Coumarins + Gefitinib

An isolated report describes an increase in the effects of warfarin when gefitinib was given.

Clinical evidence, mechanism, importance and management

A woman stabilised on **warfarin** required a gradual decrease in the dose from 4 mg to 2.5 mg daily after starting gefitinib 250 mg/m^2 daily for lung cancer. In contrast, a second patient did not have an increase in the effect of **warfarin** while taking gefitinib.[1] The US manufacturer of gefitinib notes that raised INRs and bleeding have been reported in patients taking **warfarin** and gefitinib; however, there appears to be no specific pharmacokinetic explanation for this interaction as gefitinib did not inhibit the cytochrome P450 isoenzymes CYP2C9 or CYP3A4 *in vitro*.[2] Note that factors related to illness such as decreased appetite can alter **warfarin** requirements. Nevertheless, given that there have been several reports of an interaction, it would be prudent to increase monitoring of **warfarin** effects in patients requiring gefitinib.

Note that, from a disease perspective, when treating venous thromboembolic disease in patients with cancer, **warfarin** is generally inferior (higher risk of major bleeds and recurrent thrombosis) to low-molecular-weight heparins.

2. Iressa (Gefitinib). AstraZeneca. US Prescribing information, June 2005.

Coumarins + Ginger

Evidence from pharmacological studies suggests that ginger does not increase the anticoagulant effect of warfarin, neither does it alter coagulation or platelet aggregation on its own. However, two case reports describe markedly raised INRs with phenprocoumon and warfarin, which were associated with eating dried ginger and drinking ginger tea. A prospective, longitudinal study also reports of an increased risk of self-reported bleeding events in patients taking warfarin and ginger.

Clinical evidence

In a randomised, crossover study in 12 healthy subjects, 3 ginger capsules taken three times daily for 2 weeks did not affect either the pharmacokinetics or pharmacodynamics (INR) of a single 25-mg dose of **warfarin** taken on day 7. The brand of ginger used was *Blackmores Travel Calm Ginger*, each capsule containing an extract equivalent to 400 mg of ginger rhizome powder. Moreover, ginger alone did not affect the INR or platelet aggregation.[1]

However, a case report describes a rise in INR to greater than 10, with epistaxis, in a woman stabilised on **phenprocoumon** several weeks after she started to eat ginger regularly in the form of pieces of dried ginger and

tea from ginger powder. She was eventually restabilised on the original dose of **phenprocoumon**, and was advised to stop taking ginger.[2] Another very similar case has been described in a woman taking **warfarin**.[3]

Moreover, in a prospective, longitudinal study of patients taking **warfarin** and a herbal product or dietary supplement, there was a statistically significant increased risk of self-reported bleeding events in patients taking **warfarin** and ginger (7 bleeds in 25 weeks, none of which were major: odds ratio 3.2).[4] No elevated INRs were reported for the combination. Note that the number of patients taking ginger was not reported, except to say it was less than 5% of 171; so it was less than 8 patients. Also, the ginger products used were not mentioned and some patients were taking more than one potentially interacting supplement.

Mechanism

Ginger (*Zingiber officinale*) has sometimes been listed as a herb that interacts with warfarin[5,6] on the basis that *in vitro* it inhibits platelet aggregation. However, this antiplatelet effect has generally not been demonstrated in controlled clinical studies (three of which have been reviewed[7]). Consider also 'Coumarins + Herbal medicines; Miscellaneous', p.472.

Importance and management

Evidence from a controlled study suggests that ginger does not increase the anticoagulant effect of warfarin. Despite it being cited as a herb that inhibits platelet aggregation, there is limited evidence that it increases bleeding when given alone or with warfarin, and there are just two case reports of markedly raised INRs with phenprocoumon and warfarin, which were associated with ginger root and ginger tea. Because of the many other factors influencing anticoagulant control, it is not possible to reliably ascribe a change in INR specifically to a drug interaction in a single case report without other supporting evidence. It may be better to advise patients to discuss the use of any herbal products they wish to try, and to increase monitoring if this is thought advisable. Cases of uneventful use should be reported, as they are as useful as possible cases of adverse effects.

Coumarins + Ginkgo (*Ginkgo biloba*)

Evidence from pharmacological studies in patients and healthy subjects suggests that ginkgo extracts do not interact with warfarin. However, an isolated report describes intracerebral haemorrhage associated with the use of ginkgo and warfarin, and there are a few reports of bleeding associated with the use of ginkgo alone.

Clinical evidence

In a randomised, crossover study in 21 patients stabilised on **warfarin**, ginkgo extract 100 mg daily (*Bio-Biloba*) for 4 weeks did not alter the INR or the required dose of **warfarin**, when compared with placebo.[1] Similarly, in another study in healthy subjects,[2] *Tavonin* (containing standardised dry extract EGb 761 of ginkgo equivalent to 2 g of leaf) 2 tablets three times daily for 2 weeks did not affect either the pharmacokinetics or pharmacodynamics (INR) of a single dose of **warfarin** given on day 7. Moreover, a retrospective review of 21 clinical cases involving the concurrent use of ginkgo and **warfarin** also found no evidence of altered INRs.[3]

Conversely, a report describes an intracerebral haemorrhage in an elderly woman within 2 months of her starting to take ginkgo. Her prothrombin time was found to be 16.9 seconds and her partial thromboplastin time was 35.5 seconds. She had been taking **warfarin** uneventfully for 5 years.[4] The author of the report speculated that ginkgo may have contributed towards the haemorrhage.

Mechanism

Uncertain. Isolated cases of bleeding have been reported with ginkgo alone (which have been the subject of a review[5]). In pharmacological studies, ginkgo extract alone did not alter coagulation parameters or platelet aggregation.[2,3] However, in *animal* studies it was found that the AUC of warfarin was decreased by 23% during EGb 761 administration, and the prothrombin time was also reduced by EGb 761, which would suggest that ginkgo should *reduce* the effects of warfarin.[3] In healthy subjects, ginkgo extract had no effect on diclofenac or tolbutamide, which were used as marker substrates for the cytochrome P450 isoenzyme CYP2C9, suggesting that it will not alter the metabolism of *S*-warfarin.[6]

Importance and management

There is good evidence from pharmacological studies in patients and healthy subjects that ginkgo extract would not be expected to interact with warfarin. However, there is one case report of over-anticoagulation, and a few reports of bleeding with ginkgo alone. This is insufficient evidence to justify telling patients taking warfarin to avoid ginkgo, but they should be told to monitor for early signs of bruising or bleeding and seek informed professional advice if any bleeding problems arise.

Coumarins + Ginseng

One pharmacological study found that *Panax quinquefolius* (American ginseng) modestly decreased the effect of warfarin, whereas another study found that *Panax ginseng* (Asian ginseng) did not alter the effect of warfarin. Two case reports describe decreased warfarin effects, one with thrombosis, attributed to the use of ginseng (probably *Panax ginseng*).

Clinical evidence

In a placebo-controlled study, 20 healthy subjects were given **warfarin** 5 mg daily for 3 days alone then again on days 15 to 17 of a 3-week course of *Panax quinquefolius* (American ginseng) 1 g twice daily. In the 12 subjects given ginseng, the peak INR was modesty reduced by 0.16, compared with a non-significant reduction of 0.02 in the 8 subjects given placebo. There was also a modest reduction in the AUC of **warfarin**. In this study, *Panax quinquefolius* root was ground and capsulated.[1]

Evidence from two earlier case reports supports a reduction in warfarin effect. A man taking **warfarin** long-term, and also diltiazem, glyceryl trinitrate and salsalate, had a fall in his INR from 3.1 to 1.5 within 2 weeks of starting to take ginseng capsules (*Ginsana*) three times daily. This preparation contains 100 mg of standardised concentrated ginseng [probably *Panax ginseng* (Asian ginseng)] in each capsule. Within 2 weeks of stopping the ginseng his INR had risen again to 3.3.[2] Another patient taking **warfarin** was found to have thrombosis of a prosthetic aortic valve, with a subtherapeutic INR of 1.4. Three months before this episode his INR had become persistently subtherapeutic, requiring a progressive increment in his **warfarin** dose. It was suggested that this might have been because he had begun using a ginseng product (not identified).[3]

In contrast, in a randomised, crossover study in 12 healthy subjects, ginseng capsules 1 g three times daily for 2 weeks did not affect either the pharmacokinetics or pharmacodynamics (INR) of a single 25-mg dose of **warfarin** taken on day 7. The brand of ginseng used was *Golden Glow*, each capsule containing an extract equivalent to 0.5 g of *Panax ginseng* (Asian ginseng) root.[4]

Mechanism

It is unclear why ginseng might reduce the efficacy of warfarin, particularly as no pharmacokinetic interaction occurs. *In vitro* experiments have found that *Panax ginseng* contains antiplatelet components that inhibit platelet aggregation and thromboxane formation,[5] although antiplatelet activity was not demonstrated in a study in healthy subjects.[6] If an antiplatelet effect were confirmed, this might suggest the possibility of an *increased* risk of bleeding with the combination of ginseng and warfarin. There are a few reports of vaginal bleeding in women using ginseng preparations (unspecified) in the absence of an anticoagulant,[7–9] but these are probably due to a possible hormonal effect of ginseng.

Importance and management

The available evidence suggests that ginseng might *decrease* the effect of warfarin. It is possible that the effect is greater with, or specific to, *Panax quinquefolius* (American ginseng), because this interacted in one study whereas *Panax ginseng* (Asian ginseng) did not. Although the ginseng dose was higher in the *Panax ginseng* study, the treatment duration was not as long, which may have obscured an effect. Moreover, the two case reports of decreased warfarin effects attributed to the use of ginseng were probably *Panax ginseng*.

Until further information becomes available it would seem prudent to be alert for decreased effects of warfarin and related drugs in patients using ginseng, particularly *Panax quinquefolius*. However, the possibility of an increased risk of bleeding due to the antiplatelet component of Panax ginseng cannot entirely be ruled out, although the clinical study suggests that this is unlikely.

Coumarins + Glucagon

In one early analysis, the anticoagulant effects of warfarin were markedly increased by very large doses of glucagon (total dose exceeding 50 mg over 2 days), but not by doses of less than 30 mg over one to 2 days.

Clinical evidence

In an analysis of 24 patients taking **warfarin** who were given glucagon for inadequate cardiac contractility, no potentiation of the action of **warfarin** was noted in 11 patients given a total of less than 30 mg of glucagon over one to 2 days. However, 8 out of 9 patients had a marked increase in anticoagulant effects (prothrombin times of 30 to 50 seconds or more) when they were given higher doses of glucagon (62 to 362 mg over 3 to 8 days). Three of them bled. The interaction was not able to be assessed in 4 patients.[1]

Mechanism

Unknown. Changes in the production of blood clotting factors and an increase in the affinity of warfarin for its site of action have been proposed.[1] A study in *guinea pigs* using **acenocoumarol** suggested that changes in warfarin metabolism or its absorption from the gut are *not* responsible.[2]

Importance and management

Direct information is limited to the report cited,[1] which relates to doses far in excess of those used clinically for hypoglycaemia (1 mg) or in the management of beta blocker overdose (2 to 10 mg then 50 micrograms/kg per hour). As such, its findings are probably of no general relevance. Its authors recommend that if glucagon 25 mg per day or more is given for two or more days, the dose of warfarin should be reduced in anticipation of the interaction, and prothrombin time closely monitored.[1]

Coumarins + Glucosamine ± Chondroitin

A few reports suggest that glucosamine with or without chondroitin may increase the INR in patients taking warfarin. In contrast, one case of a decreased INR has been reported when glucosamine was given with acenocoumarol.

Clinical evidence

The first indication of a possible interaction between **warfarin** and glucosamine was in 2001, when the Canadian Adverse Drug Reaction Monitoring Program briefly reported that an increase in INR had been noted when glucosamine was given to patients taking **warfarin**, and that INR values decreased when glucosamine was stopped.[1] In 2004, a full case report was published. In this case, a 69-year-old man stabilised on **warfarin** 47.5 mg weekly had an increase in his INR from 2.58 to 4.52 four weeks after starting to take 6 capsules of *Cosamin DS* (glucosamine hydrochloride 500 mg, sodium chondroitin sulfate 400 mg, manganese ascorbate per capsule) daily. His **warfarin** dose was reduced to 40 mg weekly, and his INR returned to the target range of 2 to 3 (INR 2.15) with continued *Cosamin DS* therapy.[2] A comment on this report noted that this is twice the usual dose of glucosamine.[3] Since then, one other similar case of a modest rise in INR has been published. A man taking **warfarin** and glucosamine hydrochloride 500 mg with chondroitin sulfate 400 mg twice daily had a gradual increase in his INR (from 2.3 to 4.7 over 5 weeks) when he trebled the dose of the glucosamine supplement.[4]

Analysis of regulatory authority data has revealed other unpublished reports. In 2006 the CHM in the UK reported that they had received 7 reports of an increase in INR in patients taking **warfarin** after they started taking glucosamine supplements.[5] In 2007, a search of the FDA database identified 20 possible cases,[4] and a search of the WHO database identified 22 possible case reports of an increase in **warfarin** effect with glucosamine, which originated from Australia, Canada, Denmark, Sweden, the UK and USA.[6] In two of the WHO cases, chondroitin was used, but the other cases were with glucosamine alone. Of 15 reports giving details of time to onset, the increased INR was noted within 3 days (in a 99-year-old) and up to 6 months; most commonly the interaction took several weeks to manifest.[6]

In contrast, a 71-year-old man stabilised on **acenocoumarol** 15 mg weekly had a *decrease* in his INR to 1.6 after taking glucosamine sulfate (*Xicil*) 1.5 g daily for 10 days. The glucosamine was stopped and the INR reached 2.1. When the glucosamine was restarted, with an increase in **acenocoumarol** dose to 17 mg weekly, the INR only reached 1.9. The glucosamine was eventually stopped.[7] Similarly, the WHO database contained one report of a decreased effect of warfarin with glucosamine.[6] The Australian Adverse Drug Reactions Advisory Committee have also identified 12 cases of alterations in INR in patients taking **warfarin**. Nine of these cases are included in the WHO report.[8]

There do not appear to have been any controlled studies of the effects of glucosamine supplements on the pharmacodynamics or pharmacokinetics of oral anticoagulants.

Mechanism

Unknown.

Importance and management

Glucosamine is a widely used supplement, particularly in the middle-aged and elderly, who are also the group most likely to be using warfarin or similar anticoagulants. Despite this, there are just three published reports of a possible interaction, two describing moderate rises in INR and one a decrease. Even taking into account the possible cases reported to regulatory authorities, the interaction would seem to be quite rare. Nevertheless, the cases described suggest it would be prudent to monitor the INR more closely if glucosamine is started or stopped. Also, if a patient shows an

unexpected change in INR, bear in mind the possibility of self-medication with supplements such as glucosamine.

Note that in 2006 the CHM in the UK recommend that patients taking warfarin do not take glucosamine,[5] but the subsequent 2007 UK-approved labelling for the prescription-only glucosamine product *Alateris* recommends close monitoring when a patient taking a coumarin anticoagulant starts or stops glucosamine.[9]

Coumarins + Glutethimide

The anticoagulant effects of warfarin and ethyl biscoumacetate can be decreased by glutethimide.

Clinical evidence

Ten subjects stabilised on **warfarin**, with average prothrombin times of 18.8 seconds, had a mean reduction of 2.7 seconds in their prothrombin times after they took glutethimide 500 mg at bedtime for 4 weeks.[1,2] Other studies have shown that up to 1 g of glutethimide daily for one to 3 weeks reduced the half-life of single-dose **warfarin** by between one-third to one-half.[3,4] Conversely, an unexplained report describes a paradoxical increase in prothrombin times and severe bruising in a patient stabilised on **warfarin** who took 3.5 g of glutethimide over a 5-day period.[5]

Glutethimide 500 or 750 mg daily for 10 days has been found to reduce the half-life of single-dose **ethyl biscoumacetate** by about one-third,[6,7] whereas in contrast, an early study in 25 patients taking **ethyl biscoumacetate** found no evidence of an interaction.[8]

Mechanism

Glutethimide is a liver enzyme inducer, which increases the metabolism and clearance of the anticoagulants from the body, thereby reducing their effects.[1-4,6,7] There is no obvious explanation for the reports finding no interaction or increased effects.

Importance and management

The interaction of glutethimide with warfarin is established, while the interaction with ethyl biscoumacetate is uncertain. Information about both interactions is limited and there seems to be nothing documented about any other anticoagulant. However, it would be prudent to monitor the effect of adding glutethimide to patients taking any coumarin, being alert for the need to increase the anticoagulant dose. Other interactions due to enzyme induction can take several weeks to develop fully and persist after withdrawal, so good monitoring and dose adjustment should continue until anticoagulant stability is confirmed. The benzodiazepines may be a useful non-interacting alternative, see 'Coumarins + Benzodiazepines and related drugs', p.441.

Coumarins + Grapefruit juice

Grapefruit juice may cause a modest rise in the INR some patients taking warfarin and one case report describes a marked rise in INR, which was attributed to grapefruit juice. However, other studies have suggested that grapefruit juice does not interact with warfarin or acenocoumarol.

Clinical evidence

(a) Acenocoumarol

In the preliminary report of a single-dose, placebo-controlled study in 12 healthy subjects, 150 mL of grapefruit juice did not alter the maximum INR of a 10-mg dose of acenocoumarol, and the AUCs of *S*- and *R*-acenocoumarol were not altered.[1,2]

(b) Warfarin

In a study in 9 patients stabilised on warfarin, consumption of grapefruit juice 240 mL three times daily for one week had no effect on the INR or prothrombin times.[3] Similarly, in the preliminary report of a two-way crossover study in 24 patients stabilised on warfarin, the frequency of the **warfarin** dosage adjustments needed by the group as a whole, when taking 250 mL grapefruit juice daily for 4 weeks was the same as when taking a placebo (orange juice). However, 4 individuals had a clinically significant, progressive and sustained 12 to 25% decrease in the warfarin dose to INR ratio when taking grapefruit juice, but not orange juice.[4] A 64-year-old man stabilised on warfarin was found to have an INR of 6.29 on routine testing 10 days after starting to drink about 1.5 litres of grapefruit juice daily. However, when the author took warfarin to achieve an INR of 2 to 3 and then drank 1.5 litres of grapefruit juice daily there was no clinically relevant change in his INR.[5]

Mechanism

It was suggested that the patients who showed some evidence of an interaction between grapefruit juice and warfarin may possibly have had an increased susceptibility to the inhibitory effects of grapefruit juice on the activity of the cytochrome P450 isoenzyme CYP3A4 in the gut.[4] Note that CYP3A4 has a minor role in the metabolism of *R*-warfarin, which is a much less potent anticoagulant than *S*-warfarin.

Importance and management

Information is limited. One study with warfarin suggests that some patients might require a slight reduction in dose if they regularly consume grapefruit juice, but further study is needed. Current evidence suggests that routine testing should be sufficient to detect any interaction.

For discussion of the interaction of warfarin with grapefruit seed extract, thought to be due to the preservative benzethonium chloride, see 'benzethonium chloride', (p.441).

Coumarins + Griseofulvin

The anticoagulant effects of warfarin may be reduced by griseofulvin in some patients.

Clinical evidence

The anticoagulant effects of **warfarin** were modestly and markedly reduced in 2 patients, respectively, stabilised on **warfarin** when they were given griseofulvin 1 g daily in divided doses. Griseofulvin 1 g daily had

no effect on the prothrombin time in one healthy subject given **warfarin**, whereas 2 g daily caused a marked reduction in the prothrombin time. Another healthy subject had no interaction, even when the griseofulvin dose was raised to 4 g daily for 2 weeks.[1]

In another study there was no change in the mean prothrombin time in 10 patients stabilised on **warfarin** when they were given griseofulvin 1 g daily in divided doses for 2 weeks. Four of the patients had an equivocal average reduction in prothrombin time of 4.2 seconds.[2] One case report describes decreased anticoagulant effects in a man stabilised on **warfarin** when he took griseofulvin 250 mg twice daily, which took 12 weeks to develop fully.[3] He eventually needed a 41% increase in his daily dose of **warfarin**. Another report very briefly mentions a case of a coagulation defect in a patient taking **warfarin** and griseofulvin.[4]

Mechanism

Not understood. It has been suggested that the griseofulvin acts as a liver enzyme inducer, which increases the metabolism of the warfarin, thereby reducing its effects.[1,3]

Importance and management

The interaction between warfarin and griseofulvin is poorly documented and not well established. However, it possibly results in a clinically significant interaction in some patients. Because of the uncertainty, and the known enzyme-inducing effects of griseofulvin, the prothrombin times of all patients taking warfarin who are given griseofulvin should be monitored, and suitable warfarin dose increases made as necessary.

Coumarins and related drugs + H_2-receptor antagonists

The anticoagulant effects of warfarin can be increased by cimetidine. Acenocoumarol interacts similarly, but phenprocoumon appears not to be affected. In one patient the effects of phenindione were modestly increased by cimetidine. Famotidine, nizatidine, ranitidine and roxatidine normally do not appear to interact with the coumarins, although isolated cases of bleeding have been reported.

Clinical evidence

(a) Cimetidine

A brief report in 1978, published as a letter by the manufacturers of cimetidine, stated that preliminary details of a study in healthy subjects indicated that cimetidine 1 g daily could cause a prothrombin time rise of about 20% in patients stabilised on **warfarin**. At that time, they were aware of 17 cases worldwide, most of moderate rises in prothrombin times.[1]

A number of studies[2,3] and case reports[4-8] have confirmed this interaction with **warfarin**. In the studies, plasma **warfarin** levels were reported to rise by 25% and 80%, and prothrombin times were increased by 18% and 20% by cimetidine 1.2 g daily. In the case reports, severe bleeding (haematuria, internal haemorrhages) and very prolonged prothrombin times have been seen in a few patients given cimetidine 900 mg or 1.2 g daily.[4,6-8]

In another study, 7 out of 14 patients stabilised on **warfarin** had a greater than 30 second increase in their prothrombin time, whereas the other 7 had no prolongation or only a minor prolongation in their prothrombin time when they were given cimetidine 1.2 g daily for 10 days.[9] A study in 27 patients found that, although the AUC of **warfarin** was increased by 21 to 39% and its clearance fell by 22 to 28%, prothrombin times only increased by 2 to 2.6 seconds by cimetidine 800 mg or 1.2 g daily.[10] A pharmacokinetic study in 6 healthy subjects found that cimetidine did not affect *S*-warfarin but increased the trough plasma levels of *R*-warfarin by 28%, with minimal effect on prothrombin times.[11] Other pharmacokinetic studies have confirmed that the interaction affects only *R*-warfarin.[12-15] In one analysis of the concurrent use of **warfarin** and an H_2-receptor antagonist in hospitalised patients, there was no difference in the intensity of prothrombin time monitoring, and no difference in bleeding rates between 35 patients receiving cimetidine, 38 patients receiving ranitidine, or 36 patients receiving famotidine. Two patients in the cimetidine group had a bleed after they had taken both drugs for one or two days but neither had abnormally high prothrombin times.[16]

In three studies, the AUC of single-dose **acenocoumarol** was increased by cimetidine, and the prothrombin time prolonged,[17-19] with the effect greatest for *R*-acenocoumarol.[19] However, another study found no interaction.[20] Data from one patient taking **acenocoumarol** and one taking **phenindione** showed that cimetidine increased their anticoagulant effects.[2] In one study in patients stabilised on **phenprocoumon**, cimetidine 400 mg twice daily did not alter the pharmacokinetics of **phenprocoumon** or its anticoagulant effect.[21]

(b) Famotidine

In a study in 8 healthy subjects taking doses of **warfarin** titrated to prolong the prothrombin time by 2 to 5 seconds (mean dose 4 mg daily), famotidine 40 mg daily for 7 days did not affect prothrombin times, thrombotest coagulation times or steady-state plasma **warfarin** levels.[22] No changes in prothrombin times were seen in 3 patients stabilised on **acenocoumarol** or **fluindione** when they were given famotidine.[23] However, in another report 2 patients taking **warfarin** are said to have had prolonged prothrombin times and bled when they took famotidine.[24]

(c) Nizatidine

In 7 healthy subjects taking **warfarin**, nizatidine 300 mg daily for 2 weeks had no significant effect on the prothrombin times, kaolin-cephalin clotting times, the activity of factors II, VII, XI and X, or on steady-state serum **warfarin** levels.[25] A lack of a pharmacokinetic interaction was also reported in the preliminary results of another study.[26] An isolated case of gastrointestinal bleeding, associated with markedly prolonged prothrombin times, occurred after a 78-year-old took six doses of nizatidine 300 mg.[24]

(d) Ranitidine

In a study in 5 healthy subjects, ranitidine 200 mg twice daily for 2 weeks had no effect on **warfarin** concentrations or prothrombin times.[27] In another study in 11 healthy subjects, ranitidine 150 mg twice daily for 3 days had no effect on the pharmacodynamics or pharmacokinetics of a single dose of **warfarin**.[3] The same finding was reported in another similar study.[15] In contrast, in a fourth study in 5 subjects, ranitidine 150 mg twice daily for a week reduced the clearance of a single dose of **warfarin** by almost 30%, but the half-life was not significantly changed and prothrombin times were not measured.[28] Ranitidine 750 mg daily given to 2 subjects reduced the **warfarin** clearance by more than 50%.[28] In an isolated case, a patient stabilised on ranitidine 150 mg twice daily and **warfarin** vomited blood one week after her ranitidine dose was doubled to 300 mg twice daily. Her prothrombin time had risen from 17.6 seconds to 36.7 seconds. She was subsequently restabilised on ranitidine 150 mg twice daily and the original dose of **warfarin** with a prothrombin time between 19 and 20 seconds.[29]

In one study in 10 patients stabilised on **phenprocoumon**, ranitidine 150 mg twice daily for 14 days had no effect on anticoagulation or on phenprocoumon plasma levels.[30]

(e) Roxatidine

In a study in 12 healthy subjects, roxatidine 150 mg daily for 4 days had no effect on the steady-state pharmacokinetics of **warfarin** or the prothrombin ratio.[31]

Mechanism

Cimetidine binds with the cytochrome P450 isoenzymes and inhibits oxidative metabolism in the liver. Although cimetidine is considered to be a general inhibitor, it exhibits a degree of specificity for certain isoenzymes such as CYP1A2 and CYP2C19. These isoenzymes are principally involved in the metabolism of *R*-warfarin and not *S*-warfarin (see 'metabolism of the coumarins', (p.405), for more detail). Thus, the interaction between warfarin and cimetidine has been found to be stereoselective (i.e. cimetidine interacts with the *R*-isomer but not with the *S*-isomer).[11-14] As *R*-warfarin is the less active isomer, and the pharmacokinetic interaction is not marked, the interaction is generally modest. The other H_2-receptor antagonists normally do not act as enzyme inhibitors.

Importance and management

The interaction between warfarin and cimetidine is well documented, well established and potentially clinically important. Its effects are generally modest, but rarely, patients have shown a marked interaction. Because of this unpredictability, and to avoid bleeding, the response should be closely monitored in every patient when cimetidine is first added, being alert for the need to reduce the warfarin dose. The onset of the interaction appears rapid and its effects have been seen within days,[4,7] and even as early as 24 hours.[9] The effect of low non-prescription doses of cimetidine on warfarin do not appear to have been studied. Acenocoumarol is reported to interact similarly, and there is one case of phenindione being affected. Expect other coumarins and indanediones to behave in the same way, with the possible exception of phenprocoumon, which was not affected in one study.

Famotidine, nizatidine, ranitidine and roxatidine normally appear not to interact with the coumarins although note that, in rare cases, increases in prothrombin times and bleeding have been seen.

Coumarins + Heparin

Heparin may prolong the prothrombin time, and increase the risk of bleeding with warfarin.

Clinical evidence, mechanism, importance and management

Heparin may prolong the one-stage prothrombin time.[1] The US manufacturer notes that, if a valid prothrombin time is to be obtained in a patient starting **warfarin** or other coumarins, a period of a least 5 hours after the last intravenous heparin dose or 24 hours after the last subcutaneous dose should be left before measuring the prothrombin time.[2] Note that it is usual clinical practice to start heparin and a coumarin at the same time to ensure the patient is anticoagulated until warfarin reaches steady-state, and to discontinue the heparin when the INR is stable.

2. Heparin Sodium Injection. Pharmacia & Upjohn. US Prescribing information, December 2000.

Coumarins and related drugs + Heparinoids

Some of the normal tests of anticoagulation (prothrombin time, thrombotest) are unreliable for a few hours after giving intravenous danaparoid to patients taking coumarins. Oral pentosan polysulfate sodium did not alter the pharmacokinetics or pharmacodynamics of warfarin in healthy subjects, but note that this heparinoid is associated with rectal bleeding. An isolated case report describes bleeding in a patient taking acenocoumarol after a heparinoid-impregnated bandage was applied.
In general, the use of heparinoids with coumarins or indanediones would be expected to increase the risk of bleeding.

Clinical evidence, mechanism, importance and management

(a) Intravenous danaparoid

A study in 6 healthy subjects taking **acenocoumarol** (steady-state thrombotest values of 10 to 15%), found that a single intravenous bolus injection of 3250 anti-Xa units of danaparoid prolonged the prothrombin time and thrombotest for up to one hour and 5 hours, respectively, which was more than would have been expected by the simple addition of the effects of both drugs. However, no significant differences were seen in bleeding time, and danaparoid did not alter **acenocoumarol** pharmacokinetics.[1] The authors concluded that when monitoring the anticoagulant effects of **acenocoumarol**, the prothrombin time and the thrombotest may therefore be unreliable for at least one hour and 5 hours, respectively, after intravenous danaparoid has been given. This advice would apply equally to other coumarins and other drugs monitored using these tests, such as the indanediones.

(b) Pentosan polysulfate sodium

In a placebo-controlled, crossover study in 24 healthy subjects stabilised on **warfarin**, oral pentosan polysulfate sodium 100 mg every 8 hours for 7 days did not alter the anticoagulant effect of **warfarin** or the pharmacokinetics of *R*- or *S*-warfarin.[2] The authors consider it appears that, unlike intravenous administration, oral pentosan polysulfate sodium has no anticoagulant activity. However, the manufacturer notes that rectal haemorrhage was reported as an adverse effect in 6.3% of patients receiving pentosan polysulfate sodium at a dose of 300 mg daily.[3] On the basis of the pharmacological study, the authors considered that it seems unnecessary to make changes in the warfarin dose or the oral pentosan polysulfate sodium dose when the two drugs are used together. However, they do recommend careful monitoring on starting concurrent use.[2] Logic would suggest that, if bleeding occurs, this could be more severe in anticoagulated patients. The patient information provided by the manufacturer states that concurrent use of pentosan polysulfate and warfarin should be avoided until they have spoken with their doctor.[3] See also *Topical heparinoid*, below.

(c) Topical heparinoid

A man who was well stabilised on **acenocoumarol** and also taking metoprolol, dipyridamole and isosorbide dinitrate began to bleed within about 3 days of starting to use a medicated bandage on an inflamed lesion on his

hand, probably caused by a mosquito bite. His prothrombin percentage was found to have fallen to less than 10%. The bandage was impregnated with a semi-synthetic heparinoid compound based on **xylane acid polysulfate** [possibly **pentosan polysulfate**].[4] It would appear that enough of the heparinoid had been absorbed through his skin to increase his anticoagulation to the point where he began to bleed. This case is unusual but it illustrates the need to keep a close watch on patients who are given several drugs that can potentially cause bleeding.

Coumarins + Herbal medicines; Miscellaneous

Many of the interactions of herbal medicines (health foods, dietary supplements) with warfarin in the published literature are solely hypothetical based on the postulated pharmacological effects of known chemical constituents of the plants. These mechanisms are discussed further below. Where specific clinical data on a herbal medicine interaction with warfarin are available, this is covered in a separate monograph.
All patients should be encouraged to report their use of herbal medicines and food supplements and cases of uneventful concurrent use should be published as well as cases of possible interactions to increase the clinical information available.

Clinical evidence and mechanism

(a) Antiplatelet effects

Antiplatelet doses of aspirin (see 'Coumarins and related drugs + Aspirin or other Salicylates', p.434), do not alter the anticoagulant efficacy of warfarin (INR); however, these doses of aspirin by themselves increase the risk of gastrointestinal bleeding, and the risk of this is higher in patients taking warfarin. On this basis, many herbs with antiplatelet activity *in vitro* are suggested to interact with warfarin. To establish the increased risk with antiplatelet doses of aspirin with warfarin, very large studies were needed because the absolute risks are small (about 1 in 100 in one study). Studies of this size are very unlikely to be conducted with herbal medicines. One way might be to compare the *in vivo* antiplatelet activity of the herbal product with that of aspirin 75 mg, and then to extrapolate to the likely increased risk of bleeding.

(b) Coumarin constituents

There is a misconception that if a plant contains natural coumarins it will have anticoagulant properties. More than 3 400 coumarins occur naturally throughout at least 160 plant families. Of these, just 13 have been tested for antithrombotic or anticoagulant activity, and only about half (7) were found to be active.[1] There are no established interactions between warfarin and herbal medicines that have been attributed to the coumarin content of the herb. Even in the classic case of hemorrhagic death of livestock that led to the discovery of dicoumarol, it was the action of the mould on the coumarin in the sweet clover that led to the production of the anticoagulant, so consumption of a spoiled product would seem to be necessary for this interaction to occur. This suggests that the occurrence of coumarins in dietary supplements or herbal medicines should not trigger immediate concern.[1]

(c) Vitamin K content

Vitamin K is found in highest levels in green leafy vegetables, which, if ingested in sufficient quantities, can markedly reduce the effects of warfarin and related drugs (see 'Coumarins and related drugs + Food; Vitamin K_1-rich', p.464). It would therefore not be surprising if many herbal medicines derived from dark green leaves contain vitamin K. However, whether enough of these herbs could be taken to cause an interaction seems less likely than with foods. Nevertheless, two case reports of altered coagulation status attributed to the vitamin K content of herbal preparations have been reported, see 'Coumarins + Vitamin K_1-rich herbal medicines', p.521.

Importance and management

There are many reviews of the effect of various herbal medicines on warfarin. Most of these include interactions based on theoretical data, based on the knowledge that a plant has been shown to contain antiplatelet substances or coumarins. The problem with these lists is that a suggested interaction might never be clinically relevant if, for example, the coumarins present are found not to be anticoagulants, or the substances are found in such small quantities and the herb cannot be ingested in sufficient amounts to cause an interaction. With natural substances, there is also the problem of chemical variations between batches of product if they are not standardised. Moreover, even isolated reports of an interaction between a herbal medicine and warfarin cannot definitively establish that such an interaction exists (see also 'anticoagulant interactions', (p.405)).

Because of the potential for interactions, some consider that patients taking warfarin would be well advised to avoid all herbal medications. However, this approach may not be practical: there are many papers showing that patients taking warfarin do use a number of herbal medicines and dietary supplements (19.2% in a UK survey;[2] 26% in a Hong Kong survey[3]). If patients have been told to avoid all herbal products, they may be less likely to admit to their use, and become less cautious in the future if they discover that the use of one product is uneventful. It may be better to advise patients to discuss the use of any products they wish to try, and to increase monitoring if this is thought necessary. Cases of uneventful use should be reported, as they are as useful as possible cases of adverse use.

Coumarins + Herbicides

An isolated report describes a marked increase in the anticoagulant effects of acenocoumarol, with bleeding, caused by the use of a herbicide containing thiocarbamates.

Clinical evidence, mechanism, importance and management

A 55-year-old patient with mitral and aortic prostheses, stabilised on **acenocoumarol** 2 mg daily and with an INR of 3.6 to 4.2 was hospitalised because of severe and uncontrollable gum bleeding. He responded when given a transfusion of fresh plasma. The cause of the marked increase in the anticoagulant effects of the **acenocoumarol** was eventually identified as almost certainly being due to the use of a herbicide (*SATURN-S*) containing **thiobencarb** and **molinate** (two thiocarbamates), which the patient was using to spray his rice crop. The **thiobencarb** can be absorbed through the skin and the **molinate** by inhalation. Just how these two compounds interact with **acenocoumarol** is not known but the authors of the report suggest that these herbicides may possibly have inhibited the metabolism of the anticoagulant, thereby increasing its effects. The patient was later restabilised on his former dose of **acenocoumarol**.[1]

This seems to be the first and only report of this interaction but it highlights one of the possible risks of using chemical sprays that have never been formally tested for their potential to interact with drugs. A similar problem has been seen with insecticides, see 'Coumarins + Insecticides', p.473.

1. Fernández MA, Aznar J. Potenciación del efecto anticoagulante del acenocumarol por un herbicida. *Rev Iberoamer Tromb Hemostasia* (1988) 1, 40–1.

Coumarins + Hormonal contraceptives or HRT

Acenocoumarol dose requirements appear to be about 20% lower during the use of a combined hormonal contraceptive. An isolated report describes a marked increase in the INR of a woman taking warfarin when she was given emergency contraception with levonorgestrel. In contrast, the anticoagulant effects of dicoumarol and phenprocoumon were slightly decreased by oral contraceptives. Ethinylestradiol with norgestimate did not appear to have much effect on the clearance of warfarin.
There is conflicting data on whether or not the use of HRT (oral

or topical) affects warfarin or phenindione dosing. In one case, the acenocoumarol dose was increased by 75% when oral conjugated oestrogens were changed to transdermal estradiol.

Clinical evidence

A. Hormonal contraceptives

(a) Acenocoumarol

The anticoagulant requirements of 12 patients taking acenocoumarol were about 20% lower while they were taking a combined hormonal contraceptive (average 19 months) than when they were not taking a contraceptive (average 12 months). Even then, they were anticoagulated to a higher degree while taking the contraceptive (prothrombin ratio of 1.67 compared with 1.5) than with the anticoagulant alone. The contraceptives used were *Neogynona*, *Microgynon*, *Eugynon* (**ethinylestradiol** with **levonorgestrel**) or *Topasel* (intramuscular **estradiol enantate** with **algestone**).[1]

(b) Dicoumarol

A study in 4 healthy subjects given single 150- or 200-mg doses of dicoumarol on day 17 of a 20-day course of *Enovid* (**noretynodrel** and **mestranol**) found that the anticoagulant effects were decreased in 3 of the 4 subjects, although the dicoumarol half-life remained unaltered.[2]

(c) Phenprocoumon

In a controlled study in 14 healthy women, the clearance of a single 0.22 mg/kg dose of phenprocoumon was increased by 20% in the 7 subjects taking oral combined hormonal contraceptives, compared with the 7 control subjects not taking hormonal contraceptives.[3]

(d) Warfarin

In a pharmacokinetic study, a single dose of warfarin 10 mg (given with vitamin K 10 mg to prevent anticoagulant effects) was given to 10 women before and while they were taking an oral combined hormonal contraceptive (**ethinylestradiol** 35 micrograms with **norgestimate** 180 micrograms to 250 micrograms for 3 weeks). The mean clearance of *S*-warfarin was not significantly changed, although there was wide variability with 5 subjects having an increase in clearance, 3 having a decrease, and 2 having little change.[4]

A 39-year-old woman with familial type 1 antithrombin deficiency and a history of extensive deep vein thrombosis and pulmonary embolism, taking warfarin, was given **levonorgestrel** for emergency contraception. Within 3 days her INR had risen from 2.1 to 8.1. No bleeding occurred. Her INR returned to normal after stopping the warfarin for 2 days.[5]

B. HRT

In a retrospective analysis, 18 women were identified who had started HRT while taking **warfarin** (16 patients) or **phenindione** (2 patients). A wide variety of HRT preparations were being used, including topical and oral preparations, oestrogens with or without progestogens, and progestogens alone. Half of the women taking **warfarin** had no change in their warfarin dose requirement after starting HRT. Five required a less than 10% increase or decrease in average **warfarin** dose, and 3 required a 13%, 22%, and 28% increase in their average **warfarin** dose, the latter two of these being the only 2 women taking oestrogen-only oral HRT. Of the 2 women taking **phenindione**, one needed no change in dose, and the other a 4.6% increase in dose.[6]

In one case, a postmenopausal 53-year-old woman needed an increase in her daily dose of **acenocoumarol** from 2 to 3.5 mg when her HRT was changed from **oral conjugated oestrogens** 0.625 mg daily to **transdermal estradiol** 50 micrograms daily. When the oral HRT was restarted, her **acenocoumarol** requirements returned to their former levels.[7]

Mechanism

Not understood. The oral contraceptives are known to be associated with a small increased risk of venous thromboembolism in otherwise healthy women, and are therefore contraindicated in women who have had thrombosis. HRT also increases the risk of venous thromboembolism. Oestrogens can apparently increase the metabolism (glucuronidation) of phenprocoumon.[3] The authors of the report about levonorgestrel suggest that it might have displaced the warfarin from its binding sites thereby increasing its activity,[5] although this mechanism is now generally discounted.

Ethinylestradiol with norgestimate did not appear to have an important effect on the activity of the cytochrome P450 isoenzyme CYP2C9, as assessed by the clearance of *S*-warfarin.[4]

Importance and management

Direct information seems to be limited to these reports. Combined hormonal contraceptives (both oral and patch) are normally contraindicated in those with thromboembolic disorders but if they must be used, be alert for any changes in the anticoagulant response if a hormonal contraceptive is started or stopped. The report about the apparent interaction between warfarin and postcoital levonorgestrel seems to be isolated and therefore its general importance is unknown. Note that intrauterine levonorgestrel has been used for menorrhagia in women taking warfarin.[8]

There is very limited published information available on the concurrent use of warfarin and HRT. The retrospective study suggests that usually HRT causes no or only minor changes in warfarin or phenindione requirements.

Note that, because of the increased risk of developing venous thromboembolism with HRT, the use of HRT in women already taking an anticoagulant requires careful consideration of the risks and benefits.

Coumarins + Insecticides

A patient had a marked increase in his response to acenocoumarol when exposed to insecticides containing ivermectin and methidathion. Another patient was resistant to the effects of warfarin after very heavy exposure to a toxaphene and lindane-containing insecticide.

Clinical evidence

(a) Acenocoumarol

A farmer in Spain, normally well stabilised on acenocoumarol and amiodarone, had marked rises in his INR, from 3.5 up to 7.9, requiring a reduction in his anticoagulant dose (from 12 to 8 mg weekly), which occurred during the summer months. No bleeding occurred. It was then discovered that he was using insecticides containing **ivermectin** and an organophosphate **methidathion** on his trees without any protective clothing.[1]

(b) Warfarin

A rancher in the US, who was taking warfarin, had a very marked reduction in his anticoagulant response after dusting his sheep with an insecticide containing 5% **toxaphene** (**camphechlor**) and 1% **lindane** (**gamma-benzene hexachloride**). Over a 2-year period he had periods of considerable warfarin resistance, which were linked to the use of this insecticide. Normally warfarin 7.5 mg daily maintained his prothrombin time in the therapeutic range, but after exposure to the insecticide even 15 mg daily failed to have any effect.[2] The dusting was done by putting the insecticide in a sack and hitting the sheep with it in an enclosed barn.[2]

Mechanism

The interaction between acenocoumarol and ivermectin with methidathion is not understood. When used on its own, ivermectin used for onchocerciasis normally has no effect on prothrombin times,[3,4] but two unexplained cases of prolonged prothrombin times associated with the development of haematomas have been reported.[5] Methidathion is an organophosphate. Lindane and other chlorinated hydrocarbon insecticides

are known liver enzyme inducers,[6] which increase the metabolism and clearance of the warfarin, thereby reducing or even abolishing its effects.

Importance and management

Information about these interactions appears to be limited to these isolated case reports. Neither interaction is well established or of general clinical importance. The chlorinated hydrocarbon insecticides have been withdrawn from general use in most countries so that the possibility of an interaction with any anticoagulant is now very small. No other cases of an interaction between an anticoagulant and ivermectin, whether used as an insecticide or for the treatment of onchocerciasis, appear to have been reported.

As a general rule, farm workers and others should use proper protection (gloves, masks, protective clothing) if they are exposed to substantial amounts of any insecticide, because these can be both directly toxic and can also apparently interact with some prescribed drugs, including the anticoagulants, even if only very rarely.

Coumarins + Interferons

Two isolated reports indicate that the effects of acenocoumarol and warfarin may be increased by interferons. Conversely, there is evidence that suggests that peginterferon alfa-2b might modestly increase the metabolism of warfarin and other coumarins.

Clinical evidence

The manufacturer of **peginterferon alfa-2b** notes that, in a pharmacokinetic probe study in patients with chronic hepatitis C, **peginterferon alfa-2b** increased the activity of cytochrome P450 isoenzyme CYP2C8/9 by 28%, as assessed by tolbutamide pharmacokinetics.[1,2] This suggests that this interferon might increase the metabolism of *S*-warfarin, the more potent isomer, and therefore decrease the effects of **warfarin**. However, in a similar study in healthy subjects, **peginterferon alfa-2a** had no effect on tolbutamide pharmacokinetics.[3]

However, a woman stabilised on long-term **warfarin** 2.5 to 3.5 mg daily had a prothrombin time rise from 16.7 seconds to 20.4 seconds after receiving 6 million units of **interferon-alfa** daily for 10 days, then three times a week, for chronic hepatitis C. Her serum **warfarin** levels rose from about 0.8 micrograms/mL to 5.2 micrograms/mL. She responded to a reduction in the **warfarin** dose to 2 mg daily. The authors of the report also say that they have seen 4 other patients taking **warfarin** who needed a dose reduction when given interferon, two of them while taking **interferon beta** and the other two while taking **interferon alfa-2b**.[4]

Similarly, a woman taking **acenocoumarol** 1 mg and 2 mg on alternate days had gingival bleeding and a thrombotest change from 35% to 19% (indicating an increased anticoagulant effect) within 6 weeks of starting treatment with 3 million units of **interferon-alpha 2b** three times weekly for chronic hepatitis C. Her thrombotest percentages stabilised between 25 and 40% when the **acenocoumarol** dose was reduced to 1 mg daily. A later reduction in the interferon dose caused a decrease in the anticoagulant effects of **acenocoumarol**.[5]

Mechanism

Not understood. The authors of both reports suggest that interferon reduces the metabolism of the anticoagulants by the liver, thereby reducing their clearance and increasing their effects.[4,5] Some early *in vitro* studies did show that interferons might inhibit some drug metabolising enzymes.[6] Conversely, data for peginterferon alfa-2b suggest that it might modestly increase the metabolism of warfarin by the cytochrome P450 isoenzyme CYP2C9, which would reduce its anticoagulant effects. The manufacturer suggests that this might be because of the improvement in liver function seen when peginterferon is used in chronic hepatitis,[2] rather than any direct effect of peginterferon. However, the effect was not seen for all cytochrome P450 isoenzymes, and the opposite was seen in the two case reports described when other interferons were used for chronic hepatitis.

Importance and management

These two reports seem to be the only ones to describe an increased effect of the coumarins with an interferon, so the interaction is by no means established. Conversely, the data for peginterferon alfa-2b suggest that there might be a modest increase in activity of CYP2C9. Whether this is sufficient to cause a relevant decrease in the effect of warfarin remains to be seen. Nevertheless, the manufacturer advises caution with warfarin.[1,2] It would seem prudent to consider increased monitoring if any of these interferons is given to patients taking coumarins. For a case of decreased warfarin effects in a patient given interferon alfa-2b and ribavirin, see 'Coumarins + Ribavirin', p.502.

Coumarins + Ispaghula (Psyllium)

Ispaghula (psyllium) did not affect either the absorption or the anticoagulant effects of warfarin in one study. A cohort study also found no evidence of an interaction in patients taking acenocoumarol or phenprocoumon and ispaghula.

Clinical evidence, mechanism, importance and management

In a study in 6 healthy subjects, ispaghula (given as a 14-g dose of colloid (*Metamucil*) in a small amount of water with a single 40-mg dose of **warfarin**, and three further doses of ispaghula every 2 hours thereafter) did not affect either the absorption or the anticoagulant effects of the **warfarin**.[1] Similarly, in a population-based cohort study in patients taking **acenocoumarol** or **phenprocoumon**, there was no increased risk of over-anticoagulation (INR greater than 6) associated with the use of ispaghula (psyllium seeds), although the number of people treated was small.[2] No alteration of the anticoagulant response would therefore be expected on concurrent use.

Coumarins + Lanthanum

Lanthanum does not appear to alter the pharmacokinetics of a single dose of warfarin.

Clinical evidence, mechanism, importance and management

In a pharmacokinetic study in healthy subjects, lanthanum carbonate (3 doses of 1 g the day before **warfarin**, then 1 g thirty minutes before **warfarin**) had no effect on the pharmacokinetics of a single dose of **warfarin**.[1]

Lanthanum carbonate is a phosphate-binding drug, and does not appear to alter **warfarin** absorption. This suggests that no **warfarin** dose adjustments would be expected to be needed on concurrent use. However, note that the pharmacodynamics of **warfarin** (e.g. the effects on INR) were not assessed in this study.

1. Fiddler G. Fosrenol (lanthanum carbonate) does not affect the pharmacokinetics of concomitant treatment with warfarin. *J Am Soc Nephrol* (2002) 13, 749A–750A.

Coumarins + Lasofoxifene

In a study, lasofoxifene caused a minor decrease in the prothrombin time in response to warfarin without changing warfarin pharmacokinetics.

Clinical evidence, mechanism, importance and management

In 12 healthy postmenopausal women, lasofoxifene 4 mg on day one then 500 micrograms daily for 13 days had no effect on the pharmacokinetics of *R*- or *S*-warfarin when a single 20-mg dose of **warfarin** was given on day 8. However, the maximum prothrombin time was decreased by 16%, with a similar decrease in the maximum INR, which was reduced from 1.9 to 1.6.[1]

Because this slight decrease in **warfarin** effects has been seen with raloxifene (see 'Coumarins + Raloxifene', p.502), the authors suggested that it might be because oestrogenic compounds increase plasma concentrations of vitamin K-dependent clotting factors.[1]

The authors suggest that the small decrease in **warfarin** effect with lasofoxifene may not be clinically relevant. Nevertheless, they say that until more data are available on longer-term concurrent use, it is recommended that prothrombin times should be monitored (presumably with any coumarin) when starting or stopping lasofoxifene.[1] This seems a sensible precaution.

Coumarins + Laxatives

In one cohort study, the long-term use of lactulose appeared to be associated with an increased risk of over-anticoagulation. Limited evidence suggested no interaction occurred with liquid paraffin or colocynth.

Clinical evidence

In a population-based cohort study in patients taking **acenocoumarol** or **phenprocoumon**, lactulose significantly increased the risk of over-anticoagulation (INR greater than 6) with a relative risk of 3.4 (range 2.2 to 5.3). When analysed by duration of use, less than 27 days use of **lactulose** actually decreased the risk of over-anticoagulation, whereas longer use was associated with an increased risk. In this study, neither **liquid paraffin** nor **colocynth** preparations were associated with an increased risk of over-anticoagulation, but the numbers of patients taking these drugs was small.[1]

Mechanism

In theory, drugs that shorten gastrointestinal transit time such as laxatives and liquid paraffin (mineral oil) might be expected to decrease the absorption of both vitamin K and the coumarins or indanediones. Decreasing the absorption of vitamin K would be expected to increase the effect of these anticoagulants, which could be offset by the decrease in absorption of the anticoagulant. In the case of short-term lactulose use, it was suggested that decreasing the colonic pH might have increased the absorption of vitamin K, thereby reducing the effect of the coumarin. On longer term use, it was postulated that lactulose might reduce faecal flora that produce vitamin K, so increasing the risk of over-anticoagulation.[1] Liquid paraffin might also be expected to impair the absorption of vitamin K.

Importance and management

The cohort study cited appears to be the first and only evidence of a possible interaction with laxatives, and it suggests that the long-term use of lactulose may increase the effect of coumarins. This finding requires confirmation in a controlled pharmacological study. Until further data are available, it may be prudent to consider the possibility of an interaction in any patient taking lactulose long-term. Limited evidence suggests that no interaction occurs with liquid paraffin or colocynth but this needs confirmation. Clinical evidence for an interaction with other laxatives is lacking, despite the theoretical considerations.

1. Visser LE, Penning-van Beest FJA, Wilson JHP, Vulto AG, Kasbergen AAH, De Smet PAGM, Hofman A, Stricker BHC. Overanticoagulation associated with combined use of lactulose and acenocoumarol or phenprocoumon. *Br J Clin Pharmacol* (2003) 57, 522–4.

Coumarins + Leflunomide

There are a few reports of increased INRs, some with bleeding complications, in patients taking warfarin with leflunomide.

Clinical evidence, mechanism, importance and management

A short report describes a patient taking **warfarin** whose INR rose from 2.5 to over 6, resulting in a hospital admission, shortly after she started taking leflunomide (3 days of 100 mg daily).[1]

Another report describes a patient taking **warfarin** who developed haematuria after taking leflunomide 100 mg daily for 2 days. His INR was found to have risen from 3.4 to over 11, and **warfarin** was discontinued. The haematuria spontaneously resolved, but as the INR remained elevated for the next 2 days he was given 1 mg of vitamin K, which brought his INR down to 1.9. He was later stabilised on **warfarin** 1 mg daily with a leflunomide maintenance dose of 20 mg daily.[2] The authors of this report stated that at that time (2002) the CSM in the UK had received over 300 reports of leflunomide raising the INRs of patients taking **warfarin**;[2] however, this was an error, and the report should have read that of 300 reports of raised INRs with **warfarin** and another drug, *four* reports related to leflunomide.[3] An additional case describes a patient who required a 22% decrease in her weekly **warfarin** dose after starting leflunomide.[4]

The manufacturers of leflunomide note that *in vitro*, the active metabolite of leflunomide inhibits the cytochrome P450 isoenzyme CYP2C9. They therefore advise caution if leflunomide is given with drugs metabolised by CYP2C9, of which they give **warfarin** and **phenprocoumon** as examples.[5] On the basis of the cases seen, it would seem prudent to monitor the INR of any patient taking a coumarin who starts taking leflunomide.

Coumarins + Leukotriene antagonists

Zafirlukast increases the anticoagulant effects of warfarin and bleeding has been seen. Pranlukast is predicted to interact similarly. In contrast, montelukast did not alter the pharmacokinetics or anticoagulant effects of single-dose warfarin.

Clinical evidence

(a) Montelukast

In a placebo-controlled, randomised study, 12 healthy subjects were given oral montelukast 10 mg daily for 12 days and a single 30-mg dose of **warfarin** on day 7. It was found that the pharmacokinetics of the **warfarin** were virtually unchanged by the montelukast, and prothrombin times and INRs were not significantly altered.[1]

(b) Zafirlukast

In a placebo-controlled study, 16 healthy subjects taking zafirlukast 80 mg twice daily for 10 days were given a single 25-mg dose of **warfarin** on day 5. The mean AUC of *S*-warfarin was increased by 63% and the half-life by 36%, but the pharmacokinetics of *R*-warfarin were not significantly changed. The mean prothrombin time increased by 35%.[2]

An 85-year-old woman taking **warfarin**, salbutamol (albuterol), diltiazem, digoxin, furosemide and potassium was admitted to hospital with various cardiac-related problems and bleeding (epistaxis, melaena, multiple bruising), which was attributed to the use of zafirlukast 20 mg twice daily. Her INR had risen from 1.1 (measured 6 months previously) to 4.5. The report does not say how long she had been taking the both drugs together.[3]

Mechanism

The reason for the interaction is thought to be that the zafirlukast inhibits the cytochrome P450 isoenzyme CYP2C9, which metabolises *S*-warfarin.[2,4] *In vitro* studies suggest that **pranlukast** has a similar effect.[5]

Importance and management

Information appears to be limited to these reports but the interaction with zafirlukast would seem to be established. If zafirlukast is given to patients stabilised on warfarin, monitor prothrombin times well and be alert for the need to reduce the warfarin dose to avoid over-anticoagulation. Other coumarins might be expected to be affected similarly. Pranlukast is also predicted to interact with the coumarins, as it is also an inhibitor of CYP2C9. In contrast, montelukast does not appear to interact with warfarin, and no warfarin dose adjustments are predicted to be needed on concurrent use.

Coumarins + Levetiracetam

In a controlled study, levetiracetam did not alter the pharmacokinetics or pharmacodynamics of warfarin.

Clinical evidence, mechanism, importance and management

In a randomised, double-blind, placebo-controlled study in 42 healthy subjects stabilised on **warfarin**, levetiracetam 1 g twice daily for 7 days had no significant effect on the pharmacokinetics of *R*- or *S*-warfarin and the INRs were not significantly altered.[1] No **warfarin** dose adjustments would therefore be expected to be needed on concurrent use.

1. Ragueneau-Majlessi I, Levy RH, Meyerhoff C. Lack of effect of repeated administration of levetiracetam on the pharmacodynamic and pharmacokinetic profiles of warfarin. *Epilepsy Res* (2001) 47, 55–63.

Coumarins + Levocarnitine

Two isolated reports describe a marked increase in the anticoagulant effects of acenocoumarol in patients taking levocarnitine, one of which was associated with melaena.

Clinical evidence, mechanism, importance and management

A woman who had taken **acenocoumarol** for 17 years because of aortic and mitral prosthetic valves, was admitted to hospital with melaena within 5 days of starting to take levocarnitine 1 g daily, which she was prescribed for congestive heart failure. Her INR had risen from 2.1 to 7. Endoscopy and colonoscopy revealed diffuse bleeding from superficial erosions in the gut. She was discharged 10 days later with the same dose of **acenocoumarol** and an INR of 2.1 without the levocarnitine.[1] A similar case has been described in a man stabilised on **acenocoumarol** (INR 1.99 to 2.94) who had a rise in INR to 4.65 despite a dose correction. The increases in INR occurred when he was using levocarnitine 1 g daily for 10 weeks in the form of a drink (*Maximize*) promoted for bodybuilding and fitness training. When this product was discontinued, the INR returned to the therapeutic range.[2]

The reason for this apparent interaction is not known. These seem to the only recorded cases of an interaction between a coumarin and levocarnitine, but it may be prudent to bear this interaction in mind if levocarnitine is taken with acenocoumarol, or possibly any coumarin, being alert for an increased response.

2. Bachmann HU, Hoffmann A. Interaction of food supplement L-carnitine with oral anticoagulant acenocoumarol. *Swiss Med Wkly* (2004) 134, 385.

Coumarins + Levosimendan

Levosimendan does not alter the effects of warfarin. There is no pharmacokinetic interaction between levosimendan and warfarin.

Clinical evidence, mechanism, importance and management

In an open, randomised, crossover study, 10 healthy subjects were given a single 25-mg oral dose of **warfarin** both before and on day 4 of a 9-day course of oral levosimendan 500 micrograms four times daily. No clinically relevant changes in the anticoagulant effects of the **warfarin** were seen, and levosimendan alone had no effect on blood coagulation. In addition, there was no important pharmacokinetic interaction between **warfarin** and levosimendan. No interactions would therefore be expected if both drugs are used concurrently.[1]

1. Antila S, Jarvinen A, Honkanen T, Lehtonen L. Pharmacokinetic and pharmacodynamic interactions between the new calcium sensitiser levosimendan and warfarin. *Eur J Clin Pharmacol* (2000) 56, 705–10.

Coumarins + Lycium (*Lycium barbarum*)

A case report suggests that lycium may enhance the effects of warfarin.

Clinical evidence

A 61-year-old Chinese woman stabilised on **warfarin** (INRs normally 2 to 3) had an unexpected rise in her INR to 4.1, which was identified during a routine monthly check. No bleeding was seen. She was also taking atenolol, benazepril, digoxin and fluvastatin. It was found that 4 days before visiting the clinic she had started to take one glass (about 170 mL) 3 or 4 times daily of a Chinese herbal tea made from the fruits of lycium to treat blurred vision caused by a sore eye. When the herbal treatment was stopped, her INRs rapidly returned to normal.

Mechanism

Warfarin is metabolised by a number of isoenzymes, the most important being the cytochrome P450 isoenzyme CYP2C9. Inhibition of this isoenzyme may therefore lead to increased warfarin levels and effects. The authors also carried out an *in vitro* study and concluded that although lycium is a weak inhibitor of CYP2C9, this is insufficient to cause an interaction. However, they note that other mechanisms cannot be ruled out.[1]

Importance and management

Although the authors suggest avoiding the concurrent use of lycium and warfarin,[1] because of the many other factors influencing anticoagulant control, it is not possible to reliably ascribe a change in INR specifically to a drug interaction in a single case report without other supporting evidence. It may be better to advise patients to discuss the use of any herbal products they wish to try, and to increase monitoring if this is thought advisable. Cases of uneventful use should be reported, as they are as useful as possible cases of adverse effects. It should be noted that lycium berries are also used as an ingredient in Chinese foods.

Coumarins + MAOIs or RIMAs

Although some *animal* data show that the non-selective MAOIs increase the effects of some oral anticoagulants, there appears to be no clinical evidence of an interaction. Moclobemide did not interact with phenprocoumon in a pharmacological study, and appears unlikely to interact with warfarin.

Clinical evidence, mechanism, importance and management

(a) MAOIs

A number of studies in *animals*[1-4] have shown that some of the non-selective MAOIs can increase the effects of some oral anticoagulants. However, there appear to be no clinical studies or case reports of this interaction, and therefore no special precautions seem to be necessary.

(b) Moclobemide

A study in healthy subjects found that moclobemide 200 mg three times daily for 7 days did not alter the anticoagulant effects of steady-state **phenprocoumon**.[5] No **phenprocoumon** dose adjustments would be expected to be needed on concurrent use.

There appears to be just one review that mentions the possible interaction of moclobemide with **warfarin**.[6] This review reports that (in 1996), the manufacturer had on file six possible cases of anticoagulation problems in patients taking **warfarin** and moclobemide. On the basis that moclobemide is an inhibitor of the cytochrome P450 isoenzyme CYP2C19 and possibly also CYP1A2, the reviewers considered that moclobemide could theoretically increase the levels of *S*-warfarin, and so stated that an interaction with **warfarin** was likely. However, CYP2C19 and CYP1A2 are just two of a number of isoenzymes involved in metabolism of just *R*-warfarin, which is the less pharmacologically active isomer of **warfarin**. Other CYP2C19 inhibitors, such as omeprazole (see 'Coumarins + Proton pump inhibitors', p.499), and ticlopidine (see 'Coumarins + Ticlopidine', p.514), usually have no clinically relevant effect on **warfarin** levels. This, and the absence of published reports of problems, suggests that moclobemide is unlikely to interact with **warfarin**. There appears to be no evidence about other coumarins, but there seems to be no reason to suspect that they may interact.

Coumarins + Medroxyprogesterone or Megestrol

High-dose medroxyprogesterone acetate and megestrol prolonged the half-life of single-dose warfarin in one small study in patients with advanced breast cancer.

Clinical evidence, mechanism, importance and management

In a study in patients with advanced breast cancer, a single 0.3-mg/kg dose of **warfarin** was given to 2 patients before and after oral medroxyprogesterone acetate 500 mg twice daily for 5 weeks and to 2 patients before and after megestrol 160 mg daily for 5 weeks. The half-life of **warfarin** was increased by 71% and the clearance decreased by 35%.[1] Although the evidence is limited, what is known suggests that it would be prudent to monitor prothrombin times in patients taking **warfarin** who are given high-dose medroxyprogesterone acetate or megestrol, being alert for any increased warfarin effects.

Coumarins + Mefloquine

The effects of warfarin and an unnamed coumarin were increased in two patients who took mefloquine.

Clinical evidence, mechanism, importance and management

A 66-year-old man taking **warfarin** and various other drugs presented to an emergency department unwell with a distended abdomen while travelling in Kenya. His prothrombin time was grossly prolonged and the distension was found to be due to bleeding. One week before travel he had started mefloquine 250 mg weekly without a check of his prothrombin time. He was given subcutaneous enoxaparin instead of **warfarin** while continuing the mefloquine. Another patient taking a coumarin and oral antidiabetics presented with hypoglycaemia and a large haematoma of the right leg after taking 3 doses of mefloquine 250 mg weekly. His INR was 6.4.[1]

The author considered that mefloquine may have caused the increased anticoagulation in these two cases, and suggested that mefloquine should be started several weeks before travel to allow for monitoring of any changes in anticoagulant effects.[1] The manufacturers of mefloquine also recommend that, before departure, travellers also taking anticoagulants should be checked for any alteration in anticoagulant effect.[2] This is probably prudent, although patients should be advised that many other factors associated with travel, such as altered diet, could contribute to a change in anticoagulant control.

Coumarins + Melatonin

Case reports suggest that melatonin may raise or lower the INR in response to warfarin.

Clinical evidence

Six case reports of a suspected interaction between melatonin and **warfarin** have been documented by the WHO Uppsala Monitoring Centre, and have been briefly summarised in a review of melatonin.[1] In three cases, the prothrombin time was increased, with bleeding events in two (nosebleed, eye haemorrhage, bruising) occurring up to 8 days after starting to take melatonin. The other three cases reports describe a prothrombin time decrease.[1]

Mechanism

Unknown. Melatonin did not inhibit the cytochrome P450 isoenzyme CYP2C9 *in vitro*,[2] and would not therefore be expected to alter warfarin metabolism by this mechanism.

Importance and management

These appear to be the only reports in the literature of a possible interaction between melatonin and warfarin. They are difficult to interpret, because they include both increased and decreased warfarin effects, and it is possible that they are just idiosyncratic cases. Because of these cases, a study designed to exclude a pharmacokinetic and/or pharmacodynamic interaction would be useful. Until more is known, bear these cases in mind in the event of an unexpected change in coagulation status in patients also taking melatonin supplements.

Coumarins + Melilot (*Melilotus officinalis*)

The INR of a patient taking acenocoumarol was increased after she used a melilot-containing topical cream, and a woman who had been drinking large quantities of a herbal tea containing melilot developed a prolonged prothrombin time.

Clinical evidence

A 66-year-old taking **acenocoumarol**, levothyroxine and prazepam had an increase in her INR after massaging a proprietary topical cream (*Cyclo 3*) containing melilot and butcher's broom on her legs three times daily. On the first occasion her INR rose from about 2 to 5.8 after 7 days of use,

and on a later occasion it rose to 4.6 after 10 days of use.[1] In another report, a woman with unexplained abnormal menstrual bleeding was found to have a prothrombin time of 53 seconds, and laboratory tests showed that her blood clotting factors were abnormally low. When given parenteral vitamin K her prothrombin time rapidly returned to normal (suggesting that she was taking a vitamin K antagonist of some kind). She strongly denied taking any anticoagulant drugs, but it was eventually discovered that she had been drinking large quantities of a herbal tea containing among other ingredients tonka beans, melilot and sweet woodruff, all of which might contain natural coumarins.[2]

Mechanism

Unknown. Melilot is known to contain natural coumarins, which can be turned into dicoumarol by moulds, see 'Coumarins + Herbal medicines; Miscellaneous', p.472.

Importance and management

Evidence appears to be limited to these isolated cases, which are not established. Many factors influence anticoagulant control, and therefore it is not possible to reliably ascribe a change in INR specifically to a drug interaction in a single case report without other supporting evidence. It may be better to advise patients to discuss the use of any herbal products they wish to try, and to increase monitoring if this is thought advisable. Cases of uneventful use should be reported, as they are as useful as possible cases of adverse effects.

Coumarins + Menthol

A man had a reduction in the effects of warfarin, which were attributed to the use of menthol cough lozenges during a flu-like illness.

Clinical evidence, mechanism, importance and management

A 57-year-old man taking **warfarin** 49 mg weekly with an INR in the range of 2.3 to 2.7 for the previous 3 weeks was found to have an INR of 1.45. He had been unwell with a flu-like illness over the past week, for which he had been taking about 6 *Halls* menthol cough lozenges (cough drops) per day for 4 days. He said he had not changed his diet or missed any warfarin doses. The **warfarin** dose was increased to 53 mg weekly for a week with an INR rise to 2.2, then the **warfarin** dose was decreased to 52 mg weekly with an INR of 3.06, so the previous dose of 49 mg weekly was resumed with an INR of 2.92.[1] Whether this case represents an interaction with the menthol lozenges is uncertain. Further study is needed.

1. Kassebaum PJ, Shaw DL, Tomich DJ. Possible warfarin interaction with menthol cough drops. *Ann Pharmacother* (2005) 39, 365–7.

Coumarins + Meprobamate

The anticoagulant effects of warfarin are not altered to a clinically relevant extent by meprobamate.

Clinical evidence, mechanism, importance and management

In a study, 9 patients stabilised on **warfarin** were given meprobamate 400 mg four times daily for 2 weeks. Three patients had a small increase in their prothrombin time, five had a small decrease and one patients remained unaffected: all the changes were considered to fall within the range of variations normally seen in clinical practice.[1] Moreover, in a later placebo-controlled study in 17 patients taking **warfarin**, the 8 patients who were also given meprobamate 2.4 g daily for 4 weeks had only a small clinically unimportant reduction in their prothrombin time.[2] Similar results were found in another study.[3] No **warfarin** dose adjustments would therefore seem to be needed if meprobamate is added to established treatment with **warfarin**.

Coumarins + Methaqualone

Methaqualone may cause a very small and clinically unimportant reduction in the anticoagulant effects of warfarin.

Clinical evidence, mechanism, importance and management

The average prothrombin time of 10 patients stabilised on **warfarin** was 20.9 seconds before, 20.4 seconds during, and 19.6 seconds after taking methaqualone 300 mg at bedtime for 4 weeks.[1] The plasma **warfarin** levels of another patient were unaffected by methaqualone, although there was some evidence that enzyme induction had occurred.[2] Methaqualone has some enzyme-inducing effects so that any small changes in prothrombin times reflect a limited increase in the metabolism and clearance of **warfarin**, but these appear to be too small to be of clinical significance.[2,3] No special precautions seem to be necessary.

Coumarins + Methylphenidate

Methylphenidate appears not to interact with ethyl biscoumacetate.

Clinical evidence, mechanism, importance and management

In one study in 4 healthy subjects, the half-life of a single dose of **ethyl biscoumacetate** was approximately doubled after they took methylphenidate 20 mg daily for 3 to 5 days.[1] However, a later double-blind, placebo-controlled study did not find an interaction: the half-life of **ethyl biscoumacetate** was not altered by methylphenidate 20 mg daily for 4 days in 4 healthy subjects, and was not different to that seen in 4 subjects given placebo.[2] The first authors suggested that methylphenidate inhibits the metabolism of **ethyl biscoumacetate**, but this seems unlikely given the findings of the second study.

Although the findings of these two studies are at odds with each other, the better-controlled study and the lack of reports of problems in the literature suggest that an interaction is unlikely. There does not seem to be any information about other coumarins. Nevertheless, the manufacturers recommend caution and suggest that patients taking coumarins should have their INR monitored if methylphenidate is started or stopped.[3,4] This seems over-cautious.

Coumarins + Metoclopramide

Metoclopramide caused a minor decrease in the AUC of phenprocoumon, without altering its anticoagulant effects. There is one case report of an interaction between phenprocoumon and metoclopramide.

Clinical evidence, mechanism, importance and management

An elderly women taking **phenprocoumon** and metoclopramide developed a renal bleed and a low Quick time shortly after stopping metoclopramide.[1] This prompted a study in 12 healthy subjects, in which metoclopramide 30 mg daily for 10 days slightly reduced the AUC of a single dose of **phenprocoumon** given on day 4 by 16%, but no significant

changes were seen in the anticoagulant effects.[2] The study findings suggests that no **phenprocoumon** dose adjustment would be expected to be necessary if these two drugs are given together. There seems to be no published information about a possible interaction with any other coumarins, and given the widespread use of both metoclopramide and **warfarin**, an interaction appears to be unlikely.

Coumarins + Metrifonate

Metrifonate did not interact with single-dose warfarin in one study.

Clinical evidence, mechanism, importance and management

A double-blind, placebo-controlled, crossover study in 14 healthy subjects found that metrifonate 50 mg daily for 8 days did not change the pharmacokinetics and pharmacodynamics of a single 25-mg dose of **warfarin** given on day 4. Plasma **warfarin** levels and prothrombin times remained unchanged.[1] This suggests that no **warfarin** dose adjustments are likely to be needed if these two drugs are used concurrently.

1. Heinig R, Kitchin N, Rolan P. Disposition of a single dose of warfarin in healthy individuals after pretreatment with metrifonate. *Clin Drug Invest* (1999) 18, 151–9.

Coumarins + Misoprostol

An isolated report describes a reduction in the anticoagulant effects of acenocoumarol, which was attributed to the use of misoprostol.

Clinical evidence, mechanism, importance and management

A 39-year-old woman taking **acenocoumarol**, celiprolol, triamterene, cyclothiazide, pravastatin and diosmin had a rise in her prothrombin levels from 0.3 to 1 within 8 days of starting to take diclofenac and misoprostol 400 micrograms daily. A day after these two drugs had been withdrawn her prothrombin level had fallen to 0.67, and after another 3 days to 0.32.[1] The reasons for this reaction are not known, but suspicion falls on the misoprostol because diclofenac, if and when it interacts with coumarins, increases rather than reduces their effects (see 'Coumarins + NSAIDs; Diclofenac', p.483). However, just why misoprostol should cause these changes is not clear.

This is an isolated case, complicated by the presence of a number of other drugs, which suggests that it is unlikely to be of general importance. More study is needed.

1. Martin MP, Jonville-Bera AP, Bera F, Caillard X, Autret E. Interaction entre le misoprostol et l'acénocoumarol. *Presse Med* (1995) 24, 195.

Coumarins + Modafinil

Modafinil does not alter the pharmacokinetics or effect of single-dose warfarin.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study, when 14 healthy subjects taking modafinil 200 to 400 mg daily long-term were given a single 5-mg dose of warfarin, there were no changes in the pharmacokinetics of *R*- and *S*-warfarin. In addition, there was no change in clotting time.[1]

This study was conducted because, *in vitro*, modafinil was shown to be an inhibitor of the cytochrome P450 isoenzyme CYP2C9, and warfarin is an accepted probe substrate of this isoenzyme. It is well recognised that *in vitro* findings do not always predict what will happen *in vivo*, and the findings of the study show that modafinil is not a clinically relevant inhibitor of CYP2C9. Nevertheless, on the basis that this was a single-dose study, the authors suggest some caution.[1] The manufacturers recommend that prothrombin times should be monitored more frequently[2] particularly during the first 2 months of concurrent use and after changes in modafinil dose.[3] This is a cautious interpretation, and a pharmacokinetic interaction seems unlikely.

3. Provigil (Modafinil). Cephalon (UK) Ltd. UK Summary of product characteristics, November 2009.

Coumarins + Moracizine

Moracizine did not alter the pharmacodynamics of single-dose warfarin, and had no clinically relevant effect on warfarin pharmacokinetics. However, an isolated report describes bleeding in a patient taking warfarin with moracizine.

Clinical evidence

In a study in 12 healthy subjects, moracizine 250 mg every 8 hours for 21 days caused little or no change in the pharmacokinetics of a single 25 mg dose of **warfarin** given on day 14. There was only a slight decrease in the **warfarin** elimination half-life, from 37.6 hours to 34.2 hours, and no change in prothrombin times.[1,2] The manufacturer also noted that clinical experience in 34 patients suggests that no significant changes in **warfarin** dose requirements are needed after moracizine is started.[1]

However, in one case report the prothrombin time of a woman taking **warfarin**, digoxin, captopril and prednisone rose from a range of 15 to 20 seconds up to 41 seconds within 4 days of starting moracizine 300 mg three times daily. She bled (haematemesis, haematuria), but responded rapidly to withdrawal of the **warfarin** and moracizine, and phytomenadione.[3]

Mechanism

Not understood.

Importance and management

Information appears to be limited to these reports. The study and early clinical experience suggest that no interaction occurs. The case of an increased effect seems to be an isolated report, and therefore unlikely to be of general importance.

Coumarins + Nefazodone or Trazodone

A handful of case reports describe a moderate reduction in the anticoagulant effects of warfarin caused by trazodone, and another case report describes a rise in INR. In one study, nefazodone slightly decreased the level of *S*-warfarin and did not alter the prothrombin ratio.

Clinical evidence

(a) Nefazodone

In one study, 17 healthy subjects given **warfarin** to achieve a prothrombin ratio of 1.2 to 1.5 for 14 days were then given nefazodone 200 mg or placebo every 12 hours for a further 7 days. The only pharmacokinetic changes were a 12% decrease in the AUC and maximum serum levels of *S*-warfarin. No changes occurred in the prothrombin ratios.[1]

(b) Trazodone

In an early case series, a patient stabilised on **warfarin** was given trazodone 75 mg daily for 8 days without any significant changes in the prothrombin time. Similarly, the same dose of trazodone had no obvious effect on the prothrombin time of a patient who had recently started taking **phenprocoumon** or another patient who had recently started taking **ethyl biscoumacetate**.[2]

However, in another report, a woman needed a small increase in her

warfarin dose, from 6.4 mg daily to 7.5 mg daily, when she was given trazodone 300 mg daily, in order to maintain her prothrombin time at 20 seconds. Her **warfarin** requirements fell when the trazodone was later withdrawn.[3] A retrospective review from June 1998 to June 1999 identified 75 patients taking both trazodone and **warfarin**. Of the patients who had started trazodone during this period (number not stated), at least 3 had a probable interaction. One had a decrease in INR from 2.79 to 1.07 six days after starting trazodone, and needed a 25% increase in the dose of **warfarin**. Another patient had an increase in INR when he ran out of trazodone, and a decrease in INR on restarting the trazodone. A third required a 39% increase in **warfarin** dose after starting trazodone.[4] Conversely, there is a report of a rise in INR from between 2 and 3 up to 6, without bleeding complications, that occurred in a patient 2 weeks after trazodone 50 mg daily and fish oil 2 g daily were started.[5] The manufacturer in the US notes that there have been reports of both increased and decreased prothrombin times in patients taking warfarin with trazodone.[6]

Mechanism

Unknown.

Importance and management

The limited evidence available suggests that some patients might require a moderate increase in warfarin dose when starting trazodone, and, conversely, there is one possible case of an increase in INR. Therefore, it might be prudent to monitor the INR in all patients taking warfarin if trazodone is started or stopped, adjusting the warfarin dose if necessary. The clinical relevance of the 12% decrease in *S*-warfarin levels see with nefazodone is likely to be minor. The authors of the study concluded that no change in warfarin dose is likely to be required on concurrent use.[1]

Coumarins + NNRTIs

Two reports suggest that warfarin requirements are markedly increased by nevirapine. There is one case report of an unusually low warfarin dose requirement in a patient taking an efavirenz-based regimen. The effect of other NNRTIs is unclear.

Clinical evidence

(a) Efavirenz

A woman receiving efavirenz, didanosine and lamivudine was started on **warfarin** for a deep vein thrombosis. After 12 days she was discharged with an INR between 2 and 3 on a mean daily dose of warfarin of 5 mg. About one week later her INR was 2.7, but then 3 days later she had blood in the urine and an INR of 7. She was eventually stabilised on a much lower mean dose of warfarin of 1.25 mg daily.[1]

(b) Etravirine

In a study, 12 healthy subjects were given a single 10-mg dose of **warfarin** on day one and day 14 of a 14-day course of etravirine 200 mg twice daily. Etravirine increased the ratio of the AUC of *S*-warfarin to 7-hydroxy-*S*-warfarin by 63%.[2]

(c) Nevirapine

A man taking **warfarin** 2.5 mg daily (INR 2.1 to 2.4) needed a doubled **warfarin** dose when his treatment with zidovudine and didanosine was replaced by stavudine, lamivudine and nevirapine. A few days later, when his treatment was again changed to stavudine, lamivudine and saquinavir, his original **warfarin** dose was found to be adequate. Another patient was resistant to doses of **warfarin** of up to 17 mg daily while taking zidovudine, lamivudine and nevirapine, but he responded to **warfarin** 5 mg daily when the nevirapine was withdrawn. The warfarin dose had to be raised to 12 mg daily when nevirapine was restarted. Yet another patient showed resistance to **warfarin** while taking nevirapine.[3] Similarly, in another report, a patient taking lamivudine 150 mg twice daily, zidovudine 300 mg twice daily and nevirapine 200 mg twice daily required a high **warfarin** dose of 20 mg daily to maintain a therapeutic INR. When his antiretroviral regimen was changed to nelfinavir, didanosine and tenofovir, a reduction in his warfarin dose to 12.5 mg daily was required.[4] Note that nelfinavir may also interact with warfarin, see 'Coumarins + Protease inhibitors', p.498.

Mechanism

The finding of markedly increased warfarin requirements with nevirapine was not predicted from *in vitro* studies,[5] in which nevirapine did not inhibit the cytochrome P450 isoenzyme CYP2C9, by which the more potent *S*-warfarin is metabolised, and had mixed (induced and inhibited) effects on CYP3A4, which partly metabolises *R*-warfarin. Although induction of CYP3A4 might reduce *R*-warfarin levels, the clinical effect of this would be expected to be modest.

In vitro efavirenz inhibits CYP2C9 and induces CYP3A4,[6] and its effects on the clinical pharmacokinetics of warfarin are unknown. In the case described, it was suggested that efavirenz inhibited warfarin metabolism,[1] but it is unclear why this became suddenly apparent 3 weeks after starting concurrent use.

Importance and management

Information on **nevirapine** seems to be limited to these four cases, but it would be prudent to monitor prothrombin times and INRs in any patient if warfarin and nevirapine are used concurrently, being alert for the need to increase the warfarin dose (possibly twofold). Information about other coumarins seems to be lacking, but if the suggested mechanism is correct, all coumarins would be expected to interact to some extent.

Increased monitoring on the concurrent use of **efavirenz** and warfarin would also seem advisable, the only case available appearing to suggest a decreased warfarin requirement. Until more is known, it would seem prudent to monitor all coumarins.

Etravirine has weak effects on both CYP3A4 and CYP2C9, the isoenzymes involved in the metabolism of warfarin and may therefore have some modest effects on warfarin metabolism. Until the clinical relevance of this is known it may be prudent to be alert for increased warfarin effects.

Delavirdine inhibits CYP3A4, but the effect of this alone on warfarin levels is probably modest. Nevertheless, the US manufacturer of delavirdine advises monitoring the INR of patients also given warfarin.[7]

Coumarins and related drugs + NSAIDs

The concurrent use of NSAIDs and coumarin anticoagulants increases the risk of gastrointestinal haemorrhage and, to a lesser extent, non-gastrointestinal bleeds. Care is needed with the combination. Some individual NSAIDs also alter the pharmacokinetics and/or pharmacodynamics of warfarin, and these effects are covered in specific monographs.

Clinical evidence

(a) Bleeding

In a retrospective cohort study of patients hospitalised for peptic ulcer disease, the current use of both oral anticoagulants and NSAIDs was associated with a marked increase in the risk of haemorrhagic peptic ulcer

disease of 12.7 (95% confidence interval 6.3 to 25.7). This was much higher than the risk associated with NSAIDs alone or oral anticoagulants alone (both about a fourfold increased risk). In this study, about 10% of the hospitalisations for haemorrhagic peptic ulcer disease in patients taking anticoagulants were attributed to the concurrent use of NSAIDs. The oral anticoagulants used were the coumarins **warfarin**, **phenprocoumon** and **acenocoumarol**, and the indanediones **phenindione** and **anisindione**. The NSAIDs used were nonacetylated salicylates, **ibuprofen**, **indometacin**, **sulindac**, **naproxen**, **fenoprofen**, **piroxicam**, **tolmetin**, and **meclofenamate**.[1]

In a case-control study, patients taking **warfarin** who were admitted to hospital with upper gastrointestinal haemorrhage were significantly more likely to be taking non-selective NSAIDs (odds ratio 1.9). A similar increased risk was seen with the coxibs **celecoxib** and **rofecoxib**.[2] Consider also, 'Coumarins and related drugs + NSAIDs; Coxibs', p.482. Similarly, in a large population-based, retrospective case control-study using records from the UK General Practice Research Database from 2000 to 2005, the use of **warfarin** with NSAIDs was associated with a increased risk of gastrointestinal bleeding when compared with either drug alone (rate ratio of 4.79 for concurrent use compared with 1.94 for warfarin and 1.78 for NSAIDs). The most commonly used NSAIDs were **diclofenac**, **ibuprofen**, and **naproxen**, and the full list of NSAIDs considered was **aclofenac** (sic), **dexketoprofen**, **diclofenac**, **diflunisal**, **etodolac**, **fenoprofen**, **ibuprofen**, **indomethacin**, **ketoprofen**, **ketorolac**, **mefenamic acid**, **meloxicam**, **nabumetone**, **naproxen**, **piroxicam**, **sulindac**, **tenoxicam** and **tiaprofenic acid**. A very similar increased risk (rate ratio 4.62) was seen with the coxibs, **celecoxib** and **rofecoxib**.[3]

In yet another case-control study, the use of NSAIDs with the coumarins **acenocoumarol** or **phenprocoumon** was associated with an increased risk of hospitalisation for gastrointestinal bleeding (odds ratio 4.6) and, to a lesser extent, non-gastrointestinal bleeding (odds ratio 1.7).[4] Similarly, in a questionnaire-based study, 12.2% of patients taking **acenocoumarol** or **phenprocoumon** who had a bleeding complication were found to have used an NSAID in the previous month compared with only 2.5% of coumarin users who did not have a bleed (an increased relative risk of bleeding of 5.8).[5]

In contrast, in a large analysis of claims data, use of NSAIDs (unnamed) with **warfarin** was, unexpectedly, not associated with an increased risk of haemorrhage.[6]

(b) Pharmacokinetic interactions

Phenylbutazone and related drugs (see 'Coumarins and related drugs + NSAIDs; Phenylbutazone and related drugs', p.488) are well known to inhibit the metabolism of **warfarin** by the cytochrome P450 isoenzyme CYP2C9. Few other NSAIDs are known CYP2C9 inhibitors; however; many are CYP2C9 substrates. In one cohort study in patients taking **acenocoumarol** or **phenprocoumon**, the use of NSAIDs that are known substrates of CYP2C9 (**celecoxib**, **diclofenac**, **flurbiprofen**, **ibuprofen**, **indometacin**, **ketoprofen**, **meloxicam**, **naproxen** and **piroxicam**) slightly increased the risk of over-anticoagulation (INR greater than 6) in patients with wild-type CYP2C9 (relative risk of 1.69). However, the risk was greater in patients with variant CYP2C9 (relative risk 2.28), and particularly high in those with *3 variant alleles (relative risk 10.8).[7] In another smaller retrospective cohort study, starting the CYP2C9 substrates **diclofenac**, **naproxen**, or **ibuprofen** increased the INR above the therapeutic range in 52 of 112 patients taking **acenocoumarol**. However, in this study CYP2C9 genotype did not influence the interaction between **acenocoumarol** and **diclofenac**, **naproxen**, and **ibuprofen**.[8] For more general information about the genetic variations in cytochrome P450 isoenzymes, see 'Genetic factors in drug metabolism', (p.4).

(c) Other effects

In a prospective study, the concurrent use of musculoskeletal drugs (said to be mainly NSAIDs, with none specified) was associated with an apparent risk of INR instability (odds ratio 1.68) in 125 hospitalised patients starting **acenocoumarol**.[9] Instability was defined as not having two consecutive INRs within the range of 2 to 3. However, most of the patients defined as unstable had INRs below the therapeutic range, and it was suggested that this may have just reflected conservative dosing of the anticoagulant in patients already taking NSAIDs because of the possible interaction. This would result in these patients taking longer to reach the therapeutic range, and is not therefore an interaction as such.

Mechanism

NSAIDs, to a greater or lesser extent irritate the stomach lining, which can result in gastrointestinal bleeding, which will be more severe in anticoagulated patients. Many also have antiplatelet activity, which can prolong bleeding times, and contribute to the increased bleeding risk.

Some NSAIDs are inhibitors of the cytochrome P450 isoenzyme CYP2C9, and inhibit the metabolism of warfarin by this isoenzyme. There is also possibly a pharmacokinetic interaction with NSAIDs that are substrates for CYP2C9. People with variant CYP2C9 (about 5 to 11% of Caucasians) have a lower metabolising capacity for warfarin, and require much lower maintenance doses. It is possible that use of an NSAID that is a CYP2C9 substrate may result in reduced warfarin metabolism, although this requires confirmation in controlled studies.

Importance and management

The available data indicate that the risk of bleeding is increased if NSAIDs are used in patients taking coumarin or **indanedione** anticoagulants. For this reason, it would be prudent to avoid the unnecessary concurrent use of NSAIDs when simple analgesics are adequate. When concurrent use is necessary, extra caution may be appropriate. It would be advisable to avoid NSAIDs with higher risks of inducing gastrointestinal bleeds, and possibly also to consider prophylactic mucosal protection. Note that patients at higher risk of NSAID-induced gastrointestinal bleeding and those prone to warfarin-related bleeding are likely to be at increased risk. Further study is required to ascertain whether people with CYP2C9 poor metabolising capacity are at increased risk of an interaction when given NSAIDs that are CYP2C9 substrates.

Coumarins + NSAIDs; Benzydamine

Oral benzydamine did not alter the anticoagulant effects of phenprocoumon. Topical formulations of benzydamine (mouthwash and spray) would not be expected to interact.

Clinical evidence, mechanism, importance and management

In 10 patients stabilised on **phenprocoumon**, the anticoagulant response was not significantly changed by benzydamine 50 mg three times daily for 2 weeks, although there was some evidence of an increase in blood levels of the anticoagulant.[1] This suggests that no **phenprocoumon** dose adjustments are likely to be needed on concurrent use. Note that benzydamine tends to be used as a topical mouthwash or spray. Neither of these topical formulations would be expected to interact.

Coumarins + NSAIDs; Clonixin

Clonixin lysine did not appear to alter the anticoagulant effects of phenprocoumon in a pharmacological study. However, note that

all NSAIDs increase the risk of bleeding, and an increased risk is seen when they are combined with anticoagulants.

Clinical evidence, mechanism, importance and management

In a randomised, crossover study in 12 healthy men, the pharmacokinetics and the anticoagulant activity of a single 18-mg dose of **phenprocoumon** were unchanged by clonixin lysine 125 mg five times daily, given for 3 days before and for 13 days after the **phenprocoumon**.[1]

On the basis of this study, no adjustment in coumarin dose would be expected to be needed when clonixin is used. However, care is still needed with every NSAID, because, to a greater or lesser extent, they irritate the stomach lining, which can result in gastrointestinal bleeding, which will be more severe in anticoagulated patients. Consider also, 'Coumarins and related drugs + NSAIDs', p.480.

Coumarins and related drugs + NSAIDs; Coxibs

Etoricoxib, lumiracoxib and rofecoxib cause a slight increase in the INR in response to warfarin, whereas celecoxib and parecoxib have no effect. However, raised INRs accompanied by bleeding, particularly in the elderly, have been attributed to the use of warfarin and celecoxib or rofecoxib. In addition, the use of celecoxib or rofecoxib is associated with an increased risk of hospitalisation for upper gastrointestinal haemorrhage, which was of a similar magnitude to that seen with non-selective NSAIDs.

Clinical evidence

(a) Celecoxib

In a placebo-controlled study, **warfarin** 2 to 5 mg daily was given to 24 healthy subjects to maintain a stable prothrombin time of 1.2 to 1.7 times their pretreatment values for at least 3 consecutive days. They were then given placebo or celecoxib 200 mg twice daily for a week. It was found that the steady-state pharmacokinetics of both *S*- and *R*-warfarin and the prothrombin times were unchanged by the presence of the celecoxib.[1]

Similarly, in a crossover study in 15 osteoarthritic patients stabilised on **warfarin**, celecoxib 200 mg daily for 5 weeks did not alter the mean INR when compared with codeine (see 'Coumarins + Opioids; Codeine', p.490). One patient had an INR of 4.9 when taking celecoxib.[2] However, in 16 patients stabilised on **warfarin** and given celecoxib 200 mg daily for 3 weeks, the INR increased by 13%, 6% and 5% at week one, 2 and 3, respectively, the change at week one being statistically significant.[3] Furthermore, in another analysis of 28 patients taking **warfarin** who were prescribed either celecoxib or rofecoxib, 13 had increases in their INR, of which 7 (5 taking celecoxib) had no other explanation for the INR increase other than the use of the coxib. The average increase in INR in these 7 patients was 1.5, and one patient had bruising and epistaxis and required treatment with phytomenadione.[4]

Case reports of an interaction have also been published.[5-10] In one report, an 88-year-old woman stabilised on **warfarin** had a rise in her INR from 3.1 to 5.8 when celecoxib 200 mg daily was substituted for diclofenac. After several **warfarin** dose adjustments she was later restabilised on a 25% lower **warfarin** dose.[5] There is a similar case report of a 77-year old patient who required a 10% decrease in her **warfarin** dose to maintain her target INR when celecoxib 100 mg twice daily was also given.[8] In another case, the patient was shown to have a variant of CYP2C9, with lower metabolising capacity, which was thought to explain the interaction,[10] see also *Mechanism*, below. The manufacturers also noted that bleeding events have been reported with this combination, predominantly in the elderly, which led to a change in the product labelling.[11] A 2001 report from the Australian Adverse Drug Reactions Advisory Committee noted they had received 21 reports of increases in the INR in patients taking **warfarin** with celecoxib since the introduction of celecoxib in October 1999. Six of these cases reported bleeding complications. In addition, they had 11 cases of bleeding in patients taking the combination, with no reference to INR, or with an unchanged INR in one case.[12] A review of adverse effects of coxibs mentioned 2 patients taking **warfarin** who had increases in their INR while taking celecoxib.[13]

Moreover, in a case-control study, patients taking **warfarin** and admitted to hospital with upper gastrointestinal haemorrhage were significantly more likely to be also taking celecoxib (odds ratio 1.7). A similar increased risk was seen with rofecoxib and non-selective NSAIDs[14] (see 'Coumarins and related drugs + NSAIDs', p.480). The same findings were reported in another study for celecoxib and rofecoxib considered together.[15] In a retrospective analysis, the relative risk of all bleeding complications was slightly increased (1.34) in 123 patients taking celecoxib with **warfarin** when compared with 1022 control patients taking **warfarin** alone.[16]

(b) Etoricoxib

In a controlled study in 14 healthy subjects stabilised on **warfarin**, etoricoxib 120 mg daily for 21 days increased the INR by about 13%. There was no change in the pharmacokinetics of *S*-warfarin, and the AUC of *R*-warfarin showed a minor 10% increase.[17]

(c) Lumiracoxib

The manufacturer noted that in healthy subjects stabilised on **warfarin**, lumiracoxib 400 mg daily increased the INR by about 15%.[18] Lumiracoxib has been withdrawn from a number of countries because of reports of liver toxicity.

(d) Parecoxib

In a randomised study in healthy subjects given **warfarin**, the use of intravenous parecoxib 10 mg twice daily for 7 days had no significant effects on prothrombin times when compared with placebo. Parecoxib did not affect the pharmacokinetics of *S*- or *R*-warfarin.[19]

(e) Rofecoxib

In a study in 12 healthy subjects,[20] rofecoxib 50 mg daily for 12 days increased the maximum INR after a single 30-mg dose of **warfarin** given on day 7 by about 14%. In a steady-state study, 15 healthy subjects were given **warfarin** 5 mg daily to produce a stable prothrombin time of 1.4 to 1.7 for at least 3 consecutive days. They were then additionally given rofecoxib 25 mg or placebo daily for 3 weeks. It was found that the 24-hour average INR was increased by 9% by rofecoxib. Rofecoxib had no effect on the pharmacokinetics of the more potent *S*-warfarin enantiomer, but the AUC of *R*-warfarin was increased by about 40% in both the single dose and steady-state studies.[20] Moreover, in 16 patients stabilised on **warfarin** and given rofecoxib 25 mg daily for 3 weeks, the INR increased by 5%, 9%, and 5% at week one, 2, and 3, respectively, the change at week 2 being statistically significant.[3]

In one case report, an increase in INR was seen in two elderly patients taking **warfarin** and rofecoxib. The INRs were raised, in one case from less than 3 to 4.1 within a month of starting rofecoxib 12.5 mg daily, and in the other case from 3.2 to 4.6 within 2 days of starting rofecoxib. The INRs decreased when the **warfarin** dose was reduced.[4] In another case, this time in a patient taking **acenocoumarol**, the INR rose from the range of 2 to 3 up to over 8 two weeks after starting rofecoxib 50 mg daily.[21] A further possible case with **acenocoumarol** has been reported.[22] A 2002 report from the Australian Adverse Drug Reactions Advisory Committee noted that they had received 8 reports of increases in the INR of patients taking **warfarin** with rofecoxib since the introduction of rofecoxib in late 2000. Two of these cases reported bleeding complications. A further patient died of a cerebral haemorrhage, although the INR was stable.[23] A review of the adverse effects of coxibs included 5 patients taking **warfarin** who had increases in their INR while taking rofecoxib and **warfarin**.[13] Moreover, in a case-control study, patients taking **warfarin** and admitted to hospital with an upper gastrointestinal haemorrhage were significantly more likely to be also taking rofecoxib (odds ratio 2.4).[14] The same findings were reported in another study for celecoxib and rofecoxib considered together.[15] Note that rofecoxib has generally been withdrawn because of adverse cardiovascular effects.

Mechanism

Non-selective NSAIDs (see 'Coumarins and related drugs + NSAIDs', p.480), inhibit platelet aggregation and cause gastrointestinal toxicity, which can result in bleeding, the risk of which is increased in patients taking anticoagulants. Although coxibs are generally considered to be associated with a lower risk of gastrointestinal haemorrhage than non-selective NSAIDs, the only available comparative epidemiological studies found a similar increased risk of bleeding when coxibs were given with warfarin.

There is also possibly a pharmacokinetic interaction. Both warfarin and celecoxib are substrates of the cytochrome P450 isoenzyme CYP2C9, and it is possible that people with variants of CYP2C9 with lower metabolising

capacity may develop an interaction if given the combination. See 'Coumarins and related drugs + NSAIDs', p.480, for further discussion on this, and for more general information, see 'Genetic factors in drug metabolism', (p.4).

