subcortical cerebral haemorrhage on the fourth day following the morning 20-mg dose of **tranylcypromine**, which resulted in total right-sided hemiplegia.[2,3] The patient remained significantly disabled from the sequelae of her stroke.[4] A third patient experienced a mild cerebral haemorrhage, without residual problems, when she took **phenelzine** 45 mg and **tranylcypromine** 20 mg at bedtime; the MAOIs were being switched by reducing the dose of phenelzine and gradually increasing the dose of **tranylcypromine**. Consumption of 'soy sauce', (p.1395), may have contributed to this reaction.[5] In a fourth case, **phenelzine** 45 mg daily was stopped, and then after a 2-day drug-free period **tranylcypromine** 20 mg was given, with a further 30-mg dose the next day. The patient experienced a rise in blood pressure to 240/130 mmHg, but recovered uneventfully, and a year later was successfully switched from **phenelzine** to **tranylcypromine** with a 2-week drug-free interval.[2] In another case, hypertension with severe headache, inability to walk and slurred speech, but without permanent sequelae, resulted from starting **tranylcypromine** 30 mg seven days after discontinuing **phenelzine**. **Tranylcypromine** 10 mg daily was restarted 3 days later (10 days after discontinuing the **phenelzine**) with no adverse effects, but when the dose was increased to 20 mg daily (14 days after discontinuing **phenelzine**) the patient experienced a milder version of the same symptoms.[6]

Acute CNS toxicity, hypertension, tachycardia, tremor and urinary retention occurred in a woman 48 hours after **phenelzine** was abruptly stopped and **isocarboxazid** started. In this patient, **phenelzine** was poorly tolerated causing hypertension and headache.[7]

Switching from **iproniazid** to **tranylcypromine** with trifluoperazine may have been the cause of a fatal reaction (fever, shivering, sweating, cyanosis) in a patient also given ephedrine[8,9] (consider 'MAOIs or RIMAs + Sympathomimetics; Indirectly-acting', p.1388).

In contrast, one woman was switched directly from **phenelzine** 60 mg daily to **tranylcypromine** 20 mg daily without any obvious problems (blood pressure was slightly high, but within the usual range for this patient). She was abruptly switched directly back to **phenelzine**, again without any adverse effect.[10,11] Similarly, a review of 8 cases of patients who were switched rapidly from **tranylcypromine** to **phenelzine** (3 cases) or *vice versa* (5 cases) found that 7 patients tolerated the switch well with minimal or no adverse effects. However the eighth patient experienced anxiety, nausea, hyperventilation, flushing, a sense of doom, and increased insomnia, which may have been a mild form of serotonin syndrome.[12]

The reasons for these reactions are not understood, but one idea is that the amphetamine-like properties of **tranylcypromine** may have had some part to play. Certainly there are cases of spontaneous rises in blood pressure and intracranial bleeding in patients given **tranylcypromine**.[13] Not all patients experience adverse reactions when switched from one MAOI to another,[10,12] but because of the sometimes severe reactions, it would seem prudent to have a drug-free wash-out interval when doing so (14 days is commonly suggested as a washout period for MAOIs), and to start dosing in a conservative and step-wise manner.

(b) RIMAs with MAOIs

A patient who took an overdose of **moclobemide** and **tranylcypromine** developed serotonin syndrome. In this analysis of **moclobemide** overdoses, the risk of developing serotonin toxicity was significantly increased in patients who also took another serotonergic drug, of which this case with **tranylcypromine** was one of 11 mentioned.[14]

MAOIs + Mazindol

An isolated report describes a patient taking phenelzine who had a marked rise in blood pressure when a single dose of mazindol was given.

Clinical evidence, mechanism, importance and management

A woman taking **phenelzine** 30 mg three times daily had a rise in blood pressure from 110/60 to 200/100 mmHg within 2 hours of receiving a 10-mg test dose of mazindol. The blood pressure remained elevated for another hour, but had fallen again after a further 3 hours. The patient experienced no subjective symptoms.[1] It is uncertain whether this hypertensive reaction was the result of an interaction, or simply a direct response to the mazindol alone (the dose was large compared with the recommended dosage of 2 to 3 mg daily). The general importance of this interaction is uncertain. The manufacturer advises avoiding the combination, and says that mazindol should not be used until 14 days after MAOIs have been stopped.[2]

MAOIs + Methyldopa

Theoretically hypertension may occur when non-selective MAOIs are taken with methyldopa, although additive blood-pressure lowering effects are also a possibility. The concurrent use of antidepressant MAOIs and methyldopa may not be desirable because methyldopa can sometimes cause depression.

Clinical evidence, mechanism, importance and management

Theoretically, methyldopa might cause hypertension in patients taking non-selective MAOIs, by releasing catecholamines into the circulation[1,2] On the basis of this the manufacturers of **phenelzine**, **tranylcypromine**[3,4] and methyldopa[5] contraindicate concurrent use. Nevertheless, there do not appear to be any reports of hypertension occurring as a result of concurrent use. Conversely, the UK manufacturer of **isocarboxazid**[6] mentions that it may potentiate the hypotensive effect of methyldopa, and the US manufacturer of **isocarboxazid** warns that it may potentiate the effects of antihypertensives in general.[7] MAOIs alone have hypotensive effects and additional blood pressure lowering effects have been reported in a few patients given **pargyline** (an MAOI formerly used in the treatment of hypertension) with methyldopa.[8,9] Note that the potential depressant adverse effects of methyldopa may make it an unsuitable drug for patients with depression.

MAOIs + Mirtazapine

The manufacturers say that two weeks should elapse between taking an MAOI and mirtazapine.

Clinical evidence, mechanism, importance and management

No serious adverse interactions have been reported between mirtazapine and the MAOIs[1] but, to be on the safe side, the manufacturers say that the concurrent use of mirtazapine and MAOIs should be avoided both during and within 2 weeks of stopping treatment.[1,2]

Note that there is a case of delirium possibly attributed to the use of linezolid (an antibacterial with some MAOI activity) with mirtazapine, see 'Linezolid + SSRIs', p.353, which gives weight to this warning.

MAOIs + Modafinil

An isolated case report describes a patient who developed an acute dyskinesia and symptoms suggestive of serotonin syndrome following the use of modafinil with tranylcypromine.

Clinical evidence

A case report describes a patient who had been taking tranylcypromine 80 mg daily who, 3 days after starting to take modafinil 200 mg daily, became restless, confused, and developed severe choreiform movements of her limbs, lip smacking, rhythmic rapid tongue protrusions, and opisthotonus. Her temperature rose to 38°C, and remained high for 24 hours. Her symptoms resolved within 48 hours of discontinuing both drugs.[1]

Mechanism

The authors of this report suggest that the dopaminergic and serotonergic effects of modafinil were augmented by tranylcypromine. The hyperthermia and confusion that the patient experienced may have been an incomplete form of serotonin syndrome.

Importance and management

This appears to be the only case report of an interaction between an MAOI and modafinil, although a case report describing the successful use of these two drugs has been published.[2] However, if the suggested mechanism is correct, it could occur with any MAOI. It would therefore seem prudent to be alert for these effects if modafinil is given with an MAOI.

MAOIs + Monosodium glutamate

Hypertension in patients taking MAOIs who had eaten certain foods (soy sauce, chicken nuggets) has been attributed, in anecdotal reports, to an interaction with monosodium glutamate. However, a small controlled study found no evidence to support this idea, and the reaction was probably related to tyramine.

Clinical evidence

Five healthy subjects were given monosodium glutamate 400 mg to 1.6 g or a placebo with or without **tranylcypromine** for at least 2 weeks. Episodes of hypertension were seen in 2 subjects taking **tranylcypromine** with both placebo and monosodium glutamate, but no changes in blood pressure or heart rate occurred that could be attributed to an interaction while taking monosodium glutamate. The largest dose of monosodium glutamate used was about twice the amount usually found in meals containing large amounts of monosodium glutamate.[1]

There have been anecdotal reports of hypertensive reactions in patients taking MAOIs that were attributed to interactions with the monosodium glutamate contained in soy sauce[2] and chicken nuggets.[3]

Mechanism

Monosodium glutamate alone can cause a small rise in blood pressure, and MAOIs alone very occasionally cause hypertensive episodes. However, the reactions reported with soy sauce and chicken nuggets were probably due to a high tyramine content, as a high tyramine content has subsequently been detected in some soy sauces,[4] (see 'MAOIs or RIMAs + Tyramine-rich foods', p.1395).

Importance and management

No interaction between monosodium glutamate *per se* and MAOIs has been established, although it should be pointed out that the number of subjects studied was very small. It is quite possible that the anecdotal reports were due to the tyramine content of the foods, and not to monosodium glutamate. In Hong Kong, patients taking MAOIs are not advised to avoid

monosodium glutamate, but are instructed to avoid excessive soy sauce because of its possible high tyramine content.[4]

MAOIs or RIMAs + Opioids; Dextropropoxyphene (Propoxyphene)

An isolated report describes 'leg shakes', diaphoresis and severe hypotension when a woman taking phenelzine was given dextropropoxyphene. Another isolated report describes a marked increase in sedation when a woman was given phenelzine and dextropropoxyphene. *Animal* data show moclobemide potentiates the effects of dextropropoxyphene.

Clinical evidence, mechanism, importance and management

(a) MAOIs

A woman taking **phenelzine** 15 mg three times daily, sodium valproate, lithium and trazodone, was given dextropropoxyphene 100 mg and paracetamol (acetaminophen) 650 mg for back pain and headache. Some 12 hours later she was admitted to hospital for leg shakes, discomfort and weakness. She was confused and anxious, and intensely diaphoretic. The next day she became severely hypotensive (systolic BP 55 to 60 mmHg) and needed large fluid volume resuscitation in intensive care. She later recovered fully.[1] Another woman taking propranolol, oestrogen-replacement therapy and **phenelzine** became very sedated and groggy, causing her to have to lie down on two occasions, both within 2 hours of taking dextropropoxyphene 100 mg and paracetamol 650 mg. She had experienced no problems with either paracetamol or dextropropoxyphene/paracetamol before starting the **phenelzine**, and subsequently had no problems with paracetamol alone while continuing the **phenelzine**.[2] The mechanisms of these interactions are not understood but some of the symptoms in the first case were not unlike those seen in the serotonin syndrome.

Apart from these two isolated reports, there seems to be no other clinical evidence of adverse interactions between MAOIs and dextropropoxyphene; however, some caution would seem prudent if any MAOI is given with dextropropoxyphene. For reports of the serotonin syndrome seen with pethidine (meperidine) and MAOIs, see 'MAOIs or RIMAs + Opioids; Pethidine (Meperidine)', p.1381.

(b) RIMAs

In *animals,* the effects of dextropropoxyphene were increased by **moclobemide**.[3] A brief mention is made of 3 patients, taking **moclobemide** and codeine (2 patients) or dextropropoxyphene (1 patient): one of these patients developed moderate agitation.[3]

MAOIs + Opioids; Fentanyl and related drugs

Fentanyl has been used in patients taking MAOIs without problems in some patients, but one fatal case of hyperthermia has occurred, and also a case of hypertension and tachycardia. Case reports describe the uneventful use of alfentanil, remifentanil and sufentanil in patients taking MAOIs.

Clinical evidence

(a) Alfentanil

A 54-year-old woman taking **tranylcypromine** with trifluoperazine underwent general anaesthesia with no problems. She received temazepam as premedication, and propofol induction. Supplementary alfentanil was given in increments of 250 micrograms to a total of 2.5 mg. Atracurium was given for neuromuscular block with 100% oxygen for ventilation.[1] Similarly, another report describes successful anaesthesia using propofol, alfentanil 25 micrograms/kg, and succinylcholine during ECT therapy in two patients taking a variety of drugs including **phenelzine**.[2]

(b) Fentanyl

A 71-year-old woman taking *Parstelin* (**tranylcypromine** with trifluoperazine) was given an intravenous test dose of fentanyl 20 micrograms and diazepam before surgery, without problems. She was then given another 20-microgram intravenous dose of fentanyl during surgery, followed by an epidural bolus infusion of fentanyl 50 micrograms 15 minutes before the end of the surgery. After surgery she was given a continuous epidural infusion of fentanyl 50 to 70 micrograms/hour for 4 days to control postoperative pain, also without problems.[3] Similarly, another report describes 2 patients who had stopped taking **phenelzine** 36 hours and 10 days before undergoing uneventful cardiac surgery using fentanyl, pancuronium and 100% oxygen.[4] Four further patients taking **tranylcypromine**, **isocarboxazid**, or **pargyline** had no adverse reactions to fentanyl given during surgery (3 cases) and/or for postoperative pain relief (3 cases).[5]

In contrast, a man taking **tranylcypromine** who received fentanyl during and after surgery developed postoperative hypertension, hyperthermia, and severe shivering, followed by resistant hypotension. He later died.[6] Another patient taking **phenelzine** who underwent cardiac surgery, with anaesthesia maintained by fentanyl and midazolam, developed hypertension and supraventricular tachycardia, which did not respond to digoxin and esmolol. About 15 minutes after stopping the fentanyl/midazolam and starting enflurane, the haemodynamics gradually improved, and analgesia was subsequently managed with ketorolac without problems.[7]

(c) Remifentanil

A patient taking **phenelzine** was given remifentanil for the maintenance of anaesthesia without adverse effect. An adverse interaction was considered unlikely with this combination.[8]

(d) Sufentanil

A 43-year-old woman taking **tranylcypromine** 60 mg daily underwent general anaesthesia with sufentanil, isoflurane, and nitrous oxide without problem.[9]

Mechanism, importance and management

Fentanyl has been used safely in a number of patients receiving MAOIs. However, a fatality due to a serotonin-like syndrome has occurred in a patient taking an MAOI given fentanyl, and another case of hypertension and tachycardia has occurred. The authors of one of these reports, considered that there was insufficient evidence to conclude that patients taking MAOIs can be given fentanyl safely, and call for all cases of combined use to be reported.[6] Case reports also describe the safe use of alfentanil, remifentanil, and sufentanil. However, some UK manufacturers of fentanyl patches,[10] lozenges,[11] and injection[12] contraindicate their concurrent use with, or within 14 days of stopping, an MAOI. The UK manufacturer of alfentanil similarly contraindicates MAOIs,[13] and the US manufacturer recommends fentanyl patches are not to be used within 14 days of taking MAOIs.[14]

Note that fentanyl and related drugs are frequently used during surgery, and it is generally considered that MAOIs should be discontinued 2 weeks before surgery, see 'Anaesthetics, general + MAOIs and related drugs', p.112.