Rofecoxib possibly inhibits the metabolism of the less active *R*-warfarin by inhibition of CYP1A2,[20] and the active *R*-acenocoumarol by the same isoenzyme and CYP2C19.[21] It is unclear how etoricoxib increased R-warfarin levels as it has no known inhibitory effects on cytochrome P450, and the minor rise in warfarin levels is unlikely to completely account for the modest increase in INR.[17]

Importance and management

The interaction of the coumarins with these coxibs leading to raised INRs can be clinically significant, but is apparently rare. For example, of the 4 million prescriptions for celecoxib dispensed over the 18-month period from December 1998, about 1% were estimated to be for patients who would have been taking warfarin,[11] and only a handful of cases of an interaction had been reported. However, the manufacturers recommend that anticoagulant activity should be monitored in patients taking warfarin, other coumarins, or indanediones, particularly in the first few days after initiating or changing the dose of a coxib. Others recommend increased monitoring for 3 weeks.[3] Moreover, remember that all NSAIDS, including coxibs, can irritate the gastrointestinal tract and cause bleeding, the risk of which is increased with anticoagulants. Consider also, 'Coumarins and related drugs + NSAIDs', p.480.

Coumarins + NSAIDs; Diclofenac

Diclofenac does not appear to alter the anticoagulant effect of acenocoumarol, phenprocoumon or warfarin. However, isolated cases of raised INRs have been reported. Note that all NSAIDs increase the risk of bleeding, and an increased risk is seen when they are given with anticoagulants.

Clinical evidence

In a crossover study in 29 patients stabilised on **acenocoumarol**, diclofenac 25 mg four times daily for one week did not alter the anticoagulant effect (prothrombin value) of **acenocoumarol**, when compared with placebo.[1] Other studies similarly confirm that diclofenac does not alter the anticoagulant effect of either **phenprocoumon**[2] or **warfarin**.[3]

However, a patient taking **acenocoumarol** developed a pulmonary haemorrhage associated with a very prolonged prothrombin time within 10 days of starting to take diclofenac.[4] Another report mentions a Chinese patient taking **warfarin** who developed an INR of 4 within 4 days of using a 1% diclofenac topical gel for joint pain.[5]

In a retrospective cohort study of patients taking **acenocoumarol** or **phenprocoumon**, diclofenac was associated with a 2.6-fold increased risk of hospitalisation for bleeding.[6] For a discussion of other studies, including one assessing the effect of CYP2C9 substrates such as diclofenac, on the risk of bleeding when used with **warfarin**, see 'Coumarins and related drugs + NSAIDs', p.480.

There is a report of the rare adverse effect, coumarin necrosis, occurring in an elderly man taking **acenocoumarol**, in which acute renal impairment aggravated by diclofenac was considered a contributory factor.[7]

Mechanism

See 'Coumarins and related drugs + NSAIDs', p.480.

Importance and management

On the basis of the pharmacological studies, no adjustment in coumarin dose would be anticipated to be needed when diclofenac is used. The isolated cases of raised INRs are unexplained. However, care is still needed with every NSAID because, to a greater or lesser extent, they irritate the stomach lining, which can result in gastrointestinal bleeding, which will be more severe in anticoagulated patients. For more information about this and potential CYP2C9-mediated interactions, see 'Coumarins and related drugs + NSAIDs', p.480.

Coumarins + NSAIDs; Diflunisal

There is limited evidence to suggest that diflunisal might increase the anticoagulant effects of acenocoumarol and possibly warfarin, but apparently not phenprocoumon. All NSAIDs increase the risk of bleeding, and should be used with care in patients taking oral anticoagulants.

Clinical evidence

The total plasma **warfarin** levels of 5 healthy subjects fell by about one-third (from 741 to 533 nanograms/mL) when they were given diflunisal 500 mg twice daily for 2 weeks. Also, unbound **warfarin** increased from 1.02% to 1.34%, but the anticoagulant response was unaffected. When the diflunisal was withdrawn the anticoagulant response was reduced.[1]

A brief report states that 3 out of 6 subjects taking **acenocoumarol** had significant increases in prothrombin times, but no interaction was seen in 2 subjects taking **phenprocoumon**, when they were given diflunisal 750 mg daily.[2]

Mechanism

Uncertain. Diflunisal can displace warfarin from its plasma protein binding sites, but this on its own is almost certainly not the full explanation.[1] The fall in anticoagulant response when diflunisal was stopped is possibly

linked to a difference in the rates that total and unbound plasma warfarin returned to their original levels.[1]

Importance and management

This interaction is neither well defined nor well documented and its importance is uncertain. However, the reports cited suggest that an increased anticoagulant effect should be looked for if diflunisal is added to established treatment with any anticoagulant. A decreased effect might be expected if diflunisal is withdrawn. Note that care is needed with every NSAID because, to a greater or lesser extent, they irritate the stomach lining, which can result in gastrointestinal bleeding, which will be more severe in anticoagulated patients. Consider also 'Coumarins and related drugs + NSAIDs', p.480.

Coumarins + NSAIDs; Dipyrone (Metamizole sodium)

One report claims that dipyrone does not interact with phenprocoumon or ethyl biscoumacetate, whereas another describes a rapid but transient increase in the effects of ethyl biscoumacetate with dipyrone. All NSAIDs increase the risk of bleeding, and an increased risk is seen when they are given with anticoagulants.

Clinical evidence, mechanism, importance and management

A single 1-g dose of dipyrone did not alter the steady-state anticoagulant effects of either **phenprocoumon** (5 subjects) or **ethyl biscoumacetate** (6 subjects).[1] Conversely, another report describes a short-lived but rapid increase (within 4 hours) in the effects of **ethyl biscoumacetate** caused by single 1-g dose metamizole sodium.[2] The reasons are not understood. However, care is still needed with every NSAID because, to a greater or lesser extent, they irritate the stomach lining, which can result in gastrointestinal bleeding, which will be more severe in anticoagulated patients. Consider also 'Coumarins and related drugs + NSAIDs', p.480.

2. Mehvar SR, Jamali F. Dipyrone-ethylbiscoumacetate interaction in man. *Indian J Pharm* (1981) 7, 293–9.

Coumarins + NSAIDs; Etodolac

In a pharmacological study, etodolac did not interact significantly with warfarin. Note that all NSAIDs increase the risk of bleeding, and an increased risk is seen when they are combined with anticoagulants.

Clinical evidence, mechanism, importance and management

In a three-period, crossover study, each period lasting 2.5 days, 18 healthy subjects were given **warfarin** 20 mg on day one, 10 mg on days 2 and 3 and etodolac 200 mg every 12 hours. Although the median peak serum levels of the **warfarin** fell by 19% and the median total clearance rose by 13% in the presence of etodolac, the prothrombin time response remained unchanged.[1,2] On the basis of this study, no adjustment in coumarin dose would be expected to be needed when etodolac is used. However, care is still needed with every NSAID, because, to a greater or lesser extent, they irritate the stomach lining, which can result in gastrointestinal bleeding, which will be more severe in anticoagulated patients. Consider also 'Coumarins and related drugs + NSAIDs', p.480.

Coumarins and related drugs + NSAIDs; Fenamates

The anticoagulant effects of acenocoumarol, phenprocoumon and warfarin may be increased by floctafenine, glafenine, meclofenamic acid, and mefenamic acid. Tolfenamic acid is expected to interact similarly. However, limited evidence from one small study found glafenine did not alter the response to acenocoumarol, or ethyl biscoumacetate. Note also that all NSAIDs increase the risk of bleeding, and an increased risk is seen when they are given with anticoagulants.

Clinical evidence

(a) Floctafenine

In a double-blind study in 20 patients stabilised on **acenocoumarol** or **phenprocoumon** and given either floctafenine 200 mg or placebo four times daily for 3 weeks, floctafenine prolonged their thrombotest times by an average of about one-third, even though the anticoagulant dose of some of the patients was reduced.[1]

(b) Glafenine

In a double-blind study in 20 patients stabilised on **phenprocoumon** and given either glafenine 200 mg or placebo three times daily it was noted that within a week of starting glafenine there was a significant increase in thrombotest times.[2] In another report, 5 out of 7 patients needed a **phenprocoumon** dose reduction while taking glafenine.[3] Conversely, in another study, 10 patients taking **acenocoumarol**, **ethyl biscoumacetate** or '**indanedione**' had no changes in their anticoagulant response when given glafenine 800 mg daily over a 4-week period.[4]

(c) Meclofenamic acid

After taking sodium meclofenamate 200 to 300 mg daily for 7 days, the average dose of **warfarin** required by 7 patients fell from 6.5 to 4.25 mg daily, and by the end of 4 weeks it was 5.5 mg (a 16% reduction with a 0 to 25% range).[5]

(d) Mefenamic acid

After taking mefenamic acid 500 mg four times daily for a week, the mean prothrombin concentrations of 12 healthy subjects stabilised on **warfarin** fell by about 3.5%. Microscopic haematuria was seen in 3 of them, but no overt haemorrhage occurred. Their prothrombin concentrations were 15 to 25% of normal, well within the accepted anticoagulant range.[6]

Mechanism

Uncertain. Mefenamic acid can displace warfarin from its plasma protein binding sites,[7-9] and *in vitro* studies have shown that therapeutic concentrations (equivalent to 4 g daily) can increase the unbound and active warfarin concentrations by 140 to 340%,[7,8] but this interaction mechanism alone is only likely to have a transient effect. See also 'Coumarins and related drugs + NSAIDs', p.480.

Importance and management

The pharmacological studies cited suggest that all the fenamates can cause a small to modest increase in the effects of the coumarins. If both drugs are given, increase monitoring and anticipate the need for a small reduction in the coumarin dose. Although there are no data regarding concurrent use with the fenamate **tolfenamic acid**, the manufacturer similarly recommends close monitoring of coagulation.[10] Also note that, all NSAIDs, to a greater or lesser extent irritate the stomach lining, which can result in gastrointestinal bleeding, which will be more severe in anticoagulated patients. Consider also 'Coumarins and related drugs + NSAIDs', p.480.

Coumarins + NSAIDs; Ibuprofen and related drugs

Ibuprofen, indoprofen, ketoprofen, naproxen and oxaprozin do not appear to alter the anticoagulant effect of coumarins. However, isolated cases of raised INRs have been described with ibuprofen and ketoprofen, and an increased risk of bleeding has been reported with naproxen. A slight increase in anticoagulant effect has been seen with fenbufen, flurbiprofen and tiaprofenic acid. Note also that all NSAIDs increase the risk of bleeding, and an increased risk is seen when they are given with anticoagulants.

Clinical evidence

(a) Fenbufen

In a study in 10 healthy subjects who were stabilised on **warfarin** and then given either fenbufen 400 mg twice daily or placebo for one week, the prothrombin times were increased by 1.9 seconds within 2 days in the fenbufen recipients, and the serum **warfarin** levels fell by 14%.[1]

(b) Flurbiprofen

In a study in 19 patients stable taking **phenprocoumon** and given flurbiprofen 50 mg three times daily for 2 weeks, a small but significant fall in the Quick value occurred (from 25.05% to 20.68%). Two patients bled (haematuria, epistaxis, haemorrhoidal bleeding) and the prothrombin times of 3 patients fell below the therapeutic range.[2] A case report describes 2 patients taking **acenocoumarol** who had a rise in thrombotest times and bled (haematuria, melaena, haematomas) within 2 to 3 days of starting to take flurbiprofen 150 to 300 mg daily.[3]

(c) Ibuprofen

Ibuprofen 600 mg to 2.4 g daily for 7 to 14 days did not alter the effects of coumarins in studies in patients stabilised on **phenprocoumon**;[4-6] healthy subjects[7,8] or patients[8] stabilised on **warfarin**; or patients stabilised on **dicoumarol**.[9] In one study in 20 patients taking **warfarin**, ibuprofen 600 mg three times daily for one week had no effect on prothrombin time; however, it did prolong bleeding time (4 cases above the therapeutic range) and microscopic haematuria and haematoma were seen.[10] Note that, this finding is probably more of a function of the effect of ibuprofen than an interaction *per se*,[11] although it does explain why the combination of an anticoagulant and an NSAID has an increased risk of haemorrhage.

An isolated case report describes subclinical bleeding with a raised INR in a 74-year-old woman with multiple medical problems taking **warfarin** when she was given ibuprofen.[12]

In a retrospective cohort study of patients taking **acenocoumarol** or **phenprocoumon**, ibuprofen was associated with a 2.2-fold increased risk of hospitalisation for bleeding. The study specifically looked at potentially interacting drugs taken by at least 50 patients, and there were at least 5 cases of bleeding with ibuprofen.[13] A case report describes a woman taking **warfarin**, with an INR of 2.1 on admission, who had a fatal gastrointestinal bleed after taking ibuprofen (dose unknown) for foot pain in the previous week.[14] For other studies, including one assessing the effect of CYP2C9 substrates, such as ibuprofen, on the risk of bleeding with warfarin, see 'Coumarins and related drugs + NSAIDs', p.480.

(d) Indoprofen

In a placebo-controlled study in 18 patients stabilised on **warfarin** and given indoprofen 600 mg daily for 7 days, found no changes occurred in any of the blood coagulation measurements made.[15]

(e) Ketoprofen

In a study in 15 healthy subjects stabilised on **warfarin**, ketoprofen 100 mg twice daily for 7 days had no effect on prothrombin times or coagulation cascade parameters, and there was no evidence of bleeding.[16] This contrasts with an isolated case of bleeding in a patient taking **warfarin** (prothrombin time increased from 18 seconds to 41 seconds) one week after starting ketoprofen 25 mg three times daily.[17]

(f) Naproxen

In a study in 10 healthy subjects, naproxen 375 mg twice daily for 17 days did not alter the pharmacokinetics of a single dose of **warfarin** given on day 10, or alter its anticoagulant effects.[18] Similar results were found in a study of **warfarin** at steady state.[19] A further study in patients taking **phenprocoumon** found that naproxen 250 mg twice daily transiently increased the anticoagulant effects and caused an unimportant change in primary bleeding time.[20]

In a retrospective cohort study of patients taking **acenocoumarol** or **phenprocoumon**, naproxen was associated with a 6.5-fold increased risk of hospitalisation for bleeding. The study specifically looked at potentially interacting drugs taken by at least 50 patients, and there were at least 9 cases of bleeding for naproxen.[13] For other studies, including one assessing the effect of CYP2C9 substrates, such as naproxen, on the risk of bleeding with warfarin, see 'Coumarins and related drugs + NSAIDs', p.480.

(g) Oxaprozin

In a study in 10 healthy subjects stabilised on **warfarin** for an average of 15 days, oxaprozin 1.2 g daily for 7 days did not significantly alter prothrombin times.[21]

(h) Tiaprofenic acid

In a study in 6 healthy subjects, the anticoagulant effects and the pharmacokinetic profile of **phenprocoumon** remained unchanged when they took tiaprofenic acid daily for 2 days.[22] This study is also published elsewhere.[23] No significant interaction occurred in 9 patients stabilised on **acenocoumarol** and given tiaprofenic acid 200 mg three times daily for 2 weeks, but in 4 patients a 'rebound' rise in prothrombin percentages occurred following the withdrawal of the NSAID.[24] However, an elderly man taking **acenocoumarol** had severe epistaxis and bruising 4 to 6 weeks after starting to take tiaprofenic acid 300 mg twice daily. His prothrombin time had risen to 129 seconds.[25]

Mechanism

When given alone, ibuprofen and related drugs can prolong bleeding times because of their antiplatelet effects.[11] They may also cause gastrointestinal toxicity. Because of these effects, the risk of bleeding is increased in patients taking anticoagulants by the concurrent use of NSAIDs. Most of the propionic acid derivatives can displace the anticoagulants from plasma protein binding sites to some extent, but this mechanism on its own is rarely, if ever, responsible for clinically important drug interactions.

Importance and management

It is well established that ibuprofen does not alter the anticoagulant effect of warfarin or other coumarins, (although isolated and unexplained cases of bleeding or raised INRs have occurred, but only very rarely). On the basis of these studies, no adjustment in coumarin dose would be anticipated to be needed when ibuprofen is used. Pharmacological studies also show no interaction for related propionic acid derivatives including indoprofen, ketoprofen, naproxen and oxaprozin, although the documentation is more limited. A slight increase in anticoagulant effects has been seen with fenbufen, flurbiprofen, and possibly tiaprofenic acid, although this is probably of limited clinical relevance. However, note that care is still needed with every NSAID, because, to a greater or lesser extent, they irritate the stomach lining, which can result in gastrointestinal bleeding, which will be more severe in anticoagulated patients. For more information about this, and potential CYP2C9-mediated interactions, see 'Coumarins and related drugs + NSAIDs', p.480.

Coumarins + NSAIDs; Indometacin and related drugs

The anticoagulant effects of acenocoumarol, phenprocoumon and warfarin are not affected by indometacin, and the anticoagulant effects of phenprocoumon are not affected by acemetacin. However, isolated cases of raised INRs and bleeding complications have been reported. Also, note that, like all NSAIDs, indometacin increases the risk of bleeding, the risk of which is further increased in patients taking anticoagulants.

Clinical evidence

(a) Acemetacin

In a placebo-controlled study in 20 patients stabilised on **phenprocoumon**, acemetacin 60 mg three times daily for 3 weeks did not alter the thromboplastin value.[1]

(b) Indometacin

In a placebo-controlled, double-blind study in 8 healthy subjects, indometacin 100 mg daily for 5 days had no effect on the anticoagulant effects of steady-state **warfarin**.[2] Similarly, when 19 healthy subjects took either indometacin 25 mg four times daily or placebo for 11 days, the anticoagulant effects and the half-life of single doses of **warfarin** were not affected.[2]

Other studies in healthy subjects and patients anticoagulated with **acenocoumarol**[3] or **phenprocoumon**[4-6] similarly found that the anticoagulant effects were not changed by indometacin.

However, isolated cases of possible interactions in patients taking **warfarin** have been reported.[7-9] One patient had a rise in INR from 2 to 5.3,[8] and another had a rise from 2.75 to 3.42, then to 3.6 despite a reduction in **warfarin** dose.[9] However, there are other possible interpretations of this case.[10] In another report a patient taking indometacin appeared to have an enhanced response to **warfarin**, which subsequently improved when ibuprofen was substituted for indometacin.[7] The preliminary report of an analysis of possible drug interactions with **warfarin** stated that indometacin was found to have a clinically relevant effect on the anticoagulant action of warfarin.[11] One patient taking **warfarin** and indometacin died from acute peptic ulceration.[12] In another report, a patient who was very sensitive to **acenocoumarol** was found to have melaena and an INR of greater than 10 one week after starting indometacin and tetrazepam. He was found to have low levels of the cytochrome P450 isoenzyme CYP2C9 (poor metaboliser phenotype of CYP2C9 variant *3).[13]

For studies, including one assessing the effect of CYP2C9 substrates, such as indometacin, on the risk of bleeding with warfarin, see 'Coumarins and related drugs + NSAIDs', p.480.

Mechanism

None. Indometacin reduces platelet aggregation and thereby prolongs bleeding when it occurs. Acemetacin would act similarly since it is a glycolic acid ester of indometacin and indometacin is the major metabolite.

Importance and management

In pharmacological studies it is well established that indometacin does not normally alter the anticoagulant effects acenocoumarol, phenprocoumon or warfarin. No coumarin dose adjustments would therefore expected to be needed during concurrent use. However, caution is still appropriate, because indometacin, like other NSAIDs, can cause gastrointestinal irritation, ulceration and bleeding, which will be more severe in anticoagulated patients. For more information about this and potential CYP2C9-mediated interactions, see 'Coumarins and related drugs + NSAIDs', p.480.

Coumarins and related drugs + NSAIDs; Ketorolac

Ketorolac does not alter the pharmacokinetics of, or prothrombin time response to, warfarin. However, ketorolac has been associated with serious gastrointestinal bleeding.

Clinical evidence, mechanism, importance and management

In a placebo-controlled, crossover study[1] in 10 healthy subjects, ketorolac 10 mg four times daily for 12 days caused no major changes in the pharmacokinetics of *R*- or *S*-warfarin, nor in the prothrombin time after a single 25-mg dose of **warfarin** given on day 6. This suggests that ketorolac is normally unlikely to affect the anticoagulant response of patients taking **warfarin** long-term, and that no warfarin dose adjustments would be expected to be necessary on concurrent use. However, in 1993 the CSM in the UK reported on an analysis of adverse reactions associated with ketorolac: they had received 5 reports of postoperative haemorrhage and four reports of gastrointestinal haemorrhage (one fatal) in patients taking ketorolac.[2] As result of this analysis, the use of ketorolac with anticoagulants was contraindicated in the UK.[2,3] In the US, the manufacturers stated that patients taking anticoagulants have an increased risk of bleeding complications if they are also given ketorolac, and therefore they should be used together extremely cautiously. They noted that, in particular, there is an increased risk of intramuscular haematoma from intramuscular ketorolac in patients taking anticoagulants.[4] This advice is prudent, because it is now established that use of any NSAID increases the risk of gastrointestinal bleeding when used with anticoagulants, see 'Coumarins and related drugs + NSAIDs', p.480, and it would therefore be wise to avoid the concurrent use of NSAIDs that have a higher risk of gastrointestinal toxicity such as ketorolac.

Coumarins + NSAIDs; Nabumetone

Nabumetone does not appear to alter the anticoagulant effects of acenocoumarol or warfarin. However, an isolated report describes a raised INR and haemarthrosis in one patient taking warfarin, which was attributed to an interaction with nabumetone. Note that all NSAIDs increase the risk of bleeding, and an increased risk is seen when they are given with anticoagulants.

Clinical evidence, mechanism, importance and management

In a study in 12 healthy subjects, nabumetone 2 g daily for 2 weeks did not significantly alter the anticoagulant effects of steady-state **warfarin**.[1] Similarly, nabumetone 1 to 2 g daily for 6 weeks had no effect on the INR in 58 patients stabilised on **warfarin**.[2] Another clinical study in osteoarthritis patients also found that there was no difference in the proportion of patients with no INR change and no change in **acenocoumarol** dose in 27 patients given nabumetone 1 to 2 g daily for 4 weeks and 29 patients given placebo.[3] Moreover, nabumetone does not appear to affect bleeding time, platelet aggregation or prothrombin times in the absence of an anticoagulant.[4] However, an isolated and unexplained report describes an increase in INR from 2 to 3.7 and haemarthrosis in a patient taking **warfarin** a week after nabumetone 750 mg twice daily was added.[5]

On the basis of the above studies, no coumarin dose adjustment would be expected to be needed with nabumetone. However, care is still needed with every NSAID because, to a greater or lesser extent, they irritate the stomach lining, which can result in gastrointestinal bleeding, which will be more severe in anticoagulated patients. Consider also 'Coumarins and related drugs + NSAIDs', p.480.

Coumarins + NSAIDs; Nimesulide

In pharmacological studies, nimesulide did not alter the effects of acenocoumarol or warfarin. Note that all NSAIDs increase the risk of bleeding, and an increased risk is seen when they are given with anticoagulants.

Clinical evidence, mechanism, importance and management

In a pilot study in 6 patients stabilised on **acenocoumarol**, a single 100-mg dose of nimesulide did not affect the clotting mechanisms, although the platelet aggregating response to adenosine diphosphate, adrenaline (epinephrine) and collagen was reduced for 2 to 4 hours.[1] Ten patients stabilised on **warfarin** 5 mg daily had no significant changes in their prothrombin times, partial thromboplastin time or bleeding times when they were given nimesulide 100 mg twice daily for a week.[2] However, a few patients had some increase in anticoagulant activity.[1]

These studies suggest that no coumarin dose adjustments are expected to be needed when nimesulide is used. However, care is still needed with every NSAID because, to a greater or lesser extent, they irritate the stomach lining, which can result in gastrointestinal bleeding, which will be more severe in anticoagulated patients. Consider also 'Coumarins and related drugs + NSAIDs', p.480.

Coumarins + NSAIDs; Oxicam derivatives

Piroxicam increases plasma levels of *R*-acenocoumarol, and a few cases of raised INRs and bleeding have been reported when it was given with acenocoumarol or warfarin. In pharmacological studies, lornoxicam modestly increased the anticoagulant effects of warfarin, and possibly decreased the effect of phenprocoumon, but it did not interact with acenocoumarol. Studies have indicated that meloxicam does not interact with warfarin, and that tenoxicam does not interact with warfarin or phenprocoumon. Note that all NSAIDs increase the risk of bleeding, and an increased risk is seen when they are given with anticoagulants.

Clinical evidence

(a) Lornoxicam

In an open, crossover study in 6 healthy subjects, lornoxicam 8 mg twice daily for 7 days had no effect on the pharmacokinetics or the anticoagulant activity of a single 10-mg dose of **acenocoumarol** given on day 4.[1]

In an open, crossover study in 6 healthy subjects, lornoxicam 8 mg twice daily for 21 days increased the bioavailabilities of *S*- and *R*-phenprocoumon by 14% and 6%, respectively, and decreased their clearances by 15% and 6%, respectively, after a single 9-mg dose of **phenprocoumon** given on day 4. Despite the minor pharmacokinetic changes, statistically significant reductions in the activities of factors II and VII were seen.[2]

Lornoxicam 4 mg twice daily was given to 12 healthy subjects for 5 days, and then **warfarin** was added until a stable prothrombin time, averaging about 23.6 seconds, was achieved. The period to achieve this varied from 9 to 24 days, depending on the subject. The **warfarin** was then continued and the lornoxicam withdrawn, whereupon the mean prothrombin time fell to 19.5 seconds, the INR fell from 1.48 to 1.23 and the serum **warfarin** levels fell by 25%.[3]

(b) Meloxicam

In a group of 13 healthy subjects stabilised with INRs of 1.2 to 1.8, meloxicam 15 mg daily for 7 days did not significantly affect the pharmacokinetics of **warfarin** or INR values[4].

(c) Piroxicam

1. Acenocoumarol. In a single-dose study in healthy subjects, when piroxicam 40 mg was given with acenocoumarol 4 mg the AUC of the less active *R*-isomer was increased by 47% and its maximum plasma level was increased by 28%.[5]

In patients stabilised on acenocoumarol, piroxicam 20 mg daily for 2 weeks increased the effects of acenocoumarol in 4 out of 11 patients: the effect was considered mild in 3 patients, and significant in the fourth, although no specific values were given.[6] A further patient taking acenocoumarol developed gastrointestinal bleeding 3 days after starting to take piroxicam 20 mg daily. His INR rose from 2.2 to 6.5.[7]

2. Warfarin. A man stabilised on warfarin had a fall in his prothrombin time from a range of 1.7 to 1.9 times his control value to 1.3 when he stopped taking piroxicam 20 mg daily. The prothrombin times rose and fell when he re-started and then stopped the piroxicam.[8] Another patient taking warfarin had an increase in her prothrombin time (from a range of 16.5 to 18.1 seconds, up to 24.9 seconds) when piroxicam 20 mg daily was started, and a decrease when it was then stopped.[9] The INR of two Chinese patients rose to 4.5 and 4.2 after they were given piroxicam 20 mg daily and 0.5% topical piroxicam gel. One of them had bruises over the legs within 3 days.[10]

A woman who spread **warfarin** rat poison with her bare hands developed intracerebral bleeding, possibly exacerbated by piroxicam, which she took occasionally.[11]

(d) Tenoxicam

In single-dose and steady-state studies in a total of 16 healthy subjects, tenoxicam 20 mg daily for 14 days had no significant effect on the anticoagulant effects of **warfarin** or on bleeding times.[12] This report also men-

tions case studies in a small number of patients and healthy subjects, which similarly found that tenoxicam had no significant effect on the anticoagulant effects of **phenprocoumon**.[12]

Mechanism

Piroxicam inhibits the metabolism of *R*-acenocoumarol, but its effect on the metabolism of warfarin is unknown. Lornoxicam inhibited the metabolism of warfarin, but not acenocoumarol, *in vitro*.[13] In addition NSAIDs have antiplatelet effects, which can prolong bleeding if it occurs. They may also cause gastrointestinal toxicity. Because of these effects, in patients taking anticoagulants, the risk of bleeding is increased by NSAIDs.

Importance and management

The interaction of piroxicam with acenocoumarol would appear to be established, and case reports suggest that warfarin might be similarly affected. The UK manufacturer of piroxicam[14] contraindicates the concurrent use of anticoagulants, such as warfarin. This seems overly cautious; nevertheless, if piroxicam is given with a coumarin, it would be prudent to monitor the outcome well and anticipate the need to reduce the anticoagulant dose. Lornoxicam appears to have a similar effect with warfarin, although no cases of an interaction have been reported. Meloxicam and tenoxicam appear not to interact. However, care is still needed with every NSAID because, to a greater or lesser extent, they irritate the stomach lining, which can result in gastrointestinal bleeding, which will be more severe in anticoagulated patients. Consider also 'Coumarins and related drugs + NSAIDs', p.480.

Coumarins + NSAIDs; Phenazone (Antipyrine)

The anticoagulant effects of warfarin are reduced by phenazone.

Clinical evidence

The plasma **warfarin** concentrations were halved (from 2.93 to 1.41 micrograms/mL) and the anticoagulant effects reduced accordingly after 5 patients took phenazone 600 mg daily for 50 days.[1] The thrombotest percentage of one patient rose from 5% to 50%. In an associated study it was found that phenazone 600 mg daily for 30 days caused a reduction in the **warfarin** half-life from 47 hours to 27 hours and from 69 hours to 39 hours, respectively, in 2 patients.[1,2]

Mechanism

Phenazone is an enzyme inducer, which increases the metabolism and clearance of warfarin, thereby reducing its effects.[1,2]

Importance and management

An established interaction. The effects of concurrent use should be monitored and the dose of warfarin increased appropriately. However, note that phenazone is little used clinically, and an alternative NSAID that does not alter the metabolism of coumarins would be more appropriate (see 'Coumarins and related drugs + NSAIDs', p.480). Other coumarins might be expected to be similarly affected.

Coumarins and related drugs + NSAIDs; Phenylbutazone and related drugs

The anticoagulant effects of warfarin are markedly increased by azapropazone, oxyphenbutazone and phenylbutazone. Feprazone appears to interact similarly.
Bleeding has also been seen in patients taking phenindione or phenprocoumon when given phenylbutazone, but successful concurrent use has been achieved with both phenprocoumon and acenocoumarol. Note also that all NSAIDs increase the risk of bleeding, and an increased risk is seen when they are given with anticoagulants.

Clinical evidence

(a) Azapropazone

A woman taking digoxin, furosemide, spironolactone, allopurinol, and **warfarin** (prothrombin ratio 2.8) developed haematemesis within 4 days of starting to take azapropazone 300 mg four times a day. Her prothrombin ratio was found to have risen to 15.7. Subsequent gastroscopic examination revealed a benign ulcer, the presumed site of the bleeding.[1]

Several other patients are reported to have developed this interaction. Bruising or bleeding (melaena, epistaxis, haematuria) and prolonged prothrombin times have occurred within a few days of starting azapropazone.[2-4] Two patients died.[3,4]

(b) Feprazone

Five patients stabilised on **warfarin** had a mean prothrombin time rise from 29 seconds to 38 seconds after taking feprazone 200 mg twice daily for 5 days, despite a 40% reduction in the **warfarin** dose (from 5 to 3 mg daily). Four days after feprazone was stopped, their prothrombin times were almost back to usual. The interaction with feprazone was less marked than that with phenylbutazone.[5]

(c) Oxyphenbutazone

A man stabilised on **warfarin** developed gross haematuria within 9 days of starting to take oxyphenbutazone 400 mg daily. His prothrombin time had increased to 68 seconds.[6] Two similar cases have been described elsewhere.[7,8] A clinical study has found that oxyphenbutazone slows the clearance of **dicoumarol**.[9]

(d) Phenylbutazone

In a study in 3 subjects and one patient, phenylbutazone 200 mg three times daily and twice daily, respectively, given for 11 to 19 days before and 11 days after a single dose of **warfarin**, markedly increased the prothrombin time, but *decreased* the half-life of **warfarin**, and the **warfarin** AUC.[10] In another study that gave the enantiomers of **warfarin** separately, it was found that phenylbutazone inhibited the clearance of *S*-warfarin, but increased the clearance of *R*-warfarin.[11] This was confirmed in other studies, where the AUC of *R*-warfarin was decreased by 41% and the AUC of *S*-warfarin increased by 18%.[12]

A number of other studies have found markedly increased prothrombin times in patients[5,13] or healthy subjects[14] taking **warfarin** and given phenylbutazone. Moreover, there are a number of case reports demonstrating the clinical importance of this interaction.[10,15-19] In one, a man stabilised on **warfarin** following mitral valve replacement was later given phenylbutazone for back pain by his general practitioner. On admission to hospital a week later he had epistaxis, and his face, legs and arms had begun to swell. He had extensive bruising of the jaw, elbow and calves, some evidence of gastrointestinal bleeding, and a prothrombin time of 89 seconds.

Two similar cases have also been reported.[18] A similar interaction occurs between phenylbutazone and **phenprocoumon**. In one study in healthy subjects, phenylbutazone 300 mg daily for 14 days doubled the prothrombin time response to a single dose of phenprocoumon given on day 4, while decreasing the phenprocoumon AUC by 31%.[20] Cases of a clinically important interaction have also been reported for **phenprocoumon**.[21] In one early report, the required dose of **acenocoumarol** was 25% lower in patients taking phenylbutazone.[22] A single unconfirmed report describes this interaction in two patients taking **phenindione**.[23]

Mechanism

Phenylbutazone very effectively displaces the coumarins and indanediones from their plasma protein binding sites, thereby increasing the concentrations of free and active anticoagulant (an effect easily demonstrated *in vitro*[10,24-28]). By itself, the importance of this mechanism is usually small, since any displaced drug is then available to be cleared, so any effect is usually transient (see 'Protein-binding interactions', (p.3)). However, phenylbutazone also inhibits the metabolism of *S*-warfarin (the more potent of the two warfarin enantiomers) so its effects are increased and prolonged.[11,12,29] In studies, the unbound clearance of *S*-warfarin was decreased about three- to fourfold.[29,30] In contrast, the unbound clearance of *R*-warfarin is not altered, so the total clearance of *R*-warfarin is increased due to displacement.[29] Thus, overall, it appears that phenylbutazone decreases total plasma warfarin levels, while increasing its effect. Azapropazone[31-33] and oxyphenbutazone (the major metabolite of phenylbutazone) probably act similarly.

Importance and management

The pharmacokinetic interaction between warfarin and azapropazone or phenylbutazone is very well established and clinically important. Serious bleeding can result and concurrent use should be avoided. Feprazone and oxyphenbutazone appear to interact similarly. Much less is known about phenindione with phenylbutazone, but they probably interact similarly.[23] Direct evidence of a serious interaction with phenprocoumon seems to be limited to two reports, and there is some evidence (from one paper published in 1957) that successful and apparently uneventful concurrent use is possible, presumably because in the case cited the response and the anticoagulant doses were carefully controlled.[34] However, the practicalities of such close monitoring outside of a study are unclear. One study found that 25% less acenocoumarol was needed in patients given phenylbutazone.[22] Remember too that phenylbutazone and related drugs affect platelet aggregation and can cause gastrointestinal bleeding, and the risk of this is increased in patients taking an anticoagulant. It would seem advisable to use an alternative NSAID that interacts to a lesser extent, such as ibuprofen or naproxen, although it should be noted that no NSAID is entirely free from interactions with anticoagulants. Consider also 'Coumarins and related drugs + NSAIDs', p.480.

Coumarins + NSAIDs; Sulindac

Sulindac does not usually appear to significantly alter the anticoagulant effect of warfarin or phenprocoumon; however, isolated cases of a modest to marked increase in the anticoagulant effects of warfarin have been reported. Note that all NSAIDs increase the risk of bleeding, and an increased risk is seen when they are given with anticoagulants.

Clinical evidence

In a study in healthy subjects stabilised on **warfarin**, sulindac 200 mg twice daily for 7 days did not significantly alter the prothrombin time, when compared with placebo, although the prothrombin time was slightly higher in the sulindac group.[1] Similarly, in 20 patients stabilised on **phenprocoumon**, sulindac 200 to 400 mg daily for 4 weeks did not alter measures of coagulation or bleeding time.[2]

However, a patient stabilised on **warfarin**, ferrous sulfate, phenobarbital and sulfasalazine had a marked increase in his prothrombin time ratio from about 3.2 to 10 after taking sulindac 100 mg twice daily for 5 days.[3-5] There are 5 similar cases of this interaction on record.[1,5-8] One of the patients had a gastrointestinal bleed after taking only three 100-mg doses of sulindac, although this patient was also taking flurbiprofen.[5] Another patient was stabilised on about a 40% lower dose of **warfarin** with continuation of the sulindac.[6] Another patient had a potassium-losing renal tubular defect, which was thought to contribute to the interaction.[1] In one of these cases, the patient, who was also taking a corticosteroid, developed a retropharyngeal haematoma.[8]

Mechanism

Not understood. In one patient, renal impairment may have caused sulindac accumulation, which in turn may have affected warfarin pharmacokinetics.[1] See also 'Coumarins and related drugs + NSAIDs', p.480.

Importance and management

The pharmacological studies cited suggest that usually no coumarin dose adjustment would be needed in patients given sulindac. However, the isolated cases of an interaction suggest that, rarely, some patients may be affected. Also note that all NSAIDs can irritate the gastric mucosa, affect platelet activity and cause gastrointestinal bleeding, which will be more severe in anticoagulated patients. Consider also 'Coumarins and related drugs + NSAIDs', p.480.

Coumarins + NSAIDs; Tolmetin

In pharmacological studies, tolmetin did not alter the anticoagulant effect of the coumarins; however, isolated cases of raised INRs have been described. Note that all NSAIDs increase the risk of bleeding, and an increased risk is seen when they are given with anticoagulants.

Clinical evidence

In a placebo-controlled study, no changes in prothrombin times occurred in 15 healthy subjects stabilised on **warfarin** when they took tolmetin 400 mg three times daily for 14 days.[1] Similarly, no changes in prothrombin times occurred in 15 patients taking **phenprocoumon** when they were given tolmetin 200 mg four times daily for 10 days.[2] Bleeding times were reported to be slightly prolonged, though not to a clinically relevant extent.[2] Bleeding times were not significantly altered in healthy subjects given **acenocoumarol** and tolmetin 400 mg twice daily, or patients taking **acenocoumarol** and tolmetin.[3] However, there is a single published case report of a diabetic patient stabilised on **warfarin**, insulin, digoxin, theophylline, ferrous sulfate, furosemide and sodium polystyrene sulfonate who had a nosebleed after taking three 400-mg doses of tolmetin. His prothrombin time had risen from a range of 15 to 22 seconds up to 70 seconds.[4] The manufacturers of tolmetin and the FDA in the US also have 10 other cases on record involving tolmetin and warfarin,[4,5] received over a 10-year period.[5]

Mechanism

See 'Coumarins and related drugs + NSAIDs', p.480.

Importance and management

The pharmacological studies cited suggest that usually no coumarin dose adjustment would be needed in patients given tolmetin. The isolated cases of an interaction are unexplained. However, care is needed with every NSAID because, to a greater or lesser extent, they irritate the stomach lining, which can result in gastrointestinal bleeding, which will be more severe in anticoagulated patients. Consider also 'Coumarins and related drugs + NSAIDs', p.480.

Coumarins + Olanzapine

A single dose of olanzapine did not alter the pharmacokinetics or anticoagulant effect of a single dose of warfarin.

Clinical evidence, mechanism, importance and management

In a three-way, randomised, crossover study, 15 healthy subjects were given olanzapine 10 mg, **warfarin** 20 mg or both drugs together as single doses. No significant changes were seen in the pharmacokinetics of either drug, and the adverse effects of the olanzapine and the anticoagulant effects of the **warfarin** were unchanged.[1] Similarly, a 71-year-old woman stabilised on **warfarin** 15 mg/week with an INR of 2.6 had no significant change in her INR after taking olanzapine 20 mg daily for 6 weeks (INR 2.6 when taking 15 mg/week and 2 while taking 12.5 mg/week).[2] This evidence suggests that no **warfarin** dose adjustments are expected to be needed on concurrent use with olanzapine.

Coumarins + Opioids; Codeine

Codeine does not alter the anticoagulant effect of warfarin.

Clinical evidence, mechanism, importance and management

In a crossover study in 15 patients stabilised on **warfarin** and with osteoarthritis pain, codeine phosphate 7 to 15 mg three or four times daily for 5 weeks did not alter the mean INR when compared with celecoxib[1] (see 'Coumarins and related drugs + NSAIDs; Coxibs', p.482).

Codeine was used as a control analgesic in this study because it does not interact with **warfarin**, although this appears to be based on the absence of any evidence of an interaction, and the fact that it is unlikely to alter **warfarin** metabolism, rather than any direct evidence. Nevertheless, the lack of an interaction in this study suggests that codeine is not expected to alter **warfarin** dosing requirements.

1. Dentali F, Douketis JD, Woods K, Thabane L, Foster G, Holbrook A, Crowther M. Does celecoxib potentiate the anticoagulant effect of warfarin? A randomized, double-blind, controlled trial. *Ann Pharmacother* (2006) 40, 1241–7.

Coumarins + Opioids; Dextropropoxyphene (Propoxyphene)

In one study, dextropropoxyphene did not alter the prothrombin time in patients taking unspecified coumarins. There are isolated cases of patients taking warfarin who have had a marked increase in their prothrombin time and/or bleeding when given co-proxamol (dextropropoxyphene with paracetamol (acetaminophen)).

Clinical evidence

(a) Dextropropoxyphene with Paracetamol (Acetaminophen)

A man taking **warfarin** developed marked haematuria within 6 days of starting to take two tablets of co-proxamol three times daily. Thirteen days previously his **warfarin** dose had been increased from 6 mg to 7 mg daily (thrombotest 16%), and then 9 days previously it had been reduced back to 6 mg daily (thrombotest 5%). His plasma **warfarin** levels had risen by one-third (from 1.8 to 2.4 micrograms/mL) despite the reduction in **warfarin** dose.[1] A woman, stable for 6 weeks on **warfarin**, developed gross haematuria 11 hours after starting co-proxamol. She had taken 6 tablets of co-proxamol over a 6-hour period. Her prothrombin time increased from about 30 to 40 seconds up to 130 seconds.[1]

This interaction has been reported in several other patients taking **warfarin**.[2-5] The prothrombin time of one of them rose from 28 to 44 seconds up to 80 seconds within 3 days of substituting paracetamol with two tablets of co-proxamol four times daily.[3] Another developed a prothrombin time of more than 50 seconds after taking 30 tablets of *Darvocet-N 100* (dextropropoxyphene 100 mg, paracetamol 650 mg) and possibly an unknown amount of ibuprofen over a 3-day period.[4]

(b) Dextropropoxyphene

A double-blind study in 23 patients anticoagulated with un-named coumarins and given dextropropoxyphene 450 mg daily for 15 days or ibuprofen did not find any change in prothrombin times with either drug.[6]

Mechanism

Not understood. The effect dextropropoxyphene has on the metabolism of the warfarin enantiomers does not appear to have been studied. Dextropropoxyphene does not interact with other cytochrome P450 isoenzyme CYP2C9 substrates such as tolbutamide (see 'Antidiabetics + Dextropropoxyphene (Propoxyphene)', p.552), although it does interact with the CYP3A4 substrate carbamazepine (see 'Carbamazepine or Oxcarbazepine + Dextropropoxyphene (Propoxyphene)', p.603). There is also the possibility that the paracetamol component had some part to play (see also

'Coumarins and related drugs + Paracetamol (Acetaminophen)', p.492). Alternatively, these cases may just represent idiosyncratic reactions.

Importance and management

Information about this interaction is very sparse and seems to be limited to the reports cited. The cases cited could just be idiosyncratic reactions. Bear them in mind in the event of an unexpected response to treatment.

Coumarins + Opioids; Hydrocodone

In an isolated report, the anticoagulant effects of warfarin were increased by hydrocodone in one patient and in one healthy subject.

Clinical evidence, mechanism, importance and management

A patient, stabilised on **warfarin** (and also taking digoxin, propranolol, clofibrate and spironolactone) had a rise in his prothrombin time of about 2 to 3 times his control value when he began to take *Tussionex* (hydrocodone with phenyltoloxamine) for a chronic cough. When the cough syrup was discontinued, his prothrombin time fell again. In a subsequent study in one healthy subject the equivalent dose of hydrocodone increased the elimination half-life of **warfarin** from 30 hours to 42 hours.[1] The reason for this interaction is not known, and this early report appears to be the only information available. Any interaction is not therefore established.

1. Azarnoff DL. Drug interactions: the potential for adverse effects. *Drug Inf J* (1972) 6, 19–25.

Coumarins + Opioids; Meptazinol

The anticoagulant effects of warfarin were not altered by meptazinol in one study.

Clinical evidence, mechanism, importance and management

Meptazinol 200 mg four times daily for 7 days had no significant effect on the prothrombin indexes of 6 elderly patients stabilised on **warfarin**, nor on the required **warfarin** dose.[1] No **warfarin** dose adjustments would be expected to be needed on concurrent use.

1. Ryd-Kjellen E, Alm A. Effect of meptazinol on chronic anticoagulant therapy. *Hum Toxicol* (1986) 5, 101–2.

Coumarins and related drugs + Opioids; Tramadol

In one study tramadol did not change the mean INR in response to phenprocoumon, although two patients had INR increases. Isolated cases of an increase in anticoagulant effects of warfarin, acenocoumarol, phenprocoumon and fluindione have been reported in patients given tramadol. One retrospective cohort study also found an increased risk of bleeding when acenocoumarol or phenprocoumon was given with tramadol.

Clinical evidence

In a double-blind, placebo-controlled, crossover study the mean INR of 19 patients anticoagulated with **phenprocoumon** was unchanged when they were given tramadol 50 mg three times daily for one week.[1,2] Although the mean difference was not changed, one patient had an INR rise from 4 to 7.3, and another had an INR rise from just under 5 to 6, while taking tramadol, but not while taking placebo.

A brief report describes 5 elderly patients (aged 71 to 84 years), anticoagulated with **warfarin** or **phenprocoumon** and taking a range of other drugs, who had clinically important rises in INRs (up to threefold) shortly after starting to take tramadol. One of the patients had gastrointestinal bleeding. Three of the patients were able to continue the tramadol with a reduced anticoagulant dose.[3]

In another report, a 61-year old woman with a mitral valve replacement stabilised on **warfarin** developed ecchymoses about 2 weeks after starting tramadol 50 mg every 6 hours. Her prothrombin time was found to have risen to 39.6 seconds and her INR was 10.6. These values returned to normal when the tramadol was withdrawn and **warfarin** was temporarily stopped.[4] Other cases have been reported with **warfarin**[5,6] and **phenprocoumon**.[7] In 2004, the Australian Adverse Drug Reactions Advisory Committee said they had received 11 reports of increases in INR or a haemorrhagic event in patients taking **warfarin** and given tramadol. Two patients died of haemorrhagic stroke. They note that this number of cases suggests that the interaction is an uncommon event.[8] Up until March 2003, the Swedish Adverse Drug Reactions Advisory Committee had received reports of 17 cases of a suspected interaction between tramadol and **warfarin** resulting in increases in the INR (to 3.4 to 8.5) and bleeding complications in 35% of patients. One patient who continued tramadol needed the **warfarin** dose to be almost halved.[9] The French regulatory authority has received 2 possible cases with **warfarin** and with the indanedione, **fluindione**, and one possible case with **acenocoumarol**; they note however, that other factors could have contributed to the cases reported.[10] The New Zealand regulatory authority has also commented on 4 possible cases with **warfarin**, two of which they considered were likely due to an interaction.[11]

In a retrospective cohort study of patients taking **acenocoumarol** or **phenprocoumon**, tramadol was associated with a threefold increased risk of hospitalisation for bleeding. The study specifically looked at potentially interacting drugs taken by at least 50 patients and with at least 5 cases of bleeding.[12]

Mechanism

Unknown. It has been suggested that the interaction might be related to a variation in a cytochrome P450 isoenzyme genotype. Seven of 10 patients from the 17 suspected cases of interaction in Sweden had defective CYP2D6 alleles. The authors suggested that as this isoenzyme metabolises tramadol, these patients might have changes in tramadol metabolism that could increase the risk of an interaction with warfarin by CYP3A4. However, CYP3A4 only has a role in the 'metabolism of *R*-warfarin', (p.405), and inhibition of CYP3A4 usually results in no more than a modest increase in INR. Moreover, defective CYP2D6 alleles have a population prevalence of 42.2%, so if this were the mechanism, many more cases would be expected. Because of the rarity of reports, it could just be that it is not really an interaction, and that there were unknown confounding factors in the suspected cases. Possible confounding factors include age, renal impairment, dehydration, under-nourishment, and other medications.[10]

Importance and management

An interaction between tramadol and coumarins or indanediones is not established. One pharmacological study did not show a clear interaction for phenprocoumon and tramadol, although data from 2 patients suggested the possibility. Moreover, isolated cases of an interaction with warfarin, acenocoumarol, phenprocoumon and fluindione have been published or reported to regulatory authorities, but the incidence seems to be low. Because of the uncertainty, it would be prudent to consider monitoring prothrombin times in any patient taking coumarins or indanediones when tramadol is first added, being aware that a small proportion of patients may need a reduction in the anticoagulant dose. Consider using an alternative, non-interacting opioid such as codeine, if appropriate. Further study is needed.

Coumarins and related drugs + Orlistat

Orlistat had no effect on the pharmacodynamics or pharmacokinetics of single-dose warfarin in a study in healthy subjects. However, orlistat reduces fat absorption, and might therefore reduce vitamin K absorption. There is a published report of a patient taking warfarin who developed a modest increase in INR after taking orlistat. Similar cases have been reported to regulatory authorities.

Clinical evidence

In a placebo-controlled, randomised, crossover study, 12 healthy subjects were given orlistat 120 mg three times daily for 16 days, with a single 30 mg dose of **warfarin** on day 11. The pharmacokinetics and pharmacodynamics of the **warfarin** were not altered by the orlistat, and markers of vitamin K nutritional status were not affected.[1] However, regarding this study, the manufacturers US prescribing information states that vitamin K levels did tend to decline in subjects taking orlistat.[2] It is also noted that increased INRs and changes in the anticoagulant response have been reported in patients taking orlistat and anticoagulants.[2] In addition, in 2001 the Canadian regulatory authorities reported that unexpected increases in INR were noted after orlistat was given to patients taking either **warfarin** or **acenocoumarol**. These were managed by dose adjustments of the coumarin or discontinuing orlistat.[3]

In a published report, a 66-year-old man stabilised on **warfarin** for 2.5 years who started taking orlistat 120 mg three times daily for weight reduction had a modest increase in his INR, from less than 3, to 4.7 within 18 days. **Warfarin** was withheld and he was later restabilised on approximately two-thirds of the previous dose while continuing the orlistat.[4]

Mechanism

Orlistat may reduce the absorption of fat soluble vitamins including vitamin K,[4,5] and a change to a lower fat diet associated with the use of orlistat may also contribute to changes in the balance between vitamin K and **warfarin**.[4]

Importance and management

The manufacturers say that patients stabilised on anticoagulants [coumarins and **indanediones**] and given orlistat should be closely monitored for changes in coagulation parameters.[2,5] Given the reports of changes in INRs, and the fact that changes in dietary vitamin K (see 'Coumarins and related drugs + Food; Vitamin K_1-rich', p.464), are known to affect warfarin efficacy, this seems prudent in patients taking any coumarin or indanedione.

Coumarins + Oseltamivir

No pharmacokinetic interaction occurs between oseltamivir and warfarin. However isolated cases of raised INRs have been reported.

Clinical evidence, mechanism, importance and management

In a study, 20 patients taking warfarin, with stable prothrombin times for at least 2 weeks before the study, were given oseltamivir 75 mg twice daily for 4.5 days. Oseltamivir did not affect the pharmacokinetics of warfarin and had no clinically significant effect on the INR, when compared with a control group not taking oseltamivir. No increase in bleeding events occurred.[1]

Both the MHRA in the UK and Health Canada have received reports of an increase in clotting time when patients taking warfarin were given oseltamivir.[2,3] Between January 1999 and November 2005, Health Canada received 19 reports (11 submitted by the same source) of an increase in the INR in patients taking warfarin and given oseltamivir. However, in 3 of these cases the warfarin dose had been increased after starting oseltamivir, and in 2 cases the patients were taking other drugs known to interact with warfarin. Three cases of a *decrease* in the INR were also reported. On this basis, a causative relationship could not be established.[3] Anticoagulant control can be affected by influenza and its associated symptoms (such as fever and decreased appetite), and in 2009 the MHRA in the UK stated that there is no strong evidence to suggest that a drug interaction exists between oseltamivir and warfarin.[2] Oseltamivir is not known to have a significant effect on cytochrome P450 (by which warfarin is predominantly metabolised), and the data above support the lack of a likely pharmacokinetic interaction. It is difficult to establish whether the cases reported represent a drug interaction or an effect related to the patients underlying infection. Nevertheless, it would seem unlikely that such an interaction exists. However, until further data is available to confirm a lack of an interaction, it would be prudent to bear the case reports in mind if a patient taking warfarin develops an unexpected alteration in bleeding times after starting oseltamivir.

Coumarins + Oxolamine

Oxolamine markedly increases the effect of warfarin.

Clinical evidence, mechanism, importance and management

In a retrospective study, 11 patients were identified who had been receiving stable doses of **warfarin** and were then given oxolamine in doses of 100 to 600 mg daily for 3 to 10 days. Of six patients who did not have their **warfarin** dose adjusted, the INR increased by 70 to 190% from a range of 1.51 to 2.82 up to a range of 3.24 to 6.45. One patient had a **warfarin** dose reduction of 14%, with an INR increase from 2.29 to 9.11. Four patients had their **warfarin** dose reduced by 30 to 36%, but one of these still had an INR increase from 2.14 to 4.01. Two of the 11 patients developed a haematoma.[1] In a further prospective study, 6 patients receiving stable doses of **warfarin** were given oxolamine 300 to 600 mg daily for 4 to 7 days, and the **warfarin** dose was reduced by 50% on starting oxolamine. Three patients had no change in INR, one had a 24% increase and two had a 6% and 17% decrease.[1]

The mechanism of this interaction is unknown. Although published information is limited to this study, an interaction seems to be established. If any patient taking **warfarin** requires oxolamine, anticipate the need to roughly halve the **warfarin** dose.

1. Min KA, Zhu X, Oh JM, Shin WG. Effect of oxolamine on anticoagulant effect of warfarin. *Am J Health-Syst Pharm* (2006) 63, 153–6.

Coumarins and related drugs + Paracetamol (Acetaminophen)

An equal number of randomised studies have found a modest increase in the anticoagulant effect of coumarins as have reported no effect. Other cohort studies found no evidence of a change in anticoagulant effect. One retrospective cohort study reported that concurrent use tends to increase the incidence of upper gastroin-

testinal bleeding. There are isolated case reports of an increase in anticoagulant effects in patients taking warfarin, acenocoumarol or fluindione with paracetamol.

Clinical evidence

Over 10 published studies have investigated whether or not paracetamol alters the effect of the coumarins, with equal numbers finding no effect as finding an increased effect, see 'Table 12.4', (p.494). All the randomised, controlled studies finding an interaction have demonstrated a minor to modest effect (e.g. average increase in INR of 1.2 in one well-controlled study[1,2]). The only study to show a much greater effect (an increased odds ratio of an INR above 6 ranging from 3.5 to 10 for different doses of paracetamol alone or combined with an opioid) was a retrospective case-control study,[3,4] which has the limitations of being non-randomised with all the attendant problems of controlling for possible confounding variables.[5-7] Excluding this study, there appears to be no obvious explanation for the disparate findings between the studies finding an interaction and those not, either by study group, coumarin used, or dose of paracetamol.

There are only 5 published case reports of a possible interaction between paracetamol without opioids and a coumarin (**warfarin** or **acenocoumarol**), and two case reports of a possible interaction with the indanedione, **fluindione**, which are summarised in 'Table 12.4', (p.494). In addition, there are two reports of a possible interaction with paracetamol combined with codeine or dihydrocodeine listed in 'Table 12.4', (p.494), and 7 others with paracetamol combined with 'dextropropoxyphene (propoxyphene)', (p.490). Note that this incidence is very rare, given the widespread use of paracetamol, and the fact that it is generally considered safe for use with warfarin.

Moreover, in response to one case-control study[3] other clinicians running outpatient anticoagulant clinics have contended that they have not seen an interaction with paracetamol in their experience.[6,7]

Mechanism

Not understood. It is possible that paracetamol or one of its metabolites inhibits the enzymes in the vitamin K cycle, and so has additive effects with anticoagulants.[2,8]

A pharmacokinetic interaction has been proposed, but this seems unlikely. Paracetamol does not inhibit the cytochrome P450 isoenzyme CYP2C9, which is the major isoenzyme involved in the metabolism of *S*-warfarin.[9] Paracetamol is mainly metabolised by glucuronidation and sulfation,[10,11] but CYP1A2, CYP3A4 and CYP2E1 metabolise up to 15% of paracetamol under normal conditions.[10] *R*-warfarin is mainly metabolised by CYP3A4 and CYP1A2.[10,11] It has been suggested that in conditions such as ageing, hypoxia or hypertension, the isoenzymes play a more important part in paracetamol metabolism. Consequently paracetamol may then theoretically compete with the metabolism of *R*-warfarin to a sufficient degree to provoke an interaction.[11] However, as the *S*-warfarin enantiomer has significantly greater anticoagulant activity than the *R*-warfarin enantiomer, interactions with *R*-warfarin are considered by some to be of questionable significance.[7] Moreover, this explanation might explain rare case reports, but not the slight increases in INR seen in some studies in otherwise healthy subjects and patients.

Yet another idea is that it is the indications for paracetamol use such as pain or fever that cause the interaction, rather than paracetamol *per se*,[12] but this does not explain why an interaction has been found in otherwise healthy patients or subjects given paracetamol in controlled studies.

Importance and management

Despite the number of studies, an interaction between paracetamol and the coumarins is not firmly established, and the importance of the findings remain controversial. Some consider that the dose of paracetamol and its duration of use should be minimised in patients taking coumarins.[10,13] However, in randomised controlled studies, even maximum daily doses of paracetamol (4 g daily) for 2 weeks, had, at most, a modest effect, see 'Table 12.4', (p.494). A dose-related effect has been suggested in a case-controlled study,[3] but a more recent randomised controlled study did not find a dose-response (i.e. there was a slight change in INR of 0.5 with both 1.5 g daily and 3 g daily).[12] Further evidence is therefore required on the possible dose-response effect, and whether there is any value in minimising the dose. Moreover, on the basis of the studies suggesting an interaction, many have advocated increased monitoring in patients starting regular paracetamol. However, others consider that an increase in monitoring is unnecessary, or that increased monitoring during paracetamol use is not necessary unless the underlying illness (e.g. fever) requires increased monitoring. On the basis of the available data, it is not possible to firmly recommend increased monitoring, or dismiss its advisability. Further study is clearly needed.

Paracetamol is still considered to be safer than aspirin (see 'Coumarins and related drugs + Aspirin or other Salicylates', p.434) or NSAIDs (see 'Coumarins and related drugs + NSAIDs', p.480) as an analgesic in the presence of an anticoagulant because it does not affect platelets or cause gastric bleeding.

Coumarins + Pentoxifylline

Some studies have found that pentoxifylline does not alter the anticoagulant effects of phenprocoumon or acenocoumarol; however, one study suggests that there might be an increased risk of serious bleeding if pentoxifylline is given with acenocoumarol. Pentoxifylline alone has rarely been associated with bleeding.

Clinical evidence

The anticoagulant effects of **phenprocoumon** were not altered by pentoxifylline 400 mg four times daily for 27 days in 10 patients stabilised on **phenprocoumon**. Two patients had a slight increase in platelet aggregation.[1]

In a randomised study in patients with recurrent venous thrombosis, there was no difference in the dose of **acenocoumarol** necessary to reach an INR of 2.5 to 3.5 between 100 patients taking **acenocoumarol** with pentoxifylline 1.2 g daily and 100 patients taking **acenocoumarol** alone. No patients had severe bleeding, and 3% to 4% of patients in both groups had moderate bleeding (haematomas, haematuria).[2] However, in another placebo-controlled study of either pentoxifylline 400 mg three times daily, **acenocoumarol** (adjusted to maintain an INR of 2 to 4.5), or both drugs together, three major haemorrhagic problems (2 fatal cerebral, one gastrointestinal) occurred in the 36 patients taking both drugs. In the 36 patients taking **acenocoumarol** alone, one case of cerebral haemorrhage (resulting in hemiplegia) and another of haematuria with epistaxis occurred. This difference was not statistically significant, but the authors considered that the risk of bleeding was probably increased by the combination.[3] In this study, 69% of patients had an INR within desired range, and 7% had an INR above 4.5.

Mechanism

Pentoxifylline alone has rarely been associated with bleeding,[4] which could potentially be more severe in patients taking anticoagulants. Nevertheless, the manufacturers say that a causal relationship between pentoxifylline and bleeding has not been established.[5,6]

Table 12.4 Summary of the evidence for and against an interaction between paracetamol (acetaminophen) and coumarins or indanediones

Study type (year)	*Group*	*Coumarin*	*Paracetamol*	*Outcome*	*Refs*
Studies showing no interaction					
Randomised, crossover (1999)	20 healthy subjects	Warfarin, single-dose	1 g four times daily for one day, and 22 days	No change in warfarin pharmacokinetics or anticoagulant effect with either 1 day or 22 days	1
Clinical (1970)	10 patients	Stable warfarin	3.25 g daily for 2 weeks	No change in average prothrombin time	2
Randomised, placebo-controlled (1969)	20 patients	Phenprocoumon (19 patients) Warfarin (1 patient)	Two doses of 650 mg four hours apart	No change in average prothrombin time over 3 days	3
Randomised, placebo-controlled (2003)	31 patients	Phenprocoumon	Placebo (10 patients), 500 mg three times daily (11 patients), or 1 g three times daily (10 patients) for 2 weeks	Mean rise in INR of 0.46 at day 8 for both doses, which was not considered clinically relevant	4
Cohort (2002)	54 patients taking paracetamol and 180 others not taking paracetamol	Phenprocoumon	2 to 2.5 g per day for 3 days preceding INR determination	No change in anticoagulant effect	5
Cohort (recently started) (2002)	54 patients and 20 controls not given paracetamol	Acenocoumarol or phenprocoumon	Mean of 2.1 g daily	No difference in changes in INR between groups	6
Studies showing an interaction					
Randomised, placebo-controlled, crossover (1968)	50 patients	Stable warfarin, dicoumarol, anisindione,* phenprocoumon	650 mg four times daily for 2 weeks	Average increase in prothrombin time of 3.6 seconds	7
Randomised, placebo-controlled (1982, 1983)	20 patients	Stable acenocoumarol (8 patients) or phenprocoumon (12 patients)	500 mg four times daily for 3 weeks (10 patients); placebo (10 patients)	Average increase in thrombotest value of about 20 seconds (14% increase), which necessitated a reduction in coumarin dose in 5 patients	8, 9
Randomised, placebo-controlled, crossover (1984)	15 healthy subjects	Stable warfarin	4 g daily for 2 weeks	7 of 15 subjects had a prothrombin ratio rise of more than 20% while taking paracetamol compared with 1 of 15 taking placebo	10
Randomised, placebo-controlled, crossover (2005, 2006)	19 patients	Stable warfarin	4 g daily for 2 weeks	INR increased by a mean of 1.20 to a mean maximum of 3.45 in patients taking paracetamol, but did not change with placebo	11, 12
Case-control (1998)	93 cases with INR greater than 6 and 196 controls (INR 1.7 to 3.3)	Warfarin	325 mg each week to greater than 1.3 g daily	52 cases (56%) and 70 controls (36%) reported using paracetamol in the preceding week.† The increased risk (3.5 to 10-fold) was related to paracetamol dose	13
Cohort (2001)	4204 patients	Warfarin and/or Phenprocoumon		Standardised incidence ratio of hospitalisation for upper GI bleeding was higher with combined use of paracetamol (4.4) than oral anticoagulants alone (2.8)	14
Cohort (2007)	171 patients	Warfarin		Statistically significant increased risk of self-reported bleeding events (142 bleeds in 697 weeks, none of which were serious, for an odds ratio of 1.41)	15
Case reports of an interaction: paracetamol					
Case report (1999)	72-year-old	Acenocoumarol	1 to 2 g daily long-term	13 days after stopping paracetamol, the INR decreased from a range of 2.5 to 3 down to 1.62. INR gradually increased on restarting paracetamol	16
Case report (2004)	77-year-old	Acenocoumarol	2 to 2.5 g daily for a few weeks	INR 5.4 then 9.1 one week later. Patient restabilised on same acenocoumarol dose and asked not to take more paracetamol than 2 g daily for more than 3 days	17

Continued

Table 12.4 Summary of the evidence for and against an interaction between paracetamol (acetaminophen) and coumarins or indanediones (continued)

Study type (year)	*Group*	*Coumarin*	*Paracetamol*	*Outcome*	*Refs*
Case report (2005)	72-year-old	Fluindione	4 g daily for 10 days for knee pain	INR of 8 with skin haematomas and gingival bleeding. Two weeks previously the INR had been 2.3	18
Case report (2006)	46-year-old	Fluindione	2 to 3 g daily for 10 days for phlebitis-related pain	INR of 4.46 decreased to 2.68 within 1 day of stopping paracetamol	19
Case report (2002)	62-year-old	Warfarin	4 to 5 g (duration not stated)	INR of 7.5, with retroperitoneal haematoma. One month previously the INR had been 2.5	20
Case report (2003)	74-year-old	Warfarin	a. 1 g twice daily for 3 days b. 1 g four times daily for 3 days	a. INR of 3.4 then 4 b. INR increased from 2.3 to 6.4	21
Case report (2004)	76-year-old	Warfarin	Patient recently taking more paracetamol for a flare of arthritis	INR increase from 2.1 to 7, with haematuria and gingival bleeding	22
Paracetamol in combination with opioids‡					
Case report (1991)	66-year-old	Warfarin	Paracetamol/codeine; about 1.6 g daily of paracetamol over 10 days	Increase in prothrombin time from range of 15 to 19 up to 96 seconds. Haematuria and gingival bleeding	23
Case report (1997)	63-year-old	Warfarin	a. Paracetamol/dihydrocodeine 500 mg/10 mg, four daily for 7 days b. Paracetamol/codeine 500 mg/30 mg, three daily for 8 days	a. Increase in INR to 9.6 then 12, with gingival bleeding b. Increase in INR to 8.5	24

*Note that this is an indanedione
†Including 11 cases and 6 controls who reported taking a preparation of paracetamol in combination with an opioid, mostly codeine and oxycodone
‡There are also cases reported with dextropropoxyphene/paracetamol.

Importance and management

Information is limited, and an interaction is not established. In the US, the manufacturer recommends that patients taking **warfarin** should have more frequent monitoring of coagulation parameters when given pentoxifylline,[6] and this might be a prudent precaution with this and any other coumarin.

Coumarins + Phosphodiesterase type-5 inhibitors

In pharmacological studies, sildenafil did not interact with warfarin or acenocoumarol. However, in pulmonary hypertension, there is some evidence of an increased risk of bleeding with concurrent use, and nosebleeds were a common adverse effect of sildenafil alone. Two possible cases of raised INRs have been reported in patients taking acenocoumarol or warfarin and sildenafil. Studies suggest that tadalafil and vardenafil do not interact with warfarin.

Clinical evidence

(a) Sildenafil

The manufacturer of sildenafil notes that no significant interaction occurred when sildenafil 50 mg was given with **warfarin** 40 mg,[1-4] or when sildenafil 100 mg was given with **acenocoumarol**.[3] However, in studies in pulmonary hypertension, nosebleeds were a common adverse effect (9%), and the concurrent use of vitamin K antagonists and sildenafil resulted in a greater incidence of reports of bleeding (primarily nosebleeds; 9% compared with 2%) than placebo.[4]

A 68-year-old man taking **acenocoumarol** and enalapril had an increase in his INR from 3.05 to 7.7 without bleeding complications after taking sildenafil. The patient continued to take sildenafil once a week, and the daily dose of **acenocoumarol** was split into two, with a return to stable therapeutic INR values. Another patient taking **warfarin**, ranitidine and pravastatin had a rise in INR on three occasions after taking sildenafil once a week, omitting the dose of ranitidine when he took the sildenafil. On one of these occasions, he had bleeding gums. This rise in INR no longer occurred when he started taking the ranitidine with the sildenafil.[5]

(b) Tadalafil

A double-blind, randomised, crossover study in which a single dose of **warfarin** was given on day 7 of 12 consecutive days of treatment with either tadalafil 10 mg or placebo found that tadalafil did not affect the AUCs of either *S*-warfarin and *R*-warfarin, and prothrombin times were unchanged.[6]

(c) Vardenafil

The manufacturers note that no pharmacokinetic interaction was observed when vardenafil was given with **warfarin**,[7,8] and the prothrombin time was unchanged.[8]

Mechanism

An interaction as a result of altered coumarin metabolism is unlikely with any of these phosphodiesterase type-5 inhibitors. The two cases of interactions with sildenafil are unexplained. It is not obvious why dividing the acenocoumarol dose, or using ranitidine, would have reversed an interaction.

Sildenafil alone appears to commonly cause nosebleeds in patients with pulmonary hypertension. The reason for this is unknown, but studies with human platelets indicate that sildenafil potentiates the antiaggregatory effect of sodium nitroprusside *in vitro*.[1-4]

Importance and management

There is no established pharmacokinetic or pharmacodynamic interaction between the phosphodiesterase type-5 inhibitors and warfarin, and no warfarin dose adjustment would therefore be expected to be needed on concurrent use. However, in pulmonary hypertension, sildenafil appears to increase the risk of nosebleeds, and this may be greater in patients taking coumarins. Similarly, the two possible cases with acenocoumarol and warfarin, although not conclusive, do introduce a note of caution.

Coumarins + Picotamide

Picotamide did not alter the anticoagulant effects of warfarin. Nevertheless, as with other antiplatelet drugs, concurrent use might increase the bleeding risk.

Clinical evidence, mechanism, importance and management

Picotamide 300 mg three times daily for 10 days did not alter the anticoagulant effects of established **warfarin** therapy in 10 patients with aortic or mitral valve prostheses.[1] No **warfarin** dose adjustments would therefore be expected to be needed on concurrent use. Nevertheless, as with other antiplatelet drugs, such as aspirin (see 'Coumarins and related drugs + Aspirin or other Salicylates', p.434), the concurrent use of oral anticoagulants might increase the risk or intensity of bleeding. Some caution is therefore appropriate on concurrent use.

Coumarins + Piracetam

Piracetam does not appear to affect the dose of acenocoumarol required to produce a given INR. A single case report describes a woman stabilised on warfarin who began to bleed within one month of starting to take piracetam.

Clinical evidence, mechanism, importance and management

In a randomised study in patients with severe or recurrent venous thrombosis, there was no difference in the dose of **acenocoumarol** necessary to reach an INR of 2.5 to 3.5 between 100 patients taking **acenocoumarol** with high-dose piracetam 9.6 g daily and 100 patients taking **acenocoumarol** alone. No patients had severe bleeding, and 3 to 4% of patients in both groups had moderate bleeding (haematomas, haematuria). The addition of piracetam decreased platelet aggregation, levels of fibrinogen, and blood viscosity.[1]

A woman taking **warfarin**, insulin, levothyroxine and digoxin complained of menorrhagia at a routine follow up. Investigations revealed that her British Corrected Ratio had risen to 4.1 (from a range of 2.3 to 2.8), and that one month previously she had started to take low-dose piracetam 200 mg three times daily. Within 2 days of withdrawing both the **warfarin** and piracetam her British Corrected Ratio had fallen to 2.07, and the original dose of warfarin was restarted.[2]

Piracetam alone is known to decrease platelet aggregation,[1] and might therefore be expected to increase the risk of bleeding with anticoagulants, similar to other drugs with antiplatelet activity such as aspirin (see 'Coumarins and related drugs + Aspirin or other Salicylates', p.434). The early

case appears to be the only report of a possible interaction, but some caution might be prudent on concurrent use.

2. Pan HYM, Ng RP. The effect of Nootropil in a patient on warfarin. *Eur J Clin Pharmacol* (1983) 24, 711.

Coumarins + Pirmenol

The anticoagulant effects of warfarin are not altered by pirmenol.

Clinical evidence, mechanism, importance and management

The prothrombin time response to a single 25-mg dose of **warfarin** was slightly reduced (reductions ranged from 0.2 to 1.3 seconds) in most of the 12 healthy subjects who had taken pirmenol 150 mg twice daily for 14 days, with warfarin taken on day 8.[1] This suggested that some changes in the dose of **warfarin** might be required in practice, but a later placebo-controlled study found that the prothrombin times of 10 patients stabilised on **warfarin** were not significantly changed when they were given oral pirmenol 150 mg twice daily for 14 days.[2] No **warfarin** dose adjustments would therefore be expected to be required on concurrent use.

Coumarins + Probenecid

In healthy subjects, probenecid increased the clearance of single-dose phenprocoumon without altering its anticoagulant effect. The anticoagulant effects of multiple-dose phenprocoumon might be expected to be decreased by probenecid, but this requires confirmation.

Clinical evidence, mechanism, importance and management

In 9 healthy subjects probenecid 500 mg four times daily for 7 days reduced the AUC of a single 0.22-mg/kg dose of **phenprocoumon** given on day one by 47% and reduced the elimination half-life by about one-third. Nevertheless, the reduction in prothrombin time by **phenprocoumon** was not altered by probenecid.[1]

The reasons for this interaction are not understood, but one possibility is that, while probenecid inhibits the glucuronidation of **phenprocoumon** (its normal route of metabolism), it may also increase the formation of hydroxylated metabolites so that its overall loss is increased.[1]

Although the anticoagulant effect of single-dose **phenprocoumon** was not altered in this study, its findings suggests that, in the presence of probenecid, the dose of phenprocoumon might need to be increased, but this awaits formal clinical confirmation in a multiple-dose study. Nevertheless, bear the possibility in mind. Nothing further seems to have been published on this potential interaction and there seems to be nothing documented about other coumarins.

Coumarins + Proguanil

An isolated report describes bleeding in a patient stabilised on warfarin after she took proguanil for about five weeks.

Clinical evidence, mechanism, importance and management

A woman stabilised on **warfarin** developed haematuria, bruising and abdominal and flank discomfort about 5 weeks after starting to take proguanil 200 mg daily. Her prothrombin ratio was found to be 8.6. Within 12 hours of being given fresh frozen plasma and vitamin K her prothrombin ratio had fallen to 2.3. During the 5 weeks she had travelled from Britain to Thailand, Bali, Australia and then New Zealand, and her prothrombin ratio had not been checked during this time. The mechanism of this potential interaction is unknown.[1] Its general importance is uncertain, as factors related to travel (such as a changing diet and changing dose times in different time zones) may have had a part to play in this interaction.

Coumarins + Prolintane

The anticoagulant effects of ethyl biscoumacetate are not affected by prolintane.

Clinical evidence, mechanism, importance and management

The response to a single 20-mg/kg dose of **ethyl biscoumacetate** was studied in 4 healthy subjects given prolintane 20 mg daily for 4 days. Assessments were made before prolintane, on day one of prolintane, and 8 days after prolintane was stopped. The mean half-life of the anticoagulant and prothrombin times remained unchanged.[1] No **ethyl biscoumacetate** dose adjustments would appear to be required on concurrent use.

Coumarins and related drugs + Propafenone

The anticoagulant effects of warfarin, and possibly fluindione and phenprocoumon, are increased by propafenone.

Clinical evidence

The mean steady-state plasma levels of 8 healthy subjects taking **warfarin** 5 mg daily rose by 38% after they took propafenone 225 mg three times daily for a week. Five of the 8 had a distinct prothrombin time increase. The average rise in prothrombin time of the whole group was about 7 seconds, which was considered to be clinically significant.[1] Two case reports describe marked increases in the anticoagulant effects of **fluindione** and **phenprocoumon** in 2 patients taking propafenone.[2,3]

Mechanism

Propafenone may reduce the metabolism of these anticoagulants, thereby increasing their effects. From *in vitro* data, it was concluded that propafenone would affect only *R*-warfarin, whereas both *R*- and *S*-acenocoumarol were affected.[4]

Importance and management

Information seems to be limited to these reports but they suggest that anticoagulant control should be well monitored if propafenone is given to patients taking warfarin, and probably also phenprocoumon and the indanedione fluindione. The anticoagulant dose should be reduced where necessary. It would be prudent to apply the same precautions with any other coumarin or indanedione.

Coumarins and related drugs + Prostaglandins

The concurrent use of high-dose, intravenous epoprostenol and warfarin may increase the risk of pulmonary haemorrhage. Treprostinil does not appear to alter the pharmacokinetics or the anticoagulant effects of warfarin, and also did not appear to increase the risk of bleeding when used with warfarin in clinical studies. Beraprost did not alter the pharmacokinetics of fluindione. Inhaled iloprost did not appear to increase the incidence of

bleeding in clinical studies in patients using anticoagulants. Because these prostaglandins inhibit platelet aggregation, some caution is appropriate on the concurrent use of anticoagulants.

Clinical evidence

(a) Beraprost

In a controlled study in 12 healthy subjects, oral beraprost sodium 40 micrograms three times daily for 3 days did not alter the pharmacokinetics of a single 20-mg dose of **fluindione** given on day 3. This dose of fluindione had only a marginal effect on the INR, and this effect was not altered by beraprost.[1]

(b) Epoprostenol

In a small retrospective review of 31 patients with primary pulmonary hypertension receiving **warfarin** and continuous intravenous epoprostenol, 9 patients were identified who experienced 11 bleeding episodes (9 cases of pulmonary haemorrhage, 2 of nasal bleeding). Of the 9 cases of pulmonary haemorrhage, 8 were identified clinically by persistent haemoptysis, and 2 cases were associated with severe respiratory distress. Of the 7 patients with an INR available at the time of the first bleeding episode, 6 had an INR under 2 and one had an INR of 3.1. The dose of epoprostenol in patients with bleeds ranged from 28.1 to 164 nanograms/kg per minute, and no patient receiving less than 28 nanograms/kg per minute had a bleed. There was no significant difference in survival in patients with a bleeding episode and those without.[2] In contrast, the manufacturer states that, in clinical studies, there was no evidence of increased bleeding in patients taking anticoagulants and receiving infusions of epoprostenol.[3]

(c) Iloprost

The manufacturer of iloprost notes that there was no difference in the incidence of bleeding between patients receiving inhaled iloprost and those given placebo in clinical studies in which a high proportion of patients were taking anticoagulants (unnamed). However, they note that bleeding events (mostly haematomas) were common.[4]

(d) Treprostinil

In a crossover study in 15 healthy subjects, continuous subcutaneous treprostinil 5 then 10 nanograms/kg every minute for 9 days did not alter the pharmacodynamics (INR) of a single 25-mg oral dose of **warfarin** given on day 3. In addition, there was no change in the pharmacokinetics of *R*- and *S*-warfarin.[5] In the discussion of this study, the authors mention an unpublished retrospective review of data from placebo-controlled clinical studies in patients with pulmonary artery hypertension. From this there was no evidence to suggest that the concurrent use of **warfarin** and treprostinil (155 patients) was associated with increased bleeding or coagulation-related events, when compared with warfarin and placebo (156 patients).[5]

Mechanism

Epoprostenol (prostacyclin) and its analogues beraprost, iloprost and treprostinil are vasodilators that also inhibit platelet aggregation. As such, it is anticipated that they might increase the potential for bleeding when given with anticoagulants.

Importance and management

Anticoagulants such as warfarin are commonly used in patients with pulmonary artery hypertension, a condition for which the prostaglandins beraprost, epoprostenol, iloprost and treprostinil are indicated, so the combination is likely to be used frequently. Because these prostaglandins are potent inhibitors of platelet aggregation, they might increase the risk of bleeding with anticoagulants (including coumarins and **indanediones**), although the manufacturers say that there was no evidence of increased bleeding in clinical studies using epoprostenol,[3] iloprost[4] or treprostinil.[5] Nevertheless, limited evidence from the small survey in Japanese patients given epoprostenol suggests that this may be the case with high-dose epoprostenol. In this study, the authors commented that they no longer use anticoagulants in patients receiving high-dose epoprostenol.[2] However, the manufacturer states that in clinical studies of epoprostenol almost all patients with pulmonary hypertension were receiving oral anticoagulants, and, unless contraindicated, they recommend concurrent oral anticoagulation in those patients with either primary pulmonary hypertension or pulmonary hypertension secondary to scleroderma to reduce the risk of thromboembolism.[3] Some caution would be appropriate if any of these prostaglandins is given with a coumarin or **indanedione**.

Some prostaglandins, such as epoprostenol, may also be used for other indications, such as maintaining renal dialysis catheter patency or for treating peripheral ischaemia: similar caution should be used if these patients are taking anticoagulants.[6]

Coumarins + Protease inhibitors

In pharmacokinetic studies, ritonavir slightly raised *S*-warfarin levels and modestly decreased *R*-warfarin levels, while ritonavir-boosted lopinavir decreased *R*- and *S*-warfarin levels. A number of case reports of an interaction with protease inhibitors have been reported, most of which show a decrease in warfarin or acenocoumarol effects, although a couple show an increase in warfarin effects.

Clinical evidence

(a) Acenocoumarol

A 46-year-old HIV-positive man with mitraortic valve replacements stabilised on acenocoumarol (INR 2.5 to 3.5) for 5 years and taking zidovudine and didanosine for 17 months was found to have a dramatic decrease in his INR when his drug regimen was changed to stavudine, lamivudine and **ritonavir** 600 mg twice daily. Increasing the acenocoumarol dose over 5 days from an average of 24 mg to over 70 mg failed to increase the INR to target levels. The INR returned to previous levels within 4 days of stopping **ritonavir**, and the acenocoumarol dose could be reduced to 3 mg daily. The patient was subsequently given **nelfinavir** and a similar, though less dramatic interaction occurred: while taking **nelfinavir** an INR of 2.5 was achieved with a 210% increase in the acenocoumarol dose.[1]

(b) Warfarin

1. Indinavir. A 50-year-old HIV-positive man, stabilised on warfarin (prothrombin complex activity (PCA) range of 20 to 35%), started taking indinavir 800 mg every 8 hours, but it had to be withdrawn after 12 days because of a generalised skin rash. It was then found that the indinavir had caused a moderate reduction in his level of anticoagulation: 10 and 25 days after indinavir was stopped his PCA was 53% and 43%, respectively. The warfarin dose was increased to 6.25 and 7.5 mg on alternate days for one week, during which time a PCA of 34% was achieved, and he was then subsequently given warfarin 6.25 mg daily.[2] This patient subsequently needed an increase in warfarin dose when given *ritonavir*, see below. Another patient had a modest rise in INR to 4.5 when his dose of ritonavir was reduced from 600 mg twice daily to 200 mg twice daily and indinavir 800 mg twice daily added. This case suggests that any effect of high dose ritonavir was more marked than that of ritonavir-boosted indinavir.[3]

2. Lopinavir. In a pharmacokinetic study in healthy subjects,[4] ritonavir-boosted lopinavir 100/400 mg twice daily for 10 days modestly decreased the AUCs of *R*- and *S*-warfarin by 37% and 29%, respectively, after a single 10-mg dose of warfarin and vitamin K were given on day 7. The effect of this reduction on the anticoagulant activity of warfarin was not assessed, since vitamin K was given to inhibit the pharmacological effect of warfarin without affecting its pharmacokinetics.

However, there are a couple of case reports suggesting a marked reduction in warfarin effects with ritonavir-boosted lopinavir. In one case, a man taking warfarin required a progressive daily dose increase from between 3.75 to 5 mg up to 10 mg after restarting an antiretroviral regimen including lopinavir with ritonavir. When the protease inhibitors were later stopped, the warfarin dose needed to be reduced again.[5] Another case has

been described where a man was eventually stabilised on warfarin 13 mg daily while taking ritonavir-boosted lopinavir, which was over twice his original dose of 5.5 mg daily.[6] Yet another describes a man who required a 40% warfarin dose increase from 12.5 to 17.5 mg daily when switched from nelfinavir to ritonavir-boosted lopinavir.[7]

3. Nelfinavir. A man taking abacavir, tenofovir and nelfinavir needed an increase in his warfarin dose from 45 mg weekly to 70 mg weekly to achieve a therapeutic INR.[7] Of the other drugs he was taking, ribavirin has been reported to increase warfarin requirements (see 'Coumarins + Ribavirin', p.502). Another patient required a high warfarin dose of 12.5 mg daily while taking a nelfinavir-containing regimen,[7] but this was less than that required while he was taking ritonavir-boosted lopinavir (17.5 mg daily) or nevirapine (20 mg daily). Consider also 'Coumarins + NNRTIs', p.480.

4. Ritonavir. The manufacturer reports that, in 12 healthy subjects given ritonavir 400 mg every 12 hours for 12 days, there was a 9% increase (not statistically significant) in the AUC of *S*-warfarin while the AUC of *R*-warfarin was decreased by 33%, after a single 5-mg dose of warfarin.[8] The effect of these changes on prothrombin time was not mentioned, but potentially could result in an increased warfarin effect due to the more potent *S*-warfarin, or a decreased effect due to the *R*-warfarin. Both of these outcomes have been reported in individual cases. An increase in warfarin effect was seen in a man taking warfarin 10 mg daily (INRs 2.4 to 3) when his treatment for HIV was changed from efavirenz and abacavir to ritonavir, nelfinavir and *Combivir* (zidovudine with lamivudine). Within 5 days his INR had risen to 10.4, without any sign of bleeding. It proved difficult to achieve acceptable and steady INRs both while in hospital and after discharge, but eventually it was discovered that the patient could not tolerate liquid ritonavir because of nausea and vomiting, so that he had sometimes skipped or lowered the ritonavir dose or even refused to take it. On the occasions where no ritonavir or low-dose ritonavir was taken, the INRs had been low, whereas when he took the full dose of ritonavir the INRs were high.[9]

In contrast, the INR of a 27-year-old HIV-positive woman taking warfarin fell when she was given ritonavir, clarithromycin and zidovudine. It was necessary almost to double the warfarin dose to maintain satisfactory INRs. Three months later when the ritonavir was withdrawn, her INR more than tripled within a week. Her final warfarin maintenance dose was half of that needed before the ritonavir was started, and a quarter of the dose needed just before she stopped the ritonavir. This case was complicated by the use or withdrawal of a number of other drugs (co-trimoxazole, rifabutin, an oral hormonal contraceptive, megestrol), which can also interact with warfarin.[10] Similarly, in another patient taking warfarin 6.25 mg daily with a prothrombin activity complex (PCA) of about 34%, a decrease in warfarin effects (PCA increase to 62%) was noted 20 days after starting ritonavir (escalating doses up to 600 mg every 12 hours). The warfarin dose was then increased to 8.75 mg daily and 24 days later a satisfactory PCA of 33% was achieved.[2] This patient had previously had a decrease in warfarin effects while taking *indinavir*, see above. A patient stabilised on warfarin was found to have a subtherapeutic INR of 1 and required a 62% increase in warfarin dose when his protease inhibitor was switched from saquinavir to ritonavir 600 mg twice daily. Another patient taking ritonavir and saquinavir needed a very high warfarin dose to achieve a therapeutic INR.[3]

5. Saquinavir. A 73-year-old man who was HIV-positive and who had been taking warfarin, co-trimoxazole, nizatidine, stavudine and lamivudine for 7 months started taking saquinavir 600 mg three times daily. His INR, which had been stable at around 2 for five months, rose to about 2.5 after 4 weeks, and to about 4.2 after 8 weeks, which the author of the report attributed to an interaction with the saquinavir. The situation was solved by reducing the warfarin dose by 20%.[11]

Mechanism

Protease inhibitors are well known to alter the metabolism of many drugs by inhibition, but sometimes by induction of cytochrome P450 isoenzymes, see 'Table 21.2', (p.914), so it is not surprising that they have altered warfarin effects, although the precise mechanism is unclear. The findings of the two pharmacokinetic studies suggest that, with warfarin, induction predominates, and that the anticoagulant effects are likely to be decreased. However, the modest reductions in levels seen do not explain the sometimes marked reduction in anticoagulant effects.

Importance and management

Pharmacokinetic studies have suggested that ritonavir and ritonavir-boosted lopinavir can modestly reduce warfarin levels. Clinical information on an interaction between coumarins and protease inhibitors is limited to the case reports cited, most of which show a, sometimes very marked, decrease in warfarin or acenocoumarol effects (with indinavir, ritonavir-boosted lopinavir, nelfinavir, ritonavir or ritonavir-boosted saquinavir), although a couple show an increase in warfarin effects (nelfinavir with ritonavir, or saquinavir). These cases show it would be prudent to monitor the prothrombin times and INRs of any patient if any HIV-protease inhibitor is added, being alert for the need to modify the coumarin dose.

Coumarins + Proton pump inhibitors

Omeprazole causes a minor increase in *R*-warfarin levels, no effect on *S*-warfarin, with, at most, a minor increase in anticoagulant effect. Conversely, lansoprazole, pantoprazole and rabeprazole do not alter warfarin pharmacokinetics or its anticoagulant effect. Omeprazole does not appear to alter the effects of acenocoumarol, and pantoprazole does not appear to alter the effects of phenprocoumon. Nevertheless, a few isolated reports describe increased anticoagulant effects when proton pump inhibitors were given with coumarins.

Clinical evidence

(a) Esomeprazole

Esomeprazole is the *S*-isomer of omeprazole, and would be expected to behave similarly to omeprazole, see *Omeprazole*, below. The manufacturers say that esomeprazole 40 mg daily did not cause any clinically relevant effects on anticoagulant times in patients stabilised on **warfarin**, but a few isolated cases of raised INRs have been reported post-marketing.[1,2]

(b) Lansoprazole

A study in 24 healthy subjects stabilised on **warfarin** found that lansoprazole 60 mg daily for 9 days had no effect on the pharmacokinetics of either *S*- or *R*-warfarin, and did not alter the effect of **warfarin** on prothrombin times.[3] However, in 1998 the manufacturers of lansoprazole had on record two reports of possible interactions. An elderly patient taking **warfarin** developed an INR of 7 when lansoprazole was added. Despite a **warfarin** dose adjustment he had a gastrointestinal haemorrhage, a myocardial infarction and died after 3 weeks. Another man taking **warfarin** (as well as amiodarone, furosemide and lisinopril) became confused, had hallucinations and developed an increased INR (value not known) when given lansoprazole. The lansoprazole was stopped after 4 days, and he then recovered. However, it is uncertain whether this was an interaction or whether he had taken an incorrect **warfarin** dose because of his confusion.[4]

(c) Omeprazole

1. Acenocoumarol. In a placebo-controlled study in 8 healthy subjects, omeprazole 40 mg daily for 3 days had no effect on the pharmacokinetics of *R*- or *S*-acenocoumarol when a single 10-mg dose of acenocoumarol was given on day 2. In addition, omeprazole did not alter the anticoagulant effects of acenocoumarol.[5] Similarly, there was no evidence of an interac-

tion in a retrospective study of 118 patients given acenocoumarol with omeprazole and 299 patients taking acenocoumarol without omeprazole (matched for age and sex).[6] Furthermore, in a retrospective cohort study of patients taking acenocoumarol, omeprazole was not associated with an increased risk of hospitalisation for bleeding.[7] However, an isolated case report describes a 78-year-old woman who had been taking acenocoumarol for 60 days and who developed gross haematuria within 5 days of starting omeprazole 20 mg daily. Her INR had risen from a range of 2.5 to 3 up to 5.7, and when the omeprazole was stopped, her INR fell.[8]

2. Warfarin. In 21 healthy subjects who had been stabilised on warfarin, omeprazole 20 mg daily for 2 weeks caused a small but statistically significant decrease in the mean thrombotest percentage, from 21.1% to 18.7%. *S*-warfarin serum levels remained unchanged, but a small 12% rise in *R*-warfarin levels was seen.[9] In a further study, no changes in coagulation times or thrombotest values occurred in 28 patients anticoagulated with warfarin and given omeprazole 20 mg daily for 3 weeks. *S*-warfarin levels were unchanged, while a 9.5% increase in *R*-warfarin levels occurred.[10] A study in 7 patients who were CYP2C19 poor metabolisers and 10 patients who were CYP2C19 extensive metabolisers (that is, those lacking or deficient in this isoenzyme and those with normal levels of this isoenzyme, respectively) specifically looked at the effect of different CYP2C19 genotypes on the metabolism of warfarin, and also the influence of omeprazole on this interaction. The AUC of *R*-warfarin (from a single 10-mg dose of racemic warfarin) was found to be 24% higher in poor metabolisers than in extensive metabolisers. Omeprazole 20 mg daily taken for 11 days increased the AUC of *R*-warfarin (taken on day 7) in the extensive metabolisers to a level comparable with that in the poor metabolisers. Omeprazole had no effect on *S*-warfarin, and no effect on anticoagulant activity in any subject.[11] However, a man stabilised on warfarin 5 mg daily developed widespread bruising and haematuria 2 weeks after starting to take omeprazole 20 mg daily. His prothrombin time was found to have risen to 48 seconds. He was later restabilised on omeprazole 20 mg daily with the warfarin dose reduced to 2 mg daily.[12]

3. Phenprocoumon. In a retrospective cohort study of patients taking phenprocoumon, omeprazole was not associated with an increased risk of hospitalisation for bleeding.[7]

(d) Pantoprazole

1. Phenprocoumon. The prothrombin time ratio in 16 healthy subjects taking individualised maintenance phenprocoumon doses was not changed when they were given pantoprazole 40 mg daily for 5 days, nor was there any change in the pharmacokinetics of *R*- and *S*-phenprocoumon.[13] However, there is a report of 2 possible cases of an interaction.[14] One patient who was given phenprocoumon (loading dose 12 mg on day one, 9 mg on day 2, 3 mg on day 3, and further as required) and omeprazole 20 mg daily concurrently, had an INR of 3.28 by the fourth day. The phenprocoumon was withheld, but the INR remained high for 9 days, when the omeprazole was stopped. Four days later the INR was 1.5 and phenprocoumon was restarted at 16.5 mg/week, and stabilised at 9 to 10.5 mg/week. She subsequently had a similar loading dose without problems, in the absence of omeprazole, after phenprocoumon had been stopped for 3 weeks before surgery.[14] Another patient stabilised on phenprocoumon 18 mg/week required a slight reduction in dose to 16.5 mg/week after starting omeprazole 20 mg daily.[14]

2. Warfarin. In 26 healthy subjects, pantoprazole 40 mg daily for 8 days caused no change in the response to a single 25-mg dose of warfarin given on day 2. The pharmacokinetics of *R*- and *S*-warfarin were unaltered, and no changes in the pharmacodynamics of the warfarin (prothrombin time, factor VII) were seen.[15] However, the manufacturer notes that there have been reports of increased INR and prothrombin time in patients taking pantoprazole and warfarin.[16]

(e) Rabeprazole

In a placebo-controlled study, a single 0.75-mg/kg dose of **warfarin** was given to 21 patients before and after rabeprazole 20 mg daily for 7 days. No significant changes in prothrombin times or in the pharmacokinetics of *R*- or *S*-warfarin were seen.[17] However, the manufacturer notes that there have been reports of increased INR and prothrombin time in patients receiving rabeprazole and **warfarin**.[18]

Mechanism

Studies have shown that omeprazole partially inhibits the metabolism of *R*-warfarin, but not *S*-warfarin,[19,20] which in line with the findings in the pharmacokinetic studies above. It also partially inhibits the metabolism of acenocoumarol.[19] However, these small changes would generally not be expected to be clinically relevant. It has been suggested that the interaction might occur only in patients who are poor metabolisers of the cytochrome P450 isoenzyme CYP2C19 (seen in about 5% of Caucasians), who have five to tenfold higher levels of omeprazole than extensive metabolisers.[5] Conversely, in the one study addressing this the effect of CYP2C19 genotype was not clinically relevant.[11] Other proton pump inhibitors are generally considered to have less potential for pharmacokinetic interactions than omeprazole, but even with these, isolated cases of anticoagulant interactions have been reported.

Importance and management

The very minor pharmacokinetic interaction between omeprazole and warfarin, resulting in a less than 15% rise in *R*-warfarin levels (the less active isomer), is established, but probably of limited clinical relevance. This is borne out by the fact there is only one published case report of an interaction. No pharmacokinetic or pharmacodynamic interaction occurred between warfarin and lansoprazole, pantoprazole or rabeprazole in clinical studies. However, isolated cases of raised INRs have been reported for all the proton pump inhibitors (esomeprazole, lansoprazole, pantoprazole, omeprazole and rabeprazole) with acenocoumarol (one published), phenprocoumon (2 published), and warfarin. It is possible that the isolated cases of interactions with proton pump inhibitors just represent idiosyncratic effects attributable to other factors, and not to any interaction. Nevertheless, when prescribing proton pump inhibitors to patients taking coumarins it would seem prudent to bear in mind that rarely bleeding can occur. Note that the US prescribing information for every proton pump inhibitors states that patients taking a proton pump inhibitor and warfarin may need to be monitored for increases in INR and prothrombin time. The advice in UK varies from recommending monitoring with warfarin and omeprazole[21] or esomeprazole,[1] recommending monitoring with coumarins and pantoprazole,[22] to no advice with lansoprazole[23] or rabeprazole.[24]

Coumarins + Quetiapine

A case report describes a woman taking warfarin who developed a raised INR when quetiapine was started.

Clinical evidence, mechanism, importance and management

A 71-year old woman receiving long-term treatment with **warfarin**, phenytoin, olanzapine and benztropine had her **warfarin** dose slightly reduced (from 20 to 19.5 mg weekly) because her INR was raised (from 1. to 2.6). Eight days later her treatment with olanzapine was changed to quetiapine 200 mg daily, and after 5 days her INR was 2.7. Two weeks later she was found to have an INR of 9.2. The quetiapine was stopped and she was given two doses of vitamin K by injection. The only clinical symptoms seen were a small amount of bleeding from the injection site and a bruise on her hand. She was eventually later restabilised taking phenytoin, olanzapine and **warfarin** 21 mg weekly with an INR of 1.6.

The reasons for this apparent interaction are not known, but the authors suggest that the quetiapine may have inhibited the metabolism of the **warfarin** (possibly by competitive inhibition of the cytochrome P450 isoenzymes CYP3A4 and CYP2C9), thereby increasing its effects. They also suggest that the phenytoin may have had some part to play.[1] This is only an isolated case and as such an interaction is not confirmed, but bear it in mind in the case of an unexpected response to concurrent use.

Coumarins + Quilinggao

A single case report describes a man who had a marked increase in his INR with bleeding complications, nine days after he switched the brand of quilinggao he was using.

Clinical evidence

A 61-year-old man stabilised on **warfarin** with an INR in the range of 1.6 to 2.8 was found to have an INR greater than 6 and skin bruising, and complained of gum bleeding and epistaxis in the previous 3 days. For the past 3 years he had taken quilinggao, apparently without problems. However, 9 days previously he had started taking a different brand of quilinggao. He was eventually stabilised on the previous dose of **warfarin** with an INR of 2.5, but after discharge started taking a third brand of quilinggao, and 3 days later had an INR of 5.2.[1]

Mechanism

Quilinggao is a Chinese herbal product made from a mixture of herbs. The first brand did not contain any herbs suspected to have anticoagulant effects except one with possible antiplatelet activity, but the second brand contained Chinese peony (*Paeoniae rubra*), *Poncirus trifoliata* and a couple of other herbs known to contain substances with anticoagulant or antiplatelet effects *in vitro*, but see also 'Coumarins + Herbal medicines; Miscellaneous', p.472.

Importance and management

This appears to be the only case of a possible interaction, and as such the interaction is not established. Quilinggao did not affect anticoagulant control in this patient for a number of years, and then did after switching brands. Bear the possibility of an interaction in mind.

1. Wong ALN, Chan TYK. Interaction between warfarin and the herbal product *quilinggao*. *Ann Pharmacother* (2003) 37, 836–8.

Coumarins + Quinidine

Quinidine does not appear to alter the anticoagulant effect of warfarin; however, isolated reports of increased warfarin effects and bleeding, and also decreased dicoumarol and warfarin effects have been reported. Quinidine does not alter the half-life of phenprocoumon.

Clinical evidence

In a controlled study, 10 patients receiving long-term treatment with **warfarin** 2.5 to 12.5 mg daily had no significant alteration in their prothrombin times when they were given quinidine 200 mg four times daily for 2 weeks.[1,2] Similarly, in a retrospective analysis of 8 patients stabilised on **warfarin**, there was no change in anticoagulant control associated with starting or stopping quinidine (600 mg to 1.2 g daily as sulfate or 660 mg daily as gluconate).[3] In the preliminary report of another study in 5 healthy subjects, quinidine 100 mg daily, started 7 days after a single 12-mg dose of **phenprocoumon**, did not change the elimination half-life of **phenprocoumon**.[4]

In contrast, another report described 3 patients stabilised on **warfarin**, with Quick values within the range of 15 to 25%, who began to bleed within 7 to 10 days of starting to take quinidine 800 mg to 1.2 g daily. Their Quick values were found to have fallen to 6 to 8%. Bleeding ceased when the warfarin was withdrawn.[5] There is one other case report of haemorrhage associated with the concurrent use of **warfarin** and quinidine,[6] and in an analysis of haemorrhage in patients taking anticoagulants, it was reported that quinidine seemed partly responsible for some cases.[7]

In a further report, 4 patients taking **warfarin** or **dicoumarol** needed dose *increases* of 8 to 24% to maintain adequate anticoagulation after DC conversion for atrial fibrillation and starting quinidine 400 mg three times daily.[8]

Mechanism

Uncertain. The cases of increased warfarin effects were attributed to quinidine possibly having a direct hypoprothrombinaemic effect of its own.[5] The cases of a slight decrease in anticoagulant effect were attributed to changes in haemodynamic factors as a result of cardioversion.[8]

Importance and management

In one study and one retrospective analysis, quinidine had no effect on the anticoagulant control with warfarin in patients. Therefore, no interaction would normally be anticipated. However, a few isolated cases of increased anticoagulant effect with bleeding have been reported. Nevertheless, the literature is limited, and based almost solely on evidence from more than 40 years ago. The lack of reports of any further interactions in this time suggests that a clinically relevant interaction is unlikely. Limited evidence suggests that quinidine does not alter phenprocoumon pharmacokinetics.

Coumarins + Quinine

Isolated reports describe increased anticoagulant effects in two women taking warfarin and a man taking phenprocoumon, which were attributed to the quinine content of tonic water. Limited evidence suggests that quinine does not alter the half-life of phenprocoumon.

Clinical evidence

In the preliminary report of a study in 5 healthy subjects, quinine 100 mg daily started 7 days after a single 12-mg dose of **phenprocoumon** did not change the elimination half-life of **phenprocoumon** in the following 7 days.[1]

However, a patient taking long-term **phenprocoumon** repeatedly developed extensive haematuria within 24 hours of drinking one litre of Indian tonic water containing 30 mg of quinine.[1]

A woman stabilised on **warfarin** needed a dose reduction from 6 mg to 4 mg daily when she started to drink up to 1.5 litres of tonic water containing quinine each day. Her **warfarin** requirements rose again when the ton-

ic water was stopped. Another woman needed a **warfarin** dose reduction from 4 mg to 2 mg daily when she started to drink over 2 litres of tonic water daily. These patients were probably taking about 80 to 180 mg of quinine daily.[2]

Mechanism

Not understood. Two studies[3,4] using the Page method (Russell viper venom)[5] to measure prothrombin times showed that marked increases of up to 12 seconds could occur when 330-mg doses of quinine were given in the absence of an anticoagulant, but other studies[4,6] using the Quick method found that the prothrombin times were only prolonged by up to 2.1 seconds. The changes in prothrombin times could be completely reversed by vitamin K (menadiol sodium diphosphate),[3,4] which suggests that quinine, like the **indanediones** and coumarins, is a competitive inhibitor of vitamin K.

Importance and management

The interaction between quinine and the coumarins is not established. The lack of reports relating to the therapeutic use of quinine suggest that no interaction of clinical importance occurs, and because the only reports relate to tonic water, it cannot be excluded that some other ingredient is responsible for the effect seen in these patients. Also, they may just represent idiosyncratic reactions. Nevertheless, because some isolated cases appear to suggest that very exceptionally decreased anticoagulant requirements and even bleeding can occur when large quantities of tonic water are ingested the possibility of a rare interaction cannot entirely be dismissed.

Coumarins + Raloxifene

Raloxifene may cause a minor increase in warfarin levels. However, a 10% decrease in prothrombin time may also occur. Other coumarins would be expected to be similarly affected.

Clinical evidence, mechanism, importance and management

In a study in 15 healthy postmenopausal women, raloxifene 120 mg daily for 15 days had minor effects on the pharmacokinetics and pharmacodynamics of a single 20-mg dose of **warfarin** given on day 11. The clearance of both *R*- and *S*-warfarin was slightly decreased (by 7% and 14%, respectively), with similar increases in AUC. Conversely, a 10% reduction in the maximum prothrombin time was reported.[1] As has been suggested for lasofoxifene (see 'Coumarins + Lasofoxifene', p.475), this might be because oestrogenic compounds increase plasma concentrations of vitamin K-dependent clotting factors, so antagonising the effect of **warfarin**.

The manufacturers recommend that because modest decreases in prothrombin times have been seen, which may develop over several weeks, prothrombin times should be monitored.[2,3] In the UK, they extend this recommendation to cover the use of other coumarins.[2]

3. Evista (Raloxifene hydrochloride). Eli Lilly and Company. US Prescribing information, October 2008.

Coumarins + Retinoids

Two isolated case reports describe reduced warfarin effects in one patient given etretinate, and in one patient given isotretinoin. Acitretin did not significantly alter the anticoagulant effects of phenprocoumon in healthy subjects.

Clinical evidence

(a) Phenprocoumon

Acitretin 50 mg daily for 10 days slightly increased the Quick test of 10 healthy subjects stabilised on phenprocoumon, from 22% to 24%, and the corresponding INR value decreased from 2.91 to 2.71. However, these changes were not considered to be clinically significant.[1]

(b) Warfarin

1. Etretinate. A man with T-cell lymphoma who had recently been given chemotherapy (cyclophosphamide, doxorubicin, vincristine and prednisolone) was anticoagulated with warfarin after developing a pulmonary embolism. About three weeks later, he started etretinate 40 mg daily and it was found necessary to increase his warfarin dose from 7 to 10 mg daily. His liver function tests were normal.[2] This patient had also recently started taking 'co-proxamol', (p.490), 'tolbutamide', (p.430), and 'cimetidine', (p.470), but all of these have been reported to only rarely *increase* the effect of warfarin.

2. Isotretinoin. A 61-year-old man stabilised on warfarin 2.5 mg daily for 2 to 3 years had a decrease in his INR to below 2.5 after starting oral cefpodoxime proxetil 200 mg twice daily and oral isotretinoin 30 mg daily for inflammatory lesions of the face. He required an increase in warfarin dose to 3.75 mg daily. The cefpodoxime was stopped after 10 days without a further change in his warfarin requirement. However, when the isotretinoin was discontinued after 40 days, the INR progressively increased and the warfarin dose was eventually reduced to the pre-isotretinoin dose of 2.5 mg daily.[3]

Mechanism

Not understood. It has been suggested that etretinate or isotretinoin may increase the rate of metabolism of warfarin.[2,3]

Importance and management

Information appears to be limited to these reports. The clinical relevance of the two case reports of a modest increase in warfarin requirements on starting etretinate or isotretinoin is uncertain. No definite conclusions can be drawn from these isolated cases. The study with acitretin suggests that no phenprocoumon dose adjustments are expected to be needed on starting acitretin.

Coumarins + Ribavirin

Ribavirin appears to decrease the anticoagulant effects of warfarin.

Clinical evidence

A 61-year-old patient who had been taking **warfarin** for a number of years with an INR in the range of 1.8 to 2.7 required a progressive 40% increase in his **warfarin** dose (from 45 to 62.5 mg weekly) over the month after starting oral ribavirin 600 mg twice daily and subcutaneous interferon alfa-2b for active hepatitis C infection. During the following 11 months, the **warfarin** dose was stabilised at 57.5 mg weekly. Three weeks after discontinuation of the ribavirin and interferon, his INR had increased from 2.2 to 3.4 requiring a reduction in his **warfarin** dose to 47.5 mg weekly. One year later, when the patient was rechallenged with ribavirin alone (1 g daily for 4 weeks), his INR decreased from 2.6 to 1.8 and he required a weekly **warfarin** dose of 52.5 mg.[1]

For mention of another patient requiring a high **warfarin** dose (70 mg weekly), which was attributed to nelfinavir, but who was also receiving ribavirin, see 'Coumarins + Protease inhibitors', p.498.

Mechanism

Unknown. The few cases with interferon (see 'Coumarins + Interferons', p.474) have suggested that interferon may *increase* the effect of warfarin. In this case, ribavirin seems to have decreased the effect of warfarin, and

overridden any effect of interferon. However, ribavirin is not known to be an inhibitor or inducer of any cytochrome P450 isoenzyme.

Importance and management

This is the only case of this interaction, so it is not established, although the evidence on rechallenge with ribavirin alone lends weight to the effects potentially being due to an interaction. The authors recommended increased monitoring of anticoagulant effects in patients taking warfarin requiring ribavirin. Until more is known, this may be prudent.

1. Schulman S. Inhibition of warfarin activity by ribavirin. *Ann Pharmacother* (2002) 36, 72–4.

Coumarins + Ropinirole

A man stabilised on warfarin had an increase in his INR, necessitating a 25% decrease in his warfarin dose, while taking ropinirole.

Clinical evidence, mechanism, importance and management

A frail 63-year-old man taking levodopa with carbidopa daily and **warfarin** 4 mg daily with a stable INR ranging from 1.8 to 2.6 over the past 14 months was evaluated for possible progression of Parkinson's disease. He was then given ropinirole 250 micrograms three times daily with a 25% reduction in the dose of levodopa with carbidopa, and 9 days later his INR was noted to have increased to 4.6, but there were no apparent signs of bleeding. **Warfarin** was withheld for 4 days, and then restarted at 2 mg daily, and increased to 3 mg daily 19 days later when his INR was 1.2. After one month the ropinirole was discontinued because of adverse gastrointestinal effects, and 2 months later his INR was 1.4 necessitating an increase in the **warfarin** dose to the original dose of 4 mg daily.[1] The mechanism of this probable interaction is unknown, and it appears to be the first evidence of such an interaction. No definite conclusions can be drawn from this isolated case.

1. Bair JD, Oppelt TF. Warfarin and ropinirole interaction. *Ann Pharmacother* (2001) 35, 1202–4.

Coumarins + Royal jelly

An isolated report describes a patient taking warfarin, who developed a raised INR with haematuria one week after starting a royal jelly supplement.

Clinical evidence, mechanism, importance and management

An 87-year-old man stabilised on warfarin (INR 1.9 to 2.4) and a variety of other drugs presented with haematuria and was found to have an INR of 6.88. He reported starting to take a supplement containing just royal jelly one week earlier. The name of the supplement and the dose taken were not given in the report.[1]

Royal jelly is a substance secreted by worker honeybees (*Apis mellifera*) to feed their larvae. It is essentially a nutrient substance, and why it might interact with warfarin is unknown. This appears to be an isolated case, and its general relevance is therefore uncertain.

1. Lee NJ, Fermo JD. Warfarin and royal jelly interaction. *Pharmacotherapy* (2006) 26, 583–6.

Coumarins + Salicylates; Topical

Cases of increased warfarin effects have been reported with topical methyl salicylate or trolamine salicylate.

Clinical evidence

Methyl salicylate, in the form of gels, oil, or ointment applied to the skin, has been found to increase the effects of **warfarin**. Bleeding and bruising and/or raised INRs have been seen with both high[1-4] and low doses[5] of topical **methyl salicylate**. One report[6] described the possible additive effects of **methyl salicylate oil** (*Kwan Loong Medicated Oil*) and a decoction of *Danshen* (the root of *Salvia miltiorrhiza*) on the response to **warfarin** (see also 'Coumarins and related drugs + Danshen (*Salvia miltiorrhiza*)', p.453). A raised prothrombin time has also been reported with topical **trolamine salicylate**.[3]

Mechanism

Methyl and trolamine salicylates possibly interact like high-dose aspirin (see 'Coumarins and related drugs + Aspirin or other Salicylates', p.434), if they are absorbed through the skin. In one case report, the blood level of salicylate suggested significant percutaneous absorption.[1] However, in a study in healthy subjects, systemic absorption of salicylate was low after a single application of *Deep Heat* (local absorption was comparatively high).[7]

Importance and management

Although the evidence is limited, it appears that topical methyl salicylate and trolamine salicylate might be sufficiently absorbed in some circumstances for them to increase the effect of warfarin. Bear the potential for an interaction in mind should a patient have an otherwise unexplained rise in their INR or experience bleeding.

Coumarins + Sevelamer

Sevelamer does not alter the pharmacokinetics of warfarin.

Clinical evidence, mechanism, importance and management

In a study in healthy subjects, the pharmacokinetics of a single 30-mg oral dose of **warfarin** were not statistically changed by sevelamer 2.4 g (equivalent to 6 capsules). Five more doses of sevelamer were given with meals over 2 days to check whether it had any effect on the enterohepatic circulation of **warfarin**. No effect was seen.[1] Thus it appears that sevelamer does not bind to **warfarin** within the gut to reduce its absorption. No warfarin dose adjustment would be expected to be required on concurrent use.

1. Burke SK, Amin NS, Incerti C, Plone MA, Watson N. Sevelamer hydrochloride (Renagel®), a nonabsorbed phosphate-binding polymer, does not interfere with digoxin or warfarin pharmacokinetics. *J Clin Pharmacol* (2001) 41, 193–8.

Coumarins + SNRIs

A case report describes a markedly raised INR in a patient taking warfarin when duloxetine was also given, and another case report describes a decrease in INR with acenocoumarol when duloxetine was given. Unpublished cases of bleeding and raised prothrombin times have been reported with venlafaxine and warfarin. Note that SNRIs alone have, rarely, been associated with bleeding, and there is the theoretical possibility that the risk might be increased when used with warfarin and related drugs.

Clinical evidence

(a) Duloxetine

A woman taking **warfarin** with a stable INR (mean 2.2 over the previous year) developed petechiae and purpura 55 days after starting duloxetine 30 mg daily, and was found to have an INR of 5. **Warfarin** was stopped on day 58, but the INR continued to rise to greater than 19 on day 85, and she was given vitamin K. On day 94 the duloxetine was stopped. **Warfarin** was restarted on day 110 and by day 140 the INR was 2.2 with the **warfarin** dose stabilised at the original level.[1] Conversely, another patient taking **acenocoumarol** had a decrease in INR from about 2.6 to 1.5 after

taking a single 60-mg dose of duloxetine, the effect of which persisted for 3 weeks.[2]

(b) Venlafaxine

The possible interactions of **warfarin** or other anticoagulants with venlafaxine do not appear to have been studied, but, as of May 2000, the manufacturers had on record 6 case reports of increased prothrombin times, raised INRs and bleeding (haematuria, gastrointestinal bleeding, melaena, haemarthrosis) in patients taking **warfarin** with venlafaxine.[3]

Mechanism

Just why these adverse interactions should have occurred is not understood, especially as no pharmacokinetic interaction is thought likely. Serotonin release by platelets plays an important role in haemostasis, and, as with all drugs that inhibit serotonin reuptake (see 'Coumarins and related drugs + SSRIs', below), SNRIs such as duloxetine, **milnacipran** and venlafaxine may uncommonly cause ecchymosis, mucosal bleeding and, rarely, prolonged bleeding time and haemorrhage. This theoretically might result in an increased risk of bleeding when used with warfarin and related drugs, but would not explain increased INRs. In a large case-control study, venlafaxine alone was associated with an increased risk of gastrointestinal haemorrhage (rate ratio 1.85), but the study was insufficiently powered to detect whether combined use with warfarin increased this.[4] Note that there was no interaction effect between SSRIs and warfarin for gastrointestinal bleeds in this study.

Importance and management

The interaction between the SNRIs and the coumarins is not established, and the general relevance of the unpublished cases with venlafaxine and the case with duloxetine is uncertain. If one subscribes to the view that increased monitoring is necessary when any drug is started or stopped in a patient on warfarin or related drugs, then it would be prudent to monitor prothrombin times with venlafaxine, duloxetine and milnacipran. Bear in mind the possibility of increased bleeding risk in the absence of alterations in INR when any SNRI is used with warfarin. More study is needed.

Coumarins + Sodium edetate

A man had a reduction in the effects of warfarin, which was attributed to intravenous chelation therapy that included sodium edetate.

Clinical evidence, mechanism, importance and management

A 64-year-old man who had been taking **warfarin** for 3 weeks, with a gradually increasing dose to 25 mg weekly, had an INR decrease from 2.6 to 1.6 the day after he received intravenous chelation therapy with sodium edetate. He was given a single 10-mg dose of **warfarin** that day, then continued on his 25 mg weekly dose, with an INR in the range of 2.3 to 2.8. The chelation therapy also contained high-dose vitamin C along with various other vitamins and electrolytes.[1] Whether this case represents an interaction with the chelation therapy is uncertain. Further study is needed.

Coumarins and related drugs + SSRIs

In a study, fluvoxamine increased warfarin plasma levels, and raised INRs have been seen in several cases of the concurrent use of these drugs. In another study with warfarin and paroxetine, the majority of patients experienced no interaction, but a few had minor bleeding events. Other studies suggest that citalopram and sertraline do not significantly alter the pharmacokinetics or effects of warfarin. However, isolated reports describe bleeding in patients taking SSRIs and coumarins or fluindione. In addition, SSRIs alone have, rarely, been associated with bleeding, and there is some evidence that the risk of bleeding might be increased when they are used with coumarins.

Clinical evidence

(a) Citalopram

In a study in 12 healthy subjects given a single 25-mg oral dose of **warfarin** either alone or on day 15 of a 21-day course of citalopram 40 mg daily, the pharmacokinetics of both *R*- and *S*-warfarin remained unchanged in the presence of the citalopram, but the maximum prothrombin time was increased by 6.4% (1.6 seconds). This was considered to be clinically irrelevant.[1] Nevertheless, a 63-year-old patient who had just started **acenocoumarol** 18 mg weekly developed spontaneous gingival haemorrhage 10 days after also starting citalopram 20 mg daily for depression. Her INR had increased from a value of 1.8 to greater than 15. She was treated with 2 units of blood and citalopram was withdrawn. Her INR decreased to 1.95 within 5 days and she was able to continue on **acenocoumarol** 18 mg weekly.[2]

(b) Escitalopram

Escitalopram is the *S*-isomer of citalopram, and as such would not be expected to have a pharmacokinetic interaction with **warfarin**, see *Citalopram*, above.

(c) Fluoxetine

In a study in 3 healthy subjects, the half-life of a single 20-mg dose of **warfarin** was not altered by either a single 30-mg dose of fluoxetine given 3 hours before the **warfarin**, or by fluoxetine 30 mg daily for a week with the **warfarin** dose given 3 hours after the last dose of fluoxetine. In addition, fluoxetine had no effect on the warfarin-induced prolongation of prothrombin time.[3] In another study, 6 patients stabilised on **warfarin** had no significant changes in their prothrombin times or INRs while taking fluoxetine 20 mg daily for 21 days. The maximum change was a decrease in prothrombin time of 3.5% (15%) in one patient.[4]

However, there are few reports of increases in INR in patients taking **warfarin** with fluoxetine. In one report, the INR of a man stabilised on **warfarin**, amiodarone, furosemide, digoxin, ciprofloxacin and levothyroxine rose sharply from a range of 1.8 to 2.3 up to 14.9 within 5 days of starting fluoxetine 30 mg daily.[5] The INR of another man with metastatic carcinoma taking **warfarin**, dexamethasone, bisacodyl and lactulose rose from a range of 2.5 to 3.5 up to 15.5 within 2 weeks of starting fluoxetine 20 mg daily. He showed microscopic haematuria but no bleeding.[5] Other reports describe an abdominal haematoma,[5] cerebral haemorrhage,[6] severe bruising[7] and increases in INRs[8] in patients taking fluoxetine and **warfarin**. In 1993, the CSM in the UK was also said to have 4 other similar cases on record.[8] In the preliminary report of one retrospective review of patients' records, all of 8 evaluable cases of concurrent use of fluoxetine and **warfarin** had an abnormally prolonged prothrombin time.[9]

In a case-control study in patients stabilised on **warfarin**, the increase in risk of hospitalisation for an upper gastrointestinal bleed after starting either fluvoxamine or fluoxetine was marginally higher than for other SSRIs (relative risk 1.2 versus 1.1), but neither risk was statistically significant.[10] Note that fluvoxamine and fluoxetine were not considered separately, and the number taking each one was not stated.

(d) Fluvoxamine

In a study in healthy subjects, fluvoxamine 50 mg three times daily for 12 days increased steady-state plasma **warfarin** levels by about 65% and increased prothrombin times by 28%.[11,12] A worldwide literature search by the manufacturers of fluvoxamine identified only 11 reported interactions between **warfarin** and fluvoxamine by 1995, all with clinical signs that included prolonged prothrombin times.[13] An 80-year-old woman who had recently started taking **warfarin**, digoxin and 'colchicine', (p.450), had an increase in her INR from 1.8 to about 10 within a week of starting to take fluvoxamine 25 mg daily. Both the **warfarin** and fluvoxamine were stopped, but her INR only stabilised on the original dose of **warfarin** after the colchicine was withdrawn.[14] Another report describes a 79-year-old woman admitted to hospital because of suicidal thoughts. She was taking **warfarin** (INR 1.6 to 1.8) and citalopram 10 mg at night and other medications including paracetamol with dextropropoxyphene. On the third day in hospital the citalopram dose was increased to 30 mg at bedtime and after 2 days it was discontinued and fluvoxamine 50 mg daily was started to treat depression and possibly obsessive thoughts. Within 4 days the patient's INR had increased to 3.7. Fluvoxamine was replaced

with venlafaxine and **warfarin** was omitted for one day. The INR gradually decreased to the normal range over about 7 days.[15]

A further isolated report describes a woman stabilised on **fluindione** whose INR rose to 7.13 (from a normal value of about 2.5) within 13 days of starting to take fluvoxamine 100 mg daily. She had received fluoxetine, dosulepin and lorazepam for 15 days before fluvoxamine was started.[16]

In a case-control study in patients stabilised on **warfarin**, the increase in risk of hospitalisation for an upper gastrointestinal bleed after starting either fluvoxamine or fluoxetine was marginally higher than for other SSRIs (relative risk 1.2 versus 1.1), but neither risk was statistically significant.[10] Note that fluoxetine and fluvoxamine were not considered separately, and the number taking each one was not stated.

(e) Paroxetine

Paroxetine 30 mg daily, given to healthy subjects with **warfarin** 5 mg daily, did not significantly increase mean prothrombin times, but mild, clinically significant bleeding was seen in 5 out of 27 subjects given the combination. Two withdrew from the study because of increased prothrombin times, and another because of haematuria. The pharmacokinetics of **warfarin** and paroxetine remained unchanged by concurrent use.[17] In a brief retrospective review, 4 patients taking **warfarin** were said to have had an increase in INR by an average of 3 points (increases of nearly 100% in some cases) associated with the use of paroxetine and sertraline.[18]

A single case report[19] describes severe bleeding (abdominal haematoma) in a patient taking **acenocoumarol** and paroxetine when given phenytoin, but it is by no means clear whether the paroxetine had any part to play in what happened (see 'Phenytoin + Coumarins and related drugs', p.634).

(f) Sertraline

In a placebo-controlled study in healthy subjects, sertraline, in increasing doses up to 200 mg daily for 22 days, increased the prothrombin time AUC in response to a single 0.75-mg/kg dose of **warfarin** by 8%. This was statistically significant, but regarded as too small to be clinically relevant.[20]

In a brief retrospective review, 4 patients taking **warfarin** were said to have had an increase in INR by an average of 3 points (increases of nearly 100% in some cases) associated with the use of paroxetine and sertraline.[18]

(g) Unspecified SSRIs

In a large case-control study using data from the Netherlands, the concurrent use of coumarins (**acenocoumarol** and **phenprocoumon**) and SSRIs increased the risk of hospitalisation for non-gastrointestinal bleeding (odds ratio 1.7). However, the risk of hospitalisation for gastrointestinal bleeding was not increased (odds ratio 0.8).[21] Another case-control study using data from the UK General Practice Research Database, also found no increased risk of gastrointestinal haemorrhage with the concurrent use of **warfarin** and SSRIs compared with warfarin or an SSRIs given alone (rate ratio 0.81).[22,23] In yet another analysis, **warfarin** alone was associated with an increased risk of haemorrhagic stroke (odds ratio 3) whereas SSRIs alone were not (odds ratio 0.8). The concurrent use of SSRIs and **warfarin** did not increase the risk compared with warfarin alone (odds ratios 4.7 versus 3).[24]

Mechanism

Pharmacokinetic interactions. Fluvoxamine is a moderate inhibitor of the cytochrome P450 isoenzyme CYP2C9, by which *S*-warfarin is metabolised, and is also a potent inhibitor of CYP1A2 and CYP2C19, by which the less active *R*-warfarin is partially metabolised. Consequently, fluvoxamine would be expected to increase warfarin effects. *In vitro*, fluoxetine, paroxetine, sertraline, and citalopram had little or no inhibitory effect on CYP2C9 mediated *S*-warfarin hydroxylation.[25] In addition, these SSRIs do not inhibit CYP1A2 or CYP2C19, therefore they would not be anticipated to increase warfarin levels.

Pharmacodynamic interactions. Serotonin release by platelets plays an important role in haemostasis, and epidemiological studies and case reports suggest that SSRIs alone are rarely associated with bleeding events.[21,26] Evidence to date suggests that the risk of gastrointestinal bleeding is not significantly further increased if SSRIs are given with anticoagulants,[10,22] but that the risk of non-gastrointestinal bleeding might be increased.[21]

Importance and management

A pharmacokinetic interaction between fluvoxamine and warfarin that leads to increased anticoagulant effects is established. Therefore, the response should be monitored when fluvoxamine is first added, being alert for the need to decrease the anticoagulant dose.

None of the other SSRIs studied (citalopram, fluoxetine, paroxetine) have been shown to alter the pharmacokinetics of warfarin. Neither fluoxetine nor paroxetine increased the prothrombin time, but citalopram and sertraline caused a less than 10% increase in prothrombin time, and a few patients taking paroxetine with warfarin had bleeds. However, in general, these effects would not be expected to be clinically relevant. Nevertheless, because SSRIs alone can rarely cause bleeding, some predict that this may result in additive effects with coumarins and indanediones, and recommend caution with all SSRIs. This excess risk was not apparent for gastrointestinal bleeding, but might be relevant for bleeds from other sites.[21] Note that there are case reports of interactions with warfarin for many of the SSRIs (citalopram, fluoxetine, paroxetine, sertraline); bear these in mind should bleeding occur in a patient taking both drugs.

Coumarins + St John's wort (*Hypericum perforatum*)

St John's wort can cause a moderate reduction in the anticoagulant effects of phenprocoumon and warfarin.

Clinical evidence

(a) Phenprocoumon

In a randomised, placebo-controlled crossover study in 10 healthy men,[1] St John's wort extract (*LI 160*, *Lichtwer Pharma*) 900 mg daily for 11 days reduced the AUC of a single 12-mg dose of phenprocoumon by a modest 17%. There is also a case report of a 75-year-old woman taking

phenprocoumon who had a reduced anticoagulant response (a rise in the Quick value) 2 months after starting to take St John's wort.[2]

(b) Warfarin

In a randomised, crossover study in 12 healthy subjects, one tablet of St John's wort three times daily for 3 weeks modestly decreased the AUC of both *R*- and *S*-warfarin by about 25% after a single 25-mg dose of warfarin taken on day 14. In this study, the brand of St John's wort used was *Bioglan* tablets, each tablet containing an extract equivalent to 1 g of *Hypericum perforatum* flowering herb top containing 825 micrograms of hypericin and 12.5 mg of hyperforin.[3]

Over the 1998 to 1999 period, the Swedish Medical Products Agency received 7 case reports of patients stabilised on warfarin who had decreased INRs when St John's wort was added. Their INRs fell from the normal therapeutic range of about 2 to 4 to about 1.5. Two patients needed warfarin dosage increases of 6.6% and 15%, respectively, when St John's wort was added. The INRs of 4 of the patients returned to their former values when the St John's wort was stopped.[4]

A retrospective study[5] similarly found that the concurrent use of enzyme inducers (including St John's wort) significantly influenced the total weekly warfarin dose; further analysis found that an average additional amount of warfarin required in patients taking these drugs was 17.2 mg weekly.

Mechanism

Uncertain, but it is suggested that the St John's wort increases the metabolism and clearance of the anticoagulants[1,3,4] possibly by induction of the cytochrome P450 isoenzyme CYP3A4 and possibly also CYP2C9 as both *R*- and *S*-warfarin were affected.[3] However, note that St John's wort is not usually considered to be a CYP2C9 inducer.

Importance and management

Information seems to be limited to these reports, but a modest pharmacokinetic interaction is established, which might be clinically important in some patients. It would be prudent to monitor the INRs of patients taking phenprocoumon, warfarin or any other coumarin if they start taking St John's wort, being alert for the need to slightly raise the anticoagulant dose. However, note that the advice of the CSM in the UK is that St John's wort should not be used with warfarin. They note that the degree of induction of warfarin metabolism is likely to vary because levels of active ingredients may vary between St John's wort preparations. If a patient is already taking the combination, they advise checking the INR, stopping the St John's wort and then monitoring the INR closely and adjusting the anticoagulant dose as necessary.[6]

Coumarins and related drugs + Statins

Studies and case reports have suggested that fluvastatin can increase warfarin levels and/or effects. Rosuvastatin can increase the anticoagulant effects of warfarin but does not alter warfarin levels. Other studies with atorvastatin, lovastatin, pravastatin, and simvastatin suggest that they do not usually significantly alter the effects of warfarin, although isolated cases of bleeding have been seen when these statins were given with coumarins and fluindione.

Clinical evidence

Pharmacological studies of the effect of statins on **warfarin** are summarised in 'Table 12.5', (p.507). These show that **rosuvastatin** increases **warfarin** effects without altering **warfarin** pharmacokinetics, and that **fluvastatin**, at high clinical doses, modestly increases **warfarin** levels. Conversely, **atorvastatin**, **pravastatin**, **lovastatin** and **simvastatin** appear to have little effect on the anticoagulant effects of **warfarin**. Nevertheless, isolated case reports of interactions with coumarins have been reported for all statins and these are summarised in 'Table 12.6', (p.508).

Moreover, in one analysis of 42 patients taking warfarin and starting **fluvastatin** 20 mg daily,[1] three patients had a moderate rise in INR (further details given in 'Table 12.6', (p.508)), 5 patients had possible elevations in INR, 17 patients had no change, and data were not available for 17.

An early report, from the first 7 months after **lovastatin** became available in the US, notes that the manufacturers had received 10 spontaneous reports of bleeding and/or increased prothrombin times in patients taking **warfarin** with lovastatin.[2,3] In an analysis of factors that might be useful to construct a warfarin-dosing algorithm, **warfarin** maintenance doses were found to be 12% lower in patients taking **simvastatin**.[4] In another similar analysis, there was a trend towards a lower **warfarin** dose with lower 10-hydroxywarfarin (a metabolite of ***R*-warfarin**) levels in 17 patients taking simvastatin or lovastatin.[5]

In the preliminary analysis of a large, retrospective, case-control study in patients taking warfarin, the use of statins in patients who were receiving **warfarin** did not decrease the risk for bleeding (odds ratio 0.91).[6]

Coumarins are not expected to alter statin pharmacokinetics or effects. However, an isolated report[7] describes rhabdomyolysis with acute renal failure in an 82-year-old man taking **simvastatin** 20 mg daily within 7 days of starting **warfarin** 5 mg daily; his INR was raised to 4.3.

Mechanism

Fluvastatin is a modest inhibitor of the cytochrome P450 isoenzyme CYP2C9, by which the more potent *S*-warfarin is metabolised. Evidence from an interaction study with the CYP2C9 substrate diclofenac suggests that this interaction is most likely with higher and sustained fluvastatin levels,[8] which might explain why, with warfarin, it was demonstrated in healthy subjects with the maximum recommended daily dose of 80 mg daily, but not the more commonly encountered clinical dose of 40 mg daily, and why it has not been seen in all patients.

Lovastatin and simvastatin appear less likely to interact via CYP2C9,[9] although it is possible they might interact via other isoenzymes. In one analysis, patients taking these statins had lower levels of 10-hydroxywarfarin, a metabolite of *R*-warfarin, but clearance of *R*-warfarin was not reduced.[5] It may be that because warfarin has multiple routes of metabolism that other isoenzymes can 'pick up' warfarin metabolism if competition for metabolism occurs. Interactions may therefore only occur if other confounding factors are present. Alternatively, the cases seen may just represent idiosyncratic reactions.

Rosuvastatin clearly shows a dose related increase in warfarin effects, but this was not due to an increase in *R*- or *S*-warfarin levels, and the mechanism for this effect is unknown.[10]

Bear in mind that patients starting a statin might also alter their dietary fat consumption. Vegetable fats are a good source of vitamin K (see 'Table 12.3', (p.462)), and a marked reduction in consumption of foods rich in these could increase the sensitivity to warfarin.

Importance and management

Data are limited, which is surprising given the widespread use of statins and warfarin, and are sometimes contradictory, all of which complicates making firm recommendations. Some evidence suggests that a modest pharmacokinetic interaction occurs between **fluvastatin** and warfarin at high doses, and this would explain the case reports of an interaction with this statin. The clinical evidence suggests that only some patients develop an important interaction (3 of 25 evaluable patients in one analysis). In the UK, the manufacturer states that concurrent use of fluvastatin and warfarin may commonly cause significant increases in prothrombin time.[11] Clearly, with **fluvastatin**, increased monitoring is required when starting or stopping the statin, or changing the dose. Similar advice also applies to **rosuvastatin**, which has the best pharmacological data on concurrent use in patients, clearly showing that clinically important increases in INR can occur. In contrast to fluvastatin, this interaction does not appear to have a pharmacokinetic basis.

Data for **simvastatin** appear to be limited to retrospective analyses. In general these show that simvastatin can cause a minor increase in warfarin effects. This would appear to be supported by the fact that there is only one full published report of an interaction in a patient taking warfarin and one for acenocoumarol. Some consider that any interaction is of limited clini-

Table 12.5 Summary of pharmacological studies of the effect of statins on warfarin

Study type	*Group*	*Warfarin*	*Statin dose*	*Findings*		*Refs*
				Pharmacokinetics	Anticoagulant effects	
Atorvastatin						
Prospective	12 patients	Stable therapy	80 mg daily for 14 days	NR	Prothrombin time decreased from 18.6 to 17 seconds on days 3 to 5, but was not changed on other days	1
Fluvastatin						
Placebo-controlled	Healthy subjects	Single 30-mg dose	40 mg daily for 8 days	No change in racemic warfarin levels	No change in prothrombin complex activity	2
Crossover	18 healthy subjects	Single 10-mg dose	40 mg twice daily for 18 days	Increase in AUC of *S*-warfarin of 42% in smokers and 26% in non-smokers	NR	3
Lovastatin						
NR	Patients	Stable therapy	NR	NR	No change in prothrombin time	4
Crossover, placebo-controlled	8 patients	Stable therapy	40 mg daily for 7 days	NR	INR increased from 2.6 to 3 (17%) by day 7	5
Pravastatin						
Prospective	Healthy subjects	5 mg daily	20 mg twice daily	17% increase in warfarin AUC*	No change in prothrombin time on concurrent use for 6 days	6
Crossover, placebo-controlled	8 patients	Stable therapy	20 mg daily for 7 days	NR	No change in INR over the 7 days	5
NR	Elderly healthy subjects	Stable therapy	40 mg	NR	No change in prothrombin time	7
Rosuvastatin						
Placebo-controlled, crossover	18 healthy subjects	Single 25-mg dose	40 mg daily for 10 days	No change in pharmacokinetics of *S*- or *R*-warfarin	INR AUC increased by 10%, and maximum INR increased by 19%	8
Prospective	7 patients	Stable therapy	10 mg daily for up to 14 days then 80 mg daily for up to 14 days	NR	With 10 mg daily, 2 patients had INR increases of 1.5 and 3.7 to values greater than 4. With 80 mg daily, 4 of 5 patients had increases of 1.5 to 2.6 to values greater than 4	8
Placebo-controlled, crossover	12 healthy subjects	5 mg daily for 14 days	40 mg daily for 7 days	NR	No change in steady-state warfarin pharmacodynamics	9
Simvastatin						
Retrospective analysis of a placebo-controlled study	23 patients	NR	20 mg or 40 mg daily	NR	INR increased from a mean of 2.6 to 3.4 in the simvastatin group without changes in warfarin dose, compared with a decrease from 2.6 to 2.4 in the placebo group	10
NR	Healthy subjects	NR	20 mg or 40 mg daily	NR	INR increased from a mean of 1.7 to 1.8	11, 12
Retrospective cohort	46 patients	Stable with no change	Switch from pravastatin to simvastatin	NR	Mean INR increased from 2.42 to 2.74. Eleven patients had a warfarin dose adjustment after the INR change, 7 a decrease and 4 an increase	13
Retrospective	29 patients	Stable therapy	NR	NR	Warfarin dose decreased from a mean of 4.2 mg daily before to 3.8 mg daily after, while INR increased from a mean of 2.5 to 3.15	14
Historical control group taking warfarin alone	56 patients 56 controls	Stable therapy	20 mg daily (35 patients) or 40 mg daily (21 patients)	Median clearance of *S*-warfarin was 18%, and *R*-warfarin 23%, lower in patients than controls	Mean dose of warfarin was 3.3 mg daily in patients and 4 mg in controls	15

NR = not reported.

cal importance, and that statin therapy may be switched to simvastatin without any additional monitoring over and above that usually practised for warfarin.[12] However, others,[13,14] including the manufacturers[15,16] recommend increased monitoring when starting or stopping the statin, or changing the dose, and this may be prudent. There are even less data for **lovastatin**, an analogue of simvastatin, but it appears to interact similarly to simvastatin, and the manufacturer also recommends increased monitoring.[17] There appear to be no data on the effect of lovastatin on the pharmacokinetics of coumarins, and only one poor quality study suggesting a minor reduction in warfarin clearance with simvastatin.

In one pharmacological study, **atorvastatin** did not interact with warfarin, and no cases of an interaction have been published. This suggests that with this statin, no increased monitoring is necessary. In the US, the manufacturer does not give any advice on monitoring,[18] but in the UK, the manufacturer recommends close monitoring,[19] which seems over-cautious.

Limited data for **pravastatin** also suggest that no interaction occurs with warfarin, there being just one isolated case report with the indanedione fluindione. No increased monitoring would appear to be necessary on concurrent use.

Coumarins + Sucralfate

The simultaneous administration of warfarin and sucralfate did not alter the anticoagulant effect of warfarin in studies in patients on stable therapy. However, case reports describe a marked reduction in the effects of warfarin in four patients taking sucralfate.

Clinical evidence

In an open, crossover study in 8 elderly patients taking **warfarin**, their anticoagulant response (thromboplastin time) and plasma **warfarin** levels remained unchanged while taking sucralfate 1 g three times a day over a 2-week period.[1] Similarly, in a preliminary report of another study, sucralfate 1 g four times daily for 2 weeks had no effect on prothrombin time or plasma **warfarin** levels in 5 patients on stable **warfarin** therapy.[2] In both these studies, the daily **warfarin** dose was taken simultaneously with one of the sucralfate doses.[1,2]

However, there are four case reports of reduced **warfarin** effects with sucralfate. In one of these, a man taking several drugs (digoxin, furosemide, chlorpropamide, potassium chloride) had serum **warfarin** levels that were about two-thirds lower when he was given sucralfate (dose not stated). When the sucralfate was withdrawn, his serum **warfarin** levels rose to their former levels accompanied by a prolongation of prothrombin times.[3] Another patient taking sucralfate had subtherapeutic prothrombin times on starting **warfarin**, despite **warfarin** doses of up to 17.5 mg daily. When the sucralfate was stopped his prothrombin time rose to 1.5 times the control, even though the **warfarin** dose was reduced to 10 mg daily.[4] One other patient appeared to have reduced responses to **warfarin** while taking sucralfate, despite separation of administration.[5] However, another patient taking **warfarin** and sucralfate had a reduced response to **warfarin** only when it was taken simultaneously with sucralfate, but not when administration was separated.[6]

Mechanism

Unknown. It is suggested that the sucralfate may possibly adsorb the warfarin so that its bioavailability is reduced.[4]

Importance and management

The documentation regarding an interaction between warfarin and sucralfate appears to be limited to the reports cited. Any interaction would therefore seem to be uncommon. Concurrent use need not be avoided, but bear this interaction in mind if a patient has a reduced anticoagulant response to warfarin. Note that, although separating dosing has been suggested as a strategy for avoiding this interaction, one of the cases occurred despite this.

Coumarins + Sucrose polyesters

Short-term, moderate consumption of potato crisps containing sucrose polyesters (*Olestra, Olean*), which include vitamin K_1, did not alter the INR in response to warfarin.

Clinical evidence

In a randomised, double-blind, placebo-controlled study in 36 patients stabilised on **warfarin**, sucrose polyester 12 g daily (as *Pringles Original Flavor Fat Free Potato Crisps with Olean* 42 g) for one week did not significantly alter the anticoagulant effects of **warfarin** (mean INR increase of 0.02, versus 0.17 for placebo). After one week, greater than expected numbers of patients from both the placebo and sucrose polyester groups had INRs outside the therapeutic range of 2 to 3 (3 sucrose polyester recipients and 3 placebo recipients had an INR above 3 (max 4.1) and 2 in the sucrose polyester group and one in the placebo group had an INR less than 2). Two of each group also withdrew because of diarrhoea: their INRs were therapeutic. Only 22 patients entered the second week of the study, and there was no important effect on INR in these patients after the second week.[1]

Mechanism

Sucrose polyesters are non-absorbable, non-calorific fat replacements. It has been concluded that sucrose polyesters are unlikely to reduce the absorption of oral drugs in general; however, they are known to reduce the absorption of some fat-soluble vitamins, and therefore might lower vitamin K stores.[2] Because of this, snacks containing *Olestra* are supplemented with vitamin K_1 at a level of 8 micrograms per gram of *Olestra*.[3] It is possible that this supplementation could be insufficient to offset the vitamin K-lowering effect and therefore increase patient sensitivity to warfarin, or it could be too much and result in an antagonism of warfarin.

Importance and management

No evidence was found in the above study to suggest that short-term moderate consumption of a snack containing sucrose polyesters (12 g daily, including 96 micrograms of vitamin K daily) altered the anticoagulant effect of warfarin. In 1996, the FDA in the US considered that the changes in dietary vitamin K intake attributable to eating vitamin-K compensated *Olestra* would likely be within the normal range of dietary variation.[3] However, an intake similar to this of a vitamin K_1 supplement has altered coagulation status in some subjects (see 'Coumarins + Vitamin K_1-containing dietary supplements', p.520), and pure vitamin K_1 is much more bioavailable than that from plant sources (see 'Coumarins and related drugs + Food; Vitamin K_1-rich', p.464). Some consider that the snacks may have an impact on serum vitamin K levels.[4] Given these concerns, further study is probably needed.

Coumarins + Sulfinpyrazone

The anticoagulant effects of warfarin are markedly increased by sulfinpyrazone, and there are case reports of moderate to serious bleeding on concurrent use. Acenocoumarol is modestly affected. Phenprocoumon does not appear to be significantly affected. The antiplatelet effects of sulfinpyrazone might increase the risk of bleeding with coumarins.

Clinical evidence

(a) Acenocoumarol

In a placebo-controlled, crossover study in 22 patients taking acenocoumarol, sulfinpyrazone 800 mg daily for 2 weeks led to a drop in the mean prothrombin time requiring a reduction in the anticoagulant dose by an average of 20%. Four patients withdrew because of bleeding episodes, 3 patients while taking sulfinpyrazone and one while taking placebo.[1]

(b) Phenprocoumon

In a study in 6 healthy subjects, sulfinpyrazone 400 mg daily for 17 days had little effect on phenprocoumon levels after a single 0.6-mg/kg dose of phenprocoumon given on day 4. The AUC of prothrombin time increased in 4 subjects and decreased in 2, resulting in an overall non-significant mean increase of 16%.[2] Similar findings were reported in another study of similar design.[3]

(c) Warfarin

In a double-blind, placebo-controlled study in 11 patients stabilised on warfarin, sulfinpyrazone 200 mg four times daily for 6 to 12 months reduced the average warfarin dose requirement by 44% from 7.3 to 4.1 mg week, compared with no change in the placebo group. There were four episodes of bleeding (haematoma, epistaxis and bleeding gums) in 3 patients

receiving sulfinpyrazone and one in the placebo group. The authors noted it was difficult to regulate anticoagulant control in the patients taking sulfinpyrazone.[4,5] Similarly, in another study, the prothrombin ratios of 5 patients taking warfarin rose rapidly over 2 to 3 days after sulfinpyrazone 200 mg every 6 hours was added. The average warfarin requirements fell by 46% and 2 patients needed vitamin K to combat the excessive hypoprothrombinaemia. When the sulfinpyrazone was withdrawn, the warfarin requirements returned to their former levels within one to 2 weeks.[6]

A number of case reports have described increased effects of warfarin in patients starting sulfinpyrazone,[7-12] or an exaggerated anticoagulant response in patients taking sulfinpyrazone and then starting warfarin.[13] Moderate to severe bleeding occurred in some instances.[8,10,11] An increased anticoagulant effect of warfarin in the first 15 days after starting sulfinpyrazone, followed by an unexplained progressive increased warfarin dose requirement has been described in one report.[14] However, this may have had other explanations, as a constant potentiation of warfarin is usually seen on long-term sulfinpyrazone use.[5]

In subsequent studies in healthy subjects, sulfinpyrazone 200 mg twice daily for 10 days was shown to augment the effect of warfarin (99% or 83% increase in the AUC of the prothrombin time) by inhibiting the clearance of *S*-warfarin (by 51% or 40%) when a single dose of warfarin was given on day 4. In contrast, sulfinpyrazone did not alter the effect of *R*-warfarin, and actually increased its clearance by 30% or 42%.[15,16]

Mechanism

Sulfinpyrazone inhibits the metabolism of the more potent *S*-isomer of warfarin, probably because its sulfide metabolite inhibits the cytochrome P450 isoenzyme CYP2C9.[17] It probably interacts by a similar mechanism with acenocoumarol. It could be speculated that sulfinpyrazone induces the metabolism of *R*-warfarin via CYP1A2, as it modestly induces the metabolism of theophylline (see 'Theophylline + Sulfinpyrazone', p.1459). Some early *in vitro* evidence[18] suggested that plasma protein binding displacement might explain this interaction, but a study in healthy subjects found that sulfinpyrazone did not alter the free fraction of either *R*- or *S*-warfarin.[19] Sulfinpyrazone also has antiplatelet effects, so might be expected to increase the risk or severity of bleeding should over-anticoagulation occur.

Importance and management

The increased effect of warfarin with sulfinpyrazone is a well established interaction of clinical importance. If sulfinpyrazone is added, the prothrombin time should be well monitored and suitable anticoagulant dose reductions made. Halving the dose of warfarin[4,6,20] has proven to be adequate in patients taking sulfinpyrazone 600 to 800 mg daily. The interaction with acenocoumarol[1] is less marked, and a 20% dose reduction appears adequate in patients taking sulfinpyrazone 600 to 800 mg daily. Phenprocoumon is reported not to have a pharmacokinetic interaction with sulfinpyrazone. Bear in mind that the antiplatelet effects of sulfinpyrazone might increase the risk of bleeding with coumarins.

Coumarins + Tamoxifen or Toremifene

Tamoxifen may increase the effects of warfarin and cases of serious bleeding, in one case fatal, have been reported. A case report describes a similar effect with acenocoumarol. It has been suggested that a similar interaction may occur with toremifene and the coumarins.

Clinical evidence

A woman who had been taking **warfarin** for 11 years after a heart valve replacement (prothrombin time of 23 to 34 seconds taking **warfarin** 27 to 28.5 mg weekly), was given tamoxifen 10 mg twice daily after mastectomy for early breast cancer. Three days later her prothrombin time was 39 seconds, and 3 weeks later it was 75.6 seconds, although this was attributed to a 5-day course of co-trimoxazole, and so the warfarin dose was unchanged. Six weeks later she developed haematemesis, abdominal pain and haematuria, and her prothrombin time was found to be 206 seconds. She was restabilised on a little over half the **warfarin** dose (17.5 mg weekly) while continuing to take tamoxifen.[1] One case report describes a significantly raised INR and rectal bleeding in a patient who had been taking tamoxifen 20 mg daily long-term and had recently started taking warfarin. The patient had an initial increase in the INR to about 10, which stabilised when omeprazole was stopped and the patient was discharged with an INR of 2.3. However, 7 days later, the patient was readmitted with an INR of 10.8 and rectal bleeding.[2] In another case, a 43-year-old woman was given **warfarin** for a deep vein thrombosis. Seven weeks later tamoxifen 40 mg daily was started, and her prothrombin time increased from 19 seconds to 38 seconds. A warfarin dose reduction from 5 to 1 mg daily was eventually needed to keep her prothrombin time within the range of 20 to 25 seconds. A subsequent retrospective study of the records of women with breast cancer who had been admitted to hospital for serious thromboembolism from 1981 to 1986 revealed 5 other patients taking tamoxifen when **warfarin** was started, and 13 patients not taking tamoxifen. Of the 5 patients taking tamoxifen, 2 had shown marked increases in prothrombin times, and bleeding, shortly after receiving loading doses of **warfarin** (three daily doses of 10 mg, 10 mg and 5 mg). The other 3 patients needed daily **warfarin** doses of 2 mg, 2 mg and 3 mg, respectively, which were about one-third of those taken by the 13 other patients not taking tamoxifen (mean 6.25 mg).[3] In another retrospective analysis of hospital admissions from 1980 to 1988, 22 patients were identified who had been given tamoxifen with **warfarin**. Of these, 17 had no problems, but 2 developed grossly elevated British Comparative Ratios and 3 developed serious bleeding.[4]

A 53-year-old woman who had been taking **acenocoumarol** for 2 years after a heart valve replacement died after a massive brain haemorrhage about 3 weeks after starting to take tamoxifen 20 mg daily for a benign breast condition.[5]

Mechanism

The mechanism for this interaction is unclear. However, one study has reported that tamoxifen may inhibit the metabolism of losartan by the cytochrome P450 isoenzyme CYP2C9, see 'Angiotensin II receptor antagonists; Losartan + Tamoxifen', p.44. CYP2C9 is the isoenzyme involved in the metabolism of the more potent isomer *S*-warfarin, and therefore concurrent use may lead to increased warfarin levels and effects.

Importance and management

Evidence is limited to the above reports, but it appears that a clinically important interaction between **tamoxifen** and warfarin can occur, which apparently affects some but not all patients. Monitor the effects closely if tamoxifen is given to patients taking warfarin or acenocoumarol, and reduce the anticoagulant dose as necessary; the reports indicate a reduction of between one-half to two-thirds for warfarin. Consider also that, from a disease perspective, when treating venous thromboembolic disease in pa-

tients with cancer, warfarin is generally inferior (higher risk of major bleeds and recurrent thrombosis) to low-molecular-weight heparins.[6]

Because of the data with tamoxifen, the UK manufacturer[7] of **toremifene** recommends avoiding the concurrent use of coumarins, whereas the US manufacturer recommends careful monitoring of prothrombin time.[8] However, there appear to be no published reports of any interaction between toremifene and warfarin.

Coumarins + Tegaserod

Tegaserod does not appear to alter the pharmacokinetics or pharmacodynamics of warfarin.

Clinical evidence, mechanism, importance and management

In a study in healthy subjects, tegaserod 6 mg twice daily for 7 days did not alter the pharmacokinetics of either *S*- or *R*-warfarin when a single 30 mg dose of **warfarin** was given on day 4. Similarly, tegaserod did not alter the prothrombin time response to warfarin. No warfarin dose adjustments are therefore recommended when tegaserod is given with **warfarin**.[1] Note that tegaserod has been associated with an excess risk of rare serious cardiovascular ischaemic events,[2] and it should generally not be used in patients with cardiac disease.

Coumarins + Terbinafine

Terbinafine does not affect the pharmacokinetics or anticoagulant effects of warfarin. However, there is one isolated case of markedly reduced anticoagulation, and one case of markedly increased anticoagulation when terbinafine was given with warfarin. No increased risk of over-anticoagulation appears to occur when acenocoumarol or phenprocoumon are given with oral or topical terbinafine.

Clinical evidence

In a randomised, placebo-controlled, study in 16 healthy subjects, terbinafine 250 mg daily for 14 days did not alter the pharmacokinetics or anticoagulant effects of a single 30-mg oral dose of **warfarin** given on day 8.[1] In a post-marketing surveillance study of terbinafine, 26 patients were identified who were also taking **warfarin** and there was no evidence to suggest an interaction occurred in these patients.[2,3] In one cohort study in patients taking **acenocoumarol** or **phenprocoumon**, the concurrent use of oral terbinafine (49 patients) or cutaneous terbinafine (29 patients) was not associated with an increased risk of over-anticoagulation (INR greater than 6).[4]

However, an isolated report describes a 68-year-old woman taking long-term **warfarin** whose INR fell from 2.1 to 1.1 within one month of starting a 3-month course of terbinafine 250 mg daily for tinea unguium. It was necessary to raise her **warfarin** dose from 5.5 mg daily to a range of 7.5 mg to 8 mg daily while taking the terbinafine, and to reduce it stepwise to 5.5 mg over the 4 weeks after the terbinafine was stopped.[5] In contrast, another isolated case report describes an elderly woman stabilised on **warfarin** and cimetidine who developed gastrointestinal bleeding about one month after starting to take terbinafine 250 mg daily. Her INR had increased from 3.1 (about 4 weeks previously) to 11 on admission to hospital.[6]

Mechanism

The isolated cases are not understood, and have been questioned.[7] They may simply represent idiosyncratic reactions.

Importance and management

The available evidence suggests that no interaction usually occurs between the coumarins and terbinafine, and no coumarin dose adjustment is therefore predicted to be needed during concurrent use. The two isolated cases of opposite effects are rarities, and unexplained. There is insufficient evidence to recommend monitoring all patients; however, bear the isolated case reports in mind in the event of an unexpected response.

Coumarins + Tetracyclic and related antidepressants

Mirtazapine may cause a slight increase in INR in subjects given warfarin. Maprotiline does not appear to alter the anticoagulant effect of acenocoumarol. Mianserin does not appear alter the anticoagulant effect of phenprocoumon, however, two isolated cases of an increased effect of warfarin and a decreased effect of acenocoumarol have been reported in patients taking mianserin.

Clinical evidence

(a) Maprotiline

In a study in 20 patients stabilised on **acenocoumarol**, the anticoagulant effects of **acenocoumarol** were not affected by maprotiline 50 mg three times daily for 2 weeks.[1]

(b) Mianserin

In a randomised, double-blind study in 60 patients taking **phenprocoumon** for 5 weeks, there was no difference in anticoagulant control and **phenprocoumon** dose between placebo recipients and those receiving mianserin, either up to 30 mg daily or up to 60 mg daily, for 20 days.[2]

A single case report describes a man stabilised on **warfarin** whose British standard ratio rose from 1.8 to 4.6 (prothrombin time rise from 20 to 25 seconds) after taking mianserin 10 mg daily for 7 days.[3] However, another patient taking **warfarin** received mianserin in varying doses of up to 120 mg daily for 22 weeks without any change in prothrombin ratio.[4] A further patient stabilised on **acenocoumarol** and amiodarone needed an *increase* in his **acenocoumarol** dose after starting mianserin, and a decrease when this drug was stopped.[5]

(c) Mirtazapine

In a study in healthy subjects stabilised on individual doses of **warfarin**,[6] mirtazapine 15 mg for 2 days then 30 mg daily for 5 days increased the mean INR from 1.6 to 1.8. This small increase was not considered clinically relevant by the authors of the study or by one of the UK manufacturers.[6,7] However, the manufacturer does state that a more pronounced effect cannot be excluded at higher doses of mirtazapine.[7]

Mechanism

Not understood. The cases with mianserin might just represent idiosyncratic reactions.

Importance and management

Maprotiline does not interact with acenocoumarol and mianserin does not interact with phenprocoumon. The isolated cases of an increase in warfarin effects and a decrease in acenocoumarol effects with mianserin are unexplained, and probably of little general relevance.

One UK manufacturer of mirtazapine very cautiously advises that the prothrombin time should be controlled if mirtazapine is given with warfarin.[7] However, there do not appear to be any reports of problems with this combination.

Coumarins and related drugs + Thyroid and Antithyroid compounds

Hypothyroidism decreases, and hyperthyroidism increases, the metabolism of the clotting factors. Correction of these disease states therefore alters anticoagulant requirements. Bleeding has been seen in patients given thyroid hormones without an adjustment of their warfarin dose, and increased coumarin requirements have been seen in patients given thiamazole or carbimazole.

Clinical evidence

(a) Hypothyroidism and Thyroid compounds

In a study in 7 patients with myxoedema (hypothyroidism), the response to a single dose of **warfarin** was increased after 3 months of treatment with **liothyronine** (when euthyroid), when compared with before treatment, without a change in plasma warfarin levels.[1]

Various case reports describe similar effects.[2-5] In one report, brief mention is made of one patient who had an increased response to **warfarin** after an increase in the dose of thyroid replacement therapy, and of another patient taking long-term **warfarin** who had a bleeding episode when thyroid replacement therapy was started.[2] Another patient taking **warfarin** developed oral mucosal bleeding with an INR of greater than 11 when her hypothyroidism was over-corrected with **levothyroxine**, although she had no clinical signs of hyperthyroidism.[3] In another case, a subdural haematoma occurred in a child stabilised on **warfarin** when **levothyroxine** was started, and her dose of **warfarin** was eventually reduced from 7.5 mg daily to 5 mg daily.[4]

A patient with myxoedema required a gradual reduction in his dose of **phenindione** from 200 mg daily to 75 mg daily as his thyroid status was corrected by **liothyronine**.[5] A similar patient required a reduction in the dose of **acenocoumarol**, from 16 mg daily to 5 mg daily, when hypothyroidism was corrected with **liothyronine**.[5]

(b) Hyperthyroidism and Antithyroid compounds

In 5 patients with hyperthyroidism, the response to a single dose of **warfarin** was decreased (prothrombin ratio 1.35 versus 1.75) after treatment with **iodine-131** (when euthyroid), when compared with before treatment. Three of the 5 patients required a small increase in their warfarin dose of between 0.5 mg and 1 mg. There was no significant difference in the plasma half-life of **warfarin**.[6] Another similar study also reported a decreased sensitivity to **warfarin** after correction of hyperthyroidism, but found that the plasma half-life and levels of **warfarin** were higher after treatment.[7]

Various case reports describe alterations in anticoagulant effects.[3,8-12] In one, a hyperthyroid patient taking **warfarin** had a marked increase in his prothrombin times on two occasions when his treatment with **thiamazole** (**methimazole**) was stopped and he became hyperthyroid again.[8] Another similar case has been described where the required dose of **warfarin** increased from 35 mg weekly to 65 mg weekly as the patients hyperthyroid state was corrected with **thiamazole** 30 mg daily. However, the patient then became hypothyroid and required up to 85 mg of **warfarin** weekly. When the **thiamazole** dose was withheld for 5 days and then reduced to 5 mg daily, the patient rapidly developed a raised INR of 7 without bleeding complications.[9] In another report, a patient required just 0.5 mg of **warfarin** daily while hyperthyroid.[3] Another case of possible enhanced response to **warfarin** in a hyperthyroid patient has been reported.[10,11] A woman taking **acenocoumarol**, required a dose reduction as she became hyperthyroid and the dose of **acenocoumarol** was increased again when she was treated with **carbimazole**.[12]

Mechanism

In hypothyroid patients the catabolism (destruction) of the blood clotting factors (II, VII, IX and X) is low and this tends to cancel, to some extent, the effects of the anticoagulants, which reduce blood clotting factor synthesis. Conversely, in hyperthyroid patients in whom the catabolism is increased, the net result is an increase in the effects of the anticoagulants.[13] In studies in healthy subjects, **dextrothyroxine** (which has weak thyroid activity compared with levothyroxine) potentiated the anticoagulant effect of **dicoumarol**[14] and warfarin[15] without altering the half-life and plasma levels of the anticoagulants, and without altering vitamin K-dependent clotting activity.[14] Because of this, it was suggested that the thyroid hormones might increase the affinity of the anticoagulants for its receptor sites.[14,15]

Importance and management

A well documented and clinically important interaction occurs if oral anticoagulants and thyroid hormones are taken concurrently.

Hypothyroid patients taking an anticoagulant who are subsequently treated with thyroid hormones as replacement therapy will need a downward adjustment of the anticoagulant dose as treatment proceeds if excessive hypoprothrombinaemia and bleeding are to be avoided. Conversely, as the thyroid status of hyperthyroid patients returns to normal with the use of antithyroid drugs (e.g. carbimazole, thiamazole, **propylthiouracil**) an increase in the anticoagulant requirements would be expected. As this is more of a drug-disease interaction rather than a direct drug-drug interaction, it is therefore likely to occur with any coumarin or indanedione given with any drug that affects thyroid function. Close anticoagulant monitoring and dose adjustment are required, particularly while thyroid hormone levels are being stabilised. Note that, in one case the authors commented that the magnitude and clinical complexity of the interaction between the drugs and disease state was unexpected.[9]

Note that propylthiouracil in the absence of an anticoagulant has very occasionally been reported to cause hypoprothrombinaemia and bleeding.[16,17]

Some drugs can alter thyroid status as an unwanted effect, and this will also alter the response to the oral anticoagulants. For example, amiodarone (see 'Coumarins and related drugs + Amiodarone', p.411), can cause thyrotoxicosis, which decreases warfarin requirements. Also, the use of **dextrothyroxine** for hypercholesterolaemia decreased the required dose of warfarin[18,19] and dicoumarol,[20] presumably because it has weak thyroid activity.

Coumarins + Tiabendazole

An isolated case report describes a marked increase in the anticoagulant effects of acenocoumarol in a patient given tiabendazole.

Clinical evidence, mechanism, importance and management

An increase in the anticoagulant effects of **acenocoumarol** occurred in a patient with nephrotic syndrome undergoing dialysis, who was given tiabendazole 8 g daily for 2 days, on two occasions about 7 weeks apart.[1] On both occasions, his INR rose from 2.9 to more than 5 without any clinical consequence. The reasons for this effect are not understood, nor is the general importance of this interaction known. There seem to be no other reports.

Coumarins and related drugs + Tibolone

Tibolone may increase the INR in some patients taking warfarin or phenindione.

Clinical evidence

In a well-controlled study in 16 postmenopausal women taking **warfarin**, the use of tibolone 2 mg daily for 21 days increased the mean INR by just 0.4. No clinically significant adverse effects occurred on concurrent use.[1] In a retrospective analysis, five women were identified who had started tibolone while taking **warfarin** or **phenindione**. All of the 5 patients had an increase in INR to a range of 4.6 to 9.5 after starting tibolone, and required reductions in their anticoagulant dose (range of 12 to 53% reductions in **warfarin** dose, and 56% for **phenindione**). One further patient who discontinued tibolone while taking **warfarin** required an increase in her **warfarin** dose from 6 to 7.5 mg daily.[2]

Mechanism

Not understood. Tibolone alone increases fibrinolytic activity without altering the prothrombin time,[3] and might therefore be expected to increase the risk of bleeding with anticoagulants. However, this would not result in raised INRs, and it was suggested that the effect on the INR might be because of the androgenic effect of tibolone causing a reduction in factor VIIa.[2]

Importance and management

There is very limited published information available on the concurrent use of warfarin and tibolone. The study suggests tibolone causes minor increases in INR; however, the retrospective analysis reported more clinically significant increases in the INR, and reduced warfarin and phenindione requirements of up to about 50%. Because of this, increased INR monitoring is advised when starting tibolone in patients stabilised on warfarin, other coumarins, or indanediones.

Coumarins + Ticlopidine

The anticoagulant effects of acenocoumarol may be modestly reduced by ticlopidine. However, the anticoagulant effects of warfarin are unchanged by ticlopidine. As with other antiplatelet drugs, concurrent use with coumarins might possibly increase bleeding risk. Cholestatic hepatitis has been reported in some patients given warfarin and ticlopidine.

Clinical evidence

(a) Acenocoumarol

A retrospective study of 36 patients with heart valve prostheses found that when they took ticlopidine 250 mg daily, 29 of them needed a mean 13% increase in their acenocoumarol dose from 15.5 to 17.5 mg weekly, accompanied by a small INR rise from 3.05 to 3.13. One patient needed a dose increase from 14 to 22 mg weekly. INR changes were detectable with a week of starting the ticlopidine.[1]

(b) Warfarin

Ticlopidine 250 mg twice daily for 2 weeks, given to 9 men taking warfarin long-term, increased the mean *R*-warfarin levels by 26% but did not change *S*-warfarin levels or their INRs.[2] *R*-warfarin is the much less active of the two enantiomers. In a Japanese study, 4 out of 132 patients (3%) given both warfarin and ticlopidine after cardiovascular surgery developed cholestatic hepatitis.[3]

Mechanism

It seems possible that ticlopidine inhibits the metabolism of *R*-warfarin, but the interaction with acenocoumarol is not understood. Ticlopidine alone can cause raised liver enzymes and cholestatic hepatitis,[4] and whether these cases with warfarin represent an interaction is unclear.

Importance and management

Information seems to be limited to the reports cited. A small to moderate increase in the acenocoumarol dose may be needed if ticlopidine is added, but none seems to be necessary with warfarin. However, as with other antiplatelet drugs, such as aspirin (see 'Coumarins and related drugs + Aspirin or other Salicylates', p.434), an increased risk of bleeding (a combination of anticoagulant and platelet anti-aggregant activity) might be anticipated on concurrent use. The manufacturer states that the long-term safety of concurrent use of ticlopidine with oral anticoagulants has not been established, and they recommend that if a patient is switched from an anticoagulant to ticlopidine, the anticoagulant should be discontinued before ticlopidine is given.[4] For discussion of the combined use of anticoagulants and dual antiplatelet therapy (aspirin plus a thienopyridine derivative such as ticlopidine), see under 'Coumarins and related drugs + Clopidogrel', p.448.

Whether the incidence of cholestatic hepatitis is higher with the concurrent use of warfarin and ticlopidine than with ticlopidine alone is unclear.

Coumarins + Tobacco

Smoking appears to cause a small increase in the clearance of warfarin and a minor reduction in warfarin levels, and two cases have been reported of patients who required warfarin dose reductions on stopping smoking.

One patient who stopped chewing tobacco had an increase in INR.

Clinical evidence

(a) Chewing tobacco

In a patient using smokeless tobacco (chewing tobacco) for greater than 85% of waking hours, the INR was found to have increased from 1.1 to 2.3 six days after discontinuation of tobacco use. This patient had usually had an INR of 1.1 to 1.9 since restarting warfarin 4 months earlier, despite gradually increasing the warfarin dose from 10 mg daily to 25 mg daily alternating with 30 mg daily. However, during this time, he did have two INR spikes of 2.5 and 4.2, which were attributed to dietary changes,[1] but see *Mechanism*, below.

(b) Smoking tobacco

In a controlled study in 9 healthy subjects who normally smoked at least one pack of cigarettes daily (size unknown) and who were given **warfarin** to steady-state, smoking abstention for about 6 weeks increased the average steady-state **warfarin** levels by 13%, decreased **warfarin** clearance by 13% and increased the **warfarin** half-life by 23%, but no changes in the prothrombin time occurred.[2] A population pharmacokinetic analysis similarly found that smoking appeared to increase **warfarin** clearance by 10%.[3]

An 80-year-old man taking **warfarin** had a steady rise in his INR (from a range of 2 to 2.8 up to 3.7) over a 3-month period when he gave up smoking. No bleeding occurred. His dose of **warfarin** was reduced by 14%, and the INR stabilised at 2.3 to 2.8 over the next 9 months.[4] Similarly, another patient required a 23% reduction in **warfarin** dose after stopping smoking following recovery from bacterial meningitis.[5]

In a retrospective study of factors relating to **warfarin** dose, smoking status appeared to be a factor in **warfarin** dose requirements.[6] In contrast, in one retrospective study of patients who had undergone cardiac valve replacement, there was no statistically significant difference between the **warfarin** dose requirements of 117 non-smokers, 23 light smokers (20 or less cigarettes daily) or 34 heavy smokers (greater than 20 cigarettes daily).[7] The same finding had earlier been briefly reported by the Boston Collaborative Drug Surveillance Program.[8] Note that smoking status had no effect on the AUC of *S*-warfarin in one study.[9]

Mechanism

Some of the components of tobacco smoke act as cytochrome P450 isoenzyme inducers, which might cause a small increase in the metabolism of warfarin. When smoking stops and the enzymes are no longer stimulated, the metabolism of warfarin falls slightly and its effects are correspondingly slightly increased. Tobacco smoke is known to induce CYP1A2, which has a partial role in the metabolism of the less active *R*-warfarin enantiomer. The metabolism of *S*-warfarin is primarily by CYP2C9, and this does not appear to be affected by smoking.[9]

The possible case of an interaction with smokeless tobacco was attributed to the very high vitamin K content of tobacco resulting in relative warfarin resistance (consider also 'Coumarins and related drugs + Vitamin K substances', p.520). However, there were two previous INR spikes in this patient, which were attributed to dietary changes,[1] an explanation that seems unlikely if there was a high background vitamin K intake from the tobacco. The reasons for the effects in this case are therefore unclear.

Importance and management

The overall picture seems to be that smoking (or giving up smoking) only has a slight to moderate effect on the response to warfarin, and only the occasional patient will need a small dose alteration. This should easily be detected in the course of routine INR checks. Note that tobacco smoking increases cardiovascular disease risk, and patients requiring anticoagulants should be encouraged and helped to stop smoking.

The isolated case with smokeless tobacco is unclear, further study is needed.

Coumarins + Tolterodine

In healthy subjects, tolterodine did not alter the pharmacokinetics or pharmacodynamics of warfarin, but isolated cases of raised INRs have been reported when patients taking warfarin also took tolterodine.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study in healthy subjects, tolterodine 2 mg twice daily for 7 days did not affect the pharmacokinetics of *R*- or *S*-warfarin after a single 25-mg dose of **warfarin** given on day 4, nor were the pharmacokinetics of tolterodine altered by **warfarin**. In addition, the prothrombin time and factor VII activity were not altered by tolterodine.[1]

However, a report describes 2 patients on stable **warfarin** doses who had elevated INRs shortly after tolterodine 2 mg daily was started and stopped: one patients had an INR of 6.1 one day after stopping tolterodine, which had been taken for 13 days, and the other patient had an INR of 7.4 two days after stopping tolterodine, which had been taken for 8 days. In both cases no bleeding occurred and **warfarin** was withheld for three doses and successfully reinstated at the original dose.[2] Another case report describes a patient who required a 15% reduction in her **warfarin** dose while taking tolterodine 4 mg daily. Her maximum INR had been 3.9. However, she had undergone several warfarin dose increases over the previous 2 months and her INR had been fluctuating.[3]

The controlled study suggests that no **warfarin** dose adjustment would be expected to be necessary when tolterodine is added to **warfarin**. However, the 3 cases introduce a note of caution. Although additional monitoring would seem over-cautious on the basis of these cases, bear them in mind in the case of an unexpected response to warfarin.

Coumarins + Trastuzumab

An isolated report describes an increase in the effects of warfarin in two women taking trastuzumab.

Clinical evidence, mechanism, importance and management

Two women stabilised on **warfarin** developed nosebleeds after 10 and 8 doses of trastuzumab (one dose given each week), and were found to have INRs of 6 and 5.8, respectively.[1] However, the manufacturer notes that, in an analysis of clinical study data, the rate of bleeding events was similar for patients receiving or not receiving trastuzumab, with or without anticoagulants.[2] There is no known mechanism for an interaction. Note that factors related to illness such as decreased appetite can alter **warfarin** requirements. The general relevance of these two cases is uncertain, but bear them in mind in the event of an unexpected response to treatment.

Note that, from a disease perspective, when treating venous thromboembolic disease in patients with cancer, **warfarin** is generally inferior (higher risk of major bleeds and recurrent thrombosis) to low-molecular-weight heparins.

Coumarins + Tricyclic antidepressants

Amitriptyline and nortriptyline do not appear to alter the half-life of warfarin, and probably do not alter that of dicoumarol. Limit-

ed evidence suggests that the use of tricyclics might be associated with greater variability in prothrombin times. An isolated case of the potentiation of warfarin by lofepramine has been reported.

Clinical evidence

(a) Dicoumarol

A study in 6 healthy subjects given **nortriptyline** 200 micrograms/kg three times daily for 8 days reported that it increased the mean half-life of dicoumarol from 35 hours to 106 hours. In a parallel group, the same dose of **nortriptyline** also increased the half-life of antipyrine.[1] However, in later identical studies by the same research group, **nortriptyline** decreased the half-life of antipyrine in one study, and had no effect in another.[2] The authors were unable to explain these disparate findings with antipyrine,[2] and they cast doubt on the results seen with dicoumarol. In a later study by another group, both **amitriptyline** 75 mg daily and **nortriptyline** 40 mg daily had no consistent effect on the half-life of a single dose of dicoumarol, although there was some evidence of increased dicoumarol plasma levels (about 24% with nortriptyline and 6% with **amitriptyline**).[3]

(b) Phenprocoumon

In a retrospective analysis of 7 patients taking phenprocoumon and **amitriptyline**, found unpredictable fluctuations in prothrombin times (said to be massive, both increases and decreases seen); these were absent in a control group of 7 other patients not taking **amitriptyline**. Note that the **amitriptyline** dose was not stable. Anticoagulant control improved on stopping the **amitriptyline** in 5 of the patients.[4] The same authors reported another similar case in a patient taking phenprocoumon and **amitriptyline**.[5]

(c) Warfarin

In a study in 12 healthy subjects,[3] **amitriptyline** 75 mg daily or **nortriptyline** 40 mg daily for 13 days did not affected the plasma half-life of a single dose of warfarin given on day 9. However, in the preliminary report of an analysis of 500 patients taking warfarin, a statistically significant difference in the warfarin dose index (prothrombin time prolongation/cumulative warfarin dose) before, during and after therapy was detected for a number of unexpected drugs including **amitriptyline**. However, no further details were given.[6] In another analysis of the stability of anticoagulant control in 277 patients, the use of tricyclics (**imipramine**, **amitriptyline**, **nortriptyline**) in 16 patients was associated with an increased need for anticoagulant dose modifications (average 3.56 over 6 months). Most of the patients were taking warfarin.[7]

Mechanism

Not understood. One suggestion is that the tricyclic antidepressants inhibit the metabolism of the anticoagulant (seen in *animals* with nortriptyline or amitriptyline and warfarin,[8] but not with **desipramine** and **acenocoumarol**[9]). However, the tricyclics are not established inhibitors of the metabolism of any drug so this seems unlikely. Another idea is that the tricyclics slow gastrointestinal motility because of their antimuscarinic effects, thereby increasing the time available for the dissolution and absorption of dicoumarol.[3]

Importance and management

Information about interactions between the coumarins and tricyclic antidepressants is limited, patchy and inconclusive. It appears that amitriptyline and nortriptyline do not alter the half-life of warfarin, and probably do not affect that of dicoumarol either. A greater fluctuation in anticoagulant control was noted in two analyses, one with warfarin and one with phenprocoumon. However, these were uncontrolled studies, and the findings need confirming in a randomised study. Moreover, there do not appear to be any published case reports of an interaction between tricyclics and warfarin. Thus, there is insufficient evidence to recommend any special precautions in patients taking coumarins and requiring tricyclics. However, consider the possibility of an interaction if the INR is difficult to stabilise.

Coumarins and related drugs + Vaccines; Influenza

The concurrent use of warfarin and influenza vaccination is usually safe and uneventful, but there are reports of bleeding in a handful of patients (life threatening in one case) attributed to an interaction. Acenocoumarol also does not normally interact with influenza vaccination.

Clinical evidence

(a) Effect on anticoagulant control

Seventeen studies on the effects of influenza vaccine on the anticoagulant effect of coumarins have been published, and these are summarised in 'Table 12.7', (p.517). Most of these are non-controlled studies in small to moderate numbers of patients, and the majority did not demonstrate a significant change in prothrombin time or INR in patients taking coumarins, including the only randomised placebo-controlled study, and one very large retrospective cohort study. Some studies found a slight change in anticoagulant effect (both slight increases and slight reductions), but they are probably of limited clinical relevance. However, in one large case-control study, a clear increase in INR from 2.64 to 3.85 was seen in about half of the 90 patients involved in the study, and 2 of these patients had bleeding episodes. The reasons for the clear difference between this study and the many others are not known.

There are also various brief case reports of a possible interaction. In one review paper, there is a very brief report of a patient receiving **warfarin** who had serious bleeding, which was almost fatal, after receiving a 'flu shot'. No further details are given.[1] An elderly man receiving **warfarin** developed bleeding (haematemesis and melaena) within 10 days of being given an influenza vaccination. His prothrombin time was found to be 36 seconds.[2]

(b) Route of injection of vaccine

In a randomised study in 26 patients stabilised on **warfarin**, there was no difference in injection site adverse events between intramuscular or subcutaneous injection of a standard trivalent influenza vaccine, and no patient had bruising or swelling. In addition, both routes of administration produced similar levels of antibody titres.[3] In another study that specifically assessed the local reactions to intramuscular influenza vaccination, there were no detectable local complications after intramuscular injection, including no change in arm circumference.[4]

Mechanism

Not understood. In a placebo-controlled study in healthy subjects, influenza vaccination did not alter the half-life of either *R*- or *S*-warfarin.[2] It has therefore been suggested that when an interaction occurs the synthesis of the blood clotting factors is altered.[2]

Importance and management

A well-investigated interaction, but with some contradictory data. The weight of evidence suggests that influenza vaccination in those taking warfarin is normally safe and uneventful; nevertheless, it would be prudent to be on the alert because very occasionally and unpredictably bleeding may occur. Acenocoumarol appears not to be affected. Limited evidence suggests that intramuscular administration of the vaccine is not associated with increased local complications, but also that subcutaneous administration is effective. Because of the theoretical risk of local muscle haematoma, it may be preferable to give influenza vaccines by deep subcutaneous injection in patients taking coumarins and related anticoagulants.

Table 12.7 Summary of the evidence for and against an interaction between influenza vaccine and coumarins

Study type (year)	*Group*	*Coumarin*	*Influenza vaccine*	*Route*	*Notes*	*Refs*
Studies showing no interaction						
Prospective (1983)	33 patients and 15 controls	Warfarin	Not stated	Not stated	No evidence of an interaction (one vaccinated patient had haematuria 27 days later, and one control patient had epistaxis)	1
Prospective series (1984)	21 patients	Stable warfarin	Trivalent type A and B, Wyeth	Not stated	No change in average prothrombin time at 0, 3, 7, 10 and 14 days after vaccination	2
Randomised, placebo-controlled (1984)	25 patients vaccinated and 25 placebo	Stable warfarin	Trivalent type A and B (*Fluvirin*)	Deep subcutaneous	No change in mean ratio of prothrombin times at 0, 2, 7 and 21 days after vaccination	3
Prospective (1984)	4 healthy subjects	Low-dose warfarin	*Influvac*	Intramuscular	No change in average prothrombin time at 7, 11, 14, 16, 21 and 28 days after vaccination, and no change in warfarin levels	4
Prospective series (1985)	7 patients	Stable warfarin	Trivalent type A and B, Wyeth	Not stated	No change in prothrombin time at 4, 6, 10, 14 and 21 days after vaccination	5
Prospective series (1986)	26 patients	Stable warfarin	Trivalent (subvirion) type A and B (*Fluogen*)	Intramuscular	No change in mean INR at day 14 after vaccination	6
Prospective series (1986)	7 patients and 9 controls	Stable warfarin	Trivalent type A and B, Wyeth	Not stated	No change in prothrombin time at 1, 3 and 5 weeks after vaccination, or compared with controls	7
Prospective series (1990)	9 patients	Stable warfarin	Trivalent, split virion, A and B (*MFV-Ject*)	Not stated	No significant change in INR at 3, 6, 8, 10, 13, 22 and 30 days after vaccination (mean decrease of 4.8%)	8
Prospective series (1993)	43 patients	Stable acenocoumarol	Trivalent type A and B	Subcutaneous	No change in mean INR at 7, 15 and 30 days after vaccination. INR values increased in 3 patients and decreased in 6 patients requiring modification in acenocoumarol dose	9
Prospective series (1995)	41 patients	Stable warfarin	Not stated	Intramuscular	No significant change in prothrombin time at 3, 7 and 14 days after vaccination, and no local complications	10
Prospective series (2007)	78 patients	Stable warfarin	Not stated	Not stated	No apparent effect on INR within 10 days of vaccination	11
Retrospective cohort (2007)	4923 patients	Stable warfarin	Trivalent inactivated	Not stated	No change in mean INR in the 14 or 28 days after vaccination	12
Studies showing an increase in effect						
Prospective series (1984)	8 patients	Stable warfarin	Trivalent type A and B	Not stated	All patients had an increase in prothrombin time to at least the upper limit of their range for the previous year (40% from baseline)*	13
Prospective series (1986)	10 patients	Stable warfarin	Trivalent (subvirion) type A and B (*Fluogen*)	Intramuscular	Slight maximal 7.6% increase in mean INR at day 14 after vaccination	6
Case-control (2003)	90 patients and 45 controls	Stable warfarin (98%) Acenocoumarol (2%)	*Inflexel V, Isiflu V, Fluad*, or *Agrippal*	Intramuscular	49 out of 90 patients had a clear increase in INR from a mean of 2.64 to 3.85, and 2 of these had bleeding episodes. In the remaining patients and controls there was no change in INR	14
Studies showing a decrease in effect						
Prospective series (1988)	24 patients	Stable warfarin	Trivalent type A and B	Not stated	A slight 8.3% decrease in prothrombin time occurred in the first 2 weeks after vaccination.	15
Prospective series (2002)	73 patients and 72 controls	Stable warfarin	Not stated	Subcutaneous	Overall, there was no change in anticoagulation, but the 34 vaccinated patients aged 70 or more had a slight reduction in INR in month after vaccination (mean 2.8 versus 2.99)	16

*Other researchers[5] state that their analysis of these data failed to show a statistical difference after vaccination.

Coumarins + Vaccines; Miscellaneous

Pneumococcal, tetanus with diphtheria toxoid, and hepatitis A vaccines do not appear to alter the response to warfarin.

Clinical evidence, mechanism, importance and management

In a large, retrospective, cohort study in patients stabilised on warfarin, there was no clinically relevant change in INR found between mean values in the 14 days or 28 days after vaccination with a 23-valent **pneumococcal polysaccharide** vaccine (1207 patients), **tetanus** plus **diphtheria toxoid** vaccine (1024 patients), or **hepatitis A** vaccine (121 patients) compared with mean values at other times. The change in mean INR was 0.01 to 0.03.[1] Similarly, in an earlier placebo-controlled study, a 14-valent **pneumococcal vaccine** (*Pneumovax*) did not have any effect on anticoagulant control at 2, 7 and 21 days after vaccination.[2] These studies suggest that no alteration in coagulation status would be anticipated after use of these vaccines.

For discussion of the numerous studies with influenza vaccine, see 'Coumarins and related drugs + Vaccines; Influenza', p.516.

Coumarins + Valproate

An isolated case describes a patient who had an increase in her INR the day after starting valproic acid, but was eventually restabilised on the original dose of warfarin while still taking the valproic acid. Valproic acid did not alter the anticoagulant effects of phenprocoumon in one patient. Note that valproate alone can cause altered bleeding time, bruising, haematoma, epistaxis, haemorrhage, and thrombocytopenia.

Clinical evidence

A woman was given **warfarin** for a deep vein thrombosis, and was stabilised on 5 mg alternating with 2.5 mg daily with an INR of between 1.8 and 2.6. Valproic acid 250 mg twice daily and fluphenazine 5 mg daily were then added. The morning after her first dose of valproic acid, the INR increased to 3.9, and **warfarin** dose was decreased to 2.5 mg daily. Four days later the valproic acid dose was doubled, and numerous **warfarin** dose adjustments were needed to keep the INR therapeutic. However, 3 weeks after starting the valproic acid she was discharged on the same **warfarin** dose as before the valproic acid was started.[1] In one patient taking **phenprocoumon**, valproic acid 500 mg to 1 g daily did not alter the prothrombin time ratio.[2]

Mechanism

There is *in vitro* evidence that the serum binding of warfarin is decreased by sodium valproate so that free warfarin levels rise,[1,3,4] by 32% according to one study.[1] The increase in free warfarin levels is transient until a new equilibrium is reached, but theoretically could result in a transient increase in INR, as is seen with cloral hydrate (see 'Coumarins + Cloral hydrate and related drugs', p.449).

Valproate inhibits the second stage of platelet aggregation, and a reversible prolongation of bleeding times and thrombocytopenia has been reported, usually with high doses, which can result in spontaneous bruising and bleeding.

Importance and management

Evidence for an interaction is limited. There seem to be no other reports of problems associated with the concurrent use of valproate and warfarin, nor any other direct evidence that an interaction of clinical importance normally occurs. It may be that any interaction occurs only transiently when valproate is added, and the situation rapidly restabilises without any real need to adjust the warfarin dose. Nevertheless, the manufacturers of sodium valproate and divalproex recommend closely monitoring the prothrombin time because of the possibility of warfarin protein binding displacement.[5-8] Note that valproate alone can cause thrombocytopenia and spontaneous bruising or bleeding, and if these effects occur, the manufacturers recommend withdrawing valproate pending investigations.[5-8] A reduction of the valproate dose or permanent withdrawal of valproate may be required.[6]

Coumarins + Varenicline

Varenicline does not appear to alter the pharmacokinetics or anticoagulant effect of warfarin.

Clinical evidence, mechanism, importance and management

In a controlled study in 24 smokers, varenicline 1 mg twice daily for 13 days had no effect on the pharmacokinetics of a single 25-mg dose of warfarin given on day 8. There was no difference in warfarin pharmacodynamics (INR time curve).[1] The lack of pharmacokinetic interaction is consistent with *in vitro* findings.[1] No warfarin dose adjustments would be expected to be needed in patients taking varenicline. Nevertheless, bear in mind that smoking cessation (for which varenicline is used as an aid) can sometimes cause a minor to modest decrease in warfarin requirements, see 'Coumarins + Tobacco', p.514.

Coumarins and related drugs + Viloxazine

A single report describes three cases where viloxazine possibly increased the anticoagulant effects of acenocoumarol and fluindione.

Clinical evidence

An 82-year-old woman with angina, hypertension and atrial fibrillation, who was taking **acenocoumarol**, molsidomine and flunitrazepam, had a rise in her INR from 3.3 to 7.9 when she started to take viloxazine (dose not stated) for depression. Five days after stopping the viloxazine her INR had fallen to 2.6. This report also briefly describes two other cases where viloxazine possibly caused an increase in the anticoagulant effects of **acenocoumarol** and **fluindione**.[1]

Mechanism

Not understood. The authors of the report suggest that viloxazine possibly inhibits cytochrome P450 within the liver, resulting in a reduction in the metabolism of the anticoagulants.[1]

Importance and management

Information seems to be limited to this report so that its general importance is uncertain. Be alert for the need to reduce the dose of acenocoumarol and fluindione if viloxazine is added to established anticoagulant treatment. Take the same precautions with any of the other coumarin or indanedione anticoagulants, but so far there seems to be no direct evidence that they interact.

Coumarins + Vinpocetine

In healthy subjects, the anticoagulant effect and the AUC of warfarin was slightly reduced by vinpocetine.

Clinical evidence, mechanism, importance and management

In a study in 18 healthy subjects taking vinpocetine 10 mg three times daily for 19 days, the anticoagulant effects and pharmacokinetics of a single 25-mg dose of **warfarin** were compared when given before vinpocetine was started, and on day 15.[1] A small 15% reduction in the mean prothrombin time occurred, and also an 8% reduction in the AUC of **warfarin**. The clinical relevance of these changes is unclear; however, they are slight, and a clinically relevant interaction would not be expected.

1. Hitzenberger G, Sommer W, Grandt R. Influence of vinpocetine on warfarin-induced inhibition of coagulation. *Int J Clin Pharmacol Ther Toxicol* (1990) 28, 323–8.

Coumarins + Vitamin E substances

The anticoagulant effects of warfarin are usually unchanged by small to large doses of vitamin E, although one isolated case of bleeding has been attributed to concurrent use. The effects of dicoumarol may be slightly increased by vitamin E.

Clinical evidence

(a) Dicoumarol

A study in 3 healthy subjects found that 42 units of vitamin E daily for one month increased the response to a single dose of dicoumarol after 36 hours (decrease in prothrombin activity from 52% to 33%).[1]

(b) Warfarin

In a double-blind, placebo-controlled study in 25 patients stabilised on warfarin, moderate to large daily doses of vitamin E (800 or 1200 units) for one month caused no clinically relevant changes in prothrombin times and INRs.[2] Similarly, in another study in 12 patients taking warfarin, the anticoagulant effects of warfarin were unchanged by smaller daily doses of 100 or 400 units of vitamin E given for 4 weeks.[3]

However, in one case, a patient taking warfarin (and multiple other drugs) developed ecchymoses and haematuria, which was attributed to him taking 1 200 units of vitamin E daily over a 2-month period. His prothrombin time was found to be 36 seconds. A later study in this patient found that 800 units of vitamin E daily for 6 weeks reduced his blood clotting factor levels, increased the prothrombin time from about 21 seconds to 29 seconds, and caused ecchymoses.[4] In addition, a modest rise in the INR of one patients with *Curbicin* was considered to be possible due to the presence of vitamin E in the *Curbicin* preparation (each tablet contains 10 mg).[5] For further information, see 'Coumarins + *Curbicin*', p.452.

Moreover, in a population cohort study, the concurrent use of vitamin E and warfarin was associated with an increased risk of mortality (adjusted hazard ratio 3.7). The hazard ratio for warfarin alone was 1.6 and for vitamin E alone was 0.91. The findings of this observational data require confirmation.[6]

Mechanism

Not understood. The suggested explanation is that vitamin E interferes with the activity of vitamin K in producing the blood clotting factors,[4,7] and increases in the dietary requirements of vitamin K.[8,9]

Importance and management

Information is limited but the evidence suggests that most patients taking warfarin are unlikely to have changes in coagulation status if given even quite large daily doses (up to 1 200 units) of vitamin E. Nevertheless, the isolated case cited here suggests that occasionally and unpredictably the warfarin effects can be changed. It has been recommended that prothrombin times should be monitored when vitamin E is first given (within one to 2 weeks has been recommended).[2] The same precautions could be applied to dicoumarol as well. However, as only one case of bleeding has been reported this does seem somewhat over-cautious. However, the finding of higher mortality in the observation cohort introduces some caution about the value of vitamin E supplements in patients taking warfarin. This requires further study. Information about other oral anticoagulants is lacking.

Coumarins and related drugs + Vitamin K substances

The effects of the coumarin and indanedione anticoagulants can be reduced or abolished by vitamin K_1 (phytomenadione). Unintentional and unwanted antagonism can occur in patients unknowingly taking vitamin K_1. There is also a case of antagonism of acenocoumarol in a patient using a proprietary chilblain product containing the vitamin K_4 substance acetomenaphthone.

Clinical evidence

A woman taking **acenocoumarol** had a fall in her British Corrected Ratio to 1.2 (normal range 1.8 to 3) within 2 days of starting to take a non-prescription chilblain preparation (*Gon*) containing **acetomenaphthone** 10 mg per tablet. She took a total of 50 mg of vitamin K_4 over 48 hours.[1]

Mechanism

The coumarin and indanedione oral anticoagulants are vitamin K antagonists, and probably inhibit the enzyme vitamin K epoxide reductase so reducing the synthesis of vitamin K-dependent blood clotting factors by the liver. If the intake of vitamin K_1 increases, the competition swings in favour of the vitamin and the synthesis of the blood clotting factors begins to return to normal. As a result the prothrombin time also begins to fall to its normal value. The role of other vitamin K substances, such as K_4 and K_2, in coagulation is less clear.

Importance and management

The interaction with vitamin K_1 is very well established and clinically important, and is expected to occur with every coumarin and indanedione oral anticoagulant because they have a common mode of action as vitamin K antagonists. Vitamin K treatment is used as an effective antidote for excessive oral anticoagulation. The drug intake and diet of any patient who shows warfarin resistance should be investigated for the possibility of this interaction. It can be accommodated either by increasing the anticoagulant dose, or by reducing the intake of vitamin K_1. For more information on specific situations, see 'Coumarins + Vitamin K_1-containing dietary supplements', below, 'Coumarins and related drugs + Food; Enteral and parenteral nutrition', p.461, and 'Coumarins and related drugs + Food; Vitamin K_1-rich', p.464.

However, the role of other vitamin K substances in coagulation is less clear. The case report with acetomenaphthone, a vitamin K_4 substance suggests that this can also antagonise the effect of vitamin K antagonists. It may be prudent for patients to avoid preparations containing this substance. Similarly, the antagonism of coumarins by fermented soya beans has been attributed to the vitamin K_2 content (see 'Coumarins + Food; Soya bean products', p.463).

Coumarins + Vitamin K_1-containing dietary supplements

In patients with normal vitamin K status, multivitamin supplements containing small amounts of vitamin K_1 (phytomenadione) will generally have no clinically important effect on the INR or anticoagulant requirements. Larger doses of vitamin K are likely to require a dose adjustment in a proportion of patients. Conversely, in patients with poor vitamin K status, even low vitamin K doses may have an important effect.

Clinical evidence

In a controlled study in healthy subjects stabilised on individual doses of **acenocoumarol**, the dose of vitamin K_1 tablets required to cause a statistically significant reduction in INR was 150 micrograms daily (INR 1.59 versus 2.04). Each dose of vitamin K_1 was taken daily for a week, and in successive weeks the dose was increased in increments of 50 micrograms from 50 to 300 micrograms daily, then 500 micrograms daily for the final week. The authors noted that their usual clinical criteria requiring an adjustment in **acenocoumarol** dose would have been met in 3 of the 12 subjects at a dose of vitamin K_1 of 150 micrograms daily.[1]

However, in another study in 9 patients stabilised on **warfarin** with low vitamin K levels the median INR dropped by 0.51 requiring a **warfarin** dose increase of 5.3% after they took just one multivitamin tablet containing vitamin K_1 25 micrograms daily for 4 weeks. Conversely, in a control group with normal plasma vitamin K levels, the same multivitamin did not change the INR or warfarin requirement.[2] In a well-controlled study in patients with unstable control of anticoagulation, vitamin K_1 150 micrograms daily increased the **warfarin** requirement by 16% from a mean of 3.8 mg daily to 4.4 mg daily, but also improved stability of control.[3]

In another study in patients taking **phenprocoumon**, supplementation with vitamin K_1 50 micrograms daily for 3 weeks had little effect on the INR, and required just a 3% increase in **phenprocoumon** dose. A higher dose of vitamin K_1 of 100 micrograms daily resulted in a mean dose increase of 9%. On stopping the supplements, a mean 7% decrease in dose was needed. However, there was wide variation between patients.[4]

A patient who required **warfarin** 15 to 17.5 mg daily to maintain an INR of about 3 was found to be taking vitamin K (dose not stated) as part of a vitamin supplement. When he stopped taking the vitamin K, his **warfarin** dose requirement decreased to between 10.5 and 12.5 mg daily.[5] In another report, a woman required an increase in her **warfarin** dose from 45 mg to 60 mg weekly when she started taking a daily multivitamin containing vitamin K_1 25 micrograms (*Centrum Plus*). Two weeks after stopping the multivitamin, she had haematuria and flank pain and was found to have a haematoma of the kidney and an INR of 13.2. A second patient had an acute occlusion of an aorto-bifemoral graft, requiring emergency surgery, 4 weeks after starting *Centrum Plus*. His INR had fallen from a mean of 2.48 to 1.1. A third patient had a fall in INR from a mean of 2.54 to 1.65 after taking *Centrum Plus* for 2 weeks. It was suggested that all three patients had low levels of vitamin K.[6]

Mechanism

Vitamin K_1 reduces the effect of vitamin K-antagonists (coumarins and **indanediones**). The dose of vitamin K_1 at which this becomes clinically important appears to depend on the vitamin K status of the individual.