MAOIs + Opioids; Miscellaneous

Hypotension (profound in one case) has been seen in a few patients given morphine and an MAOI. One case of hypotension and stupor has occurred with papaveretum. Single cases of the safe use of methadone and hydromorphone have also been described.

Clinical evidence

(a) Hydromorphone

No problems were encountered when a patient taking **tranylcypromine** was given hydromorphone via a patient-controlled device for postoperative pain.[1] This patient also received sufentanil during surgery without problem.

(b) Methadone

A patient receiving methadone 30 mg daily was successfully and uneventfully treated for depression with **tranylcypromine**, initially 10 mg daily gradually increased to 30 mg daily.[2]

(c) Morphine

A study in 15 patients who had been taking either **phenelzine**, **isocarboxazid**, **iproniazid** or *Parstelin* (**tranylcypromine** with trifluoperazine) for 3 to 8 weeks, had no changes in blood pressure, pulse rate or state of awareness when given test doses of up to 4 mg of intramuscular morphine. However, note that none of these patients showed an interaction with test doses of up to 40 mg of pethidine (meperidine).[3] One other study reported no adverse interaction in 3 patients taking **isocarboxazid** when they were given morphine premedication,[4] and a further study revealed no problems in 9 patients taking **tranylcypromine** who were given morphine for postoperative pain relief.[5] Another patient taking **phenelzine** was uneventfully treated with morphine postoperatively.[6] Two further patients taking MAOIs, who reacted adversely to pethidine,[7,8] had not previously done so when given morphine. In an early report, intramuscular morphine was given without apparent problem to 5 patients who had developed severe headache while taking **tranylcypromine**.[9] Another author briefly noted that he knew of about 10 cases where morphine had been used in patients taking MAOIs with no adverse effects except a more prolonged morphine action.[10]

However, a patient taking **tranylcypromine** 40 mg and trifluoperazine 20 mg daily and undergoing a preoperative test with morphine, developed pin point pupils, became unconscious and unresponsive to stimuli, and had a systolic blood pressure fall from 160 to 40 mmHg after receiving a total of 6 mg of morphine intravenously. Within 2 minutes of being given naloxone 4 mg intravenously, the patient was awake and rational with a systolic blood pressure fully restored.[11] A moderate fall in blood pressure (from 140/90 to 90/60 mmHg) was seen in another patient taking an MAOI and given morphine,[12] and a brief episode of hypotension treated with phenylephrine occurred in a patient taking **phenelzine** receiving continuous epidural morphine during surgery.[5]

(d) Papaveretum

A 54-year-old woman taking **phenelzine** was given papaveretum 10 mg as premedication, and 50 minutes later she was found to be unrousable, sweating and hypotensive.[13]

Mechanism, importance and management

Some limited evidence suggests that patients taking MAOIs who reacted adversely with pethidine (meperidine) did not do so when given morphine,[7,8] and quite a number of reports describe the safe uneventful use of morphine and MAOIs. The few hypotensive reactions cited here[5,11,12] are of a different character to the severe reaction seen with 'pethidine', (below), and appear to be rare. However, many manufacturers of morphine have contraindicated its concurrent use with, or within 2 weeks of stopping an MAOI.[14-16] In contrast, the manufacturers of one morphine preparation note that as severe CNS excitation or depression (hypertension or hypotension) has been seen when pethidine was given with an MAOI, consideration should be given to using a reduced morphine dose in patients taking MAOIs.[17]

Similarly, the manufacturers of several opioids contraindicate their use both with, and within 14 days, of the use of an MAOI. These include **codeine**,[18] diamorphine,[19] hydromorphone,[20] methadone,[21] and oxycodone.[22]

However, information is conflicting, and the manufacturers of other opioids just advise caution if MAOIs are also given. These include **codeine** (increased effects of both drugs),[23] and **dihydrocodeine**.[24]

Some authors recommend lower initial dosages of morphine or oxycodone, frequent monitoring, and gradual upward dose titration.[25] One author suggests that morphine, codeine, and oxycodone do not possess serotonin reuptake inhibitor activity and would therefore not be expected to cause serotonin syndrome when given with MAOIs.[26] In contrast, 'pethidine', (below), 'tramadol', (p.1382), 'dextropropoxyphene', (p.1380), and methadone appear to be weak serotonin reuptake inhibitors, and these drugs, with the exception of methadone, have been implicated in reports of serotonin toxicity.[26]

Clearly the advice is somewhat conflicting, with some taking a more cautious approach than others. If the decision is taken to give an opioid to a patient taking an MAOI, it would seem prudent to choose one that appears to lack serotonergic activity (e.g. codeine, morphine, oxycodone) wherever possible. Monitor concurrent use carefully for any signs of adverse effects.

MAOIs or RIMAs + Opioids; Pethidine (Meperidine)

The concurrent use of pethidine and MAOIs has resulted in a serious and potentially life-threatening reaction in several patients. Excitement, muscle rigidity, hyperpyrexia, flushing, sweating and unconsciousness can occur very rapidly. Respiratory depression and hypertension or hypotension have also been seen. A possible case of serotonin syndrome has been seen in a patient given moclobemide and pethidine (with other serotonergic drugs).

Clinical evidence

(a) MAOIs

Severe, rapid and potentially fatal toxic reactions, both excitatory and depressant can occur when MAOIs are given with pethidine:

A woman stopped taking **iproniazid** 50 mg twice daily and about a day and a half later became restless and incoherent almost immediately after being given pethidine 100 mg for chest pain. She was comatose within 20 minutes. An hour after receiving the injection she was flushed, sweating and showed Cheyne-Stokes respiration. Her pupils were dilated and unreactive. Deep reflexes could not be initiated and plantar reflexes were extensor. Her pulse rate was 82 bpm and blood pressure 156/110 mmHg. She was rousable within 10 minutes of receiving an intravenous injection of prednisolone hemisuccinate 25 mg. A very similar reaction also occurred in another patient.[1]

A woman who, unknown to her doctor, was taking **tranylcypromine**, was given pethidine 100 mg. Within minutes she became unconscious, noisy and restless, having to be held down by 3 people. Her breathing was stertorous and the pulse impalpable. Generalised tonic spasm developed, with ankle clonus, extensor plantar reflexes, shallow respiration and cyanosis. On admission to hospital she had a pulse rate of 160 bpm, a blood pressure of 90/60 mmHg and was sweating profusely (temperature 38.3°C). Her condition gradually improved and 4 hours after admission she was conscious but drowsy. Recovery was complete the next day.[2]

Other cases of this interaction have been reported in patients taking **iproniazid**,[3-5] **pargyline**,[6,7] **phenelzine**,[8-13] and **mebanazine**.[14] Fatalities have occurred. One of 8 patients taking an MAOI and given a 5-mg test dose of pethidine experienced a drop in systolic blood pressure of 30 mmHg and a rise in pulse rate of 20 bpm.[15] However, a study in 15 patients who had been taking **phenelzine**, **isocarboxazid**, **iproniazid** or *Parstelin* (**tranylcypromine** with trifluoperazine) for 3 to 8 weeks, found no changes in blood pressure, pulse rate or state of awareness with test doses of up to 40 mg of pethidine.[16] Similarly, no major problems were noted in a retrospective review of 45 episodes of anaesthesia in patients taking **isocarboxazid** who were given pethidine as part of premedication.[17]

(b) RIMAs

One report suggests that on the basis of *animal* studies the combination of **moclobemide** and pethidine should be avoided or used with caution.[18] A report of suspected serotonin syndrome in a 73-year-old woman, given pethidine in addition to her usual treatment with **moclobemide** 750 mg daily, nortriptyline 100 mg daily and lithium 750 mg daily, adds some weight to this suggestion.[19]

Mechanism

Not understood, despite the extensive studies undertaken.[20-22] The reaction has proved difficult to study in *animals*, since mice appear to be more sensitive to the reaction than humans. There is some evidence that the reactions may be due to an increase in levels of 5-HT within the brain, causing 'serotonin syndrome', (p.9). Tramadol, an opioid with additional noradrenergic and serotonergic properties, has clearly caused the serotonin syndrome when used with MAOIs, see 'tramadol', (below).

Importance and management

The interaction between pethidine and the MAOIs, which was first observed in the mid-1950s, is based on case reports. It is serious and potentially fatal. Its incidence is unknown, but it is probably quite low, because one study that attempted to produce the interaction by giving increasing test doses of pethidine to 15 patients taking various MAOIs did not show the interaction.[16] It may therefore be an idiosyncratic reaction. Nevertheless, it would be imprudent to give pethidine to any patient taking an MAOI. Bear in mind that the older MAOIs are all essentially irreversible so that an interaction is possible for many days after their withdrawal (at least 2 weeks is the official advice).

Although information is sparse, the manufacturer of moclobemide contraindicates the use of pethidine.[23] As moclobemide is a reversible inhibitor of MAO it is unlikely to interact 48 hours after it has been stopped.

Sensitivity test

A sensitivity test has been suggested,[15] but given the fact that there are many alternatives to pethidine and MAOIs readily available, and given that a drop in systolic blood pressure of 30 mmHg has been reported even with the first step of the test dose (5 mg of pethidine)[15] it would seem prudent to avoid the combination. Also, the test dose procedure is unlikely to be suitable when opioids are required in an emergency situation.

MAOIs or RIMAs + Opioids; Tramadol

Serotonin syndrome developed in one patient taking iproniazid and tramadol, and delirium occurred in another patient given tramadol shortly after stopping phenelzine. A fatal case of possible serotonin syndrome occurred in a patient taking tramadol, moclobemide and clomipramine.

Clinical evidence, mechanism, importance and management

Serotonin syndrome (myoclonus, tremor, sweating, hyperreflexia, tachycardia) developed in a patient taking **iproniazid** when tramadol was also given. When the tramadol was stopped the patient recovered within 48 hours.[1] Another single case report describes the development of severe delirium in a patient within 3 days of stopping long term treatment with **phenelzine** 45 mg daily and starting intramuscular tramadol 100 mg three times daily. The patient became anxious and confused, and developed visual hallucinations and persecutory ideation. The symptoms disappeared within 48 hours of stopping the tramadol.[2] Another report suggests that tramadol may have contributed to the development of a fatal case of serotonin syndrome in a patient abusing tramadol, **moclobemide** and clomipramine.[3]

Information is limited, but moclobemide, the MAOIs and tramadol are known to have serotonergic effects. The UK manufacturers contraindicate concurrent use,[4] whereas the US manufacturers advise great caution if tramadol is given with an MAOI.[5] In practice this probably means monitoring closely for signs of 'serotonin syndrome', (p.9).

MAOIs + Rauwolfia alkaloids or Tetrabenazine

Central excitation and possibly hypertension can occur if rauwolfia alkaloids are given to patients already taking an MAOI, but is less likely if the rauwolfia alkaloid is given first. Theoretically additive blood-pressure lowering effects are also a possibility. The use of drugs that have the potential to cause depression, such as the rauwolfia alkaloids or tetrabenazine, is generally contraindicated in patients needing treatment for depression.

Clinical evidence

A woman with a history of manic depression who had been in a depressed phase for 5 years was given **nialamide** 100 mg three times daily. Two days later, **reserpine** 500 micrograms three times daily was also started. The following day she became frankly hypomanic and almost immediately went into mania.[1]

In another report,[2] a patient who started to take **tetrabenazine** 10 mg three times daily, 2 days after stopping a week of treatment with **nialamide** 25 mg daily, collapsed 6 hours after the first **tetrabenazine** dose, and demonstrated epileptiform convulsions, partial unconsciousness, rapid respiration and tachycardia. He recovered within 15 minutes, but 3 days later he had a similar attack and the **tetrabenazine** was stopped.

Another author states that the use of **reserpine** or **tetrabenazine** after pretreatment with **iproniazid** can lead to a temporary disturbance of affect and memory, associated with autonomic excitation, delirious agitation, disorientation and illusions of experience and recognition, which lasts for up to 3 days.[3,4]

A prolonged period of increased motor activity after starting **reserpine** ('reserpine-reversal') possibly occurred in 3 patients with schizophrenia given firstly **phenelzine** for 12 weeks,, when compared with patients given **reserpine** who had not received an MAOI. Their blood pressures rose slightly and persistently, and their psychomotor activity was considerably increased, lasting in two cases throughout the 12-week period of concurrent treatment.[5]

Theoretically, **reserpine** could cause hypertension in patients taking non-selective MAOIs (see Mechanism). On the basis of this the US manufacturer of **tranylcypromine**[6] contraindicates concurrent use. Conversely, the UK manufacturer of **isocarboxazid**[7] mentions that it may potentiate the hypotensive effect of **reserpine** (MAOIs alone can have hypotensive effects).

Mechanism

Rauwolfia alkaloids, such as reserpine, cause adrenergic neurones to become depleted of their normal stores of noradrenaline (norepinephrine). In this way they prevent or reduce the normal transmission of impulses at the adrenergic nerve endings of the sympathetic nervous system, and thereby act as antihypertensives. Since the brain also possesses adrenergic neurones, failure of transmission in the CNS could account for the sedation and depression observed with these drugs. If rauwolfia alkaloids are given to patients already taking an MAOI, large amounts of accumulated noradrenaline can be released throughout the body. In the brain, 5-HT is also released. The release of these substances results in marked central excitation and hypertension. This would account for the case reports cited and the effects seen in *animals*.[8-10] These stimulant effects are sometimes called 'reserpine-reversal' because instead of the expected sedation or depression, excitation or delayed depression is seen. It depends upon the order in which the drugs are given.

Importance and management

The use of drugs that have the potential to cause depression is generally contraindicated in patients needing treatment for depression. However, one report suggests that if concurrent use is considered desirable, the MAOIs should be given after, and not before the rauwolfia alkaloid, so that sedation rather than excitation will occur.[11] Bear in mind the possibility of hypo- or hypertension.

MAOIs or RIMAs + SNRIs

Serious and potentially life-threatening reactions (serotonin syndrome) can develop if venlafaxine and non-selective MAOIs (isocarboxazid, phenelzine, tranylcypromine) are given concurrently, or even sequentially if insufficient time is left in between. Serotonin syndrome has also been reported with moclobemide and venlafaxine, but it has usually occurred during overdose, and there is also a possible case with moclobemide and duloxetine. There is a possible risk of serotonin syndrome developing when duloxetine is taken with, or shortly after, MAOIs. Milnacipran is expected to interact similarly.

Clinical evidence

A. Duloxetine

A 46-year-old woman developed symptoms which were considered to be indicative of a mild form of serotonin syndrome shortly after taking duloxetine 60 mg. The previous day she had taken the last dose of a course of treatment with **moclobemide** 600 mg daily. Her symptoms included restlessness, tremor, dizziness, headache and tics-like facial movements. On the second day of duloxetine treatment her blood pressure rose to 130/90 mmHg.[1] Duloxetine was stopped, and **moclobemide** restarted uneventfully after a one-week washout period.[1] Note that a rise in blood pressure is a known adverse effect of duloxetine alone.[2]

B. Venlafaxine

(a) MAOIs

1. Isocarboxazid. A man with recurrent depression taking isocarboxazid 30 mg daily was also given venlafaxine 75 mg. After the second dose he developed agitation, hypomania, diaphoresis, shivering and dilated pupils. These symptoms subsided when the venlafaxine was stopped. He subsequently developed myoclonic jerks and diaphoresis when given both drugs.[3]

2. Phenelzine. A woman who had stopped taking phenelzine 45 mg daily 7 days previously, developed sweating, lightheadedness and dizziness within 45 minutes of taking a single 37.5-mg dose of venlafaxine. In the emergency department she was found to be lethargic, agitated and extremely diaphoretic. The agitation was treated with lorazepam. A week later, after she had recovered, she again started taking the same regimen of venlafaxine without problems.[4] A man developed serotonin syndrome when he started venlafaxine the day after he stopped taking phenelzine,[5] and a woman developed serotonin syndrome within an hour of taking phenelzine and venlafaxine together.[6] Four other patients similarly developed the reaction when phenelzine was replaced by venlafaxine.[7]
Twelve days after an overdose of phenelzine (53 tablets of 15 mg), benzatropine, haloperidol and lorazepam, a 31-year-old man was given venlafaxine 75 mg every 12 hours in addition to existing treatment with olanzapine and diazepam. About an hour after the first dose, he developed leg shakiness and stiffness, diaphoresis, blurred vision, difficulty breathing, chills, nausea and palpitations. Venlafaxine and olanzapine were discontinued and the man recovered within 24 hours, after treatment with intravenous fluids, propranolol and paracetamol.[8]

3. Tranylcypromine. A woman who had been taking tranylcypromine for 3 weeks developed a serious case of serotonin syndrome within 4 hours of inadvertently taking a single tablet of venlafaxine. She recovered within 24 hours, when treated with ice packs, a cooling blanket, diazepam and dantrolene.[9] Serotonin syndrome developed in a man taking tranylcy-

promine within 2 hours of taking half a venlafaxine tablet,[10] and another case of serotonin syndrome has been described in a man taking tranylcypromine 60 mg daily who accidentally took venlafaxine 300 mg.[11] This case has also been published elsewhere.[12]

(b) Moclobemide

A 32-year-old man taking moclobemide 20 mg twice daily and diazepam developed serotonin syndrome 40 minutes after taking a single 150-mg dose of venlafaxine.[13] Serotonin toxicity (serotonin syndrome) occurred in 4 patients who took an overdose of moclobemide with venlafaxine (just 150 mg in one case and 750 mg in another). In this analysis of moclobemide overdoses, the risk of developing serotonin toxicity was significantly increased in patients who also took another serotonergic drug (52%; 11 of 21 patients), compared with 3% taking moclobemide alone. Venlafaxine was taken in 4 of the 11 cases mentioned.[14] Another man very rapidly developed serotonin syndrome after taking considerable overdoses of moclobemide (3 g) and venlafaxine (2.625 g).[15]

Mechanism

Serotonin syndrome is thought to occur because duloxetine and venlafaxine can inhibit serotonin reuptake (their antidepressant effect is related to this activity), and MAOIs and RIMAs inhibit the metabolism of serotonin. The result is an increase in the concentrations of serotonin apparently causing overstimulation of the 5-HT_{1A} receptors in the brain and spinal cord. For a further discussion of serotonin syndrome, see under 'Additive or synergistic interactions', (p.9).

Importance and management

The interaction with venlafaxine is established, serious and potentially life-threatening. The manufacturers of venlafaxine note that in some cases this interaction has been fatal. They recommend that venlafaxine should not be used in combination with an MAOI or within 14 days of stopping treatment with the MAOI.[16,17] Based on the half-life of venlafaxine they say that at least 7 days should elapse between stopping venlafaxine and starting an MAOI. The manufacturers do not distinguish in this recommendation between the irreversible older non-selective MAOIs and the RIMAs such as moclobemide. In one of the studies it was suggested that a wash-out period of several weeks is required between stopping MAOIs such as phenelzine and initiating a second serotonergic drug such as venlafaxine.[8]

Similarly, it is recommended that duloxetine[2,18,19] and **milnacipran**[20] should not be used in combination with an MAOI or within 14 days of stopping treatment with an MAOI. Based on the half-life of duloxetine, the manufacturers advise that at least 5 days should elapse between stopping duloxetine and starting an MAOI,[2,18,19] and the manufacturer of milnacipran recommends at least one week.[20]

The use of moclobemide is not recommended with duloxetine, but no specific advice is given regarding a washout period.[2,18] Similarly, the manufacturer of milnacipran also advises against the use of moclobemide, but they say that if the combination cannot be avoided, careful clinical monitoring is required, starting with the minimum recommended dose.[20]

MAOIs or RIMAs + SSRIs

A number of case reports describe serotonin syndrome in patients given SSRIs with MAOIs: some have been fatal. Some studies suggest that moclobemide may not interact with the SSRIs, but there have also been case reports of serotonin syndrome. A suitable washout interval is needed when switching between MAOIs or RIMAs and SSRIs.

Clinical evidence

A. MAOIs

(a) Fluoxetine

A very high incidence (25 to 50%) of adverse effects occurred in 12 patients taking fluoxetine 10 to 100 mg daily with either **phenelzine** 30 to 60 mg daily or **tranylcypromine** 10 to 140 mg daily, and in 6 other patients who started one of these MAOIs 10 days or more after stopping fluoxetine. There were mental changes such as hypomania, racing thoughts, agitation, restlessness and confusion. The physical symptoms included myoclonus, hypertension, tremor, teeth chattering and diarrhoea.[1]

A detailed review of cases reported to the manufacturers described 8 acute cases, 7 of them fatal, in patients given fluoxetine with either **tranylcypromine** or **phenelzine**.[2] Uncontrollable shivering, teeth chattering, double vision, nausea, confusion, and anxiety developed in a woman given **tranylcypromine** after stopping fluoxetine. The problem resolved within a day of stopping the **tranylcypromine**, and did not recur when fluoxetine was tried again 6 weeks later.[3]

A number of other reports describe similar reactions in patients given fluoxetine and **tranylcypromine**,[3-8] some occurring up to 6 weeks after the SSRI was stopped,[6] and several resulting in fatalities.[3,7]

(b) Sertraline

A man taking **tranylcypromine** and clonazepam was also given sertraline 25 to 50 mg daily. Within 4 days he began to experience chills, increasing confusion, sedation, exhaustion, unsteadiness and incoordination. Other symptoms included impotence, urinary hesitancy and constipation. These problems rapidly resolved when the sertraline was stopped and the **tranylcypromine** dosage reduced from 30 to 20 mg daily.[9]

A woman with a major depressive disorder taking lithium, thioridazine, doxepin and **phenelzine** was also given sertraline 100 mg daily for worsening depression. Within 3 hours she became semi-comatose, with a temperature of 41°C, a heart rate of 154 bpm and symptoms of rigidity and shivering. She was treated with diazepam, midazolam, ice packs and dantrolene.[10] Two other similar cases, involving the use of sertraline with **isocarboxazid**[11] and **phenelzine**[12] have been reported. The latter case was fatal.[12] Another case of mild serotonin syndrome (managed with cyproheptadine) occurred in a woman who took a single dose of sertraline 11 days after stopping **isocarboxazid**.[13]

B. RIMAs

(a) Citalopram

A 34-year-old man who had been taking **moclobemide** 100 mg every 8 hours for several months was switched to citalopram 20 mg daily without a washout period. An hour later he started getting agitated and had involuntary movements of the legs, which progressed to generalised rigidity. Apart from a heart rate of 100 bpm all other vital signs were normal. He was treated with benzodiazepines and recovered uneventfully.[14] Three patients developed serotonin syndrome (tremor, convulsions, hyperthermia, unconsciousness) and died 3 to 16 hours after taking overdoses of **moclobemide** and citalopram.[15] Other cases of serotonin syndrome have occurred after overdoses of **moclobemide** and citalopram:[16,17] one also included **sertraline** and sumatriptan.[16]

(b) Fluoxetine

A placebo-controlled study in 18 healthy subjects found that the use of fluoxetine 20 mg with **moclobemide** 100 to 600 mg daily for 9 days did not appear to result in an adverse interaction.[18] Other studies in healthy subjects and patients similarly found no evidence of serotonin syndrome.[19,20]

A post-marketing analysis found that at least 30 patients switched from fluoxetine to **moclobemide** within a week had experienced no adverse effects.[18,21]

However, 3 patients have developed serotonin syndrome[22-24] and one developed agitation and confusion[25] following the use of **moclobemide** and fluoxetine. A fatal case of serotonin syndrome occurred in a patient who took an overdose of **moclobemide**, fluoxetine, and clomipramine,[26] and another patient taking **moclobemide** developed serotonin syndrome after taking an overdose of fluoxetine.[27] A study suggests that the combination may cause a high rate of adverse effects (insomnia, dizziness, nausea and headache).[22]

A double-blind study in 41 healthy subjects found that when they were given fluoxetine 40 mg daily for 7 days, then 20 mg for 9 days, immediately followed by **befloxatone** (2.5, 5, 10 or 20 mg daily) for 5 days, no unusual adverse reactions occurred and no changes in body temperature, haemodynamics or ECGs were seen.[28]

(c) Fluvoxamine

When 13 of 22 healthy subjects given fluvoxamine 100 mg daily for 9 days were also given **moclobemide**, in increasing doses of 50 to 400 mg daily, from days 7 to 10, no serious adverse reactions occurred. Any adverse events were mild to moderate (some increase in headaches, fatigue, dizziness, all of which may occur with both drugs alone) and there was no evidence of serotonin syndrome.[18,29] An open study in 6 depressed patients given **moclobemide** 225 to 800 mg daily and fluvoxamine 50 to 200 mg daily found a marked improvement in depression. Insomnia was the commonest adverse effect (treated with trazodone) but none of the patients showed any evidence of serotonin syndrome.[30] Similar results were found in other studies.[20,31] However, a fatal case of serotonin syndrome occurred in a woman who took an overdose of **moclobemide** and fluvoxamine, and another fatal overdose was attributed to the same combination.[32]

(d) Paroxetine

An open 6-week study in 19 patients with major depression taking paroxetine (or fluoxetine) 20 mg daily, to which **moclobemide** up to 600 mg daily was added, indicated that these combinations were possibly effective.[33] An extension of this study with 50 patients is reported elsewhere.[22] However, a range of adverse effects occurred in some patients, the clearest one being insomnia, and serotonin syndrome was seen in one patient.[22,33] Conversely, serotonin syndrome was not seen in another study, where low initial doses and gradual up-titration of both paroxetine and **moclobemide** was used.[20] Two possible cases of mild serotonin syndrome occurred in women taking **moclobemide** within 2 to 24 hours of also starting paroxetine.[34] Similarly, cases of severe serotonin syndrome have been reported with overdoses of **moclobemide** and paroxetine.[35,36]

(e) Sertraline

In one study, 31 severely ill patients were given **moclobemide** 35 to 800 mg daily with SSRIs, including sertraline 25 to 100 mg daily, initially using lower than usual starting doses of both drugs, and then gradually titrating them slowly upwards. The other SSRIs used were fluoxetine, fluvoxamine and paroxetine. There was no evidence of serotonin syndrome.[20] An open study in 5 depressed patients given **moclobemide** 150 to 600 mg daily and sertraline 25 to 200 mg daily found improvements ranging from minimal to complete remission. Insomnia was the commonest adverse effect (treated with trazodone) but none of the patients showed any evidence of serotonin syndrome.[30] However, one case of possible serotonin syndrome occurred in a woman who took an overdose of **moclobemide** and sertraline,[34] and another possible case occurred after an overdose of **moclobemide**, **citalopram**, sertraline and sumatriptan.[16] Similarly, a fatality has been reported with an overdose of **moclobemide**, sertraline and pimozide, with blood levels suggesting that none of the drugs individually would have been fatal.[37]

(f) Unspecified SSRIs

Serotonin toxicity (serotonin syndrome) occurred in 5 patients who took an overdose of **moclobemide** with an SSRI (specific drugs not mentioned). In this analysis of **moclobemide** overdoses, the risk of developing serotonin toxicity was significantly increased in patients who also took another serotonergic drug (52% (11 of 21 patients) who also took another serotonergic drug, compared with 3% taking moclobemide alone). Of the 11 cases mentioned 5 patients were taking SSRIs.[38]

Mechanism

MAO-A is involved in the metabolism of serotonin, so the combined use of MAOIs or RIMAs with SSRIs may lead to excessive serotonin levels, which can result in serotonin syndrome. For more information see 'serotonin syndrome', (p.9).