Importance and management

The data from the controlled studies suggest that taking multivitamin supplements containing 10 to 50 micrograms of vitamin K_1 is probably acceptable in most patients taking coumarins or indanediones, and is likely to require no change or only small changes to the anticoagulant dose. However, in patients with poor vitamin K status, even these low levels of vitamin K may be sufficient to antagonise the effect of the anticoagulant. Note that a review of selected US supplements found that they contained 10 to 80 micrograms of vitamin K_1. Therefore, patients should be advised to *not* take a multivitamin preparation containing vitamin K_1 (phytomenadione) without increased monitoring when starting or stopping treatment. Because of this, and because of the increasing recognition of the importance of vitamin K in bone health, some consider that patients taking anticoagulants should be advised to consume sufficient vitamin K to meet the recommended adequate intakes.[7] Consider also *Importance and management* under 'Coumarins and related drugs + Food; Vitamin K_1-rich', p.464. Others have even suggested that a low and steady vitamin K supplement may reduce the risk of excessive anticoagulation without altering efficacy.[3,8]

Coumarins + Vitamin K_1-rich herbal medicines

A man had a modest rise in his INR after stopping taking a herbal nutritional supplement (*Nature's Life Greens*), which contained a number of plants known to be high in vitamin K_1. Another patient had a subtherapeutic INR after starting to drink a plant extract juice (called *Noni Juice*).

Clinical evidence, mechanism, importance and management

(a) Nature's Life Greens

A 72-year-old man stabilised on **warfarin** was found to have an INR of 4.43 at a routine clinic visit, which was increased from 3.07 six weeks previously. The patient had stopped taking a herbal product *Nature's Life Greens* that month because he did not have enough money to buy it. He had been taking it for the past 7 years as a vitamin supplement because he had previously been instructed to limit his intake of green leafy vegetables. He was eventually restabilised on **warfarin** and the same nutritional product.

The product label listed 25 vegetables without stating the amounts or concentrations,[1] but at least 5 of the listed ingredients are known to contain high levels of vitamin K_1 including **parsley**, **green tea leaves**, **spinach**, **broccoli**, and **cabbage** (see also 'Coumarins and related drugs + Food; Vitamin K_1-rich', p.464). It is therefore likely it contained sufficient vitamin K to antagonise the effect of the **warfarin** so that when it was stopped the warfarin requirements fell, and without an appropriate adjustment in dose, this resulted in an increased INR.

This case reinforces the view that all patients taking **warfarin** should seek advice when they want to stop or start any herbal medicine or nutritional supplement.

(b) Plant extracts juices

A 41-year-old woman stabilised on **warfarin** was found to have an INR of 1.6 at a routine clinic visit. The only possible cause identified was that the patient had begun to drink one to two small glasses daily of *Noni Juice 4 Everything*. This was identified as a brown liquid that contains extracts and derivates from more than 115 components. The authors noted that many of the listed plants contained vitamin K and that vitamin K was listed as a separate component, indicating that the juice might have been fortified with vitamin K. The patient was given heparin and then discharged on her previous dose of **warfarin**, and advised to stop taking this brand of juice.[2]

The authors concluded that this case reinforces the view that all patients taking **warfarin** should seek advice when they want to stop or start any herbal medicine or nutritional supplement.

Coumarins + Zileuton

Zileuton slightly increases the anticoagulant effects of warfarin and slightly increases *R*-warfarin levels.

Clinical evidence

In a placebo-controlled study, zileuton 600 mg every 6 hours for 6 days or placebo was given to healthy subjects who had been stabilised on racemic **warfarin** to achieve prothrombin times of 14 to 18 seconds for one week. The zileuton had no effect on the pharmacokinetics of *S*-warfarin, but the *R*-warfarin AUC rose by 22%, and its clearance fell by 15%. The mean prothrombin times increased by 2.3 seconds (morning) and 2 seconds (evening) in the zileuton group. The corresponding increases in the placebo group were 0.7 and 0.2 seconds, respectively.[1]

Mechanism

It seems likely that zileuton inhibits the metabolism of *R*-warfarin, probably by the cytochrome P450 isoenzyme CYP1A2.[2]

Importance and management

Information seems to be limited to this study, but the pharmacokinetic interaction appears to be established. The clinical significance of a 2 second rise in prothrombin times is unclear, but it seems likely to be small. The lack of any published reports of problems with the combination would tend to support this.

Drotrecogin alfa + Other drugs that affect coagulation

The concurrent use of drotrecogin alfa and prophylactic doses of heparin causes a slight increased risk of non-serious bleeding. The manufacturers of drotrecogin alfa caution its use in patients taking or who have recently received therapeutic doses of heparin, hirudins, oral anticoagulants, antiplatelet drugs, NSAIDs, prostacyclins, and thrombolytics.

Clinical evidence, mechanism, importance and management

(a) Heparins

Heparins are frequently used for prophylaxis of venous thromboembolic events in patients with severe sepsis. Because drotrecogin alfa increases the risk of bleeding, there has been concern that its use with heparin would further increase bleeding risk. Nevertheless, in phase III studies of drotrecogin alfa, two-thirds of patients received prophylactic doses of heparin or low-molecular-weight heparin with no observed increase in the risk of serious bleeding events reported.[1,2] Moreover, in a more recent study in patients treated with drotrecogin and randomised to receive prophylactic heparins or placebo, no increased risk of serious bleeding or adverse effects was found.[3] Except for a slight increase in any bleeding event in the first 6 days (10.8% heparin, 8.1% placebo), there was no difference in serious bleeding events, central nervous system bleeding events, or fatal bleeds on concurrent use. The US manufacturer notes that, in this study, the clearance and steady-state level of drotrecogin alfa (24 micrograms/kg per hour for 96 hours) was not affected by prophylactic **enoxaparin** 40 mg every 24 hours, or **unfractionated sodium heparin** 5000 units every 12 hours (although this was not evaluated when heparin 5000 units was given every 8 hours).[4] It therefore appears that low-dose heparin may be given for the prophylaxis of venous thromboembolic events concurrently with drotrecogin alfa. No dose adjustments are required.[1]

There appear to be little data on using drotrecogin alfa with therapeutic doses of heparin. The US manufacturer states that the increased risk of bleeding should be carefully considered when deciding to use drotrecogin alfa with therapeutic doses of heparin for treating an active thromboembolic event.[4] In the UK, the manufacturers specifically contraindicate use with heparin at doses of 15 units/kg per hour or more.[1]

(b) Other drugs affecting coagulation

Because of the possible increased risk of bleeding, the manufacturers state that the risks of giving drotrecogin alfa should be weighed against the benefits in patients who have received **thrombolytics** within 3 days, **oral anticoagulants** within 7 days, or **aspirin** (US information specifies greater than 650 mg daily) or other **antiplatelet drugs** within 7 days.[1,4] Caution should be used when prescribing these drugs and other drugs that affect haemostasis, such as the **hirudins**, **prostacyclins** such as **iloprost**, and other drugs that adversely affect platelet function such as **NSAIDs**, in patients given drotrecogin alfa.[1]

Fondaparinux + Antiplatelet drugs or NSAIDs

Neither aspirin nor piroxicam appear to alter the pharmacokinetics of fondaparinux, and no significant change in bleeding time has been reported with concurrent use. However, concurrent use may be expected to increase the risk of bleeding.

Clinical evidence

In a study in 16 healthy subjects, a single 975-mg dose of **aspirin** given on day 4 of an 8-day course of subcutaneous fondaparinux 10 mg daily had no effect on fondaparinux pharmacokinetics. The increase in bleeding time with fondaparinux and **aspirin** was greater than with **aspirin** alone, but this was not statistically significant. **Aspirin** had no effect on the small prolongation of aPTT seen with fondaparinux.[1]

In another study, **piroxicam** 20 mg daily for 10 days was given to 12 healthy subjects with fondaparinux 10 mg daily starting on day 7. Both drugs were also given alone. **Piroxicam** had no effect on fondaparinux pharmacokinetics, and had no effect on the small prolongation of aPTT seen with fondaparinux. There was no difference in bleeding time between the treatments.[1]

Mechanism

Fondaparinux commonly causes bleeding as a consequence of its action.[2] As antiplatelet drugs and NSAIDs also increase the risk of bleeding, the risk and severity of bleeding is likely to be increased with the combination.

Importance and management

The pharmacological studies described show that the pharmacokinetics of fondaparinux are not changed by aspirin and piroxicam, and that there is only a minor increase in bleeding time. Nevertheless, the manufacturers of fondaparinux say that antiplatelet drugs (**aspirin**, **dipyridamole**, **sulfinpyrazone**, **ticlopidine** or **clopidogrel**) and NSAIDs should be used with caution because of the possible increased risk of haemorrhage. They recommend that if concurrent use is essential, close monitoring is necessary.[2,3] This is considered particularly important in patients undergoing peridural or spinal anaesthesia or spinal puncture, in whom antiplatelet drugs, NSAIDs and fondaparinux are possible risk factors for epidural or spinal haematoma resulting in prolonged or permanent paralysis.[2,3]

Fondaparinux + Miscellaneous

In the UK, the manufacturer of fondaparinux recommends avoiding other drugs that may enhance the risk of haemorrhage. They specifically name, desirudin, fibrinolytics, glycoprotein IIb/IIIa-receptor antagonists, heparin, heparinoids and low-molecular-weight heparins.[1] Similarly, in the US, the manufacturer states that drugs that may enhance the risk of haemorrhage should be discontinued before starting fondaparinux. They say that if concurrent use is essential, close monitoring may be appropriate.[2] See also 'Coumarins + Fondaparinux', p.461, and 'Fondaparinux + Antiplatelet drugs or NSAIDs', above.

Heparin and LMWHs + Antiplatelet drugs; Aspirin

The concurrent use of aspirin with heparin or low-molecular-weight heparins slightly increases the risk of haemorrhage. Concurrent use may be a contributing factor to the very rare complication of epidural or spinal haematoma occurring after epidural anaesthesia.

Clinical evidence

(a) Heparin

Eight out of 12 patients with hip fractures developed serious bleeding when they were given heparin 5 000 units subcutaneously every 12 hours and aspirin 600 mg twice daily as perioperative prophylaxis for deep vein thrombosis. Haematomas of the hip and thigh occurred in 3 patients, bleeding through the wound in 4, and uterine bleeding in the other patient.[1] In a large, randomised, placebo-controlled study, aspirin 500 mg three times daily, subcutaneous heparin 5000 units twice daily, or the combination were compared for prophylaxis of deep vein thrombosis in 1 210 patients undergoing surgery. Haemorrhage severe enough to discontinue the prophylaxis occurred in significantly more patients in the combination group (11 of 402 patients versus 3 of 404 patients in the heparin and aspirin alone groups). In addition, minor haemorrhage occurred more frequently in the combination group (89 patients) compared with aspirin alone (41 patients) or heparin alone (30 patients).[2] In another randomised study in patients with acute unstable angina, the combination of aspirin 325 mg twice daily and an intravenous infusion of heparin 1 000 units/hour resulted in slightly greater incidence of serious bleeding than either drug alone (3.3% for concurrent use versus 1.7% for either drug alone).[3]

In an epidemiological study of hospitalised patients receiving heparin, the incidence of bleeding was almost 2.4 times higher in 302 patients also receiving aspirin than in 2354 patients not given aspirin (doses not stated). Surgical patients were excluded from this analysis, as were patients with a discharge diagnosis of cancer or haematological disease.[4]

(b) LMWHs

In a crossover study in 9 healthy subjects, the bleeding time was prolonged by the use of aspirin 300 mg daily and subcutaneous **reviparin** 6 300 units daily, when compared with either drug alone (9.6 minutes versus 5.5 minutes and 5 minutes, respectively). However, the affect of aspirin on platelet aggregation and the effect of **reviparin** on aPTT were not altered by concurrent use.[5] However, in a clinical study in patients undergoing surgery for total hip or knee replacement, there was no difference in risk of bleeding or other bleeding-related parameters (total blood loss, need for transfusion, mean change in haemoglobin levels) between patients receiving **enoxaparin** and aspirin (51 patients) and those receiving **enoxaparin** and no aspirin (394 patients). Aspirin use was low-dose (up to 500 mg daily).[6] In addition, in an analysis of risk factors for bleeding in patients receiving **enoxaparin** for treating acute coronary syndrome, the use of aspirin was not associated with an increased risk of any bleeding.[7]

During a 5-year period in one hospital, 3 elderly patients had presented with sudden severe abdominal pain after coughing, which was found to be due to a rectus muscle sheath haematoma. These patients had been receiving subcutaneous **enoxaparin** 40 mg daily for an average of 6 days with aspirin 100 mg daily.[8] Other cases of retroperitoneal haematoma have been reported with **enoxaparin** in which aspirin may have been one of various contributing factors.[9-12] Similarly, the use of aspirin may have been one of a number of contributing factors in a case of spinal epidural haematoma occurring with **enoxaparin**.[13]

Mechanism

Aspirin inhibits platelet aggregation and prolongs bleeding times, and increases the risk of upper gastrointestinal haemorrhage, even at doses of 300 mg daily and less.[14] This risk is likely to be higher in patients also taking anticoagulants. See also 'Coumarins and related drugs + Aspirin or other Salicylates', p.434.

Importance and management

The concurrent use of heparin or LMWHs with aspirin is indicated in specific situations such as the prophylaxis of ischaemic complications of

unstable angina.[15] However, unless specifically indicated, it may be prudent to avoid the concurrent use of aspirin with these drugs, because of the likely increased risk of bleeding. If they are used together, some caution and consideration of increased monitoring would seem appropriate.

Heparin and some LMWHs have rarely caused epidural or spinal haematomas resulting in long-term or permanent paralysis when used for thromboprophylaxis in procedures involving spinal/epidural anaesthesia or spinal puncture. The risk of this may be increased if they are used concurrently with other drugs affecting haemostasis such as aspirin, and extreme caution is needed if concurrent use is considered appropriate in these situations.

Heparin and LMWHs + Antiplatelet drugs; Miscellaneous

The dose of heparin does not need adjusting when clopidogrel is also given. The antiplatelet effects of clopidogrel are not altered by heparin. Nevertheless, the concurrent use of heparin or low-molecular-weight heparins with antiplatelet drugs, such as clopidogrel, prasugrel, and ticlopidine, may increase the risk of bleeding.

Clinical evidence

(a) Clopidogrel

In a placebo-controlled study in 12 healthy subjects, the dose of heparin given over 4 days did not need modification when clopidogrel 75 mg daily was also given, and the inhibitory effects of clopidogrel on platelet aggregation were unchanged by concurrent use.[1] Moreover, the manufacturers of clopidogrel note that in various large clinical studies in patients with acute coronary syndrome or myocardial infarction, most patients received heparin or LMWHs without an obvious difference in the rate of bleeding or the incidence of major bleeding.[2,3] Nevertheless, in an analysis of risk factors for bleeding in 208 patients receiving **enoxaparin** for acute coronary syndrome, the use of clopidogrel was associated with an increased risk of any bleeding (odds ratio 2.49).[4]

In one case the use of **enoxaparin** with clopidogrel was considered to be a contributing factor in a case of spinal epidural haematoma occurring after spinal anaesthesia.[5] Another similar case occurred in a patient taking clopidogrel and given **dalteparin**,[6] and serious retroperitoneal bleeding occurred in a patient with acute coronary syndrome receiving **enoxaparin**, clopidogrel and aspirin.[7]

(b) Prasugrel

The manufacturer reports that heparin, given as a single intravenous bolus of 100 units/kg, had no significant effect on the antiplatelet effect of prasugrel. They also report that no clinically significant interaction was reported with the use of prasugrel and LMWHs in phase III clinical studies. However, they advise that concurrent use may possibly increase the risk of bleeding.[8]

(c) Ticlopidine

The manufacturer of ticlopidine notes that it has been used concurrently with heparin for about 12 hours in studies of cardiac stenting, but that longer-term safety has not been established.[9]

Mechanism

Antiplatelet drugs increase the risk of bleeding, and the risk is likely to be increased further in patients who are anticoagulated with heparin or LMWHs.

Importance and management

The concurrent use of heparin or LMWHs with antiplatelet drugs such as clopidogrel is indicated in specific conditions such as acute coronary syndrome. However, unless specifically indicated, the concurrent use of heparin or LMWHs with antiplatelet drugs should probably be avoided because of the likely increase in haemorrhagic risk. If they are used together, the manufacturers of the LMWHs (**bemiparin**, dalteparin, enoxaparin, **tinzaparin**) recommend caution or careful clinical and laboratory monitoring.

Heparin and some LMWHs have rarely caused epidural or spinal haematomas resulting in long-term or permanent paralysis when used for thromboprophylaxis in procedures involving spinal/epidural anaesthesia or spinal puncture. The risk of this may be increased if they are used concurrently with other drugs affecting haemostasis such as antiplatelet drugs, and extreme caution is needed if concurrent use is considered appropriate in these situations.

Heparin + Aprotinin

The activated clotting time (ACT) may not be a reliable method to monitor heparin when aprotinin is used concurrently. This is because aprotinin increases the ACT monitored by some methods, without actually increasing anticoagulation.

Clinical evidence, mechanism, importance and management

Aprotinin prolongs the activated clotting time (ACT) as measured by a celite surface activation method, although the kaolin ACT is much less affected.[1] Therefore, if the ACT is used to monitor the effectiveness of heparin anticoagulation during cardiopulmonary bypass incorporating aprotinin, this may lead to an overestimation of the degree of anticoagulation. This may result in patients not receiving additional necessary heparin during extended extracorporeal circulation, or receiving excess protamine to reverse the effects of heparin at the end of the procedure. The UK manufacturer of aprotinin noted that it is not necessary to adjust the usual reg-

imen of heparin and protamine used in cardiopulmonary bypass procedures when aprotinin is also used.[2] The US manufacturer provided additional detailed information on appropriate methods to monitor heparin anticoagulation in the presence of aprotinin.[1] Note that aprotinin has generally been withdrawn because of a possible increased risk of death when it is used in cardiac surgery.

Heparin + Dextrans

The concurrent use of heparin and dextrans can further prolong clotting time and increase the risk of bleeding.

Clinical evidence, mechanism, importance and management

A study in 9 patients with peripheral vascular disease given 500 mL of dextran found that the mean clotting time one hour after an infusion of 10 000 units of heparin was increased from 36 minutes to 69 minutes. Dextran alone had no effect, but the mean clotting time after 5000 units of heparin with dextran was almost the same as after 10 000 units of heparin alone.[1,2] This study would seem to support two other reports[3,4] of an increase in the incidence of bleeding in those given both heparin and dextran 70. Uneventful concurrent use[5,6] has been described with dextran 40.

Note that these findings are probably of little clinical significance if these drugs are given for their anticoagulant effects; however, increased anticoagulation may be undesirable if dextrans are used as volume expanders in patients already receiving heparin. In this situation some caution is warranted.

Heparin + LMWHs; Enoxaparin

There is some evidence that patients receiving enoxaparin preoperatively require more heparin during surgery.

Clinical evidence, mechanism, importance and management

In a clinical study, 30 patients with unstable coronary disease treated preoperatively with enoxaparin needed more heparin to maintain an activated clotting time above 480 seconds during surgery than 31 stable control patients not treated with enoxaparin. In addition, the enoxaparin recipients had higher heparin levels and lower antithrombin values compared with control patients. All patients were taking low-dose aspirin until the day before surgery, and received tranexamic acid as a bolus dose before cardiopulmonary bypass.[1]

The reasons for these differences are unclear, and their clinical relevance is uncertain. Further study is needed.

Heparin + Miscellaneous

Changes in the protein binding of diazepam, propranolol, quinidine and verapamil caused by heparin do not appear to be of clinical importance.

Clinical evidence, mechanism, importance and management

A number of studies have found that heparin reduces the plasma protein binding of several drugs including **diazepam**,[1,2] **propranolol**,[1] **quinidine**[3] and **verapamil**[4] in man and in *animals*. For example, 3 patients taking oral **propranolol** and 5 patients given intramuscular **diazepam** 10 mg were given 3000 units of heparin just before cardiac catheterisation. Five minutes after the heparin was given, the free fraction of **diazepam** was found to have risen fourfold (from 1.8 to 7.9%) while the free **diazepam** levels had similarly risen (from 2 to 8.4 nanograms/mL). The free fraction of the **propranolol** rose from 7.4% to 12.5% and the free levels rose from 1.7 nanograms/mL to 2.7 nanograms/mL.[1]

It was suggested that these changes occur because heparin displaces these drugs from their binding sites on the plasma albumin and that these changes in protein binding might possibly have some clinical consequences. For example, there could, theoretically, be sudden increases in sedation or respiratory depression because of the rapid increase in the active (free) fraction of **diazepam**.

However, these changes are unlikely to be of clinical importance (see 'Protein-binding interactions', (p.3)). One study even suggested that the heparin-induced protein binding changes are an artefact of the study methods used,[5] and this would seem to be supported by an experimental study, which found that heparin did not have any effect on the beta-blockade caused by **propranolol**.[6] Moreover, there seem to be no other reports confirming that these interactions are of real clinical importance. No special precautions would seem to be necessary.

Heparin + Nitrates

The effects of heparin were reduced by an infusion of glyceryl trinitrate in some studies, but other studies have not confirmed this interaction. No interaction has been seen with heparin and isosorbide dinitrate or molsidomine.

Clinical evidence

(a) Glyceryl trinitrate (Nitroglycerin)

An interaction between heparin and glyceryl trinitrate was originally reported[1] in 1985. A lower aPTT value was found in patients receiving both intravenous glyceryl trinitrate and heparin, when compared with control patients receiving heparin alone. In a further study in healthy subjects, the same effect was seen with the propylene glycol diluent alone, so the interaction was attributed to the diluent.[1] However, in another study, the same interaction was noted in 2 patients receiving a glyceryl trinitrate preparation without propylene glycol. In this study, while receiving intravenous glyceryl trinitrate, 7 patients with coronary artery disease needed an increased dose of intravenous heparin to achieve satisfactory aPTT ratios of 1.5 to 2.5 on eight occasions. When the glyceryl trinitrate was stopped, in 6 out of 8 occasions there was a marked increase in aPTT values to 3.5. One patient had transient haematuria.[2]

Four other studies have also found a reduction in the effects of heparin in the presence of intravenous glyceryl trinitrate.[3-6] In one of these, the prothrombin time of 27 patients given heparin was more than halved (from 130 to about 60 seconds) when they were given intravenous glyceryl trinitrate 2 to 5 mg/hour. The prothrombin time rose again when the glyceryl trinitrate was stopped.[3] In one study, there was some evidence that the effect might occur only at higher doses of intravenous glyceryl trinitrate (above 350 micrograms/minute),[5] whereas in another, an effect was seen at low doses of 25 to 50 micrograms/minute.[6]

In contrast to the above studies, a total of 12 other studies have found no changes in aPTT in patients[7-16] or healthy subjects[17,18] given intravenous glyceryl trinitrate with heparin. In the randomised, placebo-controlled studies in healthy subjects, a 60-minute infusion of glyceryl trinitrate 5 mg had no effect on the aPTT or prothrombin time following a 5000 unit intravenous injection of heparin,[17] and a 100 micrograms/minute infusion of glyceryl trinitrate did not alter the anticoagulant effect of a 40 units/kg bolus of intravenous heparin in 7 healthy subjects.[18] Two randomised, pla-

cebo-controlled studies in patients have also not found any effect of intravenous glyceryl trinitrate on a heparin infusion titrated to a given effect,[12] or on an intravenous heparin bolus dose.[14] In the first of these studies, the glyceryl trinitrate preparation contained propylene glycol.[12]

(b) Isosorbide dinitrate

In a randomised, placebo-controlled study in 12 patients receiving a stable infusion of heparin, the use of isosorbide dinitrate 4.8 ± 0.8 mg/hour for 24 hours did not alter the AUC of the prothrombin time, when compared with placebo, nor was there any change in prothrombin time in the 5 hours after stopping the nitrate.[12] Similarly, other studies have not found any important change in anticoagulation when intravenous isosorbide dinitrate is given with heparin.[8,14,16]

(c) Molsidomine

In a study in 15 patients given intravenous heparin then intravenous molsidomine 2 mg/hour, molsidomine had no effect on the prothrombin time.[19]

Mechanism

Not understood. One study suggests that what occurs is related to a glyceryl trinitrate-induced antithrombin III abnormality, and is apparent at doses above 350 micrograms/minute.[5] One study found that heparin levels were lowered,[6] whereas another reported unchanged heparin levels.[3]

Importance and management

The discord between these reports for glyceryl trinitrate infusion is not understood. However, the best controlled studies in the largest number of patients have not found any evidence of an interaction. On balance therefore, it appears that a clinically relevant interaction is generally unlikely to be seen. Moreover, given that heparin is routinely monitored, it is likely that if any interaction occurs, it will be rapidly detected and compensated for. No special precautions would appear to be needed if heparin is given with molsidomine or isosorbide dinitrate.

Heparin and LMWHs + NSAIDs

Some evidence suggests that the bleeding risk is increased when enoxaparin is used with NSAIDs, whereas other evidence suggests no increased bleeding risk with these drugs. The bleeding time was prolonged when ketorolac was given with dalteparin, but not when it was given with heparin. Parecoxib does not alter the effect of heparin on aPTT. Cases of spinal haematomas after epidural anaesthesia have been reported with the concurrent use of heparin or low-molecular-weight heparins and NSAIDs.

Clinical evidence

(a) Heparin

In a crossover, placebo-controlled study in healthy subjects, there was no evidence of an interaction between **ketorolac** and heparin in terms of prolongation of skin bleeding time, platelet aggregation, anti-factor Xa activity, or kaolin-cephalin clotting time. In this study, two doses of oral **ketorolac** were given (the previous evening, and in the morning), then two 10-mg intramuscular doses of ketorolac were given at 10 am and 2 pm, with simultaneous doses of subcutaneous heparin 5000 units.[1] Similarly, in an open-label, crossover study in 18 healthy subjects, giving heparin on day 5 of the use of intravenous **parecoxib** 40 mg twice daily for 6 days produced no clinically or statistically significant differences in coagulation parameters (prothrombin time, aPTT and platelet counts), when compared with heparin alone (bolus dose of heparin 4000 units then a 36-hour infusion of 10 to 14 units/kg). The use of these drugs together was well tolerated. However, prolongation of bleeding time was not assessed.[2]

Use of heparin and **ibuprofen** were considered to be contributing factors in a case of spinal haematoma occurring after epidural anaesthesia.[3]

(b) Low-molecular-weight heparins

In a placebo-controlled, crossover study in healthy subjects, giving **ketorolac** with **dalteparin** resulted in prolongation of the skin bleeding time, when compared with ketorolac alone (13.95 minutes versus 10.55 minutes). **Dalteparin** alone had no effect on the bleeding time when compared with placebo. In this study, two doses of oral **ketorolac** 30 mg were given the day before, and one dose an hour after a single 5000-unit subcutaneous dose of **dalteparin**. The combination did not have any greater effect on platelet aggregation, anti-factor Xa activity, or aPTT time than the individual drugs alone.[4] In an analysis of risk factors for bleeding in patients receiving **enoxaparin** for acute coronary syndrome, the use of NSAIDs was associated with an increased risk of any bleeding (odds ratio 3.44), but not major bleeding.[5] However, a study in hip replacement patients given subcutaneous **enoxaparin** 40 mg daily found that there were no significant differences in intra-operative blood loss, post-operative drainage, transfusion requirements, bruising, wound oozing, and leg swelling between 34 patients given intramuscular **ketorolac** 30 mg on induction of anaesthesia then daily for 4 days postoperatively and 26 patients given unnamed opioids. Patients in this study had any previous NSAID medication stopped 4 weeks before admission, and were not taking aspirin.[6] Similarly, in a large study in patients undergoing surgery for total hip or knee replacement, there was no difference in risk of bleeding or other bleeding-related parameters (total blood loss, need for transfusion, mean change in haemoglobin levels) between patients receiving **enoxaparin** and NSAIDs (830 patients) and those receiving **enoxaparin** and no NSAIDs (394 patients). NSAIDs permitted in this study were said to be short-acting (with a half-life up to 20 hours), but none were specifically named.[7]

The use of **enoxaparin**, **ketorolac**, and aspirin were considered to be contributing factors in a case of spinal haematoma occurring after lumbar puncture, which resulted in paraplegia.[8] Another case has also been briefly described.[9] In an analysis of reports from the FDA in the US, 16 of 43 patients who developed spinal or epidural haematoma after receiving **enoxaparin** had received concurrent drugs known to prolong bleeding, such as **ketorolac** or other NSAIDs.[10]

Mechanism

NSAIDs, to a greater or lesser extent, irritate the stomach lining. This can result in gastrointestinal bleeding, which will be more severe in anticoagulated patients. Many NSAIDs also have antiplatelet activity, which can prolong bleeding times. There are studies showing that use of NSAIDs

increases the risk of perioperative bleeding (one is cited as an example[11]), and theoretically this might be greater in those also receiving heparins.

Importance and management

An interaction between NSAIDs and heparins (including low-molecular-weight heparins) is established. The CSM in the UK and the UK manufacturers say that ketorolac is contraindicated with anticoagulants, including low-dose **heparin**.[12,13] Conversely, the US manufacturers of ketorolac advise that physicians should carefully weigh the benefits against the risks and use concurrent heparin only extremely cautiously.[14]

If NSAIDs and LMWHs are used together, the manufacturers of the LMWHs (**bemiparin**, **dalteparin**, **enoxaparin**, **tinzaparin**) recommend caution or careful clinical and laboratory monitoring.

Heparin and some LMWHs have rarely caused epidural or spinal haematomas resulting in long-term or permanent paralysis when used for thromboprophylaxis in procedures involving spinal/epidural anaesthesia or spinal puncture. The risk of this may be increased if they are used concurrently with other drugs affecting haemostasis such as ketorolac or other NSAIDs, and extreme caution is needed if concurrent use is considered appropriate in these situations.

Heparin + Probenecid

An isolated case report from the 1950s suggests that the effects of heparin may be possibly increased by probenecid, and bleeding may occur.

Clinical evidence, mechanism, importance and management

In 1950 (but not reported until 1975) a woman with subacute bacterial endocarditis was given probenecid orally and penicillin by intravenous drip, which was kept open with minimal doses of heparin. After about 20 000 units of heparin had been given over a 3-week period, increasing epistaxis developed and the clotting time was found to be 24 minutes (reference range 5 to 6 minutes). This was controlled with protamine.[1] However, no reports of this interaction appear to have been made subsequently. This interaction seems unlikely to be of general significance.

1. Sanchez G. Enhancement of heparin effect by probenecid. *N Engl J Med* (1975) 292, 48.

Heparin and LMWHs + SSRIs

Severe bleeding was attributed to the use of tinzaparin in an elderly woman with renal impairment taking fluoxetine.

Clinical evidence, mechanism, importance and management

A 78-year-old woman taking **fluoxetine** was started on once-daily subcutaneous injections of weight-adjusted **tinzaparin** for a deep vein thrombosis. Five days later she suffered a massive intraperitoneal and parietal haematoma. Poor renal function in this patient could have led to accumulation of the low-molecular-weight heparin, but **fluoxetine** was also considered a contributing factor because SSRIs have antiplatelet effects and can contribute to bleeding.[1] Consider also 'Coumarins and related drugs + SSRIs', p.504. The general relevance of this isolated case is unclear.

Heparin and LMWHs + Tobacco

There is some evidence that heparin and dalteparin might be slightly less effective in smokers. However, smoking status is probably not important in predicting the dose of heparin and LMWHs.

Clinical evidence, mechanism, importance and management

In a study of the factors affecting the sensitivity of individuals to heparin, the heparin half-life in smokers was 0.62 hours compared with 0.97 hours in non-smokers. The dose requirements of the smokers were slightly increased (18.8 units/hour compared with 16 units/hour; both per lean body-weight). However, when lean body-weight was taken into account, smoking status was no longer related to heparin clearance.[1] In a retrospective analysis of weight-based heparin dosing, smoking was predictive of a subtherapeutic aPTT response, which is consistent with the idea that heparin has a shorter half-life in smokers.[2]

In a sub-study of dalteparin for unstable coronary artery disease, high-dose weight-adjusted dalteparin was associated with lower anti-factor Xa levels and a lower risk of bleeding in smokers. This suggests that dalteparin was slightly less effective in smokers.[3]

The limited data provide some evidence that heparin and LMWHs might be slightly less effective in smokers. Nevertheless, smoking status is not usually a factor used in calculating the dose of heparins. Note that as unfractionated heparin is usually dose adjusted according to bleeding times, any minor interaction should be accounted for in this adjustment.

Heparinoids; Danaparoid + Antiplatelet drugs or NSAIDs

No haemostatic interaction was noted between danaparoid and aspirin in healthy subjects. However, caution is recommended on concurrent use because of the possibility of increased bleeding risk.

Clinical evidence

In a randomised, crossover study in healthy subjects, there were no important alterations in coagulation tests and plasma anti-Xa activity when danaparoid (3250 anti-Xa units intravenous bolus followed by 750 units subcutaneously twice daily for 8 days) was given with **aspirin** 500 mg, 14 hours and 2 hours before the intravenous danaparoid. Similarly, danaparoid did not alter the effects of **aspirin** on platelet function, but the prolongation in bleeding time tended to be longer after the combination.[1]

Mechanism

The manufacturer notes that, in general, combination with antithrombotics that act by other mechanisms, such as aspirin, would be additive.[2]

Importance and management

Any effects in the study with aspirin where not considered to be clinically relevant.[1,2] The manufacturers note that danaparoid may be used with drugs that interfere with platelet function, such as aspirin and NSAIDs, but considers that caution remains necessary.[2,3] This is considered particularly important in patients undergoing peridural or spinal anaesthesia or spinal puncture, in whom the use of NSAIDs, and probably also danaparoid, are risk factors for epidural or spinal haematoma resulting in prolonged or permanent paralysis.[2,3]

Heparinoids; Danaparoid + Diuretics

Chlortalidone had no clinically relevant effect on the anti-Xa activity of danaparoid in healthy subjects, but it caused an increase in the volume of distribution of antithrombin activity of uncertain relevance. Nevertheless, in clinical use danaparoid is frequently used with a number of other drugs including diuretics, and there is no evidence of an interaction.

Clinical evidence, mechanism, importance and management

In a randomised, crossover study in healthy subjects, a slight decrease in clearance (7%) and volume of distribution (19%) of the anti-Xa activity of danaparoid (3250 anti-Xa units intravenous bolus) occurred when it was given about 12 hours after a single 100-mg dose of chlortalidone. Conversely, the apparent volume of distribution of antithrombin activity was increased by 80%. However, chlortalidone did not change the effect of danaparoid on clotting tests, except for a 4% increase in prothrombin time, which was thought to be a spurious finding.[1] The reasons for these changes are uncertain.

The minor changes in anti-Xa activity are unlikely to be clinically relevant.[1,2] However, the authors considered that relevance of the change in antithrombin activity was uncertain.[1] Nevertheless, the manufacturer notes that, in clinical use, danaparoid has frequently been used with a variety of drugs, including diuretics, and that there is no evidence of any direct interaction with danaparoid.[2]

1. de Boer A, Stiekema JC, Danhof M, Breimer DD. Influence of chlorthalidone on the pharmacokinetics and pharmacodynamics of Org 10172 (Lomoparan®), a low molecular weight heparinoid, in healthy volunteers. *J Clin Pharmacol* (1991) 31, 611–17.
2. Orgaran (Danaparoid). Organon Canada Ltd. Canadian Prescribing information, June 2001.

Heparinoids; Danaparoid + Penicillins

Cloxacillin and ticarcillin caused an increase in elimination half-life of anti-Xa activity of danaparoid in one study. Ticarcillin had no effect on haemostasis, but cloxacillin appeared to have some pro-coagulant effects, which were not likely to be due to an interaction with danaparoid.

Clinical evidence

(a) Cloxacillin

In a randomised, crossover study in 6 healthy subjects, there was a 74% increase in the elimination half-life of the plasma anti-Xa activity of danaparoid (3250 anti-Xa units intravenous bolus) when it was given with oral cloxacillin 500 mg four times daily for 3 days beginning 24 hours before the danaparoid. Unexpectedly, there were slight decreased effects on thrombin time and bleeding time, and increased effects on aPTT with the combination, effects that were attributed to cloxacillin alone.[1]

(b) Ticarcillin

In a randomised, crossover study in 12 healthy subjects, there was a 56% increase in the elimination half-life of the plasma anti-Xa activity of danaparoid (3250 anti-Xa units intravenous bolus) when it was given with intravenous ticarcillin 4 g four times daily for 2 days beginning immediately before the danaparoid. There were no changes in haemostatic parameters when ticarcillin was given with danaparoid.[1]

Mechanism

Uncertain, but penicillins might compete with danaparoid for renal tubular secretion.[1]

Importance and management

The pharmacokinetic changes seen in the studies with cloxacillin and ticarcillin were not considered clinically relevant.[1,2] In addition, the haemostatic changes seen in the study with cloxacillin were unlikely to be due to an interaction.[1] The manufacturer notes that in clinical use danaparoid has frequently been used with a variety of drugs, including antibacterials, and that there is no evidence of any direct interaction with danaparoid.[2]

2. Orgaran (Danaparoid). Organon Canada Ltd. Canadian product monograph, June 2001.

Indanediones + Haloperidol

A single case report describes a marked reduction in the anticoagulant effects of phenindione in a patient given haloperidol.

Clinical evidence, mechanism, importance and management

A man stabilised on **phenindione** 50 mg daily was given haloperidol by injection (5 mg every 8 hours for 24 hours) followed by 3 mg twice daily by mouth. Adequate anticoagulation was not achieved even when the **phenindione** dose was increased to 150 mg daily. When the haloperidol dose was halved, the necessary dose of anticoagulant was reduced to 100 mg daily, and only when the haloperidol was withdrawn was it possible to achieve adequate anticoagulation with the original dose.[1] The reasons for this effect are not understood. This appears to be the only report of an interaction, and its general importance is therefore limited. Bear it in mind in the event of an unexpected response to treatment.

1. Oakley DP, Lautch H. Haloperidol and anticoagulant treatment. *Lancet* (1963) ii, 1231.

Indanediones + Oxaceprol

An isolated report describes a marked reduction in the response to fluindione in a patient given oxaceprol.

Clinical evidence, mechanism, importance and management

A 77-year-old woman with hypertension and atrial fibrillation, taking propafenone, furosemide, enalapril and **fluindione** 15 mg daily, started taking oxaceprol 300 mg daily. Within 2 days her Quick Time had risen from 26% to 57% and by the end of the week to 65%. When the oxaceprol was withdrawn, her Quick value returned to its previous range of 23 to 30%.[1] The mechanism for this effect is not understood. The general importance of this interaction is unclear, but bear it in mind when prescribing oxaceprol and **fluindione**. Be alert for the need to modify the anticoagulant dose.

1. Bannwarth B, Tréchot P, Mathieu J, Froment J, Netter P. Interaction oxacéprol-fluindione. *Therapie* (1990) 45, 162–3.

Rivaroxaban + Antiplatelet drugs or NSAIDs

Neither aspirin nor naproxen alter the pharmacokinetics of rivaroxaban, or cause a clinically relevant change in the anticoagulant effects of rivaroxaban. However, the bleeding time during concurrent use may be slightly prolonged. Note that all NSAIDs and antiplatelets increase the risk of bleeding, and concurrent use with rivaroxaban may possibly increase this risk.

Clinical evidence

(a) Aspirin

In a controlled study in 13 healthy subjects, aspirin 500 mg on day one then 100 mg on day 2 had no effect on the pharmacokinetics of a single 15-mg dose of oral rivaroxaban given at the same time as aspirin on day 2. Concurrent use slightly increased the bleeding time (by 2.28 minutes) compared with aspirin alone. Rivaroxaban did not alter the effect of aspirin on platelet aggregation and aspirin did not alter the effects of rivaroxaban on clotting parameters (inhibition of factor Xa activity, prolongation of prothrombin time, aPTT and HepTest).[1]

(b) Clopidogrel

The manufacturer of rivaroxaban reports that no pharmacokinetic interaction occurred in patients given rivaroxaban with clopidogrel 300 mg as a single dose followed by 75 mg daily. However, an increase in bleeding times was reported in some patients.[2]

(c) NSAIDs

In a controlled study in 11 healthy subjects, **naproxen** 500 mg daily on two consecutive days was given with a single 15-mg dose of oral rivaroxaban on the second day. Concurrent use increased bleeding time by a mean of 3.43 minutes compared with naproxen alone, and one subject had a greater increase. **Naproxen** slightly increased the rivaroxaban AUC (by 10%), but this was not statistically significant. Naproxen did not have any clinically relevant effect on the pharmacodynamics of rivaroxaban (prolongation of aPTT, prothrombin time and HepTest and inhibition of factor Xa activity).[3]

Mechanism

Rivaroxaban (a inhibitor of activated factor X) alone does not increase the bleeding time, but it appears to increase this effect with aspirin and NSAIDs. There is the possibility that some patients might be at increased risk of bleeding on concurrent use.

Importance and management

The pharmacological studies described show that the pharmacokinetics of rivaroxaban are not changed by aspirin and naproxen, and that, in general, there is only a minor increase in bleeding time. Nevertheless, it would be prudent to use NSAIDs and antiplatelet drugs, such as aspirin and clopidogrel, with caution because of the possible increased risk of haemorrhage.[2] Additional care should also be taken in those patients given combination antiplatelet therapies. Note that aspirin and naproxen do not affect the clotting parameters used to monitor the effect of rivaroxaban.

2. Xarelto (Rivaroxaban). Bayer plc. UK Summary of product characteristics, May 2009.
3. Kubitza D, Becka M, Mueck W, Zuehlsdorf M. Rivaroxaban (BAY 59-7939) – an oral, direct Factor Xa inhibitor – has no clinically relevant interaction with naproxen. *Br J Clin Pharmacol* (2007) 63, 469–76.

Rivaroxaban + Miscellaneous

Ketoconazole and ritonavir can increase rivaroxaban levels and increase the risk of bleeding: other azoles may interact similarly, although fluconazole is likely to interact to a lesser extent. Clarithromycin and erythromycin may cause a small increase in rivaroxaban levels. Rifampicin (rifampin) a potent CYP3A4 inducer) reduces the levels of rivaroxaban: other potent CYP3A4 inducers are predicted to interact similarly. Food moderately increases the oral absorption of rivaroxaban, but antacids and ranitidine have no effect. Atorvastatin, digoxin and midazolam do not interact with rivaroxaban.

Clinical evidence, mechanism, importance and management

(a) Anticoagulants

Enoxaparin does not affect the pharmacokinetics of rivaroxaban; however, the concurrent use of single doses of rivaroxaban 10-mg and enoxaparin 40-mg had an additive effect on anti-factor Xa levels, with no additional effects on either prothrombin time or the aPTT. The manufacturers advise caution in patients taking other drugs that affect coagulation such as anticoagulants (not specified) due to the increased risk of additive bleeding effects.[1]

(b) CYP3A4 inducers

The manufacturer reports that **rifampicin** reduces the AUC of rivaroxaban by about 50%, with an associated reduction in its anticoagulant effects. Therefore they recommend caution with concurrent use of other strong inducers of CYP3A4 such as **carbamazepine**, **phenobarbital**, **phenytoin**, and **St John's wort**. If possible, it would be prudent to consider using an alternative drug; however, if this is not possible, consider monitoring the prothrombin time to ensure the anticoagulant effect of rivaroxaban is maintained.[1]

(c) CYP3A4 and P-glycoprotein inhibitors

In a clinical study, **ketoconazole** 400 mg daily increased the maximum levels and AUC of rivaroxaban by 70% and 2.6-fold, respectively. Similarly, **ritonavir** 600 mg twice daily increased the maximum levels and AUC of rivaroxaban by 60% and 2.5-fold, respectively. In both cases the pharmacodynamic effects of rivaroxaban were increased, which may increase the risk of bleeding.[1]

Rivaroxaban is metabolised by the cytochrome P450 isoenzyme CYP3A4 and is also a substrate for P-glycoprotein. Ritonavir and ketoconazole are considered to be potent inhibitors of both CYP3A4 and P-glycoprotein, and therefore concurrent use increases rivaroxaban levels. The manufacturers therefore recommend against the concurrent use of rivaroxaban with ketoconazole or ritonavir. They also suggest that other azole antifungals (they name **itraconazole**, **posaconazole** and **voriconazole**) may interact similarly.[1] **Fluconazole** is predicted to have less effect on rivaroxaban levels than the other azoles, and therefore the manufacturers recommend caution on concurrent use. It would therefore seem prudent to monitor the prothrombin time more frequently if **fluconazole** is given. Other less potent inhibitors of CYP3A4 and P-glycoprotein have less effect on rivaroxaban levels. **Clarithromycin** 500 mg twice daily increased the maximum levels and AUC of rivaroxaban by 40% and 50%, respectively; and **erythromycin** 500 mg three times daily increased the maximum levels and AUC of rivaroxaban by 30%.[1] These changes were not considered to be clinically relevant.

(d) Drugs that affect gastric pH

In a controlled study in fasted healthy subjects, simultaneous administration of a single 10-mL dose of an **aluminium/magnesium hydroxide** antacid (*Maalox*) had no effect on the pharmacokinetics or pharmacodynamics of a single 30-mg dose of oral rivaroxaban.[2] Similarly, in a study in 12 healthy subjects, pretreatment with **ranitidine** 150 mg twice daily for 3 days did not alter the pharmacokinetics or pharmacodynamics of single dose rivaroxaban.[2] These studies show that alteration of the gastric pH does not affect rivaroxaban absorption. On the basis of these studies, no interaction would be anticipated with antacids or ranitidine in clinical use.

(e) Food

In controlled studies in healthy subjects, the absorption of rivaroxaban was moderately increased and delayed when it was given within 30 minutes of a high-fat, high-calorie meal, when compared with the fasted state, as reflected by an increase in the AUC of 28% and an increase in time to maximum level from 2.75 hours to 4 hours. Elimination was not altered. The increase in inhibition of factor Xa activity mirrored the increase in absorption (26% increase). Further study did not find any difference between the effect of a high-carbohydrate meal and a high-fat meal.[2] In clinical studies in elective surgery, rivaroxaban has been given within one to 2 hours of food before surgery, and in the fasting state in the postoperative period. The authors of this report studies speculate that the moderately smaller peak levels of rivaroxaban in the fasted state may be somewhat beneficial for wound haemostasis in the postoperative period.[2] The manufacturers state that rivaroxaban may be taken with or without food.[1]

(f) Other drugs

The manufacturers note that rivaroxaban has no significant pharmacokinetic or pharmacodynamic interaction with midazolam, digoxin or atorvastatin. No dose adjustments are therefore necessary if these drugs are given together. This also suggests that rivaroxaban has no clinically rele-

vant effect on drugs that are substrates of P-glycoprotein or the cytochrome P450 isoenzyme CYP3A4.[1]

1. Xarelto (Rivaroxaban). Bayer plc. UK Summary of product characteristics, May 2009.
2. Kubitza D, Becka M, Zuehlsdorf M, Mueck W. Effect of food, an antacid, and the H_2 antagonist ranitidine on the absorption of BAY 59-7939 (rivaroxaban), an oral, direct factor Xa inhibitor, in healthy subjects. *J Clin Pharmacol* (2006) 46, 549–58.

Thrombin inhibitors + Antiplatelet drugs

Low-dose aspirin does not appear to alter the pharmacokinetics or pharmacodynamic effects of argatroban. Neither abciximab nor eptifibatide appear to alter argatroban pharmacokinetics. The concurrent use of aspirin and high-dose dabigatran slightly increased the risk of major haemorrhage. There is no pharmacodynamic interaction between bivalirudin and aspirin, ticlopidine, clopidogrel, abciximab, eptifibatide or tirofiban.

Clinical evidence, mechanism, importance and management

A. Synthetic thrombin inhibitors

(a) Argatroban

In a study in healthy subjects, pretreatment with oral **aspirin** 162.5 mg, given 26 and 2 hours before argatroban 1 microgram/kg per minute over 4 hours, caused no changes in the pharmacokinetics or pharmacodynamic effects of the argatroban.[1]

In a large clinical study of the concurrent use of argatroban and a glycoprotein IIb/IIIa-receptor antagonist (**abciximab** or **eptifibatide**) in patients undergoing percutaneous coronary intervention, using a population model assessment, the pharmacokinetics of argatroban were similar to those previously seen in healthy subjects. This suggests that neither **abciximab** nor **eptifibatide** alter argatroban pharmacokinetics.[2] Nevertheless, the manufacturer warns that the use of argatroban with **antiplatelet drugs** may increase the risk of bleeding.[3]

(b) Dabigatran

In a study in patients with atrial fibrillation given dabigatran 50 to 300 mg twice daily alone or with **aspirin** 81 mg or 325 mg daily, the risk of major haemorrhage was higher with concurrent use of **aspirin** and dabigatran 300 mg twice daily (4 of 64 patients) than with dabigatran 300 mg twice daily alone (0 of 105 patients). Three major haemorrhages occurred at the 325 mg **aspirin** dose and one at the 81 mg dose, and **aspirin** was subsequently stopped in all patients receiving the 300 mg twice daily dose of dabigatran. With the lower doses of dabigatran, the total number of bleeding events tended to be higher in the groups also receiving **aspirin** (about 22% versus 15% for the 150 mg twice daily dabigatran dose, and 9.5% versus 3.4% for the 50 mg twice daily dose).[4] Note that this is not a licensed indication for dabigatran, and the 600 mg daily dose is much higher than that recommended in elective orthopaedic surgery.

A study in patients undergoing total hip replacements and randomised to receive either dabigatran 150 mg or 220 mg daily or enoxaparin allowed patients to continue to take low-dose **aspirin** (less than 160 mg daily) during the study. The full paper gave no specific data on the distribution of **aspirin** use between the groups or specifically if **aspirin** use contributed to the risk of bleeding;[5] however, some data were given in a subsequent letter.[6] The authors stated that there was no significant difference in efficacy or safety outcomes among patients receiving low-dose **aspirin** and those not taking **aspirin**, although the proportion of patients taking **aspirin** with dabigatran was small, at about 4 to 5%.[6]

The manufacturer states that drugs that may enhance the risk of haemorrhage should not be given concurrently or should be given with caution with dabigatran. They specifically recommend avoiding the use of the antiplatelet drugs **clopidogrel**, **ticlopidine**, **glycoprotein IIb/IIIa inhibitors**, and **sulfinpyrazone**, and say that if concurrent use is essential, patients should be closely monitored for signs and symptoms of bleeding.[7] Although not specifically mentioned, it would be prudent to similarly monitor the concurrent use of antiplatelet doses of **aspirin**.

B. Hirudins

(a) Bivalirudin

The UK manufacturer says that no pharmacodynamic interactions were detected when bivalirudin was used with platelet inhibitors, including **aspirin**, **ticlopidine**, **clopidogrel**, **abciximab**, **eptifibatide**, and **tirofiban**.[8] The US manufacturer states that bivalirudin is intended for use with **aspirin** 300 to 325 mg daily, and has been studied only in patients receiving **aspirin**.[9] Both manufacturers state that bivalirudin may be used with a glycoprotein IIb/IIIa-receptor antagonist[8,9] (e.g. **abciximab**, **eptifibatide**, **tirofiban**). Nevertheless, the US manufacturer states that in clinical studies, the concurrent use of bivalirudin with these inhibitors was associated with increased risks of major bleeding events compared to patients not receiving them.[9] The UK manufacturer recommends regular monitoring of haemostasis when bivalirudin is used with platelet inhibitors.[8]

(b) Lepirudin

The manufacturers of lepirudin say that no formal interaction studies have been done but they reasonably warn about the increased risks of bleeding if antiplatelet drugs such as **clopidogrel**, **ticlopidine**, **abciximab**, **eptifibatide** or **tirofiban** are used concurrently.[10,11]

Thrombin inhibitors + Other drugs that affect coagulation

The use of argatroban with warfarin and related oral anticoagulants has an effect on the measurement of the INR, and the manufacturer provides equations to adjust for this. Argatroban does not alter warfarin pharmacokinetics. The manufacturers warn of the increased bleeding risks if argatroban, bivalirudin, dabigatran, or lepirudin are used with other anticoagulants.

Clinical evidence, mechanism, importance and management

A. Synthetic thrombin inhibitors

(a) Argatroban

In a study in 12 healthy subjects, argatroban 1.25 micrograms/kg per minute was given for 100 hours, with a single 7.5-mg dose of **warfarin** given at hour 4. Neither drug affected the pharmacokinetics of the other. The single dose of **warfarin** in this study did not add to the anticoagulant effect of argatroban.[1] However, a previous study found that the INR and prothrombin time were increased when **warfarin** (7.5 mg on day one, then 3 to 6 mg for 9 days) was used with argatroban (1 to 4 micrograms/kg per minute for 5 hours daily for 11 days), but without any additional effect on vitamin K-dependent factor Xa activity.[2] A similar finding was reported in a study using **acenocoumarol** or **phenprocoumon** and argatroban.[3]

This means that the INR reading needs to be corrected before it can be used as a clinical indicator of coagulation status when **warfarin** or other vitamin K antagonists (i.e. any coumarin or **indanedione**) are used with argatroban. The manufacturer provides detailed information on how this should be done while switching from argatroban to **warfarin**.[4]

Argatroban is currently licensed for use in patients with or at risk of heparin-induced thrombocytopenia, and the manufacturer states that if **heparin** is to be switched to argatroban, sufficient time for the effect of heparin on the aPTT to decrease should be allowed before starting argatroban. They recommend that all parenteral anticoagulants should be discontinued before starting argatroban.[4]

(b) Dabigatran

The manufacturer states that drugs that may enhance the risk of haemorrhage should not be given concurrently or should be given with caution to patients receiving dabigatran. They specifically recommend avoiding the concurrent use of dabigatran and vitamin K antagonist anticoagulants[5] (i.e. **coumarins** and **indanediones**). They also advise against the use of parenteral anticoagulants such as **heparin**, heparin derivatives, **low-molecular-weight heparins**, **dextrans**, **desirudin** and **fondaparinux**, although they note that **heparin** can be given at doses necessary to maintain a patent central venous or arterial catheter. They recommend waiting 24 hours after the last dose of dabigatran before starting parenteral anticoagulants. They also state that, as there are no data available on switching patients from a parenteral anticoagulant to dabigatran, dabigatran should not be started before the next scheduled dose of the parenteral anticoagulant would have been due.[5]

B. Hirudins

(a) Bivalirudin

In the US, the manufacturers state that the concurrent use of bivalirudin with **heparin** or **warfarin** was associated with increased risks of major bleeding events, when compared with patients not receiving these drugs concurrently.[6] In the UK, the manufacturers state that bivalirudin can be started 30 minutes after stopping intravenous **heparin**, but 8 hours should be left after stopping a **low-molecular-weight heparin** given subcutaneously.[7] They recommend regular monitoring of haemostasis when bivalirudin is used with other anticoagulants.[7]

(b) Lepirudin

The manufacturers of lepirudin say that no formal interaction studies have been done but they reasonably warn about the increased risks of bleeding if vitamin K antagonists (i.e. **coumarins** and **indanediones**) are used concurrently.[8,9] Their recommendation for changing from lepirudin to an oral anticoagulant is to reduce the lepirudin dose gradually to reach an aPTT ratio just above 1.5 before beginning the oral anticoagulant, which should be started at the intended maintenance dose without a loading dose. They suggest that parenteral anticoagulation should be continued for 4 to 5 days, and then stopped when the INR stabilises within the target range.[8,9]

Thrombin inhibitors + Thrombolytics

The risks of bleeding are expected to be increased if argatroban, bivalirudin, dabigatran or lepirudin are used with thrombolytics.

Clinical evidence, mechanism, importance and management

A. Synthetic thrombin inhibitors

(a) Argatroban

The manufacturer of argatroban notes that, in patients with acute myocardial infarction receiving both argatroban and a thrombolytic (**streptokinase** or **alteplase**), the incidence of intracranial bleeding was 1% (8 out of 810 patients).[1] They therefore state that the safety and effectiveness of argatroban with thrombolytics has not been established, and that concurrent use may increase the risk of bleeding.[1]

(b) Dabigatran

The manufacturer of dabigatran advises against the use of thrombolytics (e.g. **streptokinase**, **alteplase**) because of the potential increased risk of haemorrhage.[2]

B. Hirudins

(a) Bivalirudin

The US manufacturer of bivalirudin states that the concurrent use of thrombolytics was associated with increased risks of major bleeding events.[3]

(b) Lepirudin

The manufacturers of lepirudin say that no formal interaction studies have been undertaken but they reasonably warn that the concurrent use of lepirudin and thrombolytics (they name **alteplase** and **streptokinase**) may increase the risk of bleeding complications and considerably enhance the effect of lepirudin on the aPTT.[4,5] The UK manufacturers advise a dose reduction of lepirudin with concurrent use; however, they state that the optimal dose for concurrent use with a thrombolytic is not known.[4]

5. Refludan (Lepirudin). Bayer HealthCare Pharmaceuticals Inc. US Prescribing information, December 2006.

Thrombin inhibitors; Argatroban + Erythromycin

Erythromycin has no effect on the pharmacokinetics or anticoagulant activity of argatroban.

Clinical evidence, mechanism, importance and management

In 10 healthy subjects, erythromycin 500 mg four times daily was given for 7 days with a 5-hour intravenous infusion of argatroban 1 microgram/kg per minute on day 6. Erythromycin had no effect on the pharmacokinetics of argatroban, and had no effect on the argatroban-induced prolongation of the aPTT.[1] No special precautions are likely to be required on the concurrent use of argatroban and erythromycin.

1. Tran JQ, Di Cicco RA, Sheth SB, Tucci M, Peng L, Jorkasky DK, Hursting MJ, Benincosa LJ. Assessment of the potential pharmacokinetic and pharmacodynamic interactions between erythromycin and argatroban. *J Clin Pharmacol* (1999) 39, 513–19.

Thrombin inhibitors; Argatroban + Lidocaine

No pharmacokinetic interaction occurs between argatroban and lidocaine, and lidocaine does not appear to alter the anticoagulant effects of argatroban.

Clinical evidence, mechanism, importance and management

In a study in 12 healthy subjects, lidocaine 2 mg/kg per hour was infused for 16 hours (after a loading dose of 1.5 mg/kg over 10 minutes) alone, then with intravenous argatroban 1.5 micrograms/kg per minute for 16 hours. Concurrent use did not affect the pharmacokinetics of either drug, and lidocaine did not alter the effect of argatroban on aPTT.[1] No special precautions appear likely to be necessary on concurrent use of lidocaine and argatroban.

1. Inglis AML, Sheth SB, Hursting MJ, Tenero DM, Graham AM, DiCicco RA. Investigation of the interaction between argatroban and acetaminophen, lidocaine, or digoxin. *Am J Health-Syst Pharm* (2002) 59, 1257–66.

Thrombin inhibitors; Argatroban + Paracetamol (Acetaminophen)

No pharmacokinetic interaction occurs between argatroban and paracetamol, and paracetamol does not alter the anticoagulant effects of argatroban.

Clinical evidence, mechanism, importance and management

In 11 healthy subjects, paracetamol 1 g every 6 hours for 5 doses had no effect on the pharmacokinetics of a 19-hour infusion of argatroban 1.5 micrograms/kg per minute, started with the second dose of paraceta-

mol. In addition, argatroban had no effect on paracetamol pharmacokinetics. Paracetamol did not alter the effect of argatroban on the aPTT.[1] No special precautions appear necessary on the concurrent use of paracetamol and argatroban.

1. Inglis AML, Sheth SB, Hursting MJ, Tenero DM, Graham AM, DiCicco RA. Investigation of the interaction between argatroban and acetaminophen, lidocaine, or digoxin. *Am J Health-Syst Pharm* (2002) 59, 1257–66.

Thrombin inhibitors; Dabigatran + Amiodarone and other drugs that affect P-glycoprotein

Amiodarone increases the levels of dabigatran. Verapamil, clarithromycin and quinidine are predicted to have a similar effect. Rifampicin and St John's wort are predicted to decrease the efficacy of dabigatran.

Clinical evidence

The manufacturer briefly notes that in an interaction study, amiodarone increased the AUC and maximum concentration of dabigatran by 60% and 50%, respectively. Dabigatran did not affect the pharmacokinetics of amiodarone and of its active metabolite.[1]

Mechanism

Dabigatran etexilate, the prodrug for the active dabigatran, is a substrate for P-glycoprotein and it is thought that the interaction may be due to inhibition of P-glycoprotein by amiodarone; however, the mechanism has not been clarified.[1]

Importance and management

Evidence for an interaction between dabigatran and amiodarone is limited. The manufacturer recommends that the dose of dabigatran should be reduced to 150 mg daily in patients who are also taking amiodarone, and this seems a prudent precaution. Note that amiodarone has a long half-life and therefore the potential for an interaction with dabigatran may still exist for weeks after stopping amiodarone.[1]

On the basis of the predicted mechanism for this interaction, the manufacturer recommends caution when dabigatran is given with other drugs that are potent inhibitors of P-glycoprotein. They specifically contraindicate the concurrent use of **quinidine** and caution use with **verapamil** and **clarithromycin**[1] (for a list of other P-glycoprotein inhibitors, see 'Table 1.6', (p.8)). The dose of dabigatran should be reduced to 150 mg daily with concurrent use of verapamil, and a further dose reduction to 75 mg daily should also be considered in those patients with moderate renal impairment.[1]

Close monitoring for signs of bleeding or anaemia is required on concurrent use, and dabigatran should be discontinued if severe bleeding occurs. Conversely, the manufacturer of dabigatran recommends caution when it is given with drugs that are potent inducers of P-glycoprotein, such as **rifampicin** (**rifampin**) and **St John's wort**.[1] Note that dabigatran is used without routine coagulation monitoring, but it can be monitored with aPTT and ecarin clotting time (ECT).[2,3] ECT is the more sensitive and accurate measure, but is not widely available. Study of the pharmacokinetic interaction of these drugs with dabigatran would be helpful in assessing the relevance of any interaction.

3. Stangier J, Rathgen K, Stähle H, Gansser D, Roth W. The pharmacokinetics, pharmacodynamics and tolerability of dabigatran etexilate, a new oral direct thrombin inhibitor, in healthy male subjects. *Br J Clin Pharmacol* (2007) 64, 292–303.

Thrombin inhibitors; Dabigatran + Miscellaneous

No significant pharmacokinetic interaction occurs between dabigatran and atorvastatin, diclofenac, or digoxin. However, concurrent use with NSAIDs might increase the risk of haemorrhage, and should be well monitored. Ranitidine has no effect on the absorption of dabigatran. Pantoprazole modestly reduces the bioavailability of dabigatran but does not reduce its therapeutic efficacy.

Clinical evidence, mechanism, importance and management

(a) Atorvastatin

In a study in 22 healthy subjects, atorvastatin 80 mg daily for 4 days slightly reduced the overall exposure to dabigatran 150 g twice daily taken for 4 days by a minor 16%.[1] Atorvastatin is a substrate of the cytochrome P450 isoenzyme CYP3A4, and the results of this study suggest that dabigatran does not significantly affect CYP3A4. These findings confirmed *in vitro* interaction studies, which found that dabigatran does not inhibit or induce CYP3A4. Therefore no special precautions are necessary on the concurrent use of atorvastatin and dabigatran.

(b) Digoxin

In a study in 24 healthy subjects, there was no evidence of a pharmacokinetic interaction between dabigatran and digoxin.[2] Digoxin is a substrate of P-glycoprotein, and the findings of this study suggest that dabigatran does not alter P-glycoprotein. No special precautions are therefore needed on the concurrent use of dabigatran and digoxin.

(c) Food

In a study in 18 healthy subjects, although food delayed the time to the peak plasma concentration of dabigatran by around 2 hours, it had no effect on the overall bioavailability (AUC) of dabigatran when compared with fasting conditions.[3] Therefore, the manufacturer states that it may be taken with or without food.[2]

(d) NSAIDs

No pharmacokinetic interaction occurred between dabigatran and **diclofenac** in a study in healthy subjects.[2] Diclofenac is a substrate of the cytochrome P450 isoenzyme CYP2C9, and the findings confirmed *in vitro* interaction studies, which found that dabigatran does not inhibit or induce CYP2C9. Nevertheless, drugs such as the NSAIDs may increase the risk of haemorrhage, and should be used cautiously with dabigatran. The manufacturers advise that patients taking NSAIDs with dabigatran should be closely monitored for signs of bleeding, particularly with NSAIDs that have a half-life of greater than 12 hours.[2] Caution would seem appropriate.

(e) Proton pump inhibitors

In a study in 18 healthy subjects, pre-treatment with **pantoprazole** 40 mg twice daily for 2 days reduced the AUC and maximum concentration of a single 150-mg dose of dabigatran by around 22% and 33%, respectively. However, high intersubject variability in these parameters was reported, which the authors suggested may have been due to the interindividual efficacy of pantoprazole.[3] Similarly, in another study in 35 healthy elderly subjects, **pantoprazole** 40 mg twice daily for 10 days, started 2 days before dabigatran 150 mg twice daily for 7 days, reduced the overall bioavailability of dabigatran by around 20 to 24%. However these decreases in bioavailability did not result in a significant reduction in the anticoagulant effect of dabigatran, as measured by the aPTT and ecarin clotting time (ECT). The pharmacokinetic interaction was slightly greater (29% reduction in bioavailability) when the 4 subjects who did not respond to pantoprazole were excluded, along with the one subject with hypoacidity.[4] This suggests that the effect of pantoprazole on dabigatran absorption might be due to reduced gastric acidity, but see also *Ranitidine*, below.

The effect of pantoprazole on dabigatran pharmacokinetics is modest, and probably unlikely to be clinically relevant. The manufacturer notes that the concurrent use of pantoprazole and other proton pump inhibitors with dabigatran in clinical studies did not result in a reduction in its efficacy and no effects on bleeding were seen.[2] Therefore no dabigatran dose alteration appears to be necessary if dabigatran is given with pantoprazole, and probably also other proton pump inhibitors.

(f) Ranitidine

The manufacturer of dabigatran briefly states that ranitidine had no clinically relevant effect on the extent of absorption of dabigatran.[2] No special precautions are therefore needed on the concurrent use of dabigatran and ranitidine.

1. Stangier J, Rathgen K, Stähle H, Reseski K, Körnicke T, Roth W. Coadministration of dabigatran etexilate and atorvastatin: assessment of potential impact on pharmacokinetics and pharmacodynamics. Am J Cardiovasc Drugs (2009) 9, 59–68.
2. Pradaxa (Dabigatran etexilate). Boehringer Ingelheim Ltd. UK Summary of product characteristics, October 2009.

3. Stangier J, Eriksson BI, Dahl OE, Ahnfelt L, Nehmiz G, Stähle H, Rathgen K, Svärd R. Pharmacokinetic profile of the oral direct thrombin inhibitor dabigatran etexilate in healthy volunteers and patients undergoing total hip replacement. *J Clin Pharmacol* (2005) 45, 555–63.
4. Stangier J, Stähle H, Rathgen K, Fuhr R. Pharmacokinetics and pharmacodynamics of the direct oral thrombin inhibitor dabigatran in healthy elderly subjects. Clin Pharmacokinet (2008) 47, 47–59.

Thrombin inhibitors; Ximelagatran + Miscellaneous

Aspirin did not alter the pharmacokinetics of melagatran, the active metabolite of ximelagatran, or its effects on the aPTT, but the combination had additive effects on bleeding time. Erythromycin and azithromycin increase the AUC of melagatran, the active metabolite of ximelagatran, and cause a small additional effect on coagulation parameters. The concurrent use of amiodarone and ximelagatran caused a slight increase in the AUC of melagatran and a slight decrease in the AUC of amiodarone.
No pharmacokinetic interaction occurs between ximelagatran and atorvastatin or digoxin, and concurrent use does not change coagulation status. No pharmacokinetic interaction appears to occur between ximelagatran and diazepam, diclofenac or nifedipine. This suggests that ximelagatran has no clinically relevant effect on drugs that are substrates for the cytochrome P450 isoenzymes CYP2C9, CYP2C19, and CYP3A4.

Clinical evidence, mechanism, importance and management

(a) Amiodarone

In a placebo-controlled study in 26 healthy subjects, ximelagatran 36 mg was given every 12 hours for 8 days with a single 600-mg dose of amiodarone on day 4. Concurrent use resulted in a slight 21% increase in the AUC of melagatran (the active metabolite of ximelagatran), and a slight 15% decrease in the AUC of amiodarone. Amiodarone did not alter the effect of melagatran on aPTT.[1] The mechanism of this interaction is unknown. The pharmacokinetic changes seen were not considered to be clinically relevant.

(b) Antibacterials

In 16 healthy subjects, **erythromycin** 500 mg three times daily was given for 5 days with a single 36-mg oral dose of ximelagatran given before erythromycin, and on day 5. Erythromycin increased the AUC of melagatran (the active metabolite of ximelagatran) by 82%, and the maximum plasma level by 76%. This resulted in a small increase in peak aPTT from 41 seconds to 44 seconds.[2] In another study, healthy subjects were given a single 36-mg dose of ximelagatran on day 1 and 5 of a 5-day course of azithromycin (500 mg on day 1 followed by 250 mg on days 2 to 5). **Azithromycin** increased the AUC of melagatran by 60% and caused a minor 15% increase in the peak aPTT. **Cefuroxime** (250 mg twice daily for 9 doses) also caused a minor increase in the AUC of melagatran of 23%, without affecting the aPTT, and **amoxicillin**, **ciprofloxacin** and **doxycycline** did not interact.[3]

Ximelagatran is not metabolised by cytochrome P450 isoenzymes, so the known inhibitory effect of erythromycin on CYP3A4 is not thought to be the mechanism for this interaction. The mechanism may involve inhibition of transport proteins, possibly P-glycoprotein.[2,3]

Based on the findings of a pharmacokinetic interaction with a small pharmacodynamic effect it would certainly be prudent to be cautious if ximelagatran is used in patients taking azithromycin or erythromycin, although note that the pharmacodynamic effect was small and the combination of erythromycin and ximelagatran was well tolerated.[2]

(c) Aspirin

In young healthy subjects, aspirin 450 mg the day before, and 150 mg just before melagatran had no effect on the pharmacokinetics of intravenous melagatran 4.12 mg. In addition, aspirin did not alter the increases seen in aPTT or activated clotting time seen with melagatran. Both aspirin and melagatran increased bleeding time, and the increase with the combination was additive.[4]

(d) Atorvastatin

In 15 healthy subjects, ximelagatran 36 mg twice daily was given for 5 days with a single 40-mg dose of atorvastatin on day 4. There was no change in the pharmacokinetics of either drug or their active metabolites. Atorvastatin did not alter the effect of melagatran on aPTT.[5] No special precautions are expected to be needed if ximelagatran is used in patients taking atorvastatin.

(e) Diazepam

In 24 healthy subjects, ximelagatran 24 mg twice daily was given for 8 days with a single 100-microgram/kg intravenous dose of diazepam on day 3. There was no change in the pharmacokinetics of either drug or of *N*-desmethyl-diazepam.[6]

Metabolism of diazepam to *N*-desmethyl-diazepam occurs via the cytochrome P450 isoenzyme CYP2C19, and *in vitro* studies had shown that melagatran was a weak inhibitor of this isoenzyme.[6] However, the lack of a pharmacokinetic interaction with diazepam suggests that no clinically relevant interaction occurs, and is also unlikely with other CYP2C19 substrates[6] by this mechanism (for a list see 'Table 1.3', (p.6)).

(f) Diclofenac

In a single-dose study in 24 healthy subjects, simultaneous administration of ximelagatran 24 mg and enteric-coated diclofenac 50 mg caused no change in the pharmacokinetics of either drug. In this study, there was also no additional effect of the combination on activated partial thromboplastin time or capillary bleeding time, suggesting that no pharmacodynamic interaction occurs.[6]

Diclofenac is a substrate for the cytochrome P450 isoenzyme CYP2C9, and *in vitro* study has shown that ximelagatran and melagatran are weak inhibitors of this isoenzyme.[6] However, the lack of a pharmacokinetic interaction with diclofenac suggests that no clinically relevant interaction occurs, and is also unlikely with other CYP2C9 substrates[6] by this mechanism (for a list see 'Table 1.3', (p.6)).

(g) Digoxin

In a double-blind, crossover study, 16 healthy subjects were given oral ximelagatran 36 mg twice daily or placebo for 8 days and a single 500-microgram oral dose of digoxin on day 4. Ximelagatran had no effects on the pharmacokinetics of digoxin. Similarly, digoxin had no effects on the pharmacokinetics of melagatran (the active metabolite) when ximelagatran was given orally. The anticoagulant effect of melagatran (measured as aPTT prolongation) was not altered by digoxin.[7]

(h) Nifedipine

In a single-dose study in 34 healthy subjects, giving ximelagatran 24 mg four hours after slow-release nifedipine 60 mg caused no change in the pharmacokinetics of either drug.[6]

Nifedipine is a substrate for the cytochrome P450 isoenzyme CYP3A4, and *in vitro* studies had shown that ximelagatran metabolites might be weak inhibitors of this isoenzyme.[6] However, the lack of a pharmacokinetic interaction with nifedipine suggests that no clinically relevant interaction occurs, and is also unlikely with other CYP3A4 substrates[6] by this mechanism (for a list see 'Table 1.4', (p.6)).

Antidiabetics

The antidiabetics are used to control diabetes mellitus, a disease in which there is total or partial failure of the beta-cells within the pancreas to secrete enough insulin, one of the hormones concerned with the handling of glucose. There are two main types of diabetes: one develops early in life and occurs when the ability of the pancreas suddenly, and often almost totally, fails to produce insulin. This type is called type 1, juvenile, or insulin-dependent diabetes (IDDM), and requires insulin replacement therapy. The other form is type 2, maturity-onset, or non-insulin dependent diabetes mellitus (NIDDM), which is most often seen in those over 40 years old. This occurs when the pancreas gradually loses the ability to produce insulin over a period of months or years and/or resistance to the action of insulin develops. It is often associated with being overweight and can sometimes be satisfactorily controlled simply by losing weight and adhering to an appropriate diet. This may then be augmented with oral antidiabetic drugs, and eventually insulin. A classification of the antidiabetics is given in 'Table 13.1', (p.534).

Modes of action of the antidiabetics

A. Parenteral antidiabetics

(a) Amylin analogues

Pramlintide is a synthetic analogue of amylin, a pancreatic hormone involved in glucose homoeostasis. It slows the rate of gastric emptying and reduces appetite. It is given subcutaneously immediately before meals, and is used in patients already receiving insulin.

(b) Incretin mimetics

Exenatide and liraglutide are incretin mimetics that act as a glucagon-like peptide-1 (GLP-1) receptor agonist. This increases insulin secretion when glucose levels are high. These drugs are given subcutaneously, as an adjunct, in patients with type 2 diabetes who are already receiving metformin, a sulfonylurea, or both.

(c) Insulin

Insulin extracted from the pancreatic tissue of pigs and cattle is so similar to human insulin that it can be used as a replacement. However, human insulin, manufactured by genetically engineered microorganisms, is more commonly used. Insulin is usually given by injection in order to bypass the enzymes of the gut, which would digest and destroy it like any other protein. The onset and duration of action of insulin may be prolonged by complexing with zinc or protamine. Various insulin analogues have been developed, which have specific pharmacokinetic profiles. Insulin aspart, glulisine and lispro have a faster onset and shorter duration of action than soluble insulin. Insulin glargine and detemir both have a prolonged duration of action.

An inhaled form of insulin for use in adult patients with diabetes mellitus was launched and subsequently discontinued (*Exubera*), but others are still in development.

B. Oral antidiabetics

(a) Aldose reductase inhibitors

Epalrestat inhibits the enzyme aldose reductase, which converts glucose to sorbitol. The accumulation of sorbitol may play a role in some diabetic complications.

(b) Alpha-glucosidase inhibitors

Acarbose, miglitol and voglibose act against alpha glucosidases and specifically against sucrase in the gut to delay the digestion and absorption of monosaccharides from starch and sucrose.

(c) Biguanides

The mode of action of the biguanides, such as metformin, is obscure, but they do not stimulate the pancreas like the sulfonylureas to release insulin, but appear to facilitate the uptake and utilisation of glucose by the cells in some way. Their use is restricted to type 2 diabetes because they are not effective unless insulin is present.

(d) Dipeptidylpeptidase-4 inhibitors

Saxagliptin, sitagliptin and vildagliptin increase the level of incretin hormones, and so augment insulin secretion, and are principally used in type 2 diabetes in combination with metformin and/or a sulfonylurea.

(e) Meglitinides

The meglitinides (e.g. nateglinide and repaglinide) increase endogenous insulin secretion, and so are used in type 2 diabetes.

(f) Sulfonylureas

The sulfonylurea and other sulfonamide-related compounds such as chlorpropamide and tolbutamide were the first synthetic compounds used in medicine as antidiabetics. Among their actions they stimulate the remaining beta-cells of the pancreas to grow and secrete insulin which, with a restricted diet, controls blood glucose levels and permits normal metabolism to occur. Clearly they can only be effective in those diabetics whose pancreas still has the capacity to produce some insulin, so their use is confined to type 2 diabetes.

(g) Thiazolidinediones

The thiazolidinediones (e.g. rosiglitazone) appear to decrease insulin resistance through activation of gamma-PPAR (peroxisome proliferator-activated receptor). They are used in type 2 diabetes.

(h) Other oral antidiabetics

Outside orthodox Western medicine, there are herbal preparations which are used to treat diabetes and which can be given by mouth. Blueberries were traditionally used by the Alpine peasants, and bitter gourd or karela (*Momordica charantia*) is an established part of herbal treatment in the Indian subcontinent and elsewhere. Traditional Chinese medicine also has herbal medicines for diabetes. As yet it is not known how these herbal medicines act and their efficacy awaits formal clinical evaluation.

Interactions

The commonest interactions with antidiabetic drugs are those that result in a rise or fall in blood glucose levels, thereby disturbing the control of diabetes. These are detailed in this section. Other interactions where the antidiabetic drug is the affecting drug are described elsewhere.

Table 13.1 Drugs used in the management of diabetes

Group		*Drugs*
Parenteral antidiabetics		
Amylin analogues		Pramlintide
Incretin mimetics (Glucagon like peptide-1 receptor agonists)		Exenatide
Insulins	Short-acting	Soluble insulin
	Intermediate- and long-acting	Insulin zinc suspension, Isophane insulin, Protamine zinc insulin
	Short-acting analogues	Insulin aspart, Insulin glulisine, Insulin lispro
	Intermediate to long-acting analogues	Insulin aspart protamine, Insulin detemir, Insulin glargine, Insulin lispro protamine
Oral antidiabetics		
Aldose reductase inhibitors		Epalrestat
Alpha glucosidase inhibitors		Acarbose, Miglitol, Voglibose
Biguanides		Buformin, Metformin, Phenformin
Meglitinides		Nateglinide, Repaglinide
Dipeptidyl peptidase-4 inhibitors		Alogliptin, Linagliptin, Saxagliptin, Sitagliptin, Vildagliptin
Sulphonylureas		Acetohexamide, Carbutamide, Chlorpropamide, Glibenclamide (Glyburide), Glibornuride, Gliclazide, Glimepiride, Glipizide, Gliquidone, Glisentide, Glisolamide, Glisoxepide, Glycyclamide, Tolazamide, Tolbutamide
Thiazolidinediones		Pioglitazone, Rosiglitazone
Other drugs		Guar gum

Acarbose + Miscellaneous

Neomycin may increase the efficacy and the gastrointestinal adverse effects of acarbose. Paralytic ileus has been reported in a Japanese patient given acarbose and promethazine. A study in *animals* suggested that acarbose alone or with alcohol may increase the hepatotoxicity of paracetamol (acetaminophen).

Clinical evidence, mechanism, importance and management

(a) Antimuscarinics

A 69-year-old man with a partial gastrectomy and type 2 diabetes, receiving insulin 24 units and acarbose 300 mg daily, was admitted to hospital with diabetic gangrene. After developing cold symptoms he was given *PL granules* (salicylamide, paracetamol, caffeine, and **promethazine** methylene disalicylate). The next day he experienced sudden abdominal pain, nausea and vomiting, which was diagnosed as paralytic ileus. He was given intravenous fluids and piperacillin. Oral intake and acarbose were withheld and the ileus resolved after 2 days. The authors note that there are several reports of ileus developing in Japanese patients within 3 months of treatment with alpha-glucosidase inhibitors such as acarbose. The risk seems to be increased with increasing age, a history of abdominal surgery, and a Japanese diet (high in carbohydrates and fibre) rather than Western diet. However, in this case the patient had been taking acarbose for 15 months without problem and it is possible that the antimuscarinic effects of **promethazine** may have contributed to the development of ileus.[1] The general clinical relevance of this case is uncertain. However, the authors consider that patients at risk should be monitored if they are given alpha-glucosidase inhibitors, especially if the dose is increased or if antimuscarinics are also given.[1]

(b) Neomycin

Neomycin alone can reduce postprandial blood glucose levels and may enhance the reduction in postprandial glucose levels associated with acarbose.[2] In 7 healthy subjects, neomycin 1 g three times daily increased the unpleasant gastrointestinal adverse effects (flatulence, cramps and diarrhoea) of acarbose 200 mg three times daily.[3] The manufacturers suggest that if these adverse effects are severe, a temporary reduction in the dose of acarbose may be needed.[4]

(c) Paracetamol

Studies in *rats* have found that acarbose alone or in combination with alcohol may potentiate the hepatotoxicity of paracetamol. Both acarbose and alcohol induced the cytochrome P450 isoenzyme CYP2E1, by which paracetamol is metabolised to its hepatotoxic metabolite.[5] These findings require confirmation in humans, because *animal* data are not always reproduced in humans.

Alpha-glucosidase inhibitors + Antacids

Antacids appear not to interact with acarbose or miglitol.

Clinical evidence, mechanism, importance and management

(a) Acarbose

In 24 healthy subjects given a 75-g dose of sucrose, a placebo-controlled study found that 10 mL of *Maalox 70* (**aluminium**/**magnesium hydroxide**) had no effect on the blood glucose- and insulin-lowering effects of acarbose 100 mg. It was concluded that no special precautions are needed if this or similar antacids are used with acarbose.[1]

(b) Miglitol

The manufacturer notes that an antacid (not specified) did not alter the pharmacokinetics of miglitol in healthy subjects.[2] No miglitol dose adjustment would be expected to be necessary on concurrent use.

2. Glyset (Miglitol). Pharmacia & Upjohn Company. US Prescribing information, September 2009.

Alpha-glucosidase inhibitors + Charcoal or Digestive enzymes

The manufacturers of acarbose[1,2] and miglitol[3] reasonably suggest that intestinal adsorbents (e.g. charcoal) or digestive enzyme preparations containing carbohydrate splitting enzymes (such as amylase, pancreatin) should be avoided because, theoretically, they would be expected to reduce the effects of these alpha glucosidase inhibitors.

2. Precose (Acarbose). Bayer Pharmaceuticals Corporation. US Prescribing information, August 2008.
3. Glyset (Miglitol). Pharmacia & Upjohn Company. US Prescribing information, September 2009.

Alpha-glucosidase inhibitors + Other antidiabetics

Some minor decreases in the plasma levels of glibenclamide (glyburide), metformin, and rosiglitazone have been seen with acarbose or miglitol. Voglibose had no effect on glibenclamide pharmacokinetics. Alpha-glucosidase inhibitors cause a moderate additional blood glucose-lowering effect when used with other antidiabetics, and a possible increased risk of hypoglycaemia should be borne in mind with insulin and sulfonylureas. In patients taking alpha-glucosidase inhibitors, treatment of hypoglycaemia should be with a monosaccharide such as glucose (dextrose) or glucagon, not a disaccharide such as sucrose. The manufacturer of pramlintide recommends that it should not be used in patients taking alpha-glucosidase inhibitors.

Clinical evidence

(a) Glibenclamide (Glyburide)

Voglibose had no effect on the pharmacokinetics of glibenclamide in a double-blind crossover study in 12 healthy male subjects. In this study, subjects were given either **voglibose** 5 mg or a placebo three times daily for 8 days and a single 1.75-mg dose of glibenclamide on the morning of day 8, taken at the same time as the first dose of the **voglibose** or placebo.[1] Similarly, the manufacturers of **acarbose** note that it had no effect on the absorption or disposition of glibenclamide in diabetic patients.[2] However, in a randomised, placebo-controlled study in 28 patients with type 2 diabetes mellitus, **miglitol** reduced the maximum plasma glibenclamide levels and AUC by 16% and 19%, respectively. The patients were given glibenclamide 2.5 mg twice daily with either **miglitol** 100 mg three times daily or placebo for 2 days. Nevertheless, the average blood glucose levels were reduced more by the drug combination than by the glibenclamide alone: over 5 hours there was a 15% greater reduction, and over 10 hours a 9% greater reduction.[3] There was no increased incidence of hypoglycaemia when **miglitol** was used with sulfonylureas in clinical studies.[4]

(b) Metformin

A study in 6 healthy subjects found that **acarbose** 50 to 100 mg three times daily reduced the maximum serum levels and the AUC_{0-9} of metformin 1 g by about 35%, but the 24-hour urinary excretion was unchanged.[5] Another study in 19 diabetic patients given **acarbose** 50 or 100 mg three times daily and metformin 500 mg twice daily, also found that **acarbose** lowered metformin levels (AUC reduced by 12 to 13%, maximum plasma levels reduced by 17 to 20%). Nevertheless, the drug combination reduced the postprandial glucose concentration at 3 hours by 15% more than metformin alone.[6] There was no increased incidence of

hypoglycaemia when **acarbose** was used with metformin.[2]

The manufacturer notes that, in a study in healthy subjects, **miglitol** 100 mg three times daily for 7 days reduced the AUC and maximum level of a single 1-g dose of metformin by 12% and 13%, respectively, although this difference was not statistically significant.[4]

(c) Pramlintide

The manufacturer of pramlintide suggests that it should not be used in patients taking drugs that slow the intestinal absorption of nutrients, such as the alpha-glucosidase inhibitors.[7] This is because pramlintide slows gastric emptying (see also 'Pramlintide + Miscellaneous', p.585). Clinical study is needed to see if there is any important effect if the drugs are used together.

(d) Rosiglitazone

A study in 16 healthy subjects found that **acarbose** 100 mg three times daily for a week slightly reduced the absorption of a single 8-mg oral dose of rosiglitazone (AUC reduced by 12%), but this was not considered to be clinically relevant.[8]

Mechanism

The reason for the minor pharmacokinetic changes is uncertain.

Importance and management

The pharmacokinetic changes seen are minor and unlikely to be clinically relevant. The manufacturers say that while alpha-glucosidase inhibitors such as acarbose and miglitol do not cause hypoglycaemia when given alone, they may increase the blood glucose-lowering effects of insulin and the sulfonylureas, for which reason it may be necessary to reduce their doses. Monitor the outcome when acarbose, miglitol, or voglibose is first given. Any hypoglycaemic episodes should be treated with glucose (dextrose), not sucrose, because alpha-glucosidase inhibitors delay the digestion and absorption of disaccharides such as sucrose, but do not affect monosaccharides.[2,4,9] Patients taking alpha-glucosidase inhibitors should not be given pramlintide until the combination has been studied clinically.

Antidiabetics + ACE inhibitors

The concurrent use of ACE inhibitors and antidiabetics normally appears to be uneventful but hypoglycaemia, marked in some instances, has occurred in a small number of diabetic patients taking insulin or sulfonylureas with captopril, enalapril, lisinopril or perindopril. This has been attributed, but not proved, to be due to an interaction. The United Kingdom Prospective Diabetes Study Group (UKPDS) found no difference in the incidence of hypoglycaemia between patients taking atenolol and those taking captopril. No pharmacokinetic interaction has been found to occur between spirapril and glibenclamide. Subcutaneous exenatide has no important effect on the pharmacokinetics of lisinopril, and does not alter its efficacy.

Clinical evidence

(a) Hypoglycaemia

Numerous case reports, small case-control studies, and a pharmacological study in healthy subjects suggest that ACE inhibitors increase the risk of hypoglycaemia when used with insulin or oral antidiabetics (mainly sulfonylureas where specified), and these are summarised in 'Table 13.2', (p.537). Conversely several larger case-control studies and two randomised controlled studies have not found a significantly increased risk of hypoglycaemia with ACE inhibitors in patients with diabetes, and these are also summarised in Table 13.2. It is worth highlighting that one of these, the United Kingdom Prospective Diabetes Study Group (UKPDS), found that the number of patients experiencing hypoglycaemic attacks did not differ between patients receiving atenolol 50 to 100 mg daily or **captopril** 25 to 50 mg twice daily for hypertension.[1] For more information about the use of beta blockers with antidiabetics, see 'Antidiabetics + Beta blockers', p.547.

(b) Pancytopenia

There is an isolated case of pancytopenia (possibly drug related) that occurred in a 72-year old man taking enalapril, an alpha blocker and a calcium antagonist (glomerular filtration rate 60 mL/minute), shortly after he started to take **glipizide** 5 mg twice daily for diabetes.[2]

(c) Pharmacokinetics

A brief report states that **spirapril** does not have a pharmacokinetic interaction with **glibenclamide**.[3]

The manufacturer of **exenatide** notes that, in a study in hypertensive patients, exenatide 10 micrograms twice daily did not alter the steady-state AUC or maximum level of **lisinopril** 5 to 20 mg daily, but it did delay the time to maximum level by 2 hours. **Exenatide** did not alter the blood-pressure lowering effect of **lisinopril**.[4,5]

Mechanism

The hypoglycaemia is not understood. An increase in glucose utilisation and increased insulin sensitivity have been suggested.[6,7] Other possibilities (e.g. altered renal function) are discussed in a series of letters in *The Lancet*.[8-13] There is also an isolated report of persistent severe hypoglycaemia in a non-diabetic patient associated with both **captopril** and **ramipril**.[14] Conversely, high natural ACE activity has been associated with a higher risk of severe hypoglycaemia in type 1 diabetics receiving insulin and not taking ACE inhibitors, leading to the hypothesis that ACE inhibitors might reduce the risk of hypoglycaemia in these individuals.[15]

Blood dyscrasias are a rare adverse effect of ACE inhibitors used alone, and have also occurred with glipizide alone. Whether concurrent use could increase this risk is uncertain.

Importance and management

This interaction is not well established and not understood, and it remains the subject of considerable study and debate. However, some cases of severe hypoglycaemia have undoubtedly occurred in diabetic patients managed with insulin or sulfonylureas as a result of the use of ACE inhibitors. Nevertheless, some authors consider the risk of severe hypoglycaemia in diabetic patients taking ACE inhibitors to be very low and negligible compared with the benefits of this class of drugs in diabetes.[16] Moreover, a number of guidelines on the treatment of hypertension in diabetes recommend that all patients with diabetes and hypertension should be given an ACE inhibitor.[17,18] To be on the safe side, it might be prudent to warn all patients receiving insulin or sulfonylureas who are just starting any ACE inhibitor (although only captopril, enalapril, lisinopril and perindopril have been implicated) that excessive hypoglycaemia has been seen very rarely and unpredictably. The problem has been resolved in some patients by reducing the sulfonylurea dose by 50 to 75%.[19,20]

Subcutaneous exenatide has no important pharmacokinetic interaction with lisinopril, and pharmacokinetic interactions with other ACE inhibitors would not be expected.

A false positive urine ketone test can also occur with captopril when using the alkaline-nitroprusside test (*Ketodiastix*), which may affect the monitoring of diabetic control.[21]

The isolated case of pancytopenia is probably of limited general relevance.

Table 13.2 Interactions between antidiabetics and ACE inhibitors

Patients	*ACE inhibitor*	*Antidiabetic*	*Notes*	*Refs*
Evidence for hypoglycaemia				
1 case	Captopril 50 mg/day	Glibenclamide (glyburide) 10.5 mg/day Metformin 1.7 g/day	Blood glucose 2.2 mmol/L 24 hours after the addition of captopril.	1
1 case	Captopril	Glibenclamide 10.5 mg/day Metformin 1.7 g/day	Blood glucose of 2.9 mmol/L 48 hours after starting captopril. Antidiabetic drugs stopped.	1
3 cases	Captopril	Glibenclamide	Hypoglycaemia reported to a Spanish Regional Pharmacosurveillance centre.	2
1 case	Captopril 12.5 mg/day	Glibenclamide 2.5 mg/day	Hypoglycaemia 7 hours after first dose, blood glucose 2.1 mmol/L, glibenclamide stopped.	3
1 case	Captopril	Unspecified oral antidiabetic	Hypoglycaemia, oral antidiabetic withdrawn.	4
5 cases	Captopril	Unspecified sulfonylureas	Hypoglycaemia reported to Centres Regionaux de Pharmacovigilance in France.	5
3 cases case control study	Captopril	Unspecified oral antidiabetics	Risk of hypoglycaemia increased 3.1-fold.	6
9 cases case control study	Captopril	Insulin	Risk of hypoglycaemia increased 3.7-fold.	6
4 cases	Captopril	Insulin	Hypoglycaemia reported to a Spanish Regional Pharmacosurveillance centre.	2
3 cases	Captopril	Insulin	Unexplained hypoglycaemia.	4
1 case	Enalapril 5 mg/day	Glibenclamide 5 mg/day	Hypoglycaemia, blood glucose 2.3 mmol/L. Dose of glibenclamide reduced to 2.5 mg/day.	3
2 cases	Enalapril 5 mg/day	Glibenclamide 5 mg/day	Hypoglycaemic attacks, glibenclamide reduced to 1.25 mg/day.	7
9 healthy subjects (double-blind, crossover study)	Enalapril 5 mg/day, then 10 mg/day	Glibenclamide 3.5 mg single dose	Hypoglycaemic effects of glibenclamide temporarily enhanced between 2 and 4 hours after enalapril was taken.	8
4 cases	Enalapril	Glibenclamide	Hypoglycaemia reported to a Spanish Regional Pharmacosurveillance centre.	2
1 case	Enalapril	Gliclazide 80 mg/day	Hypoglycaemia when enalapril dose increased from 5 to 10 mg/day.	9
4 cases	Enalapril	Unspecified sulfonylureas	Hypoglycaemia reported to Centres Regionaux de Pharmacovigilance in France.	5
1 case	Enalapril	Unspecified sulfonylurea	Recurrent hypoglycaemia, sulfonylurea withdrawn.	10
10 cases case control study	Enalapril	Unspecified sulfonylurea Insulin	2.4-fold increase in the risk of hypoglycaemia with sulfonylureas. However, no increased risk was seen in insulin users. In addition when all ACE inhibitors were considered together, no significant increase in risk was seen.	11
2 cases case control study	Enalapril	Unspecified oral antidiabetics	Non-significant 5.4-fold increase in the risk of hypoglycaemia.	6
3 cases case control study	Enalapril	Insulin	Non-significant 1.7-fold increase in the risk of hypoglycaemia.	6
1 case	Enalapril	Insulin	Reduced insulin requirements.	10
11 cases	Enalapril	Insulin	Hypoglycaemia reported to a Spanish Regional Pharmacosurveillance centre.	2
1 case	Lisinopril	Glibenclamide and metformin	Hypoglycaemia reported to a Spanish Regional Pharmacosurveillance centre.	2
1 case	Lisinopril 10 mg/day	Gliclazide	Hypoglycaemia resolved on stopping gliclazide.	9
1 case	Perindopril	Glibenclamide	Hypoglycaemia reported to a Spanish Regional Pharmacosurveillance centre.	2

Continued

Table 13.2 Interactions between antidiabetics and ACE inhibitors (continued)

Patients	*ACE inhibitor*	*Antidiabetic*	*Notes*	*Refs*
1 case	Ramipril 2.5 mg/day	Glibenclamide 5 mg/day Metformin 1.7 g/day	Patient also on naproxen, renal function deteriorated causing hypoglycaemia due to accumulation of oral antidiabetics.	12
7 cases case control study	Unspecified ACE inhibitor	Insulin or oral antidiabetics	3.2-fold increase in the risk of hypoglycaemia leading to hospitalisation.	13
Evidence of no interaction				
8 cases	Captopril 37.5 mg/day	Insulin	No change to daily insulin requirements. No evidence of symptomatic hypoglycaemia.	14
38 cases	Captopril 50 to 100 mg/day or Enalapril 20 to 40 mg/day	Insulin or oral antidiabetics	Antidiabetic treatment unaltered, no evidence of unusual or unexplained hypoglycaemia.	15
18 cases double blind controlled study	Enalapril 20 to 40 mg/day	Insulin	No change to daily insulin requirements. No evidence of unexplained hypoglycaemia.	15
428 patients randomised controlled study	Lisinopril 10 to 20 mg/day or placebo	Insulin	No difference in the number of hypoglycaemic episodes between lisinopril and placebo recipients.	16
22 cases case control study	Captopril or Enalapril	Insulin or oral antidiabetics	Data from Centres Regionaux de Pharmacovigilance in France used. No increased risk of hypoglycaemia detected.	17
598 cases of hypoglycaemia in a retrospective study	Captopril or Enalapril or other classes of antihypertensive	Insulin or oral antidiabetics	No statistically significant increase or decrease in the risk of serious hypoglycaemia among users of ACE inhibitors or any other class of antihypertensives compared with non users of antihypertensives.	18
758 patients randomised controlled study	Captopril 50 to 100 mg/day or atenolol	Insulin or oral antidiabetics or diet alone	The proportion of patients with hypoglycaemic attacks did not differ between the captopril and atenolol groups.	19
336 reports case control study	Captopril or Enalapril	Antidiabetics	Data from the French pharmacovigilance database used. No increased risk of hypoglycaemia detected when confounding by indication considered.	20

Antidiabetics + Alcohol

Diabetic patients managed with insulin, oral antidiabetics or diet alone need not abstain from alcohol, but they should drink only in moderation and accompanied by food. Epidemiological evidence suggests that heart disease may be less common in diabetic patients who drink in moderation. However, alcohol makes the signs of hypoglycaemia less clear and delayed hypoglycaemia can occur. The CNS depressant effects of alcohol in conjunction with hypoglycaemia can make driving or the operation of dangerous machinery much more hazardous. A flushing reaction is common in patients taking chlorpropamide who drink alcohol, but is less common with other sulfonylureas. Limited evidence suggests that alcoholic patients may require above-average doses of tolbutamide.