Importance and management

A reasonably well documented and established interaction. Severe, sometimes fatal interactions (serotonin syndrome or similar) have occurred when MAOIs were given with fluoxetine or sertraline. The incidence appears to be low, possibly as the combined use of any MAOI and any SSRI is contraindicated. In addition, at least 2 weeks should elapse between stopping any MAOI and starting any SSRI to allow for the effects of the MAOI to diminish. Moreover, the manufacturers of each SSRI give guidance on the appropriate intervals that should be left between stopping the SSRI and starting an MAOI; that is, 14 days for sertraline,[39,40] seven days for citalopram,[41] **escitalopram**,[42] fluvoxamine[43] or paroxetine[44] (14 days in the US),[45-47] and at least 5 weeks for fluoxetine, with an even longer interval if long-term or high-dose fluoxetine has been used.[48,49]

The RIMAs (e.g. moclobemide) also have serotonergic effects, and so they are unlikely to be any safer than the non-selective MAOIs in regard to interactions with SSRIs. The few cases of serotonin syndrome cited with therapeutic doses of this combination confirm that it is not necessarily safe. The combination may be particularly problematic in overdose, and negates the generally benign course of moclobemide overdose alone. It should be noted that the manufacturer of moclobemide contraindicates its use with SSRIs.[50] Because the effects of moclobemide are readily reversible, only one day need elapse between stopping moclobemide and starting an SSRI. However, if stopping an SSRI and starting moclobemide, the same intervals are required as for the irreversible MAOIs.

For the management of serotonin syndrome, see Importance and management under 'MAOIs or RIMAs + Tricyclic and related antidepressants', p.1391.

MAOIs or RIMAs + Sympathomimetics; Amfetamines and related drugs

The concurrent use of non-selective MAOIs with amfetamines and related drugs can result in a potentially fatal hypertensive crisis and/or serotonin syndrome. Interactions have been reported for amfetamine, dexamfetamine, metamfetamine, and methylphenidate. Interactions have also been reported with the illicit drug ecstasy (MDMA, methylenedioxymethamfetamine) when taken with phenelzine or moclobemide.

Clinical evidence

A. MAOIs

(a) Amfetamines

A 30-year-old depressed woman who was taking **phenelzine** 15 mg three times daily and trifluoperazine 2 mg at night, acquired some **dexamfetamine sulfate** tablets from a friend and took 20 mg. Within 15 minutes she complained of severe headache, which she described as if "her head was bursting". An hour later her blood pressure was 150/100 mmHg. Later she became comatose with a blood pressure of 170/100 mmHg and died. A postmortem examination revealed a brain haemorrhage.[1]

This interaction has also been reported with:

- **Amfetamine** (single intravenous or oral dose) with **phenelzine**[2,3] or tranylcypromine.[4]
- **Amfetamine** and **dexamfetamine** with phenelzine.[5,6]
- **Metamfetamine** (single intravenous dose) with **isocarboxazid**,[7,8] **phenelzine**,[7,9] or tranylcypromine.[7,10]

A woman who had been addicted to high-dose **dexamfetamine**/amobarbital was hospitalised and had the **dexamfetamine**/amobarbital withdrawn. Five days later she was given a single dose of **tranylcypromine** and within an hour had a 20-minute episode of hypertension, tachycardia, headache, sweating, lacrimation and altered consciousness, which abated without treatment. She had similar attacks at 2-hourly intervals over about 5 days, which gradually became milder and shorter.[11]

Extreme hyperpyrexia, apparently without hypertension, has been described in a woman who took **tranylcypromine** with **dexamfetamine**/amobarbital. She developed progressive agitation, diaphoresis, hyperkinesis, opisthotonus, coma and convulsions, but recovered following the use of an ice bath and other supportive measures.[12,13]

(b) Dexfenfluramine or Fenfluramine

A woman taking **phenelzine** developed severe headache, neck stiffness and nausea within an hour of taking fenfluramine 20 mg, and then collapsed and remained stuporous for about 4 hours. This reaction was considered similar to that seen with MAOIs and amfetamines.[14]

The manufacturer recommended that fenfluramine should not be used in patients with a history of depression, or during treatment with antidepressants (especially the MAOIs), and there should be an interval of 3 weeks between stopping the MAOIs and starting fenfluramine.[15] The manufacturer of dexfenfluramine similarly contraindicated its use with or within 2 weeks of stopping an MAOI,[16] and advised waiting 3 weeks between stopping dexfenfluramine and starting an MAOI. This is due to the potential risk of the serotonin syndrome,[17,18] which has rarely occurred with the concurrent use of two or more serotonergic drugs (see 'serotonin syndrome', (p.9)). The manufacturer of dexfenfluramine and fenfluramine had found no clinical evidence of serious problems with either of these drugs when taken with MAOIs,[19] so that the published warnings about possible interactions would appear to be based on theoretical considerations.

Note that dexfenfluramine and fenfluramine have generally been withdrawn because their use was found to be associated with a high incidence of abnormal echocardiograms indicating abnormal functioning of heart valves.

(c) Ecstasy (MDMA, methylenedioxymethamfetamine)

Marked hypertension, diaphoresis, altered mental status and hypertonicity (slow forceful twisting and arching movements) occurred in one patient taking **phenelzine** with ecstasy.[20] Increased muscle tension, decorticate-like posturing (arms, wrists and fingers bent inwards and legs extended), fever, tachycardia and coma occurred in another patient taking **phenelzine**, 15 minutes after drinking juice containing ecstasy.[21] Both patients recovered.[20,21]

(d) Methylphenidate

A patient started taking **tranylcypromine**, then 4 days later methylphenidate was added. After 15 days of concurrent use he had a hypertensive crisis and both drugs were stopped.[22] In a study of the use of **phenelzine** as an antagonist to stimulants, 3 patients also took oral or intravenous methylphenidate and all three experienced moderate to severe headache.[6] An episode of symptoms consistent with serotonin syndrome occurred in a man taking **isocarboxazid** and trazodone, 2 months after the dose of these drugs was increased and methylphenidate was added. He had experienced two similar episodes 4 and 8 weeks previously, which had each resolved spontaneously over 12 hours. All three drugs have serotonergic properties and were thought to have contributed to the reaction.[23]

Conversely, a man taking **tranylcypromine** for depression was successfully treated with methylphenidate for attention deficit/hyperactivity disorder (ADHD). He was given methylphenidate 2.5 mg daily, which was very gradually increased over a number of months to 45 mg daily. He was successfully treated with the combination for 6 months and periodic blood pressure measurements did not change significantly from baseline.[24] Another similar case of uneventful concurrent use has been described with **phenelzine** and methylphenidate.[25] No cases of hypertensive crisis were seen in 4 patients taking **tranylcypromine** or **phenelzine** when treated concurrently with methylphenidate for periods of 6 to 30 months.[26]

B. RIMAs

Four patients died after taking **moclobemide** and **ecstasy** (MDMA, methylenedioxymethamfetamine). The clinical evidence is limited, but in each

case the forensic pathologist concluded that the cause of death was the combined use of these drugs. It was suggested that what happened is consistent with the serotonin syndrome, although the evidence is fairly slim. Two patients had taken maximum therapeutic doses and two moderate overdoses of **moclobemide**. Note that **moclobemide** had not been prescribed to any of them. Post-mortem analysis also found the presence of **dextromethorphan** in one patient, which was thought to have contributed,[27] see also 'MAOIs or RIMAs + Dextromethorphan', p.1375.

Mechanism

The hypertensive reaction can be attributed to overstimulation of the adrenergic receptors of the cardiovascular system.[28] During treatment with non-selective MAOIs, large amounts of noradrenaline (norepinephrine) accumulate at adrenergic nerve endings not only in the brain, but also within the sympathetic nerve endings, which innervate arterial blood vessels. Stimulation of these latter nerve endings by sympathomimetic amines with indirect actions causes the release of the accumulated noradrenaline and results in the massive stimulation of the receptors. An exaggerated blood vessel constriction occurs and the blood pressure rise is proportionately excessive. Intracranial haemorrhage can occur if the pressure is so high that a blood vessel ruptures.[1]

Some of the reactions may also possibly be related to serotonin syndrome. Amfetamines act by releasing serotonin (and possibly also dopamine) from neurones in the brain, so that increased stimulation of the serotonin receptors occurs. This possibly explains their mood-modifying effects. MAOIs prevent the breakdown of serotonin within neurones so that more serotonin is available for release, and in excess this can apparently result in the toxic and even fatal serotonin syndrome. The RIMAs (such as moclobemide) appear to behave like the older non-selective MAOIs in this context.

Importance and management

The hypertensive reaction is a very well-documented, serious, and potentially fatal interaction, whereas the serotonin syndrome appears to be rarer. Patients taking any of the non-selective MAOIs should not normally take amfetamines, or related drugs such as methylphenidate. A possible exception to this prohibition is that under very well controlled conditions dexamfetamine and methylphenidate may sometimes be effectively (and apparently safely) used with MAOIs for refractory depression,[25,26,29] or ADHD.[24] Direct evidence implicating central stimulants such as 'mazindol', (p.1378), and 'modafinil', (p.1379), appears to be limited. Interactions with other central stimulants such as **diethylpropion**, **pemoline**, **phendimetrazine**, and **phenmetrazine** seem not to have been documented, but on the basis of their known pharmacology their concurrent use with the MAOIs should be avoided. Patients taking MAOIs should be warned to avoid the illicit use of amfetamines and ecstasy. It would also be prudent to avoid the use of moclobemide with amfetamines and related drugs, although the incidence of the interactions with moclobemide is unlikely to be as great as that seen with the non-selective MAOIs. In the cases with ecstasy, it seems likely that high doses of moclobemide were used to try to enhance the actions of the ecstasy, but these cases, nevertheless, show that combined use is potentially life threatening.

Treatment

For a brief mention of the treatment of hypertensive crisis, see Importance and Management under 'MAOIs or RIMAs + Sympathomimetics; Indirectly-acting', p.1388. For the management of fever and other symptoms of serotonin syndrome, see Importance and management under 'MAOIs or RIMAs + Tricyclic and related antidepressants', p.1391.

MAOIs or RIMAs + Sympathomimetics; Beta-agonist bronchodilators

An isolated case of tachycardia and apprehension occurred in an asthmatic taking phenelzine after salbutamol (albuterol) was added. Hypomania was seen in another asthmatic taking phenelzine when inhaled isoetarine was added. Hypertensive crisis occurred in a woman taking toloxatone and phenylephrine when she was given [oral] terbutaline.

Clinical evidence

(a) MAOIs

A report briefly describes a case of tachycardia and apprehension in a patient taking **phenelzine** when **salbutamol** (**albuterol**) was started (route of administration not stated).[1] Hypomania has been described in a patient taking **phenelzine** in the few weeks after starting inhaled **isoetarine** 680 micrograms up to every 4 hours.[2]

(b) RIMAs

A 72-year old woman taking long-term levothyroxine, **toloxatone** 400 mg daily (for 2 months), and **phenylephrine** (for 3 weeks) developed episodes of hypertension, sweating, tachycardia, and headache within 3 days after starting to take [oral] **terbutaline** 10 mg daily. She had extremely high plasma catecholamine levels. All drugs were stopped on admission to hospital and she recovered over 2 to 3 days.[3] An interaction between phenylephrine and toloxatone may have contributed to the effects seen. Consider also, 'MAOIs or RIMAs + Sympathomimetics; Phenylephrine', p.1390.

Mechanism

Note that drugs with directly-acting sympathomimetic effects (of which beta agonists are an example) do not normally interact to cause hypertension with MAOIs, see 'sympathomimetics; directly-acting', (p.1388). However, phenylephrine (which has some indirect actions, see 'sympathomimetics; phenylephrine', (p.1390)) may have contributed to the reaction between toloxatone and terbutaline, and the fact that terbutaline seems to have been given orally would also have contributed. The reaction resulting in hypomania is not understood.

Importance and management

These appear to be isolated cases, and are possibly not of general importance. Bear them in mind in the event of an unexpected response to treatment.

MAOIs or RIMAs + Sympathomimetics; Directly-acting

The pressor effects of adrenaline (epinephrine), isoprenaline (isoproterenol), noradrenaline (norepinephrine) and methoxamine may be unchanged or only moderately increased in patients taking MAOIs. There is limited evidence that the increase may be somewhat greater in those who show a significant hypotensive response to the MAOI. Moclobemide does not appear to interact.

Clinical evidence

(a) MAOIs

In a randomised, placebo-controlled study in 12 healthy subjects, **phenelzine** 15 mg three times daily for 7 days had no effect on the dose of intravenous **noradrenaline** (**norepinephrine**) required to raise the systolic blood pressure by 25 mmHg. In addition, **phenelzine** had no effect on the diastolic blood pressure rises and heart rate reductions seen with **noradrenaline**. In this study, **phenelzine** itself had no effect on blood pressure or heart rate.[1]

Similarly, in an earlier study in two healthy subjects given **phenelzine** 15 mg three times daily and two given **tranylcypromine** 10 mg three times daily for 7 days, there was no significant change in pressor response to intravenous **adrenaline** (**epinephrine**) or **isoprenaline** (**isoproterenol**) after treatment with the MAOI. However, the tachycardia caused by **isoprenaline** was antagonised by the MAOIs (109 bpm with the MAOI versus 127 bpm without). No clinically significant potentiation of the pressor effect of **noradrenaline** was seen, although one of the subjects taking **tranylcypromine** had a twofold increase in the pressor response in the mid-range of **noradrenaline** concentrations infused, but not in the upper or lower ranges. None of these 4 subjects had a change in blood pressure or heart rate caused by the MAOI alone.[2] In yet another study in 3 healthy subjects given **tranylcypromine** for 8 to 14 days, the effects of intravenous **noradrenaline** were slightly increased, while with intravenous **adrenaline** a moderate two to fourfold increase in the effects on heart rate and diastolic pressure took place, but a less marked increase in systolic pressure was seen. Intravenous **isoprenaline** behaved very much like **adrenaline**, but there was no enhancement of systolic pressure. This study did not state the effect of the MAOI alone on blood pressure.[3]

A patient using 1% **adrenaline** eye drops twice daily had no increase in blood pressure or heart rate when given **tranylcypromine** 20 mg, rising to 50 mg daily.[4] Another patient taking **phenelzine** presented with severe anaphylaxis after taking two doses of flucloxacillin, and was initially treated unsuccessfully with hydrocortisone, chlorphenamine and ranitidine because of concerns about using **adrenaline** with MAOIs. However, as her condition worsened she was given two 100-microgram boluses of intravenous **adrenaline**, with rapid improvement. No adverse reaction was noted.[5] In another study, one healthy subject given **phenelzine** for 8 days experienced a marked reduction in blood pressure, but showed no significant changes in pressor response to **noradrenaline**.[6]

In contrast, in a study in hypertensive patients who had postural hypotension after being given either **pheniprazine** (a formerly investigational older MAOI; 6 patients) or **tranylcypromine** (one patient), the dose of **noradrenaline** required to produce a 25 mmHg rise in systolic pressure was reduced by 62 to 87%. In three of these patients taking **pheniprazine** the dose of **methoxamine** was reduced by 61 to 70%, compared with that required in the absence of an MAOI. Three patients were later given **nialamide**: augmentation of the pressor response of **noradrenaline** or **methoxamine** only occurred in the one patient who had developed postural hypotension.[7]

(b) RIMAs

In a randomised, placebo-controlled study in 12 healthy subjects, **moclobemide** 100 mg three times daily for 7 days had no effect on the dose of intravenous **noradrenaline** (**norepinephrine**) required to raise the systolic blood pressure by 25 mmHg. In addition, **moclobemide** had no effect on the diastolic blood pressure rises and heart rate reductions seen with **noradrenaline**. In this study, **moclobemide** itself had no effect on blood pressure or heart rate.[1] A review paper also briefly mentions that **moclobemide** 600 mg daily for 3 weeks had no relevant effect on the heart rate response to intravenous **isoprenaline** (**isoproterenol**).[8]

Mechanism

These sympathomimetic amines act directly on the receptors at the nerve endings, which innervate arterial blood vessels, so that the presence of the MAOI-induced accumulation of noradrenaline within these nerve endings would not be expected to alter the extent of direct stimulation (contrast 'Sympathomimetics; indirectly-acting', (p.1388)). The enhancement seen in those patients whose blood pressure was lowered by the MAOI might possibly be due to an increased sensitivity of the receptors, which is seen if the nerves are cut, and is also seen during temporary 'pharmacological severance'.

Importance and management

The overall picture is that no clinically relevant enhancement of the effects of adrenaline (epinephrine), isoprenaline (isoproterenol), or noradrenaline (norepinephrine) occurs in patients taking MAOIs, although some uncertainty remains about those who show MAOI-induced hypotension (see below). The authors of three of the reports cited[2-4] are in broad agreement that problems are unlikely to occur, and others consider that intravenous adrenaline may be used in life-threatening situations in patients taking MAOIs, albeit with caution.[5] Others also consider that adrenaline in eye drops or adrenaline as a component of local anaesthesia in dental and other procedures may be used in patients receiving MAOIs,[4,9] and that there is no justification for the continued listing of an interaction between MAOIs and local anaesthetics with vasoconstrictors in US prescribing information.[9] It is worth noting that there are no case reports of interactions with these drugs.

The situation in patients who show a reduced blood pressure due to the use of an MAOI is less clear. One early study[7] found an increase in the pressor effects of noradrenaline and methoxamine in hypertensive patients who had developed orthostatic hypotension when taking pheniprazine or tranylcypromine. Bear this possibility in mind.

Moclobemide does not appear to alter the pressor response to noradrenaline.

Other directly-acting sympathomimetics, such as the 'beta-agonist bronchodilators', (p.1387) do not appear to interact. However, in contrast, the directly-acting sympathomimetic 'phenylephrine', (p.1390), may interact, but this is possibly due to an inhibition of its metabolism.

MAOIs or RIMAs + Sympathomimetics; Indirectly-acting

The use of indirectly-acting sympathomimetic amines concurrently with, and for 2 weeks after stopping, non-selective MAOIs can result in a potentially fatal hypertensive crisis. Note that these amines are commonly in many proprietary cough, cold and influenza preparations (e.g. ephedrine, phenylpropanolamine and pseudoephedrine), or for their vasoconstrictor effects in migraine (e.g. isometheptene). Indirectly-acting amines are also used parenterally for treating hypotension occurring during spinal anaesthesia (e.g. ephedrine, mephentermine, metaraminol). Potentially serious interactions have also been seen with moclobemide and indirectly-acting sympathomimetics.

Clinical evidence

(a) MAOIs

A study in 3 healthy subjects, given **phenelzine** 45 mg or **tranylcypromine** 30 mg daily for 5 to 14 days, found that the blood pressure rise following oral **ephedrine** 30 mg was enhanced. The maximal increase in mean arterial pressure was 22 mmHg (compared with 4 to 6 mmHg without the MAOI). A similar increase was seen up to 10 days after discontinuation of the MAOI. A similar increase in blood pressure was also seen in one of the subjects given intravenous **ephedrine** 2 mg per minute for 6 minutes.[1] In another subject given **tranylcypromine** 30 mg daily for 20 to 30 days, **phenylpropanolamine** in capsules or a linctus preparation caused a rapid and marked rise in blood pressure to 210/140 mmHg within 2 hours, necessitating the use of phentolamine to reverse the effect.[2] Slow-release **phenylpropanolamine** caused a smaller and more gradual rise to 160/100 mmHg over 2 hours.[2] Similarly, the pressor effect of intravenous **phenylpropanolamine** was potentiated by about four to fivefold (systolic) and three to tenfold (diastolic) in 3 subjects given **tranylcypromine** 30 mg daily for 8 to 14 days, and the reflex bradycardia was potentiated by about 2.5- to 6-fold.[3]

Numerous case reports describe similar rapid and serious rises in blood pressure, accompanied by tachycardia, chest pains and severe occipital headache when MAOIs were given with indirectly-acting sympathomimetics. Other symptoms that have occurred include neck stiffness, flushing, sweating, nausea, vomiting, hypertonicity of the limbs, and sometimes epileptiform convulsions. Fatal intracranial haemorrhage, cardiac arrhythmias and cardiac arrest have resulted.

This interaction has been reported between:

- oral **ephedrine** and **nialamide**[4]
- oral **isometheptene mucate** and **phenelzine**[5]
- intravenous **mephentermine** and **phenelzine**[6]
- intramuscular **metaraminol** and **pargyline**[7]
- oral **phenylpropanolamine** and **mebanazine**,[8,9] **pargyline**,[10] or **phenelzine**[8,9,11-14]
- and oral **pseudoephedrine** and **iproniazid**.[15]

Tachycardia and *hypotension*, then pyrexia has been described in a woman who took a single *Do-Do* tablet (**ephedrine**, caffeine, theophylline) the day after stopping **phenelzine**.[16] Similarly, fatal hyperpyrexia without hypertension occurred in a man taking **tranylcypromine**/trifluoperazine when he was given oral **ephedrine**,[17] although switching his MAOI without a full washout period may have caused, or contributed to, this reaction[18] (see 'MAOIs + MAOIs or RIMAs', p.1378). A woman taking **phenelzine** developed bradycardia of 40 bpm after taking one tablet of *Sinutab* (without codeine),[19] which probably contained **pseudoephedrine**.

(b) RIMAs

No interaction was seen in subjects taking **brofaromine** 75 mg twice daily for 10 days when given 75 mg of slow-release **phenylpropanolamine** (*Acutrim Late Day*), but immediate-release **phenylpropanolamine** in gelatin capsules caused a 3.3-fold increase in pressor sensitivity.[20] The pressor effects of high-dose oral **ephedrine** (two doses of 50 mg with a 4-hour interval) in 11 healthy subjects taking **moclobemide** 300 mg twice daily were increased about three to fourfold, and this resulted in an increase in palpitations and headache.[21,22]

Mechanism

The reaction can be attributed to over-stimulation of the adrenergic receptors of the cardiovascular system. During treatment with non-selective MAOIs, large amounts of noradrenaline (norepinephrine) accumulate at adrenergic nerve endings not only in the brain, but also within the sympathetic nerve endings, which innervate arterial blood vessels. Stimulation of these latter nerve endings, by sympathomimetic amines with indirect actions, causes the release of the accumulated noradrenaline and results in the massive stimulation of the receptors. An exaggerated blood vessel constriction occurs and the blood pressure rise is proportionately excessive. Intracranial haemorrhage can occur if the pressure is so high that a blood vessel ruptures. Directly-acting sympathomimetics do not cause this severe effect, see 'MAOIs or RIMAs + Sympathomimetics; Directly-acting', p.1388.

Importance and management

(a) MAOIs

A very well-documented, serious, and potentially fatal interaction. Patients taking any of the MAOIs should not normally take any sympathomimetic amine with indirect activity. These include ephedrine, isometheptene mucate, mephentermine, metaraminol, phenylpropanolamine and pseudoephedrine. Direct evidence implicating **methylephedrine** and **pholedrine** seems not to have been documented, but on the basis of their known pharmacology their concurrent use with the MAOIs should be avoided. There also appears to be no documented interactions between the MAOIs and **dopamine** (a sympathomimetic with both direct and indirect actions). Nevertheless, the manufacturers predict that the effects of dopamine will be potentiated. They suggest that patients who have been taking an MAOI should be given a starting dose of dopamine that is one-tenth of the usual dose.[23] Similarly, there appears to be a lack of data regarding **dopexamine**, possibly because the concurrent use of MAOIs is contraindicated.[24]

Note that some of the indirectly-acting amines, including ephedrine, phenylpropanolamine and pseudoephedrine, are used as vasoconstrictor decongestants in numerous oral non-prescription cough, cold and influenza preparations. Isometheptene is used in non-prescription analgesic preparations for migraine. Patients taking MAOIs should be strongly warned not to take any of these drugs concurrently or for 2 weeks after stopping their MAOI. Also, note that serious interactions have occurred because of confusion between non-prescription products with very similar names that contain different active ingredients.[13]

Physicians should also avoid the use of indirectly-acting vasoconstrictor amines such as ephedrine, mephentermine and metaraminol for reversing hypotension during spinal anaesthesia in patients taking MAOIs or patients who have stopped an MAOI within the previous 2 weeks.

(b) RIMAs

The data with high-dose ephedrine show that moclobemide is not free of this interaction, and the manufacturer of moclobemide[25] advises avoiding sympathomimetics such as ephedrine, **pseudoephedrine** and **phenylpropanolamine**. It would also be prudent to avoid moclobemide with any of the other indirectly-acting sympathomimetics cited here, although the severity of the interactions with moclobemide is unlikely to be as great as that seen with the MAOIs. For example, ephedrine and phenylephrine have been successfully and uneventfully used in the presence of moclobemide (omitted on the day of surgery) during anaesthesia to control hypotension.[26]

(c) Treatment

Hypertensive reactions have been controlled by intravenous phentolamine, phenoxybenzamine, intramuscular chlorpromazine, labetalol or sublingual nifedipine. The manufacturers of phenelzine state that on the basis of present evidence, slow intravenous injection of phentolamine is recommended.[27,28] However, it is advisable to refer to current guidelines on the management of hypertensive crises for up-to-date advice.