Clinical evidence

(a) Antidiabetics, general

1. Effect on glucose levels. The blood glucose levels of diabetics may be reduced, remain unchanged, or be increased by alcohol, depending on the amount drunk at one time, if it is drunk with food or not, and if use is chronic and excessive.[1] In one early study, 2 out of 7 diabetic patients receiving **insulin** became severely hypoglycaemic after drinking the equivalent of about 3 measures of spirits.[2] In a hospital study over a 3-year period, five type 1 diabetics were hospitalised with severe hypoglycaemia after binge-drinking. Two of them died without recovery from the initial coma and the other 3 suffered permanent damage to the nervous system.[3] In another study it was found that alcohol was involved in about 4% of hypoglycaemic episodes requiring hospitalisation.[4] In contrast to these alcohol-induced hypoglycaemic episodes, it was found in two other studies[5,6] that pure alcohol and dry wine had little effect on blood glucose levels. In a recent review of six studies, it was concluded that consumption of a moderate amount of alcohol does not acutely impair glycaemic control in diabetic patients, and may in fact result in a small decrease in plasma glucose concentrations.[7] However, another study found that 46 patients with type 2 diabetes and a mean age of 67 years who were regular chronic alcohol users (mean 45 g/day) had a reversible deterioration in metabolic control (higher fasting and postprandial glucose levels and higher HbA_{1c} levels), when compared with 35 non-alcohol users.[8] Another study reported similar findings.[9]

2. Effect on diabetic complications. A review of 4 epidemiological studies concluded that heart disease is less common in people with diabetes who drink moderate amounts of alcohol than in those who do not.[7]

(b) Biguanides

A controlled study in 5 ketosis-resistant patients with type 2 diabetes taking **phenformin** 50 to 100 mg daily found that the equivalent of about 85 mL (3 oz) of whiskey markedly raised their blood lactate and lactate-pyruvate levels. Two of them had blood-lactate levels of more than 50 mg%, and one of these patients had previously experienced nausea, weakness and malaise while taking **phenformin** and alcohol.[10] The ingestion of alcohol is described in other reports as having preceded the onset of **phenformin**-induced lactic-acidosis.[11-13] Some patients have complained that alcohol tastes metallic.

(c) Rosiglitazone

An 8-week study in type 2 diabetics taking rosiglitazone 8 mg daily or a placebo found that 0.6 g/kg of alcohol taken with a meal did not have a clinically relevant effect on plasma glucose levels and no episodes of hypoglycaemia were seen.[14]

(d) Sulfonylureas

About one-third of patients taking **chlorpropamide** who drink alcohol, even in quite small amounts, experience a warm, tingling or burning sensation of the face, and sometimes the neck and arms as well. It may also involve the conjunctivae. This can begin within 5 to 20 minutes of drinking, reaching a peak within 30 to 40 minutes, and may persist for one to 2 hours. Very occasionally headache occurs, and light-headedness, palpitations, wheezing and breathlessness have also been experienced.[15,16]

This disulfiram-like flushing reaction has been described in numerous reports (far too many to list here) involving large numbers of patients taking **chlorpropamide**. These reports have been extensively reviewed.[15,17-19] A similar reaction can occur, but much less frequently, with other sulfonylureas including **carbutamide**,[20] **glibenclamide** (**glyburide**),[16,21] **gliclazide**,[22] **glipizide**,[16] **tolazamide**,[23] and **tolbutamide**.[24,25] In one crossover study, evident flushing phenomenon after an oral ethanol-loading test was seen in 6 of 10 patients taking **chlorpropamide**, 3 of 10 taking **tolbutamide**, 2 of 10 taking **glibenclamide**, one of 10 taking **glibornuride** and none of 10 taking **glipizide**.[26]

A study found that the mean half-life of **tolbutamide** in alcoholics was about one-third lower than in control subjects.[27] Alcohol is also reported to prolong but not increase the blood glucose-lowering effects of **glipizide**.[28] Another study in 10 elderly patients (age range 60 to 75 years) with type 2 diabetes taking **glibenclamide** 20 mg daily found that intravenous infusion of ethanol (equivalent to one to 2 units of alcoholic drinks) significantly decreased the nadir plasma glucose level during a fast.[29]

Mechanism

The exacerbation of hypoglycaemia by alcohol is not fully understood. However, it is known that if hypoglycaemia occurs when liver glycogen stores are low, the liver turns to the formation of new glucose from amino acids (gluconeogenesis). This gluconeogenesis is inhibited by the presence of alcohol so that the fall in blood glucose levels may not be prevented and a full-scale hypoglycaemic episode can result.

The chlorpropamide-alcohol flush reaction, although extensively studied, is by no means fully understood. It seems to be related to the disulfiram-alcohol reaction, and is accompanied by a rise in blood-acetaldehyde levels (see also 'Alcohol + Disulfiram', p.66). It also appears to be genetically determined[16] and may involve both prostaglandins and endogenous opioids.[30] The decreased half-life of tolbutamide in alcoholics is probably due to the inducing effects of alcohol on liver microsomal enzymes.[27,31,32]

The reasons for the raised blood lactate levels seen during the concurrent use of phenformin and alcohol are not clear, but one suggestion is that it may possibly be related to the competitive demands for isoenzymes by the reactions that convert alcohol to acetaldehyde, and lactate to pyruvate.[10] A study in healthy subjects found that moderate alcohol consumption both improves insulin action, without affecting non-insulin mediated glucose uptake, and decreases lactate clearance. The increase in blood lactate with alcohol is therefore mainly due to inhibition of clearance. Alcohol did not appear to significantly affect beta-cell function.[33]

Importance and management

The documentation of the interactions between antidiabetic drugs and alcohol is surprisingly patchy (with the exception of chlorpropamide and alcohol) but they are of recognised clinical importance.

General comments

The following contains the main recommendations of Diabetes UK (formerly The British Diabetic Association) based on a review of what is currently known:[34,35] most diabetics need not avoid alcohol totally, but they are advised not to exceed 2 drinks (for women) or 3 drinks (for men) daily. A drink (or unit) is defined in 'Table 3.1', (p.47). The intake of drinks with high-carbohydrate content (sweet sherries, sweet wines, most liqueurs, and low alcohol wines) should be limited. Diabetics should not drink on

an empty stomach and they should know that the warning signs of hypoglycaemia may possibly be obscured by the effects of the alcohol. Driving or handling dangerous machinery should be avoided because the CNS depressant effects of alcohol plus hypoglycaemia can be particularly hazardous. Warn patients of the risks of hypoglycaemia occurring several hours after drinking. Those with peripheral neuropathy should be told that alcohol may aggravate the condition and they should not have more than one drink daily. Provided drinking is restricted as suggested, and drinks containing a lot of carbohydrate are avoided, there is no need to include the drink in the dietary allowance. However, diabetics on a weight-reducing diet should try to limit intake to the occasional drink and should include it in their daily calorie allowance.

The advice of the American Diabetes Association is similar: if individuals choose to drink alcohol, daily intake should be limited to one drink (for women) or 2 drinks (for men). [This equates to about 1.75 units for women and 3.5 units for men]. To reduce the risk of hypoglycaemia in individuals using insulin or oral insulin secretagogues, alcohol should be consumed with food.[1]

There is some evidence that heart disease in patients with diabetes may be less common in patients who consume moderate amounts of alcohol, but this is currently not sufficient to recommend that patients who do not drink alcohol should begin to drink in moderation.[7]

Specific comments about oral antidiabetics

The **chlorpropamide**-alcohol interaction (flushing reaction) is very well documented, but of minimal importance. It is a nuisance and possibly socially embarrassing but normally requires no treatment. Patients should be warned. The incidence is said to lie between 13 and 33%[36,37] although one study claims that it may be as low as 4%.[38] As it can be provoked by quite small amounts of alcohol (half a glass of sherry or wine) it is virtually impossible for sensitive patients to avoid it if they drink. Most manufacturers issue warnings about the possibility of this reaction with other sulfonylureas, but it is very rarely seen and can therefore almost always be avoided by replacing chlorpropamide with another sulfonylurea.

Alcoholic subjects may need above-average doses of tolbutamide. **Metformin** does not carry the same risk of lactic acidosis seen with phenformin and it is suggested in a paper[34] prepared for and approved by The British Diabetic Association [now Diabetes UK] that one or two drinks a day are unlikely to be harmful in patients taking **metformin**. However, the drug should not be given to alcoholic patients because of the possibility of liver damage.

Antidiabetics + Allopurinol

Allopurinol adversely affected glycaemic control in a patient with type 2 diabetes receiving insulin. Marked hypoglycaemia and coma occurred in one patient taking gliclazide and allopurinol. Allopurinol causes an increase in the half-life of chlorpropamide, and a minor decrease in the half-life of tolbutamide.

Clinical evidence

A. Insulin

A case report describes improved glycaemic control in a type 2 diabetic patient after allopurinol was stopped. Despite restricted food intake and an increasing dose of insulin, his glycaemic control was poor (fasting blood glucose 14.8 mmol/L) when he took allopurinol 100 mg twice daily. However, within a few days of stopping the allopurinol, an unexpected improvement in glycaemic control was observed (fasting blood glucose reduced to less than 11 mmol/L). He was later rechallenged with allopurinol, which resulted in reduced glucose tolerance, but increased insulin response, suggesting increased insulin resistance. Hyperuricaemia was later controlled with **probenecid**, which did not adversely affect glycaemic control.[1]

B. Sulfonylureas

(a) Chlorpropamide

A brief report describes 6 patients taking chlorpropamide with allopurinol. The half-life of chlorpropamide in one patient with gout and normal renal function exceeded 200 hours (normally 36 hours) after allopurinol had been taken for 10 days, and in 2 other patients the half-life of chlorpropamide was extended to 44 hours and 55 hours. The other 3 patients were given allopurinol for only one or 2 days and the half-life of chlorpropamide remained unaltered.[2]

(b) Gliclazide

Severe hypoglycaemia (1.6 mmol/L) and coma occurred in a patient with renal impairment taking gliclazide and allopurinol.[3] Hypoglycaemia has been seen in another patient taking both drugs, but an interaction is less clear, as enalapril and ranitidine, which may also (rarely) interact were also involved.[3]

(c) Tolbutamide

In 10 healthy subjects, allopurinol 2.5 mg/kg twice daily for 15 days reduced the half-life of intravenous tolbutamide by 25% (from 360 to 267 minutes).[4,5]

Mechanism

Not understood. In the case of chlorpropamide it has been suggested that the interaction possibly involves some competition for renal tubular mechanisms.[2]

Importance and management

Information regarding interactions between the sulfonylureas and allopurinol is very limited. Only gliclazide has been implicated in severe hypoglycaemia with allopurinol and there seem to be no reports of either grossly enhanced hypoglycaemia with chlorpropamide and allopurinol, or a reduced effect with tolbutamide and allopurinol. More study is needed to find out whether any of these interactions has general clinical importance, but it seems unlikely.

Antidiabetics + Anabolic steroids or Androgens

Nandrolone, methandienone, testosterone and stanozolol can enhance the blood glucose-lowering effects of insulin, and testosterone may also improve glycaemic control in those taking oral antidiabetics.

Clinical evidence

(a) Insulin

In a study in 54 diabetic patients taking **nandrolone phenylpropionate** 25 mg weekly or **nandrolone decanoate** 50 mg given every 3 weeks by intramuscular injection, it was found necessary to reduce the **insulin** dose by an average of 36% (reduction of 4 to 56 units) in about one-third of the patients.[1] In another placebo-controlled study in hypogonadal men with type 2 diabetes, of 10 patients using **insulin**, 5 reduced their daily insulin dose (by a mean of 7 units) while receiving intramuscular **testosterone esters** (*Sustanon*) once every 2 weeks for 3 months.[2]

Other reports similarly describe an enhanced reduction in blood glucose levels in diabetics receiving **insulin** and **nandrolone**,[3,4] **methandienone**,[5] **testosterone propionate**[6] or **stanozolol**.[7] No changes were seen when **ethylestrenol** was used.[1,3]

(b) Oral antidiabetics

In a placebo-controlled study in hypogonadal men with type 2 diabetes, intramuscular **testosterone esters** (*Sustanon*) once every 2 weeks for 3 months reduced fasting glucose by a mean of 1.6 mmol/L and HbA_{1c} by 0.37% (from over 7.4% to about 7.1%) in the 14 who were taking oral antidiabetics (11 patients) or diet alone (3 patients). The oral antidiabetics being taken were **metformin** alone or with **gliclazide** and/or **rosiglitazone**.[2]

Mechanism

Uncertain. Some evidence suggests that androgens improve insulin sensitivity, although androgens are often considered to impair glucose tolerance. A reduction in blood glucose levels has been seen in healthy subjects given testosterone propionate.[8]

Importance and management

The interactions between the anabolic steroids or androgens and antidiabetics are established but the total picture is incomplete because not all of the anabolic steroids appear to have been studied and they may not necessarily behave identically. A fall in the dose requirements of insulin (of an average of one-third[1]) may be expected in many patients with the steroids cited. Some improvement in glycaemic control may also occur in patients receiving oral antidiabetics. Given these results, and the fact that, conversely, anabolic steroids have also been shown to *impair* glucose tolerance it would seem prudent to closely monitor the concurrent use of any antidiabetic drug.

Antidiabetics + Angiotensin II receptor antagonists

Glibenclamide (glyburide) causes a small reduction in valsartan levels. No clinically relevant pharmacokinetic interaction occurs between glibenclamide and candesartan or telmisartan, or between tolbutamide and irbesartan. Eprosartan does not alter the efficacy of glibenclamide. There is some experimental evidence that suggests that losartan and eprosartan may possibly reduce awareness of hypoglycaemic symptoms, but no increased risk was seen in a large epidemiological study.

Clinical evidence

(a) Hypoglycaemia

A study in 16 healthy subjects found that a single 600-microgram dose of **eprosartan** did not significantly affect adrenaline (epinephrine) release in response to **insulin**-induced hypoglycaemia, but the eprosartan tended to blunt some of the haemodynamic responses to hypoglycaemia.[1] Theoretically, therefore, hypoglycaemic symptoms could be reduced in some diabetic patients. Three patients with type 1 diabetes spontaneously reported reduced awareness of hypoglycaemic symptoms (tremor, palpitations, nervousness) after **losartan** was started. A placebo-controlled study in 16 healthy subjects given **losartan** 50 mg daily for 8 days confirmed an attenuation of the symptomatic and hormonal responses to hypoglycaemia.[2] However, in contrast, an early similar study found no such effect.[3]

The French pharmacovigilance database was examined for an association between angiotensin II receptor antagonists and reported hypoglycaemia. Although an association was found (odds ratio 2) this was confounded by an association between use of angiotensin II receptor antagonists and antidiabetic drugs. When looking specifically at patients taking antidiabetic drugs, there was no association between angiotensin II receptor antagonist use and hypoglycaemia, and in fact, a reduced risk of reporting hypoglycaemia (odds ratio 0.4). Angiotensin II receptor antagonists used in order of frequency included **losartan**, **irbesartan**, **valsartan**, **candesartan**, **telmisartan** and **eprosartan**.[4]

(b) Pharmacokinetic studies

1. Candesartan. **Glibenclamide (glyburide)** 3.5 mg daily did not significantly affect the pharmacokinetics of candesartan 16 mg daily, both given for 7 days, although the maximum plasma concentration of candesartan was slightly increased by 12%. The pharmacokinetics of glibenclamide were not altered by the candesartan.[5]

2. Eprosartan. Fifteen patients with type 2 diabetes stable taking **glibenclamide (glyburide)** 3.75 to 10 mg daily for at least 30 days had no changes in their 24-hour plasma glucose concentrations when eprosartan 200 mg twice daily was added, for a further 7 days. It was concluded that there is no clinically relevant interaction between these two drugs.[6]

3. Irbesartan. A study in 18 healthy subjects given irbesartan 300 mg daily and **tolbutamide** 1 g daily, either alone or in combination, found that no clinically important pharmacokinetic interactions occurred.[7]

4. Valsartan. In a randomised, crossover study, 12 healthy subjects were given single oral doses of valsartan 160 mg and **glibenclamide (glyburide)** 1.75 mg, alone and together.[8] Glibenclamide appeared to decrease the valsartan AUC by 16%, but the plasma concentrations of valsartan

showed wide variations between subjects. The pharmacokinetics of glibenclamide were not affected.[8] The changes in valsartan pharmacokinetics seen with glibenclamide appear to have little or no clinical relevance.

Mechanism

It has been suggested that blocking angiotensin II will block the adrenaline (epinephrine) response to insulin-induced hypoglycaemia, and thereby reduce awareness of hypoglycaemia. However, early studies found that angiotensin II receptor antagonists of the AT1 subtype such as losartan were not able to do this on their own, and AT2 subtype blockers were needed as well.[3,9]

Importance and management

No special precautions would appear to be needed if candesartan, eprosartan, telmisartan or valsartan are given with glibenclamide (glyburide), or if irbesartan is given with tolbutamide. However, there is some experimental evidence that suggests that symptoms of hypoglycaemia might be reduced by losartan and possibly other angiotensin II receptor antagonists, although one epidemiological study provided some reassurance that this may not be clinically important. Bear the possibility in mind. Further clinical study is needed, but note that this is similar to the possible effect of ACE inhibitors, see 'Antidiabetics + ACE inhibitors', p.536.

Antidiabetics + Antimalarials

Hydroxychloroquine may reduce insulin requirements by about 25%, and two cases of hypoglycaemia have been reported. It has also improved glycaemic control in patients taking glibenclamide (glyburide). Similarly, hypoglycaemia has occurred in a patient taking chloroquine and insulin. Reduced glucose levels or hypoglycaemia have been reported with mefloquine, quinidine, quinine, and sulfadoxine with pyrimethamine. Note that falciparum malaria *per se* can result in severe hypoglycaemia, and quinine in particular may contribute to this.

Clinical evidence

(a) Effect on diabetic control

1. Chloroquine. A case report describes a patient with type 1 diabetes who had developed insulin resistance and was maintained on intravenous **insulin**, who showed a dramatic return of sensitivity to subcutaneous **insulin**, heralded by a series of hypoglycaemic attacks, within 15 days of starting to take chloroquine phosphate 200 mg every 8 hours.[1] Similarly, chloroquine phosphate (150 mg of chloroquine base) four times daily improved glucose tolerance in 5 out of 6 patients with type 2 diabetes controlled by diet, but had little effect in healthy subjects.[2]

2. Hydroxychloroquine. The effect of hydroxychloroquine on diabetic control with **insulin** or **glibenclamide** (**glyburide**) was investigated in a randomised, double-blind, placebo-controlled study in 38 patients with poorly controlled type 2 diabetes. The addition of hydroxychloroquine 200 mg three times daily to **insulin** caused a significant improvement in the glycaemic profile and the daily **insulin** dose had to be reduced by about 25%. Patients taking **glibenclamide** with hydroxychloroquine also had a significant improvement in their plasma glucose levels. One patient receiving **insulin** and hydroxychloroquine had severe hypoglycaemia after 2 months of concurrent use, and it was necessary to drastically reduce the daily dose of **insulin**.[3] In another similar study, 135 patients with poorly controlled type 2 diabetes taking **glibenclamide** 10 mg twice daily were randomised to receive placebo or hydroxychloroquine 300 mg daily, increased up to a maximum of 300 mg twice daily. Fewer patients discontinued hydroxychloroquine than placebo because of a lack of effect on improving blood glucose control (54% versus 82%). In addition, hydroxychloroquine reduced HbA_{1c} by 0.96% more than placebo.[4]

A case report describes a 77-year old man receiving a stable dose of **insulin** of 16 units twice daily who was diagnosed with rheumatoid arthritis. He was started on prednisolone 5 mg daily and hydroxychloroquine 400 mg daily, with an increase in insulin dose of 4 units daily in anticipation of prednisolone-induced impairment of glucose control. However he continued to have nightly hypoglycaemic episodes, and, one week later he had a hypoglycaemic attack requiring intravenous dextrose. His insulin dose was reduced back to the original dose, and over 6 weeks was gradually reduced to 10 units twice daily with good glycaemic control.[5]

3. Quinine. A study in 12 patients (age 51 to 79 years) with type 2 diabetes taking **gliclazide**, and 10 similar, non-diabetic subjects, found that a single 600-mg dose of **quinine sulphate** at night reduced serum glucose levels in both groups, without affecting serum insulin concentrations.[6] **Quinine** has been responsible for hypoglycaemia in non-diabetic patients, one of whom was taking **quinine sulphate** 325 mg four times daily for leg muscle cramps.[7] Two other non-diabetic patients, one with congestive heart failure and the other with terminal cancer, similarly developed hypoglycaemia when given **quinine** for leg cramps.[8,9]

(b) Treatment of malaria

Hypoglycaemia is a complication of falciparum malaria, which occurs mainly in severe life-threatening disease,[10,11] in pregnant women[10] or children,[12,13] and in patients who are given **quinine** or **quinidine**.[11,13-16] The reasons are not fully understood but renal impairment and poor nutrition may be contributing factors. In severe malaria, hypoglycaemia may increase as the patient's glucose production becomes insufficient for the host/parasite demand because in this situation glucose utilisation can be increased by 50%.[17]

Additionally, **quinine** reduces plasma glucose by stimulating the release of large amounts of **insulin** from the pancreas,[18] possibly associated with an increase in the sensitivity to **insulin** as the malaria improves,[19] although other factors may also be involved. A study in 32 patients with malaria found that their pre-treatment capillary glucose was below normal in 12.5% of cases. One hour after intravenous **quinine** was given, glucose levels in all patients fell by an average of 11.4% and after 6 hours a further fall of 20.5% was found in 75% of patients (with an increase at 6 hours in the remaining 25% of patients).[16] **Quinidine** has been shown to have a similar effect.[20] Whether these changes can also occur in patients with **quinine**- or **quinidine**-treated malaria and diabetes, despite their pancreatic beta cell impairment, seems not to have been studied, although one isolated report argues against significant **quinine**-mediated mechanisms. Profound and persistent hypoglycaemia was seen in a diabetic patient (type 2 diabetes) with severe falciparum malaria treated with **quinine**, but the hypoglycaemia evolved before the use of **quinine** and resolved as the parasitaemia was successfully eradicated, despite continuation of the **quinine**. Subsequently, as she had discontinued antidiabetic medication (chlorpropamide) before hospital admission, hyperglycaemia developed (blood glucose ranging from 7.5 to 16 mmol/L) despite continuing to take **quinine**.[21] Any interpretation of disturbances in the control of the diabetes should take into account the severity of the malaria and the possible effects of these drugs.

An isolated report describes life-threatening hypoglycaemia in a 3-year-old boy, with uncomplicated malaria, 90 minutes after he took **sulfadoxine** with **pyrimethamine** (*Fansidar*).[22] **Artemisinin derivatives** such as **artemether** may be associated with fewer episodes of hypoglycaemia than **quinine** in children with severe malaria.[13]

Mefloquine has been reported to reduce plasma glucose levels in healthy subjects.[23]

Mechanism

Both quinine and quinidine have been shown in experimental studies to stimulate insulin release, whereas this was not shown for chloroquine, mefloquine, amodiaquine and halofantrine.[20] A later study in patients with diabetes found that chloroquine both inhibits insulin degradation and increases insulin secretion.[24]

Importance and management

Not well established, but it appears that hydroxychloroquine can cause a modest reduction in blood glucose, which is additive with antidiabetic

treatment such as insulin and glibenclamide (glyburide). Bear this in mind if hydroxychloroquine is required in a patient with diabetes. Chloroquine appears to act similarly. Mefloquine and quinine have also been reported to reduce blood glucose. Some evidence is complicated by the malaria indication, as malaria can also cause hypoglycaemia.

Antidiabetics + Antineoplastics

Asparaginase sometimes induces temporary diabetes mellitus. It seems possible that some diabetic patients will need changes in the dose of their antidiabetic drugs. There is also evidence that the control of diabetes can be severely disturbed in patients given cyclophosphamide. Capecitabine may cause hyperglycaemia and therefore could aggravate diabetes.

Clinical evidence and mechanism

(a) Asparaginase (Colaspase)

Three patients with acute lymphocytic leukaemia developed diabetes after receiving asparaginase with or without corticosteroids. In two of them this occurred 2 and 4 days after a single dose of asparaginase, and in another patient it occurred 2 days after the fourth dose. Plasma insulin was undetectable. A normal insulin response returned in one patient after 23 days, whereas the other 2 patients continued to have a suboptimal response 2 weeks, and 9 months afterwards.[1] In another study in 39 patients, 3 adults and 2 children developed hyperglycaemia and glycosuria after treatment with asparaginase. This responded to insulin, and blood glucose levels returned to normal in about 2 weeks.[2] In a retrospective analysis, it was found that about 10% of 421 children with leukaemia given asparaginase and prednisone developed hyperglycaemia, which resolved in all patients. A family history of diabetes and obesity were found to be risk factors.[3] Other cases of this effect have been described,[4-6] including one patient who, unusually, developed persistent hyperglycaemia and required long-term treatment with oral antidiabetics.[5] The reasons for this reaction are not understood but suggestions include inhibition of insulin synthesis,[7] direct damage to the islets of Langerhans,[1] and reduced insulin binding.[7] Hyperglycaemia can be caused by corticosteroids (see 'Antidiabetics + Corticosteroids', p.551) and their concurrent use with asparaginase is probably a contributing factor.

(b) Capecitabine

There appear to be no reports of adverse interactions between antidiabetics and capecitabine, but the manufacturer notes that the control of diabetes mellitus may be affected by capecitabine, for which reason they advise caution.[8]

(c) Cyclophosphamide

Acute hypoglycaemia has been described in 2 diabetic patients receiving **insulin** and **carbutamide** who were also given cyclophosphamide.[9] Three cases of diabetes, apparently induced by the use of cyclophosphamide, have also been reported.[10] The reasons for this reaction are not understood.

Importance and management

Strictly speaking probably none of these reactions is a drug interaction, but they serve to underline the importance of monitoring the diabetic control of patients receiving asparaginase, capecitabine or cyclophosphamide.

Antidiabetics + Antipsychotics

Chlorpromazine may raise blood glucose levels, particularly in daily doses of 100 mg or more, and other classical antipsychotics appear to act similarly. The atypical antipsychotics, clozapine, olanzapine and risperidone are also associated with an increased risk of glucose intolerance. One epidemiological study found classical antipsychotics (haloperidol, pipamperone, levomepromazine, and zuclopenthixol) to be associated with an increased risk of needing insulin. Another epidemiological study found that patients with diabetes were particularly at risk of hospitalisation for hyperglycaemia during their first month of treatment with both classical and atypical antipsychotics.

Clinical evidence

(a) Classical antipsychotics

Early in the use of classical antipsychotics it was shown that they were associated with new-onset diabetes and impaired glucose control. For example, one long-term study was undertaken over the period 1955 to 1966 in a large number of women treated for a year or longer with **chlorpromazine** 100 mg daily or more, or corresponding doses of **perphenazine**, **thioridazine**, **trifluoperazine**. This found that about 25% developed hyperglycaemia accompanied by glycosuria, compared with less than 9% in a control group who were not taking phenothiazines. Of those given a phenothiazine, about a quarter had complete remission of the symptoms when the drug was withdrawn or the dosage reduced.[1]

There are other reports of this response to **chlorpromazine**.[2-11] However, in contrast one study in 850 patients suggests that **chlorpromazine** has no effect on blood glucose levels. Five patients developed diabetes, but this was believed to be due to factors other than the use of **chlorpromazine**.[12] **Chlorpromazine** 50 to 70 mg daily does not affect blood glucose levels significantly.[11] Further, a more recent analysis (discussed further under *Atypical antipsychotics*, below) did not find an increased risk of glucose intolerance with **chlorpromazine** or **haloperidol**, and notes that the number of reports of glucose intolerance with these drugs has remained small.[13]

Very much less appears to have been published about the effect of these antipsychotics on the control of existing diabetes. The large study above that found no effect of **chlorpromazine** on blood glucose levels included 22 diabetic patients, who also had no significant changes in their blood glucose levels.[12] Nevertheless, in a large cohort study in 2585 patients with type 2 diabetes who had been taking oral antidiabetics for at least 2 years, the use of antipsychotics was associated with a twofold increased risk of needing **insulin** at 2 years after diagnosis when compared with non-users of antipsychotics (18.4% versus 9.3%). In addition, more patients taking antipsychotics were switched to insulin alone rather than receiving oral antidiabetics with insulin. However, no difference in rates of initiation of insulin was found for later years after the diagnosis of diabetes (3, 4 or 5 years). The antipsychotics most frequently being used were **haloperidol**, **pipamperone**, **levomepromazine**, and **zuclopenthixol**. Too few patients were receiving an atypical antipsychotic for these results to be analysed separately.[14] Moreover, in a case-control study of older patients with diabetes hospitalised for hyperglycaemia, the concurrent use of a classical antipsychotic (not named) was associated with an increased risk of hyperglycaemia. This occurred irrespective of diabetes treatment. With **insulin** use the adjusted rate ratio was 1.27, with **oral antidiabetics** alone was 1.31, and with diet alone was 3.43. The risk appeared to be greater during initial use, with the adjusted rate ratio 8 to 15 times higher. Furthermore, of those patients who had taken an antipsychotic for up to one month, almost 70% of the episodes of hyperglycaemia occurred within the first 14 days of treatment.[15]

(b) Atypical antipsychotics

There are lots of data on the increased risk of new-onset diabetes with atypical antipsychotic drugs, and this is not cited here. There is some evidence that the risk of new-onset diabetes may be higher with atypical antipsychotics than classical antipsychotics. For example, an analysis of reports of glucose intolerance in the adverse reaction database of the WHO Collaborating Centre for International Drug Monitoring found that **clozapine**, **olanzapine** and **risperidone** were associated with an increased risk of glucose intolerance, whereas the classical antipsychotics chlorpromazine and haloperidol were not. It is uncertain whether this is a dose-related effect. Additional risk factors with these antipsychotics were an underlying diabetic condition, weight increase, male gender, or the concurrent use of valproic acid, SSRIs or buspirone.[13] However, a recent meta-analysis of all the available evidence found that the atypical antipsychotics were associated with only a tentative small increased risk of diabetes when compared with classical antipsychotics (relative risk 1.32).[16]

Very much less appears to have been published about the effect of any antipsychotics on control of existing diabetes. In a case-control study of older patients with diabetes hospitalised for hyperglycaemia, current atypical antipsychotic treatment (**olanzapine**, **quetiapine** or **risperidone**), was associated with an increased risk of hyperglycaemia, particularly during the first month of treatment. The adjusted relative risk of developing hyperglycaemia in patients taking an atypical antipsychotic and managed with insulin, oral hypoglycaemic drugs. or diet alone was 1.4, 1.37, and 2.37, respectively.[15]

Mechanism

Although some studies found that drugs such as chlorpromazine and haloperidol were not associated with glucose intolerance,[11,13] it seems that chlorpromazine can inhibit the release of insulin, and possibly cause adrenaline release from the adrenals, both of which could result in a rise in blood glucose levels. This may be a dose-related effect.[11] Further, chlorpromazine may cause aggregation and inactivation of insulin by reduction of disulfide bonds.[17] Clozapine may induce insulin resistance and a compensatory increase in insulin secretion. Patients may develop diabetes if this compensatory increase is not achieved. Alternatively or additionally, weight gain is a common adverse effect of antipsychotics, and may contribute to worsening of metabolic control.[13,14] Schizophrenia itself may be associated with an increased risk of hyperglycaemia.

Importance and management

A long-established reaction first recognised in the early 1950s. The incidence of hyperglycaemia with chlorpromazine in doses of 100 mg or more is about 25%. Increases in the dosage requirements of the antidiabetic should be anticipated during concurrent use.[1] Smaller chlorpromazine doses, of 50 to 70 mg daily do not appear to cause hyperglycaemia. Other classical and atypical antipsychotics appear to act similarly. In patients with diabetes, one study found evidence of an association between antipsychotic drug use and worsening of metabolic control and another found an increased risk of hospitalisation for hyperglycaemia, especially in the first month of use of the antipsychotic. It would seem prudent to increase monitoring for glycaemic control, particularly when starting or stopping any classical or atypical antipsychotic in a patient with diabetes.

Antidiabetics + Azoles; Fluconazole

Fluconazole does not appear to affect the diabetic control of most patients taking sulfonylureas, but isolated reports describe hypoglycaemic coma in one patient taking glipizide and hypoglycaemia and aggressive behaviour in a patient taking gliclazide. There is some evidence that the blood glucose-lowering effects of both glipizide and glibenclamide (glyburide) may be modestly increased by fluconazole. Fluconazole may cause increases in plasma levels of glimepiride (marked) and nateglinide (modest).

Clinical evidence

(a) Chlorpropamide

After 18 healthy subjects took fluconazole 100 mg daily for 7 days, the AUC of single 250-mg doses of chlorpropamide was increased by 28% but the maximum plasma levels and blood glucose levels were unchanged. There was no evidence of hypoglycaemia.[1]

(b) Glibenclamide (Glyburide)

After 20 healthy subjects took fluconazole 100 mg daily for 7 days, the AUC of a single 5-mg dose of glibenclamide was increased by 44% and its maximum plasma levels rose by 19%. The change in blood glucose levels was not statistically significant but the number of subjects who had symptoms of hypoglycaemia increased.[2] In another study, a group of 14 postmenopausal women with diabetes and vulvovaginal candidiasis, taking either gliclazide or glibenclamide, were given fluconazole 50 mg daily for 14 days. None of the patients in this study developed symptoms

of hypoglycaemia and their HbA_{1c} and fructosamine concentrations were unchanged. No pharmacokinetic data were reported.[3]

(c) Gliclazide

A group of 14 postmenopausal diabetic women with vulvovaginal candidiasis taking either gliclazide or glibenclamide were given fluconazole 50 mg daily for 14 days. None of the patients developed symptoms of hypoglycaemia and their HbA_{1c} and fructosamine concentrations were unchanged. No pharmacokinetic data were reported.[3] However, a 56-year-old HIV-positive patient (antiretroviral treatment refused) and type 2 diabetes who had been taking gliclazide for 2 years was given fluconazole 50 mg daily for 2 weeks for oral candidiasis, and prophylactic co-trimoxazole (sulfamethoxazole 400 mg and trimethoprim 80 mg daily). One week after the re-introduction of fluconazole at a higher dose of 200 mg daily he was hospitalised because of weakness and aggressive behaviour. His blood glucose level was 2.2 mmol/L and gliclazide was stopped. He experienced brief loss of consciousness 2 days later while driving his car, but his condition then improved and neurological symptoms did not recur during 3 months of follow-up without gliclazide treatment.[4] For the possible contribution of sulfamethoxazole to this interaction, see *Mechanism*, below.

(d) Glimepiride

A double-blind study in 12 healthy subjects found that fluconazole 400 mg on day one then 200 mg daily for a further 3 days increased the AUC and peak plasma level of a single 500-microgram dose of glimepiride about 2.5-fold and 1.5-fold, respectively. Fluconazole increased the mean elimination half-life of glimepiride from 2 hours to 3.3 hours.[5]

(e) Glipizide

After 13 healthy subjects took fluconazole 100 mg daily for 7 days, the AUC of a single 2.5-mg dose of glipizide was increased by 49% and its maximum serum levels rose by 17%. Although blood glucose levels were lowered the change was not statistically significant. However, the number of subjects who had symptoms suggestive of hypoglycaemia increased.[6]

A diabetic patient taking glipizide 2.5 mg three times daily went into a hypoglycaemic coma within 4 days of starting to take fluconazole 200 mg daily. Her blood glucose levels had fallen to less than about 0.05 mmol/L. She rapidly recovered when given glucose.[7]

(f) Nateglinide

In a randomised, double-blind, crossover study, 10 healthy subjects were given a single 30-mg dose of nateglinide on day 4 of a course of fluconazole (given as 400 mg on day one, then 200 mg daily). Fluconazole raised the AUC of nateglinide by 48% (range 20 to 73%) and increased the nateglinide half-life from 1.6 hours to 1.9 hours. Despite these pharmacokinetic changes fluconazole did not potentiate the blood glucose lowering effects of nateglinide.[8] It was predicted that this interaction may occur with **miconazole** (which inhibits the same isoenzymes as fluconazole), but this needs confirmation.

(g) Tolbutamide

After 13 healthy subjects took a single 150-mg dose of fluconazole, and then 6 doses of fluconazole 100 mg daily, the AUC of a single 500-mg dose of tolbutamide was increased by about 50%, and its peak plasma levels were raised. The half-life of the tolbutamide was increased about 40%. Blood glucose levels remained unaltered and none of the subjects showed any evidence of hypoglycaemia.[9,10] However, the authors caution against extrapolating this finding to diabetic patients taking tolbutamide regularly.[9,10]

Mechanism

Fluconazole is an inhibitor of the cytochrome P450 isoenzyme CYP2C9, by which many of the sulfonylureas are metabolised. Inhibition of this isoenzyme leads to an accumulation of the sulfonylurea and therefore an increase in its effects. The hypoglycaemia in the patient taking gliclazide and fluconazole may have been enhanced by sulfamethoxazole, which also inhibits CYP2C9 (see also 'Antidiabetics + Sulfonamides', p.574).[4] The moderate pharmacokinetic changes seen when fluconazole is given with nateglinide are also thought to be mediated by CYP2C9.

Importance and management

The almost total absence of adverse reports implies that fluconazole does not usually markedly disturb the control of diabetes in patients taking sulfonylureas. For fluconazole the increased plasma levels of glipizide and glimepiride, and the single case of severe hypoglycaemia, as well as the hypoglycaemic symptoms shown by those taking glibenclamide (glyburide) or gliclazide suggest that patients taking these sulfonylureas in particular should be warned to be alert for any evidence of hypoglycaemia. However, there seems to be no reason for avoiding concurrent use. Note that in the study of fluconazole with nateglinide a sub-therapeutic dose was given to healthy subjects, so in clinical practice a greater blood glucose-lowering effect may possibly occur.

Antidiabetics + Azoles; Itraconazole or Ketoconazole

Itraconazole also appears not to affect diabetic control in most patients, but there are reports of hypoglycaemia or hyperglycaemia associated with its use in patients taking a variety of antidiabetics. Itraconazole causes modest increases in repaglinide and nateglinide levels, but has no effect on pioglitazone pharmacokinetics. Ketoconazole increases the blood glucose-lowering effects of tolbutamide in healthy subjects and possibly increases the AUC of rosiglitazone and pioglitazone.

Clinical evidence

(a) Itraconazole

Post-marketing surveillance over 10 years indicated that in most patients itraconazole given with either **insulin** or **oral antidiabetics** did not affect diabetic control. However, there were 15 reports suggesting hyperglycaemia and 9 reports suggesting hypoglycaemia when itraconazole was given to patients taking antidiabetics.[1] In clinical studies only one of 189 patients with diabetes experienced aggravated diabetes when given itraconazole.[1] The patient in question was also receiving ciclosporin for a kidney transplant.

In a study in 12 healthy subjects, itraconazole 200 mg then 100 mg twice daily for 4 days did not alter the pharmacokinetics of a single 15-mg dose of **pioglitazone**.[2]

In healthy subjects, itraconazole 200 mg then 100 mg twice daily for 3 days increased the AUC of a single 250-microgram dose of **repaglinide** by 40%. No change was noted in blood glucose levels, when compared with **repaglinide** alone.[3] However, itraconazole enhanced the pharmacokinetic interaction between gemfibrozil and **repaglinide**; itraconazole with gemfibrozil increased the AUC of **repaglinide** nearly 20-fold and considerably enhanced the blood glucose-lowering effect of **repaglinide**. In a similar study in healthy subjects, itraconazole with gemfibrozil increased the AUC of a single 30-mg dose of **nateglinide** by 47%, without causing any significant change in blood glucose response to **nateglinide**.[4]

(b) Ketoconazole

After an overnight fast and breakfast the next morning, 7 healthy subjects were given a single 500-mg dose of **tolbutamide** before and after taking ketoconazole 200 mg daily for a week. Ketoconazole increased the elimination half-life of **tolbutamide** more than threefold (from 3.7 to 12.3 hours) and increased its AUC by 77%. Ketoconazole increased the blood glucose-lowering effects of **tolbutamide** by about 10 to 15%, and 5 of the subjects experienced mild hypoglycaemic symptoms (weakness, sweating and a reeling sensation) at about 2 hours after the dose.[5]

In healthy subjects, ketoconazole 200 mg daily for 5 days increased the AUC and maximum plasma levels of a single 2-mg dose of **repaglinide** by 15% and 8%, respectively.[6]

In 10 healthy Korean subjects, ketoconazole 200 mg twice daily for 5 days increased the AUC of a single 8-mg dose of **rosiglitazone** by 47%.[7]

The US manufacturer refers to a 7-day study in which ketoconazole 200 mg twice daily modestly increased the AUC of **pioglitazone** by 34%.[8]

Mechanism

The modest changes in repaglinide pharmacokinetics with ketoconazole and itraconazole may be because repaglinide is metabolised by both of the cytochrome P450 isoenzymes CYP2C8 and CYP3A4, and one pathway may have the capacity to compensate if the other is inhibited.[9] Similarly, itraconazole modestly affects nateglinide metabolism by CYP3A4.[4]

Although it has been suggested that ketoconazole may inhibit the metabolism of rosiglitazone by CYP2C8 and CYP2C9, ketoconazole is normally only considered to be a significant inhibitor of CYP3A4.

Importance and management

Itraconazole does not usually disturb the control of diabetes, although there are rare reports of hyperglycaemia or hypoglycaemia associated with its use. The effect of itraconazole on repaglinide could potentially be important, especially if a drug that inhibits CYP2C8 such as gemfibrozil is also given, so increased monitoring of blood glucose levels is advisable. Similarly, itraconazole may interact with nateglinide to a modest extent. Itraconazole is unlikely to interact with pioglitazone.

Information about ketoconazole and sulfonylureas appears to be limited to one study in healthy subjects. The reaction in diabetics is uncertain, but if ketoconazole is added to tolbutamide, patients should be warned to be alert for any evidence of increased hypoglycaemia. It may become necessary to reduce the tolbutamide dose. Ketoconazole increases the AUC of rosiglitazone and pioglitazone, and more frequent blood glucose monitoring is recommended in the presence of this azole. The pharmacokinetic changes with ketoconazole and repaglinide are minor, and unlikely to be of any clinical relevance.

Antidiabetics + Azoles; Miscellaneous

Hypoglycaemia has been seen in few diabetic patients taking tolbutamide, glibenclamide or gliclazide when they were given miconazole tablets. Posaconazole slightly enhanced the blood glucose-lowering effects of glipizide in healthy subjects, but did not affect the metabolism of a single dose of tolbutamide. Voriconazole is predicted to increase the levels of the sulfonylureas. Clotrimazole used intravaginally appears not to interact with gliclazide or glibenclamide.

Clinical evidence

(a) Clotrimazole

A group of 15 postmenopausal diabetic women with vulvovaginal candidiasis taking either **gliclazide** or **glibenclamide** (**glyburide**) were treated with intravaginal clotrimazole 100 mg daily for 14 days. None of the patients developed symptoms of hypoglycaemia and their HbA_{1c} and fructosamine concentrations were unchanged. No pharmacokinetic data were reported.[1]

(b) Miconazole

A diabetic patient taking **tolbutamide** was hospitalised with severe hypoglycaemia about 10 days after starting to take miconazole tablets.[2] In 1983 the French Commission Nationale de Pharmacovigilance reported 6 cases of hypoglycaemia in diabetic patients taking sulfonylureas (5 with **gliclazide** and one with **glibenclamide** (**glyburide**)), which occurred within 2 to 6 days of miconazole being started.[2] The same organisation reported a further 8 cases in the 1985 to 1990 period.[3] Three other cases of hypoglycaemia (two with **gliclazide** and one with **glibenclamide**) are reported elsewhere, in patients given miconazole up to 750 mg daily.[4] Miconazole has been predicted to interact with **nateglinide**, see 'Antidiabetics + Azoles; Fluconazole', p.544.

(c) Posaconazole

A study in 12 healthy subjects found that posaconazole 400 mg twice daily for 10 days had no significant effects on the steady-state pharmacokinetics of **glipizide** 10 mg daily, but there was a small significant decrease in blood glucose levels following concurrent use. **Glipizide** did not affect the pharmacokinetics of posaconazole.[5] In another study, posaconazole 200 mg daily for 10 days had no effect on **tolbutamide** metabolism.[6]

(d) Voriconazole

The manufacturers of voriconazole predict that it will raise the levels of the sulfonylureas.[7,8]

Mechanism

Miconazole and voriconazole are inhibitors of the cytochrome P450 isoenzyme CYP2C9, by which many of the sulfonylureas are metabolised. Inhibition of this isoenzyme would therefore be expected to lead to an accumulation of the sulfonylurea and therefore an increase in its effects, as seen with miconazole tablets. Clotrimazole is probably not absorbed in sufficient quantities to cause an interaction.

Importance and management

The interaction between miconazole tablets and the sulfonylureas is established and clinically important, but of uncertain incidence. Concurrent use need not be avoided but it should be monitored and the dose of the sulfonylurea reduced if necessary. Although there are no specific data, a large proportion of miconazole oral gel (both prescription and non-prescription doses) may be swallowed and therefore adequate systemic absorption may occur to produce an interaction. It is therefore possible that oral miconazole gel might interact similarly. Intravaginal miconazole and miconazole topical creams are probably unlikely to interact, because absorption by these routes is minimal.

Posaconazole slightly enhanced the blood glucose-lowering effects of glipizide in healthy subjects, but the clinical relevance of this is not known. Posaconazole does not appear to affect tolbutamide metabolism.

The manufacturers of voriconazole advise increased blood-glucose monitoring in patients taking sulfonylureas,[7,8] and until more is known this seems prudent.

Information about intravaginal clotrimazole is very sparse, but it appears not to interact with gliclazide or glibenclamide, and probably not with any of the other oral antidiabetics, not least because its absorption from the vagina is very small.

Antidiabetics + Benzodiazepines

No adverse interaction normally occurs between antidiabetics and benzodiazepines, but an isolated case of hyperglycaemia has been seen in an insulin-treated patient with type 2 diabetes associated with the use of chlordiazepoxide. The effects of lorazepam were found to be increased in patients given beef/pork insulin rather than human insulin. Pioglitazone caused a minor decrease in the AUC of midazolam, which is probably not clinically relevant.

Clinical evidence, mechanism, importance and management

(a) Insulin

A woman with long-standing type 2 diabetes, which was stabilised with 45 units of isophane insulin suspension daily, had a rise in her mean fasting blood glucose from about 12 mmol/L to 21 mmol/L during a 3-week period while taking **chlordiazepoxide** 40 mg daily.[1] A preliminary report in 8 healthy type 1 diabetics given **lorazepam** 2 mg suggested that while they were taking human insulin they were more alert and less sedated than when taking beef/pork insulin.[2]

There seems to be nothing in the literature to suggest that a clinically important adverse interaction normally takes place between insulin and the benzodiazepines. No special precautions would appear to be necessary.

(b) Oral antidiabetics

Four patients with type 2 diabetes, two diet-controlled and two taking **tolbutamide**, had no changes in blood glucose levels while taking **chlordiazepoxide**.[1] In another study **diazepam** did not change the half-life of **chlorpropamide**.[3]

The manufacturer notes that **pioglitazone** 45 mg daily for 15 days reduced the AUC and maximum level of a single dose of **midazolam** syrup by 26% in healthy subjects.[4] This is possibly because **pioglitazone** is a weak inducer of the cytochrome P450 isoenzyme CYP3A4,[4] by which **midazolam** is metabolised. The clinical relevance of this small decrease in **midazolam** levels has not been assessed, but it is likely to be minor.

Antidiabetics + Beta blockers

In diabetics using insulin, the normal recovery reaction (blood sugar rise) if hypoglycaemia occurs may be impaired to some extent by propranolol, but serious and severe hypoglycaemia seems rare. Cardioselective beta blockers seem less likely to interact.
The blood glucose-lowering effects of the sulfonylureas may possibly be reduced by the beta blockers. Whether insulin or oral antidiabetic drugs are given, patients should be made aware that some of the familiar warning signs of hypoglycaemia (tachycardia, tremor) may not occur, although sweating may be increased. Hypoglycaemia in patients taking beta blockers has been noted to result in significant increases in blood pressure and possibly bradycardia in some studies. Miglitol has been found to reduce the bioavailability of propranolol by 40%.

Clinical evidence

(a) Insulin

1. Hypoglycaemia. Although **propranolol** has occasionally been associated with spontaneous episodes of hypoglycaemia in non-diabetics,[1] and a number of studies in diabetic patients[2] and healthy subjects[3-6] have found that **propranolol** impairs the normal blood sugar rebound if blood sugar levels fall, there appear to be few reports of severe hypoglycaemia or coma in diabetics receiving insulin and **propranolol**. Marked hypoglycaemia and/or coma occurred in 5 diabetic patients receiving insulin as a result of the use of **propranolol**,[1,7,8] **pindolol**,[8] or **timolol** eye drops.[9] Other contributory factors (fasting, haemodialysis, etc.) probably had some part to play.[8] **Metoprolol** interacts like **propranolol** but to a lesser extent,[3,5,10] whereas **acebutolol**,[2,5] **alprenolol**,[11] **atenolol**,[2,12,13] **oxprenolol**,[10] **penbutolol**,[6] and **pindolol**[14] have been found to interact minimally or not at all. The situation with **pindolol** is therefore not clear. **Carvedilol** has been associated with the onset of diabetes mellitus in one patient.[15] **Propranolol** (a peripheral vasoconstrictor) has also been found to reduce the rate of absorption of subcutaneous insulin by almost 50%, but the importance of this is uncertain.[16] However, a large case-control study found no statistically significant increase or decrease in the risk of a serious hypoglycaemic episode in patients over 65 years of age receiving insulin and taking either cardioselective beta blockers (**atenolol** and **metoprolol**) or non-cardioselective beta blockers (**propranolol** and **nadolol**) when compared with patients taking no antihypertensive drugs. Overall, of the different antihypertensive drug classes, the risk of hypoglycaemia was lowest with cardioselective beta blockers and highest with non-cardioselective beta blockers, although none of the changes were statistically significant when controlled for demographic factors and markers of comorbidity.[17] Similarly, in two other case-control studies, there was no increase in the risk of hypoglycaemia in patients with diabetes receiving insulin and also taking a beta blocker.[18,19]

2. Hypertension. Marked increases in blood pressure and bradycardia may develop if hypoglycaemia occurs in diabetic patients receiving **insulin** and a beta blocker.[20] In one study in diabetic patients, insulin-induced hypoglycaemia resulted in blood pressure rises of 38.8/14.3 mmHg in those taking **propranolol** 80 mg twice daily, 27.9/0 mmHg in those taking **atenolol** 100 mg daily and in those taking placebo the systolic blood pressure rose by 15.2 mmHg whereas the diastolic blood pressure fell by 9.9 mmHg.[21] In another study, **insulin**-induced hypoglycaemia resulted in blood pressure rises of 27/14 mmHg in those taking **alprenolol** 200 to 800 mg daily, but no rise occurred in those taking **metoprolol** 100 to 400 mg daily.[22] A report describes a blood pressure rise to 258/144 mmHg in a patient having a hypoglycaemic episode within 2 days of starting **propranolol**.[7] Another patient taking **metoprolol** 50 mg twice daily experienced a rise in blood pressure from 190/96 mmHg to 230/112 mmHg during a hypoglycaemic episode.[20]

(b) Oral antidiabetics

1. Effects on blood glucose. The sulfonylurea-induced insulin release from the pancreas can be inhibited by beta blockers so that the blood glucose-lowering effects are opposed to some extent.

- **Acebutolol** appears to inhibit the effects of **glibenclamide** (**glyburide**),[23] but has no effect on **tolbutamide**.[24] Also, two isolated cases of hypoglycaemia have been seen with acebutolol, in one patient taking **gliclazide** and one patient taking **chlorpropamide**.[25]
- **Betaxolol** had no effect on the response to **glibenclamide** or **metformin** in one study.[26]
- **Metoprolol** did not affect the insulin-response to **tolbutamide** in one study.[27]
- **Propranolol** inhibits the effects of **glibenclamide**,[23] and **chlorpropamide**[28] and reduced the insulin-response to **tolbutamide** in one study,[29] but not in another.[27] Also, an isolated report describes hyperosmolar non-ketotic coma in a patient taking **tolbutamide** and propranolol.[30]

It is worth noting that the United Kingdom Prospective Diabetes Study Group (UKPDS) used **atenolol** 50 to 100 mg daily or captopril 25 to 50 mg twice daily for hypertension in diabetic patients taking a range of antidiabetic drugs. Those given **atenolol** had a slightly greater increase in HbA_{1c} levels, and gained slightly more weight (3.4 kg for the **atenolol** group compared with 1.6 kg for the captopril group over 9 years). However, both drugs were equally effective in reducing the risk of predefined clinical end points (e.g. diabetic complications, death related to diabetes, heart failure). The number of patients experiencing hypoglycaemic attacks did not differ between the two antihypertensives.[31] This would suggest that beta blockers are generally useful in the treatment of diabetic patients. Another large case-control study found no statistically significant increase or decrease in the risk of a serious hypoglycaemic episode in elderly patients taking sulfonylureas with either cardioselective beta blockers (**atenolol** and **metoprolol**) or non-cardioselective beta blockers (**propranolol** and **nadolol**) when compared with patients taking no antihypertensive drugs.[17]

2. Pharmacokinetic studies. **Acarbose** 300 mg daily for one week had no effect on the pharmacokinetics or pharmacodynamics of a single 80-mg dose of **propranolol** in healthy subjects.[32] Conversely, the manufacturer of **miglitol** notes that it reduced the bioavailability of **propranolol** by a modest 40%.[33]

No pharmacokinetic interaction was seen in a study in healthy subjects given a single 1.75-mg dose of **glibenclamide** (**glyburide**) with **carvedilol** 25 mg daily for 6 days.[34]

For a theoretical pharmacokinetic interaction between tolbutamide and propranolol, see 'Beta blockers; Propranolol + Miscellaneous', p.1023.

Mechanism

One of the normal physiological responses to a fall in blood sugar levels is the mobilisation of glucose from the liver under the stimulation of adrenaline from the adrenals. This sugar mobilisation is blocked by non-cardioselective beta blockers (such as propranolol) so that recovery from hypoglycaemia is delayed and may even proceed into a full-scale episode in a hypoglycaemia-prone diabetic. Normally the adrenaline would also increase the heart rate, but with the beta-receptors in the heart already blocked this fails to occur. A rise in blood pressure occurs because the stimulant effects of adrenaline on the beta-2 receptors (vasodilation) are blocked leaving the alpha (vasoconstriction) effects unopposed.

Non-selective beta blockers can also block beta-2 receptors in the pancreas concerned with insulin-release, so that the effects of the sulfonylureas may be blocked.

Importance and management

Extremely well-studied interactions. Concurrent use can be uneventful but there are some risks. Diabetics receiving insulin may have a prolonged or delayed recovery response to hypoglycaemia while taking a beta blocker, but very severe hypoglycaemia and/or coma is rare. If hypoglycaemia occurs it may be accompanied by a sharp rise in blood pressure. The risk is greatest with propranolol and possibly other non-cardioselective blockers and least with the cardioselective blockers. The cardioselectivity of a number of beta blockers is given in 'Table 22.1', (p.995). Monitor the effects of concurrent use well, avoid the non-cardioselective beta blockers where possible, and check for any evidence that the insulin dose needs some adjustment. Warn all patients that some of the normal premonitory signs of a hypoglycaemic attack may not appear, in particular tachycardia and tremors, whereas the hunger, irritability and nausea signs may be unaffected and sweating may even be increased.

Diabetics taking oral sulfonylureas rarely seem to have serious hypoglycaemic episodes caused by beta blockers, and any reductions in the blood glucose-lowering effects of the sulfonylureas normally appear to be of little clinical importance. The cardioselective beta blockers are probably safer than those that are non-selective. Nevertheless, always monitor concurrent use to confirm that diabetic control is well maintained, adjusting the dose of antidiabetic as necessary, and warn all patients (as above) that some of the premonitory signs of hypoglycaemia may not occur.

One experimental study indicated that no interaction occurred between betaxolol and **metformin**,[26] but direct information about other beta blockers seems to be lacking.

There is also a hint from one report that the peripheral vasoconstrictive effects of non-cardioselective beta blockers and the poor peripheral circulation in diabetics could be additive,[7] which is another possible reason for avoiding this type of beta blocker in diabetic patients.

Antidiabetics + Bile-acid binding resins

A report suggests that the hypocholesterolaemic effect of colestipol is unaffected in insulin-treated diabetics but it may be reduced in patients taking phenformin and sulfonylureas. Colestyramine may enhance the effect of acarbose, and insulin levels may rebound if both drugs are stopped at the same time. The absorption of glipizide may be reduced by about 30% if it is taken at the same time as colestyramine, but tolbutamide does not appear to be affected. Colesevelam may reduce the absorption of glibenclamide if it is taken at the same time. The absorption of pioglitazone and repaglinide are not significantly affected by colesevelam.

Clinical evidence

(a) Colesevelam

1. Glibenclamide. Colesevelam 3.75 g reduced the AUC and maximum concentration of glibenclamide 3 mg by 32% and 47%, respectively, when taken at the same time. When glibenclamide was taken one hour before colesevelam, the AUC and maximum concentration were still slightly reduced, by 20% and 15%, respectively. When glibenclamide was taken 4 hours before colesevelam, the reduction was minimal.[1,2]

2. Repaglinide. Colesevelam 3.75 g caused a minor 19% reduction in the maximum concentration of repaglinide 2 mg when taken at the same time, and a 7% reduction in the AUC of repaglinide. No clinically relevant interaction was seen when repaglinide was taken one hour after colesevelam.[1,2]

3. Other antidiabetics. The manufacturers state that colesevelam does not alter the bioavailability of **pioglitazone**, but no study details are given.[1,2] The US manufacturers of colesevelam state that **metformin** did not bind with colesevelam during *in vitro* testing, so they consider a clinical interaction unlikely.[1]

(b) Colestipol

The concurrent use of **phenformin** and a sulfonylurea (**chlorpropamide**, **tolbutamide** or **tolazamide**) inhibited the normal hypocholesterolaemic effects of the colestipol in 12 diabetic patients with elevated serum cholesterol levels. No such antagonism was seen in 2 patients with type 2 diabetes receiving **insulin**. The control of diabetes was not affected by the colestipol.[3]

(c) Colestyramine

1. Acarbose. Colestyramine 12 g daily for 6 days, given to 8 healthy subjects taking acarbose 100 mg three times daily, improved the reduction in postprandial insulin levels.[4] The mean serum insulin levels fell by 23% while taking both drugs, but showed a rebound 31% increase above baseline when both drugs were stopped.[4]

2. Glipizide. In 6 healthy subjects, colestyramine 8 g in 150 mL of water reduced the absorption of a single 5-mg dose of glipizide by a mean of 29%. One subject had a 41% reduction in glipizide levels. Peak serum levels were reduced by 33%. The AUC_{0-10} was used to measure absorption.[5]

3. Tolbutamide. A single-dose study indicated that colestyramine 8 g, given 2 minutes before, and 6 and 12 hours after a 500-mg dose of tolbutamide, did not reduce the amount of tolbutamide absorbed, although the rate of absorption may have changed.[6]

Mechanism

Colestyramine, colestipol, and colesevelam are bile-acid binding resins, intended to bind to bile acids within the gut, but they can also bind with some acidic drugs thereby reducing the amount available for absorption.

Importance and management

Information about glipizide is limited to a single-dose study so that the clinical importance of the reduction in glipizide levels with colestyramine is unknown, but it would seem prudent to monitor the effects of concurrent use in patients. It has been suggested[5] that the glipizide should be taken one to 2 hours before the colestyramine to minimise admixture in the gut, but this may only be partially effective because it is believed that glipizide undergoes some entero-hepatic circulation (i.e. after absorption it is excreted in the bile and reabsorbed). The effect of colestyramine on other sulfonylureas is uncertain, with the exception of tolbutamide, which is reported not to interact. The clinical importance of the effects of colestyramine on acarbose in diabetics is uncertain, although the manufacturers note that some enhancement of the effects of acarbose may occur, and they suggest care if both drugs are stopped at the same time because of the possible rebound phenomenon with respect to insulin levels.[7]

The study with colestipol suggests that it may not be suitable for lowering the blood cholesterol levels of diabetics taking chlorpropamide, tolbutamide, tolazamide or phenformin, but more study is needed to confirm these findings. Phenformin has been withdrawn from many countries because of severe, often fatal, lactic acidosis.

Colesevelam appears to reduce the absorption of glibenclamide and this may have a modest clinically significant effect. Therefore the manufacturers recommend that glibenclamide should be taken at least 4 hours before colesevelam.[1] As colesevelam does not appear to interact to a clinically relevant extent with repaglinide or pioglitazone, there would appear to be no reason to separate administration.

Antidiabetics + Calcium-channel blockers

Calcium-channel blockers are known to have effects on insulin secretion and glucose regulation, but significant disturbances in the control of diabetes caused by these drugs appear to be rare. A report describes a patient whose diabetes worsened, requiring an increase in the dose of insulin, when diltiazem was given, and a similar case has occurred in a patient taking nifedipine. Deterioration in glucose tolerance has also occurred during nifedipine use. Hypoglycaemia occurred in a patient taking gliclazide and nicardipine. No clinically important changes in nifedipine pharmacokinetics have been seen with acarbose, miglitol, pioglitazone or rosiglitazone; in glibenclamide pharmacokinetics with nimodipine or verapamil; in glipizide, metformin or repaglinide pharmacokinetics with nifedipine; or between tolbutamide and diltiazem.

Clinical evidence

A. Dihydropyridines

(a) Effect on glucose tolerance

A study in 20 patients with type 2 diabetes (5 taking **metformin** and 15 diet-controlled) found that both **nifedipine** 10 mg every 8 hours and **nicardipine** 30 mg every 8 hours for 4 weeks did not affect either glucose tolerance tests or the control of the diabetes, but both systolic and diastolic blood pressures were reduced by 4 to 7 mmHg.[1] No important changes in glucose metabolism occurred in 6 patients with type 2 diabetes taking **glibenclamide** (**glyburide**) when they were given **nifedipine** 20 to 60 mg daily for 12 to 25 weeks.[2] Similarly, other studies have found no important changes in glucose tolerance or the control of diabetes in patients taking **chlorpropamide**,[3] **glibenclamide**,[4] **gliclazide**,[5] **glipizide**[3,6] or unspecified antidiabetics[7,8] while also taking **nifedipine**,[3,5-7] **nimodipine**[4] or **nitrendipine**.[8] No change in **insulin** dose was needed in one patient taking **nicardipine**[9] and in 4 patients taking **nitrendipine**.[8] However, there are reports of a deterioration in glucose tolerance during the use of **nifedipine** in a total of 12 subjects with impaired glucose tolerance.[10,11] A further case report describes a 30% increase in the **insulin** requirements of a diabetic man after he took **nifedipine** 60 mg daily.[12] An isolated case of hypoglycaemia has been described in a patient taking **gliclazide** when **nicardipine** was given.[13] However, a large case-control study found no statistically significant increase or decrease in the risk of a serious hypoglycaemic episode in patients over 65 years of age taking insulin or sulfonylureas, who were also taking calcium-channel blockers (**nifedipine** and **verapamil** were the most frequently used), when compared with patients not taking antihypertensive drugs.[14]

(b) Pharmacokinetic studies

1. Alpha-glucosidase inhibitors. The manufacturers of **acarbose** state that in a pilot study of a possible interaction with **nifedipine**, no significant or reproducible changes were seen in plasma **nifedipine** profiles.[15,16] Similarly, the manufacturers of **miglitol** note that it had no effect on the pharmacokinetics and pharmacodynamics of **nifedipine**.[17]

2. Insulin. One study found that **nifedipine** 10 mg increased the rate of absorption of subcutaneous insulin by about 50%.[18]

3. Metformin. One US manufacturer of nifedipine noted that in a single-dose study in healthy subjects, nifedipine very slightly increased the AUC of metformin by 9%, and increased its maximum level by 20%.[19]

4. Pioglitazone or Rosiglitazone. Rosiglitazone 8 mg daily for 2 weeks was found to have no clinically relevant effect on the pharmacokinetics of **nifedipine** in 28 healthy subjects.[20] The manufacturer notes that pioglitazone 45 mg daily for 7 days given with **nifedipine** extended-release 30 mg daily for 4 days resulted in a small change in **nifedipine** pharmacokinetics (12% decrease in AUC).[21]

5. Repaglinide. A three-period, crossover study in healthy subjects found that **nifedipine** 10 mg daily decreased the maximum plasma level of repaglinide 2 mg three times daily by 3% and increased the bioavailability of repaglinide by 11%, but this was not statistically significant. There was a higher incidence of adverse effects during concurrent use.[22]

6. Sulfonylureas. A study in 6 patients type 2 diabetes found that a single 20-mg dose of **nifedipine** had no effect on the pharmacokinetics of **glipizide** 5 to 30 mg daily.[6] Similarly, **nimodipine** caused no change in the pharmacokinetics of **glibenclamide** in 11 patients.[4]

B. Diltiazem

A patient with type 1 diabetes developed worsening and intractable hyperglycaemia (mean serum glucose levels above 13 mmol/L) when given diltiazem 90 mg every 6 hours. Her **insulin** requirements dropped when the diltiazem was withdrawn. When she started taking diltiazem 30 mg every 6 hours her blood glucose levels were still high, but she needed less **insulin** than when taking the higher diltiazem dose.[23]

A study in 12 healthy subjects found that diltiazem 60 mg three times daily had no effect on the secretion of **insulin** or glucagon, or on plasma glucose levels.[24] Similarly, diltiazem 120 mg three times daily for 3 days had no effect on **insulin** and glucose levels during an oral glucose tolerance test in 10 patients taking **gliclazide**.[5]

A study in 8 healthy subjects found that a single 500-mg dose of **tolbutamide** had no effect on the serum levels of a single 60-mg dose of diltiazem. There was a minor increase of about 10% in the AUC_{0-24} and maximum serum levels of **tolbutamide** in the presence of diltiazem but the blood glucose-lowering effects of **tolbutamide** were not significantly changed.[25]

C. Verapamil

A study in 23 patients with type 2 diabetes, 7 of whom were taking **glibenclamide** (**glyburide**), found that verapamil improved the response to an oral glucose tolerance test but did not increase the blood glucose-lowering effects of the **glibenclamide**.[26] Two studies in type 2 diabetics found that verapamil improved the response to glucose tolerance tests,[27,28] but in one of the studies, no alterations in the blood glucose-lowering effects of **glibenclamide** were found.[27] A study in healthy subjects found that verapamil modestly raised the **glibenclamide** AUC by 26% but plasma glucose levels were unchanged.[29] A large case-control study found no statistically significant increase or decrease in the risk of a serious hypoglycaemic episode in patients over 65 years of age taking insulin or sulfonylureas, who were also taking calcium-channel blockers (**nifedipine** and **verapamil** were the most frequently used), when compared with patients not taking antihypertensive drugs.[14]

Mechanism

The changes that occur are not fully understood. Suggestions include: inhibition of insulin secretion by the calcium-channel blockers and inhibition of glucagon secretion by glucose; changes in glucose uptake by the liver and other cells; blood glucose rises following catecholamine release after vasodilation, and changes in glucose metabolism. In contrast, one study in non-diabetics suggested that long-acting nifedipine could improve insulin sensitivity.[30]

Importance and management

Very extensively studied, but many of the reports describe single-dose studies or multiple-dose studies in healthy subjects (only a few are cited here), which do not give a clear picture of what may be expected in diabetic patients. Those studies that have concentrated on diabetic patients indicate that the control of the diabetes is not usually adversely affected by calcium-channel blockers, although isolated cases with diltiazem, nicardipine and nifedipine have been reported.[12,13,23] Similarly, there appear to be no important pharmacokinetic interactions with any of the combinations studied. Therefore, in general, no particular precautions normally seem necessary. However, if an otherwise unexplained worsening of diabetic control occurs it may be prudent to consider the use of a calcium-channel blocker as a possible cause.

Antidiabetics + Cibenzoline (Cifenline)

Hypoglycaemia has been seen in patients taking cibenzoline alone, and in one case with gliclazide.

Clinical evidence, mechanism, importance and management

Cibenzoline occasionally and unpredictably causes hypoglycaemia, which may be severe. Marked hypoglycaemia was seen in a 67-year-old non-diabetic patient when cibenzoline was given.[1] A further case report describes hypoglycaemia in an 84-year-old, in whom age, renal impairment and/or malnutrition acted as facilitating factors.[2] The authors of this report noted that hypoglycaemia has been reported in another 20 cases, where the dose was not corrected for age and renal function.[2] A more recent report describes an elderly patient with type 2 diabetes controlled by diet who developed hypoglycaemia and associated dementia-like symptoms while taking low-dose cibenzoline.[3] Hypoglycaemia also occurred in a 61-year-old patient with renal impairment taking **gliclazide** and cibenzoline.[4] In a study of reports of hypoglycaemia in the French pharmacovigilance database, cibenzoline was used as a positive control, and a very strong association between cibenzoline and hypoglycaemia was noted, both in reports including antidiabetic drugs (odds ratio 5) and in reports not including antidiabetic drugs (odds ratio 174). The odds ratio of hypoglycaemia compared with all reports for the study as a whole was 107 (78 to 148).[5]

The reasons for this effect are not understood. However, in a controlled study in patients with abnormal glucose tolerance and ventricular arrhythmias, cibenzoline exerted a hypoglycaemic effect by facilitating insulin secretion.[6]

This appears to be a drug-disease rather than a drug-drug interaction and diabetic patients do not seem to be more at risk than non-diabetics, but good monitoring is advisable if cibenzoline is given, particularly if risk factors such as increased age, renal impairment, malnutrition and high cibenzoline dose are present..

Antidiabetics + Clonidine

Some evidence suggests that clonidine may possibly suppress the signs and symptoms of hypoglycaemia in diabetic patients. Marked hyperglycaemia occurred in a child using insulin when clonidine was given. However, the effect of clonidine on carbohydrate metabolism appears to be variable, as other reports have described both increases and decreases in blood glucose levels. Clonidine premedication may decrease or increase the hyperglycaemic response to surgery.

Clinical evidence

(a) Non-diabetics

Studies in healthy subjects and patients with hypertension found that their normal response to hypoglycaemia (tachycardia, palpitations, perspiration) caused by a 0.1 unit/kg dose of **insulin** was markedly reduced when they were taking clonidine 450 to 900 micrograms daily.[1,2] A study in healthy subjects and non-diabetic patients found that clonidine raises blood glucose levels, apparently by reducing **insulin** secretion,[3] whereas, in contrast, hypoglycaemia was associated with clonidine testing for growth hormone deficiency in 4 children.[4] Furthermore, in yet another study, clonidine 100 or 200 micrograms twice daily had no effect on fasting glucose levels or oral glucose tolerance testing.[5]

(b) Diabetic patients

A 9-year-old girl with type 1 diabetes stabilised with **insulin** 4 units daily, developed substantial hyperglycaemia and needed up to 56 units of **insulin** daily when she began to take clonidine 50 micrograms daily for Tourette's syndrome. When the clonidine was stopped, she had numerous hypoglycaemic episodes, and within a few days it was possible to reduce her daily dose of **insulin** to 6 units.[6] A patient with type 2 diabetes and hypertension experienced elevated blood glucose levels and decreased **insulin** secretion when clonidine was given.[7] However, a study in 10 diabetic patients with hypertension found that although clonidine impaired the response to an acute glucose challenge, it did not significantly affect diabetic control over a 10-week period.[8] Similarly, in 20 patients with type 2 diabetes and hypertension, clonidine 75 to 300 micrograms daily for 3 months had no effect on glucose control. The antidiabetic therapy (sulfonylureas (11 patients), metformin (2 patients), a combination (3 patients), or diet alone (4 patients)) was kept constant.[9]

In contrast, a placebo-controlled, crossover study in 20 patients with type 2 diabetes found that transdermal clonidine significantly reduced mean fasting plasma glucose levels by 9%.[10]

(c) Hyperglycaemia during surgery

Forty patients with type 2 diabetes (controlled by diet alone, **sulfonylureas**, **biguanides**, or **insulin**), having eye surgery under general anaesthesia, were given either clonidine 225 to 375 micrograms or flunitrazepam as premedication. In diabetic patients there is an increase in blood glucose during stress because of an increase in catecholamine release. Therefore the patients were also given a continuous infusion of **insulin** to maintain blood glucose at 5.5 to 11.1 mmol/L. Clonidine decreased the **insulin** requirement because of improved blood glucose control due to inhibition of catecholamine release.[11] Contrasting results were found in a study in 16 non-diabetic women undergoing abdominal hysterectomy. Eight were given intravenous clonidine 1 microgram/kg and 8 control patients were given saline. Intraoperative plasma glucose levels were higher in the clonidine group and these patients also had lower insulin levels.[12]

Mechanism

The suggested reason for a reduced response to hypoglycaemia is that clonidine depresses the output of the catecholamines (adrenaline (epinephrine), noradrenaline (norepinephrine)), which are secreted in an effort to raise blood glucose levels, and which are also responsible for these signs.[2] It seems possible that clonidine will similarly suppress the signs and symptoms of hypoglycaemia that can occur in diabetics, but there seem to be no reports confirming this.

Importance and management

The effect of clonidine on carbohydrate metabolism in diabetic patients appears to be variable and the general importance of these interactions is uncertain. In diabetic patients there is an increase in blood glucose levels during stress because of an increase in catecholamine release. The influence of clonidine on the surgical stress response appears to vary depending on the dose of clonidine and the type of surgery.[12] Thus, clonidine at about 4 micrograms/kg may attenuate the hyperglycaemic response to neurosurgical and non-abdominal procedures, but low-dose clonidine accentuates the hyperglycaemic response to lower abdominal surgery, which results from a decrease in plasma insulin.[11,12]

Antidiabetics + Corticosteroids

The blood glucose-lowering effects of the antidiabetics are opposed by corticosteroids with glucocorticoid (hyperglycaemic) activity and significant hyperglycaemia has been seen with systemic corticosteroids. A report also describes deterioration in diabetic control with *inhaled* high-dose fluticasone, then high-dose budesonide, in a patient taking glibenclamide and metformin. High doses of high-potency corticosteroid creams may also, rarely, cause hyperglycaemia.

Clinical evidence, mechanism, importance and management

(a) Local corticosteroids

1. Inhaled. A 67-year-old man with diabetes taking **glibenclamide** 5 mg daily and **metformin** 1.7 g daily had a deterioration in diabetic control (glycosuria and an increase in HbA_{1c}) 3 weeks after starting inhaled **fluticasone** 2 mg daily, by metered dose inhaler with a spacer device, for asthma. The **fluticasone** dose was gradually decreased to 500 micrograms daily after about 3 months, with an improvement in diabetic control. Subsequently, the **fluticasone** dose was increased from 500 micrograms to 1 mg, and within a week he again developed glycosuria.[1] This same patient was later given inhaled high-dose **budesonide** 2 mg daily and he again developed glycosuria and increased HbA_{1c} levels, which improved as the dose was gradually decreased to 800 micrograms daily.[2] The adverse effects of *systemic* corticosteroids on glucose tolerance are well known. Although only one case appears to have been reported, it suggests that high-dose inhaled corticosteroids may have a similar effect. It may be prudent to increase monitoring of diabetic control in patients requiring high-dose corticosteroids and consider reducing the dose of the inhaled corticosteroid if possible, or adjusting the dose of the antidiabetic medication as necessary.

2. Topical. Two patients with an abnormal response to the glucose tolerance test, but without overt signs of diabetes mellitus, developed postprandial hyperglycaemia and one developed glycosuria when they used topical corticosteroids for severe psoriasis. These patients were given 15 g of **halcinonide** 0.1% or **betamethasone** 0.1% cream, applied every 12 hours for 15 days under occlusive dressings.[3] These cases appear to be rare, and were associated with high doses of potent or very potent corticosteroids,

used under occlusive dressings, which increases systemic absorption. No additional special precautions would generally appear to be necessary in diabetics using moderate amounts of topical corticosteroids.

(b) Systemic corticosteroids

Systemic corticosteroids with glucocorticoid activity can raise blood glucose levels and induce diabetes.[4] This can oppose the blood glucose-lowering effects of the antidiabetics used in the treatment of diabetes mellitus. For example, a disturbance of the control of diabetes is very briefly described in a patient given **insulin** and **hydrocortisone**.[5] A study in 5 patients with type 2 diabetes taking **chlorpropamide** found that a single 200-mg dose of **cortisone** modified their glucose tolerance. The blood glucose levels of 4 of them rose (3 showed an initial fall), whereas in a previous test with **chlorpropamide** alone the blood glucose levels of 4 of them had fallen.[6] This almost certainly reflects a direct antagonism between the pharmacological effects of the two drugs. Another glucocorticoid, **prednisone**, had no significant effect on the metabolism or clearance of **tolbutamide** in healthy subjects.[7]

There are very few studies of this interaction, probably because the hyperglycaemic activity of the **corticosteroids** has been known for such a long time that the outcome of concurrent use is self-evident. A case-control study found that in patients taking glucocorticoids, the relative risk for development of hyperglycaemia requiring treatment was 2.23, when compared with controls. The risk increased with an increasing daily dose of **hydrocortisone**: doses of 1 to 39 mg were associated with a 1.77-fold increase in risk, doses of 40 to 79 mg were associated with a 3.02-fold increase in risk, doses of 80 to 119 mg were associated with a 5.82-fold increase in risk, and doses of greater than 120 mg were associated with a 10.34-fold increase in risk.[8] Similarly, another study, in healthy subjects, found dose-related decreases in glucose tolerance and higher serum insulin levels associated with single intravenous doses of **hydrocortisone** and **methylprednisolone,** but these changes were more marked with **methylprednisolone** than **hydrocortisone**.[9] **Dexamethasone** has also been shown to cause a deterioration in glucose tolerance with an incidence of about 35% in non-diabetic, first-degree relatives of patients with type 2 diabetes, primarily due to reduced insulin secretory capacity.[10]

The effects of systemic corticosteroids in diabetics should be closely monitored and the dose of the antidiabetic raised as necessary. Antidiabetics are sometimes needed in non-diabetic patients taking **corticosteroids** to reduce blood glucose levels.

Antidiabetics + Danazol

Danazol causes insulin resistance. Therefore, on theoretical grounds, danazol would be expected to oppose the effects of antidiabetics.

Clinical evidence, mechanism, importance and management

Danazol can disturb glucose metabolism. A study in 14 non-diabetic subjects found that 3 months of treatment with danazol 600 mg daily caused a mild but definite deterioration in glucose tolerance, associated with high insulin levels. Insulin resistance was also seen in 5 subjects taking danazol when they were given intravenous **tolbutamide**.[1] Similarly, another study in 9 non-diabetic women found that danazol 600 mg daily raised insulin levels in response to glucose or intravenous **tolbutamide**.[2] A further study in 9 non-diabetic women also found that danazol caused a mild deterioration in glucose tolerance and a marked increase in the insulin response to glucose loading.[3] Other studies have found that danazol causes marked resistance to both insulin[4-6] and glucagon,[5,6] which could be due to receptor down-regulation resulting from hypersecretion of insulin and glucagon.[5,6]

There is also a report of danazol-associated type 1 diabetes in a patient with endometriosis who took danazol 400 mg twice daily for 8 weeks. The diabetes resolved on withdrawal of danazol, but the development of hyperglycaemia about 5 months later suggested a predisposition to diabetes.[7] However, it has been suggested that the patient probably had type 2 diabetes precipitated by danazol-induced insulin resistance, which would possibly have responded to dietary restriction. Danazol-associated hyperglucagonaemia may have exacerbated the symptoms.[8,9]

For these reasons the manufacturer of danazol advises caution if danazol is given to diabetic patients.[10] Danazol would be expected to oppose the actions of antidiabetics to some extent, but there do not appear to be any studies assessing the clinical relevance of this.

Antidiabetics + Dextropropoxyphene (Propoxyphene)

Dextropropoxyphene does not appear to affect the pharmacokinetics of tolbutamide. Hypoglycaemia was seen in a patient taking an unnamed sulfonylurea with co-proxamol, and has also been reported in non-diabetic patients given dextropropoxyphene alone.

Clinical evidence, mechanism, importance and management

After 6 healthy subjects took dextropropoxyphene 65 mg every 8 hours for 4 days, the clearance of a 500-mg intravenous dose of **tolbutamide** was not affected.[1] There is an isolated case of hypoglycaemia in a patient taking an unnamed **sulfonylurea** with **co-proxamol** (dextropropoxyphene with paracetamol (acetaminophen)).[2] There are also several reports of hypoglycaemia in non-diabetic patients taking dextropropoxyphene alone,[3-7] sometimes associated with renal failure,[3,4] advanced age,[5] or with high doses or in overdose.[6] The general importance of these isolated reports is uncertain, and there would normally seem to be little reason for avoiding the concurrent use of antidiabetics and dextropropoxyphene, or for taking particular precautions.

Antidiabetics + Disopyramide

Disopyramide occasionally causes hypoglycaemia, which may be severe. Isolated reports describe severe hypoglycaemia when dis-

opyramide was given to diabetic patients taking gliclazide, or metformin and/or insulin.

Clinical evidence, mechanism, importance and management

Disopyramide occasionally and unpredictably causes hypoglycaemia, which may be severe.[1-7] The reasons for this effect are not fully understood, but *in vitro* studies suggest that disopyramide and its main metabolite may enhance insulin release from the pancreas.[8] A case report describes severe hypoglycaemia in an 82-year-old woman with diabetes who was taking **gliclazide**, which occurred 6 months after she started taking disopyramide 300 mg daily.[9] A further case of hypoglycaemia associated with disopyramide occurred in a 70-year-old woman who had been taking **metformin** 500 mg twice daily and **insulin** 62 units daily. Within 3 months of starting disopyramide 250 mg twice daily her **insulin** dose was reduced to 24 units daily, she stopped taking **metformin** and was eating 'substantial snacks' to avoid hypoglycaemia.[10] The **insulin** requirements of another patient with type 2 diabetes were markedly reduced when disopyramide was started.[11]

The manufacturers note that patients at particular risk for hypoglycaemia are the elderly, the malnourished, and diabetics, and that impaired renal function and impaired cardiac function may be predisposing factors.[12,13] They advise close monitoring of blood glucose levels[12,13] and withdrawal of disopyramide if problems arise.[12] This is not simply a problem for diabetics, but certainly within the context of diabetes the blood glucose-lowering effects of disopyramide may possibly cause particular difficulties. Although not strictly an interaction, the concurrent use of disopyramide and antidiabetics should be well monitored because of the potential for severe hypoglycaemia, as the cases show.

Antidiabetics + Disulfiram

Disulfiram appears not to affect the control of diabetes mellitus. Disulfiram does not affect the pharmacokinetics of tolbutamide.

Clinical evidence, mechanism, importance and management

The manufacturers of disulfiram say that caution should be exercised if it is used in diabetics,[1] but a reviewer[2] who had given disulfiram to over 20 000 alcoholics said that he had prescribed disulfiram for several hundred patients with diabetes mellitus over 20 years without any apparent adverse effects and therefore any theoretical interaction is rarely, if ever, applicable to clinical practice. It would be reasonable to assume that many of these patients were also taking **insulin** or one of the older oral antidiabetics. There do not appear to be any reported cases in the literature of adverse interactions between disulfiram and any of the antidiabetics. In a study in 5 healthy subjects, disulfiram (400 mg three times daily for one day, then once daily for one day, then 200 mg daily for 2 days) had no significant effect on the half-life or clearance of intravenous **tolbutamide** 500 mg.[3] The conclusion to be drawn from all of this is that any reaction is very rare (if it ever occurs), and no special precautions would normally appear to be necessary.

Antidiabetics + Diuretics; Loop

The control of diabetes is not usually disturbed to a clinically relevant extent by etacrynic acid, furosemide, or torasemide. However, there are a few reports suggesting that etacrynic acid and furosemide can, rarely, raise blood glucose levels.

Clinical evidence

(a) Etacrynic acid

A double-blind study in 24 hypertensive patients, one-third of whom were diabetics, found that etacrynic acid 200 mg daily for 6 weeks impaired their glucose tolerance and raised the blood glucose levels of the diabetic patients to the same extent as hydrochlorothiazide 200 mg daily in diabetic patients and non-diabetics .[1] However, in other studies no change in carbohydrate metabolism or glucose tolerance was seen in 6 diabetic patients given etacrynic acid 150 mg daily for a week,[2] or in 10 patients described as pre-diabetic given etacrynic acid 50 mg for a week.[3]

(b) Furosemide

Although furosemide can elevate blood glucose levels,[4] worsen glucose tolerance[5] and occasionally cause glycosuria or even acute diabetes in individual patients,[6,7] the general picture is that the control of diabetes is not usually affected by furosemide.[8] No change in glucose tolerance was seen in 10 patients described as pre-diabetic when they were given furosemide 40 mg daily for a week.[3] No clinically relevant changes in the control of diabetes were seen in a 3-month study of 29 patients with type 2 diabetes taking furosemide 40 mg daily and an average of 7 mg of **glibenclamide** (**glyburide**) daily.[9]

(c) Torasemide

A three-month study in 32 patients with congestive heart failure and type 2 diabetes mellitus taking **glibenclamide** found that torasemide 5 mg daily caused a small but clinically insignificant fall in blood glucose levels.[9]

Mechanism

Uncertain.

Importance and management

Information is limited. Some impairment of glucose tolerance may possibly occur, but there seems to be a lack of evidence in the literature to show that any loop diuretic has much effect on the control of diabetes in most patients.

Antidiabetics + Diuretics; Thiazide and related

By raising blood glucose levels, the thiazide and related diuretics can reduce the effects of the antidiabetics and impair the control

of diabetes. However, this effect appears to be dose related, and is less frequent at the low doses now more commonly used for hypertension. Hyponatraemia has rarely been reported when chlorpropamide was given with a thiazide and potassium-sparing diuretic. An isolated report describes severe hypoglycaemia in a patient taking glibenclamide (glyburide) shortly after metolazone was started. Voglibose had no important effect on the pharmacokinetics of hydrochlorothiazide, and hydrochlorothiazide did not appear to alter metformin pharmacokinetics.

Clinical evidence

(a) Effects on glucose control

Chlorothiazide, the first of the thiazide diuretics, was found within a year of its introduction in 1958 to have hyperglycaemic effects.[1] Since then a very large number of reports have described hyperglycaemia, the precipitation of diabetes in pre-diabetics, and the disturbance of blood sugar control in diabetics taking thiazides. One example from many:

A long-term study in 53 patients with type 2 diabetes found that **chlorothiazide** 500 mg or 1 g daily or **trichlormethiazide** 4 or 8 mg daily caused a mean rise in blood glucose levels from about 6.7 mmol/L to 7.8 mmol/L. Only 7 patients needed a change in their treatment: 4 required more of their oral antidiabetic, 2 an increase in **insulin** dose, and one was transferred from **tolbutamide** to **insulin**. The oral antidiabetics used included **tolbutamide**, **chlorpropamide**, **acetohexamide** and **phenformin**.[2]

A rise in blood glucose levels has been observed with **bendroflumethiazide**,[3,4] **benzthiazide**,[5] **hydrochlorothiazide** 100 to 300 mg daily,[3] and **chlortalidone** 50 to 100 mg daily.[6] A study in hypertensive patients found that **chlortalidone** 50 mg daily increased glucose and insulin levels, but **hydrochlorothiazide** 50 mg daily alone or as part of a potassium and/or magnesium-sparing regimen did not.[7]

More recent data suggest that the effects of thiazides on blood glucose may be dose related. In a double-blind randomised study comparing the effects of 1.25 or 5 mg of **bendroflumethiazide** on blood glucose, the lower dose had no effects on insulin action, whereas when the higher dose was given, there was evidence of impaired glucose tolerance.[8] A review of the literature on **hydrochlorothiazide** similarly reports that low doses (6.25 to 12.5 mg) lack significant effects on blood glucose levels.[9]

A man with type 2 diabetes, stabile taking **glibenclamide** (**glyburide**) 10 mg daily and hospitalised for congestive heart failure, became clinically hypoglycaemic (blood glucose levels unmeasurable by *Labstix*) within 40 hours of starting **metolazone** 5 mg daily. He was treated with intravenous glucose. Although both **glibenclamide** and **metolazone** were stopped, he had 4 further hypoglycaemic episodes over the next 30 hours.[10] The reasons are not understood. *In vitro* studies did not find any evidence that **metolazone** displaces **glibenclamide** from its protein binding sites, which might possibly have provided some explanation for what happened.[10]

The hypoglycaemic responses of 10 healthy subjects were studied following an intravenous infusion of **tolbutamide** 3 mg/kg, given 3 days before and one hour after the last dose of oral **cicletanine** 100 mg daily for a week.[11] No clinically relevant changes were seen. Note that, studies in *animals* and in non-diabetic hypertensive patients found that, at therapeutic doses, **cicletanine** did not affect glycoregulation.[12] The conclusion to be drawn is that **cicletanine** is unlikely to affect the control of diabetes in patients, but this needs confirmation from longer-term clinical studies.

(b) Hyponatraemia

A hospital report describes 8 cases of low serum sodium concentrations observed over a 5-year period in patients taking **chlorpropamide** and **hydrochlorothiazide** 50 mg with amiloride 5 mg.[13]

(c) Pharmacokinetics

A study in 12 healthy subjects given a single 25-mg dose of **hydrochlorothiazide** before and after taking **voglibose** 5 mg three times daily for 11 days found that the **hydrochlorothiazide** plasma levels were slightly increased by the **voglibose** (AUC increased 8%, maximum plasma levels increased 15%) but these changes were considered to be clinically irrelevant. The combination was well tolerated and adverse events were unchanged.[14]

In a study in 6 patients with diabetes taking **metformin**, adding **hydrochlorothiazide** for 2 weeks (4 patients) or stopping **hydrochlorothiazide** for 2 weeks (2 patients) had no effect on metformin AUC or clearance. This study was undertaken because of an earlier indication in 2 of these patients that hydrochlorothiazide might have increased metformin levels, but this was not confirmed.[15]

Mechanism

Not understood. One study suggested that the hyperglycaemia is due to the inhibition of insulin release by the pancreas.[16] Another suggestion is that the peripheral action of insulin is affected in some way.[5,17] There is also evidence that the effects may be related in part to potassium depletion.[18] The hyponatraemia appears to be due to the additive sodium-losing effects of chlorpropamide, the thiazide and amiloride. Obese patients may be more sensitive to the effects of hydrochlorothiazide on insulin metabolism.[7]

Importance and management

The reduction in the blood glucose-lowering effects of the antidiabetics with thiazides is extremely well documented (not all references are given here) but of only moderate practical importance, particularly as much of the data relates to higher doses of thiazides than those now used clinically for hypertension. Low doses of thiazides have a lesser effect on plasma glucose, and 2009 guidelines on the treatment of hypertension in diabetes recommend the use of thiazides as add-on therapy if ACE inhibitors or angiotensin II receptor antagonists alone are not effective.[19] If higher doses are used, increased monitoring of diabetic control would seem prudent. There is evidence that the full effects may take many months to develop in some patients.[4] Most patients respond to a modest increase in the dose of their antidiabetics. This interaction may be expected to occur with all thiazides and possibly related diuretics, such as clopamide and metolazone. Hyponatraemia is a rare but recognised adverse effect of the thiazides and no additional precautions would therefore seem necessary.

Antidiabetics + Fenfluramine

Fenfluramine has inherent blood glucose-lowering activity that can add to, or in some instances replace, the effects of conventional antidiabetic drugs.

Clinical evidence, mechanism, importance and management

A study of the substitution of fenfluramine (initially 40 mg daily, increased to 120 mg daily) for a biguanide found that diabetes was equally

well controlled by either drug in 4 of 6 patients.[1] The blood glucose-lowering effects of fenfluramine have also been described elsewhere.[2,3] It seems that fenfluramine increases the uptake of glucose into skeletal muscle, thereby lowering blood glucose levels.[3,4]

This is a well established and, on the whole, an advantageous rather than an adverse reaction, but it would be prudent to check on the extent of the response if fenfluramine is added or withdrawn from the treatment being received by diabetics. However, note that fenfluramine was generally withdrawn in 1997 because its use was found to be associated with a high incidence of abnormal echocardiograms indicating abnormal functioning of heart valves.

Antidiabetics + Fibrates

A number of reports describe hypoglycaemia and/or an enhancement of the effects of antidiabetic drugs (mostly insulin and sulfonylureas) in patients given fibrates. The combination of gemfibrozil and repaglinide should be avoided, because a marked pharmacokinetic interaction can result in serious hypoglycaemia. Gemfibrozil also causes large increases in the AUCs of pioglitazone and rosiglitazone. Only a modest pharmacokinetic interaction occurs between gemfibrozil and nateglinide. The antidiuretic effects of clofibrate in the treatment of diabetes insipidus are opposed by glibenclamide (glyburide). There are cases of paradoxical reductions in HDL-cholesterol with the combination of fibrates and thiazolidinediones.

Clinical evidence

A. Bezafibrate

(a) Repaglinide

In a study in healthy subjects bezafibrate 400 mg daily for 5 days had no effect on the pharmacokinetics of a single 250-microgram dose of repaglinide, and did not alter the blood glucose-lowering effect of repaglinide.[1]

(b) Sulfonylureas and Biguanides

Three elderly patients with type 2 diabetes and mild renal impairment taking **glibenclamide** (**glyburide**) developed hypoglycaemia when they were given bezafibrate: one of them needed a 60% dose reduction, another was given **tolbutamide** instead, and the third was able to stop both **glibenclamide** and **buformin**.[2] During the period 1985 to 1990, the French Centres Régionaux de Pharmacovigilance recorded 7 cases of hypoglycaemia, which developed in patients taking unnamed sulfonylureas when they were given fibrates (one case with bezafibrate).[3]

B. Ciprofibrate

During the period 1985 to 1990, the French Centres Régionaux de Pharmacovigilance recorded 7 cases of hypoglycaemia, which developed in patients taking unnamed **sulfonylureas** when they were given fibrates (3 cases with ciprofibrate).[3]

C. Clofibrate

(a) Hypoglycaemia

Over a 5-day period while taking clofibrate 2 g daily, the control of diabetes was improved in 6 out of 13 patients with type 2 diabetes taking various unnamed sulfonylureas. Hypoglycaemia (blood glucose levels of about 1.7 to 2.2 mmol/L) was seen in 4 patients.[4] Other studies confirm that some, but not all, patients have a fall in blood glucose levels while taking clofibrate and the control of the diabetes can improve.[5-12] In one study[13] the half-life of **chlorpropamide** ranged from 40 to 62 hours in 5 subjects taking clofibrate compared with a mean of about 36 hours in control subjects.