MAOIs or RIMAs + Sympathomimetics; Phenylephrine

The concurrent use of oral phenylephrine and the non-selective MAOIs can result in a potentially life-threatening hypertensive crisis. Phenylephrine is commonly found in non-prescription cough, cold and influenza preparations. The effects of parenteral phenylephrine may be approximately doubled by MAOIs. Some interaction occurs between phenylephrine and the RIMAs moclobemide or brofaromine, but the blood pressure response appears to be much smaller than that seen with the non-selective MAOIs.

Clinical evidence

(a) MAOIs

A study in 3 healthy subjects, given **phenelzine** 45 mg or **tranylcypromine** 30 mg daily for 7 days, found that the blood pressure rise following oral phenylephrine was markedly enhanced. On 2 of 3 occasions when 45 mg of phenylephrine was given orally, the rise in blood pressure became potentially disastrous and had to be reversed with phentolamine. On these two occasions the maximal increase in mean arterial pressure was 67 mmHg (compared with 1 or 11 mmHg without the MAOI). On the other occasion, the maximal increase in mean arterial pressure was 48 mmHg. The rise in blood pressure was accompanied by a severe headache. With 3 and 10 mg of phenylephrine, the maximal increase was 7 mmHg and 20 mmHg, respectively. After intravenous phenylephrine 3 mg was given over 20 minutes, the maximal increase in mean arterial pressure was 45 mmHg, compared with 23 mmHg without an MAOI.[1]

Another study describes a similar 2- to 2.5-fold increase in the pressor effects of *intravenous* phenylephrine following the use of **phenelzine** or **tranylcypromine**.[2]

A patient taking **tranylcypromine** who developed hypotension (40/0 mmHg) during surgery had an exaggerated pressor response (250/140 mmHg) when an intravenous infusion of phenylephrine 4 mg/500 mL was started.[3] However, in another report, repeated 100-microgram doses of intravenous phenylephrine were successfully used to treat hypotension in a patient taking an MAOI, without any hypertensive reaction.[4]

A case report of hypertension that was initially attributed to phenylephrine was later corrected to pseudoephedrine.[5]

(b) RIMAs

No clinically important interaction occurred in healthy subjects taking **brofaromine** 75 mg twice daily when they were given a single 2.5-mg dose of phenylephrine as nasal drops.[6] However, higher doses (exact amount not stated) did produce a blood pressure response,[6] with a maximum recorded diastolic blood pressure of 100 mmHg.

A study in 7 healthy subjects found that **moclobemide** 100 mg three times daily for one week had no effect on the increase in blood pressure induced by intravenous phenylephrine.[7] Another study reported similar results.[8] However, when **moclobemide** was given in a dose of 200 mg three times daily for up to 3 weeks the blood pressure response to infusions of phenylephrine was increased by up to 1.8-fold.[7] In one patient taking **moclobemide** (dose withheld on the morning of surgery), ephedrine and phenylephrine were used successfully and uneventfully to control hypotension during anaesthesia.[9]

A case of life-threatening hypertension[10] occurred in a patient taking **toloxatone**, non-prescription phenylephrine. Terbutaline was also taken, and may have contributed to the effects described, see 'MAOIs or RIMAs + Sympathomimetics; Beta-agonist bronchodilators', p.1387.

Mechanism

If given by mouth phenylephrine is used in large doses because much of it is destroyed by MAO in the gut and liver, and only a small amount gets into the general circulation. If MAO is inhibited, most of the oral dose escapes destruction and passes freely into circulation, hence the gross enhancement of the pressor effects. Phenylephrine has mainly direct sympathomimetic activity, but it may also have some minor indirect activity as well, which would be expected to result in the release of some of the MAOI-accumulated noradrenaline (norepinephrine) at adrenergic nerve endings (see also 'MAOIs or RIMAs + Sympathomimetics; Indirectly-acting', p.1388). This might account for the increased response to phenylephrine given parenterally.

Importance and management

The interaction between the MAOIs and oral phenylephrine is established, serious and potentially life-threatening. Phenylephrine commonly occurs in oral non-prescription cough, cold and influenza preparations, so patients should be strongly warned about them. Whether the effects of nasal drops and sprays and eye drops are also enhanced is uncertain, but it would be prudent to avoid them until they have been shown to be safe (note that one manufacturer of phenylephrine eye drops[11] contraindicates MAOIs). The response to parenteral phenylephrine is also approximately doubled, so that a dosage reduction is necessary if it is given to a patient taking an MAOI.

The few studies that are available suggest that any interaction with RIMAs is less severe than that with MAOIs, but this needs confirmation.

Treatment

These hypertensive reactions have been controlled by intravenous phentolamine,[1] chlorpromazine, or nifedipine.[12] However, it is advisable to refer to current guidelines on the management of hypertensive crises for up-to-date advice. In the US, the manufacturers of phenelzine advise intravenous **phentolamine** 5 mg, given slowly to avoid excessive hypotension.[13]

MAOIs + Trazodone

There have been isolated reports of serotonin syndrome in patients receiving trazodone and MAOIs, usually in association with other serotonergic drugs.

Clinical evidence, mechanism, importance and management

A case report describes a patient taking trazodone 50 mg daily and **isocarboxazid** 20 mg daily, who developed symptoms of serotonin syndrome and was hospitalised 2 months after dose increases to trazodone 150 mg daily and isocarboxazid 30 mg daily and the addition of methylphenidate.[1]

The US manufacturer says that, due to the absence of clinical experience, if MAOIs are discontinued shortly before or are to be given concurrently with trazodone, concurrent use should be initiated cautiously with a gradual increase in dosage until optimum response is achieved.[2] However, the UK manufacturer of trazodone says possible interactions with MAOIs have occasionally been reported, and do not recommend concurrent use. They say trazodone should not be given within 2 weeks of stopping an MAOI and MAOIs should not be taken within one week of stopping trazodone.[3]

MAOIs or RIMAs + Tricyclic and related antidepressants

Because of the very toxic and sometimes fatal reactions (the serotonin syndrome or similar) that have occurred in patients taking either MAOIs or RIMAs with tricyclic antidepressants, concurrent use is regarded as contraindicated in all but rare circumstances, and a suitable washout interval is needed when switching between MAOIs or RIMAs and tricyclics.

Clinical evidence

A. MAOIs

The toxic reactions that occur when the tricyclics are given with MAOIs have included (with variations) sweating, flushing, hyperpyrexia, restlessness, excitement, tremor, muscle twitching and rigidity, convulsions and coma. Two illustrative examples:

A woman who had been taking **tranylcypromine** 10 mg twice daily for about 3 weeks, stopped taking it 3 days before she took a single tablet of **imipramine**. Within a few hours she complained of an excruciating headache, and soon afterwards lost consciousness and started to convulse. The toxic reactions manifested were a temperature of 40.6°C, pulse rate of 120 bpm, severe extensor rigidity, carpal spasm, opisthotonos and cyanosis. She was treated with amobarbital and phenytoin, and her temperature was reduced with alcohol-ice-soaked towels. The treatment was effective and she recovered.[1]

In a recent case, a patient was given **imipramine** 75 mg daily for 7 weeks with the addition of lithium for the last 3 weeks. These drugs were discontinued and after one week of washout he started **tranylcypromine**, which was gradually increased to 50 mg twice daily. After 2 weeks at this dose, he received a single 225-mg dose of **imipramine** in error. Four hours later his condition deteriorated rapidly. He was agitated, confused, with severe rigidity, myoclonic jerks, hyperthermia, hypertension and tachycardia, and 2 hours later had a cardiac and respiratory arrest. He was resuscitated and given midazolam, pancuronium, dantrolene sodium, and a cooling mattress. The following day he had a sudden fall in blood pressure, and was eventually pronounced brain dead, and artificial respiration was terminated.[2]

Similar reactions have been recorded with oral therapeutic doses of:

- **amitriptyline** with **phenelzine**[3,4]
- **clomipramine** with **phenelzine**[5,6] or **tranylcypromine** (with or without trifluoperazine)[7-9]
- **desipramine** with **phenelzine**[10]
- **imipramine** with **iproniazid**,[11] **isocarboxazid**,[11] **pargyline**,[12] **phenelzine**[13-15] or **tranylcypromine**.[11,16]

There have been a number of fatalities.[7,8,10,17] Reactions have also occurred when intramuscular **imipramine** was given with **phenelzine**.[18-20] In some instances the drugs were not taken together, but were substituted without a washout period in between.[5,16] In some other reports there was an overdose of one or both drugs,[21-24] and/or the presence of other potentially interacting drugs.[22,23] There are many more reports of these interactions than are listed here: those published prior to 1977 have been extensively reviewed elsewhere.[15,25,26]

Three patients with bipolar disorder developed mania when given **isocarboxazid** and **amitriptyline**.[27]

A case report describes hypertension (blood pressure 180/125 mm/Hg) in a patient who took **mianserin** 2 weeks after stopping **tranylcypromine**. The blood pressure normalised when the mianserin was stopped.[28] In contrast, one report suggested that the use of **mianserin** with **tranylcypromine** was safe and effective in 39 patients. However, one patient, who continued to take both drugs after the study period, and who was also taking methyldopa, died suddenly.[29]

In contrast, there are a number of other uncontrolled studies[30-32] and reviews[25,26] describing the beneficial use of an MAOI with a tricyclic antidepressant. In addition, one study has reported switching 178 patients from tricyclics to MAOIs with a washout period of 4 days or less. Of these patients, 63 were given the MAOI while still being tapered from the tricyclic, all without any apparent problems.[33] A study in 60 patients given **isocarboxazid** and **mianserin** found a faster onset of antidepressant activity than would have been expected from either drug alone, and did not identify any drug interactions. The authors state that subsequently 120 patients were given the combination without any notable adverse effects.[34] However, in a 6-week randomised double-blind study in patients with mild to moderate depression, giving **phenelzine** or **isocarboxazid** with **trimipramine** was less effective than giving **trimipramine** alone.[35] Similarly, in a smaller randomised open study, the combination of **amitriptyline** and **tranylcypromine** was no more effective than either drug alone.[36]

B. RIMAs

(a) Amitriptyline

Two small studies in healthy subjects and patients found no problems when **moclobemide** was given with, or 24 hours after, amitriptyline;[37,38] or when amitriptyline was given immediately after **moclobemide**.[37] However, a patient taking amitriptyline and clomipramine developed symptoms of serotonin syndrome within 30 minutes of taking a 300-mg dose of **moclobemide**, and died.[39]

Only a minor and clinically unimportant change in the pharmacokinetics of amitriptyline occurs in patients given **toloxatone**.[40]

(b) Clomipramine

A small study in healthy subjects found no problems when **moclobemide** was given 24 hours after clomipramine.[38] However, serotonin syndrome occurred in 3 patients when clomipramine was replaced by **moclobemide** without a washout period[41,42] or with only a 24-hour washout period;[43] and in another patient when **moclobemide** was replaced by clomipramine after only 12 hours.[44] A fatal case of serotonin syndrome occurred in a patient taking clomipramine and amitriptyline, with symptoms manifesting within 30 minutes of a 300-mg dose of **moclobemide**.[39] Two other patients developed fatal serotonin syndrome after taking moderate overdoses of **moclobemide** and clomipramine.[45] The serotonin syndrome has been reported in at least 8 other cases of **moclobemide** and clomipramine overdose.[46-52] Some of these involved other serotonergic drugs, including 'tramadol', (p.1382), 'fluoxetine, (p.1384)) and buspirone. Conversely, a case of an overdose of **moclobemide** and clomipramine resulted in no adverse effects except sinus tachycardia.[53] Note that the concurrent use of more than one serotonergic drug is thought to be a risk factor for the development of 'serotonin syndrome', (p.9).

(c) Desipramine

A small single dose study in healthy subjects found no problems when **moclobemide** was given with desipramine.[37]

(d) Doxepin

Serotonin toxicity (serotonin syndrome) occurred in a patient who took an overdose of **moclobemide** and doxepin. In this analysis of **moclobemide** overdoses, the risk of developing serotonin toxicity was significantly increased in patients who also took another serotonergic drug, of which this case with doxepin was one of 11 mentioned.[54]

(e) Imipramine

Serotonin syndrome occurred in a patient who had been taking **moclobemide** for about a month and imipramine (50 mg at night increased to 200 mg at night) for about 17 days.[55]

(f) Maprotiline

One study found a non-significant 25% rise in the serum levels of maprotiline (a tetracyclic antidepressant) in 6 patients also taking **moclobemide**. No serious toxic reactions were reported.[56]

(g) Trimipramine

One study found a 39% rise in serum trimipramine levels in 15 patients also taking **moclobemide**. No serious toxic reactions were reported.[56]

Mechanism

Not understood. One idea is that both drugs cause grossly elevated monoamine levels (5-HT, noradrenaline (norepinephrine)) in the brain, which 'spill-over' into areas not concerned with mood elevation. It may be related to, or the same as 'serotonin syndrome', (p.9). Of the tricyclics, clomipramine in particular is a potent inhibitor of serotonin uptake. Less likely suggestions are that the MAOIs inhibit the metabolism of the tricyclic antidepressants, or that active and unusual metabolites of the tricyclic antidepressants are produced.[25]

Importance and management

An established and fairly common interaction, but serious and life-threatening occurrences seem rare. If concurrent use is to be avoided, the following guidelines[57] are recommended:

- Tricyclic antidepressants should *not* be started until 2 weeks after treatment with MAOIs has been stopped (3 weeks if starting clomipramine or imipramine).
- MAOIs should *not* be started until at least 7 to 14 days after a tricyclic or related antidepressant has been stopped (3 weeks in the case of clomipramine or imipramine).
- Moclobemide has a short duration of action so no treatment-free period is required after it has been stopped before starting a tricyclic antidepressant. [Note that some recommend waiting 24 hours.[44]]
- Moclobemide should *not* be started until at least a week after a tricyclic antidepressant has been stopped.