(b) Reduced antidiuretic effects

Clofibrate 2 g daily reduced the volume of urine excreted by 2 patients with pituitary diabetes insipidus, but when **glibenclamide** was also given the volume increased once again. Without treatment they excreted 5.8 litres and 6.5 litres of urine daily, and this reduced to only 2.4 litres and 1.7 litres, respectively, while taking clofibrate, whereas with **glibenclamide** and clofibrate they excreted 3.6 litres and 3.7 litres daily, respectively.[14]

D. Fenofibrate

(a) Pioglitazone or Rosiglitazone

There are reports of paradoxical reductions in HDL-cholesterol levels in a few patients taking a fibrate (bezafibrate, fenofibrate) with a thiazolidinedione, and a few are cited as examples.[15-19] In one analysis, this was more likely with the combination than either fibrates or rosiglitazone alone.[18]

(b) Repaglinide

In a study in healthy subjects, fenofibrate 200 mg daily for 5 days had no effect on the pharmacokinetics of a single 250-microgram dose of repaglinide, and did not alter the glucose-lowering effect of repaglinide.[1]

(c) Sulfonylureas

During the period 1985 to 1990, the French Centres Régionaux de Pharmacovigilance recorded 7 cases of hypoglycaemia, which developed in patients taking unnamed sulfonylureas when they were given fibrates (3 cases with fenofibrate).[3]

E. Gemfibrozil

(a) Nateglinide or Repaglinide

In a randomised, crossover study, 12 healthy subjects were given gemfibrozil 600 mg twice daily for 5 doses, with a 250-microgram dose of repaglinide one hour after the final gemfibrozil dose. Gemfibrozil raised the AUC of repaglinide eightfold and increased the plasma levels nearly 29-fold.[20] The interaction was still marked even when the dose of repaglinide was taken 12 hours after the final dose of gemfibrozil (fivefold increase in AUC).[21] Itraconazole (which may interact, see 'Antidiabetics + Azoles; Itraconazole or Ketoconazole', p.545) given with gemfibrozil and repaglinide further increased these effects. The blood glucose-lowering effects of repaglinide were considerably enhanced and prolonged, both by gemfibrozil alone and in combination with itraconazole.[20] In 2003, the European Agency for the Evaluation of Medicinal Products had received five reports of serious hypoglycaemic episodes with gemfibrozil and repaglinide.[22]

In contrast, in a very similar study by the same research group, the concurrent use of gemfibrozil and itraconazole caused only a modest 47% increase in the AUC of a single 30-mg dose of nateglinide, and did not significantly alter the blood glucose response to nateglinide in healthy subjects.[23]

(b) Pioglitazone or Rosiglitazone

In a study in healthy subjects, gemfibrozil 600 mg twice daily for 4 days increased the mean AUC of a single 4-mg dose of rosiglitazone 2.3-fold, the peak plasma level by 20% and the 24-hour plasma level almost ten-fold.[24] In the same way, gemfibrozil increased the mean AUC of a single dose of pioglitazone 3.2-fold without altering its maximum level, but raised the 48-hour plasma level approximately 15-fold.[25] A similar increase in the AUC of pioglitazone was reported in another study.[26] In these studies, the effects of these pharmacokinetic changes on the pharmacodynamics of rosiglitazone or pioglitazone were not assessed.[24-26]

(c) Sulfonylureas or Insulin

Fasting blood glucose levels decreased in 10 patients with diabetes, and increased in 4 of 14 patients with diabetes receiving insulin, **acetohexamide**, **chlorpropamide** or **glipizide** who were given gemfibrozil (800 mg daily initially, reduced later to 400 to 600 mg daily).[27] Another study found that of 20 patients, 9 required a slight increase in the dose of insulin or sulfonylurea (**glibenclamide** or **chlorpropamide**), and one a decreased dose, when they were given gemfibrozil 800 mg to 1.6 g daily.[28] A single report describes hypoglycaemia, which occurred in a diabetic taking **glibenclamide** when they were given gemfibrozil 1.2 g daily. The **glibenclamide** dose was reduced from 5 to 1.25 mg daily with satisfactory diabetic control. When the gemfibrozil was later stopped and restarted, the dose of the **glibenclamide** had to be increased and then reduced.[29] A placebo-controlled study in 10 healthy subjects found that gemfibrozil 600 mg twice daily for 5 doses increased the AUC of a single 500-microgram dose of **glimepiride** by 23%, but there were no significant changes in serum insulin or blood glucose.[30]

Mechanism

The suggested reasons for the alteration in diabetic control with fibrates include the displacement of the sulfonylureas from their plasma protein binding sites,[7] alterations in their renal excretion,[13] and a decrease in insulin resistance.[6,31] Clofibrate has also been shown to have a blood glucose-lowering action of its own, which improves the glucose tolerance of diabetics.[12]

It is thought that gemfibrozil inhibits the metabolism of repaglinide by the cytochrome P450 isoenzyme CYP2C8, and that inhibition of CYP3A4 (its other main route of metabolism) by itraconazole further blocks repaglinide metabolism.[20] The organic anion transporting polypeptide 1B1 (OATP1B1) appears to have a limited role in the interaction of gemfibrozil with repaglinide.[32] Gemfibrozil also inhibits the CYP2C8-mediated metabolism of rosiglitazone and pioglitazone.[24,25] In addition, gemfibrozil may inhibit CYP2C9-mediated metabolism of glimepiride and other sulfonylureas such as glipizide, glibenclamide or **gliclazide**,[30] and also nateglinide.[23] It seems possible that any or all of these mechanisms might contribute towards enhanced hypoglycaemia.

Usually, fibrates, and also thiazolidinediones, increase HDL-cholesterol, but both thiazolidinediones and fibrates alone have caused paradoxical reductions in HDL-cholesterol. The reason for this is unknown.

Importance and management

The interaction between the sulfonylureas and clofibrate is established and well documented. The incidence is uncertain, but what is known suggests that between about one-third and one-half of patients may be affected. Alteration in diabetic control, most usually hypoglycaemia, has been seen in diabetics taking sulfonylureas with bezafibrate, ciprofibrate, fenofibrate, and gemfibrozil. There would seem to be no good reason for avoiding the concurrent use of sulfonylureas and fibrates, but be aware that the dose of the antidiabetic may need adjustment. Patients should be warned that excessive hypoglycaemia occurs occasionally and unpredictably.

Note that on the basis of the study,[20] and following five reports of serious hypoglycaemic episodes with gemfibrozil and repaglinide, the European Agency for the Evaluation of Medicinal Products decided to contraindicate concurrent use.[22]

Marked increases in the AUC of rosiglitazone and pioglitazone have been seen with gemfibrozil, but the clinical relevance of these has not been assessed. Until further experience is gained, caution is warranted. Only modest increases in plasma levels of nateglinide have been seen with gemfibrozil, but the manufacturer recommends caution if nateglinide is given with gemfibrozil.[33]

The general relevance of the cases of paradoxical reductions in HDL-cholesterol in patients taking a fibrate with rosiglitazone or pioglitazone is unclear, but bear them in mind in the event of an unexpected response to treatment.

Information about reduced diuretic effects is limited. It would seem prudent to avoid the concurrent use of drugs with actions that are antagonistic.

Antidiabetics + Glucosamine ± Chondroitin

In a controlled study, glucosamine supplements with chondroitin had no effect on glycaemic control in patients taking oral antidiabetic drugs but one report notes that unexpected increases in blood glucose levels have occurred.

Clinical evidence, mechanism, importance and management

In 2000, the Canadian Adverse Drug Reaction Monitoring Programme (CADRMP) briefly reported that unexpected increases in blood glucose levels had occurred in diabetic patients taking glucosamine sulfate, or glucosamine with chondroitin.[1] However, in a well controlled study, *Cosamin DS* (glucosamine hydrochloride 1.5 g daily plus chondroitin sulfate sodium 1.2 g) daily for 90 days had no effect on the control of diabetes (HbA_{1c}) in 22 patients with type 2 diabetes, 18 of whom were receiving oral antidiabetics (specific drugs not named) and 4 who were diet controlled.[2]

Endogenous glucosamine has a role in glucose metabolism, and may increase insulin resistance. In one case, glucosamine also reduced hypoglycaemic episodes in a patient with metastatic insulinoma.[3]

The interaction is not established, and the results of the controlled study suggest that glucosamine supplements are unlikely to affect the control of diabetes. However, it has been suggested that the results may not be applicable to patients with later stages of diabetes[4] (i.e. those with type 2 diabetes who require, or are expected to require, insulin). Therefore, it may be prudent to increase monitoring of blood glucose in these patients if glucosamine supplements are taken. Also, if glucose control unexpectedly deteriorates, bear in mind the possibility of self-medication with supplements such as glucosamine.

Antidiabetics + Guanethidine and related drugs

Limited evidence suggests that guanethidine has blood glucose-lowering activity, which may possibly add to the effects of conventional antidiabetics. One case report suggests soluble insulin may exaggerate the hypotensive effects of debrisoquine.

Clinical evidence

(a) Debrisoquine

An man with type 1 diabetes taking debrisoquine 20 mg twice daily developed severe postural hypotension within an hour of receiving 28 units of a short-acting **insulin** (soluble insulin) and 20 units of **isophane insulin**. He became dizzy and was found to have a standing blood pressure of 97/72 mmHg. The postural fall in systolic pressure was 65 mmHg. He had no evidence of hypoglycaemia and no hypotension when using 48 units of **isophane insulin** without the soluble insulin.[1] **Insulin** can cause hypotension but this is only seen in those with an impaired reflex control of blood pressure.[1]

(b) Guanethidine

A diabetic needed an **insulin** dose increase from 70 to 94 units daily when guanethidine was withdrawn.[2] A later study in 3 patients with type 2 diabetes found that guanethidine 50 to 90 mg daily caused a significant improvement in their glucose tolerance.[3] Two other reports also suggest that guanethidine has blood glucose-lowering effects.[4,5]

Mechanism

It has been suggested that the interaction between insulin and guanethidine occurs because guanethidine can impair the homoeostatic mechanism concerned with raising blood glucose levels, by affecting the release of catecholamines. The balance of the system thus impaired tends to be tipped in favour of a reduced blood glucose level, resulting in a reduced requirement for the antidiabetic. The interaction between debrisoquine and insulin is not understood.

Importance and management

Information about both of these interactions is very limited, and their general importance is uncertain. Increase the frequency of blood glucose monitoring if guanethidine or related drugs are started or stopped. Also check patients given debrisoquine (no longer generally available) and insulin, particularly if they are taking vasodilators, to ensure that excessive hypotension does not develop.

Antidiabetics + Guar gum or Glucomannan

Guar gum appeared not to affect the absorption of glipizide or glibenclamide (glyburide) to a clinically relevant extent. Although guar gum modestly reduced the absorption of metformin, it enhanced its postprandial hypoglycaemic effect. Glucomannan appeared to reduce the initial absorption of glibenclamide, but also enhanced its hypoglycaemic effect.

Clinical evidence, mechanism, importance and management

(a) Glucomannan

Glucomannan 3.9 g reduced the plasma levels of a single 2.5-mg dose of **glibenclamide** (**glyburide**) in 9 healthy subjects. Four samples taken over 30 to 150 minutes found that the plasma levels of **glibenclamide** were reduced by about 50%.[1] Despite this, plasma glucose levels were lower with the combination than with **glibenclamide** alone. Because plasma samples were not taken beyond 150 minutes, it is unclear what effect glucomannan has on the extent of **glibenclamide** absorption. The clinical relevance of these changes is unclear, but they seem unlikely to be important.

(b) Guar gum

In one study in 10 healthy subjects guar gum was found to have no effect on the AUC or maximum serum levels of a single 2.5-mg dose of **glipizide**. In this study **glipizide** was given alone, or 30 minutes before breakfast, and this treatment was compared with guar gum granules (4.75 g guar gum) given either with the breakfast or with the **glipizide**.[2]

In one comparative study, guar gum was found to reduce the AUC of **glibenclamide** from one formulation (*Semi-Euglucon*) by about 30%, but not another formulation (*Semi-Euglucon-N*),[3] possibly because the latter preparation is more rapidly and completely absorbed. Similarly, in a crossover study in 9 patients with type 2 diabetes, guar gum granules 5 g three times daily with meals did not significantly affect the AUC or maximum serum level of **glibenclamide** 3.5 mg twice daily from *Semi-Euglucon-N*. In addition, the combination slightly reduced fasting blood glucose when compared with baseline values.[4]

In a single-dose study, guar gum 10 g reduced the absorption rate of **metformin** 1.7 g and reduced the AUC by 39% in healthy subjects, but the total reduction in postprandial blood glucose levels was increased.[5]

It seems doubtful if any of these modest pharmacokinetic interactions has much, if any, clinical relevance because guar gum can improve the metabolic control and decrease serum lipids in patients with type 2 diabetes.[4]

Antidiabetics + H_2-receptor antagonists

On the whole cimetidine and ranitidine do not appear to significantly alter diabetic control with sulfonylureas, although cases of adverse effects have been seen when glibenclamide (glyburide) was given with ranitidine, and when gliclazide or glipizide were given with cimetidine.

Cimetidine appears to reduce the clearance of metformin, and may have contributed to a case of metformin-associated lactic acidosis. Cimetidine does not appear to alter repaglinide pharmacokinetics, and ranitidine does not appear to alter pioglitazone or rosiglitazone pharmacokinetics. Acarbose did not alter ranitidine pharmacokinetics in one study, but miglitol decreased the AUC of ranitidine by 60%.

Clinical evidence

A. Alpha-glucosidase inhibitors

The manufacturer of **acarbose** notes that it had no effect on the pharmacokinetics or pharmacodynamics of **ranitidine** in healthy subjects.[1] The manufacturer of **miglitol** notes that it reduced the bioavailability of **ranitidine** by 60%.[2]

B. Biguanides

Cimetidine 800 mg daily was found to reduce the renal clearance of **metformin** in 7 healthy subjects by 27% and increase the AUC by 50%.[3] A 59-year-old woman with type 2 diabetes taking long-term **metformin** 500 mg three times daily developed severe metabolic acidosis with cardiovascular collapse and acute renal failure. Three months previously she had started orlistat 120 mg three times daily, which caused chronic diarrhoea. During the 4 days before hospital admission, she was prescribed **cimetidine** 400 mg twice daily for her abdominal pain. The **metformin**-associated lactic acidosis was considered to have been precipitated by the orlistat and **cimetidine**.[4]

C. Sulfonylureas

(a) Chlorpropamide

Cimetidine had no effect on the pharmacokinetics of chlorpropamide in healthy subjects,[5] and in another study the blood glucose-lowering effects of chlorpropamide remained unaltered when **cimetidine** was given.[6]

(b) Glibenclamide (Glyburide)

A study in healthy subjects reported that the blood glucose-lowering effects of glibenclamide were slightly reduced by **cimetidine** and **ranitidine**. This occurred despite the fact that **cimetidine** increased the AUC of glibenclamide by 37% and ranitidine had no significant pharmacokinetic effect on glibenclamide.[7] Marked hypoglycaemia was seen in a patient taking glibenclamide 5 mg daily when **ranitidine** 150 mg twice daily was also taken.[8] Conversely, a study in healthy subjects found that the blood glucose-lowering effects of glibenclamide remained unaltered by **cimetidine**.[6]

(c) Gliclazide

An elderly patients with type 2 diabetes taking gliclazide 160 mg daily developed very low blood glucose levels (1 mmol/L) after starting to take **cimetidine** 800 mg daily.[9]

(d) Glimepiride

In a study in healthy subjects no relevant interactions, either pharmacokinetic or pharmacodynamic, were seen when glimepiride was given with either **cimetidine** or **ranitidine**.[10]

(e) Glipizide

Six patients with type 2 diabetes were given **cimetidine** 400 mg one hour before taking a dose of glipizide (average dose 5.8 mg) and then 3 hours later they were given a standard meal with **cimetidine** 200 mg. The expected rise in blood glucose levels after the meal was reduced by 40% and in two of the patients plasma glucose levels fell to less than 3 mmol/L. Cimetidine increased the glipizide AUC by 23%.[11,12] However, a study in healthy subjects found that the hypoglycaemic activity of glipizide remained unaltered by **cimetidine**.[6] Two studies in type 2 diabetics found that **ranitidine** 150 mg increased the AUC of glipizide by 29% and 34%,[12,13] and reduced the expected rise in blood sugar levels after a meal by 22%.[12] However, another study by the same research group reported that **ranitidine** 300 mg had no significant effects on either the pharmacokinetics or the effects of glipizide, except that the absorption was delayed.[14]

(f) Tolbutamide

The pharmacokinetics of tolbutamide 250 mg daily for 4 days were not significantly changed in 7 healthy subjects when **cimetidine** 800 mg daily was added for a further 4 days.[15] Other studies also found no pharmacokinetic interaction between tolbutamide and **cimetidine**,[16,17] or between tolbutamide and **ranitidine**,[17] and the hypoglycaemic activity of tolbutamide remained unaltered by **cimetidine**.[6] In contrast, in another study in healthy subjects, the AUC of tolbutamide was found to be slightly increased by 20% and the elimination half-life decreased by 17% by **cimetidine** 1.2 g daily, but plasma glucose levels were not significantly changed. **Ranitidine** 300 mg had no effect.[18] A later study found effectively the same results.[19]

(g) Unnamed sulfonylureas

A report briefly describes hypoglycaemia when 2 patients taking unnamed sulfonylureas were given **cimetidine**.[20]

D. Other oral antidiabetics

(a) Pioglitazone

A study in healthy subjects found that when pioglitazone 45 mg daily was given with **ranitidine** 150 mg twice daily the pharmacokinetics of both drugs were not significantly affected.[21]

(b) Repaglinide

An open-label, crossover study in 14 healthy subjects found that **cimetidine** 400 mg twice daily had no effect on the pharmacokinetics of repaglinide 2 mg three times daily.[22]

(c) Rosiglitazone

A crossover study in 12 healthy subjects found that pre-treatment with **ranitidine** 150 mg twice daily for 4 days had no effect on the pharmacokinetics of either a single 4-mg oral dose or a single 2-mg intravenous dose of rosiglitazone.[23]

Mechanism

Where an interaction occurs[18] it may be because the cimetidine inhibits the metabolism of the sulfonylurea by the liver, thereby increasing its effects. Cimetidine appears to inhibit the excretion of metformin by the kidneys,[3] and this may have contributed to the case of metformin-associated lactic acidosis described.[4]

Importance and management

The many studies cited here show that cimetidine generally causes no important changes in the pharmacokinetics or pharmacodynamics of the sulfonylureas (chlorpropamide, glimepiride and tolbutamide). Similarly, ranitidine did not interact with glimepiride or tolbutamide. Only a few isolated cases of hypoglycaemia have been reported with ranitidine or cimetidine and sulfonylureas (glibenclamide (glyburide), gliclazide and unnamed), and only one research group has found a possible increase in the blood glucose-lowering effect of glipizide with cimetidine and ranitidine.

It has been suggested that the dose of metformin may need to be reduced if cimetidine is used, bearing in mind the possibility of lactic acidosis if levels become too high,[3] and there is one case where cimetidine may have contributed to lactic acidosis.

The only other possible interaction of significance appears to be that between miglitol and ranitidine, although the clinical relevance of this has not been assessed.

Antidiabetics + Hormonal contraceptives

Some women may require small increases or decreases in their dose of antidiabetic drug while taking hormonal contraceptives, but it is unusual for the control of diabetes to be seriously disturbed. Irrespective of diabetic control, hormonal contraceptives should be used with caution in patients with diabetes because of the increased risk of arterial disease. Exenatide, pioglitazone, rosiglitazone and repaglinide do not appear to have a clinically significant effect on the pharmacokinetics of contraceptive steroids, and a hormonal contraceptive containing ethinylestradiol and levonorgestrel does not appear to have an important effect on the pharmacokinetics of repaglinide.

Clinical evidence

There are numerous reports of the effect of contraceptive steroids on glucose tolerance in non-diabetics. More recent reports from studies using low-dose oral hormonal contraceptives, support the suggestion that changes in glucose metabolism are minimal.[1,2] Problems with glucose metabolism seem very unlikely when the dose of oestrogen is less than 50 micrograms.[3] The progestogen in the hormonal contraceptive may also be important.[3-6] Progestogens with androgenic properties, such as **norgestrel**, **levonorgestrel** and to a lesser extent **norethisterone** (**norethindrone**), may affect carbohydrate metabolism. **Etynodiol** (**etynodrel**), which has weak androgenic activity, was found to cause smaller reductions in glucose tolerance, and **noretynodrel** was found to have no effect.[3-5] Studies of healthy, non-diabetic women using oral hormonal contraceptives containing **ethinylestradiol** 20 to 40 micrograms with third generation progestogens (**gestodene**, **desogestrel** or **norgestimate**) found no effect on carbohydrate metabolism in women using monophasic oral hormonal contraceptives, but impaired glucose tolerance developed in 10% of the women taking triphasic oral hormonal contraceptives. It was considered that the clinical consequences of impaired glucose tolerance and reduced **insulin** sensitivity induced by hormonal contraceptives are probably confined to risk groups e.g. women with ovarian hyperandrogenism, obesity, previous gestational diabetes mellitus, perimenopausal women, or women with a family history of diabetes.[7]

A study in 11 **insulin**-dependent diabetics, free of vascular complications, taking low-dose oral hormonal contraceptives (**ethinylestradiol** 30 micrograms with **gestodene** 75 micrograms) found that although the plasma levels of most haemostatic variables were comparable to those of non-diabetics using the same contraceptive preparation, the rate of fibrin formation was increased and the fibrinolytic response attenuated. This implies that women with diabetes can have a higher sensitivity to the thrombogenic effects of hormonal contraceptives.[7]

1. Exenatide. The manufacturers state that when an oral combined hormonal contraceptive (**ethinylestradiol** 30 micrograms with **levonorgestrel** 150 micrograms) was given one hour before exenatide 10 micrograms twice daily the AUC and maximum levels of the contraceptive steroids were unaffected. Giving the contraceptive 30 minutes after exenatide delayed the time to maximum level by 2 to 4 hours and reduced the maximum levels of **ethinylestradiol** and **levonorgestrel** by up to about 40%, but without any effect on AUC.[8] This is not clinically relevant.

2. Insulin. In one study in 179 diabetic women, 34% needed an increase and 7% needed a decrease in their insulin dose when they were given an oral hormonal contraceptive.[9] There are also a few scattered reports of individual diabetics who experienced a marked disturbance of their diabetic control when given an oral hormonal contraceptive, some of which were low dose.[10-13]

However, in a study of 38 patients with type 1 diabetes it was found that progestogen-only and oral combined hormonal contraceptives had little effect on the control of diabetes,[14] and another report[15] about women taking *Orthonovin* (**norethisterone** with **mestranol**) stated that no insulin dose changes were necessary. Similarly, no change in glycaemic control was found in 22 women with well-regulated type 1 diabetes who took a monophasic combination of **ethinylestradiol** and **gestodene** for one year.[7]

3. Pioglitazone. In a study in 35 healthy women given pioglitazone 45 mg daily with either an oral combined hormonal contraceptive (**ethinylestradiol** 35 micrograms with **norethisterone** 1 mg) or placebo for 21 days, pioglitazone slightly reduced the AUC of ethinylestradiol by 11%, but had no effect on the AUC of norethisterone.[16] Similar results were reported in another study.[17] This is unlikely to be clinically relevant.

4. Repaglinide. A crossover study in healthy subjects found that an oral combined hormonal contraceptive (**ethinylestradiol** 30 micrograms with **levonorgestrel** 150 micrograms) slightly increased the maximum plasma level of repaglinide 2 mg three times daily by 17%, although the bioavailability of repaglinide was not altered.[18] Repaglinide did not significantly alter the bioavailability of **ethinylestradiol** or **levonorgestrel**.[18]

5. Rosiglitazone. Rosiglitazone 8 mg daily, given for the first 2 weeks of two cycles in 32 women taking an oral combined hormonal contraceptive (**ethinylestradiol** 35 micrograms with **norethisterone** 35 micrograms), was found to have no effect on the pharmacokinetics of either contraceptive steroid.[19]

6. Sitagliptin. Sitagliptin did not appear to alter the pharmacokinetics of **norethisterone** or **ethinylestradiol** given as part of an oral hormonal contraceptive.[20]

Mechanism

The reasons for changes in glucose metabolism are not understood. Many mechanisms have been considered including changes in cortisol secretion, alterations in tissue glucose utilisation, production of excessive amounts of growth hormone, and alterations in liver function.[21] The effect of exenatide on contraceptive levels is thought to occur because exenatide delays gastric emptying.[8]

Importance and management

The interactions between hormonal contraceptives and antidiabetic drugs are moderately well documented. Concurrent use need not be avoided, but some patients may need a small adjustment in their dose of antidiabetic (increases or decreases). However, it seems likely that routine blood glucose monitoring will identify any problems. Serious disturbances of diabetic control seem extremely rare. Bear in mind that the lowest-strength oral combined hormonal contraceptive preparations (20 micrograms of oestrogen) are recommended for patients with risk factors for circulatory disease (such as diabetics), so the potential for interference with their diabetic control will be minimised if this recommendation is followed. The choice of progestogen may also be important, with levonorgestrel having the most detrimental effect.

Antidiabetics + Isoniazid

Some reports suggest that isoniazid causes an increase in blood glucose levels in diabetics, whereas another suggests it causes a decrease.

Clinical evidence

A study in 6 diabetics taking **insulin** found that isoniazid 300 to 400 mg daily increased their fasting blood glucose levels by 40% (from an average

of about 14.2 mmol/L to 19.8 mmol/L), and their glucose tolerance curves rose and returned to normal levels more slowly. After 6 days of treatment the average rise was only 20%. Two other patients needed an increased dose of **insulin** while taking isoniazid 200 mg daily, but this was reduced again when the isoniazid was withdrawn.[1]

Another report describes glycosuria and the development of frank diabetes in 3 out of 50 patients given isoniazid 300 mg daily,[2] and hyperglycaemia has been seen in cases of isoniazid poisoning.[3]

In contrast, another study found that isoniazid had a hypoglycaemic effect in 6 out of 8 diabetics.[4] A 500-mg dose of isoniazid caused an 18% (range 5 to 34%) reduction in blood glucose levels after 4 hours; 3 g of **tolbutamide** caused a 28% (19 to 43%) reduction, and together they caused a 35% (17 to 57%) reduction. However, one patient had a 10% increase in blood glucose levels after taking isoniazid, a 41% decrease after **tolbutamide**, and a 30% decrease after taking both drugs. The diabetic control of another patient was not affected by either drug.[4]

Mechanism

Not understood.

Importance and management

The major documentation for these reactions dates back to the 1950s, since when the literature has been virtually (and perhaps significantly) silent. The outcome of concurrent use is therefore somewhat uncertain. Nevertheless, given the effects of isoniazid alone on blood glucose, it would be prudent for diabetics given isoniazid to be monitored for changes in the control of the diabetes. Appropriate dose adjustments of the antidiabetic should be made where necessary.

Antidiabetics + Karela (*Momordica charantia*)

The blood glucose-lowering effects of chlorpropamide and other antidiabetics can be increased by karela.

Clinical evidence

A report of a patient whose diabetes was poorly controlled on diet and **chlorpropamide**, but much better controlled when she ate curry containing karela, provides evidence that the blood glucose-lowering effects of karela and conventional oral antidiabetics can be additive.[1] Other small, non-controlled studies have subsequently shown that karela produces a significant improvement in glucose tolerance in patients with type 2 diabetes, both when they are taking **chlorpropamide**,[2] **tolbutamide**,[2] **glibenclamide**,[2,3] **glymidine**[2] or **metformin**,[3] and when they are not taking antidiabetics.[4-6] In these studies, karela was given orally as a juice from the fruit,[2,4] dried powdered fruit,[5,6] fried fruits,[2] aqueous extract,[6] or solvent extract from the fruit.[3]

However, in a small randomised placebo-controlled study in 40 patients with type 2 diabetes given karela capsules (*Charantia*) taken three times daily after meals for 3 months, both karela and placebo had no statistically significant effect on HbA_{1c} (there was a very slight *increase* of 0.28% and 0.5%, respectively) and there was no change in mean fasting blood glucose (slight decrease with karela and increase with placebo). In this study, karela was taken in addition to standard **oral antidiabetics** (types not stated) and patients included both those newly diagnosed and those with established diabetes, with HbA_{1c} levels of 7 to 9%.[7]

A case report describes hypoglycaemic coma and seizures in two young non-diabetic children after they were given bitter melon (karela) tea.[8]

Mechanism

Karela (also known as bitter melon, bitter gourd, balsam pear, cundeamor) is the fruit of *Momordica charantia* which is indigenous to Asia and South America. The blood glucose-lowering effects of karela may be due to its content of polypeptide P, a blood glucose-lowering peptide,[9] also known as vegetable insulin (v-insulin).[10] This substance is effective when given subcutaneously,[10] but its oral activity is uncertain.[11] Other blood glucose-lowering compounds isolated from karela include charantin (sterol glucoside mixture in the fruit) and vicine a pyrimidine nucleoside found in the seeds). Karela fruit may have both insulin-like effects and stimulate insulin secretion.[11]

Importance and management

Karela is available in the UK and elsewhere, and is used to flavour foods such as curries, and also used as a herbal medicine for the treatment of diabetes mellitus. Its blood glucose-lowering activity appears to be established, although the best-controlled study so far found its effects to be minimal. Health professionals should therefore be aware that patients may possibly be using karela as well as more orthodox drugs to control their diabetes. Irregular consumption of karela as part of the diet could possibly contribute to unexplained fluctuations in diabetic control.

Antidiabetics + Ketotifen

The concurrent use of sulfonylureas or biguanides and ketotifen appears to be well tolerated, but a fall in the number of platelets has been seen in one study in patients taking biguanides with oral ketotifen.

Clinical evidence, mechanism, importance and management

A study in 30 hospitalised diabetics (10 diet controlled, 10 taking unnamed **sulfonylureas**, 10 taking unnamed **biguanides**) found that the concurrent use of oral ketotifen 4 mg daily for 14 days was generally well tolerated. However, those taking **biguanides** had a significant decrease in platelet counts and 3 had a marked fall on day 14 to slightly below 100×10^9/L, which returned to normal after a few days.[1] This finding underlies the precaution issued by the UK manufacturers of oral ketotifen,[2] that the concurrent use of oral antidiabetics and ketotifen should be avoided until this effect is explained. However, no other studies appear to have confirmed the fall in platelet count so that its importance remains uncertain.[3]

Antidiabetics + Lithium

An isolated report describes a diabetic patient receiving insulin who developed hyperglycaemia when his lithium levels were high, but not when the lithium dose was reduced. Conversely, in another isolated case of a patient with type 2 diabetes, glucose control improved when lithium was started. Lithium use has been associated with raised blood glucose levels and the development of diabetes mellitus, but the association is unclear and there is little or

no evidence that its use normally causes significant changes in diabetic control.

Clinical evidence

One patient with mania and diabetes developed hyperglycaemia, in the presence of a constant **insulin** dose, when his serum lithium levels were high (about 1.4 mmol/L), but reducing the lithium level to 1.1 mmol/L led to a lowering of the fasting blood glucose.[1] In contrast, a patient with type 2 diabetes managed with diet and insulin, had a reduction in blood glucose on starting lithium. Insulin was stopped, and at a on-year follow up she was said to have normal blood glucose levels without dietary restrictions or insulin.[2]

However, in a study in 6 patients with type 2 diabetes controlled by diet alone, lithium, taken for one week, did not alter the metabolic response to a standard 50 g carbohydrate breakfast.[3]

Mechanism

Uncertain. A study in 10 psychiatric patients found that lithium carbonate for 2 weeks raised their blood glucose levels and impaired their glucose tolerance.[4] There are also a few case reports of hyperglycaemia, impaired glucose tolerance and diabetes mellitus in patients taking lithium.[5-7] However, a long-term investigation over a period of 6 years, involving 460 patients, found that the mean blood glucose levels remained the same before and after the use of lithium. One patient did develop diabetic ketoacidosis after 4 years of uneventful lithium use, but the authors concluded that the long-term use of lithium did not increase the risk of developing diabetes mellitus.[8] Conversely, there is an isolated case of a patient who developed temporary diabetes requiring insulin after the *withdrawal* of lithium.[9] Note that the incidence of diabetes tends to be higher in patients with manic depression than in the general population.[10]

Importance and management

There are only a couple of reports of disturbed diabetic control in patients taking lithium. Bear the possibility of an interaction in mind if glycaemic control changes when lithium is started in a patient with diabetes.

Antidiabetics + Macrolides

An isolated report describes severe liver damage with prolonged cholestasis in a patient taking chlorpropamide and erythromycin. Isolated cases of hypoglycaemia have been described in patients taking glibenclamide (glyburide) or glipizide with clarithromycin or erythromycin, and, in a pharmacokinetic study, clarithromycin modestly increased glibenclamide levels. A study in healthy subjects found that hypoglycaemia may occur if tolbutamide and clarithromycin are given concurrently. Pharmacokinetic studies suggest that clarithromycin and telithromycin may enhance the effects of repaglinide, and a case report describes severe hypoglycaemia in a patient taking repaglinide with clarithromycin.

Clinical evidence, mechanism, importance and management

(a) Effects on the liver

A man with type 2 diabetes taking **chlorpropamide** was given **erythromycin ethylsuccinate** 1 g daily for 3 weeks for a respiratory infection. Two weeks later he complained of increasing fatigue and fever. A short episode of pruriginous skin rash was followed by the appearance of dark urine, jaundice and hepatomegaly. The picture over the next 2 years was that of profound cholestasis, complicated by steatorrhoea and marked hyperlipidaemia with disappearance of interlobular bile ducts. He died of ischaemic cardiomyopathy.[1] The reasons for this serious reaction are not understood, but the authors point out that liver damage occurs in a very small number of patients given sulfonylureas, such as **chlorpropamide**, and also with **erythromycin**. They suggest that there may have been an interaction between the two drugs. This case is also complicated by a history of long-term use of phenformin, which is known to be hepatotoxic.[1] No general conclusions can be drawn from this unusual case.

(b) Hypoglycaemia

1. Repaglinide. **Clarithromycin** 250 mg twice daily given to healthy subjects increased the AUC and maximum plasma concentrations of a single 250-microgram dose of repaglinide, given on day 5, by 40% and 67%, respectively. There was a similar corresponding rise in circulating insulin levels.[2] In another similar study, **telithromycin** 800 mg daily for 3 days increased the AUC of a single 250-microgram dose of repaglinide, given on day 3, by 77%. In addition, it increased the blood glucose lowering effect of repaglinide.[3]

An 80-year-old man with diabetes taking repaglinide 500 micrograms three times daily had a hypoglycaemic episode requiring intravenous glucose within 48 hours of starting **clarithromycin** 500 mg twice daily, and another similar episode 2 days later. Repaglinide was stopped.[4]

Clarithromycin and **telithromycin** may inhibit the metabolism of repaglinide by inhibition of cytochrome P450 isoenzyme CYP3A4. The effect of the concurrent use of these drugs should therefore be monitored. Other macrolides that inhibit CYP3A4 (such as erythromycin) would be expected to interact in a similar manner.

2. Sulfonylureas. Two isolated cases of severe hypoglycaemia occurred in elderly, type 2 diabetic patients, with renal impairment, given **glibenclamide** (**glyburide**) or **glipizide** and **clarithromycin**.[5] A further case of hypoglycaemia occurred when an elderly diabetic patient with normal renal function, taking **glibenclamide** 5 mg daily, also took **clarithromycin** 1 g daily as part of an *Helicobacter pylori* eradication regimen.[6] However, in a later pharmacokinetic study, **clarithromycin** had only modest effects on **glibenclamide** levels. In this study, the AUC of **glibenclamide** was increased by 35% when a single 875-microgram dose of **glibenclamide** was given after **clarithromycin** 250 mg twice daily for 2 days.[7] It is possible that **clarithromycin** causes this effect by inhibiting P-glycoprotein.[7]

A case of hypoglycaemia was reported in a patient taking **glibenclamide** and **erythromycin**.[8] However, an earlier single-dose study in 12 patients with type 2 diabetes found that **erythromycin** had little effect on **glibenclamide** pharmacokinetics or on its blood glucose-lowering effects.[9] Nevertheless, a placebo-controlled study involving 34 patients with type 2 diabetes (most of whom were taking **glibenclamide** or **glipizide**) found that oral **erythromycin** 400 mg three times daily for a week reduced fructosamine and fasting blood glucose concentrations and increased insulin secretion. Glycaemic control was also improved in a similar study using oral **erythromycin** 200 mg three times daily for 4 weeks.[10] A later study by the same research group found greater improvements in glucose control in patients with type 2 diabetes taking **glibenclamide** when given **erythromycin** 400 mg daily before sleep.[11] Further studies have shown that **erythromycin** increases gastric motility, which results in better control of blood glucose in patients with type 2 diabetes.[12,13]

A single-dose study in 9 healthy subjects found that **clarithromycin** 250 mg increased the rate of absorption of **tolbutamide** 500 mg by about 20% and increased its bioavailability by 26%. Hypoglycaemia, reported as uneasiness and giddiness, occurred on taking the combination.[14]

The general importance of these cases is uncertain, but some caution may be warranted on concurrent use,[5] and the dose of the sulfonylurea may need to be reduced.

Antidiabetics + MAOIs or RIMAs

The blood glucose-lowering effects of insulin and the oral antidiabetics can be increased by MAOIs. This may improve the control of blood glucose levels in most diabetics, but in a few it may cause undesirable hypoglycaemia. Moclobemide appears not to interact.

Clinical evidence

(a) Moclobemide

A study in healthy subjects given **glibenclamide** 2.5 mg daily found that moclobemide 200 mg three times daily for a week had no effect on glucose or insulin concentrations after oral glucose tolerance tests.[1] In clinical studies, 8 diabetics taking **glibenclamide** (**glyburide**), **gliclazide**, **metformin** or **chlorpropamide** were given moclobemide, and there was no effect on blood glucose levels or any other evidence of an interaction.[1]

(b) Non-selective MAOIs

A diabetic patient receiving **insulin** experienced postural syncope and hypoglycaemia, which required a reduction in **insulin** dose, when **mebanazine** was also taken.[2] Other reports in diabetics indicate that **mebanazine** increases the blood glucose-lowering effects of **insulin**, **tolbutamide** and **chlorpropamide,** and improves diabetic control.[3-6]

Mechanism

Not fully understood. Mebanazine,[4] iproniazid,[7] isocarboxazid,[8] phenelzine,[4] and tranylcypromine[9] have all been shown to reduce blood glucose levels in the absence of conventional antidiabetics, possibly due to some direct action on the pancreas, which causes the release of insulin.[9] It would seem that this can be additive with the effects of the conventional hypoglycaemics.

Importance and management

The interaction of the non-selective MAOIs and antidiabetics is an established interaction of only moderate clinical importance. It can benefit the control of diabetes in many patients, but some individuals may need a reduction in the dose of their antidiabetic to avoid excessive hypoglycaemia. The effects of concurrent use should be monitored. This interaction would seem possible with any combination of an antidiabetic and a non-selective MAOI.

No clinically important interaction seems to occur between antidiabetics and moclobemide.

Antidiabetics + Nicotinic acid (Niacin)

Nicotinic acid causes a deterioration in glucose tolerance, which may be dose-related.

Clinical evidence

It is well recognised that nicotinic acid can cause a deterioration in blood glucose tolerance. For example, in a small randomised crossover study, immediate-release nicotinic acid 1.5 g three times daily caused a 16% increase in mean plasma glucose levels and a 21% increase in HbA_{1c} levels in 13 patients with type 2 diabetes.[1] In a retrospective study of patients taking controlled-release nicotinic acid (average dose about 1.5 g daily), nicotinic acid was discontinued in 106 out of 160 patients who were diabetics; of these, 43 patients (about 40%) had the nicotinic acid discontinued because of poor glycaemic control. Furthermore, 14 patients required the addition of oral antidiabetic drugs to control their diabetes.[2]

In contrast, in another placebo-controlled study including 125 patients with diabetes, immediate-release nicotinic acid 3 g daily (or the maximum tolerated dose) only modestly increased plasma glucose levels in patients with diabetes. Moreover, there were no significant differences in antidiabetic medication in diabetic patients taking nicotinic acid versus placebo, although insulin use was increased by 13% in the nicotinic acid group, when compared with 4% in the placebo group.[3] In a placebo-controlled study in patients with type 2 diabetes taking controlled-release nicotinic acid 1 g daily or 1.5 g daily, HbA_{1c} marginally increased by 0.29% in the group receiving 1.5 g daily. There was an initial rise in fasting blood glucose levels between weeks 4 and 8, but this had returned to baseline by week 16. This was probably because some adjustment was made in antidiabetic medication; 29% of patients taking nicotinic acid 1.5 g required an increase in antidiabetic medication compared with 16% taking placebo (difference not significant). Only one patient (2%) taking nicotinic acid 1 g and 3 patients (6%) taking nicotinic acid 1.5 g discontinued treatment because of inadequate glucose control.[4] However, it has been noted that patients enrolled in both these studies had good glycaemic control, and that the findings may not be applicable to those with poor glycaemic control.[5]

Mechanism

Nicotinic acid reduces glucose tolerance, possibly by causing or aggravating insulin resistance.

Importance and management

It is well known that nicotinic acid can cause a deterioration in glycaemic control in patients with diabetes, but the incidence and clinical relevance of this finding is more controversial. The beneficial lipid-modifying effects of nicotinic acid directly improve the main lipid disorders seen in diabetes, which are considered an important contributing factor to the high incidence of cardiovascular disease seen in diabetic patients. The question then is, do the lipid-regulating benefits of nicotinic acid outweigh its adverse effects on glucose homoeostasis? Some consider that they do, especially if low doses of nicotinic acid (2 g or less) are used, and recommend the use of nicotinic acid in diabetic patients in some situations.[6,7] Whenever nicotinic acid is used, diabetic control should be closely monitored, recognising that adjustment of antidiabetic medication may be needed.

Antidiabetics + NSAIDs

No adverse interaction normally occurs between most NSAIDs and antidiabetic drugs. However, there are isolated cases of hypoglycaemia in patients given fenclofenac with chlorpropamide and metformin; ibuprofen with glibenclamide; indometacin with chlorpropamide; and naproxen with glibenclamide and metformin. Rofecoxib and celecoxib may have been a precipitating factor in cases of acute renal failure and metformin-associated lactic acidosis. The risk of fluid retention with pioglitazone or rosiglitazone is increased by the NSAIDs.

Clinical evidence

A. Metformin

A 58-year-old woman with longstanding type 2 diabetes taking metformin 500 mg twice daily developed serious acute renal failure and lactic acidosis one month after starting **rofecoxib**. She made a full recovery. **Rofecoxib** could have precipitated acute renal failure, which would lead to the accumulation of metformin, and metformin-associated lactic acidosis.[1] Another similar case has been reported in a 61-year-old woman taking metformin and given **rofecoxib**.[2] Similarly, renal failure and metformin-associated lactic acidosis occurred in a 50-year-old woman taking metformin 2 months after starting **celecoxib**. In this case, hydrochlorothiazide and candesartan were thought to have contributed to the renal failure.[3] For a case of hypoglycaemia attributed to ramipril and **naproxen**-induced renal failure in a patient taking metformin and glibenclamide, see *Glibenclamide (Glyburide)*, below.

B. Nateglinide

In a randomised crossover study, 18 healthy subjects were given modified-release **diclofenac** 75 mg on the same day as two 120-mg doses of nateglinide, given 4 hours apart. The pharmacokinetics of both drugs were unaltered by concurrent use.[4]

C. Pioglitazone or Rosiglitazone

In a single-dose study in healthy subjects, there was no change in the pharmacokinetics of a single 8-mg dose of rosiglitazone when it was given with a single 400-mg dose of **ibuprofen**.[5]

The manufacturers say that pioglitazone and rosiglitazone can cause fluid retention, which may exacerbate or precipitate heart failure, particularly in those with limited cardiac reserve.[6,7] Because NSAIDs can also cause fluid retention, the manufacturers issue a warning that concurrent use may possibly increase the risk of oedema.[7]

D. Sulfonylureas

(a) Chlorpropamide

Ibuprofen 1.2 g daily for 4 weeks had no significant effect on the blood glucose levels of 10 patients with type 2 diabetes taking chlorpropamide 62.5 to 375 mg daily.[8]

A woman whose type 2 diabetes was well controlled with chlorpropamide 500 mg daily and metformin 1.7 g daily, developed hypoglycaemia within 2 days of changing her NSAIDs from **flurbiprofen** 150 mg daily and **indometacin** 150 mg daily to **fenclofenac** 1.2 g daily. The antidiabetic drugs were withdrawn the next day, but later in the evening she went into a hypoglycaemic coma. The reason for this is not understood, but it was attributed to a protein binding interaction between chlorpropamide and **fenclofenac**.[9]

(b) Glibenclamide (Glyburide)

1. Acemetacin. No changes in the control of diabetes were seen in 20 patients with type 2 diabetes taking glibenclamide when they were given acemetacin 60 mg three times daily.[10]

2. Bromfenac. The blood glucose levels of 12 diabetic patients taking glibenclamide 10 mg daily were unchanged by bromfenac 50 mg three times daily for 3 days, and the pharmacokinetics of glibenclamide were also unaltered.[11]

3. Diclofenac. The blood glucose levels of 12 diabetic patients with rheumatic diseases taking glibenclamide were unchanged by diclofenac 150 mg daily for 4 days.[12]

4. Diflunisal. An isolated case of hypoglycaemia has been reported in a patient taking glibenclamide with diflunisal.[13]

5. Etodolac. Etodolac does not appear to affect the pharmacokinetics of glibenclamide.[14]

6. Ibuprofen. A study in 16 healthy subjects found that ibuprofen did not affect the pharmacokinetics of glibenclamide. However, ibuprofen with glibenclamide caused a greater blood glucose-lowering effect than glibenclamide alone, but the clinical significance of this was uncertain.[15] A 72-year-old man with longstanding type 2 diabetes, well-controlled with glibenclamide 2.5 mg daily took a single 150-mg dose of ibuprofen, and 30 minutes later experienced severe nausea, sweating and palpitations, which were immediately relieved by taking sugar. The symptoms occurred again the next morning after a second dose of ibuprofen and after a further dose in the afternoon he became unconscious and was given intravenous glucose. Ibuprofen was withdrawn and there were no further episodes of hypoglycaemia. It was also noted that hypoglycaemia had not occurred when he had previously taken aspirin, paracetamol or diclofenac.[16]

7. Lornoxicam. In 15 healthy subjects, lornoxicam 4 mg twice daily for 6 days had no effect on the pharmacokinetics of a single 5-mg dose of glibenclamide. The pharmacokinetics of lornoxicam also remained unchanged. However, concurrent use significantly increased plasma insulin levels (AUC increased by 47%) and lowered serum glucose levels (by 8%), but this is probably not clinically important.[17]

8. Naproxen. A case of severe hypoglycaemia in a diabetic patient was attributed to the accumulation of glibenclamide and **metformin** due to deterioration in renal function caused by the concurrent use of ramipril and naproxen.[18]

9. Nimesulide. Although a preliminary report suggested that nimesulide slightly increased the effects of glibenclamide,[19] a later study using various [unnamed] sulfonylureas did not find that it affected fasting blood glucose levels or the glucose tolerance of diabetic patients.[19]

10. Parecoxib. Valdecoxib, the active metabolite of parecoxib, does not appear to affect either the pharmacokinetics of glibenclamide or its effects on insulin or blood glucose levels.[20]

11. Piroxicam. Healthy subjects and type 2 diabetic patients had an increased hypoglycaemic response to glibenclamide (blood glucose levels reduced by 13 to 15%) when they were given piroxicam 10 mg.[21]

12. Tenoxicam. Tenoxicam 20 mg daily was found not to affect the glycoregulation of 8 healthy subjects given glibenclamide 2.5 mg daily.[22]

13. Tolmetin. No changes were seen in the blood glucose levels of 40 diabetic patients taking glibenclamide when they were given either tolmetin 1.2 g or placebo daily for 5 days.[23]

(c) Glibornuride

A study in healthy subjects found that **tenoxicam** 20 mg daily did not affect the pharmacokinetics of glibornuride or its effect on plasma insulin and blood glucose levels.[24]

(d) Glipizide

In a study in 6 healthy subjects, **indobufen** 200 mg twice daily for 5 days caused a 25% rise in the AUC of a single 5-mg dose of glipizide and a non-significant reduction in their blood glucose levels.[25] No important changes in blood glucose levels occurred in 24 patients with type 2 diabetes taking tolbutamide or glipizide when they took **indoprofen** 600 mg daily for 5 days.[26] A study found that although **indoprofen** (200 mg on day one, then 600 mg daily on days 3 to 8) lowered the plasma levels of a single 5 mg dose of glipizide, the blood glucose levels remained unaffected.[27]

(e) Tolbutamide

A report briefly states that no changes in blood tolbutamide levels or in fasting blood glucose levels were seen in diabetic patients given **diflunisal** 375 mg twice daily.[28] In a study in 12 patients with type 2 diabetes, **sulindac** 400 mg daily did not affect the half-life, plasma levels, time-to-peak levels or AUC of tolbutamide. An unimportant reduction in fasting blood glucose levels was seen.[29] **Naproxen** 375 mg every 12 hours for 3 days had no effect on the pharmacokinetics or pharmacological effects of tolbutamide in 10 patients with type 2 diabetes.[30] The pharmacokinetics of a single 500-mg dose of tolbutamide were unaffected in 7 healthy subjects

after they took **tenoxicam** 20 mg daily for 14 days, and blood glucose concentrations were not altered.[31] No important changes in blood glucose levels occurred in 24 patients with type 2 diabetes taking tolbutamide or glipizide when they were given **indoprofen** 600 mg daily for 5 days.[26] In other patients taking tolbutamide it was found that **ibuprofen** lowered fasting blood glucose levels, but not below the lower limits of normal.[32]

Mechanism, importance and management

The reports briefly cited here indicate that no adverse or clinically relevant interaction normally occurs between the oral antidiabetics and the NSAIDs named. The general silence in the literature would seem to confirm this. Caution is appropriate with pioglitazone or rosiglitazone and NSAIDs, and patients should be monitored for signs of heart failure. Note that the NSAIDs, including coxibs, can cause renal failure, which can precipitate metformin-associated lactic acidosis. In addition, a reduction in the renal clearance of antidiabetic drugs can result in hypoglycaemia. Adverse interactions can certainly occur between antidiabetics and azapropazone, phenylbutazone, oxyphenbutazone and the salicylates, see 'Antidiabetics + NSAIDs; Phenylbutazone and related drugs', below and 'Antidiabetics + Salicylates', p.569.

Antidiabetics + NSAIDs; Phenylbutazone and related drugs

The blood glucose-lowering effects of acetohexamide, carbutamide, chlorpropamide, glibenclamide (glyburide), glymidine and tolbutamide can be increased by phenylbutazone. Severe hypoglycaemia has occurred in a few patients. Similarly, azapropazone can increase the effects of tolbutamide and cause severe hypoglycaemia. Oxyphenbutazone may be expected to behave similarly. Dipyrone and mofebutazone did not interact with glibenclamide.

Clinical evidence

(a) Azapropazone

A woman whose diabetes was well controlled for 3 years with **tolbutamide** 500 mg twice daily, became confused and semi-comatose 4 days after starting to take azapropazone 900 mg daily. She complained of having felt agitated since starting the azapropazone, so it was withdrawn on suspicion of causing hypoglycaemia. Later that evening she became semi-comatose and was found to have a plasma glucose level of 2 mmol/L.[1] A subsequent study in 3 healthy subjects found that azapropazone 900 mg daily increased the plasma half-life of **tolbutamide** 500 mg threefold (from 7.7 to 25.2 hours) and reduced its clearance accordingly.[1] Acute hypoglycaemia occurred in another patient taking **tolbutamide** 500 mg three times daily, 5.5 hours after a single 600-mg dose of azapropazone was taken.[2]

(b) Dipyrone (Metamizole)

One randomised, placebo-controlled, crossover study in 12 diabetic patients taking **glibenclamide** suggested that metamizole 1 g daily for 2 days did not interact with **glibenclamide**: no relevant alteration in blood glucose levels was found.[3]

(c) Mofebutazone

Mofebutazone 900 mg daily has not been found to cause any clinically important changes in blood glucose levels in patients taking **glibenclamide**.[4]

(d) Oxyphenbutazone

Oxyphenbutazone has been found to alter[5] or raise **glymidine** levels[6] and **tolbutamide** levels.[7,8]

(e) Phenylbutazone

A man with type 2 diabetes taking **tolbutamide** experienced an acute hypoglycaemic episode 4 days after starting phenylbutazone 200 mg three times daily, although there was no change in his diet or in the dose of **tolbutamide**. He was able to control the hypoglycaemia by eating a large bar of chocolate.[9]

There are numerous other case reports and studies of this interaction involving phenylbutazone with **acetohexamide**,[10] **carbutamide**,[11] **chlorpropamide**,[12-14] **glibenclamide** (**glyburide**),[15] **glymidine**,[16] and **tolbutamide**,[13,17-23] some of which describe acute hypoglycaemic episodes.[10,12,13,18,20] Several of these interactions have been fatal.[13,23] There is a report suggesting that the interaction between **glibornuride** and phenylbutazone may not be clinically important.[24] In contrast to these reports, a single study describes a paradoxical *rise* in blood glucose levels in 3 African patients taking **tolbutamide** and phenylbutazone.[25] In addition to these reports there is some evidence that **tolbutamide** increases the metabolism of phenylbutazone by 42%,[22] but the extent to which this affects its therapeutic effects is uncertain.

Mechanism

Not fully resolved. Some evidence suggests that phenylbutazone can inhibit the renal excretion of glibenclamide (glyburide),[15] tolbutamide,[19] and the active metabolite of acetohexamide[10] so that they are retained in the body longer and their blood glucose-lowering effects are increased and prolonged. It has also been shown that phenylbutazone can inhibit the metabolism of the sulfonylureas[7,22] as well as causing their displacement from protein binding sites.[26] Azapropazone also possibly inhibits the metabolism of tolbutamide,[1] as well as maybe causing displacement from plasma protein binding sites.[2]

Importance and management

The interactions between the antidiabetics and phenylbutazone are well documented and potentially clinically important. Blood glucose levels may be lowered, but the number of reports of acute hypoglycaemic episodes seems to be small. Concurrent use should therefore be well monitored. A reduction in the dose of the sulfonylurea may be necessary if excessive hypoglycaemia is to be avoided. Not all sulfonylureas have been shown to interact (glibornuride probably does not do so) but it would be prudent to assume that they all interact until there is good evidence to suggest otherwise. Oxyphenbutazone may be expected to interact like phenylbutazone (it is a metabolite of phenylbutazone) but, unexpectedly, possibly not mofebutazone, although more study would be needed to confirm this.

The information regarding an interaction between azapropazone and the sulfonylureas seems to be limited to the cases and small study involving tolbutamide. Nevertheless, the manufacturers of azapropazone state that the concurrent use of sulfonylureas is not recommended.[27]

Antidiabetics + Orlistat

Orlistat improved glycaemic control, which resulted in the need to reduce the dose of glibenclamide (glyburide) or glipizide in almost half the patients in one study. In other studies, orlistat also reduced the dose requirement for metformin and for insulin. Orlistat does not appear to alter the pharmacokinetics of glibenclamide or metformin. Orlistat and cimetidine may have contributed to a case of metformin-associated lactic acidosis. The manufacturers recommend avoiding the concurrent use of acarbose and orlistat because of the lack of interaction studies.

Clinical evidence

(a) Acarbose

The UK manufacturer of orlistat says that in the absence of pharmacokinetic studies its concurrent use with acarbose should be avoided.[1]

(b) Insulin

In a randomised, placebo-controlled, double-blind study in patients with type 2 diabetes receiving insulin with or without metformin or a sulfonylurea, orlistat 120 mg three times daily for one year, and a reduced-calorie diet improved glycaemic control and allowed a greater reduction in insulin dose (mean reduction of 8.1 units daily versus 1.6 units daily for placebo). Hypoglycaemic episodes occurred in about 17% of orlistat recipients and about 10% of placebo recipients: three orlistat recipients and one placebo recipient required medical intervention due to hypoglycaemia.[2]

(c) Metformin

In a randomised study, 21 healthy subjects were given metformin 500 mg daily for 6 days, with or without orlistat 120 mg three times daily. Orlistat had no effect on the pharmacokinetics of metformin, and concurrent use was well-tolerated.[3] In a randomised, placebo-controlled, study in patients with type 2 diabetes taking metformin with or without a sulfonylurea (mainly glibenclamide (glyburide) or glipizide), orlistat 120 mg three times daily for one year improved glycaemic control and allowed a small reduction in the dose of metformin (mean daily reduction of 16 mg versus a mean increase of 49 mg for placebo). Twice as many patients in the orlistat group either reduced or discontinued one or more of their antidiabetics (17% versus 8% with placebo). Hypoglycaemic episodes (mild to moderate and not requiring treatment) occurred in 10% of orlistat recipients and 4% of placebo recipients.[4] Similarly, improvement in glycaemic control and a reduced requirement for oral antidiabetics was reported in another study.[5]

A 59-year-old woman with type 2 diabetes taking long-term metformin 500 mg three times daily, developed severe metabolic acidosis with cardiovascular collapse and acute renal failure. Three months previously she had started orlistat 120 mg three times daily, which caused abdominal pain and chronic diarrhoea. During the 4 days before hospital admission, she was prescribed cimetidine 400 mg twice daily for her abdominal pain. The metformin-associated lactic acidosis[6] was considered to have been precipitated by the orlistat and cimetidine.

(d) Sulfonylureas

A placebo-controlled study in 12 healthy subjects found that orlistat 80 mg three times daily for a little over 4 days had no effect on the pharmacokinetics of a single 5-mg oral dose of **glibenclamide** (**glyburide**) and the blood glucose lowering effects remained unchanged.[7] A later one-year, randomised, placebo-controlled, study in obese patients with type 2 diabetes, in which 139 patients took orlistat, found that orlistat reduced fasting blood glucose and HbA_{1c} levels. In addition, 43% of patients taking orlistat 120 mg three times daily were able to decrease their sulfonylurea dose (**glibenclamide** or **glipizide**), and 11.7% of them were able to discontinue the sulfonylurea. The average dose decrease was 23% compared with 9% in the placebo group.[8]

Mechanism

The benefits of orlistat are likely to be as a result of the beneficial effects of weight reduction on glycaemic control, although in some studies the reduction in HbA_{1c} was not entirely dependent on the magnitude of weight loss.[2]

Importance and management

The benefits of orlistat on glycaemic control in overweight or obese patients with diabetes are established. Antidiabetic treatment should be more closely monitored in patients taking orlistat, and the dose adjusted as necessary.

Antidiabetics + Pentoxifylline

The UK manufacturer notes that, rarely, high-dose *injections* of pentoxifylline have intensified the blood glucose-lowering effects of insulin and oral antidiabetic drugs. This effect has not been seen with oral pentoxifylline.[1] For example, in one study oral pentoxifylline 600 mg daily for 9 months did not affect HbA_{1c} levels in type 2 diabetic patients.[2] It may therefore be prudent to be alert for alterations in diabetic control in patients given intravenous pentoxifylline, but no particular precautions seem necessary with oral pentoxifylline.

Antidiabetics + Quinolones

A number of reports describe severe hypoglycaemia in diabetic patients treated with gatifloxacin and various antidiabetics including insulin, metformin, pioglitazone, repaglinide, rosiglitazone, some sulfonylureas, or voglibose. In contrast, other reports describe hyperglycaemia when diabetics taking metformin and/or glipizide were given gatifloxacin. Retrospective reviews have revealed the high incidence of adverse events associated with gatifloxacin involving abnormal glucose homoeostasis, including both hypoglycaemia and hyperglycaemia, which was 4.3 to 16.7-fold higher than with other quinolones. Interaction studies have shown that gatifloxacin may cause hypoglycaemia and hyperglycaemia, and systemic formulations of this fluoroquinolone have been withdrawn in many countries.
Studies using ciprofloxacin and levofloxacin with glibenclamide suggest plasma glucose levels are not usually affected to a clinically relevant extent. However, isolated reports describe hypoglycaemia in diabetic patients taking glibenclamide, when ciprofloxacin, levofloxacin, or norfloxacin was given, and deaths associated with abnormal glucose homoeostasis have been reported in patients taking ciprofloxacin or levofloxacin.

Clinical evidence

A search of the FDA database for adverse drug events associated with **gatifloxacin**, **ciprofloxacin**, **levofloxacin**, and **moxifloxacin** between November 1997 and September 2003 found 10 025 unique adverse events, including 568 involving glucose homoeostasis abnormalities, of which 25 were fatal. **Gatifloxacin** use was associated with 453 (80%) of the adverse events involving glucose homoeostasis, and 17 of these were fatal compared with 3, 5, and 0 fatalities with **ciprofloxacin**, **levofloxacin**, and **moxifloxacin**, respectively. Of all the adverse events associated with **gatifloxacin**, 24% involved glucose homoeostasis, compared with **ciprofloxacin** (1.3%), **levofloxacin** (1.6%) and **moxifloxacin** (1.3%). The risk of adverse events involving glucose homoeostasis was higher in older patients, in patients taking medications for diabetes (almost 70% of those taking **gatifloxacin** were also using **insulin** or **oral antidiabetics**) and in patients with renal dysfunction whose dosage had not been appropriately adjusted.[1]

In another analysis, large case-control studies were conducted in a cohort of elderly patients from Ontario, Canada, who had received broad-spectrum antibacterials and been treated in hospital for either hypoglycaemia or hyperglycaemia within 30 days of receiving the antibacterial. **Gatifloxacin** was associated with a marked 4.3-fold risk of hypoglycaemia, as compared to macrolide antibacterials, and **levofloxacin** was associated with a slight 1.5-fold increased risk, whereas there was no increased risk with **moxifloxacin** or **ciprofloxacin**. Similarly, **gatifloxacin** was associated with a very marked 16.7-fold increased risk of hyperglycaemia when compared with macrolides, whereas no other quinolones were associated with an increased risk. The risk for hypoglycaemia or hyperglycaemia with **gatifloxacin** was not significantly different between those patients receiving treatment for diabetes and those not. Overall, 1.1% of courses of **gatifloxacin** were associated with hospital visits for dysglycaemia compared with 0.3% for **ciprofloxacin**, 0.3% for **levofloxacin,** 0.2% for **moxifloxacin** and 0.1% for macrolides.[2]

(a) Ciprofloxacin

A study in 12 patients with type 2 diabetes mellitus taking **glibenclamide** (**glyburide**) 10 mg in the morning, plus in some instances 5 mg in the evening, found that ciprofloxacin 1 g daily for a week caused rises in maximum serum **glibenclamide** levels of 20 to 30%, and a rise in the AUC of 25 to 36%. However, none of these changes were statistically significant, and, more importantly, blood glucose levels were not altered.[3] In another study in 9 healthy subjects, a single 200-mg intravenous dose of ciprofloxacin had no effect on the pharmacokinetics of a single 1.25-mg oral dose of **glibenclamide** given 20 minutes later.[4] Ciprofloxacin was not associated with an increased risk of hospital treatment for hypo or hyperglycaemia in the Canadian study, above.

Nevertheless, an elderly patient who had been taking **glibenclamide** 5 mg daily for over 2 years was found to be confused, with slurred speech and diaphoresis within a week of starting ciprofloxacin 250 mg twice daily for acute cystitis, and was found to have a serum **glibenclamide** level several times greater than that normally seen.[5] She needed treatment with intravenous glucose to correct the hypoglycaemia. Two further similar cases have been reported, in which hypoglycaemia developed after the first or second dose of ciprofloxacin, for either a wound infection[6] or a urinary tract infection,[7] although the association of this latter case with ciprofloxacin has been questioned.[8]

In a single-dose study in healthy subjects, there was no change in the pharmacokinetics of **rosiglitazone** 8 mg when given with ciprofloxacin 500 mg.[9]

(b) Gatifloxacin

In a study in patients with type 2 diabetes controlled by diet and exercise, gatifloxacin 400 mg daily for 10 days had no significant effect on glucose tolerance or most aspects of glucose homoeostasis, but did cause a brief increase in serum insulin levels.[10] In contrast, the US manufacturer of gatifloxacin noted that in another study in patents with type 2 diabetes taking **metformin** with or without **glibenclamide**, oral gatifloxacin 400 mg daily for 14 days was associated with initial hypoglycaemia followed by hyperglycaemia.[11]

Moreover, there is a report of 3 cases of hypoglycaemia in elderly type 2 diabetic patients given gatifloxacin. In one of these cases a patient taking **glibenclamide** 5 mg daily and **pioglitazone** 30 mg daily experienced severe, persistent hypoglycaemia within an hour of the first dose of oral gatifloxacin 200 mg. It resolved on withdrawal of all three drugs and she had no further episodes of hypoglycaemia when **glibenclamide** and **pioglitazone** were restarted.[12] Another case describes a patient taking **glimepiride** 2 mg before breakfast and 1 mg before dinner who developed severe hypoglycaemia 12 hours after the first dose of intravenous gatifloxacin 400 mg. Both drugs were discontinued and **glimepiride** was later restarted without further hypoglycaemia.[12] In the remaining case, a patient taking **repaglinide** 500 micrograms every 8 hours was given oral gatifloxacin 400 mg daily for a urinary-tract infection. **Repaglinide** was discontinued 6 hours after the first dose of gatifloxacin because of the patient's lack of appetite. Two hours after the second dose of gatifloxacin, he developed severe hypoglycaemia and also experienced a tonic-clonic seizure. Gatifloxacin was discontinued but hypoglycaemia persisted for 32 hours. **Repaglinide** was restarted 4 days later without further hypoglycaemia.[12] Other case reports have described severe hypoglycaemia when gatifloxacin was given to patients with diabetes taking **insulin** with **repaglinide** and **voglibose**,[13] **glibenclamide**,[14-16] **glibenclamide** with **metformin**,[17] **glibenclamide** with **rosiglitazone**,[16] or **glipizide**.[14]

In contrast, an 82-year-old woman taking **metformin** and **glipizide** who was discharged from hospital taking gatifloxacin 200 mg daily developed

severe *hyperglycaemia* within 48 hours. Her serum glucose rapidly reduced with low-dose intravenous **insulin**, but increased again the following day after she took oral gatifloxacin while receiving subcutaneous **insulin**.[14] A similar case was described in an 80-year-old man taking glipizide and gatifloxacin.[18] Hyperglycaemia has also been noted in 2 non-diabetic patients within 48 to 72 hours of starting gatifloxacin.[13,14]

Analysis of adverse events in large numbers of patients in the US and in Canada have confirmed that gatifloxacin is associated with a markedly increased risk of hypo and hyperglycaemia, see above.

(c) Levofloxacin

A study in 24 healthy subjects found that oral levofloxacin had no effect on the pharmacokinetics of a single oral dose of **glibenclamide** nor its effect on plasma glucose levels.[19] No recurrence of hypoglycaemia occurred in a patient taking **gliclazide** and oral levofloxacin who had a severe hypoglycaemic episode while receiving **glibenclamide** and gatifloxacin.[15] However, a fatal case of hypoglycaemia related to intravenous levofloxacin use occurred in an elderly patient with diabetes who was taking **glibenclamide**.[20] Similarly, hypoglycaemia developed in a malnourished 58-year-old man taking oral levofloxacin 750 mg once every 2 days and **glipizide**.[21] Levofloxacin was associated with a slight 1.5-fold increased risk of hospital treatment for hypoglycaemia, but no increased risk of hyperglycaemia, in the Canadian study, above.

(d) Moxifloxacin

The manufacturer notes that the concurrent use of moxifloxacin and **glibenclamide** resulted in an approximate 21% decrease in the peak plasma level of **glibenclamide** in diabetic subjects, but this did not alter blood glucose and endogenous insulin.[22] A pooled analysis from clinical and postmarketing studies suggested that moxifloxacin had no clinically relevant effect on blood glucose homoeostasis, even in patients with diabetes mellitus.[23] Moxifloxacin was not associated with an increased risk of hospital treatment for hypo or hyperglycaemia in the Canadian study, above.

(e) Norfloxacin

The manufacturer notes that the concurrent use of norfloxacin with **glibenclamide** has resulted in severe hypoglycaemia.[24]

(f) Ofloxacin

The manufacturer of ofloxacin states that it may cause a slight increase in the serum concentration of glibenclamide: they advise that this is based on unpublished case reports of an interaction and the possibility that the interaction is due to a class effect of the quinolones.[25,26]

Mechanism

Uncertain. However, it has also been postulated that quinolones may increase insulin secretion,[7,20] similar to 'quinine', (p.542). Gatifloxacin appears to increase insulin release initially, but then it appears to decrease insulin productivity or increase insulin disintegration.[27] Of the quinolones, the severe effects of gatifloxacin on glucose homoeostasis appear to be unique, with levofloxacin and ciprofloxacin having very much less effect.[2,12]

The authors of one report suggest that the ciprofloxacin may have inhibited the metabolism of the glibenclamide, thereby raising its serum levels.[5] This may possibly be exaggerated in elderly patients whose liver function may be reduced. Ciprofloxacin appears not to affect hepatic uptake of glibenclamide via OATP2B1.[4]

Importance and management

Gatifloxacin has been much more frequently associated with disturbances of blood glucose than other fluoroquinolones. The US manufacturer noted that when systemic gatifloxacin was to be used in diabetic patients, blood glucose should be closely monitored. Signs and symptoms of *hypo*glycaemia should be monitored, especially in the first 3 days of therapy, and signs and symptoms of *hyper*glycaemia should be monitored, especially with continued treatment beyond 3 days.[11] However, later they contraindicated its use in patients with diabetes,[28] and then withdrew the product.[29] These concerns do not apply to the topical eye drop product.

Isolated cases of hypoglycaemia in patients with diabetes have also been reported for ciprofloxacin, levofloxacin and norfloxacin. The general clinical relevance of these cases is uncertain but probably minor. However, it may be prudent to consider increasing the frequency of blood glucose monitoring in the elderly, who appear more at risk.

Antidiabetics + Rifamycins

Rifampicin (rifampin) reduces the serum levels and blood glucose lowering effects of tolbutamide, gliclazide, chlorpropamide (single case) and glibenclamide (glyburide), and to a lesser extent glimepiride, glipizide and glymidine. Conversely, a single intravenous dose of rifampicin given with glibenclamide markedly increased its levels and effect.

Rifampicin reduces the effects of repaglinide, and possibly also nateglinide. Rifampicin also reduces the AUCs of pioglitazone and rosiglitazone. An isolated report describes an increased insulin requirement in a patient with type 1 diabetes taking rifampicin.

Clinical evidence

(a) Insulin

A case report describes a 54-year-old woman with type 1 diabetes whose insulin requirements increased from 36 units daily to 48 units daily when she took **rifampicin**. Immediately on discontinuing her antimycobacterials, she developed frequent hypoglycaemic attacks, which persisted until her insulin dose was reduced back to 36 units daily.[1]

(b) Nateglinide

In a randomised, crossover study, 10 healthy subjects were given a single 60-mg dose of nateglinide the day after a 5-day course of **rifampicin** 600 mg daily. **Rifampicin** reduced the AUC_{0-7} of nateglinide by 24%

(range 5 to 53%) and decreased the nateglinide half-life from 1.6 hours to 1.3 hours. Overall **rifampicin** did not significantly decrease the blood glucose-lowering effects of nateglinide.[2] However, because of the high degree of intersubject variation, the authors suggest that the blood glucose-lowering effects of nateglinide may be reduced in some subjects.[2]

(c) Pioglitazone

A randomised study in 10 healthy subjects found that **rifampicin** 600 mg daily for 6 days decreased the AUC of a single 30-mg dose of pioglitazone by 54%. In addition, **rifampicin** decreased the AUC and shortened the half-life of the active metabolites of pioglitazone by about 50% and 35%, respectively.[3]

(d) Repaglinide

In a study in healthy subjects, a single 4-mg dose of repaglinide was given one hour after the final dose of **rifampicin** 600 mg daily for 7 days. **Rifampicin** decreased the AUC and the mean maximum plasma concentration of repaglinide by 31% and 26%, respectively, but the blood glucose-lowering effect of repaglinide was not affected.[4] In another study,[5] pre-treatment with **rifampicin** 600 mg daily for 5 days decreased the AUC and maximum level of a single 500-microgram dose of repaglinide given on day 6 by 57% and 41%, respectively. In this study, **rifampicin** reduced the blood glucose-lowering effect of repaglinide by 35%. A third study investigated the effect of **rifampicin** 600 mg daily for 7 days on a single 4-mg dose of repaglinide given at the same time as the last **rifampicin** dose on day 7, or 24 hours later. When **rifampicin** was given simultaneously, the median AUC of repaglinide was reduced by almost 50%, but when the repaglinide was given 24 hours after the last **rifampicin** dose, the median AUC was reduced by 80%. The size of the effect of **rifampicin** on repaglinide may therefore depend on the administration schedule.[6]

(e) Rosiglitazone

In a study in healthy subjects, **rifampicin** 600 mg daily for 5 days reduced the AUC of a single 4-mg dose of rosiglitazone by 54% and reduced the maximum plasma level by 28%. **Rifampicin** increased the formation of the metabolite, *N*-desmethylrosiglitazone.[7] Very similar findings were reported in a study in healthy Korean subjects.[8]

(f) Sulfonylureas

1. Chlorpropamide. A single case report describes a man with type 2 diabetes who needed an increase in his dose of chlorpropamide from 250 to 400 mg daily when he was given **rifampicin** 600 mg daily. His serum chlorpropamide levels rose dramatically 12 months later when the **rifampicin** was withdrawn.[9]

2. Glibenclamide (Glyburide). A study in 29 patients with type 2 diabetes taking glibenclamide, found that when they were also given **rifampicin** 450 or 600 mg daily for 10 days, their blood glucose levels, both fasting and after meals, were raised. Glibenclamide dose changes were needed in 15 out of 17 patients in whom the diabetes became uncontrolled. Their blood glucose levels normalised 6 days after stopping the **rifampicin**.[10] Another patient with type 2 diabetes taking glibenclamide had a deterioration in diabetic control over the 8 months after she started **rifampicin**, which required an increase in glibenclamide dose and the addition of insulin. On stopping **rifampicin**, she had a marked rise in trough serum glibenclamide levels, from 40 nanograms/mL to 200 nanograms/mL, but no appreciable change in blood glucose concentrations.[11]

A study in 10 healthy subjects found that **rifampicin** 600 mg daily for 5 days decreased the AUC and peak plasma level of a single 1.75-mg dose of glibenclamide given on day 6 by 39% and 22%, respectively. The elimination half-life was shortened from 2 hours to 1.7 hours. The maximum reduction in blood glucose level was decreased by 36% by **rifampicin**.[12] Similarly, one week of **rifampicin** markedly reduced the AUC of a single 1.25-mg dose of glibenclamide given 2 days later by 65%. However, in contrast, a single 600-mg intravenous dose of **rifampicin** given over 30 minutes immediately before a single 1.25-mg dose of glibenclamide, caused about a twofold marked *increase* in the AUC of glibenclamide, leading to a greater reduction in blood glucose and hypoglycaemia in one subject. When a single intravenous dose of rifampicin was given on day 7 after 6 days of oral rifampicin, there was a 28% reduction in the AUC of glibenclamide given on the same day, which was less than the 65% reduction seen 2 days later.[13]

3. Gliclazide. A 65-year-old patient with type 2 diabetes taking gliclazide 80 mg daily for 2 years without problem was given **rifampicin** 450 mg daily, isoniazid, ethambutol and clarithromycin for an atypical mycobacteriosis. Fasting blood glucose levels became elevated requiring an increase in the dose of gliclazide to 120 mg daily then 160 mg daily. The plasma level of gliclazide on day 75 was 1.4 micrograms/mL, 2 hours after an 80-mg dose. When **rifampicin** was discontinued the gliclazide level increased to 4.7 micrograms/mL and the dose was reduced back to 80 mg daily.[14] A study in 9 healthy subjects found that pre-treatment with **rifampicin** 600 mg for 6 days decreased the AUC of a single 80-mg dose of gliclazide given on day 7 by 70%. The mean elimination half-life of gliclazide was reduced from 9.5 hours to 3.3 hours and the gliclazide oral clearance was increased by about fourfold. The blood glucose-lowering effects of gliclazide were significantly reduced by **rifampicin**.[15]

4. Glimepiride. A placebo-controlled study in 10 healthy subjects found that **rifampicin** 600 mg daily for 5 days decreased the AUC of a single 1-mg dose of glimepiride given on day 6 by 34%. **Rifampicin** reduced the elimination half-life of glimepiride by 25%. However, no significant differences in blood glucose were found between the **rifampicin** and placebo regimens.[16]

5. Glipizide. A placebo-controlled study in 10 healthy subjects found that **rifampicin** 600 mg daily for 5 days decreased the AUC of a single 2.5-mg dose of glipizide given on day 6 by 22%. The elimination half-life was shortened from 3 hours to 1.9 hours by **rifampicin**. However, no significant differences in blood glucose concentrations were found.[12]

6. Glymidine. In one study the half-life of glymidine was reduced by about one-third by the concurrent use of **rifampicin**.[17]

7. Tolbutamide. After treatment for 4 weeks with **rifampicin** the half-life of tolbutamide in 9 diabetic patients with tuberculosis was reduced by 43%, and the serum concentrations measured at 6 hours were halved, when compared with other patients not taking **rifampicin**.[18] Similar results have been found in other studies in patients with cirrhosis or cholestasis,[19] in healthy subjects[20] and in other patients.[21]

Mechanism

Rifampicin is a potent inducer of the liver enzymes concerned with the metabolism of tolbutamide (the cytochrome P450 isoenzyme CYP2C9), which hastens its clearance from the body, thereby reducing its effects.[18-20] The interaction between rifampicin and glibenclamide (glyburide), gliclazide, glimepiride, glipizide, and nateglinide is probably also due to induction of CYP2C9.[2,12,14,15] However, rifampicin is also an inhibitor of hepatic organic anion-transporting polypeptide 1B1 (OATP1B1), and acute administration of a single intravenous dose of rifampicin with glibenclamide inhibited glibenclamide uptake into the liver, and therefore reduced its metabolism.[13]

The interaction of rifampicin with repaglinide, rosiglitazone and pioglitazone is probably due to induction of CYP2C8,[7-9] although in the case of rosiglitazone, CYP2C9 may also play some part.[7,8] The case report with insulin is unexplained, although there is a case of a patient who developed diabetes requiring insulin treatment while receiving rifampicin and ethambutol, which resolved when the antimycobacterials were stopped.[22] It is possible that rifampicin or tuberculosis *per se* might cause hyperglycaemia.[22]

Importance and management

Information is limited, but the interactions of tolbutamide, glibenclamide (glyburide) and gliclazide with rifampicin (rifampin) appear to be established. Patients taking these sulfonylureas may need an increase in the dose while taking rifampicin. This also seems possibly true for chlorpropamide, but the documentation for this interaction is even more limited. The effect of rifampicin on the blood glucose-lowering effects of glimepiride, glipizide or glymidine may be of only limited clinical significance, but it should be noted that these were single-dose studies and it is possible that some effect may occur with multiple dosing. Caution is warranted. Conversely, bear in mind that the first intravenous dose of rifampicin may increase the effect of oral glibenclamide given at a similar time. Whether this occurs with the first oral dose of rifampicin remains to be determined.

Although the information regarding **nateglinide** and **repaglinide** is limited, a significant interaction is possible, especially with repaglinide, and so an increase in blood glucose monitoring would be prudent. Similarly, the reduction in the AUCs of **pioglitazone** and **rosiglitazone** also indicates that diabetic control should be closely monitored if rifampicin is started or stopped.

The isolated case of increased **insulin** requirement suggests that ri-

fampicin may possibly affect the glycaemic control of patients with type 1 diabetes, but this needs further investigation.

There does not seem to be any information regarding the other rifamycins, **rifabutin** (a weak enzyme inducer) and **rifapentine** (a moderate enzyme inducer). However, the manufacturers and the CSM in the UK warn that rifabutin may possibly reduce the effects of a number of drugs, including oral antidiabetics.[23,24]

Antidiabetics + Salicylates

Aspirin and other salicylates can lower blood glucose levels, but small analgesic doses do not normally have an adverse effect on patients taking antidiabetics. Larger doses of salicylates may have a more significant effect.

Clinical evidence

(a) Chlorpropamide

In 5 healthy subjects the blood glucose-lowering effects of chlorpropamide and **sodium salicylate** were found to be additive. A further study in 6 healthy subjects found that chlorpropamide 100 mg given with **sodium salicylate** 1.5 g lowered blood glucose levels by the same amount as either chlorpropamide 200 mg or **sodium salicylate** 3 g alone.[1]

The blood glucose levels of a patient taking chlorpropamide 500 mg daily were lowered about two-thirds by **aspirin** in doses sufficient to give serum salicylate levels of about 1.9 mmol/L.[2]

(b) Glibenclamide (Glyburide)

In a study, 16 healthy subjects took a single 5-mg dose of glibenclamide both before and on the fourth day of taking **aspirin** 975 mg four times daily for 4 days. It was found that the **aspirin** reduced the AUC_{0-4} of the glibenclamide by 68% and reduced its mean peak serum levels by 35%. The effects of these changes on glucose tolerance tests and insulin responses were difficult to interpret, but there was no clear evidence that any clinically relevant changes occurred.[3]

(c) Insulin

Twelve children with type 1 diabetes receiving insulin had a reduction in their blood glucose levels (from about 10.4 to 8.8 mmol/L) averaging 15% when they were given **aspirin** (patients under 27.2 kg given 1.2 g daily, patients over 27.2 kg given 2.4 g daily) for a week. No significant changes in insulin doses were necessary.[4]

Eight patients receiving 12 to 48 units of insulin zinc suspension daily required no insulin when, for 2 to 3 weeks, they took **aspirin** in doses of 3.5 to 7.5 g daily, which were large enough to give maximum therapeutic serum salicylate levels of about 2.5 to 3.3 mmol/L. Six other patients were able to reduce their insulin requirements by about 20 to 65%.[5]

Mechanism

It has been known for over 100 years that aspirin and salicylates have blood glucose-lowering properties and in relatively large doses can be used on their own in the treatment of diabetes.[6-10] The simplest explanation for this interaction with antidiabetics is that the blood glucose lowering effects are additive,[1] but there is some evidence that other mechanisms may come into play.[10] In addition aspirin can raise serum chlorpropamide levels, possibly by interfering with renal tubular excretion, and therefore the effects of chlorpropamide are enhanced.[2]

Importance and management

The interaction between the sulfonylureas or insulin and the salicylates is established but of limited importance. Considering the extremely wide use of aspirin it might reasonably be expected that any generally serious interaction would have come to light by now. The data available, coupled with the common experience of diabetic patients,[11] is that excessive and unwanted hypoglycaemia is very unlikely with small to moderate analgesic doses of salicylates. Some downward adjustment of the dose of the antidiabetic may be appropriate if large doses of salicylates are used. Information about other antidiabetics and salicylates appears to be lacking, but they are expected to behave similarly.

Antidiabetics + Somatostatin analogues

Octreotide decreases insulin resistance so that the dose of insulin used by type 1 diabetics can be reduced. Fatal diabetic ketoacidosis occurred in one patient when octreotide was withdrawn. Octreotide appears to have little effect in those with intact insulin reserves (type 2 diabetes), and it may actually reduce insulin secretion and impair glucose tolerance in non-diabetic patients. In addition, octreotide has been reported to reduce sulfonylurea-induced hypoglycaemia. Lanreotide may also affect glucose levels in diabetic patients.

Clinical evidence

Changes in glucose tolerance may occur in patients with acromegaly who are given somatostatin analogues. In a prospective study, in 24 acromegalic patients given long-acting **octreotide** or **lanreotide,** insulin resistance

was reduced, but insulin secretion was impaired resulting in deterioration of glucose homoeostasis in non-diabetic patients. Of 16 patients with normal glucose tolerance before receiving **octreotide**, 4 developed impaired glucose tolerance, and of 7 patients with impaired glucose tolerance, 4 improved, one remained stable and 2 deteriorated to diabetes mellitus; the status of one diabetic patient remained the same.[1] In another study in patients with acromegaly given **octreotide**, impaired glucose tolerance or frank diabetes developed in about half of the 55 patients who initially had normal glucose tolerance, but glucose tolerance improved in 3 of the 11 patients who were diabetic.[2] Similar results were reported in a further study, although **octreotide** appeared to be more detrimental to glucose metabolism than **lanreotide**.[3]

(a) Insulin

1. Type 1 diabetes. When 7 patients with type 1 diabetes with poor metabolic control were given **octreotide** 50 micrograms subcutaneously three times daily (at 8, 15 and 23 hours) or by continuous subcutaneous infusion (62.5 or 112.5 micrograms over 24 hours), their blood glucose levels were about 50% lower than when they were given insulin alone. The effects of **octreotide** on blood glucose levels were virtually the same regardless of route of administration or dose.[4] Another study in 6 patients with type 1 diabetes also found that **octreotide** 50 micrograms subcutaneously before meals reduced their daily insulin requirements by about 50%,[5] and other studies confirm that **octreotide** behaves in this way.[6,7] An isolated report describes clinical and biochemical improvement with **lanreotide** 30 mg intramuscularly every 10 days, in a diabetic acromegalic man whose glucose levels were poorly controlled with insulin. However, he experienced hypoglycaemia when the **lanreotide** was replaced with intramuscular **octreotide** 20 mg (depot preparation) and he had to reduce his insulin dose by 30 to 50% for the first week after each **octreotide** injection.[8] Another report describes deterioration in glucose tolerance leading to death from diabetic ketoacidosis when **octreotide** was stopped in a patient with acromegaly and insulin-resistant diabetes mellitus.[9]

2. Type 2 diabetes. Eight obese type 2 diabetic patients whose diabetes was not controlled with oral antidiabetics and who needed insulin, had no significant increases in blood glucose levels following a meal when they were given subcutaneous **octreotide** 25 micrograms.[10] **Octreotide** reduced insulin requirements in 6 patients with type 2 diabetes and chronic renal failure, but did not significantly affect the glycaemic profile of similar diabetic patients with normal renal function. This effect was thought to be due to a greater reduction in glucagon levels, which are elevated in renal failure.[11]

(b) Oral antidiabetics

Octreotide does not appear to have a clinically relevant beneficial or harmful effect on the blood glucose-lowering effects of oral antidiabetics such as **glibenclamide** (**glyburide**) in patients with type 2 diabetes, although some metabolic changes can occur including suppression of postprandial serum insulin levels.[12,13] A retrospective study of 9 patients with hypoglycaemia occurring as a result of a sulfonylurea overdose (with **glibenclamide** or **glipizide**) found that there was a dramatic and significant reduction in the number of episodes of hypoglycaemia after **octreotide** was given (29 episodes before, versus 2 episodes after, **octreotide**).[14]

Mechanism

Octreotide is an analogue of the natural hormone somatostatin, and similarly has blood glucose-lowering effects because it inhibits the actions of glucagon and growth hormone (which raise blood glucose levels), and because it also delays the absorption of carbohydrate from the gut. However, somatostatin is also diabetogenic, because it suppresses insulin release. In type 1 diabetes, because there is no endogenous insulin, the blood glucose-lowering effects predominate. In non-diabetics and type 2 diabetics, the actions may cancel out, or there may be poorer glycaemic control. Octreotide is thought to cause less suppression of insulin release than somatostatin, but this may still be important in those with insulin-secreting reserves.

Lanreotide, like somatostatin and its analogues, may produce a transient inhibition of the secretion of insulin and glucagon,[15] but lanreotide may have less affinity for receptors found in the pancreas and so possibly produces a different response to that of octreotide.[1,8]

Sulfonylureas lower blood glucose levels primarily by facilitating preformed insulin release from pancreatic beta cells, and octreotide may oppose this by directly inhibiting insulin secretion from the pancreas.[14]

Importance and management

The interaction between insulin and octreotide in patients with type 1 diabetes is established, and hypoglycaemia has been reported. If both drugs are used, anticipate the need to reduce the insulin dose. The studies cited above[4,5] suggest that a reduction of about 50% is possible.

The manufacturers of octreotide state that in patients with type 2 diabetes with intact insulin reserves, octreotide may result in prandial *increases* in glycaemia,[16] but two clinical studies in patients with type 2 diabetes given glibenclamide (glyburide) did not show any deterioration (or benefit) in glycaemia.[12,13] However, octreotide has been reported to reduce sulfonylurea-induced hypoglycaemia. Octreotide may affect insulin secretion, and therefore glucose tolerance, and so it would certainly be prudent to monitor the effects of giving octreotide with any of the oral antidiabetics.

The manufacturer of lanreotide also recommends that blood glucose levels should be checked in diabetic patients to determine whether antidiabetic treatment needs to be adjusted,[15] which seems prudent.

Antidiabetics + SSRIs

In various clinical studies in patients with diabetes, SSRIs have generally caused minor improvements in glycaemic control. However, isolated cases of severe hypoglycaemia, hyperglycaemia and hypoglycaemia unawareness have been reported.
Fluvoxamine slightly reduces the clearance of tolbutamide and increases the maximum plasma levels of glimepiride, and slightly increased the AUC of rosiglitazone. Fluoxetine did not alter the pharmacokinetics of tolbutamide, and sertraline did not significantly affect the pharmacokinetics of glibenclamide (glyburide) or tolbutamide.

Clinical evidence

One research group from the Netherlands have conducted a number of analyses to look at the association between antidepressants and dysglycaemia.[1-3] In one analysis of cases of patients hospitalised for hypoglycaemia, use of antidepressants (including SSRIs) was not associated with an increased risk. The authors suggested that there was a trend for an increased risk with SSRIs when compared with antidepressants not affecting serotonin uptake,[1] but there were too few cases to reasonably assess

this. Conversely, in an analysis of spontaneous reports in the WHO adverse drug reaction database, use of antidepressants was associated with a small increased risk of both hyperglycaemia (odds ratio 1.5) and hypoglycaemia (odds ratio 1.8). SSRIs had a slightly greater risk of hypoglycaemia than hyperglycaemia (odds ratio 2 versus 1.4), which was not statistically significant.[2] In a further longitudinal study in 133 patients using **insulin** for at least 12 months before starting an antidepressant, and for at least 6 months with an antidepressant, the dose of insulin used did not change after starting the antidepressant. When analysed by type, the 85 SSRI users (individual SSRIs not named) had a small 13% decrease in dose of **insulin** while taking the antidepressant.[3]

(a) Citalopram

In a small uncontrolled study in 14 patients with diabetes (type 1 or 2 managed with **insulin** and/or **oral antidiabetics**) given citalopram (10 mg daily increased to 20 mg daily if needed for 16 weeks), there was a non-statistically significant modest improvement in measures of glycaemic control (HbA_{1c} decreased by 0.36%).[4] The fact that this study was small and not placebo-controlled limits its findings, but it does provide some indication that major effects of citalopram on glucose control are possibly uncommon.

(b) Fluoxetine

In a drug interaction study in healthy subjects, single, or multiple doses of fluoxetine 30 mg daily for 8 days, did not affect the pharmacokinetics or the blood glucose-lowering effects of a single 1-g dose of **tolbutamide**.[5]

Various placebo-controlled clinical studies in patients with type 1 or 2 diabetes receiving insulin and/or oral antidiabetics have shown that fluoxetine can cause weight loss, reduce fasting plasma glucose levels and improve glycaemic control (modest decrease in HbA_{1c} levels),[6-8] which in some cases were statistically greater than with placebo. In one study in patients receiving **insulin**, a decrease in the daily **insulin** dose was required over the 24 weeks (44% reduction in dose compared with 20% for placebo).[9]

An **insulin**-dependent diabetic experienced symptoms of hypoglycaemia (nausea, tremor, sweating, anxiety, lightheadedness) after starting to take fluoxetine 20 mg each night. The symptoms disappeared when the fluoxetine was stopped and reappeared when it was restarted. However, blood glucose levels were found to be normal (9 to 11 mmol/L), so it is likely that the effects were purely adverse effects of fluoxetine that were mistaken for symptoms of hypoglycaemia.[10] A further case report describes a patient who experienced symptoms of hypoglycaemia and whose blood glucose levels fell on several occasions (lowest result, 2.36 mmol/L) while taking **glibenclamide** (**glyburide**) 20 mg daily and fluoxetine 20 mg daily.[11] In contrast, another patient with type 1 diabetes experienced a loss of hypoglycaemic awareness while taking fluoxetine 40 mg daily. Approximately one month after fluoxetine was started, he reported an increased incidence of hypoglycaemia, but these episodes were not accompanied by typical adrenergic symptoms (which he had previously experienced). After 3 grand mal seizures which occurred with blood glucose readings ranging from 1.9 to 2.2 mmol/L, the dose of fluoxetine was gradually decreased. Hypoglycaemic unawareness resolved when the fluoxetine dose was reduced to 10 mg every second day. Within weeks of discontinuing fluoxetine, blood glucose levels had risen considerably and hypoglycaemia did not recur.[12] These authors reported two very similar cases with **paroxetine** and **sertraline**.[13] However, in a placebo-controlled study in 18 patients with type 1 diabetes, fluoxetine 20 mg daily titrated to 80 mg daily over 6 weeks actually had no effect on hypoglycaemic symptoms experienced during induced hypoglycaemia (clamp study). Moreover, fluoxetine markedly increased the physiological counter-regulatory responses (e.g. adrenaline (epinephrine) release) to induced hypoglycaemia.[14]

The manufacturers of fluoxetine say that hypoglycaemia has occurred in diabetic patients when they took fluoxetine alone, and hyperglycaemia has developed following discontinuation.[15,16]

(c) Fluvoxamine

Hyperglycaemia occurred in a 60-year-old woman with type 2 diabetes managed with **insulin**, 5 days after fluvoxamine was started. Blood glucose levels, which had approximately doubled, decreased when the fluvoxamine was stopped, but increased and then decreased again when the fluvoxamine was restarted and then stopped.[17]

A study in 14 healthy subjects given fluvoxamine 75 or 150 mg daily for 5 days, with a single 500-mg dose of **tolbutamide** on the third day, found that the clearance of **tolbutamide** was modestly reduced by 19% by the 75 mg dose and by 33% by the 150 mg dose of fluvoxamine. The clearance of its metabolites (4-hydroxytolbutamide and carboxytolbutamide) was also significantly decreased.[18]

A randomised, crossover study in 12 healthy subjects given fluvoxamine 100 mg or placebo daily for 4 days, with a single 500-microgram dose of **glimepiride** on the fourth day, found the AUC of **glimepiride** was not significantly affected by fluvoxamine. Peak plasma levels of **glimepiride** were increased by 43% and the elimination half-life was prolonged from 2 hours to 2.3 hours, but there was no significant change in the effects of **glimepiride** on blood glucose concentrations.[19]

In a study in healthy subjects, fluvoxamine 50 mg daily for 4 days slightly increased the AUC of **rosiglitazone** by 21% when a single 4-mg dose was given on day 4. There was no change in pharmacokinetics of the *N*-desmethyl metabolite.[20]

(d) Paroxetine

In a small placebo-controlled study in 15 patients with type 2 diabetes given paroxetine 20 mg daily, there was a non-statistically significant modest improvement in measures of glycaemic control. HbA_{1c} decreased by 0.44% compared with 0.07% in the placebo group.[21] This study provides some indication that major effects of paroxetine on glucose control are possibly uncommon.

For mention of a case of reduced hypoglycaemic awareness in a type 1 diabetic given paroxetine, see *Fluoxetine*, above.

(e) Sertraline

After taking sertraline 200 mg daily for 22 days the clearance of a single intravenous dose of **tolbutamide** was decreased by 16% in 25 healthy subjects.[22] In another study in 11 healthy subjects, the pharmacokinetics of a single 5-mg dose of **glibenclamide** (**glyburide**) were found to be unaffected by sertraline, taken in increasing doses up to 200 mg daily over 15 days. Blood glucose levels were also unchanged.[23] However, there is a report of a patient with schizoaffective disorder and type 2 diabetes who developed hypoglycaemia during treatment with sertraline, risperidone and **glibenclamide**.[24] For mention of a case of reduced hypoglycaemic awareness in a type 1 diabetic given sertraline, see *Fluoxetine*, above. In contrast, another report describes a patient with diet-controlled, type 2 diabetes, whose glucose levels increased after initiation of sertraline treatment.[25]

Mechanism

Fluvoxamine probably decreases the clearance of tolbutamide by inhibition of its metabolism by the cytochrome P450 isoenzyme CYP2C9. This mechanism may also partly explain the increase in plasma levels of glimepiride. However, as the glimepiride AUC was not increased and the half-life was only slightly increased, the increase in plasma levels may also be due to an increased rate of glimepiride absorption caused by the SSRI.[18,19] Fluvoxamine may have a weak inhibitory effect on CYP2C8, by which rosiglitazone is metabolised.[20] The effects of other SSRIs may also be associated with enzyme inhibition.[24] However, these pharmacokinetic effects seem minor.

The SSRIs themselves appear to be associated with some effects on glucose homeostasis. For example, in one pharmacodynamic study, fluoxetine improved insulin sensitivity in type 2 diabetics managed with diet alone.[26]

Importance and management

Fluoxetine, fluvoxamine and sertraline do not appear to cause any clinically relevant pharmacokinetic interactions with sulfonylureas, neither does fluvoxamine with rosiglitazone. However, note that all SSRIs may affect diabetic control, usually causing a minor improvement, although isolated cases of marked effects have been reported. The dose requirements of insulin or oral antidiabetics, may therefore change. It may therefore be prudent to consider increasing the frequency of blood glucose monitoring if an SSRI is started or stopped.

Antidiabetics + St John's wort (*Hypericum perforatum*)

St John's wort modestly decreases the AUC of rosiglitazone. Pioglitazone and repaglinide are similarly metabolised and may therefore be expected to interact similarly. St John's wort also modestly decreased the AUC of gliclazide, but, in contrast, it did not affect the metabolism of tolbutamide.

Clinical evidence

(a) Gliclazide

In a study in 21 healthy subjects, a 300-mg dose of a St John's wort preparation with a high hyperforin content (*LI 160, Lichtwer Pharma*) was given 3 times daily for 15 days. On the last day of treatment, a single 80-mg dose of gliclazide was given, followed 30 minutes later by glucose 75 g. St John's wort reduced the maximum levels and AUC of gliclazide by 22% and 35%, respectively. The clearance was increased by 47%. No statistically significant changes were found in the AUC_{0-4} or blood levels of glucose or insulin.[1]

(b) Rosiglitazone

A preliminary report of a pharmacokinetic study[2] states that St John's wort 900 mg daily decreased the AUC of a single dose of rosiglitazone by 26% and increased its clearance by 35%.

(c) Tolbutamide

In a study using tolbutamide as a probe drug for CYP2C9 activity, St John's wort 900 mg daily had no effect on the metabolism of a single dose of tolbutamide either after one day or after 2 weeks of use. The St John's wort product used was from *Sundown Herbals* and provided about 33 mg of hyperforin daily.[3] Similarly, in another study, a St John's wort preparation with low hyperforin content (*Esbericum*) at a dose of 240 mg daily (which provided about 3.5 mg of hyperforin daily) had no effect on tolbutamide metabolism.[4]

Mechanism

Gliclazide is a substrate of the cytochrome P450 isoenzyme CYP2C9 and the authors suggest that St John's wort induces this isoenzyme, thereby increasing the metabolism of gliclazide and reducing its levels. The magnitude of this effect was not influenced by CYP2C9 genotype.[1] However, the fact that **tolbutamide**, another CYP2C9 substrate, was unaffected by St John's wort suggests that other factors may be involved.

Rosiglitazone is known to be metabolised principally by the cytochrome P450 isoenzyme CYP2C8, and it was therefore concluded that St John's wort induces this isoenzyme. The magnitude of the effect of St John's wort was not influenced by CYP2C8 genotype.[2]

Importance and management

The clinical relevance of the modest reduction in rosiglitazone levels has not been assessed, but it would seem unlikely to be important. However, the authors state that St John's wort use should be monitored when patients are given CYP2C8 substrates. **Pioglitazone** and **repaglinide** are also substrates of CYP2C8, and would therefore be expected to be similarly affected, although possibly not to a clinically relevant extent. A large decrease in pioglitazone levels would not be expected on the basis that rifampicin, a more potent enzyme inducer than St John's wort, only caused a 54% reduction in the AUC of pioglitazone. However, the UK manufacturer[5] recommends caution when prescribing pioglitazone with drugs that induce CYP2C8. All three drugs are also substrates for CYP3A4, of which St John's wort is an established inducer. Further study is needed.

The small reduction in the levels of gliclazide does not appear to be clinically important as its blood-glucose-lowering effects were unaffected. No special precautions appear to be necessary if tolbutamide and St John's wort are used together.

Antidiabetics + Statins

No clinically relevant adverse interactions appear to have been reported between the statins and the sulfonylureas, but in one pharmacokinetic study, fluvastatin increased the AUC of glibenclamide (glyburide) in diabetic patients. Simvastatin had no clinically relevant effect on the pharmacokinetics of repaglinide, and fluvastatin did not affect nateglinide. Most studies have shown no pharmacokinetic interaction or increased incidence of adverse effects when pioglitazone or rosiglitazone were used with atorvastatin or simvastatin, but one study suggested a possible excess of hepatic adverse events in patients taking atorvastatin with these drugs. Subcutaneous exenatide modestly decreased the AUC of lovastatin, but no clear pattern of altered efficacy of statins was noted in exenatide clinical studies.

Clinical evidence

A. Exenatide

In a study in healthy subjects, subcutaneous exenatide 10 micrograms twice daily for 3 days decreased the AUC of a single 40-mg dose of **lovastatin** given on day 2 by 40%, and decreased its maximum level by 28% and increased the median time to maximum level by 4 hours.[1] In an analysis of three phase III clinical studies of exenatide in patients with type 2 diabetes, the use of exenatide for 30 weeks in the subset of 348 patients already taking

statins (51% **atorvastatin**, 31% **simvastatin**, 11% **pravastatin**, 5% **lovastatin**, 3% **fluvastatin**) was not associated with consistent changes in lipid profiles or statin doses when compared with placebo.[1]

B. Meglitinides

In the preliminary report of a study in healthy subjects, **fluvastatin** 30 mg daily for 8 days caused a minor 18% increase in the AUC of a single 120-mg dose of **nateglinide**, with no change in glucose levels.[2]

In a three-period, crossover, study in 12 healthy subjects, the concurrent use of **simvastatin** 20 mg daily and **repaglinide** 2 mg three times daily for 5 days increased the AUC of repaglinide by just 8%, and increased its maximum level by 26%, although there was high variability in these findings. There was a higher incidence of adverse events (headache was most common, then hypoglycaemia) during concurrent use compared with either drug alone (45 with the combination, 23 with **repaglinide** and 13 with **simvastatin**). However, these adverse events were mild or moderate, and were considered to be due to the additive effects of both drugs.[3] In another study in healthy subjects, atorvastatin 40 mg daily for 3 doses had little effect on the pharmacokinetics of a single 250-microgram dose repaglinide given one hour after the final dose of atorvastatin. The only statistically significant changes (minor 18% increase in AUC, and 41% increase in maximum level) were in the subset of subjects with a genetically reduced ability to metabolise repaglinide by the organic anion transporting polypeptide 1B1 (OATP1B1).[4]

C. Sulfonylureas

(a) Chlorpropamide

A study in 7 patients with type 2 diabetes and hypercholesterolaemia, taking chlorpropamide 125 to 750 mg daily, found that **lovastatin** 20 mg twice daily for 6 weeks reduced low-density lipoprotein cholesterol by 28%, total cholesterol by 24% and apolipoprotein B by 24%. The chlorpropamide plasma levels were unchanged, and the diabetic control remained unaltered.[5]

(b) Glibenclamide (Glyburide)

Groups of 16 healthy subjects taking **fluvastatin** 40 mg or **simvastatin** 20 mg daily were given a single 3.5-mg oral dose of glibenclamide on days one, 8 and 15. The maximum plasma concentration and the AUC of glibenclamide were increased by about 20% by the statins. The blood glucose-lowering effects of glibenclamide remained virtually unchanged by both **fluvastatin** and **simvastatin** in these subjects, and also when **fluvastatin** was tested in a group of 32 patients with type 2 diabetes.[6] Nevertheless, the manufacturers of **fluvastatin** report a study in which a higher dose of **fluvastatin**, of 40 mg twice daily for 14 days, was given to 32 patients with diabetes stable taking glibenclamide 5 to 20 mg daily. **Fluvastatin** increased the AUC of glibenclamide by 70%, increased the maximum serum levels by 60% and increased the elimination half-life from about 8.5 hours to 19 hours, although there were no significant changes in glucose levels.[7,8]

(c) Tolbutamide

A single 1-g dose of oral tolbutamide was given to two groups of 16 healthy subjects taking **fluvastatin** 40 mg or **simvastatin** 20 mg. The pharmacokinetics of the tolbutamide were affected only to a very minor extent, and the blood glucose-lowering effects of the tolbutamide were unchanged.[6]

D. Thiazolidinediones

One review suggested that patients receiving thiazolidinediones (95% taking **troglitazone**) were more likely to develop hepatotoxicity if taking **atorvastatin** than when taking **simvastatin**.[9] However, **troglitazone** has now been withdrawn due to its hepatotoxic effects. The same authors subsequently conducted a similar study. They analysed the adverse event reporting database of the FDA in the US for reactions affecting muscle, liver, pancreas, or bone marrow where **simvastatin** or **atorvastatin** were implicated. They then looked for events where antidiabetic drugs also featured. Of the 3767 events identified for **atorvastatin**, 40 also involved rosiglitazone and 20 also involved pioglitazone. Of the 3651 events identified for **simvastatin**, 10 also involved rosiglitazone and 9 also involved pioglitazone. About half of these events involving pioglitazone or rosiglitazone resulted in hospitalisation or death. Although the data did not allow for an assessment of whether this rate was greater than that expected, the authors say that if **simvastatin** is used as the control, the data suggest that the number of cases of adverse events with **atorvastatin** and a thiazolidinedione are greater than would be expected by chance alone.[10]

However, in a study in healthy subjects, **pioglitazone** 45 mg daily did not significantly affect the pharmacokinetics of **simvastatin** 80 mg daily and concurrent use was well tolerated.[11] Similarly, there was no pharmacokinetic interaction between **pioglitazone** 45 mg daily and **atorvastatin** 80 mg daily.[12] Moreover, clinical use of **rosiglitazone** with **atorvastatin** in patients with type 2 diabetes for 16 weeks was well tolerated,[13] as was the clinical use of **rosiglitazone** or **pioglitazone** with **simvastatin**.[14]

Mechanism

The changes in the pharmacokinetics of glibenclamide (glyburide) caused by fluvastatin and simvastatin are not understood. The interaction between atorvastatin or simvastatin and the thiazolidinediones is thought to involve the cytochrome P450 isoenzyme CYP3A4, although this is as yet unconfirmed.

Importance and management

There is little evidence to suggest that special precautions appear to be needed by diabetic patients taking any of the pairs of sulfonylureas and statins cited here (chlorpropamide with lovastatin; or glibenclamide or tolbutamide with fluvastatin or simvastatin). Nevertheless, one study found a fairly marked increase in exposure to glibenclamide with fluvastatin, and the UK manufacturers of fluvastatin say that there is a potential for serious hypoglycaemia and therefore advise that the use of glibenclamide should be avoided wherever possible.[7] However, the US manufacturers just advise close monitoring, which should continue if the fluvastatin dose is increased to 40 mg twice daily.[8]

Most studies have shown no pharmacokinetic interaction or increased incidence of adverse effects when pioglitazone or rosiglitazone were used with atorvastatin or simvastatin. The clinical relevance of the apparent increased incidence of adverse muscle and liver effects with the use of pioglitazone or rosiglitazone together with atorvastatin is unclear. Further study is needed.

The clinical relevance of the modest decrease in lovastatin levels with exenatide is also unclear, but experience in clinical studies suggests that it is unlikely to be significant.

Note that a number of the large-scale studies of the use of lipid-regulating drugs in primary or secondary prevention of cardiovascular events included patients with diabetes. A review of these subgroups concluded that statins were the drug of choice for lipid-lowering therapy in patients with type 2 diabetes and known coronary artery disease or other cardiovascular risk factors. There was no evidence to recommend one statin over another.[15]

Antidiabetics + Sucralfate

Sucralfate appears not to affect the pharmacokinetics of chlorpropamide or rosiglitazone.

Clinical evidence, mechanism, importance and management

(a) Chlorpropamide

A two-way, crossover study in 12 healthy subjects found that sucralfate 1 g four times daily, given one hour before meals, had no significant effect on the pharmacokinetics of a single 250-mg dose of chlorpropamide.[1] No additional precautions would therefore seem to be necessary on concurrent use.

(b) Rosiglitazone

A single-dose study found that sucralfate 2 g taken 45 minutes before rosiglitazone 8 mg had no significant effect on the pharmacokinetics of rosiglitazone. No special precautions are needed during concurrent use.[2]

Antidiabetics + Sugar-containing pharmaceuticals

Some pharmaceutical preparations may contain sufficient amounts of sugar to affect the control of diabetes.

Clinical evidence, mechanism, importance and management

Pharmaceuticals, especially liquid formulations, may contain sugar in significant amounts. The extent to which the use of preparations like these will affect the control of diabetes clearly depends upon the amounts taken, but the problem is by no means merely theoretical. One report describes the loss of diabetic control (glycosuria) in a woman with type 1 diabetes receiving insulin when given psyllium effervescent powder (*Metamucil* instant-mix), which contains sugar.[1]

The range of other sugar-containing preparations is far too extensive to be listed here. Because of concerns over sugar-containing medicines and dental caries, in children in particular, the number of sugar-free preparations has grown considerably over recent years. In the UK the BNF and MIMS provide guidance as to which preparations are sugar-free. Diabetics should be warned about sugar-containing medicines, and given guidance about the terminology used in labelling. Sweetening agents of note to diabetics include: **invert sugar** (dextrose and fructose), **invert syrup** (67% w/w invert sugar), **syrup BP** (66% w/w sucrose), **glucose liquid** (dextrose content 10 to 20%), **glucose syrup** (33.3% liquid glucose in syrup) and **honey** (70 to 80% glucose and fructose).[2]

Antidiabetics + Sulfinpyrazone

Sulfinpyrazone has no effect on the insulin requirements of diabetics, nor does it affect the control of diabetes in patients taking glibenclamide (glyburide). Increased blood glucose-lowering effects might occur if sulfinpyrazone is given with tolbutamide, but as yet there appear to be no case reports of this interaction. Sulfinpyrazone modestly increased the AUC of nateglinide in one study.

Clinical evidence

(a) Insulin

A double-blind study in 41 adult patients with diabetes found that sulfinpyrazone 600 to 800 mg daily had no clinically significant effects on insulin requirements over a 12-month period.[1]

(b) Nateglinide

In a crossover study in healthy subjects, sulfinpyrazone 200 mg twice daily for 7 days increased the mean AUC of a single 120-mg dose of nateglinide by 28%, but did not change the mean maximum plasma level.[2]

(c) Sulfonylureas

A study in 19 patients with type 2 diabetes taking **glibenclamide** found that sulfinpyrazone 800 mg daily did not affect diabetic control.[3]

A detailed study of the pharmacokinetics of **tolbutamide** in 6 healthy subjects found that sulfinpyrazone 200 mg every 6 hours for a week, almost doubled the half-life of a 500-mg intravenous dose of **tolbutamide**, from 7.3 hours to 13.2 hours, and reduced the plasma clearance by 40%.[4]

Mechanism

Sulfinpyrazone is an inhibitor of the cytochrome P450 isoenzyme CYP2C9, by which tolbutamide and some other sulfonylureas, and nateglinide are metabolised.

Importance and management

Information about an interaction between tolbutamide and sulfinpyrazone appears to be limited to the report cited. So far there appear to be no reports of adverse interactions in patients, but what is known suggests that increased blood glucose-lowering effects, and possibly hypoglycaemia could occur if the dose of tolbutamide is not reduced. Such an interaction has been described with phenylbutazone, which has a close structural similarity to sulfinpyrazone (see 'Antidiabetics + NSAIDs; Phenylbutazone and related drugs', p.564). Patients should be warned if sulfinpyrazone is added to established treatment with tolbutamide. It is also possible that other sulfonylureas metabolised similarly to tolbutamide may be affected in the same way.

The modest increase in nateglinide exposure when given with sulfinpyrazone has not been assessed in diabetics, but it seems unlikely to be clinically relevant. There seems to be nothing documented about any other clinically important interactions between antidiabetics and sulfinpyrazone.

Antidiabetics + Sulfonamides

The blood glucose-lowering effects of some of the sulfonylureas are increased by some, but not all, sulfonamides, due to inhibition of their metabolism. Occasionally and unpredictably acute hypoglycaemia has occurred in individual patients taking various combinations of sulfonamides and sulfonylureas. There appear to be no reports of a serious adverse interaction between insulin and the sulfonamides. Co-trimoxazole alone may rarely cause hypoglycaemia.

Clinical evidence

'Table 13.3', (p.575) summarises the information on the interactions between sulfonylureas and sulfonamides. For a report of the concurrent use of co-trimoxazole and fluconazole causing hypoglycaemia with gliclazide, see 'Antidiabetics + Azoles; Fluconazole', p.544.

Mechanism

The sulfonamides may inhibit the metabolism of the sulfonylureas so that they accumulate in the body. In this way their serum levels and

Table 13.3 Interactions between antidiabetics and sulfonamides

Drugs	*Information documented*	*Refs*
Chlorpropamide		
+ sulfafurazole (sulfisoxazole)	1 case of acute hypoglycaemia	1
+ sulfadimidine	1 case of acute hypoglycaemia	2

blood glucose-lowering effects are enhanced.[1-4] Greater understanding of metabolic mechanisms has led to the realisation that some sulfonamides are inhibitors of the cytochrome P450 isoenzyme CYP2C9 by which many of the sulfonylureas are metabolised. Tolbutamide, in particular, is now recognised as an important substrate of CYP2C9.[5,6] Of the sulfonamides, *in vitro* data suggest that sulfaphenazole is a potent inhibitor of CYP2C9, with sulfadiazine, sulfamethizole, sulfafurazole (sulfisoxazole) and sulfamethoxazole being moderate to minor inhibitors, and sulfapyridine, sulfadimethoxine and sulfamonomethoxine having little inhibitory activity.[6] CYP2C9 shows genetic polymorphism, therefore any interaction might only be clinically relevant in a subgroup of the population. There is also some evidence that the sulfonamides can displace the sulfonylureas from their protein binding sites.[4]

Where some of the cases of hypoglycaemia cannot be predicted on pharmacokinetic grounds, it is worth noting that hypoglycaemia induced by co-trimoxazole, in the absence of a conventional antidiabetic,[7-11] and sometimes associated with renal failure,[9] high dose of sulfonamide,[7,11] advanced age,[8,10] or malnutrition,[7] has been described. Note that trimethoprim alone may cause interactions by inhibiting CYP2C8 and CYP2C9, see 'Antidiabetics + Trimethoprim', p.579.

Importance and management

Information is very patchy and incomplete. Most sulfonamides seem to have caused marked problems (acute hypoglycaemia) in only a few patients and serious interactions are uncommon. When a sulfonamide is first added to established treatment with a sulfonylurea, warn the patient that increased blood glucose-lowering effects, sometimes excessive, are a possibility, but that problems appear to be uncommon or rare. Nevertheless, the cautious approach would be to increase the frequency of blood glucose monitoring. In one study, co-trimoxazole did not appear to cause any significant changes in blood glucose or insulin concentrations in patients receiving **insulin**.[12] However, note that co-trimoxazole alone may rarely cause hypoglycaemia (see *Mechanism*, above). For the interactions of trimethoprim alone, see 'Antidiabetics + Trimethoprim', p.579.

Antidiabetics + Terbinafine

Terbinafine is reported not to interact with tolbutamide, and did not affect glucose control in a study in patients receiving insulin or oral antidiabetics.

Clinical evidence

A large-scale post-marketing survey did not find any interaction in patients taking terbinafine with **tolbutamide** (number unknown).[1] In a subgroup of this survey no additional risk was noted in 154 patients taking antidiabetics with terbinafine.[2] In a clinical study in 89 patients with diabetes and toenail fungal infections, oral terbinafine 250 mg daily for 12 weeks had no effect on blood glucose levels in 83% of patients. Eleven (12.4%) of the patients had an elevated blood glucose level at baseline, which was normal at the end of the study, and 4 patients had a normal baseline blood glucose, which became elevated at the end of the study. No episodes of hypoglycaemia were reported. Patients in this study were receiving **insulin** or **oral antidiabetics** (not specified).[3]

Mechanism

On the basis of studies with human liver microsomes, terbinafine is unlikely to alter the metabolism of tolbutamide.[4]

Importance and management

Terbinafine does not appear to interact with tolbutamide or affect glucose control in patients receiving insulin or oral antidiabetics. No special precautions are required on concurrent use.

Antidiabetics + Tetracyclines

A few early reports indicated that the blood glucose-lowering effects of insulin and the sulfonylureas may sometimes be increased by oxytetracycline. There is also a case of hypoglycaemia involving insulin and doxycycline. Phenformin-induced lactic acidosis may be precipitated by tetracyclines.

Clinical evidence

(a) Insulin

A diabetic with poorly controlled blood glucose levels needed a marked reduction in his insulin dose, from 208 to 64 units daily, in order to control the hypoglycaemia that developed when **oxytetracycline** 250 mg four times daily was given. This reaction was also seen when the patient was

given a second course of antibacterials, and in another patient.[1] A report briefly lists a case of hypoglycaemia when a patient receiving insulin was given **doxycycline**,[2] and another case describes doxycycline-induced hypoglycaemia in an elderly diabetic patient managed by diet alone.[3]

(b) Phenformin

There are at least 6 cases on record of lactic-acidosis in patients taking phenformin that were apparently precipitated by the concurrent use of **tetracycline**.[4-7]

(c) Sulfonylureas

Marked hypoglycaemia occurred in an elderly patient taking **tolbutamide** when **oxytetracycline** was given,[8] and another study in diabetic patients similarly found that **oxytetracycline** could reduce blood glucose levels.[9] The half-life of **glymidine** has been found to be prolonged from 4.6 hours to 7.6 hours by **doxycycline**,[10] whereas a brief comment in another report suggests that **demeclocycline** and **doxycycline** may not affect **chlorpropamide** disposition.[11]

Mechanism

Not understood. Several mechanisms have been suggested including a prolongation of the half-life of insulin and interference with adrenaline-induced glycaemia.[3]

Importance and management

Information about the interactions between the sulfonylureas or insulin and the tetracyclines is very limited indeed, and clinically important interactions appear to be very uncommon. Concurrent use need not be avoided, but be aware of this interaction in case of an unexpected response to treatment.

Phenformin was withdrawn in some countries because it was associated with a high incidence of lactic acidosis; where available, concurrent use with tetracyclines should be avoided. However, there is nothing to suggest that there is an increased risk if tetracyclines are given with **metformin**.

Antidiabetics + Thioctic acid

Thioctic acid is reported not to interact with acarbose, metformin or glibenclamide (glyburide).

Clinical evidence, mechanism, importance and management

A study in 24 healthy subjects given tablets containing thioctic acid 200 mg and **metformin** 500 mg found that the pharmacokinetics of the **metformin** were unchanged by the presence of the thioctic acid, and the authors of the report say that there was also no pharmacodynamic interaction.[1] The report gives very few details. A further study in 24 healthy subjects found that a single 600-mg dose of thioctic acid given with **glibenclamide** (**glyburide**) 3.5 mg did not result in any clinically relevant pharmacokinetic interaction, and thioctic acid did not alter the effect of **glibenclamide** on glucose or insulin levels.[2] Similarly, there was no evidence of a change in thioctic acid pharmacokinetics or pharmacodynamics when it was given to healthy subjects with **acarbose**.[2]

No special precautions seem to be required if thioctic acid is given to patients taking **acarbose**, **metformin** or **glibenclamide**.

Antidiabetics + Tibolone

Tibolone may slightly impair glucose tolerance and therefore possibly reduce the effects of the antidiabetics.

Clinical evidence, mechanism, importance and management

One woman developed diabetes 14 weeks after starting tibolone 2.5 mg daily. However, she had a high normal fasting blood glucose level before starting tibolone, and the diabetes did not resolve on withdrawing the drug.[1] In 1994, the manufacturers of tibolone noted that on their adverse drug event database they had only 3 cases of diabetes occurring during the use of tibolone, and 3 cases of aggravation of diabetes during its use, which they considered a very low number in relation to the extent of tibolone use.[2]

A metabolic study in 10 women with type 2 diabetes stabilised with diet and oral antidiabetics, and given tibolone 2.5 mg daily found there were no changes in glycaemic control, as measured by HbA_{1c} levels.[3] Conversely, a longer 12-month study in 14 women with type 2 diabetes given tibolone found a slight deterioration in glycaemic control (as measured by serum fructosamine),[4] and an early study found that tibolone caused a slight decrease in glucose tolerance in non-diabetic patients.[5]

The manufacturers of tibolone say that patients with diabetes should be closely supervised.[6] It would therefore seem prudent to increase the frequency of blood glucose monitoring if tibolone is started or stopped.

Antidiabetics + Tobacco or Nicotine

Diabetics who smoke tobacco may need more subcutaneous insulin than non-smokers. Smoking and, to a lesser extent, nicotine patches, may increase insulin resistance, and stopping smoking can improve glycaemic control in both type 1 and type 2 diabetics. However, the effects of smoking on diabetes appear to be complex, as some studies have reported that smoking does not affect insulin sensitivity or glycaemic control. Preliminary evidence shows that smoking increases the absorption of inhaled insulin.

Clinical evidence, mechanism, importance and management

A study in 163 patients with type 1 diabetes found that, on average, the 114 who smoked needed 15 to 20% more subcutaneous **insulin** than the non-smokers, and up to 30% more **insulin** if they smoked heavily.[1] Possible mechanisms include decreased absorption of **insulin** from the subcutaneous tissue because of peripheral vasoconstriction,[2] and a significant rise (40 to 100%) in the levels of the hormones that oppose the actions of **insulin**.[3,4]

Serum **insulin** levels during the first 6 hours after inhaled **insulin** were 58% higher in smokers than in non-smokers, and peak **insulin** levels were about threefold higher. Minor hypoglycaemia requiring a glucose infusion occurred in 12 smokers but in only one non-smoker. The increased absorption was possibly due to cigarette smoke increasing the permeability of the alveolar-capillary barrier.[5] It should be noted that the first marked inhaled insulin (*Exubera*, now withdrawn) was contraindicated in patients who smoked, or had smoked within the past 6 months.[6]

In a double-blind, crossover study in 12 smokers with type 2 diabetes, stabilised with diet alone or with **oral antidiabetics**, the effect of smoking one cigarette every hour for 6 hours was compared with transdermal nicotine (30 cm^2 patch) or a placebo patch. Cigarette smoking and the nicotine patch did not affect endogenous insulin secretion, when compared with placebo, but smoking impaired peripheral insulin action, and resulted in lower rates of glucose utilisation and greater hepatic glucose production. The nicotine patch similarly impaired insulin action, but this was much less pronounced than after cigarette smoking, possibly due to the lower plasma levels of nicotine attained with the patch.[7]

In another study, glycaemic control (as measured by HbA_{1c}) was modestly improved in 7 subjects with type 1 diabetes and 27 subjects with type 2 diabetes, one year after they had stopped smoking. This improved control was considered clinically significant.[8] In a study in patients with type 2 diabetes stabilised with diet alone or diet and **sulfonylureas** with or without **metformin**; insulin resistance was higher in the 28 smokers than the 12 non-smokers.[9] Further studies have reported that smoking in diabetics is associated with poor glycaemic control,[10] microalbuminuria,[10] and impaired insulin clearance.[11] However, other studies have suggested that smoking does not affect **insulin** requirement in type 1 diabetics[12] or have a significant effect on glycaemic control in type 1 or type 2 diabetics.[3,12,13] There are numerous other studies on the relationship between smoking and diabetes or insulin resistance in non-diabetics, and only a few are cited here as examples. Some studies have indicated that smoking could increase the risk of type 2 diabetes (relative risk of 2.6) and that tobacco use is associated with a low insulin response.[14] However, other studies suggest that a causal relationship between smoking and insulin resistance is unlikely,[15,16] although in one of the studies[16] exposure to environmental tobacco smoke was associated with lower insulin sensitivity.

Glycaemic control is not the only factor of importance with smoking in diabetics. Cigarette smoking may also accelerate progression of atherosclerosis, increase blood pressure, and increase macrovascular complications.[7,16,17] Diabetics who smoke should be given all the help they need to stop smoking.[10,17]

Antidiabetics + Tricyclic and related antidepressants

Interactions between antidiabetics and tricyclic or tetracyclic antidepressants appear to be rare, but isolated cases of hypoglycaemia have been reported.

Clinical evidence

(a) Retrospective evidence

One research group from the Netherlands have conducted a number of analyses to look at the association between antidepressants and dysglycaemia.[1-3] In one analysis of cases of patients hospitalised for hypoglycaemia, the use of antidepressants (including tricyclics and related drugs) was not associated with an increased risk. The authors suggested that there was a trend for an increased risk with amitriptyline, doxepin and imipramine, as a group, when compared with maprotiline, nortriptyline, mianserin and mirtazapine, as a group,[1] but there were too few cases to reasonably assess this. Conversely, in an analysis of spontaneous reports in the WHO adverse drug reaction database, the use of antidepressants was associated with a small increased risk of both hyperglycaemia (odds ratio 1.5) and hypoglycaemia (odds ratio 1.8). Tricyclics and related drugs had a slightly greater risk of hyperglycaemia than hypoglycaemia, but this was not statistically significant.[2] In a further longitudinal study in 133 patients using **insulin** for at least 12 months before starting an antidepressant, and for at least 6 months with an antidepressant, the dose of insulin used did not change after starting the antidepressant. When analysed by antidepressant type, no change in insulin requirement was seen with tricyclic antidepressants.[3]

(b) Prospective studies

A study in 4 patients suggested that **amitriptyline** 75 mg daily for 9 days did not affect the half-life of a single 500-mg dose of **tolbutamide**.[4] Although there is some evidence of a change in glucose metabolism during treatment with **mianserin**,[5-7] the alteration did not affect the control of diabetes in a study in 10 patients and there appear to be no reports of adverse effects caused by concurrent use.[6]

(c) Case reports

In contrast to the above data, there are four case reports describing hypoglycaemic interactions:

- A patient taking **tolazamide** became hypoglycaemic 11 days after starting to take **doxepin** 250 mg daily. The patient was eventually stabilised on a daily dose of **tolazamide** that was only 10% of that used before the **doxepin** was given.[8]
- A patient taking **chlorpropamide** (initially 25 mg increased to 75 mg daily) developed marked hypoglycaemia 3 days after starting **nortriptyline** 125 mg daily. The **chlorpropamide** was stopped.[8]
- A patient receiving **insulin** developed violent and agitated behaviour (but no adrenergic symptoms) and hypoglycaemia when she started to take **amitriptyline** 25 mg at bedtime.[9]
- An elderly diabetic woman taking **glibenclamide** (**glyburide**) and **phenformin** developed hypoglycaemia when given **maprotiline**. She was restabilised on half the dose of **glibenclamide** and **phenformin**.[10]

Mechanism

The reason for the cases of hypoglycaemia is unknown. Depression *per se*, may alter factors (e.g. weight gain or weight loss) that influence glucose homeostasis.

Importance and management

Apart from the isolated cases there seems to be very little evidence that the tricyclic or tetracyclic antidepressants can cause hypoglycaemia in patients with diabetes. Bearing in mind the length of time these groups of drugs have been available, the risk of a clinically important interaction would seem to be very small. Therefore no particular precautions seem warranted on concurrent use

Antidiabetics + Trimethoprim

Trimethoprim increases the AUC of repaglinide and might be expected to increase its effects in some patients. The effect of trimethoprim on the AUC of pioglitazone and rosiglitazone is somewhat more modest and probably less likely to be clinically relevant. Trimethoprim does not appear to significantly affect the pharmacokinetics of intravenous tolbutamide.

Clinical evidence

(a) Pioglitazone

In a study in 16 healthy subjects, trimethoprim 160 mg twice daily for 6 days increased the AUC of a single 15-mg dose of pioglitazone given on day 3 by 42%, without any relevant change in the peak plasma level. The formation of various pioglitazone metabolites was slightly reduced.[1]

(b) Repaglinide

In a study in 9 healthy subjects, trimethoprim 160 mg twice daily for 3 days increased the AUC and the maximum plasma level of a single 250-microgram dose of repaglinide by 61% and 41%, respectively. However, the blood glucose-lowering effect of this small dose of repaglinide was unchanged.[2]

(c) Rosiglitazone

In a study in 10 healthy subjects, trimethoprim 160 mg twice daily for 4 days increased the AUC of a single 4-mg dose of rosiglitazone given on day 3 by 37%. The half-life of rosiglitazone was increased by 26% but the peak plasma level was only slightly affected (14% increase).[3] Similarly, in another study, trimethoprim 200 mg twice daily for 5 days increased the AUC of a single 8-mg dose of rosiglitazone by 31% and increased its half-life by 27%.[4]

(d) Tolbutamide

In a study in 7 healthy subjects, trimethoprim 150 mg twice daily for 7 days prolonged the elimination half-life of a single intravenous 500-mg dose of tolbutamide by 19%.[5]

Mechanism

Data suggest that trimethoprim inhibits the metabolism of repaglinide, pioglitazone and rosiglitazone by the cytochrome P450 isoenzyme CYP2C8. Tolbutamide is metabolised by CYP2C9, and it is thought possible that trimethoprim may have a slight inhibitory effect on this isoenzyme, although there is very little information about this.[6]

Importance and management

The clinical relevance of the pharmacokinetic changes has not been assessed. However, the fairly marked changes seen with repaglinide suggest that some patients might experience an increase in the effects of this drug when trimethoprim is also given. The UK manufacturers of repaglinide[7] suggest that the concurrent use of trimethoprim should be avoided as the effect of larger doses of both drugs is unknown. The US manufacturers suggest caution, and advise that repaglinide dose adjustments may be necessary.[8] If trimethoprim is required in a patient taking repaglinide, it would seem prudent to increase the frequency of blood glucose monitoring.

The more modest increase in the AUC of pioglitazone and rosiglitazone seen with trimethoprim is less likely to be clinically important, but, until more experience is gained, some caution is warranted. No interaction would be expected between trimethoprim and tolbutamide, although note that co-trimoxazole has rarely caused hypoglycaemia, both alone and when given with various sulfonylureas, see 'Antidiabetics + Sulfonamides', p.574.

Antidiabetics + Tyrosine kinase inhibitors

An improvement in diabetic control with a reduction in dose of insulin or oral antidiabetics has been seen in a few reports of diabetics given imatinib for chronic myelogenous leukaemia, but one report found no benefit. In one case, an increased insulin dose was required with imatinib and then subsequently also with nilotinib, but a reduced insulin requirement then occurred with dasatinib.

Clinical evidence

Use of **imatinib** 400 or 600 mg daily for the treatment of chronic myelogenous leukaemia (CML) was associated with improved glycaemic control in 6 of 7 diabetic patients who had a clinical response to the drug. This allowed a reduction in **insulin** dose in 2 patients and a reduction in the dose of the **oral antidiabetic** in 4 patients.[1] The same research group described a further case, in a woman with type 2 diabetes managed with insulin, who had a sequential reduction in fasting blood glucose and HbA_{1c} over 18 weeks after starting **imatinib** 400 mg daily.[2] Another case report describes a 70-year-old woman with type 2 diabetes who needed a reduction in her **insulin** dose when she was given imatinib for CML. Later, while still taking imatinib, she was able to stop the **insulin** completely.[3] However, in a retrospective review of patients who had received **imatinib**, of 7 patients who had pre-existing type 2 diabetes, and 2 who developed diabetes during therapy, no effect of **imatinib** on glycaemic control was noted.[4]

In yet another case report, the use of **imatinib** was associated with an increased insulin dose, and, the use of **nilotinib** (which proved ineffective for CML) for 3 months was also associated with a further increased insulin requirement. In contrast, the subsequent use of **dasatinib** resulted in two episodes of hypoglycaemia, and a reduced insulin requirement.[5]

Mechanism

It was thought that imatinib and dasatinib may have a direct effect on glycaemic control,[1,3,5] rather than an indirect effect by improving the leukaemia.[1] Nilotinib is reported to cause hyperglycaemia,[5,6] so it is perhaps not surprising that this drug caused an increased insulin requirement.

Importance and management

These preliminary findings suggest that diabetic patients should be well monitored in those given tyrosine kinase inhibitors such as dasatinib, imatinib and nilotinib, because of the possibility of altered glucose metabolism. Further study is needed.

Dipeptidylpeptidase-4 inhibitors + Calcium-channel blockers

Diltiazem markedly increased the AUC of saxagliptin and modestly reduced that of its active metabolite (which is about half as potent as saxagliptin) in one study. Verapamil is expected to interact similarly. No clinically relevant pharmacokinetic interaction has been detected between vildagliptin and amlodipine.

Clinical evidence

(a) Amlodipine

In a crossover study in 19 healthy subjects, there were no clinically relevant changes in the pharmacokinetics of **vildagliptin** or amlodipine when **vildagliptin** 100 mg daily was given with amlodipine 5 mg daily for 10 days, when compared with either drug alone.[1]

(b) Diltiazem

In a study in 12 healthy subjects, modified-release diltiazem 360 mg daily for 8 days increased the maximum level and AUC of **saxagliptin** by 63% and 2.1-fold, respectively, when a single 10-mg dose of saxagliptin was given on day 8. In addition, there was a 36% reduction in the AUC of the active metabolite of **saxagliptin** (which is about half as potent as saxagliptin). **Saxagliptin** did not alter the AUC of diltiazem.[2]

Mechanism

Diltiazem is a modest inhibitor of the cytochrome P450 isoenzyme CYP3A4 by which saxagliptin is metabolised to its principal metabolite (which is about half as active as the parent compound).

Importance and management

The pharmacokinetic interaction between diltiazem and **saxagliptin** is established, but its clinical relevance has not yet been assessed. **Verapamil**, also an inhibitor of CYP3A4, is predicted to interact similarly.[3] Nevertheless, the US manufacturer does *not* recommend any saxagliptin dose reduction in the presence of diltiazem or verapamil.[3]

There is no clinically relevant pharmacokinetic interaction between **vildagliptin** and amlodipine.

Dipeptidylpeptidase-4 inhibitors + Ketoconazole and other CYP3A4 inhibitors

Ketoconazole, a CYP3A4 inhibitor, markedly raises the levels of saxagliptin and markedly reduces the levels of the active metabolite (which is about half as potent as saxagliptin). Other inhibitors of CYP3A4 would be expected to interact similarly. Sitagliptin and vildagliptin would not be expected to interact to a clinically relevant extent with CYP3A4 inhibitors.

Clinical evidence

In studies in healthy subjects, ketoconazole 200 mg every 12 hours until steady-state increased the AUC of a single 100-mg dose of **saxagliptin** (high-dose) 2.5-fold and increased the AUC of a single 20-mg dose of **saxagliptin** 3.7-fold. In addition, there was a marked 90% reduction in the AUC of the active metabolite of **saxagliptin** (which is about half as potent as saxagliptin). **Saxagliptin** 100 mg caused a minor 13% decrease in the AUC of ketoconazole.[1,2]

Mechanism

Ketoconazole is a potent inhibitor of the cytochrome P450 isoenzyme CYP3A4 by which saxagliptin is metabolised to its principal metabolite (which is about half as active as the parent compound). Metabolism by CYP3A4 is a minor route for **sitagliptin** (up to 16% of a dose),[3,4] and **vildagliptin** is not metabolised by P450 isoenzymes.[5]

Importance and management

It appears that ketoconazole markedly increases **saxagliptin** levels, but any effect of this should be partially offset by a marked reduction in active metabolite levels. The clinical relevance of this interaction with clinical use of the lower daily doses of saxagliptin recommended (5 mg daily) is not known. Nevertheless, the US manufacturer recommends that the saxagliptin dose be limited to 2.5 mg daily when used with ketoconazole and other similar potent inhibitors of CYP3A4, and they specifically name **atazanavir**, **clarithromycin**, **indinavir**, **itraconazole**, **nefazodone**, **nelfinavir**, **ritonavir**, **saquinavir** and **telithromycin**.[1] No dose adjustment is recommended for moderate inhibitors of CYP3A4, and they specifically name **amprenavir**, **aprepitant** [and therefore its prodrug, **fosaprepitant**], diltiazem and verapamil (see 'Dipeptidylpeptidase-4 inhibitors + Calcium-channel blockers', p.580), **erythromycin**, **fluconazole**, **fosamprenavir**, and **grapefruit juice**.[1] Conversely, the UK manufacturer does not give any advice about the use of CYP3A4 inhibitors.[6] Further study is needed to establish the clinical relevance of these interactions.

Sitagliptin and **vildagliptin** would not be expected to be affected by ketoconazole by inhibition of CYP3A4. However, the UK manufacturer of sitagliptin does not rule out the possibility of an interaction with potent CYP3A4 inhibitors (they name **clarithromycin**, **itraconazole**, **ketoconazole**, **ritonavir**) in patients with severe renal impairment or end-stage renal disease, in whom metabolism may play a more important role in elimination. However, they also state that, because of limited clinical experience, sitagliptin should not be used in patients with more than mild impairment of renal function.[4] The US manufacturer recommends sitagliptin dose reductions by degree of renal impairment, and this is likely to compensate for any theoretical interaction with potent CYP3A4 inhibitors.[3]

Dipeptidylpeptidase-4 inhibitors + Metformin

No clinically relevant pharmacokinetic interactions have been detected between linagliptin, saxagliptin, sitagliptin or vildagliptin and metformin.

Clinical evidence and mechanism

(a) Linagliptin

In a study in healthy subjects, the concurrent use of linagliptin 10 mg daily and metformin 850 mg three times daily had no effect on the pharmacokinetics of metformin. In addition, there was no change in pharmacokinetics of linagliptin, except for a minor 20% increase in its AUC.[1]

(b) Saxagliptin

In a single-dose study in 16 healthy subjects, there was no change in the pharmacokinetics of metformin 1 g when it was given with saxagliptin 100 mg. In addition, there was no change in the AUC of saxagliptin and just a minor 21% decrease in the maximum saxagliptin level.[2]

(c) Sitagliptin

In a study in 13 patients with type 2 diabetes, there were no changes in the pharmacokinetics of sitagliptin or metformin when sitagliptin 50 mg twice daily was given with metformin 1 g twice daily for 7 days, when compared with either drug alone.[3]

(d) Vildagliptin

In a study in 17 patients with type 2 diabetes, when vildagliptin 100 mg daily was given with metformin 1 g daily, there was a slight 15% increase in AUC of metformin, but no change in AUC of vildagliptin.[4] This small change in metformin levels is unlikely to be clinically relevant.

Importance and management

These combinations of drugs are being used in the management of diabetes for their additive blood glucose lowering effects, and the studies show that there are no pharmacokinetic interactions that will complicate such use.

Dipeptidylpeptidase-4 inhibitors + Rifampicin (Rifampin) and other CYP3A4 inducers

Rifampicin, a potent CYP3A4 inducer, markedly reduces the levels of saxagliptin and did not alter the levels of the active metabolite (which is about half as potent as saxagliptin). Other potent inducers of CYP3A4 might be expected to interact similarly. Sitagliptin and vildagliptin would not be expected to interact with CYP3A4 inducers.

Clinical evidence

In a study in healthy subjects, rifampicin 600 mg daily until steady-state reduced the AUC of a single 5-mg dose of **saxagliptin** by 76%. There was no change in the AUC of the active metabolite of **saxagliptin** (which is about half as potent as saxagliptin). However, the US manufacturer notes that there was no change in the dipeptidylpeptidase-4 inhibitory activity of **saxagliptin** over 24 hours when given with rifampicin.[1]

Mechanism

Rifampicin is a potent inducer of the cytochrome P450 isoenzyme CYP3A4 by which saxagliptin is metabolised to its principal metabolite (which is about half as active as the parent compound).[1] Metabolism by CYP3A4 is a minor route for **sitagliptin** (up to 16% of a dose),[2,3] and **vildagliptin** is not metabolised by cytochrome P450 isoenzymes.[4]

Importance and management

It appears that rifampicin markedly reduces saxagliptin exposure, and there is no increase in exposure to the active metabolite to offset this. The clinical relevance of this has not been assessed, but the US manufacturer considers that no dose adjustment of saxagliptin is needed because dipeptidylpeptidase-4 inhibitory activity was not altered.[1] Nevertheless, until more is known, it cannot be ruled out that rifampicin might reduce the blood glucose lowering effect of saxagliptin, and the UK manufacturer recommends caution with the use of potent inducers of CYP3A4, and they specifically name **carbamazepine**, **dexamethasone**, **phenobarbital**, **phenytoin** and **rifampicin**.[5] Some caution would therefore seem prudent with **primidone**, which is metabolised to phenobarbital, and **fosphenytoin**, a prodrug of phenytoin. Further study is needed to establish the clinical relevance of these interactions.

Sitagliptin and vildagliptin would not be expected to be affected by rifampicin by induction of CYP3A4.

Dipeptidylpeptidase-4 inhibitors + Sulfonylureas

No clinically relevant pharmacokinetic interactions have been detected between alogliptin, saxagliptin, sitagliptin or vildagliptin and glibenclamide (glyburide). The risk of hypoglycaemia may be increased by the concurrent use of a dipeptidylpeptidase-4 inhibitor and a sulfonylurea.

Clinical evidence

(a) Alogliptin

In a study in 24 healthy subjects, there was no change in the pharmacokinetics of **glibenclamide** (glyburide) when a single 5-mg dose was given before and on the last day of alogliptin 25 mg daily for 7 days, except for a minor 15% increase in the glibenclamide maximum level.[1]

(b) Saxagliptin

In a single-dose study in 30 healthy subjects, there was no change in the AUC of **glibenclamide** or saxagliptin when both drugs were given together, and a minor 16% increase in the maximum glibenclamide level and an 8% increase in the maximum saxagliptin level.[2]

In a large placebo-controlled study where saxagliptin 2.5 mg or 5 mg was given to patients with type 2 diabetes taking **glibenclamide**, there was a slightly increased incidence of reports of hypoglycaemia in patients taking saxagliptin (13.3% and 14.6% for the two doses, respectively) when compared with placebo (10.1%).[3]

(c) Sitagliptin

In a study in 8 healthy subjects,[4] sitagliptin 200 mg daily for 6 days had no effect on the AUC of a single 1.25-mg dose of **glibenclamide** given on day 5.

In a large placebo-controlled study where sitagliptin 100 mg was given to patients with type 2 diabetes taking **glimepiride**, there was an increased incidence of hypoglycaemia in patients taking sitagliptin (12.2%) when compared with placebo (1.8%).[5]

(d) Vildagliptin

In a study in 17 patients with type 2 diabetes, there were no clinically relevant changes in the pharmacokinetics of vildagliptin or **glibenclamide** when vildagliptin 100 mg twice daily was given with glibenclamide 10 mg daily, when compared with either drug alone. As expected, the combination had greater glucose lowering effects than either drug alone.[6]

In clinical studies, the incidence of hypoglycaemia when vildagliptin 50 mg daily was added to **glimepiride** was 1.2%, compared with 0.6% for placebo added to **glimepiride**.[7]

Mechanism

Sulfonylureas increase the risk of hypoglycaemia because they increase the secretion of insulin. Dipeptidylpeptidase-4 inhibitors may increase this risk because they slow the inactivation of incretin hormones, which also increases the release of insulin.

Importance and management

Sulfonylureas and dipeptidylpeptidase-4 inhibitors are being used concurrently in the management of diabetes for their additive blood glucose lowering effects, and the studies show that there are no pharmacokinetic interactions that will complicate this use. Bear in mind that the risk of hypoglycaemia may be greater with the combination of a dipeptidylpeptidase-4 inhibitor and a sulfonylurea. Because of this, when starting the dipeptidylpeptidase-4 inhibitor in a patient already taking a sulfonylurea, consideration should be given to lowering the dose of the sulfonylurea.

Dipeptidylpeptidase-4 inhibitors + Thiazolidinediones

No clinically relevant pharmacokinetic interactions have been seen between sitagliptin and rosiglitazone, or between alogliptin, saxagliptin or vildagliptin with pioglitazone. There may be an increased risk of peripheral oedema if saxagliptin is used with a thiazolidinedione.

Clinical evidence and mechanism

(a) Alogliptin

In a crossover study in 27 healthy subjects, the concurrent use of alogliptin 25 mg daily and **pioglitazone** 45 mg daily for 12 days slightly increased the AUC of alogliptin by 10% and caused no changes in the pharmacokinetics of pioglitazone or its active metabolites.[1] In a phase III clinical study, there was no difference in incidence of peripheral oedema when alogliptin was used with pioglitazone. However, cardiac disorders of any cause (e.g. atrial fibrillation, heart failure, myocardial infarction, angina, tachycardia, palpitations) occurred more frequently in those receiving alogliptin than placebo (alogliptin 25 mg 6.5%, alogliptin 12.5 mg 3%, placebo 1%). One possible explanation for this was that the groups were not equally matched for pre-existing cardiac disorders [it should be possible to retrospectively analyse the data to see if this was so]. The authors considered the cardiac events unlikely to be attributable to a drug interaction.[2] However, further study is needed to establish any cardiovascular adverse effect and its relationship to the concurrent use of these drugs.

(b) Saxagliptin

In a study in 28 healthy subjects, when saxagliptin 10 mg daily and pioglitazone 45 mg daily were given together for 5 days, there was no change in the pharmacokinetics of saxagliptin and just a minor 14% increase in the maximum level of **pioglitazone** (no change in AUC), when compared with either drug alone.[3] In a placebo-controlled clinical study where saxagliptin 2.5 mg daily or 5 mg daily was added to the established use of **pioglitazone** or **rosiglitazone** in patients with type 2 diabetes, there was a higher incidence of peripheral oedema in those given saxagliptin 5 mg than those given saxagliptin 2.5 mg or placebo (8.1%, 3.1% and 4.3%, respectively).[3]

(c) Sitagliptin

In a study in healthy subjects,[4] sitagliptin 200 mg daily for 5 days had no effect on the AUC of a single 4-mg dose of **rosiglitazone** given on day 5.

(d) Vildagliptin

In a study in 15 patients with type 2 diabetes, there were no clinically relevant changes in the pharmacokinetics of vildagliptin or **pioglitazone** when vildagliptin 100 mg twice daily was given with pioglitazone 45 mg daily compared with either drug alone. As expected, the combination had greater glucose lowering effects than either drug alone.[5]

Importance and management

Dipeptidylpeptidase-4 inhibitors and thiazolidinediones may be used in the management of diabetes for their additive blood glucose lowering effects, and the studies show that there are no pharmacokinetic interactions that will complicate such use. Bear in mind the possibility of an increased risk of peripheral oedema if saxagliptin is added to thiazolidinedione therapy.

Dipeptidylpeptidase-4 inhibitors; Saxagliptin + Drugs that affect gastric pH

The pharmacokinetics of saxagliptin are not altered by antacids, famotidine or omeprazole.

Clinical evidence, mechanism, importance and management

(a) Antacids

In a study in 15 healthy subjects, the AUC of saxagliptin was unchanged when a single 10-mg dose of saxagliptin was given at the same time as 30 mL of an antacid containing **aluminium/magnesium hydroxide** with simeticone.[1] The saxagliptin maximum level was slightly decreased (by 26%), but this is not expected to be clinically relevant. No saxagliptin dose adjustment is likely to be needed if antacids are also given.

(b) Famotidine

In a study in 15 healthy subjects, the AUC of saxagliptin was unchanged when a single 10-mg dose of saxagliptin was given 3 hours after a single 40-mg dose of famotidine .[1] No saxagliptin dose adjustment is likely to be needed if famotidine is also given.

(c) Omeprazole

In a study in 15 healthy subjects, there was no change in the pharmacokinetics of saxagliptin when a single 10-mg dose of saxagliptin was given on day 5 of omeprazole 40 mg daily for 5 days.[1] No saxagliptin dose adjustment is likely to be needed if omeprazole is also given.

1. Boulton DW, Adams D, Li L, Patel CG, Komoroski BJ, Whigan D, Frevert EU, Goyal A, Kornhauser DM. 36th Annual Meeting of the American College of Clinical Pharmacology, San Francisco, California, 2007.

Dipeptidylpeptidase-4 inhibitors; Sitagliptin + Ciclosporin

Single-dose ciclosporin slightly increased the absorption of sitagliptin, although this was not considered clinically relevant.

Clinical evidence, mechanism, importance and management

A crossover study in 8 healthy subjects found that when a single 100-mg dose of sitagliptin was given with a single 600-mg dose of ciclosporin there was a 68% increase in the maximum plasma levels of sitagliptin, with a slight increase in overall exposure to sitagliptin (AUC increased by 28%). There was no change in renal clearance of sitagliptin.[1]

It is likely that ciclosporin enhances the absorption of sitagliptin by inhibiting P-glycoprotein. However, these changes were considered unlikely to be clinically meaningful, because of the apparent wide therapeutic index of sitagliptin.[1] However, note that one of the rare adverse effects of ciclosporin is hyperglycaemia.

1. Krishna R, Bergman A, Larson P, Cote J, Lasseter K, Dilzer S, Wang A, Zeng W, Chen L, Wagner J, Herman G. Effect of a single cyclosporine dose on the single-dose pharmacokinetics of sitagliptin (MK-0431), a dipeptidyl peptidase-4 inhibitor, in healthy male subjects. *J Clin Pharmacol* (2007) 47, 165–74.

Dipeptidylpeptidase-4 inhibitors; Vildagliptin + ACE inhibitors or Angiotensin II receptor antagonists

No clinically relevant pharmacokinetic interactions have been detected between vildagliptin and ramipril or valsartan.

Clinical evidence, mechanism, importance and management

In a crossover study in 18 healthy subjects, there were no clinically relevant changes in the pharmacokinetics of **vildagliptin**, **ramipril** or its active metabolite ramiprilat when **vildagliptin** 100 mg daily was given with **ramipril** 5 mg daily for 7 days, when compared with either drug alone.[1]

In another similar study in 28 healthy subjects, there were no clinically relevant changes in the pharmacokinetics of **vildagliptin** when **vildagliptin** 100 mg daily was given with **valsartan** 320 mg daily for 7 days, whereas **vildagliptin** modestly increased the AUC of **valsartan** by 24%.[1]

These studies provide evidence that there is no clinically relevant pharmacokinetic interaction between **vildagliptin** and **ramipril** or **valsartan**. On this basis, no pharmacokinetic interaction would be anticipated with **vildagliptin** and any ACE inhibitor or angiotensin II receptor antagonist.

For the conflicting data on the possible increased risk of hypoglycaemia when some antidiabetics are used with ACE inhibitors, see 'Antidiabetics + ACE inhibitors', p.536.

Vildagliptin, a novel dipeptidyl peptidase IV inhibitor, has no pharmacokinetic interactions with the antihypertensive agents amlodipine, valsartan, and ramipril in healthy subjects. J Clin Pharmacol (2008) 48, 85–95.

Exenatide + Miscellaneous

The rate of paracetamol (acetaminophen) absorption is reduced by exenatide, even when the paracetamol is given up to four hours after the exenatide. The manufacturer therefore recommends that exenatide be used with caution with drugs that require rapid gastrointestinal absorption or drugs that require a threshold level for efficacy (such as some antibacterials).

Clinical evidence

In a single-dose, placebo-controlled study using oral **paracetamol** (**acetaminophen**) elixir as a marker of gastric emptying, subcutaneous exenatide 10 micrograms, given before breakfast, reduced the maximum plasma levels of **paracetamol** by 56% and delayed the time to maximum level from 0.6 hours to 4.2 hours when the paracetamol was given one hour after the exenatide. The overall extent of absorption was slightly reduced (23% reduction in AUC), This effect was seen when **paracetamol** was given at the same time as exenatide, or 2, and 4 hours after exenatide although the extent of the interaction was smaller. It was not seen when **paracetamol** was given one hour *before* exenatide.[1]

Mechanism

Exenatide markedly slows gastric emptying, and has the potential to delay the absorption of other drugs.

Importance and management

Because exenatide delays gastric emptying and may reduce the rate of absorption of orally administered drugs, the manufacturers recommend that exenatide should be used with caution in patients receiving oral drugs that require rapid gastrointestinal absorption. They do not give any specific examples.[2,3] However, where a rapid effect of an oral drug is required, for example, an analgesic for acute pain or fever, it may be prudent to give the drug at least one hour before exenatide, or delay exenatide until more than 2 hours after the drug.

The manufacturers also suggest that exenatide should be used with caution in patients receiving oral drugs that are dependent on threshold concentrations for efficacy. They give **antibacterials** as an example (but no drugs are specifically named), and recommend that they should be taken at least one hour before exenatide.[2,3] Whether this is clinically necessary remains to be shown.

In addition, for drugs that are formulated as gastric-resistant formulations, or that are sensitive to degradation by gastric acid, the UK manufacturer recommends that they are taken one hour before exenatide or at least 4 hours afterwards.[3]

Insulin + Naltrexone

The insulin requirements of a patient rose by about 30% when naltrexone was given.

Clinical evidence, mechanism, importance and management

A patient with type 1 diabetes was given naltrexone in an experimental study of the treatment of anorexia nervosa. During two periods of 5 days while taking the naltrexone (dose not stated), the blood glucose levels of the patient remained unchanged but the insulin dose requirements rose from 52.8 and 61.4 units daily to 71.4 and 76 units daily (a rise of about 30%). The reason is not known but the authors of this report point out that this apparent interaction must have been due to the actions of insulin rather than on its release because this patient had no endogenous insulin.[1]

The general clinical importance of this interaction is not known but it would be prudent to be alert for any evidence of increased insulin requirements if naltrexone is used in any patient.

1. Marrazzi MA, Jacober S, Luby ED. A naltrexone-induced increase in insulin requirement. *J Clin Psychopharmacol* (1994) 14, 363–5.

Liraglutide + Miscellaneous

Liraglutide had no clinically relevant effects on the pharmacokinetics of atorvastatin, an oral combined hormonal contraceptive, digoxin, griseofulvin, lisinopril or paracetamol (acetaminophen). Although theoretically unlikely, the manufacturer does not rule out an interaction with warfarin

Clinical evidence, mechanism, importance and management

(a) Atorvastatin

In a pharmacokinetic study, liraglutide modestly decreased the maximum level of a single 40-mg dose of atorvastatin by 38% and its median time to maximum level was delayed from one to 3 hours, but there was no change the overall exposure (AUC).[1]

This study shows that liraglutide modestly delays the rate, but not extent, of atorvastatin absorption; a finding that is not likely to have clinically relevant adverse effects. Therefore, no adjustment of the atorvastatin dose is likely to be needed in patients also given liraglutide.

(b) Combined hormonal contraceptives

After administration of a single dose of an oral combined hormonal contraceptive (ethinylestradiol with levonorgestrel), liraglutide had no effect on overall exposure (AUC) of the contraceptive steroids. There was a slight decrease in the maximum level of ethinylestradiol and levonorgestrel, by 12% and 13%, respectively, and the time to maximum level was slightly delayed by 1.5 hours.[1] No clinically relevant pharmacokinetic interaction is therefore anticipated when oral hormonal contraceptives are given with liraglutide.

(c) Digoxin

Liraglutide slightly reduced the AUC of a single 1-mg dose of digoxin by 16% and decreased its maximum level by 31%, with a slight delay in time to maximum level of 30 minutes.[1] These pharmacokinetic changes are unlikely to be clinically relevant, and no adjustment of digoxin dose is expected to be needed in patients also given liraglutide.

(d) Griseofulvin

In a pharmacokinetic study, liraglutide modestly increased the maximum level of a single 500-mg dose of griseofulvin by 37% without any change in median time to maximum level or in the overall exposure (AUC).[1] Therefore, no adjustment of the griseofulvin dose is likely to be needed in patients also given liraglutide.

(e) Insulin

The manufacturer of liraglutide states that the concurrent use of insulin is not recommended because it has not been evaluated.[1]

(f) Lisinopril

Liraglutide slightly reduced the AUC of a single 20-mg dose of lisinopril by 15% and decreased the maximum level by 27%, with a delay in time to maximum level from 6 hours to 8 hours.[1] These pharmacokinetic changes are unlikely to be clinically relevant, and no adjustment of the lisinopril dose is expected to be needed in patients also given liraglutide.

(g) Paracetamol (Acetaminophen)

When paracetamol was given as a single 1-g dose, liraglutide did not change the overall exposure (AUC), and only slightly decreased the rate of absorption (maximum level decreased by 31% and median time to maximum level delayed by up to 15 minutes).[1]

Paracetamol is often used to assess gastric emptying rate, and these findings suggest that liraglutide actually has little effect on gastric emptying. This is confirmed from the pharmacokinetic studies with other drugs mentioned here, where no examples of clinically relevant delays in absorption have been found. Nevertheless, the manufacturer states that the small delay of gastric emptying with liraglutide may influence absorption of oral medicinal products given concurrently. Note that they also say that severe diarrhoea has been reported in a few patients given liraglutide, and that diarrhoea may affect the absorption of oral medicinal products given concurrently.[1]

(h) Warfarin

On the basis of other studies discussed here, liraglutide would not be expected to alter the absorption of warfarin. In addition, liraglutide does not affect cytochrome P450, by which warfarin is principally metabolised. No interaction would therefore be anticipated. However, the manufacturer says that a clinically relevant interaction with active substances with narrow therapeutic index such as warfarin cannot be excluded. They therefore recommend that more frequent monitoring of the INR is recommended if patients taking warfarin are given liraglutide. As there is little clinical experience with liraglutide this may be prudent.

Metformin + Aliskiren

The concurrent use of metformin and aliskiren modestly reduced aliskiren levels and slightly reduced metformin levels in one study.

Clinical evidence, mechanism, importance and management

In a study in 19 healthy subjects, giving aliskiren 300 mg daily with metformin 1 g daily for 4 days reduced the AUC of aliskiren by 27% and reduced the AUC of metformin by 12%, when compared with either drug given alone.[1] The reason for these minor changes is unclear; however, they are not considered to be clinically relevant.

1. Vaidyanathan S, Maboudian M, Warren V, Yeh C-M, Dieterich HA, Howard D, Dole WP. A study of the pharmacokinetic interactions of the direct renin inhibitor aliskiren with metformin, pioglitazone and fenofibrate in healthy subjects. Curr Med Res Opin (2008) 24, 2313–26.

Metformin + Cefalexin

Cefalexin modestly increased metformin levels in a single-dose study.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study in 12 healthy subjects, cefalexin 500 mg increased the AUC and maximum serum levels of a single 500-mg dose of metformin by 24% and 34%, respectively. Cefalexin reduced the renal clearance of metformin by 14% by inhibiting metformin tubular secretion via the organic cation system.[1] The clinical relevance of these small changes is uncertain, but they could possibly be greater with longer-term use. The authors recommend that patients receiving metformin with cefalexin should have metformin levels monitored or an alternative antibacterial to cefalexin should be considered.[1] However, based on the available evidence this seems somewhat overcautious.

Metformin + Eslicarbazepine

Eslicarbazepine did not alter the pharmacokinetics of metformin in one study.

Clinical evidence, mechanism, importance and management

In a study[1] in 19 healthy subjects, eslicarbazepine 1.2 g daily for 6 days had no effect on the pharmacokinetics of a single 850-mg dose of metformin given on day 5. This study provides evidence that no pharmacokinetic interaction would be expected on the concurrent use of these drugs and therefore no metformin dose adjustment would be expected to be necessary if eslicarbazepine is also given.

1. Rocha JF, Vaz-da-Silva M, Almeida L, Falcão A, Nunes T, Santos AT, Martins F, Fontes-Ribeiro C, Macedo T, Soares-da-Silva P. Effect of eslicarbazepine acetate on the pharmacokinetics of metformin in healthy subjects. Int J Clin Pharmacol Ther (2009) 47, 255–61.

Metformin + Ginkgo (*Ginkgo biloba*)

Ginkgo did not appear to alter the pharmacokinetics of metformin, and appeared to have a slight beneficial effect on glycaemic control.

Clinical evidence, mechanism, importance and management

In a small crossover study that included 10 patients with type 2 diabetes taking metformin, ginkgo (EGb 761) 120 mg daily for 3 months slightly improved HbA_{1c} when compared with placebo (HbA_{1c} 7.2% versus 7.7%). The pharmacokinetics of metformin were assessed on one day at the end of the study, when the usual daily dose of metformin was taken with the daily dose of ginkgo. Ginkgo did not appear to have any effects on metformin pharmacokinetics.[1] In a further 10 healthy subjects, ginkgo 120 mg daily had no effect on the pharmacokinetics of a single 500-mg dose of metformin, except for a reduction in the time to reach the maximum plasma level.[1]

This study indicates that ginkgo is unlikely to alter the pharmacokinetics of metformin. In addition, it provides some limited evidence that it may have a slight beneficial effect on glycaemic control, although this requires confirmation in a larger study.

1. Kudolo GB, Wang W, Javors M, Blodgett J. The effect of the ingestion of Ginkgo biloba extract (EGb 761) on the pharmacokinetics of metformin in non-diabetic and type 2 diabetic subjects--a double blind placebo-controlled, crossover study. *Clin Nutr* (2006) 25, 606–16.

Metformin + Iodinated contrast media

Parenteral administration of iodinated contrast media may cause renal failure, which could result in lactic acidosis in patients taking metformin.

Clinical evidence, mechanism, importance and management

Parenteral administration of iodinated contrast media to patients taking metformin may result in lactic acidosis. However, the problem is reported to occur only if the contrast media causes renal failure and metformin use is continued. This is because metformin is mainly excreted by the kidneys and in renal failure toxic levels may accumulate,[1] which may result in lactic acidosis. A literature search identified 18 cases of lactic acidosis after the use of contrast media in patients taking metformin.[2] Of these 18 cases, 14 or 15 were associated with pre-existing renal impairment and 2 cases with other contraindications to metformin (sepsis and cirrhosis). The remaining case was in an elderly woman with neurological disease. Note that diabetes-related renal impairment *per se* is an important risk factor for contrast-media associated renal failure.[3,4]

The manufacturers of metformin say that it should be stopped before, or at the time of giving the contrast media and not restarted until 48 hours lat-

er, and then only after renal function has been re-checked and found to be normal.[5,6] Guidelines issued by the European Society of Urogenital Radiology,[7] suggest that there is no need to stop metformin before giving the contrast media in patients with normal renal function. In patients with an estimated glomerular filtration rate of 30 to 60 mL/minute, or a raised serum creatinine level, then metformin should be withheld for 48 hours before and after the contrast media, and only restarted if creatine levels are unchanged.[7] Metformin and/or contrast media are not usually recommended in patients with an estimated glomerular filtration rate of less than 30 mL/minute. In emergency cases where renal function is abnormal or unknown, alternative imaging should be used, if possible. If this is not possible, then the risks and benefits of using contrast media should be weighed carefully. If concurrent use is necessary, the metformin should be stopped, and special care taken with intravenous hydration and monitoring of renal function and lactic acidosis.[7] The American College of Radiologist make similar recommendations, but additionally mention risk factors for lactic acidosis with metformin (e.g. liver impairment, alcohol abuse, myocardial ischaemia, sepsis), and recommend additional caution if these factors are also present.[8] For example, patients with normal renal function and multiple risk factors should withhold from taking metformin for 48 hours after the administration of iodinated contrast media, and consideration should be given to measuring the serum creatinine before re-starting metformin.[8]

Although these guidelines minimise the risk, some patients may still develop an adverse reaction. For example, an analysis of 97 patients taking metformin who were given intravenous contrast media, 4 developed contrast media-associated nephropathy (all 4 had baseline normal renal function). These patients could have been at increased risk of metformin-associated lactic acidosis had the metformin not been stopped and withheld.[9] Furthermore, a fatal case of metformin-induced lactic acid occurred in a 47-year-old man with normal renal function who was admitted as an emergency for aneurysmal subarachnoid haemorrhage and who underwent two contrast procedures (CT scan and angiography) with ionic contrast iohexol.[10]

Pramlintide + Miscellaneous

Pramlintide modestly slows gastric emptying, and therefore it has been recommended that it should not be used with other drugs that alter gastrointestinal motility.

Clinical evidence, mechanism, importance and management

In a single-dose study using oral **paracetamol** (**acetaminophen**) elixir as a marker of gastric emptying, subcutaneous pramlintide, given immediately before breakfast, increased the time to maximum plasma **paracetamol** levels by up to 72 minutes and reduced the maximum **paracetamol** level by about 29%, without altering the overall extent of absorption, when compared with placebo. This effect was seen when **paracetamol** was given at the same time as pramlintide, or for up to 2 hours after pramlintide. It was not seen when **paracetamol** was given one to 2 hours before pramlintide.[1]

This study demonstrates that pramlintide modestly slows gastric emptying, and has the potential to delay the absorption of other drugs.

The manufacturer notes that if a rapid onset of action is required (for example when giving an oral **analgesic**), the drug should be given at least one hour before or 2 hours after pramlintide.[2] Furthermore, because of this delay in gastric emptying, the manufacturer recommends that pramlintide should not be used in patients taking other drugs that alter gastrointestinal motility. They specifically name **antimuscarinics** such as **atropine**,[2] which delay gastric emptying. Note that pramlintide could, theoretically, oppose the effects of **metoclopramide**, which increases gastric emptying.

Repaglinide + Enzyme inducers

Phenytoin, barbiturates and carbamazepine might reduce repaglinide levels and efficacy.

Clinical evidence, mechanism, importance and management

The plasma levels and effects of repaglinide are known to be reduced by rifampicin (see 'Antidiabetics + Rifamycins', p.567), probably principally via induction of the cytochrome P450 isoenzyme CYP2C8 and also CYP3A4. The manufacturers state that they cannot exclude the possibility that other enzyme inducers may interact similarly, and they also name mention **phenytoin**,[1] **carbamazepine**,[1,2] and **phenobarbital**.[1,2] Bear the possibility of reduced repaglinide efficacy in mind if any of these enzyme inducing drugs is used. Note that **fosphenytoin** is a prodrug of phenytoin, and **primidone** is metabolised to phenobarbital, and therefore some caution also seems warranted with these drugs.

For a list of CYP2C8 inducers, see 'Table 1.3, (p.6) and for CYP3A4 inducers, see 'Table 1.4', (p.6). For mention that high doses of phenytoin have rarely caused hyperglycaemia, see 'Phenytoin + Antidiabetics', p.627.

Repaglinide + Grapefruit juice

Grapefruit juice caused a small increase in repaglinide levels in one study.

Clinical evidence, mechanism, importance and management

In a study in 36 healthy subjects, drinking 300 mL of grapefruit juice with a single dose of repaglinide increased the AUC of repaglinide by 13% without any effect on blood glucose levels. The effect was more noticeable with a low 250 microgram dose of repaglinide than with the therapeutic dose of 2 mg.[1] The small increase in AUC of repaglinide in this study is most likely due to inhibition of intestinal CYP3A4 by grapefruit juice constituents; however, and increase of this size is not clinically relevant.

1. Bidstrup TB, Damkier P, Olsen AK, Ekblom M, Karlsson A, Brøsen K. The impact of CYP2C8 polymorphism and grapefruit juice on the pharmacokinetics of repaglinide. *Br J Clin Pharmacol* (2006) 61, 49–57.

Repaglinide + Montelukast

Montelukast did not alter the pharmacokinetics of repaglinide.

Clinical evidence, mechanism, importance and management

In a controlled study[1] in healthy subjects, montelukast 10 mg daily for 3 days had no effect on the AUC of a single 250-microgram dose of repaglinide given on day 3.

In vitro, montelukast inhibited the cytochrome P450 isoenzyme CYP2C8, by which repaglinide is principally metabolised. This study provides conclusive evidence that this interaction does not occur *in vivo*. No repaglinide dose adjustment is therefore expected to be necessary if montelukast is also given.

Sulfonylureas + Antacids

The rate of absorption of some sulfonylureas is increased by some antacids, but there appear to be no reports of adverse responses in diabetic patients as a result of any of these interactions.

Clinical evidence

(a) Chlorpropamide

Magnesium hydroxide 850 mg increased the rate of absorption of chlorpropamide 250 mg in healthy subjects, but the insulin and glucose responses were unaffected.[1]

(b) Glibenclamide (Glyburide)

A single-dose study in healthy subjects found that **magnesium hydroxide** 850 mg had little effect on the rate or extent of absorption of a micronised glibenclamide preparation (*Semi-Euglucon*), but it caused a threefold increase in the peak plasma concentration and the bioavailability of a non-micronised preparation (*Gilemid*).[2] *Maalox* (**aluminium**/**magnesium hydroxide**) increased the AUC of glibenclamide (given as *Daonil*) by one-third, and increased its maximum serum level by 50%.[3]

Sodium bicarbonate 1 to 3 g very markedly increased the early bioavailability of non-micronised glibenclamide in healthy subjects, but its activity remained unaltered.[4]

(c) Glipizide

Sodium bicarbonate 3 g significantly increased the absorption of glipizide 5 mg and enhanced its effects to some extent, but the total absorption was unaltered.[5] The 30 minute, 1-hour, and 2-hour AUCs, were increased sixfold, fourfold and twofold, respectively, and the time to reach the peak serum level fell from 2.5 hours to one hour. **Aluminium hydroxide** 1 g did not appear to affect the absorption of glipizide 5 mg.[5] **Magnesium hydroxide** 850 mg considerably increased the rate of absorption of glipizide 5 mg: the 30-minute and one-hour AUCs being increased by 180% and 69%, respectively.[6]

(d) Tolbutamide

In healthy subjects **magnesium hydroxide** 850 mg increased the 1-hour and 2-hour AUCs of a single 500-mg dose of tolbutamide 5-fold and 2.5-fold, respectively. The total AUC was unaffected. The maximum insulin response was increased fourfold and occurred about an hour earlier, and the glucose responses were also larger, and occurred earlier.[1]

Mechanism

Uncertain. The small increase in gastric pH caused by these antacids possibly increases the solubility of these sulfonylureas and therefore increases their absorption.[7]

Importance and management

Although some interactions between antacids and sulfonylureas certainly occur in healthy subjects, their clinical importance in patients with diabetes is uncertain. No reports of adverse reactions appear to have been published, but note that patients taking glipizide with sodium bicarbonate or magnesium hydroxide, or tolbutamide with magnesium hydroxide may experience transient hypoglycaemia. Generally no action seems necessary, but if a problem does occur, separating the doses as much as possible would probably minimise any effects. Giving glibenclamide 30 minutes to one hour before the antacid has been suggested as a strategy to minimise any interaction.[3]

Sulfonylureas + Bosentan

There appears to be an increased risk of liver toxicity if bosentan is given with glibenclamide. Glibenclamide (glyburide) modestly reduces the plasma levels of bosentan, and bosentan reduces the plasma levels of glibenclamide. Bosentan is predicted to reduce the plasma levels, and possibly effect, of other similarly metabolised antidiabetics, which would include many other sulfonylureas.

Clinical evidence and mechanism

In clinical studies, bosentan was noted to be associated with dose-related asymptomatic elevations in liver enzymes in some patients, and these elevations were higher in patients also receiving **glibenclamide** (**glyburide**).[1] Study in *rats* suggested that the concurrent use of bosentan and **glibenclamide** caused increases in serum bile salt levels that were greater than with either drug alone.[1] In addition, *in vitro* study showed that bosentan inhibits the bile salt export pump,[1] which is also inhibited by **glibenclamide**.

Because of the possibility that there may be a pharmacokinetic component to the interaction, the pharmacokinetics of both bosentan and **glibenclamide** were determined in a crossover study in 12 healthy subjects. However, **glibenclamide** actually reduced the maximum plasma levels and AUC of bosentan by 24% and 29%, respectively, while bosentan reduced the maximum plasma levels and AUC of **glibenclamide** by 22% and 40%, respectively. Two subjects had asymptomatic elevated liver enzyme levels while taking bosentan with **glibenclamide**.[2] Bosentan is an inducer of the cytochrome P450 isoenzymes CYP2C9 and CYP3A4,[3] both of which may be responsible for **glibenclamide** metabolism, and this may explain the reduced **glibenclamide** levels seen.

Importance and management

Based on the limited evidence available about the increased risk of liver toxicity, the manufacturer of bosentan recommends that bosentan should not be used with glibenclamide. They suggest that an alternative antidiabetic drug should be used.[3,4] This seems a sensible precaution. However, note that a decrease of 40% in the AUC of glibenclamide may possibly decrease its blood glucose-lowering effects to a clinically relevant extent,[2-4] and although there are no data, bosentan would be expected to reduce the plasma concentrations of other oral antidiabetics that are predominantly metabolised by CYP2C9 or CYP3A, which includes many other **sulfonylureas**. The possibility of worsened glucose control in patients using these drugs should be considered.[3]

Sulfonylureas + Chloramphenicol

The blood glucose-lowering effects of tolbutamide and chlorpropamide can be increased by chloramphenicol and acute hypoglycaemia can occur.

Clinical evidence

A man taking chloramphenicol 2 g daily started taking **tolbutamide** 2 g daily. Three days later he had a typical hypoglycaemic collapse and was found to have serum **tolbutamide** levels three- to fourfold higher than expected.[1]

Studies in diabetics have found that chloramphenicol 2 g daily can increase the serum level and half-life of **tolbutamide** two- to threefold.[1,2] Blood glucose levels were reduced by about 25 to 30%.[2,3] Hypoglycaemia, acute in one case, developed in two other patients taking **tolbutamide** with chloramphenicol.[4,5] In another study chloramphenicol 1 to 2 g daily caused an average twofold increase in the half-life of **chlorpropamide**.[6]

Mechanism

Chloramphenicol inhibits the liver enzymes concerned with the metabolism of tolbutamide, and probably chlorpropamide as well, leading to their accumulation in the body. This is reflected in prolonged half-lives, reduced blood glucose levels and occasionally acute hypoglycaemia.[1-4,6]

Importance and management

The interaction between tolbutamide and chloramphenicol is well established and of clinical importance. The incidence is uncertain, but increased blood glucose-lowering effects should be expected if both drugs are given. The interaction between chlorpropamide and chloramphenicol is less well documented. Nevertheless, monitor concurrent use carefully and reduce the dose of the sulfonylurea as necessary. Some patients may show a particularly exaggerated response. The manufacturers of other sulfonylureas often list chloramphenicol as an interacting drug, based on its interactions with tolbutamide and chlorpropamide, but direct information of an interaction does not appear to be available. No interaction would be expected with chloramphenicol eye drops, because the systemic absorption is likely to be small.

Sulfonylureas + Grapefruit juice

Grapefruit juice did not alter the pharmacokinetics of glibenclamide in one study.

Clinical evidence, mechanism, importance and management

In a study in healthy subjects, grapefruit juice 200 mL three times daily for 2 days and then simultaneously with a single 875-microgram dose of **glibenclamide** had no effect on the pharmacokinetics of **glibenclamide**.[1]

No pharmacokinetic interaction would therefore be expected on clinical use, either with glibenclamide, or other sulfonylureas that are similarly metabolised.

1. Lilja JJ, Niemi M, Fredrikson H, Neuvonen PJ. Effects of clarithromycin and grapefruit juice on the pharmacokinetics of glibenclamide. *Br J Clin Pharmacol* (2007) 63, 732–40.

Sulfonylureas + Probenecid

The clearance of chlorpropamide is reduced by probenecid. Tolbutamide appears not to interact with probenecid.

Clinical evidence, mechanism, importance and management

A study in 6 patients given single oral doses of **chlorpropamide** found that probenecid 1 to 2 g daily increased the **chlorpropamide** half-life from about 36 hours to 50 hours.[1] It seems that the probenecid reduces the renal excretion of **chlorpropamide**. Another report in healthy subjects suggested that the half-life of **tolbutamide** was also prolonged by probenecid,[2] but this was not confirmed by a further controlled study.[3]

Information is very limited but it may possibly be necessary to reduce the dose of **chlorpropamide** in the presence of probenecid. It seems unlikely that a clinically important interaction will occur with **tolbutamide**. Information about other sulfonylureas appears to be lacking.

Sulfonylureas; Chlorpropamide + Nevirapine

In a single-dose study, nevirapine did not alter the levels or blood glucose-lowering effects of chlorpropamide.

Clinical evidence, mechanism, importance and management

In a single-dose study in 6 fasting subjects, simultaneous administration of **nevirapine** 200 mg with **chlorpropamide** 250 mg had no effect on the AUC of chlorpropamide, when compared with chlorpropamide alone, and no effect on plasma glucose levels.[1]

This study provides some evidence that nevirapine might not alter the levels or effect of chlorpropamide, but it needs confirming in a study with longer-term nevirapine use, as the enzyme-inducing effects of nevirapine would not be maximal with a simultaneous single dose.

1. Bakare-Odunola MT, Enemali I, Garba M, Obodozie OO, Mustapha KB. The influence of lamivudine, stavudine and nevirapine on the pharmacokinetics of chlorpropamide in human subjects. Eur J Drug Metab Pharmacokinet (2008) 33, 165–71.

Sulfonylureas; Chlorpropamide + NRTIs

In a single-dose study, lamivudine and stavudine reduced the levels of chlorpropamide and thereby reduced its effects on blood glucose levels.

Clinical evidence, mechanism, importance and management

In a single-dose study in 6 fasting subjects, the simultaneous administration of **lamivudine** 150 mg with **chlorpropamide** 250 mg reduced the AUC of chlorpropamide by 42% when compared with chlorpropamide alone. A similar 41% reduction in the AUC of chlorpropamide was seen when **stavudine** 40 mg was given simultaneously. With both NRTIs, the plasma glucose levels were higher than with chlorpropamide alone.[1]

The finding of this study is surprising as NRTIs are not known to decrease the absorption or induce the metabolism of any other drugs. Further study is needed to confirm these findings, especially with multiple doses. Until such time, bear the possibility of an interaction in mind if chlorpropamide efficacy is poor in patients taking these NRTIs.

Sulfonylureas; Chlorpropamide + Urinary acidifiers or alkalinisers

On theoretical grounds the response to chlorpropamide may be decreased if the urine is made alkaline, and increased if urine is acidified.

Clinical evidence, mechanism, importance and management

A study in 6 healthy subjects given a 250-mg oral dose of chlorpropamide found that when the urine was made alkaline (pH 7.1 to 8.2) with **sodium bicarbonate**, the half-life of the chlorpropamide was reduced from 50 hours to 13 hours, and the 72-hour clearance was increased fourfold. In contrast, when the urine was acidified (pH 5.5 to 4.7) with **ammonium chloride**, the chlorpropamide half-life was increased from 50 hours to 69 hours and the 72-hour urinary clearance was decreased to 5%, and non-renal (i.e. metabolic) clearance predominated.[1] Another study found that the renal clearance of chlorpropamide was almost 100 times greater at pH 7 than at pH 5.[2] The reason for this effect is that changes in urinary pH affect the ionisation of chlorpropamide, and this affects the ability of the kidney to reabsorb it from the kidney filtrate (see more details under 'Drug excretion interactions', (p.7)). Thus, urinary pH determines the relative contribution of renal and metabolic clearance.

There appear to be no reports of adverse interactions between chlorpropamide and drugs that can alter urinary pH, but prescribers should be

aware of the possibilities: a reduced response if the pH is raised significantly and renal clearance predominates (e.g. with **sodium bicarbonate**, **acetazolamide**, some **antacids**); an increased response if the pH is made more acid than usual and metabolic clearance predominates (e.g. with **ammonium chloride**). Perhaps more importantly, the effects of drugs that alter the hepatic clearance of chlorpropamide are likely to be more significant when its renal clearance is low (i.e. when the urine is acid).[2]

Sulfonylureas; Glibenclamide (Glyburide) + Pantoprazole

The concurrent use of glibenclamide (glyburide) and pantoprazole does not affect the pharmacokinetics of either drug, and pantoprazole does not alter the glucose-lowering effect of glibenclamide.

Clinical evidence, mechanism, importance and management

Pantoprazole 40 mg daily or placebo, were given to 20 healthy subjects for 5 days. On day 5 the subjects were also given 3.5 mg of a micronised preparation of glibenclamide. The pharmacokinetics of the glibenclamide and the pharmacodynamic profiles of glucose and insulin serum concentrations were not significantly altered, and the pharmacokinetics of pantoprazole were not affected. It was concluded that dose changes of the micronised preparation of glibenclamide are not needed during treatment with pantoprazole.[1]

1. Walter-Sack IE, Bliesath H, Stötzer F, Huber R, Steinijans VW, Ding R, Mascher H, Wurst W. Lack of pharmacokinetic and pharmacodynamic interaction between pantoprazole and glibenclamide in humans. *Clin Drug Invest* (1998) 15, 253–60.

Sulfonylureas; Glibenclamide (Glyburide) + Vinpocetine

Vinpocetine does not alter the pharmacokinetics or efficacy of glibenclamide.

Clinical evidence, mechanism, importance and management

A study in 18 elderly patients, with type 2 diabetes and symptoms of dementia, who were taking glibenclamide (glyburide), found that 4 days of treatment with vinpocetine 10 mg three times daily did not affect either the pharmacokinetics of the glibenclamide or the control of blood glucose levels.[1] There would seem to be no reason for avoiding concurrent use.

1. Grandt R, Braun W, Schulz H-U, Lührmann B, Frercks H-J. Glibenclamide steady-state plasma levels during concomitant vinpocetine administration in type II diabetic patients. *Arzneimittelforschung* (1989) 39, 1451–4.

Sulfonylureas; Glipizide + Heparin

An isolated report describes hypoglycaemia in a diabetic patient taking glipizide. The effects were attributed to the concurrent use of heparin.

Clinical evidence, mechanism, importance and management

A diabetic, taking glipizide 5 mg daily for 6 months, with fair control of the diabetes was hospitalised for the treatment of a foot ulcer. Over a period of 4 days he experienced recurring episodes of hypoglycaemia after taking a routine 5-mg dose of glipizide. It was suggested that this might possibly have been due to an interaction with subcutaneous heparin calcium 5000 units every 12 hours which, it is suggested, might have displaced the glipizide from its protein binding sites.[1] No other information seems to be available. The general importance of this report is unknown, but seems likely to be small.

1. McKillop G, Fallon M, Slater SD. Possible interaction between heparin and a sulphonylurea a cause of prolonged hypoglycaemia? *BMJ* (1986) 293, 1073.

Sulfonylureas; Tolbutamide + Aprepitant

Aprepitant slightly reduces tolbutamide levels.

Clinical evidence, mechanism, importance and management

In a study in 12 healthy subjects, aprepitant (125 mg on day one, then 80 mg daily on days 2 and 3) decreased the AUC of a single 500-mg dose of tolbutamide by 23%, 28% and 15%, when given on days 4, 8, and 15, respectively, when compared with 12 subjects not given aprepitant.[1] Even less effect was seen in another study where a single 40-mg oral dose of aprepitant given on day one decreased the AUC of tolbutamide by 8% on day 2, by 16% on day 4, by 15% on day 8, and by 10% on day 15.[2]

Aprepitant is a mild inducer of the cytochrome P450 isoenzyme CYP2C9 by which tolbutamide is metabolised. It therefore slightly increases tolbutamide metabolism, which leads to a reduction in tolbutamide levels. The clinical relevance of these small changes has not been assessed, but is unlikely to be important. Nevertheless, the manufacturer recommends caution when tolbutamide is used with aprepitant (at the higher doses for chemotherapy induced nausea and vomiting).[2,3] No clinically relevant interaction is expected with the low single-dose of aprepitant used for post-operative nausea and vomiting.[2] Note that **fosaprepitant** is a prodrug of aprepitant, and it may therefore be expected to interact similarly.

Sulfonylureas; Tolbutamide + Echinacea

Echinacea does not have a clinically relevant effect on the pharmacokinetics of tolbutamide.

Clinical evidence

In a pharmacokinetic study, 12 healthy subjects were given *Echinacea purpurea* root 400 mg four times daily for 8 days with a single 500-mg dose of tolbutamide on day 6. The AUC of tolbutamide was increased by 14%, and the time to maximum levels was increased from 4 to 6 hours.[1] The oral clearance was decreased by a mean of 11%, although 2 subjects had a 25% or greater reduction.

Mechanism, importance and management

This one study suggests that echinacea does not significantly affect the pharmacokinetics of tolbutamide, and therefore no tolbutamide dose adjustments appear necessary if echinacea is also taken.

1. Gorski JC, Huang S-M, Pinto A, Hamman MA, Hilligoss JK, Zaheer NA, Desai M, Miller M, Hall SD. The effect of echinacea (*Echinacea purpurea* root) on cytochrome P450 activity in vivo. *Clin Pharmacol Ther* (2004) 75, 89–100.

Sulfonylureas; Tolbutamide + Methysergide

A preliminary study indicated that methysergide may enhance the effects of tolbutamide.

Clinical evidence, mechanism, importance and management

In 8 patients with type 2 diabetes, pretreatment with methysergide 2 mg every 6 hours for 2 days increased the amount of insulin secreted in response to a 1-g intravenous dose of **tolbutamide** by almost 40%.[1] Whether in practice the addition or withdrawal of methysergide adversely affects

the control of diabetes is uncertain, but the possibility should be borne in mind.

1. Baldridge JA, Quickel KE, Feldman JM and Lebovitz HE. Potentiation of tolbutamide-mediated insulin release in adult onset diabetics by methysergide maleate. *Diabetes* (1974) 23, 21–4.

Sulfonylureas; Tolbutamide + Tolcapone

Tolcapone did not alter tolbutamide pharmacokinetics in a single-dose study.

Clinical evidence, mechanism, importance and management

In a single-dose study in 12 healthy subjects, tolcapone 200 mg had no effect on the pharmacokinetics of tolbutamide 500 mg, and did not alter the glucose-lowering effect of tolbutamide.[1] This study was conducted because *in vitro* evidence had shown that tolcapone inhibits the cytochrome P450 isoenzyme CYP2C9, by which tolbutamide is metabolised. However, the findings in healthy subjects suggest that no clinically relevant changes in pharmacokinetics of tolbutamide are likely.

Thiazolidinediones + Insulin

Pioglitazone and rosiglitazone may cause fluid retention and peripheral oedema, which can worsen or cause heart failure. There is evidence that the incidence of these effects is higher with the concurrent use of insulin. In addition, there may be an increased risk of myocardial ischaemia when rosiglitazone is used with insulin. The incidence of hypoglycaemia may also be increased, and the required dose of insulin reduced.

Clinical evidence

(a) Pioglitazone

In one 16-week, randomised, placebo-controlled study,[1] pioglitazone 15 or 30 mg with insulin was compared with insulin alone in 566 patients with long-standing diabetes. Oedema was reported in 15.3% of the patients receiving pioglitazone with insulin (12.6% and 17.6% with pioglitazone 15 mg and 30 mg, respectively) compared with 7% when insulin was given alone. Four of the 379 patients given pioglitazone and insulin developed congestive heart failure compared with none of the 187 patients given insulin alone; all 4 had a history of cardiovascular disease. Analysis of this study did not identify specific factors that predict this possible increased risk of congestive heart failure in patients taking insulin.[2] In an analysis of 8 randomised controlled studies of giving pioglitazone to patients already receiving insulin, concurrent use was associated with a tendency for more hypoglycaemic episodes (relative risk 1.27), a greater increase in weight (about 3 kg), a reduction in required insulin dose (about 12 units/day), and a more frequent incidence of peripheral oedema.[3]

One case report describes a 57-year-old obese man with type 2 diabetes, no history of heart failure and excellent exercise tolerance, who was given insulin and pioglitazone 30 mg daily. Over the first 4 weeks after starting pioglitazone he developed significant weight gain and subsequently developed heart failure and pulmonary oedema.[4]

(b) Rosiglitazone

A randomised, double-blind, placebo-controlled study in patients with poorly-controlled type 2 diabetes receiving insulin twice daily found that the addition of rosiglitazone 2 or 4 mg twice daily for 26 weeks improved the control of their blood glucose levels and they needed less insulin.[5] Mean total daily insulin reductions were 12% for the 4 mg dose, 5.6% for the 2 mg dose, and 0.6% for placebo. Symptoms consistent with hypoglycaemia also occurred more frequently with the combination; 67% with the 4 mg rosiglitazone dose, 53% with the 2 mg dose, and 38% with placebo. The incidence of oedema was about threefold higher in those patients given insulin and rosiglitazone; 16.2% with the 4 mg dose, and 13.1% with the 2 mg dose, compared with 4.7% in those given placebo. Congestive heart failure occurred in 4 of 209 patients receiving the combination compared with one of 104 receiving placebo. However, 2 of the patients receiving rosiglitazone had a history of coronary heart disease.[5] Other cases of peripheral oedema and congestive heart failure have been reported.[6-8]

From results of 5 placebo-controlled clinical studies, the manufacturer has reported an incidence of heart failure of 1.1% with insulin monotherapy and 2.4% when combined with rosiglitazone (about a twofold increase).[9,10]

In addition, subsequent analyses of clinical study data have suggested an increased risk of myocardial ischaemia when rosiglitazone is used with insulin, leading to a possible increased risk of myocardial infarction. The US manufacturer reports an incidence of myocardial ischaemic events of 2.8% for rosiglitazone with insulin compared with 1.4% for placebo with insulin, which is about a twofold increase (odds ratio of 2.1).[10]

Mechanism

Pioglitazone or rosiglitazone alone can exacerbate or precipitate heart failure because they can cause fluid retention and weight gain.[2,9-11] The incidence appears to be greatly increased in patients who are also receiving insulin. An estimated 2 to 5% of patients receiving thiazolidinedione monotherapy and 5 to 15% receiving concurrent insulin experience peripheral oedema.[12] Fluid retention and tissue oedema appear to be part of a vascular 'leak' syndrome but, additionally, thiazolidinediones may potentiate the renal effects of insulin on sodium and water retention. It is conceivable that increased fluid retention caused by thiazolidinediones may alter the already precarious volume status in patients with underlying cardiac or renal impairment thus leading to congestive heart failure.[12] However, congestive heart failure has been estimated to occur in as many as 12% of patients who have type 2 diabetes[12] and whether the incidence of heart failure in patients given thiazolidinediones and insulin is simply a reflection of other factors that increase the risk in these patients, or due to some specific interaction with insulin, remains to be established.

Importance and management

The fact that rosiglitazone and pioglitazone can cause weight gain and peripheral oedema, and that the incidence of this is greater in patients who are also using insulin is well established. However, the relevance of this appears to be controversial. In addition, the relationship of rosiglitazone to myocardial ischaemia is also uncertain. Nevertheless, as a result of a review, in October 2007 the European Medicines Agency concluded that the combination of rosiglitazone and insulin should only be used in exceptional cases and under close supervision, and this recommendation was not considered necessary for pioglitazone.[13] Similarly, in the US, pioglitazone[2] is licensed for use with insulin, and the use of rosiglitazone with insulin is not recommended.[10] If oedema occurs in a patient taking a thiazolidinedione it has been recommended that the possible causes be assessed, and that if symptoms and signs suggest congestive heart failure, a dose change and temporary or permanent discontinuance of the thiazolidinedione should be considered.[14]

Concurrent use of insulin and a thiazolidinedione increases the incidence of hypoglycaemia. It has been noted that in patients receiving insulin, the insulin dose may need to be reduced by 10 to 25% if pioglitazone 15 or 30 mg daily is given.[2]

Thiazolidinediones + Leukotriene antagonists

Montelukast and zafirlukast do not alter the pharmacokinetics of pioglitazone, and montelukast does not alter the pharmacokinetics of rosiglitazone.

Clinical evidence

In a controlled study in healthy subjects, both **montelukast** 10 mg daily for 6 days and **zafirlukast** 20 mg twice daily for 6 days did not affect either the AUC of a single 15-mg dose of **pioglitazone** given on day 3, or the metabolites of pioglitazone.[1] Similarly, montelukast 10 mg daily for 6 days had no effect on the AUC of a single 4-mg dose of **rosiglitazone** 4 mg given on day 5. In addition, there was no change in the AUC ratio of the *N*-desmethyl metabolite to **rosiglitazone**.[2]

Mechanism

In vitro, the leukotriene antagonists inhibited the metabolism of pioglitazone and rosiglitazone by the cytochrome P450 isoenzyme CYP2C8.[3,4] However, the clinical studies provide conclusive evidence that this interaction does not occur *in vivo*, and this emphasises the fact that positive *in vitro* findings will not always directly translate to the clinical situation.

Importance and management

No pharmacokinetic interaction is expected if montelukast or zafirlukast are used with pioglitazone or rosiglitazone, and therefore dose adjustments of these antidiabetics are not expected to be necessary on concurrent use.

Thiazolidinediones + Metformin

The pharmacokinetics of metformin are not altered by pioglitazone or rosiglitazone, and metformin does not alter the pharmacokinetics of rosiglitazone.

Clinical evidence, mechanism, importance and management

In healthy subjects, **pioglitazone** 45 mg daily for 7 days did not alter the pharmacokinetics of a single 1-g dose of metformin.[1,2]

The steady-state pharmacokinetics of metformin 500 mg twice daily and **rosiglitazone** 2 mg twice daily were not affected when they were given to healthy subjects for 4 days.[3]

The combination of a thiazolidinedione and metformin is used in the management of diabetes for additive blood glucose lowering effects, and the studies show that there are no pharmacokinetic interactions that will complicate their use. Because neither metformin nor thiazolidinediones increase the secretion of insulin, the risk of hypoglycaemia is not raised by the combination.

Thiazolidinediones + Nitrates

There may be an increased risk of myocardial ischaemia when rosiglitazone is used with nitrates.

Clinical evidence, mechanism, importance and management

Meta-analysis of clinical studies[1,2] suggest that treatment with **rosiglitazone** is associated with an increased risk for myocardial ischaemic events, such as angina or myocardial infarction, especially in patients taking nitrates or insulin (consider also 'Thiazolidinediones + Insulin', p.589). In patients taking nitrates, the odds ratio of myocardial ischaemic events was 2.9 for **rosiglitazone** recipients, when compared with controls, while for patients not taking nitrates, the odds ratio was 1.3 for **rosiglitazone** recipients, when compared with controls. This increased risk represents a difference of 12 myocardial ischaemic events per 100 patient-years. Most of the nitrate users had established coronary heart disease. Among patients with known coronary heart disease who were not taking a nitrate, an increased risk of myocardial ischaemic events for **rosiglitazone** versus controls was not demonstrated.[1]

Definitive conclusions regarding this risk await completion of an adequately-designed cardiovascular outcome study. Until such time, in the US, the use of **rosiglitazone** with nitrates is not recommended.[1] This advice is not specifically stated by the UK manufacturer, who state that, as a precaution, rosiglitazone should not be used in patients with myocardial ischaemia, particularly if this is symptomatic (which is the main indication for nitrates).[2] Pioglitazone has not been associated with similar risks of myocardial ischaemia, see 'Thiazolidinediones + Insulin', p.589.

2. Avandia (Rosiglitazone maleate). GlaxoSmithKline UK. UK Summary of product characteristics, May 2009.

Thiazolidinediones + Sulfonylureas

Pioglitazone does not alter glipizide pharmacokinetics. Rosiglitazone does not have an important effect on glibenclamide (glyburide) pharmacokinetics, and does not alter glimepiride pharmacokinetics. The use of thiazolidinediones with sulfonylureas increases the risk of hypoglycaemia, and sulfonylurea dose reductions might be required. The concurrent use of rosiglitazone and sulfonylureas may be associated with a greater risk of fluid retention, particularly with higher rosiglitazone doses.

Clinical evidence

(a) Pioglitazone

In healthy subjects, pioglitazone 45 mg daily for 7 days did not alter the steady-state pharmacokinetics of **glipizide** 5 mg daily.[1,2] The manufacturer notes that hypoglycaemia is more common when pioglitazone is given with a sulfonylurea.[1,3]

(b) Rosiglitazone

Rosiglitazone 2 mg twice daily for 7 days did not alter the mean steady-state 24-hour plasma glucose levels in diabetic patients taking **glibenclamide** (**glyburide**) 3.75 to 10 mg daily. However, rosiglitazone 8 mg daily for 8 days caused a decrease of about 30% in the AUC of **glibenclamide** in healthy Caucasian subjects, and a slight increase in the AUC of **glibenclamide** in Japanese subjects.[4] These changes are not considered clinically relevant.[4,5] No pharmacokinetic interaction appears to occur between **glimepiride** and rosiglitazone.[4]

The manufacturer notes that hypoglycaemia is more common when rosiglitazone is given with a sulfonylurea.[4,5] Furthermore, the combined use of rosiglitazone and a sulfonylurea leads to an increase in weight, which is greater than with rosiglitazone alone or concurrent use with metformin.[4] In addition, in clinical studies, the incidence of oedema was greater with rosiglitazone and sulfonylureas than with rosiglitazone and metformin,[4,5] and an increased incidence of heart failure has been seen when rosiglitazone was given with a sulfonylurea (either as dual or triple therapy), and appeared higher with rosiglitazone 8 mg daily compared with 4 mg daily.[5]

Mechanism

Thiazolidinediones increase insulin sensitivity, and therefore cause an increased incidence of hypoglycaemia when used with sulfonylureas.

Importance and management

No dose changes as a result of pharmacokinetic interactions appear to be needed if these sulfonylureas are used with the thiazolidinediones. However, if hypoglycaemia occurs, consider reducing the sulfonylurea dose.[1,3-5] The UK manufacturer advises that when rosiglitazone is used with a sulfonylurea, the dose of rosiglitazone should be increased to 8 mg daily only with caution, assessing the risk of fluid retention.[5] Note that, in the UK, the concurrent use of a pioglitazone or rosiglitazone with a sulfonylurea is a second-line option only where metformin cannot be given with the sulfonylurea.[3,5]

Thiazolidinediones; Pioglitazone + Aliskiren

There was no pharmacokinetic interaction between pioglitazone and aliskiren in one study.