No detailed clinical work has been done to find out precisely what sets the scene when the interaction does occur, but some general empirical guidelines have been suggested so that it can, as far as possible, be avoided if concurrent treatment is thought appropriate:[14,15,25,26,58]

- Treatment with both types of drug should only be undertaken by those well aware of the problems and who can undertake adequate supervision.
- Only patients refractory to all other types of treatment should be considered.
- Tranylcypromine, phenelzine, clomipramine and possibly imipramine appear to be high on the list of drugs that have interacted adversely. Giving clomipramine with tranylcypromine is particularly dangerous. Amitriptyline, trimipramine and isocarboxazid are possibly safer.
- Drugs should be given orally, not parenterally.
- It has been suggested that small doses should be given initially, increasing the levels of each drug, one at a time, over a period of 2 to 3 weeks to levels generally about half those used for each one individually.

Although information is limited, it seems that **maprotiline** (and therefore probably **mianserin**) will interact similarly. It would therefore seem advisable to follow the same precautions if these tetracyclic antidepressants are given with MAOIs.

Treatment of serotonin syndrome

In the management of serotonin syndrome, it is important to recognise the possibility of the syndrome early, as the patient's condition can rapidly deteriorate. Potentially precipitating drugs should be stopped and agitation should be managed with benzodiazepines. The intensity of therapy depends on the severity of the condition. Moderately ill patients may benefit from the administration of 5-HT antagonists such as cyproheptadine. The 5-HT antagonist, chlorpromazine, has also been used and can be beneficial, but should not be given if the patient is hypotensive or if neuroleptic malignant syndrome is a possible diagnosis. Hyperthermic patients should be immediately sedated, given neuromuscular blockers and intubated, since the rise in temperature is due to muscular activity. MAOI-induced hypotension should be managed with low doses of direct-acting sympathomimetics. Propranolol, bromocriptine, and dantrolene have been used, but these are no longer recommended. Because of the potential severity of the condition, a poison-control centre, clinical pharmacology service or medical toxicologist should be consulted for up-to-date advice.[59]

MAOIs + Tryptophan

A number of patients have developed severe behavioural and neurological signs of toxicity (some similar to serotonin syndrome) after taking MAOIs with tryptophan. Fatalities have occurred.

Clinical evidence

A man taking **phenelzine** 90 mg daily developed behavioural and neurological toxicity within 2 hours of being given 6 g of tryptophan.[1] He had shivering and diaphoresis, his psychomotor retardation disappeared and he became jocular, fearful, and moderately labile. His neurological signs included bilateral Babinski signs (abnormal plantar reflexes), hyperreflexia, rapid horizontal ocular oscillations, shivering of the jaw, trunk and limbs, mild dysmetria and ataxia. The situation resolved on withdrawal of the drugs.[1]

Similar symptoms have been reported in other studies and cases. In an early study, giving tryptophan 20 to 50 mg/kg to 7 patients with hypertension taking an unknown MAOI, produced neurological effects including alcohol-like intoxication, drowsiness, hyperreflexia and clonus.[2] Similar symptoms with the addition of sweating, flushing and paraesthesias were described in 5 patients who were given tryptophan 30 mg/kg orally with **pargyline** or **isocarboxazid**.[3] In another study, in 14 depressed patients taking various MAOIs, 4 patients had muscular jactitation and hyperreflexia when they were also given tryptophan 2.5 to 5 g three times daily, and in 2 patients this was severe enough to discontinue the tryptophan.[4] Other reports describe similar symptoms when patients taking **phenelzine**[5,6] or **tranylcypromine**[7] were given tryptophan.

One patient taking **tranylcypromine** and lithium had transient episodes of toxicity with hyperthermia (and other symptoms of neurological toxicity) when the dose of tryptophan was increased to 2 g at night. He had a total of about 12 of these episodes over several weeks before tryptophan was stopped and the episodes ceased.[8] Malignant hyperpyrexia occurred in a patient taking **phenelzine** and tryptophan,[9] and fatal malignant hyperpyrexia occurred in two patients taking **phenelzine**, tryptophan and lithium.[10,11] Another patient who had been taking **tranylcypromine** for 2 weeks developed serious hyperpyrexia and muscular rigidity 2 days after starting tryptophan 6 g daily: she had discontinued levodopa with carbidopa one month previously.[12] Tryptophan may have contributed to a fatal case of serotonin syndrome in a patient switched from fluoxetine to **tranylcypromine**.[13]

Hypomania without neurological symptoms has occurred in 2 patients when tryptophan was added to **phenelzine** or **tranylcypromine**,[14] and delirium or disorientation, (sometimes with neurological symptoms) has occurred in 8 patients taking **tranylcypromine** within 2 to 4 days of starting tryptophan, or within one day of increasing the dose of tryptophan.[15] A further patient also experienced delirium within hours of tryptophan being added to her **phenelzine** treatment.[16]

In contrast, concurrent use has been reported as both safe and effective.[17]

Mechanism

Not understood. The reactions appear to be related to serotonin syndrome, which can occur with two or more serotonergic drugs (see 'serotonin syndrome', (p.9)). MAOIs may inhibit the metabolism of 5-hydroxytryptamine (serotonin), formed from tryptophan, so resulting in its accumulation.[3,9]

Importance and management

Information seems to be confined to the reports listed. Concurrent use can be effective in the treatment of depression,[17] but occasionally and unpredictably severe and even life-threatening toxicity occurs. The authors of one of the reports detailed above[1] recommend that patients taking MAOIs should start treatment with a low dose of tryptophan (500 mg). This should be gradually increased while monitoring the mental status of the patient for changes suggesting hypomania, and neurological changes, including ocular oscillations and upper motor neurone signs.

Note that products containing tryptophan for the treatment of depression were withdrawn in many countries because of a possible association with the development of an eosinophilia-myalgia syndrome. However, since the syndrome appeared to have been associated with tryptophan from one manufacturer, tryptophan preparations were reintroduced in the UK in 1994 for restricted use.[18,19]

MAOIs or RIMAs + Tyramine-rich drinks

Patients taking non-selective MAOIs (e.g. tranylcypromine, phenelzine) can suffer a serious hypertensive reaction if they consume drinks rich in tyramine (some beers or lagers, including low-alcohol brands, or wines), but no serious interaction is likely with the RIMAs (e.g. moclobemide). The hypotensive adverse effects of the MAOIs may be exaggerated in a few patients by alcohol, and they may experience dizziness and faintness after drinking relatively modest amounts. Moclobemide does not appear to alter the psychomotor effects of alcohol to a clinically relevant extent.

Clinical evidence, mechanism, importance and management

A. Hypertensive reactions

A severe and potentially life-threatening hypertensive reaction can occur in patients taking MAOIs if they consume alcoholic drinks containing significant amounts of tyramine. The details of the tyramine/MAOI reaction, its mechanism, the names of the non-selective MAOIs that interact, and the RIMAs that are unlikely to do so are described in the monograph 'MAOIs or RIMAs + Tyramine-rich foods', p.1395. The specific case reports for various tyramine-containing drinks are outlined in the sub-sections below. Note that an 8 to 20-mg dose of tyramine is required before an important rise in blood pressure takes place in a patient taking **tranylcypromine**, and this dose may be higher for other MAOIs (see under 'tyramine-rich foods', (p.1395)). 'Table 32.2', (p.1394) summarises the reported tyramine-content of some drinks,[1-7] and more extensive lists have been published elsewhere.[6-8] These can be used as a broad general guide when advising patients, but they cannot be an absolute guide because alcoholic drinks are the end product of a biological fermentation process and no two batches are ever absolutely identical. For example there may be a 50-fold difference even between wines from the same grape stock.[5] There is no way of knowing for certain the tyramine-content of a particular drink without a detailed analysis.

Table 32.2 The tyramine-content of some drinks

	Tyramine content (mg/L)	*Refs*
Ales, beers and lagers		
Beer (Canada)	0 to 11.2, 27.1, 29.5, 112.9	1,2
Beer (Former Czechoslovakia)	10.4, 47 to 60	3
Beer (Germany)	1	3
Beer (Ireland)	0.5 to 4, 54	2,3
Beer (Netherlands)	1	3
Beer (UK)	0.3 to 1.34	2-4
Beer (USA)	0.7 to 4.4	2,3,5
Low-alcohol beers	0 to 10	2,6
Wines		
Chianti (Italy)		
Governo process	1.8 to 10.4, 25.4	1,5
Newer process	0.0 to 4.7	3,4,7,8
Champagne	1, 13.7 to 18	3,9
Wine, red (Canada, France, Italy, Spain, USA)	0 to 8.6 (mean 5.2)	9
Wine, white (France, Germany, Italy, Portugal, Spain, Former Yugoslavia)	0.4 to 6.5	4,5,9
Fortified wines and spirits		
Gin	0	8
Port	Less than 0.2 (undetectable)	5
Sherry	0.2 to 3.6	1,3,5,8
Vodka	0	8
Whiskey	0	8

(a) Ales, Beers and Lagers

Some ales, beers and lagers in 'social' amounts contain enough tyramine to reach the 8 to 20 mg dose needed to provoke a reaction; for example a litre (a little under 2 pints) of some samples of **Canadian ale or beer** (see 'Table 32.3', (p.1396)). Case reports of reactions have been published. A man taking **phenelzine** 60 mg daily developed a typical hypertensive reaction after drinking only 14 oz. (about 400 mL) of **Upper Canada lager beer on tap** (containing about 113 mg of tyramine/litre).[8] In addition, **alcohol-free beer** and **lager** may have a tyramine-content that is equal to ordinary beer and lager.[9,10] One patient taking **tranylcypromine** suffered an acute cerebral haemorrhage after drinking a **de-alcoholised Irish beer**,[9] and hypertensive reactions occurred in three other patients taking **tranylcypromine** or **phenelzine** after drinking no more than about 375 mL of **alcohol-free beer or lager**.[10] A further patient taking **tranylcypromine** developed a vascular headache after drinking 3 bottles of **non-alcoholic beer**.[11] A very extensive study of 79 different brands of beer (from Canada, England, France, Germany, Holland, Ireland, Scotland, USA) found that the tyramine content of the **bottled** and **canned beers** examined was generally too low to matter (less than 10 mg/L), but four of 37 **beers on tap** (all 4 were lagers) contained more than enough tyramine (27 to 113 mg/L) to cause a hypertensive reaction.[8] It was concluded in this report that the consumption of **canned** or **bottled beer**, including **de-alcoholised beer**, in moderation (fewer than four bottles, 1.5 litres in a 4-hour period) was safe in patients taking MAOIs, but, to be on the cautious side, all **beers on tap**, including **lagers** should be avoided.[8] The RIMAs are less likely to interact, see 'MAOIs or RIMAs + Tyramine-rich foods', p.1395.

(b) Spirits

Gin, **whisky**, **vodka** and **other spirits** do not contain significant amounts of tyramine because they are distilled, and the volumes drunk are relatively small.[7] There seem to be no reports of hypertensive reactions in patients taking MAOIs after drinking spirits and none would be expected. One author[12] anecdotally noted that 'bottles of whisky have been drunk by some patients on the MAOIs, the only result being that they got drunk more easily and cheaply.' However, a 38-year-old man collapsed with tachycardia the morning after taking an overdose of **moclobemide** and drinking half a bottle of **whisky** (more than 350 mL). He then suffered a cardiac arrest, and resuscitation was unsuccessful. His blood pressure was not recorded. The authors attributed this case to an interaction between moclobemide and tyramine,[13] although the tyramine content of the whisky was not assessed, so any interaction is not established, especially since whisky does not usually contain tyramine.

(c) Wines

In the context of adverse interactions with MAOIs, **Chianti** has developed a sinister reputation, because 400 mL of one early sample of **Italian Chianti** wine (see 'Table 32.2', above) contained enough tyramine to reach the 8 to 20 mg threshold for causing important hypertensive reactions. However, it is claimed[14] that the newer methods that have replaced the ancient 'governo alla toscana' process result in negligible amounts of tyramine in today's **Chianti**. This seems to be borne out by the results of analyses,[3,5-7] two of which failed to find any tyramine at all in some samples.[3,7] Some of the other wines listed in 'Table 32.2', (above) also contain tyramine, but patients would have to drink as much as 2 litres or more before reaching what is believed to be the threshold dosage. This suggests that small or moderate amounts (1 or 2 glasses) are unlikely to be hazardous in patients taking MAOIs.

B. Hypotensive reactions

Some degree of hypotension can occur in patients taking MAOIs and this may be exaggerated by the vasodilation and reduced cardiac output caused by alcohol. In one report, a patient taking an MAOI describes drinking **gin** and orange and then becoming unsteady when standing up and hitting her head on the wall.[15] Patients taking MAOIs should therefore also be warned of the possibility of orthostatic hypotension and syncope if they drink. They should be advised not to stand up too quickly, and to remain sitting or lying if they feel faint or begin to 'black out'.

C. Psychomotor performance

The possibility that **alcohol**-induced deterioration in psychomotor skills (i.e. those associated with safe driving) might be increased by the RIMAs has been studied. Moclobemide appears to have only a minor and clinically unimportant effect.[16,17]

MAOIs or RIMAs + Tyramine-rich foods

A potentially life-threatening hypertensive reaction can develop in patients taking non-selective MAOIs (tranylcypromine, phenelzine etc.) who eat tyramine-rich foods. Deaths from intracranial haemorrhage have occurred. Significant amounts of tyramine occur in some aged cheeses, yeast extracts (e.g. *Marmite*) and some types of salami. Caviar, pickled herrings, soy sauce, avocados and other foods have been implicated in this interaction. Note that any food high in aromatic amino acids can become high in tyramine if spoilage occurs or after storage. The RIMAs (moclobemide, toloxatone) interact with tyramine to a lesser extent, such that dietary restrictions are generally unnecessary.

Clinical evidence

A. Reactions to foods

(a) MAOIs

A rapid, serious, and potentially fatal rise in blood pressure can occur in patients taking MAOIs who ingest tyramine-rich foods or drinks. A violent occipital headache, pounding heart, neck stiffness, flushing, sweating, nausea and vomiting may be experienced. One of the earliest recorded observations specifically linking this reaction to **cheese** was in 1963 by a pharmacist called Rowe, who wrote to Blackwell[1] after seeing the reaction in his wife who was taking *Parstelin* (**tranylcypromine** with trifluoperazine).

'After **cheese on toast**; within a few minutes face flushed, felt very ill; head and heart pounded most violently, and perspiration was running down her neck. She vomited several times, and her condition looked so severe that I dashed over the road to consult her GP. He diagnosed 'palpitations' and agreed to call if the symptoms had not subsided in an hour. In fact the severity diminished and after about 3 hours she was normal, other than a severe headache — but 'not of the throbbing kind'. She described the early part of the attack 'as though her head must burst'.'

Blackwell and his colleagues[1] discuss a series of 25 early cases, and the information that led to this interaction becoming established. **Tranylcypromine** was the most frequently implicated MAOI: of 25 cases, 17 were with **tranylcypromine**, 6 with **phenelzine** and one each with **pargyline** and **mebanazine**. In addition, **cheese** was the most frequently implicated food, being named in 18 of 25 cases, with *Marmite* (**yeast** extract) in 3 and **pickled herrings** in one. Four patients had intracranial haemorrhages and one died.[1] From 1961 up to February 1964 the FDA in the US found about 500 cases of induced hypertension with **tranylcypromine** and 38 cases of cerebral vascular accidents with 21 deaths. As a result, **tranylcypromine** was withdrawn in the US, although it was later reintroduced with many restrictions, including the need to avoid **cheese** while taking the drug.[2]

In addition to reactions to **cheese**, cases of hypertensive reactions have been reported with **avocados**,[3] **beef livers**[4] and **chicken livers**,[5] **caviar**,[6] **pickled herrings**,[7] **soused herrings**,[8] **tinned fish**,[8] **tinned milk**,[1] **peanuts**,[8] **soy sauce**,[9] **miso**,[10] a **powdered protein diet supplement** (*Ever-so-slim*[11] or *Complan*[1]), **packet soup** (containing hydrolysed **yeast**),[12] **sour cream** in coffee,[8] and **New Zealand prickly spinach**[13] (*Tetragonia tetragonoides*). [Note this is not a true spinach as found in the USA or Europe.] These reactions occurred with **tranylcypromine**,[3,5-9] **phenelzine**[4,10,11,13] or unspecified MAOIs.[8,12]

(b) RIMAs

There do not appear to be any published reports of the '**cheese** reaction' with **moclobemide**. The combination of *Bovril* (**yeast** extract) 12 g and **moclobemide** 150 mg, both three times daily, was used to normalise blood pressure in a patient with severe postural hypotension as a result of central autonomic failure.[14]

B. Tyramine studies

Pharmacodynamic studies comparing RIMAs with MAOIs using oral tyramine sensitivity tests have revealed that only 20 to 50 mg of oral tyramine (given with a meal) is required to raise the systolic BP by 30 mmHg in subjects taking **tranylcypromine** 10 mg twice daily.[15] In other studies, the pressor tyramine dose was only 8 mg in those given **tranylcypromine**.[16] Other studies have reported the pressor tyramine dose as 15 mg[17] or 33 mg[16] in those taking **phenelzine**.

In a placebo-controlled study in healthy subjects the mean dose of oral tyramine (added to a meal) required to raise systolic BP by 30 mmHg (the tyramine 30 dose) was decreased fivefold (from 1450 mg to 306 mg, range 150 to 500 mg) by **moclobemide** 200 mg three times daily,. In comparison, **tranylcypromine** 10 mg twice daily decreased the tyramine 30 dose by about 38-fold.[15] In another study, the reduction in the tyramine 30 dose for **moclobemide** 150 mg three times daily was sevenfold; for **phenelzine** 60 mg daily, 13-fold; and for **tranylcypromine** 20 mg daily, 55-fold. After stopping the drugs, the pressor effect to tyramine normalised within 3 days for **moclobemide**, and 30 days for **tranylcypromine**. However, the pressor response had normalised in only two subjects 2 to 4 weeks after they stopped **phenelzine**, and had not normalised during the 11-week study period in the other 4 subjects.[16] In a further study the tyramine 30 dose was reduced by about 4-fold by **moclobemide** 100 mg three times daily and 10.3-fold by **phenelzine** 15 mg three times daily.[18] Numerous other pharmacological studies have confirmed the low increase in pressor response to tyramine with **moclobemide**.[17,19-22]

The pressor response to oral tyramine 200 mg was not altered by pretreatment with **toloxatone** 200 mg or 400 mg three times daily in healthy subjects, although the effect of higher doses of tyramine was increased.[23] Similar results were reported in an earlier study.[24]

Mechanism

Tyramine is formed in foods such as cheese by the bacterial degradation of milk and other proteins, firstly to tyrosine and other amino acids, and the subsequent decarboxylation of the tyrosine to tyramine. This interaction is therefore not associated with fresh foods, but with those which have been allowed to over-ripen or 'mature' in some way,[3] or if spoilage occurs. Tyramine is an indirectly-acting sympathomimetic amine, one of its actions being to release noradrenaline (norepinephrine) from the adrenergic neurones associated with blood vessels, which causes a rise in blood pressure by stimulating their constriction.[3]

Normally any ingested tyramine is rapidly metabolised by the enzyme monoamine oxidase in the gut wall and liver before it reaches the general circulation. However, if the activity of the enzyme at these sites is inhibited (by the presence of an MAOI), any tyramine passes freely into the circulation, causing not just a rise in blood pressure, but a highly exaggerated rise due to the release from the adrenergic neurones of the large amounts of noradrenaline that accumulate there during inhibition of MAO.[3] This final step in the interaction is identical to that which occurs with any other indirectly-acting sympathomimetic amine in the presence of an MAOI (see 'MAOIs or RIMAs + Sympathomimetics; Indirectly-acting', p.1388).

RIMAs such as moclobemide and toloxatone selectively inhibit MAO-A, which leaves MAO-B still available to metabolise tyramine. This means that they have less effect on the tyramine pressor response than non-selective MAOIs.

Importance and management

An extremely well-documented, well-established, serious interaction. A potentially fatal hypertensive reaction can occur between the irreversible, non-selective MAOIs (see 'Table 32.1', (p.1370)) and tyramine-rich foods. Tranylcypromine is more likely to cause the reaction than phenelzine. The incidence is uncertain, but early estimates of hypertensive reactions to tranylcypromine (before restrictions in its use with indirectly-acting sympathomimetics and foods) range from 0.03% to 20%.[2,25,26] Patients taking any of the non-selective MAOIs should not eat foods reported to contain substantial amounts of tyramine (see 'Table 32.3', (p.1396) and 'Table 32.4', (p.1397)). As little as 8 to 20 mg of tyramine can raise the

blood pressure in patients taking tranylcypromine, and this may be present in usual portions of hard cheeses.[16] In addition, avoidance of the prohibited foods should be continued for 2 to 3 weeks after stopping the MAOI to allow full recovery of the enzymes. However, note that in one study some patients took over 11 weeks to recover from the effects of phenelzine.[16]

Because tyramine levels vary so much it is impossible to guess the amount present in any food or drink. Old, over-ripe strong smelling cheeses with a salty, biting taste or those with characteristic holes due to fermentation should be avoided as they generally contain high levels of tyramine. Fresh cheeses made from pasteurised milk tend to have lower levels of tyramine.[27] The tyramine-content can even differ significantly within a single cheese: the centre having the lowest levels of tyramine and the rind containing the most.[27,28] There is no guarantee that patients who have uneventfully eaten these hazardous foodstuffs on many occasions may not eventually experience a full-scale hypertensive crisis, if all the many variables conspire together.[29]

The need to plan a sensible and safe diet for those taking MAOIs is clear, and over the years attempts have been made to produce simplified, practical diets for those taking MAOIs.[30-37] A total prohibition should be imposed on the following: **aged cheese** and **yeast extracts** such as *Marmite,* and possibly also *Bovril* and **pickled herrings** (see 'Table 32.3', above). A number of other foods should also be viewed with suspicion such as **sauerkraut**, **fermented bologna** and **salami**, **pepperoni**, and **summer sausage** because some of them may contain significant amounts of tyramine (see 'Table 32.3', above). Some preserved and fermented Far Eastern foods such as **fermented soya beans**, **soya bean paste** and **soya bean curd** (**tofu**) can also contain relatively high tyramine levels.[34,38] However, **yoghurt**, **fresh cream** and possibly **chocolate** are often viewed with unjustifiable suspicion. It also seems very doubtful if either **cream cheese** or **cottage cheese** represent a hazard, or **processed cheese** slices.[33] **Whole green bananas** contain up to 65 micrograms of tyramine per gram, but this is mostly in the skin as the pulp contains relatively small amounts. Although case reports have occurred with a variety of other foods, it is generally acknowledged that widespread restrictions should not be imposed on a food based solely on an unsubstantiated isolated report,[30,31,33] and that some reports could equally be attributed to spoilage.[31,39] Therefore, of perhaps more importance is the advice to only eat protein-based foods (particularly meat, fish and liver) when fresh (within their sell-by date and after correct storage).[31,33] Note that cooking does not inactivate tyramine. For the need to avoid broad-bean pods because of their dopamine content, see 'MAOIs + Dopa-rich foods', p.1376.

In the context of interactions with tyramine-rich foods and drinks the RIMAs are safer than the older MAOIs, because they are more readily reversible and selective. Therefore the risk of a serious hypertensive reaction with moclobemide is very much reduced. The authors of one study calculate that the lowest amount of tyramine (150 mg) found to cause a 30 mmHg rise in systolic BP with moclobemide is equivalent to that found in about 200 g of Stilton cheese or 300 g of Gorgonzola cheese, which are really excessive amounts of cheese to be eaten in a few minutes.[15]

Table 32.4 The tyramine content of some cheeses
This table is principally intended to show the extent and the variation that can occur

Moreover, no 'cheese reactions' appear to have been published for moclobemide. Most patients therefore do not need to follow the special dietary restrictions required with the non-selective MAOIs, but, to be on the safe side, the manufacturers of moclobemide advise all patients to avoid large amounts of tyramine-rich foods, because a few individuals may be particularly sensitive to tyramine.[40] This warning would also seem appropriate for all RIMAs. Note that if moclobemide were given with an MAO-B inhibitor such as selegiline, it would essentially be the same as giving a non-selective MAOI, and dietary tyramine restrictions would then be required, see 'MAO-B inhibitors + Tyramine-rich foods', p.809.

Treatment

Severe hypertensive reactions require urgent immediate treatment. The drug most commonly used to control hypertensive reactions with MAOIs is phentolamine, given as a slow intravenous injection. However, the need for the patient to get to an emergency treatment centre delays treatment, and as a consequence, providing the patient with a drug they could self administer has been suggested. Sublingual nifedipine has been advocated,[41] but does not appear to have been widely adopted, perhaps because the possibility of a sudden dramatic drop in blood pressure is just as dangerous. Another similar option is a small dose of chlorpromazine.[42]

It is advisable to refer to current guidelines on the management of hypertensive crises for up-to-date advice.

Moclobemide + Cimetidine

Cimetidine increases the plasma levels of moclobemide. Moclobemide dosage reductions are recommended.

Clinical evidence, mechanism, importance and management

In a study in 8 healthy subjects, cimetidine 200 mg five times daily for 2 weeks increased the maximum plasma levels of a single 100-mg dose of moclobemide by 39% and its clearance was reduced by 52%.[1] The probable reason for this effect is that the cimetidine (a well-recognised enzyme inhibitor) reduces the first-pass metabolism of the moclobemide.

It has been recommended that if moclobemide is given to a patient taking cimetidine it should be started at the lowest therapeutic dose, and titrated as required. If cimetidine is given to a patient taking moclobemide, the dosage of the moclobemide should initially be reduced by 50% and later adjusted as necessary.[2,3]

Moclobemide + Omeprazole

Omeprazole doubled the AUC of moclobemide in extensive metabolisers of CYP2C19, effectively making them poor metabolisers. Similarly, moclobemide doubled the AUC of omeprazole in one study. The clinical relevance of these findings is uncertain.

Clinical evidence

Omeprazole 40 mg daily for 7 days increased the AUC of a single 300-mg dose of moclobemide by about twofold in 8 healthy subjects who were extensive metabolisers of CYP2C19.[1] After this increase, the AUC of moclobemide in these subjects was still lower than that seen in 8 healthy subjects who were poor metabolisers of CYP2C19 (without omeprazole). Omeprazole had no appreciable effect on the pharmacokinetics of moclobemide in the 8 subjects who were poor metabolisers of CYP2C19. Further study in the same subjects showed that, in the extensive metabolisers, a single 300-mg dose of moclobemide approximately doubled the AUC and maximum plasma level of omeprazole 40 mg, and the production of omeprazole sulfone was similarly increased. The pharmacokinetics of omeprazole and omeprazole sulfone were not significantly altered in the poor metabolisers.[2]

Mechanism