Clinical evidence, mechanism, importance and management

In a study in 29 healthy subjects, the concurrent use of aliskiren 300 mg daily with pioglitazone 45 mg daily for 7 days had no effect on the AUC of aliskiren and very slightly reduced the AUC of pioglitazone by 6%, when compared with either drug given alone. There was no change in AUC of pioglitazone metabolites.[1] No dose adjustment of either drug would therefore be expected to be needed if aliskiren is given with pioglitazone.

1. Vaidyanathan S, Maboudian M, Warren V, Yeh C-M, Dieterich HA, Howard D, Dole WP. A study of the pharmacokinetic interactions of the direct renin inhibitor aliskiren with metformin, pioglitazone and fenofibrate in healthy subjects. Curr Med Res Opin (2008) 24, 2313–26.

Thiazolidinediones; Pioglitazone + Fexofenadine

A study in healthy subjects indicated that the pharmacokinetics of pioglitazone 45 mg daily are not significantly affected by fexofenadine 60 mg twice daily, and that pioglitazone does not affect the pharmacokinetics of fexofenadine.[1]

1. Robert M. Pharmacokinetics of coadministration of pioglitazone with fexofenadine. *Diabetes* (2001) 50 (Suppl 2), A443.

Thiazolidinediones; Rosiglitazone + NNRTIs

Rosiglitazone appears to have no effect on the pharmacokinetics of efavirenz, but limited evidence suggests it may decrease nevirapine levels.

Clinical evidence, mechanism, importance and management

In a study which included 10 patients taking **efavirenz** 600 mg daily and four taking **nevirapine** 200 mg twice daily (both given with NRTIs), **rosiglitazone** 4 mg daily for 28 days had no effect on the AUC, minimum levels or maximum levels of **efavirenz**. However, the AUC, minimum level and maximum level of **nevirapine** appeared to decrease, with the 44% decrease in maximum level reaching statistical significance.[1] A mechanism for this effect is not clear, as **rosiglitazone** is not known to be an enzyme inducer.

Because of the small number of patients taking **nevirapine**, the findings of this study require confirmation. Until more is known, it may be prudent to increase monitoring of antiretroviral efficacy and/or drug levels when **rosiglitazone** is used with **nevirapine**. **Rosiglitazone** appears not to alter the pharmacokinetics of **efavirenz**.

1. Oette M, Kurowski M, Feldt T, Kroidl A, Sagir A, Vogt C, Wettstein M, Häussinger D. Impact of rosiglitazone treatment on the bioavailability of antiretroviral compounds in HIV-positive patients. *J Antimicrob Chemother* (2005) 56, 416–19.

Thiazolidinediones; Rosiglitazone + Protease inhibitors

Atazanavir alone modestly increased the AUC of rosiglitazone, but ritonavir-boosted atazanavir slightly decreased it. Rosiglitazone appears to have no effect on the pharmacokinetics of lopinavir taken as lopinavir. Protease inhibitors themselves may rarely cause hyperglycaemia and have been associated with an exacerbation of diabetes.

Clinical evidence

(a) Atazanavir

The US manufacturer notes that atazanavir 400 mg daily for 6 days modestly increased the AUC of a single 4-mg dose of **rosiglitazone** given on day 7 by 35%. Conversely, ritonavir-boosted atazanavir 100/300 mg daily caused a minor 17% decrease in rosiglitazone AUC.[1]

(b) Lopinavir

In a study that included 4 patients taking ritonavir-boosted lopinavir 100/400 mg twice daily with NRTIs, **rosiglitazone** 4 mg daily for 28 days had no effect on the AUC, minimum levels and maximum levels of lopinavir.[2]

Mechanism

Atazanavir alone is a weak inhibitor of the cytochrome P450 isoenzyme CYP2C8, by which rosiglitazone and pioglitazone are principally metabolised. The finding that rosiglitazone appears not to affect lopinavir pharmacokinetics is not unexpected as rosiglitazone does not affect CYP3A4.

Importance and management

The modest changes in rosiglitazone pharmacokinetics seen with atazanavir alone and ritonavir-boosted atazanavir are probably unlikely to be clinically relevant. The manufacturer cautions the use of atazanavir monotherapy in patients taking drugs that are CYP2C8 substrates with a narrow therapeutic window, and they specifically name the antidiabetic **repaglinide**.[1] Note that repaglinide is also partially metabolised by CYP3A4, therefore all protease inhibitors might be expected to increase its levels. Until further information is available with this antidiabetic, some caution may be appropriate.

Rosiglitazone appears not to affect lopinavir pharmacokinetics. The effect of ritonavir-boosted lopinavir on rosiglitazone pharmacokinetics does not appear to have been studied, but it might be expected to interact like ritonavir-boosted atazanavir causing a minor decrease in the AUC of rosiglitazone AUC. Therefore, it appears that a clinically relevant pharmacokinetic interaction is unlikely.

Bear in mind that new onset diabetes mellitus, hyperglycaemia or exacerbation of existing diabetes mellitus has been reported in patients receiving protease inhibitors.

Antiepileptics

The antiepileptic drugs find their major application in the treatment of various kinds of epilepsy, although some of them are also used for other conditions, such as pain management.

Drug interactions

The drugs used as antiepileptics are a disparate group, and their interactions need to be considered individually. Carbamazepine and phenytoin have established ranges of therapeutic plasma levels and these are typically fairly narrow. Modest changes in their plasma levels may therefore be clinically important.

(a) Carbamazepine or Oxcarbazepine

Carbamazepine is extensively metabolised by the cytochrome P450 isoenzyme CYP3A4 to the active metabolite, carbamazepine-10,11-epoxide, which is then further metabolised. The concurrent use of carbamazepine and CYP3A4 inhibitors or inducers may therefore lead to toxicity or reduced efficacy. However, importantly, carbamazepine induces CYP3A4 and also induces its own metabolism (autoinduction). Because of this, it is important that drug interaction studies are multiple dose and carried out at steady state. Autoinduction also means that moderate inducers of CYP3A4 may have less of an effect on steady-state carbamazepine levels than expected.

Oxcarbazepine is a derivative of carbamazepine, but it has less effect on CYP3A4. Both carbamazepine and oxcarbazepine can act as inhibitors of CYP2C19, see 'Phenytoin + Carbamazepine', p.632.

(b) Phenobarbital

Phenobarbital is an inducer of a wide range of cytochrome P450 isoenzymes, and may increase the metabolism of a variety of drugs. It may, itself, also be affected by some enzyme inducers or inhibitors, although these interactions are less established.

(c) Phenytoin

Phenytoin is extensively metabolised by hydroxylation, principally by CYP2C9, although CYP2C19 also plays a role. These isoenzymes show 'genetic polymorphism', (p.4), and CYP2C19 may assume a greater role in individuals who have are CYP2C9 poor metabolisers (that is, patients lacking this isoenzyme). The concurrent use of inhibitors of CYP2C9, and sometimes also CYP2C19, can lead to phenytoin toxicity. In addition, phenytoin metabolism is saturable (it shows non-linear pharmacokinetics), and therefore small changes in either the metabolism or the dose of phenytoin can result in marked changes in its plasma levels. Moreover, phenytoin is highly protein bound, and drugs that alter its protein binding may alter its levels. Although protein binding interactions are usually not clinically relevant (unless metabolism is also inhibited, see 'Phenytoin + Valproate', p.646), they can be important in interpreting drug levels.

(d) Valproate

Valproate is a generic name that is applied in this section to cover valproic acid and its salts and esters. Valproate undergoes glucuronidation and β-oxidation, and possibly also some metabolism by CYP2C isoenzymes. It can therefore undergo drug interactions by a variety of mechanisms. It acts as an inhibitor of glucuronidation and so may affect other drugs that undergo glucuronidation. Valproate also has non-linear pharmacokinetics due to saturation of plasma protein binding, and so may interact with drugs that alter its protein binding. However, note that, although protein binding interactions are usually not clinically relevant unless metabolism is also inhibited, they can be important in interpreting drug levels.

(e) Other antiepileptics

Of the newer antiepileptics, both felbamate and topiramate are weak inducers of CYP3A4. They may also inhibit CYP2C19. They are also partially metabolised by the cytochrome P450 isoenzyme system, so may have their metabolism altered by other drugs such as the enzyme-inducing antiepileptics.

Gabapentin, lamotrigine, levetiracetam, tiagabine, vigabatrin, and zonisamide do not appear to act as inhibitors or inducers of cytochrome P450 isoenzymes, and so appear to cause less drug interactions than the older antiepileptics. Moreover, gabapentin, levetiracetam, and vigabatrin do not appear to be metabolised by the cytochrome P450 system, so appear to be little affected by drug interactions that result from this mechanism. Tiagabine and zonisamide are metabolised by the cytochrome P450 system, so may have their metabolism altered by other drugs such as the enzyme-inducing antiepileptics. Lamotrigine is metabolised by glucuronidation, and may be affected by inhibitors (e.g. valproate) or inducers (e.g. carbamazepine, phenytoin) of this process. Lamotrigine may also act as an inducer of glucuronidation, and may therefore affect the pharmacokinetics of valproate.

Rufinamide undergoes hydrolysis by carboxylesterases. It is not significantly metabolised by cytochrome P450 isoenzymes, but its plasma concentrations are slightly reduced by other antiepileptics such as phenytoin, phenobarbital and primidone. It does act as a modest inducer of CYP3A4, although clinically significant interactions by this mechanism are uncommon.

Stiripentol is metabolised by a number of isoenzymes but interactions as a result of this effect have yet to be established. Stiripentol inhibits CYP3A4, and may inhibit CYP1A2 and CYP2C19, but the clinical relevance of its effects on these latter two isoenzymes have not been established.

Antiepileptics; Enzyme-inducing + Acetazolamide

Severe osteomalacia and rickets have been seen in a few patients taking phenytoin, phenobarbital, or primidone with acetazolamide. A marked reduction in serum primidone levels with a loss in seizure control, rises in serum carbamazepine levels with toxicity, and rises in phenytoin levels have also been described in a very small number of patients given acetazolamide.

Clinical evidence

(a) Osteomalacia

Severe osteomalacia developed in 2 women taking **phenytoin** or **primidone** and **phenobarbital** when they were given acetazolamide 750 mg daily, despite a normal intake of calcium. When acetazolamide was withdrawn, the hyperchloraemic acidosis that had been seen in both patients abated and their high urinary excretion of calcium fell by 50%.[1,2]

Similar cases have been described in 3 children, who developed rickets after taking acetazolamide, **phenytoin** and **primidone**, with **phenobarbital** and/or metharbital.[3]

(b) Reduced serum primidone levels

A patient taking primidone had an increase in seizure-frequency and a virtual absence of primidone (or its metabolite, phenobarbital) in the serum while taking acetazolamide 250 mg daily. Primidone levels rose when the acetazolamide was withdrawn, probably due to improved absorption. A subsequent study in 2 other patients found that acetazolamide had a small effect on primidone absorption in one patient, and no effect in the other.[4]

(c) Increased serum carbamazepine levels

A 9-year-old girl and two teenage boys, all of them taking the highest doses of carbamazepine tolerable without adverse effects, developed signs of toxicity after taking acetazolamide 250 to 750 mg daily. Their serum carbamazepine levels were found to have increased by about 25 to 50%. In one instance toxicity appeared within 48 hours.[5]

The seizure control of 54 children with grand mal and temporal lobe epilepsy was improved when acetazolamide 10 mg/kg daily was given with carbamazepine. Serum carbamazepine levels rose by 1 to 6 mg/L in 60% of the 33 patients sampled. Adverse effects developed in 10 children, and in 8 children this was within 1 to 10 days of starting the acetazolamide. The adverse effects responded to a reduction in the carbamazepine dose.[6]

(d) Increased serum phenytoin levels

When acetazolamide was given with phenytoin to 6 children, 5 of them had an increase in their phenytoin level (range 20 to 132%, representing an increase of 3 to 12.5 mg/L), and one had a slight decrease (20% or 3 mg/L) [values estimated from figure].[7]

Mechanism

Uncertain. Mild osteomalacia induced by antiepileptics is a recognised phenomenon[8] (see also 'Vitamin D substances + Antiepileptics; Enzyme-inducing', p.1410). It seems that this is exaggerated by acetazolamide, which increases urinary calcium excretion, possibly by causing systemic acidosis, which results from the reduced absorption of bicarbonate by the kidney. The changes in the antiepileptic levels are not understood.

Importance and management

The documentation of all of these interactions is very limited, and their incidence is uncertain. Concurrent use should be monitored for the possible development of osteomalacia or altered antiepileptic levels (reduced primidone efficacy, and increased carbamazepine or phenytoin adverse effects) and steps taken to accommodate them. Withdraw the acetazolamide if necessary, or adjust the dose of the antiepileptic appropriately. In the case of the children with rickets[3] the acetazolamide was withdrawn and high doses of vitamin D was given. It seems possible that other carbonic anhydrase inhibitors may behave like acetazolamide.

Antiepileptics + Aciclovir

Isolated reports describe a marked reduction in phenytoin and valproate levels in two children given aciclovir. Seizure frequency increased.

Clinical evidence, mechanism, importance and management

A 7-year-old boy with epilepsy taking **phenytoin**, **valproate** and nitrazepam was given oral aciclovir 1 g daily for 6 days. After 4 days his trough plasma **phenytoin** levels had fallen from 17 micrograms/mL to 5 micrograms/mL, and his trough **valproate** levels similarly fell, from 32 micrograms/mL to 22 micrograms/mL. When the aciclovir was stopped the plasma levels of both antiepileptics rose over a period of 3 to 6 days. During the period when the antiepileptic levels were restabilising, the seizure frequency markedly increased and his EEG worsened.

The reason for this apparent interaction is not known, but the authors of the report suggest that aciclovir may possibly have reduced the absorption of these antiepileptics, in some way not understood.[1] Reduced **phenytoin** and **valproate** levels during treatment with aciclovir have been reported in another child.[2]

These cases appear to be the only reports of an interaction between aciclovir and valproate or phenytoin, and their general clinical importance is not known. More study is needed to establish an interaction.

Antiepileptics + Antineoplastics; Cytotoxic

Carbamazepine, phenytoin and valproate serum levels can be reduced by several antineoplastic drug regimens and seizures can occur if the antiepileptic doses are not raised appropriately. In contrast, phenytoin toxicity has occurred when fluorouracil and fluorouracil prodrugs, such as capecitabine, doxifluridine and tegafur, were given. The effects of many antineoplastics are reduced or changed by enzyme-inducing antiepileptics. Increased haematological toxicity may occur if valproate is given with fotemustine and cisplatin.

Clinical evidence

(a) Antiepileptic levels reduced

There are a number of reports (mainly case reports) that implicate a variety of types of chemotherapy in reducing the levels of **carbamazepine**, **phenytoin**, and **valproate**. See 'Table 14.1', (p.594) for details.

(b) Phenytoin levels raised

A patient with epilepsy taking phenytoin developed phenytoin toxicity when given **fluorouracil** to treat colon cancer.[1] Three patients with malignant brain tumours developed acute phenytoin toxicity associated with raised serum phenytoin levels when they were given *UFT* (**uracil** and **tegafur**, a prodrug of **fluorouracil**).[2] Another case of phenytoin toxicity has been reported with *UFT*.[3] Phenytoin toxicity was also seen in a woman treated with combination therapy that included the fluorouracil prodrug **doxifluridine**.[4] Similarly, phenytoin toxicity has occurred in a patient given **capecitabine** (another prodrug of fluorouracil).[5] Although in one report,[2] no interaction occurred in one of the patients when the *UFT* was replaced by **fluorouracil**, cases of phenytoin toxicity have been reported in 3 patients receiving **fluorouracil** with folinic acid.[5,6]

Table 14.1 Reduced antiepileptic levels during antineoplastic therapy

Antiepileptic	*Antineoplastic*	*Malignancy*	*Outcome*	*Refs*
Phenytoin	Cisplatin Carmustine	Brain tumours	A retrospective study reviewed the effects of 3 or more cycles of 72 hours of carmustine and cisplatin chemotherapy in 19 patients who did not vomit. A phenytoin dose increase was required in three-quarters of patients, which was, on average, 40% of the original dose (range 20 to 100%). The effect on phenytoin levels persisted after the chemotherapy had finished, with levels returning to normal 2 to 3 weeks later.	1
Phenytoin	Cisplatin Vinblastine Bleomycin	Metastatic germ cell tumour	Estimated phenytoin level 15 micrograms/mL, but level only reached 2 micrograms/mL. Patient fitted.	2
Phenytoin Primidone	Cisplatin Vinblastine Bleomycin	Metastatic embryonal cell cancer	Phenytoin 800 mg daily gave a level of 15 micrograms/mL whilst receiving chemotherapy. After chemotherapy the same dose produced a toxic level of 42.8 micrograms/mL. Phenobarbital levels unaffected.	3
Phenytoin Phenobarbital	Vinblastine Carmustine Methotrexate	Lung cancer with brain metastases	Phenytoin levels fell from 9.4 micrograms/mL to 5.6 micrograms/mL 24 hours after vinblastine. Patient fitted. Phenytoin levels returned to normal 2 weeks after chemotherapy. Phenobarbital levels unaffected.	4
Phenytoin Carbamazepine Sodium valproate	Doxorubicin Cisplatin Cyclophosphamide Altretamine	Papillary adenocarcinoma of the ovaries	Seizures occurred 2 to 3 days after starting chemotherapy. All drug levels dropped to one-third or lower. Doses increased to compensate, which led to phenytoin toxicity when the chemotherapy finished.	5
Phenytoin	Carboplatin	Small cell lung cancer with brain metastases	Phenytoin level dropped from 9.7 micrograms/mL to 4.6 micrograms/mL 10 days into chemotherapy, resulting in seizures. Phenytoin dose had to be increased by 35% to achieve a level of 10.7 micrograms/mL.	6
Phenytoin	Dacarbazine Carmustine Cisplatin Tamoxifen	Malignant melanoma with brain metastases	Phenytoin level of only 2.5 micrograms/mL despite a loading 1-g dose and a daily dose of 500 mg phenytoin.	7
Phenytoin followed by Carbamazepine	Vincristine Cytarabine Hydroxycarbamide Daunorubicin Methotrexate Tioguanine Cyclophosphamide Carmustine	Stage IV T-cell lymphoma	Phenytoin failed to reach therapeutic levels and so was substituted with carbamazepine. Chemotherapy caused carbamazepine levels to drop below therapeutic levels resulting in seizures. Increasing the dose from 30 mg/kg to 50 mg/kg per day prevented subtherapeutic levels.	8
Phenytoin	Methotrexate Mercaptopurine Vincristine	Acute lymphoblastic leukaemia	Phenytoin levels dropped from 19.8 micrograms/mL on the day before chemotherapy to 3.6 micrograms/mL on the 6th day of chemotherapy.	9
Phenytoin	Cisplatin Carmustine Etoposide	CNS tumours	Dose of phenytoin had to be increased by 50 to 300% in 10 patients to maintain phenytoin levels in the therapeutic range.	10
Sodium valproate	Methotrexate (high dose)	Acute lymphoblastic leukaemia	A child had a seizure a few hours after methotrexate. Serum valproate levels reduced by 75%. The valproate dose was increased by 50% and clonazepam added.	11
Sodium valproate	Methotrexate Cytarabine Nimustine (by CSF perfusion)	Glioblastoma	CSF valproic acid levels reduced by 70% during the perfusion, but returned to normal levels within 7 hours.	12
Sodium valproate Phenytoin	Cisplatin Etoposide Bleomycin	Testicular cancer	Serum valproate levels reduced by 50% after the first cycle and generalised tonic-clonic seizures occurred. There was no effect on phenytoin levels.	13

(d) Miscellaneous

One report found that **valproate** increased haematological toxicity in patients taking **fotemustine** and **cisplatin**.[7]

Mechanism

Not fully understood, but a suggested reason for the fall in serum antiepileptic levels is that these antineoplastics damage the intestinal wall, which reduces the absorption of the antiepileptic. Other mechanisms may also have some part to play. The raised serum phenytoin levels possibly occur because the liver metabolism of phenytoin is reduced by these antineoplastics. Changes in plasma protein binding may also have been involved.

Importance and management

Information is scattered and incomplete. However, it appears that altered antiepileptic levels can occur, possibly leading to loss of efficacy or toxicity. Where possible, it may be prudent to avoid the concurrent use of enzyme-inducing antiepileptics and antineoplastics. If this is not possible, serum antiepileptic levels should be closely monitored during treatment with any of these antineoplastics, making dose adjustments as necessary. Advice on the management of altered antineoplastic levels with antiepileptics is discussed in the individual monographs.

Antiepileptics; Enzyme-inducing + Calcium carbimide or Disulfiram

Phenytoin levels are markedly and rapidly increased by disulfiram. Phenytoin toxicity can develop. There is evidence that phenobarbital and carbamazepine levels are not affected by disulfiram, and that phenytoin levels are not affected by calcium carbimide.

Clinical evidence

(a) Calcium carbimide

A study in 4 patients found that calcium carbimide 50 mg daily for a week followed by 100 mg daily for 2 weeks had no effect on serum **phenytoin** levels.[1]

(b) Disulfiram

The serum **phenytoin** levels of 4 patients rose by 100 to 500% over a 9 day period when they were given disulfiram 400 mg daily. **Phenytoin** levels were still rising even 3 to 4 days after the disulfiram was withdrawn, and had still not returned to normal after 14 days. Two patients developed signs of mild **phenytoin** toxicity.[2] In a follow-up study in two of the patients, one developed ataxia and both had a rise in serum **phenytoin** levels, of 25% and 50%, respectively, during 5 days of disulfiram treatment.[1] In 10 healthy subjects disulfiram increased the half-life of **phenytoin** from 11 hours to 19 hours.[3] There are also other case reports describing this interaction.[4-8]

Phenobarbital levels (from **primidone** in 3 patients and **phenobarbital** in one patient) fluctuated by about 10% (which is unlikely to be clinically significant) when disulfiram was given for 9 days.[1,2]

A case report suggested that **carbamazepine** did not interact with disulfiram,[6] and this has been confirmed in a study of 5 epileptic, non-alcoholic patients.[9]

Mechanism

Disulfiram inhibits the liver enzymes concerned with the metabolism of phenytoin (possibly the cytochrome P450 isoenzyme CYP2C9) thereby reducing its metabolism and resulting in a rise in its serum levels, to toxic concentrations in some instances. One study concluded that the inhibition was non-competitive.[7]

Importance and management

The interaction between phenytoin and disulfiram is established, moderately well documented, clinically important and potentially serious. It seems to occur in most patients and develops rapidly. Recovery may take 2 to 3 weeks after the disulfiram is withdrawn. It has been suggested that the dose of phenytoin could be reduced to accommodate the interaction, but it may be difficult to maintain the balance required. Monitor for phenytoin adverse effects (e.g. blurred vision, nystagmus, ataxia or drowsiness) and monitor phenytoin levels if both drugs are given.[1]

Carbamazepine and phenobarbital do not appear to interact with disulfiram, and calcium carbimide does not appear to interact with phenytoin.

Antiepileptics + Chinese herbal medicines

A study in patients with epilepsy found that Saiko-ka-ryukotsu-borei-to (TJ-12) enhanced the antiepileptic effects of carbamazepine. Paeoniae radix does not appear to affect the pharmacokinetics of valproic acid.

Clinical evidence

(a) Carbamazepine

A study in patients with epilepsy found the antiepileptic effects of carbamazepine were enhanced by concurrent **Saiko-ka-ryukotsu-borei-to** (**TJ-12**);[1] patients experienced fewer seizures and had improved neurological symptoms.[2]

(b) Valproate

In 6 healthy subjects, the pharmacokinetics of a single 200-mg dose of valproic acid were unaffected by 1.2 g of a powder extract of **Paeoniae radix** taken daily for 7 days.[3]

Mechanism

Not fully understood. As a pharmacokinetic interaction has not been found between Saiko-ka-ryukotsu-borei-to and carbamazepine, the enhanced effects found in the patients with epilepsy may therefore have been due to a pharmacodynamic interaction.[2] Paeoniae radix (the dried root of *Paeonia lactiflora*[3]) is reported to reduce the rate of gastric emptying;[3] however, this does not appear to affect valproate absorption.

Importance and management

Evidence is limited, but there appears to be no evidence of an adverse effect when using Paeoniae radix with valproate, or Saiko-ka-ryukotsu-borei-to with carbamazepine. More study is needed to confirm all these findings. Note that adulteration of Chinese medicines with various antiepileptics may lead to unexpected toxicity.[4]

Antiepileptics + Folinates

If folate supplements are given to treat folate deficiency, which can be caused by the use of antiepileptics (phenytoin, phenobarbital, primidone and possibly carbamazepine and pheneturide), the serum antiepileptic levels may fall, leading to decreased seizure control in some patients.

Clinical evidence

A study in 50 folate-deficient patients with epilepsy (taking **phenytoin**, **phenobarbital** and **primidone** in various combinations) found that after one month of treatment with folic acid 5 mg daily, the plasma **phenytoin** levels of one group of 10 patients had fallen from 20 micrograms/mL to 10 micrograms/mL. In another group of patients taking folic acid 15 mg daily, the levels of **phenytoin** fell from 14 micrograms/mL to 11 micrograms/mL. Only one patient (in the 5-mg folic acid group) had a marked increase in seizure frequency and severity. No alterations were seen in **phenobarbital** levels.[1]

Another long-term study in 26 patients with folic acid deficiency (serum folate less than 5 nanograms/mL) and taking two or more drugs (**phenytoin**, **phenobarbital**, **primidone**), found that the mental state of 22 patients (as shown by increased alertness, concentration, sociability etc.) improved to a variable degree when they were given folic acid 5 mg three times daily. However, the frequency and severity of seizures in 13 patients (50%) increased to such an extent that the folic acid had to be withdrawn from 9 of them.[2]

Similar results, both of increased seizure activity and decreased serum folate levels, have been described in other studies and reports in patients taking **phenytoin**, **phenobarbital**, **primidone** and **pheneturide**.[3-7]

Another report describes a lack of **phenytoin** efficacy in a patient receiving *UFT* (tegafur and uracil) with **folinic acid**, which was attributed to the effect of the **folinic acid** on **phenytoin** levels.[8]

Mechanism

Patients taking antiepileptics may have subnormal serum folic acid levels. Frequencies of 27 to 76% have been reported for phenobarbital, primidone, and phenytoin, alone or in various combinations.[9] There is conflicting information regarding **carbamazepine**[10-13] and **valproate**[10,11,13] causing reduced folic acid levels. **Zonisamide** has not been shown to reduce serum folate levels.[10] One possible explanation is that a reduction in folate occurs with enzyme-inducing antiepileptics, which make excessive demands on folate for the synthesis of the enzymes concerned with drug metabolism, but does not occur with valproate and zonisamide, which are not enzyme inducers. Ultimately the metabolism of the enzyme-inducing antiepileptics becomes limited by the lack of folate, and patients may also develop a reduction in their general mental health[2] and even frank megaloblastic anaemia.[9,14] If folic acid is then given to treat this deficiency, the metabolism of the antiepileptic increases,[15] resulting in a reduction in serum antiepileptic levels, which in some instances may become so low that seizure control is partially or totally lost.

Importance and management

A very well documented and clinically important interaction, which has been the subject of review.[16] Reductions in serum phenytoin levels of 16 to 50% have been described in patients taking 5 to 15 mg folic acid daily for 2 to 4 weeks.[1,3,17] One report suggests that folate doses as low as 1 mg daily may affect phenytoin levels and that even smaller doses may be advisable.[6]

If folic acid supplements are given to folate-deficient patients with epilepsy taking phenytoin, phenobarbital, primidone, and possibly pheneturide, their serum antiepileptic levels should be well monitored so that suitable dose increases can be made. Less information is available about primidone and phenobarbital, but similar precautions would seem prudent. An interaction with carbamazepine is not established, but as some evidence suggests that it may interact similarly some caution is warranted.

Antiepileptics + Ginkgo (*Ginkgo biloba*)

Case reports describe seizures in three patients taking valproate, or valproate and phenytoin, when ginkgo was also taken.

Clinical evidence

A 55-year-old man taking **valproate** and **phenytoin** for a seizure disorder that developed following coronary artery bypass surgery, suffered a fatal breakthrough seizure while swimming a year later. Analysis of his medical history showed that he had unexplained subtherapeutic serum levels of **valproate** and **phenytoin** on three occasions over the previous year. It was later found that the patient had also been taking numerous vitamins, supplements and herbal medicines without the knowledge of his physician, of which a ginkgo extract was stated to be the most common ingredient.[1] The only other herbal medicines named in the report were ginseng and saw palmetto.

In another case, a 78-year-old man, whose epileptic seizures had been well controlled by **valproate** 1.2 g daily for 7 years, suffered a cluster of seizures after taking a ginkgo extract 120 mg daily for 2 weeks for the management of mild cognitive impairment. The ginkgo was stopped and the patient was reportedly seizure-free 8 months later. All other medications taken by the patient remained unchanged.[2]

An 84-year-old epileptic woman with severe dementia taking **valproate** 1.2 g daily had been seizure-free for 2 years. After taking a ginkgo extract 120 mg daily for 12 days prescribed by her psychiatrist, she suffered a cluster of seizures, which were treated with intravenous diazepam in the emergency department. The ginkgo extract was stopped on admission and the patient remained free of seizures 4 months later. All other medications taken by the patient were unchanged.[2]

Mechanism

Unknown. Ginkgo *seeds* (nuts) contain the neurotoxin 4-*O*-methoxypyridoxine (ginkgotoxin), which indirectly inhibits the activity of glutamate decarboxylase, which in turn results in seizure induction by lowering the levels of γ-amino-butyric acid (GABA). A large quantity of ginkgo nuts (about 70 to 80) alone have been reported to be the cause of seizures in a healthy 36-year-old woman.[3] However, leaf extracts would not generally be expected to contain sufficient levels of this neurotoxin to be a problem.

Another possible mechanism is induction of the cytochrome P450 isoenzyme CYP2C19 by ginkgo. Phenytoin is a substrate of CYP2C19 and therefore, in theory, ginkgo may increase the metabolism of phenytoin and thereby reduce its levels. Ginkgo has been seen to induce CYP2C19 in clinical studies. See 'Proton pump inhibitors + Ginkgo (*Ginkgo biloba*)', p.1159.

Importance and management

Evidence for an interaction between ginkgo and valproate and phenytoin appears to be limited to case reports. The only case that measured serum levels of these antiepileptics is complicated by the use of numerous other supplements. An interaction is therefore by no means established. Nevertheless, it may be prudent to consider the possibility of reduced effects if a patients taking phenytoin and/or valproate wishes to also take ginkgo.

Antiepileptics + Mefloquine

A woman whose epilepsy was controlled with valproic acid developed convulsions when she took mefloquine.

Clinical evidence, mechanism, importance and management

An isolated report describes a 20-year-old woman, with a 7-year history of epilepsy (bilateral myoclonus and generalised tonic-clonic seizures) controlled with **valproic acid** 1.3 g daily, who developed tonic-clonic seizures 8 hours after taking the second of 3 prophylactic doses of mefloquine 250 mg.[1] It is not clear whether this resulted from a drug-drug or a drug-disease interaction. The manufacturer of mefloquine advises its avoidance in those with a history of convulsions as it may increase the risk of convulsions. In these patients mefloquine should be used only for curative treatment if compelling reasons exist.[2]

Antiepileptics + Melatonin

Carbamazepine levels are not affected by melatonin. Melatonin levels are predicted to be reduced by carbamazepine.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study on the effects of melatonin on antioxidant enzymes, melatonin 6 to 9 mg/kg daily for 14 days was given to children with epilepsy taking carbamazepine. The serum levels of carbamazepine and its metabolite carbamazepine-10,11-epoxide were not affected by melatonin. Melatonin appeared to antagonise the accumulation of reactive oxygen species (which can be damaging to cells in the body) caused by carbamazepine.[1]

One manufacturer predicts that carbamazepine may increase the metabolism of melatonin (by induction of the cytochrome P450 isoenzyme CYP1A2), thereby decreasing its levels.[2] However, note that carbamazepine is not a particularly potent inducer of this isoenzyme. Furthermore, when 22 children with epilepsy were given either **carbamazepine** or **valproate**, with a single 6- or 9-mg dose of melatonin, the serum levels of melatonin increased from 1.5 picograms/mL to 165 picograms/mL (range: 50 to 350 picograms/mL) in the **carbamazepine** group and from 1.3 picograms/mL to 78 picograms/mL (range 13 to 260 picograms/mL) in the **valproate** group. Although median levels of melatonin in the **carbamazepine** group were about twice those in the **valproate** group, the difference was not statistically significant because of the wide range of results.[3]

It appears that dose adjustments are unlikely to be needed on the concurrent use of melatonin and carbamazepine.

Antiepileptics; Enzyme-inducing + Quinine

Preliminary evidence suggests that the effects of carbamazepine and phenobarbital may be increased by quinine, possibly leading to toxicity. An isolated report suggests that phenytoin may reduce the levels of quinine but the levels of phenytoin do not appear to be affected by quinine.

Clinical evidence, mechanism, importance and management

Single doses of **carbamazepine** 200 mg, **phenobarbital** 120 mg or **phenytoin** 200 mg were given to 3 groups of 6 healthy subjects, with and without a single 600-mg dose of quinine sulfate. The AUC of **carbamazepine** and **phenobarbital** were increased by 104% and 57%, respectively, and the peak plasma levels were increased by 81% and 53%, respectively. **Phenytoin** was not significantly affected. The reasons for these effects are not known but the authors suggest that quinine inhibits the metabolism of **carbamazepine** and **phenobarbital** (but not **phenytoin**) by the liver, so that their levels become raised.[1]

In an earlier study in 2 healthy subjects, **phenobarbital** 125 mg daily for 4 days caused only a small reduction in the plasma half-life of quinine.[2]

Information seems to be limited to these studies. The importance of the interactions with **carbamazepine** and **phenobarbital** await assessment in a clinically realistic situation (i.e. in patients taking multiple doses) but in the meantime it would seem prudent to monitor for adverse effects of **carbamazepine** (e.g. nausea, vomiting, ataxia, drowsiness) or **phenobarbital** (e.g. hypotension, irritability, sedation) if quinine is also taken.

An isolated report describes a 22-month-old girl taking **phenytoin**, **sodium valproate** and **topiramate** for epilepsy was given quinine sulfate

(initially intravenously, then orally) followed by a single dose of sulfadoxine with pyrimethamine for malaria. Her malaria film became negative after 4 days of the 7-day quinine course. About one month later she was found to have recrudescent falciparum malaria, and so she was given quinine sulfate and then atovaquone with proguanil. Although it is possible that quinine resistance may have occurred, the authors also considered that enzyme induction by **phenytoin** may have led to suboptimal quinine levels.[3]

Although quinine does not appear to affect **phenytoin** levels, the isolated case report suggests that levels of quinine may be reduced in the presence of **phenytoin**. Until more is known it would seem prudent to monitor concurrent use carefully.

Antiepileptics + Quinolones

Studies suggest that ciprofloxacin, clinafloxacin, and enoxacin do not usually have a clinically significant effect on phenytoin levels. However, case reports describe both a rise and a fall in phenytoin levels in patients given ciprofloxacin.

Clinical evidence

(a) Ciprofloxacin

In a study in 4 healthy subjects there was no difference in the pharmacokinetics of **phenytoin** 200 mg daily when it was given with ciprofloxacin 500 mg twice daily. However, one of the 4 subjects experienced a 30% decrease in the **phenytoin** maximum serum levels when ciprofloxacin was added.[1] Four case reports describe falls of 50% or more in **phenytoin** serum levels when ciprofloxacin was added, accompanied by seizures in 3 instances.[2-5] Another report describes unexpectedly low **phenytoin** levels (measured after a loading dose) in a woman taking ciprofloxacin.[6]

Conversely, **phenytoin** levels rose in an elderly woman, possibly as a result of the ciprofloxacin she was taking.[7] In another study in 7 patients taking **phenytoin**, ciprofloxacin 500 mg twice daily for 10 days caused no significant change in **phenytoin** levels, although there was a tendency for an increase (mean 24% rise).[8]

In one report, blood levels of **phenytoin** and **valproic acid** were not affected by ciprofloxacin although a seizure occurred on the fourth day of concurrent use.[9] Other cases describe seizures in patients taking **phenytoin** when given ciprofloxacin, but with little or no information on **phenytoin** levels.[10]

(b) Clinafloxacin

In a study, **phenytoin** 300 mg daily was given to healthy subjects for 10 days, then clinafloxacin 400 mg twice daily was added for a further 2 weeks. The maximum serum **phenytoin** levels rose by 18% (from 6.74 to 7.95 mg/L), the AUC rose by 20% and the clearance fell by 17%.[11]

(c) Enoxacin

In a study in healthy subjects, enoxacin did not appear to alter **phenytoin** serum levels, nor were multiple-dose serum enoxacin levels significantly altered by **phenytoin**.[12]

Mechanism

Fluoroquinolones alone rarely cause convulsions both in patients with and without a history of seizures. The mechanism for the effect of ciprofloxacin on phenytoin levels is unknown, and is unlikely to be due to effects on hepatic metabolism or oral absorption.[13,14] However, ciprofloxacin decreased phenytoin levels in an *animal* study, and a suggested reason for this was increased urinary excretion.[15]

Importance and management

The known potential for quinolones to induce seizures suggests that these antibacterials should either be avoided in patients with epilepsy, or only used when the benefits of treatment outweigh the potential risks of seizures. Some of the reactions seem to be drug-disease interactions rather than drug-drug interactions, the usual outcome being that the control of epilepsy is worsened. However, it appears that ciprofloxacin may also alter (usually decrease) phenytoin levels, and if this combination is used it would be prudent to consider monitoring phenytoin levels. Enoxacin appears not to alter phenytoin levels.

Antiepileptics + St John's wort (*Hypericum perforatum*)

St John's wort modestly increased the clearance of single-dose carbamazepine in one study, but had no effect on multiple-dose carbamazepine pharmacokinetics in another study. Carbamazepine does not appear to significantly affect the pharmacokinetics of hypericin or pseudohypericin (constituents of St John's wort). St John's wort increases the clearance of mephenytoin, and is predicted to reduce the blood levels of phenytoin and phenobarbital, but this awaits clinical confirmation.

Clinical evidence

In a multiple-dose study in 8 healthy subjects, St John's wort had no effect on the pharmacokinetics of **carbamazepine** or its active metabolite, carbamazepine-10,11-epoxide. In this study, subjects took **carbamazepine** 200 mg increased to 400 mg daily alone for 20 days, then with St John's wort 300 mg (standardised to 0.3% hypericin) three times daily for a further 14 days.[1] In contrast, the AUC of a single 400-mg dose of **carbamazepine** was reduced by 21% after St John's wort 300 mg was given three times daily for 14 days, and the AUC of the 10,11-epoxide metabolite was increased by 26%.[2]

A double-blind, placebo-controlled study in healthy subjects found that, apart from a modest 29% decrease in the AUC of pseudohypericin, **carbamazepine** did not significantly affect the pharmacokinetics of either hypericin or pseudohypericin, which are both constituents of St John's wort.[3]

In another placebo-controlled study in 6 extensive metabolisers of CYP2C19 (that is, those with normal levels of this isoenzyme), St John's wort 300 mg three times daily for 14 days increased the clearance of a single oral dose of **mephenytoin** 100 mg given on day 15, by about 3-fold. There were no significant effects when **mephenytoin** was given to 6 poor metabolisers of CYP2C19 (that is, those lacking this isoenzyme). Each St John's wort tablet contained 0.3% hypericin and 4% hyperforin.[4]

Mechanism

St John's wort is a known inducer of the cytochrome P450 isoenzyme CYP3A4, and the results with single-dose carbamazepine are as predicted. However, carbamazepine is also an inducer of CYP3A4, which induces its own metabolism (autoinduction). It is suggested that St John's wort is not sufficiently potent an inducer to further induce carbamazepine metabolism

when autoinduction has occurred,[1] and therefore a small interaction is seen with single doses but no interaction is seen with multiple doses. However, the lack of effect seen in some of these studies may also be due to the different preparations used, and therefore differing levels of hyperforin.

Mephenytoin is a substrate of CYP2C19 and St John's wort appears to induce this isoenzyme.

Importance and management

The available evidence suggests that a clinically significant interaction between carbamazepine and St John's wort is unlikely. Before the publication of the above reports, the CSM in the UK had advised that patients taking a number of drugs including the antiepileptics carbamazepine, **phenytoin** and **phenobarbital** should not take St John's wort.[5] This advice was based on predicted pharmacokinetic interactions. In the light of the above studies, this advice may no longer apply to carbamazepine, although further study is needed. As the pharmacokinetic effects reported were modest, it may not be necessary for patients taking carbamazepine to avoid St John's wort; however, concurrent use should probably still be monitored to ensure adequate carbamazepine levels and efficacy.

Until more is known, it would probably be prudent to avoid the concurrent use of St John's wort in patients taking mephenytoin, **phenytoin** and **phenobarbital** (and therefore **primidone**), especially as **phenytoin** is also a substrate of CYP2C19, which St John's wort also appears to induce.

Antiepileptics + Terbinafine

A report describes the development of fatal toxic epidermal necrolysis shortly after a patient taking phenobarbital and carbamazepine started taking terbinafine. Another report describes elevated carbamazepine levels with symptoms of toxicity when a patient taking carbamazepine also took terbinafine.

Clinical evidence

A report describes a 26-year-old woman with cerebral palsy who had been taking **phenobarbital** 15 mg with **carbamazepine** 400 mg daily for 12 years to control epilepsy, and who developed fatal toxic epidermal necrolysis 2 weeks after starting oral terbinafine 250 mg daily for tinea corporis. The reasons are not understood, but the authors point out that all three drugs can cause adverse skin reactions (erythema multiforme) and suggest that some synergism may have occurred.[1] It is uncertain whether this was a true interaction or a terbinafine adverse effect.

A further report describes a 50-year-old man taking **carbamazepine** who developed symptoms of **carbamazepine** toxicity including gait ataxia, dizziness and falls and raised carbamazepine levels about 3 days after starting to take terbinafine 250 mg daily. These symptoms resolved on stopping the terbinafine, but recurred when treatment was restarted. It was suggested that terbinafine may have inhibited the metabolism of **carbamazepine**. A **carbamazepine** level of 17.2 micrograms/mL was recorded, which had only fallen to 2 micrograms/mL 10 days after stopping all treatment.[2]

Mechanism

The mechanism of this interaction is unclear, as terbinafine is thought to only affect the cytochrome P450 isoenzyme CYP2D6, which is not a major route of carbamazepine metabolism.

An antiepileptic drug hypersensitivity syndrome characterised by fever, skin rash (which may rarely be severe) and internal organ involvement (agranulocytosis, hepatitis, nephritis, and myositis) may occur 2 to 8 weeks after starting treatment with carbamazepine or phenytoin. As the patient in the first case report had been taking these drugs for several years, they are unlikely to be the cause, but this syndrome may also occur with other drugs including terbinafine.[3]

Importance and management

These appear to be isolated cases, and their general significance is unknown. If a patient taking terbinafine and carbamazepine experiences otherwise unexplained signs of carbamazepine toxicity (e.g. nausea, vomiting, ataxia and drowsiness) it may be prudent to suspect an interaction. Take carbamazepine levels and adjust the dose accordingly.

Antiepileptics; Enzyme-inducing + Tobacco

Smoking tobacco appears to have no important effect on the serum levels of phenytoin, phenobarbital or carbamazepine.

Clinical evidence, mechanism, importance and management

A comparative study in 88 patients with epilepsy, taking **phenobarbital**, **phenytoin** and **carbamazepine** alone or in combination, found that although tobacco smoking had a tendency to lower the steady-state serum levels of these drugs, a statistically significant effect on the concentration-dose ratios was only found in the patients taking **phenobarbital**.[1] However, in another study in healthy subjects, there was no difference in the pharmacokinetics of a single 60-mg dose of **phenobarbital** in smokers and non-smokers.[2] In practical terms smoking appears to have only a negligible effect on the serum levels of these antiepileptic drugs and patients with epilepsy who smoke are unlikely to need higher doses than non-smokers.

Antiepileptics; Enzyme-inducing + Vitamin B substances

High daily doses of pyridoxine can reduce phenytoin and phenobarbital levels in some patients. Some evidence suggests that high doses of nicotinamide reduce the conversion of primidone to phenobarbital, and increase carbamazepine levels.

Clinical evidence

(a) Nicotinamide

Nicotinamide 41 to 178 mg/kg daily increased the levels of **primidone** and decreased the levels of **primidone**-derived phenobarbital in 3 children. Although two of the children had refractory seizures, seizure frequency decreased while they were taking nicotinamide. Two of the children taking **carbamazepine** had increases in their **carbamazepine** levels.[1]

(b) Pyridoxine

Pyridoxine 200 mg daily for 4 weeks reduced the **phenobarbital** serum levels of 5 patients with epilepsy by about 50%. Reductions in serum **phenytoin** levels of about 35% (range 17 to 70%) were also seen when patients were given pyridoxine 80 to 400 mg daily for 2 to 4 weeks. However, no interaction occurred in a number of other patients taking these drugs.[2]

Mechanism

It is suggested that the pyridoxine increases and nicotinamide decreases the activity of the liver enzymes concerned with the metabolism of these antiepileptics.[1,2]

Importance and management

Information seems to be limited, but what is known suggests that the concurrent use of carbamazepine, phenytoin, phenobarbital or primidone should be monitored if large doses of pyridoxine or nicotinamide are used, being alert for the need to modify the antiepileptic dose. It seems unlikely that small doses (as in multivitamin preparations) will interact to any great extent.

Carbamazepine + Allopurinol

There is some evidence to suggest that high-dose allopurinol (15 mg/kg or 600 mg daily) can gradually raise serum carbamazepine levels by about one-third. It appears that allopurinol 300 mg daily has no effect on carbamazepine levels.

Clinical evidence

In a 6-month study, 7 patients with epilepsy taking antiepileptics including carbamazepine, were also given allopurinol 100 mg three times daily for 3 months then 200 mg three times daily for 3 months. The mean trough steady-state serum carbamazepine levels of 6 of the patients rose by 30% or more and the carbamazepine clearance fell by 32% during the second 3-month period. A reduction in the carbamazepine dose was needed in 3 patients because of the symptoms that developed.[1] Similarly, in 11 patients taking antiepileptics including carbamazepine, allopurinol 10 mg/kg increased to 15 mg/kg daily for 12 weeks increased carbamazepine levels by 29%.[2] Conversely, in another study, allopurinol (150 mg daily in those less than 20 kg, and 300 mg daily for other patients) for 4 months had no effect on carbamazepine levels in 53 patients taking antiepileptics including carbamazepine.[3]

Mechanism

Uncertain. A possible explanation is that allopurinol can act as a liver enzyme inhibitor, which reduces the metabolism and clearance of carbamazepine.

Importance and management

Information is limited to these studies, but be alert for the need to reduce the dose of carbamazepine if high doses of allopurinol are used long-term. This interaction apparently takes several weeks or even months to develop fully. From one study, it appears that no interaction occurs between carbamazepine and low-dose allopurinol (such as that used for gout).

Carbamazepine + Amiodarone

Amiodarone does not appear to affect the pharmacokinetics of carbamazepine.

Clinical evidence, mechanism, importance and management

A single 400-mg dose of carbamazepine was given to 9 patients with cardiac disease (premature ventricular contractions, supraventricular tachycardia, sinus arrhythmia) before and after they took amiodarone 200 mg twice daily for a month. The pharmacokinetics of carbamazepine were found to be unchanged by amiodarone. This suggests that no clinically important interaction occurs, but it needs confirmation in patients who are given both drugs long term. Furthermore, the authors postulate that a higher amiodarone dose may inhibit the metabolism of the carbamazepine by the liver,[1] this also needs confirmation.

1. Leite SAO, Leite PJM, Rocha GA, Routledge PA, Bittencourt PRM. Carbamazepine kinetics in cardiac patients before and during amiodarone. *Arq Neuropsiquiatr* (1994) 52, 210–15.

Carbamazepine + Aspirin or NSAIDs

Carbamazepine levels are unaffected by aspirin or tolfenamic acid.

Clinical evidence, mechanism, importance and management

The carbamazepine levels of 10 patients were unaffected when they took aspirin 1.5 g daily for 3 days.[1] Similarly, the carbamazepine levels of 11 patients were not significantly affected by tolfenamic acid 300 mg, given for 3 days. It would appear that no carbamazepine dose adjustments are necessary in patients also given aspirin or tolfenamic acid.

Carbamazepine + Azoles

Ketoconazole causes a small to moderate rise in serum carbamazepine levels. Case reports describe a marked rise in carbamazepine levels in patients taking fluconazole; sometimes accompanied by toxicity. Adverse effects were seen in another patient when carbamazepine was given with miconazole. Carbamazepine may markedly reduce the levels of itraconazole, and is predicted to lower the levels of posaconazole and voriconazole.

Clinical evidence

(a) Fluconazole

A 33-year-old man whose seizures were stabilised by carbamazepine became extremely lethargic after taking fluconazole 150 mg daily for 3 days. His carbamazepine level was found to have risen from 11.1 micrograms/mL to 24.5 micrograms/mL. Symptoms resolved when both drugs were stopped, and carbamazepine was later re-introduced without problem.[1] Another patient, treated with carbamazepine, lamotrigine and barbexaclone for many years, developed blurred vision and dizziness when she took fluconazole 150 mg with her morning dose of antiepileptics. The symptoms worsened over 11 days of fluconazole treatment during which she complained of severe diplopia, oscillopsia, nausea, vomiting and gait instability and levels of carbamazepine were found to have more than doubled. Twenty-four hours after fluconazole withdrawal, carbamazepine levels returned to normal and the symptoms resolved. Lamotrigine and **barbexaclone** levels were not significantly affected by concurrent fluconazole.[2] Another well-documented case report describes a threefold increase in carbamazepine levels (without any signs of toxicity) 10 days after fluconazole 400 mg daily was started.[3]

(b) Itraconazole

A patient taking itraconazole 200 mg daily was noted to have low itraconazole levels (0.15 mg/L) about 14 days after starting carbamazepine 400 mg daily; about 2 months later itraconazole was undetectable. About 3 weeks after stopping carbamazepine, the itraconazole levels had reached the reference range (0.36 mg/L).[4]

For mention of 2 patients taking carbamazepine with phenytoin, who had undetectable or very low itraconazole levels, and who relapsed or did not respond to itraconazole, see 'Phenytoin + Azoles', p.630.

(c) Ketoconazole

A study in 8 patients with epilepsy taking carbamazepine found that oral ketoconazole 200 mg daily for 10 days increased their serum carbamazepine levels by 29% (from 5.6 micrograms/mL to 7.2 micrograms/mL) without affecting carbamazepine-10,11-epoxide levels. When the ketoconazole was stopped the serum carbamazepine levels returned to their former levels.[5]

(d) Miconazole

A patient receiving long-term treatment with carbamazepine 400 mg daily developed malaise, myoclonia and tremor within 3 days of being given oral miconazole 1.125 g. The same reaction occurred on each subsequent occasion that miconazole was given. These toxic effects disappeared when miconazole was withdrawn.[6]

Mechanism

Carbamazepine levels are thought to rise because azole antifungals inhibit the cytochrome P450 isoenzyme CYP3A4, which is concerned with the metabolism of carbamazepine. Different azoles affect CYP3A4 to varying degrees, see 'azole antifungals', (p.233). Carbamazepine is an enzyme inducer, and appears to decrease the levels of azole antifungals by increasing their metabolism.

Importance and management

Evidence for these interactions is limited and in some cases the effects are only modest. Nevertheless, it would seem prudent to monitor the outcome of adding azole antifungals to established carbamazepine treatment, being alert for any evidence of increased carbamazepine adverse effects (e.g. nausea, vomiting, ataxia and drowsiness).

Note also that carbamazepine may reduce the levels of azole antifungals: a marked reduction in itraconazole levels has been reported, and one manufacturer of itraconazole consequently says that the concurrent use of carbamazepine is not recommended.[7] Based on the interaction with 'phenytoin', (p.630), which results in reduced **posaconazole** levels, the manufacturer of posaconazole suggests that concurrent use of carbamazepine should be avoided, unless the benefits outweigh the risks.[8] If both drugs are given it would seem sensible to consider increasing the posaconazole dose, and increase monitoring of carbamazepine levels. Similarly, the manufacturers of **voriconazole** contraindicate the concurrent use of carbamazepine.[9,10]

Carbamazepine + Bile-acid binding resins

In a study in 6 healthy subjects, colestyramine 8 g did not affect the absorption of carbamazepine 400 mg, whereas colestipol 10 g reduced it by 10%. Both colestyramine and colestipol were given as a single dose 5 minutes after the carbamazepine.[1] This small reduction is unlikely to be clinically important.

1. Neuvonen PJ, Kivistö K, Hirvisalo EL. Effects of resins and activated charcoal on the absorption of digoxin, carbamazepine and frusemide. *Br J Clin Pharmacol* (1988) 25, 229–33.

Carbamazepine or Oxcarbazepine + Calcium-channel blockers

Both diltiazem and verapamil can increase carbamazepine levels causing toxicity. A single case report describes neurological toxicity in a patient taking phenytoin and carbamazepine with isradipine. Limited evidence suggests that amlodipine and nifedipine do not affect carbamazepine levels.

The plasma levels of felodipine, nifedipine, nilvadipine, and nimodipine are reduced by carbamazepine. Felodipine levels are slightly reduced by oxcarbazepine.

Clinical evidence

(a) Diltiazem

An patient with epilepsy taking carbamazepine 400 mg in the morning and 600 mg in the evening developed symptoms of toxicity (dizziness, nausea, ataxia and diplopia) within 2 days of starting to take diltiazem 60 mg three times daily. His serum carbamazepine levels had risen by about 40% to 21 micrograms/mL, but fell again when the diltiazem was stopped. No interaction occurred when the diltiazem was replaced by **nifedipine** 20 mg three times daily.[1] Other case reports describe carbamazepine toxicity and a rise in serum levels of up to fourfold in a total of 11 patients given diltiazem.[2-7] One patient required a 62% reduction in the carbamazepine dose.[2] Another patient had a marked fall in serum carbamazepine levels of 54% when diltiazem was *stopped*.[8]

For a further case report involving diltiazem, see *Nifedipine*, below.

(b) Felodipine

After taking felodipine 10 mg daily for 4 days, 10 patients with epilepsy (including 4 taking carbamazepine alone and 3 taking carbamazepine with phenytoin) had markedly reduced plasma felodipine levels (peak levels of 1.6 nanomol/L compared with 8.9 nanomol/L in 12 control subjects). The felodipine bioavailability was reduced to 6.6%.[9] A study in 8 subjects found that the AUC of felodipine was reduced by only 28% by oxcarbazepine 600 to 900 mg daily for a week.[10]

(c) Isradipine

A man taking carbamazepine and phenytoin developed neurological toxicity while taking isradipine, which was attributed to an interaction between the phenytoin and isradipine.[11] However, although carbamazepine levels remained within normal limits, a commentator suggested that an interaction between carbamazepine and isradipine was plausible.[12]

(d) Nifedipine

In 12 patients with epilepsy, nifedipine 20 mg twice daily for 2 weeks did not affect the steady-state carbamazepine levels.[13] Similarly, a retrospective study of 5 patients suggested that nifedipine does not usually raise carbamazepine levels or cause toxicity.[4] However, a man had a marked rise in serum carbamazepine levels when nifedipine was replaced by **diltiazem**. When **diltiazem** was replaced by **amlodipine**, his carbamazepine levels returned to normal, suggesting that neither nifedipine nor **amlodipine** interact with carbamazepine.[14] Another patient had no change in carbamazepine levels when also given nifedipine.[1]

A study in 12 patients with epilepsy receiving long-term treatment with carbamazepine found that the AUC of concurrent nifedipine 20 mg was only 22% of the values seen in 12 healthy subjects not taking carbamazepine.[13]

(e) Nilvadipine

A 59-year-old man taking nilvadipine 8 mg daily for hypertension and haloperidol for psychotic symptoms was given carbamazepine because haloperidol alone did not control symptoms of mania. The carbamazepine dose was gradually increased from 100 mg to 600 mg daily. Although the manic symptoms were improved, his blood pressure rose to 230/140 mmHg after 3 days of treatment with carbamazepine 600 mg daily. Blood pressure was temporarily controlled by **nifedipine** 10 mg sublingually. Retrospective analyses found that plasma levels of nilvadipine were reduced during the use of carbamazepine 100 and 300 mg daily and undetectable when the carbamazepine dose was increased to 600 mg daily. Plasma levels of nilvadipine rose after carbamazepine was discontinued and blood pressure returned to normal after about 2 weeks.[15]

(f) Nimodipine

A study in 8 patients with epilepsy receiving long-term treatment (including 2 taking carbamazepine with phenobarbital, one taking carbamazepine with clobazam, and one taking carbamazepine with phenytoin) found that the AUC of a single 60-mg oral dose of nimodipine was only about 15% of that achieved in a group of healthy subjects,[16] suggesting that carbamazepine lowers nimodipine exposure.

(g) Verapamil

Carbamazepine toxicity developed in 6 patients with epilepsy within 36 to 96 hours of them starting to take verapamil 120 mg three times daily. The symptoms disappeared when the verapamil was withdrawn. Total carbamazepine plasma levels had risen by 46% (a 33% rise in free plasma carbamazepine levels). Rechallenge of two of the patients, who only experienced mild toxicity with a lower dose of verapamil 120 mg twice a day, caused a similar rise in serum verapamil levels, again with mild toxicity. This report also describes another patient who had elevated serum carbamazepine levels while also taking verapamil.[17] Carbamazepine toxicity is described in 3 other patients, again caused by verapamil.[18,19] The verapamil was successfully replaced by **nifedipine** in one patient.[18]

In a study, 10 healthy subjects were given oxcarbazepine 450 mg twice

daily and then also verapamil 120 mg twice daily for 5 days. The AUC of the monohydroxy derivative of the oxcarbazepine (the active metabolite) fell by about 20% but oxcarbazepine levels were unaltered.[20]

Mechanism

It would appear that diltiazem and verapamil inhibit the metabolism of carbamazepine by the cytochrome P450 isoenzyme CYP3A4, thereby reducing its loss from the body and increasing serum levels. In contrast, carbamazepine is an enzyme inducer, which increases the metabolism of the calcium-channel blockers by the liver, resulting in a very rapid loss from the body.

Importance and management

Information about the effects of calcium-channel blockers on carbamazepine is limited, but what is known indicates that if carbamazepine is given with verapamil or diltiazem, the carbamazepine dose may possibly need to be reduced to avoid toxicity. A 50% reduction in the dose of carbamazepine has been suggested if diltiazem is to be used.[5] Nifedipine and amlodipine normally appear to be non-interacting alternatives. Oxcarbazepine appears to be a non-interacting alternative for carbamazepine.

Carbamazepine has been shown to lower the levels of a number of calcium-channel blockers. Given that the majority are metabolised by CYP3A4 (see 'calcium-channel blockers', (p.1025)) most calcium-channel blockers would be expected to interact similarly. If a calcium-channel blocker is given to a patient taking carbamazepine expect to need to use a larger dose. If carbamazepine is added to existing treatment with a calcium-channel blocker monitor the blood pressure and expect to need to increase the dose. Note that the manufacturer of nimodipine[21] contraindicates its use with carbamazepine. Oxcarbazepine interacts to a lesser extent than carbamazepine and it may therefore be a suitable alternative in some patients.

Carbamazepine + Danazol

Serum carbamazepine levels can be doubled by danazol and carbamazepine toxicity may occur.

Clinical evidence

The serum carbamazepine levels of 6 patients with epilepsy approximately doubled within 7 to 30 days of taking danazol 400 to 600 mg daily. Acute carbamazepine toxicity (dizziness, drowsiness, blurred vision, ataxia, nausea) was experienced by 5 out of the 6 patients.[1]

Other reports similarly describe rises in serum carbamazepine levels of 50 to 100% (with toxicity seen in some instances) when danazol was given.[2-4]

Mechanism

Danazol inhibits the metabolism (by the epoxide-trans-diol pathway) of carbamazepine by the liver, thereby reducing its loss from the body.[2,5] During the use of danazol the clearance of carbamazepine has been found to be reduced by 60%.[2]

Importance and management

An established and clinically important interaction. If concurrent use is necessary carbamazepine serum levels should be monitored and the dose reduced as necessary.

Carbamazepine + Dantrolene and Oxybutynin

Carbamazepine toxicity has been reported in a patient given oxybutynin and dantrolene.

Clinical evidence, mechanism, importance and management

A woman with incomplete tetraplegia who had taken carbamazepine 1 g daily for neuropathic pain for 2 years was given dantrolene in a gradually increasing dose and oxybutynin 5 mg twice daily. Two weeks after starting oxybutynin and while receiving dantrolene 125 mg daily, she experienced dizziness and vomiting, drowsiness, confusion, slurred speech, and nystagmus, and was found to have a raised carbamazepine level of 16 micrograms/mL. All drugs were stopped and the plasma carbamazepine level fell to 8.3 micrograms/mL (reference range 4 to 12 micrograms/mL). Because of pain, urinary frequency and spasticity, daily doses of carbamazepine 600 mg, oxybutynin 10 mg and dantrolene 100 mg were restarted, which resulted in a carbamazepine level of 9.2 micrograms/mL. The dantrolene dose was increased to 125 mg daily because of continuing spasticity, but after one day, symptoms of carbamazepine toxicity occurred and the carbamazepine plasma level was 29 micrograms/mL. Carbamazepine and oxybutynin were discontinued and the dantrolene dose was reduced to 25 mg. In order to relieve the patient's symptoms of pain and spasticity, carbamazepine 400 mg daily and dantrolene 25 mg daily were given (carbamazepine levels of 8.4 micrograms/mL at 7 days). The addition of oxybutynin 5 mg daily was associated with an increase in the carbamazepine level to 32 micrograms/mL and symptoms of toxicity. Carbamazepine was replaced by valproate 600 mg daily, which appeared to be beneficial and without an interaction with dantrolene or oxybutynin.[1]

Oxybutynin was being taken on each occasion when carbamazepine levels increased and therefore it was suggested that oxybutynin inhibited the metabolism of carbamazepine by the cytochrome P450 isoenzyme CYP3A4. Dantrolene was also being taken and the second episode of carbamazepine toxicity occurred after the dantrolene dose was increased. The exact mechanism of dantrolene metabolism is not known but it may decrease the activity of cytochrome P450 isoenzymes in a dose-dependent manner. However, there appears to be little evidence to suggest that these two drugs generally inhibit the metabolism of other drugs, and therefore the mechanism, and an interaction, is not established. The authors recommend careful monitoring and, if necessary, dose adjustments if carbamazepine is given with dantrolene and/or oxybutynin.[1]

Carbamazepine + Dextromethorphan

Dextromethorphan appears not to affect the serum levels of carbamazepine.

Clinical evidence, mechanism, importance and management

A double-blind, crossover study in 5 patients with severe complex partial seizures found that dextromethorphan 120 mg daily in liquid form (*Delsym*) over 3 months had no effect on their serum carbamazepine levels. There was a non-significant alteration in the complex partial seizure and tonic-clonic seizure frequency.[1] No carbamazepine dose adjustment therefore appears necessary if dextromethorphan is also taken.

Carbamazepine or Oxcarbazepine + Dextropropoxyphene (Propoxyphene)

Carbamazepine levels can be raised by dextropropoxyphene. Oxcarbazepine appears not to interact with dextropropoxyphene.

Clinical evidence

(a) Carbamazepine

The observation of toxicity (headache, dizziness, ataxia, nausea, tiredness) in patients taking both carbamazepine and dextropropoxyphene prompted further study. Five patients taking carbamazepine who were given dextropropoxyphene 65 mg three times daily had a mean rise in their serum carbamazepine levels of 65%, and 3 patients developed signs of carbamazepine toxicity. Carbamazepine levels were not taken in a further 2 patients because they withdrew from the study after 2 days of treatment due to adverse effects.[1,2] In a further study a 66% rise in carbamazepine levels was seen after 6 days of treatment with dextropropoxyphene.[3]

Carbamazepine toxicity due to this interaction has been reported elsewhere,[4-7] and rises in trough serum carbamazepine levels of 69% to 600% have been described.[8] A study in the elderly compared groups of patients taking either carbamazepine or dextropropoxyphene alone, with patients taking both drugs (21 subjects). The carbamazepine dose was about one-third lower in those taking both drugs, yet the mean serum carbamazepine levels were still 25% higher than in the patients not taking dextropropoxyphene. The prevalence of adverse effects was also higher in patients taking both drugs.[9]

(b) Oxcarbazepine

In a study in 7 patients with epilepsy or trigeminal neuralgia, dextropropoxyphene 65 mg three times daily for 7 days did not affect the steady-state levels of the active metabolite of oxcarbazepine.[10]

Mechanism

Uncertain. It is suggested that dextropropoxyphene inhibits the metabolism of carbamazepine by the liver, leading to its accumulation in the body.[1,2]

Importance and management

The interaction between carbamazepine and dextropropoxyphene is very well established and clinically important. If concurrent use is necessary reduce the dose of carbamazepine appropriately to prevent the development of toxicity. In many cases it may be simpler to use a non-interacting analgesic, although the occasional single dose of dextropropoxyphene probably does not matter. No special precautions seem necessary with oxcarbazepine.

Carbamazepine or Oxcarbazepine + Diuretics

Hyponatraemia has been reported in patients taking carbamazepine with furosemide, hydrochlorothiazide, or hydrochlorothiazide and paroxetine. Hyponatraemia occurred in another patient taking oxcarbazepine and furosemide.

Clinical evidence, mechanism, importance and management

Two patients with epilepsy taking carbamazepine developed symptomatic hyponatraemia while also taking **hydrochlorothiazide** or **furosemide**.[1] Another case has been described when a patient taking carbamazepine also took **hydrochlorothiazide** and paroxetine.[2] A further case describes a patient taking **hydrochlorothiazide** who developed hyponatraemia within 2 weeks of starting to take carbamazepine 200 mg twice daily. Carbamazepine was continued but **hydrochlorothiazide** was stopped and sodium levels returned to normal within one week indicating that in this patient each drug appeared to be well tolerated alone.[3]

Another report describes a patient with a 20-year history of complex partial seizures treated with oxcarbazepine 1800 mg daily (30 mg/kg daily) who developed confusion, auditory and visual hallucinations and delirium about one month after starting to take **furosemide** 25 mg daily for hypertension. Sodium levels were found to have decreased from 138 mmol/L to 115 mmol/L with concurrent **furosemide** and an EEG showed abnormal activity compared to baseline values before she started **furosemide**. Oxcarbazepine and **furosemide** were stopped and valproic acid and amlodipine started, and within 20 days the neurological symptoms had stopped, the EEG normalised to baseline, and sodium levels increased to within the reference range.[4]

The reasons for the interaction between carbamazepine or oxcarbazepine and diuretics are uncertain but all these drugs can cause sodium to be lost from the body. This seems to be an uncommon interaction, but be aware that it can occur.

Carbamazepine + Felbamate

Felbamate modestly reduces serum carbamazepine levels but increases the levels of the active metabolite, carbamazepine-10,11-epoxide. Carbamazepine may reduce felbamate levels.

Clinical evidence

The serum carbamazepine levels of 22 patients, with doses adjusted to keep levels in the range of 4 to 12 micrograms/mL, fell by 25% (range 10 to 42%) when they were given felbamate 3 g daily. The decrease occurred within a week, reaching a plateau after 2 to 4 weeks, and returning to the original levels within 2 to 3 weeks of stopping the felbamate.[1] Other studies in patients with epilepsy have found reductions in carbamazepine levels of between 18 and 31% when felbamate was given.[2-7] Some of these studies also found that the serum levels of the active carbamazepine metabolite carbamazepine-10,11-epoxide rose by 33 to 57%.[1,4,5]

Carbamazepine increases the clearance of felbamate by up to about 50%.[8-10]

Mechanism

Not established. Felbamate does not induce the metabolism of carbamazepine by the cytochrome P450 isoenzyme CYP3A4, but it does appear to alter the interaction of carbamazepine with CYP3A4.[11]

Importance and management

This interaction is established, but its clinical importance is uncertain because the modest fall in serum carbamazepine levels would seem to be offset by the rise in the levels of its metabolite, carbamazepine-10,11-epoxide, which also has antiepileptic activity. However, be alert for any changes in the antiepileptic control and consider monitoring carbamazepine levels, adjusting the dose as necessary. The importance of the increased felbamate clearance is uncertain. More study is needed.

Carbamazepine + Gemfibrozil

Two patients had a rise in their carbamazepine levels after they took gemfibrozil.

Clinical evidence, mechanism, importance and management

Two patients, stable taking carbamazepine, had rises in their serum carbamazepine levels when they were given gemfibrozil for type IV hyperlipoproteinaemia. One patient had a rise of about 30% (from 8.8 micrograms/mL to 11.4 micrograms/mL) within 4 days of starting to take gemfibrozil 300 mg daily, and the other patient had a rise of 65% (from 8.3 micrograms/mL to 13.7 micrograms/mL) three months after gemfibrozil 300 mg twice daily was started.[1] It was suggested that the clearance of carbamazepine is increased in those with elevated cholesterol and total lipids. Thus, when the condition is treated with gemfibrozil, the clearance becomes more normal, which results in a rise in the serum carbamazepine levels.[2] These appear to be the only reports of an interaction, and their clinical importance is uncertain, but consider the possibility of an interaction if carbamazepine toxicity (nausea, vomiting, ataxia and drowsiness) develops in a patient given gemfibrozil.

Carbamazepine + Grapefruit juice

Grapefruit juice increases carbamazepine levels. A case of possible carbamazepine toxicity has been seen when a man taking carbamazepine started to eat grapefruit.

Clinical evidence

A 58-year-old man, taking carbamazepine 1 g daily for epilepsy, developed visual disturbances with diplopia, and was found to have a carbamazepine level of 11 micrograms/mL (reference range 4 to 10 micrograms/mL). Previous levels had not exceeded 5.4 micrograms/mL. The patient said that one month previously he had started to eat one whole grapefruit each day. The levels restabilised at 5.1 micrograms/mL after the carbamazepine dose was reduced to 800 mg daily.[1]

A randomised, crossover study in 10 patients with epilepsy taking carbamazepine 200 mg three times daily found that a single 300-mL drink of grapefruit juice increased the plasma levels and AUC of carbamazepine by about 40%.[2]

Mechanism

The cytochrome P450 isoenzyme CYP3A4 is the main enzyme involved in the metabolism of carbamazepine.[3] Components of whole grapefruit and grapefruit juice are known to inhibit CYP3A4, which could lead to a reduction in the metabolism of carbamazepine, and therefore an increase in its levels.[1,2,4]

Importance and management

Although the information is sparse, the interaction has been predicted, demonstrated in a study, and has also occurred in practice. The authors of the study[2] suggest that grapefruit juice should be avoided in patients taking carbamazepine. In the case report,[1] the patient continued to eat grapefruit, and this was successfully managed by a reduction in the carbamazepine dose. However, it should be noted that intake of a set amount of grapefruit would need to be maintained for this approach to have a chance of working, and even then, the natural variability in the constituents of grapefruit may make adequate control difficult. The manufacturers advise carbamazepine dose adjustment and monitoring of carbamazepine levels in patients taking substances that may raise carbamazepine levels, such as grapefruit juice.[3] If monitoring is not practical, or regular intake of grapefruit is not desired, it would seem prudent to avoid grapefruit and grapefruit juice.

Carbamazepine or Oxcarbazepine + H_2-receptor antagonists

The serum levels of those taking long-term carbamazepine may transiently increase, possibly accompanied by an increase in adverse effects, for the first few days after starting to take cimetidine, but these adverse effects rapidly disappear. Cimetidine does not appear to have this effect on oxcarbazepine levels. Ranitidine appears not to interact with carbamazepine.

Clinical evidence

(a) Carbamazepine

The steady-state carbamazepine levels of 8 healthy subjects taking carbamazepine 300 mg twice daily were increased by 17% within 2 days of them starting to take **cimetidine** 400 mg three times daily. Adverse effects occurred in 6 subjects, but after 7 days of treatment the carbamazepine levels had fallen again and the adverse effects disappeared.[1]

Conversely, the steady-state carbamazepine levels of 7 epileptic patients receiving long-term treatment remained unaltered when they were given **cimetidine** 1 g daily for a week.[2] Another study also found a lack of an interaction in 11 patients with epilepsy.[3] However, an 89-year-old woman taking carbamazepine 600 mg daily developed symptoms of carbamazepine toxicity within 2 days of starting to take **cimetidine** 400 mg daily, and had a rise in serum carbamazepine levels, which fell when the **cimetidine** was withdrawn.[4] The effects of **cimetidine** may be additive with those of isoniazid, see 'Carbamazepine + Isoniazid or Rifampicin (Rifampin)', p.605.

The results of these studies in patients and subjects taking carbamazepine long-term differ from single-dose studies and short-term stud-

ies in healthy subjects. For example, a 20% fall in clearance[5] and a 26% increase in the AUC[6] have been reported, which would indicate that there may be some potential for a clinically significant interaction (see 'Mechanism' below).

In 8 healthy subjects **ranitidine** 300 mg daily did not affect the pharmacokinetics of a single 600-mg dose of carbamazepine.[7]

(b) Oxcarbazepine

In 8 healthy subjects, **cimetidine** 400 mg twice daily for 7 days did not affect the pharmacokinetics of a single 600-mg oral dose of oxcarbazepine.[8]

Mechanism

Not fully understood. It is thought that cimetidine can inhibit the activity of the liver enzymes concerned with the metabolism of carbamazepine (such as the cytochrome P450 isoenzyme CYP3A4), resulting in its reduced clearance from the body. The auto-inducing effects of carbamazepine oppose this, although one study suggests the autoinducing effects of carbamazepine are blocked by cimetidine.[9] However, autoinduction would possibly explain why the single-dose and short-term studies in healthy subjects suggest that a clinically important interaction could occur, but in practice the combination causes few problems in patients receiving long-term carbamazepine.

Importance and management

The interaction between carbamazepine and cimetidine is established but of minimal importance. Patients receiving long-term treatment with carbamazepine should be warned that for the first few days after starting to take cimetidine they may possibly experience some increase in carbamazepine adverse effects (nausea, headache, dizziness, fatigue, drowsiness, ataxia, an inability to concentrate, a bitter taste). However, because the serum levels are only transiently increased, these effects should subside and disappear by the end of a week. Ranitidine appears to be a non-interacting alternative to cimetidine.

Carbamazepine + Influenza vaccines

Influenza vaccination appears to raise carbamazepine levels. In one case this resulted in carbamazepine toxicity.

Clinical evidence, mechanism, importance and management

The serum carbamazepine levels of 20 children rose by 47% from 6.17 micrograms/mL to 9.04 micrograms/mL 14 days after they were given 0.5 mL of influenza vaccine USP, types A and B, whole virus (Squibb). Levels remained elevated on day 28.[1] A teenager taking carbamazepine 400 mg in the morning and 600 mg at night with gabapentin 600 mg three times daily developed signs of carbamazepine toxicity (unsteady, lethargic, slurred speech) 13 days after she was given an influenza vaccination (*Fluzone*, Aventis Pasteur). Her serum carbamazepine level was 27.5 micrograms/mL (previous levels 8.2 to 12.4 micrograms/mL), and she required ventilation for 19 hours. A urine drug screen was positive for tricyclic antidepressants and cocaine, but it was eventually concluded that these were likely to represent false-positive results.[2]

It has been suggested that the vaccine inhibits the liver enzymes concerned with the metabolism of carbamazepine, and therefore raises its levels. The moderate increase in serum carbamazepine levels seen in the first study is unlikely to have much clinical relevance as the vaccine is usually given as a single dose and therefore levels will decline over time. However, the case report of markedly increased carbamazepine levels introduces a note of caution.

Carbamazepine + Isoniazid or Rifampicin (Rifampin)

Carbamazepine levels are markedly and very rapidly increased by isoniazid and toxicity can occur. Rifampicin has been reported both to augment and negate this interaction. There is evidence to suggest that carbamazepine may potentiate isoniazid hepatotoxicity.

Clinical evidence

Disorientation, listlessness, aggression, lethargy and, in one case, extreme drowsiness developed in 10 out of 13 patients taking carbamazepine when they were given isoniazid 200 mg daily. Serum carbamazepine levels were measured in 3 of the patients and they were found to have risen above the reference range (initial level not stated).[1]

Carbamazepine toxicity, associated with marked rises in serum carbamazepine levels, has been described in other reports.[2-5] Some of the patients were also taking sodium valproate, which does not seem to be implicated in the interaction, and in one case cimetidine (see also 'Carbamazepine or Oxcarbazepine + H_2-receptor antagonists', p.604) was thought to have potentiated the interaction.[5]

One report describes carbamazepine toxicity in a patient given isoniazid, but only when rifampicin was present as well. Usually the enzyme-inducing effects of rifampicin would be expected to counteract any enzyme inhibition by isoniazid, so this report is somewhat inexplicable.[6] Conversely, a case report describes reduced carbamazepine levels in a woman given rifampicin and isoniazid, which resulted in reduced carbamazepine efficacy (symptoms of hypomania).[7]

Isoniazid-induced fulminant liver failure occurred in a 16-year-old girl taking carbamazepine and clonazepam, within 5 days of starting isoniazid, rifampicin and pyrazinamide. She recovered with supportive measures and later tolerated the antiepileptics with concurrent rifampicin and pyrazinamide.[8] Isoniazid hepatotoxicity has also occurred in a 74-year-old woman[9] and a 10-year-old boy[10] taking carbamazepine, shortly after treatment with isoniazid, rifampicin, and ethambutol, with or without pyrazinamide, was started.

Mechanism

Unknown. It has been suggested that isoniazid inhibits the activity of the cytochrome P450 isoenzyme CYP3A4, which is concerned with the metabolism of carbamazepine, causing it to accumulate in the body;[11] however, isoniazid does not usually cause clinically relevant interactions by this mechanism. Rifampicin is a potent enzyme inducer, and would be expected to negate the effects of isoniazid, and to induce the metabolism of carbamazepine. This is supported by one report, but not another.

Importance and management

The documentation is limited, but a clinically important and potentially serious interaction is established between isoniazid and carbamazepine. Toxicity can develop quickly (within 1 to 5 days) and also seems to disappear quickly if the isoniazid is withdrawn. Concurrent use should not be undertaken unless the effects can be closely monitored and suitable downward dose adjustments made (a carbamazepine dose reduction of between one-half and two-thirds was effective in 3 patients[1]). It seems probable that slow metabolisers of isoniazid may develop this interaction more quickly and to a greater extent than fast metabolisers.[2]

The effect of concurrent rifampicin on the interaction between isoniazid and carbamazepine is unclear. One report showed negation of the interaction, whereas another showed potential augmentation.

Limited evidence suggests that carbamazepine may potentiate isoniazid

hepatotoxicity; routine isoniazid monitoring should be adequate to detect any interaction.

Carbamazepine + Lamotrigine

Most studies have found that lamotrigine has no effect on the pharmacokinetics of carbamazepine or its metabolite, carbamazepine-10,11-epoxide. However, some studies have found that lamotrigine raises the serum levels of carbamazepine-10,11-epoxide. Carbamazepine reduces lamotrigine levels. Symptoms of toxicity have been seen irrespective of changes in levels.

Clinical evidence

(a) Effects on carbamazepine

In 3 patients with epilepsy, the addition of lamotrigine increased the serum levels of carbamazepine-10,11-epoxide, the active metabolite of carbamazepine, but carbamazepine levels remained unchanged. One of the patients had carbamazepine-10,11-epoxide serum levels of 2 to 2.2 micrograms/mL while taking carbamazepine 1.1 g daily. The levels rose to 4.7 to 8.7 micrograms/mL when lamotrigine was added. Symptoms of toxicity occurred in 2 patients (dizziness, double vision, sleepiness, nausea).[1]

In another study in 9 patients, the addition of lamotrigine 200 mg increased the mean serum carbamazepine-10,11-epoxide levels by 45%. Toxicity was seen in 4 patients (dizziness, nausea, diplopia).[2] The addition of lamotrigine resulted in cerebellar toxicity (nausea, vertigo, nystagmus, ataxia) in 8 out of 9 patients taking subtoxic and just-tolerated doses of carbamazepine when lamotrigine was added. Analysis showed that in all 8 cases at least one of the levels of carbamazepine, carbamazepine-10,11-epoxide or lamotrigine had become unusually high.[3]

In contrast other studies have found that the concurrent use of lamotrigine and carbamazepine does not result in any clinically significant pharmacokinetic changes. Lamotrigine caused no changes in carbamazepine levels[4-8] or carbamazepine-10,11-epoxide levels in several studies[6,7,9] However, in one study 9 of 47 subjects developed diplopia or dizziness, predominantly in those whose carbamazepine levels were already high before the lamotrigine was added.[6] In another study in 14 children, lamotrigine had no effect on mean carbamazepine levels, and actually decreased mean carbamazepine-10,11-epoxide levels by 23%. Two children developed diplopia, which was unrelated to drug levels, but responded to a reduction in the lamotrigine dose in one, and a reduction in the carbamazepine dose in the other.[10]

(b) Effects on lamotrigine

In a retrospective study, the lamotrigine serum concentration to dose ratio was much lower in patients also taking carbamazepine than in those taking lamotrigine monotherapy (0.38 versus 0.84).[11] Other studies have reported similar findings.[12-14] In one of these studies, mean increases in lamotrigine levels of about 60% occurred in patients taking lamotrigine with carbamazepine when the carbamazepine was withdrawn.[14] Similarly, a case report describes a rapid increase in lamotrigine levels when carbamazepine was withdrawn.[15] A review of patients taking antiepileptics found that carbamazepine increased the clearance of lamotrigine by 30 to 50%.[16]

Mechanism

One suggestion to account for the toxic symptoms seen in some patients is that an interaction occurs at the site of action (a pharmacodynamic interaction) rather than because lamotrigine increases the carbamazepine-10,11-epoxide serum levels.[3,6] Carbamazepine may induce the glucuronidation of lamotrigine.

Importance and management

Overall lamotrigine does not appear to significantly alter carbamazepine levels. However, toxicity has occurred, and therefore patients should be well monitored if lamotrigine is added, and the carbamazepine dose reduced if CNS adverse effects occur. In one case, reducing the dose of lamotrigine was effective.

Carbamazepine induces the metabolism of lamotrigine, and the recommended starting dose and long-term maintenance dose of lamotrigine in patients already taking carbamazepine is twice that of patients taking lamotrigine monotherapy.[17,18] However, if patients are also taking valproate in addition to carbamazepine, the lamotrigine dose should be reduced.[17,18] See 'Lamotrigine + Valproate', p.620.

Carbamazepine + Loxapine

An increase in the serum levels of the epoxide metabolite of carbamazepine has been reported in patients given loxapine.

Clinical evidence, mechanism, importance and management

One patient taking loxapine 500 mg daily developed toxicity (ataxia, nausea, anxiety) when given carbamazepine 600 mg daily, even though the serum carbamazepine level was low to normal.[1] In another case, neurotoxicity (ataxia, lethargy, visual disturbances) developed in a man given carbamazepine and loxapine.[2] In both cases, the toxicity appeared to be due to elevated carbamazepine-10,11-epoxide levels (the metabolite of carbamazepine).[1,2] The problem resolved when the carbamazepine doses were reduced. The reasons for these effects are not understood, and evidence appears to be limited to the two cases cited. The general significance of these reports is therefore unclear. Consider the possibility of an interac-

tion if a patient taking carbamazepine and loxapine develops neurotoxic adverse effects.

Carbamazepine + Macrolides

Carbamazepine levels are markedly and rapidly increased by clarithromycin, erythromycin or troleandomycin, and toxicity can often develop within 1 to 5 days. Telithromycin is predicted to interact similarly. Studies suggest that azithromycin, flurithromycin, josamycin, midecamycin, and roxithromycin have no interaction, or no clinically significant interaction, with carbamazepine, but note that a case of carbamazepine toxicity has been reported in a patient given roxithromycin.

Clinical evidence

(a) Azithromycin

In a study in healthy subjects, azithromycin 500 mg daily for 3 days had no effect on the pharmacokinetics of carbamazepine 200 mg twice daily or its active metabolite, carbamazepine-10,11-epoxide.[1]

(b) Clarithromycin

A pharmacokinetic study[2] in healthy subjects found that clarithromycin 500 mg every 12 hours for 5 days increased the AUC of a single 400-mg dose of carbamazepine by 26%. A retrospective study of 5 patients with epilepsy found that when they were given clarithromycin (dose not stated) their serum carbamazepine levels rose by 20 to 50% within 3 to 5 days, despite 30 to 40% reductions in the carbamazepine dose in 4 of them. Carbamazepine levels in the toxic range were seen in 3 of them, and their carbamazepine doses were then even further reduced.[3] A number of case reports have described carbamazepine toxicity following the addition of clarithromycin in adults,[4-7] and children.[7-9] Two other patients with epilepsy had marked rises in serum carbamazepine levels when they were given clarithromycin 500 mg three times daily and omeprazole.[10] It is not clear whether the omeprazole also had some part to play.[11,12] See also 'Carbamazepine + Proton pump inhibitors', p.610. One case report describes a patient taking carbamazepine 200 mg twice daily who developed hyponatraemia 4 days after the addition of clarithromycin 500 mg twice daily: the hyponatraemia resolved when the clarithromycin was stopped.[13]

(c) Erythromycin

An 8-year-old girl taking phenobarbital 50 mg and carbamazepine 800 mg daily was given 500 mg, then later 1 g of erythromycin daily. Within 2 days she began to experience balancing difficulties and ataxia, which were eventually attributed to carbamazepine toxicity. Her serum carbamazepine levels were found to have risen from a little below 10 micrograms/mL to over 25 micrograms/mL (reference range 2 to 10 micrograms/mL). The levels rapidly returned to normal after carbamazepine was withheld for 24 hours and the erythromycin stopped.[14]

A study in 7 healthy subjects confirmed that erythromycin can cause significant increases in carbamazepine levels,[15] and a study in 8 healthy subjects found that the clearance of carbamazepine is reduced by an average of 20% (range 5 to 41%) by erythromycin 1 g daily for 5 days.[16] Another study, in healthy subjects given erythromycin 500 mg three times daily for 10 days, found that the clearance of a single dose of carbamazepine was reduced by about 20% and the maximum serum levels of carbamazepine-10,11-epoxide were reduced by about 40% by erythromycin.[17]

Marked rises in serum carbamazepine levels (up to fivefold in some cases) and/or toxicity (including cases of hepatorenal failure and AV block as well as more typical signs of carbamazepine toxicity) have been described in over 30 cases involving both children and adults. Symptoms commonly began within 24 to 72 hours of starting erythromycin, although in some cases it was as early as 8 hours. In most cases toxicity resolved within 3 to 5 days of stopping the erythromycin.[8,18-36]

(d) Flurithromycin

In a study in healthy subjects, flurithromycin 500 mg three times daily for a week increased the AUC of a single 400-mg dose of carbamazepine by about 20% and moderately reduced the production of carbamazepine-10,11-epoxide.[37]

(e) Josamycin

In studies in healthy subjects and in patients, josamycin 1 g twice daily for a week reduced the clearance of carbamazepine by about 20%.[38-40]

(f) Midecamycin acetate

A single-dose study in 14 subjects found that after taking midecamycin acetate 800 mg twice daily for 8 days the AUC of a single 200-mg dose of carbamazepine was increased by 15%, and the AUC of its active metabolite, carbamazepine-10,11-epoxide, was reduced by 26%.[41] Another study in patients taking carbamazepine found that the addition of midecamycin acetate 600 mg twice daily caused a small increase in the trough serum levels of carbamazepine, and only a 12% increase in its AUC.[42]

(g) Roxithromycin

In a study in healthy subjects, roxithromycin 150 mg twice daily for 8 days did not affect the pharmacokinetics of a single 200-mg dose of carbamazepine.[43] However, an isolated report describes carbamazepine toxicity (levels increased to 21.7 mg/L) in a patient taking carbamazepine and atorvastatin the day after she started to take roxithromycin 150 mg twice daily. Roxithromycin and atorvastatin were stopped and the carbamazepine level fell to 12.5 mg/L within a day. The increased carbamazepine levels were attributed to the concurrent use of roxithromycin.[44]

(h) Troleandomycin

In 8 patients with epilepsy, symptoms of carbamazepine toxicity (dizziness, nausea, vomiting, excessive drowsiness) developed within 24 hours of them also starting to take troleandomycin. The 2 patients available for examination had a sharp rise in serum carbamazepine levels, from about 5 micrograms/mL to 28 micrograms/mL over 3 days, and a rapid fall following withdrawal of the troleandomycin.[45,46]

Another report by the same authors describes a total of 17 similar cases of carbamazepine toxicity caused by troleandomycin.[18] Some of the patients had three or fourfold increases in serum carbamazepine levels. Another case has been described elsewhere.[14] In most instances the serum carbamazepine levels returned to normal within about 3 to 5 days of withdrawing the macrolide.[18]

Mechanism

It seems probable that clarithromycin, erythromycin and troleandomycin, and to a lesser extent some of the other macrolides, slow the rate of metabolism of the carbamazepine by the cytochrome P450 isoenzyme CYP3A4 so that the antiepileptic accumulates within the body.[47,48] Telithromycin is predicted to interact similarly.[49] It was suggested that the carbamazepine toxicity seen with roxithromycin may have been mediated by P-glycoprotein inhibition, which occurred as a result of an interaction between roxithromycin and atorvastatin; however, roxithromycin is a modest CYP3A4 inhibitor, and so it seems possible that it may have interacted by this mechanism.

Importance and management

The interaction between carbamazepine and troleandomycin is established, clinically important and potentially serious. The incidence is high. The rapidity of its development (within 24 hours in some cases) and the extent of the rise in serum carbamazepine levels suggest that it would be difficult to control carbamazepine levels by reducing the dose. Concurrent use should probably be avoided.

The interaction between carbamazepine and erythromycin is also very well documented, well established and of clinical importance. Concurrent use should be avoided unless the effects can be very closely monitored by measurement of serum carbamazepine levels and suitable dose reductions made. Toxic symptoms (ataxia, vertigo, drowsiness, lethargy, confusion, diplopia) can develop within 24 hours, but serum carbamazepine levels can return to normal within 8 to 12 hours of withdrawing the antibacterial.[38] Similar precautions would seem prudent if **telithromycin** is given with carbamazepine. However, the manufacturer of telithromycin advises avoidance of the combination, and suggests that telithromycin should not be used within 2 weeks of stopping carbamazepine. They also suggest that the levels of the antibacterial may be reduced.[49]

The interaction between carbamazepine and clarithromycin is also established, clinically important and potentially serious. It has been recommended that the carbamazepine dose should be reduced by 30 to 50% during treatment with clarithromycin, with monitoring within 3 to 5 days,

and patients should be told to tell their doctor of any symptoms of toxicity (dizziness, diplopia, ataxia, mental confusion).

Analysis of the interactions between the macrolides and carbamazepine has shown that patients requiring high doses of carbamazepine to reach therapeutic levels are likely to have a greater rise in their carbamazepine levels.[50] The extent of the interactions is also correlated with the macrolide dose.[50]

Josamycin, flurithromycin, midecamycin acetate and roxithromycin appear to be safer alternatives to either clarithromycin, erythromycin, telithromycin or troleandomycin. Nevertheless a small or moderate reduction in the dose of carbamazepine may be needed, with subsequent good monitoring. Pharmacokinetic data suggest that azithromycin does not interact.

Carbamazepine or Oxcarbazepine + MAOIs

Phenelzine, moclobemide and tranylcypromine appear not to interact adversely with carbamazepine, although both carbamazepine and oxcarbazepine are predicted to interact with the MAOIs.

Clinical evidence, mechanism, importance and management

There appear to be no reports of adverse reactions during the concurrent use of MAOIs and carbamazepine or oxcarbazepine. However, the manufacturers of carbamazepine[1] and oxcarbazepine[2] suggest that an interaction is possible because of the close structural similarity between carbamazepine and the tricyclic antidepressants (and therefore the theoretical risk of an adverse interaction). The UK manufacturer of carbamazepine[1] does not recommend concurrent use and suggests that MAOIs should be discontinued at least 2 weeks before carbamazepine is started. Several reports describe the successful use of carbamazepine and MAOIs, namely **tranylcypromine**,[3-5] **phenelzine**,[5,6] and **moclobemide**.[7] Bearing in mind that the MAOIs and the tricyclics can be given together under certain well controlled conditions (see 'MAOIs or RIMAs + Tricyclic and related antidepressants', p.1391), the warning about the risks may possibly prove to be over-cautious.

Note that, rarely, the MAOIs have been seen to cause convulsions and they should therefore be used cautiously in patients with epilepsy.

Carbamazepine + Metronidazole

Increased serum carbamazepine levels and toxicity have been seen in a patient given metronidazole.

Clinical evidence, mechanism, importance and management

A woman taking carbamazepine 1 g daily started taking co-trimoxazole twice daily and metronidazole 250 mg three times daily for diverticulitis. After 2 days the co-trimoxazole was stopped, she was changed to intravenous metronidazole 500 mg three times daily, and cefazolin 500 mg every 8 hours. After 2 days she complained of diplopia, dizziness and nausea, and her serum carbamazepine levels were found to have risen from 9 micrograms/mL to 14.3 micrograms/mL. A month later (presumably

after the metronidazole had been withdrawn) her serum carbamazepine levels had fallen to 7.1 micrograms/mL. The reasons for this reaction are not understood.[1]

This appears to be the only report of an interaction between carbamazepine and metronidazole, so its general importance is uncertain.

Carbamazepine + Nefazodone

Five patients developed elevated serum carbamazepine levels and toxicity when nefazodone was given. A study in healthy subjects using lower carbamazepine doses found only modest increases in carbamazepine levels, and no evidence of toxicity when nefazodone was given. Carbamazepine markedly reduces nefazodone levels.

Clinical evidence

A patient taking carbamazepine 1 g daily developed evidence of toxicity (light-headedness, ataxia) within 15 days of starting to take nefazodone (initially 100 mg twice daily increasing to 150 mg twice daily after a week). Her serum carbamazepine levels had risen from below 8.3 micrograms/mL up to 10.8 micrograms/mL. It was found necessary to reduce the carbamazepine dose to 600 mg daily to eliminate these adverse effects and to achieve a serum level of 7.4 micrograms/mL.[1] In 4 other patients taking carbamazepine 800 mg or 1 g daily the addition of nefazodone caused up to threefold rises in carbamazepine levels. The carbamazepine dose was reduced by 25 to 60%.[1,2] In a study in 12 healthy subjects, no evidence of toxicity was seen when carbamazepine 200 mg twice daily was given with nefazodone 200 mg twice daily for 5 days. However, the exposure to carbamazepine was slightly increased (23% increase in AUC) and the exposure to nefazodone markedly decreased (93% decrease in AUC). The authors suggest that there may be a greater effect with higher doses of carbamazepine.[3]

Mechanism

Both drugs are metabolised by the cytochrome P450 isoenzyme CYP3A4. Nefazodone is known to inhibit CYP3A4, whereas carbamazepine is a potent inducer of CYP3A4. Hence concurrent use reduces carbamazepine metabolism, leading to raised levels, and increases nefazodone metabolism, leading to lowered levels.

Importance and management

Information is limited, but it would seem prudent to monitor for signs of carbamazepine toxicity if nefazodone is added to established treatment, especially with doses of carbamazepine above 800 mg. The nefazodone dose may need to be increased in the presence of carbamazepine, so be alert for a reduced effect. Nefazodone has largely been withdrawn, but the US manufacturer of nefazodone did contraindicate its concurrent use with carbamazepine.[4]

Carbamazepine + Phenobarbital

Carbamazepine levels are reduced to some extent by phenobarbital, whereas the levels of its active metabolite carbamazepine-10,11-epoxide are raised. In children, phenobarbital clearance is decreased by carbamazepine.

Clinical evidence

A comparative study found that, on average, patients taking both carbamazepine and phenobarbital (44 patients) had carbamazepine serum levels that were 18% lower than those taking carbamazepine alone (43 patients).[1] Similar results were found in other studies in both adult and paediatric patients taking both drugs.[2-5] Levels of the active metabolite, carbamazepine-10,11-epoxide, were increased.[3-6] However, one study found that, after a single dose of carbamazepine, the clearance of carbamazepine-10,11-epoxide was higher and its plasma half-life shorter in patients with epilepsy taking phenobarbital, when compared with healthy subjects not taking phenobarbital.[7]

In a prospective study, the clearance of phenobarbital in 222 patients receiving monotherapy was compared with that in 63 patients who were also taking carbamazepine. The clearance of carbamazepine was found to be decreased by phenobarbital. Further, the effects of carbamazepine on phenobarbital clearance were maximal in young children (about 54%) and minimal in adults.[8]

Mechanism

Phenobarbital and carbamazepine are both known enzyme inducers, and may therefore increase each others metabolism. Phenobarbital may also induce the metabolism of carbamazepine-10,11-epoxide.[7]

Importance and management

An established interaction. It would be prudent to monitor phenobarbital levels in children also given carbamazepine, as changes in clearance may affect dose requirements. The small fall in serum carbamazepine levels probably has little practical importance, especially as the metabolite carbamazepine-10,11-epoxide also has antiepileptic activity. Carbamazepine + Primidone

A single case report suggests that primidone can reduce the effects of carbamazepine. Other evidence suggests that carbamazepine may reduce primidone serum levels and increase primidone-derived phenobarbital levels.

Clinical evidence

A 15-year-old boy had complex partial seizures that were not controlled despite treatment with primidone 12 mg/kg daily and carbamazepine 10 mg/kg daily, both in three divided doses. Even when the carbamazepine dose was increased to 20 mg/kg daily and then 30 mg/kg daily his serum carbamazepine levels only reached 4.8 micrograms/mL, and his seizures continued. When the primidone was gradually withdrawn his serum carbamazepine levels increased to 12 micrograms/mL and his seizures completely disappeared.[1]

An analysis of the serum levels of antiepileptic drugs in children found that the serum levels of primidone tended to be lower in those also taking carbamazepine, but no details were given.[2] Another study found that the levels of phenobarbital derived from primidone were 42 micrograms/mL in patients taking primidone, carbamazepine and phenytoin, 24.7 micrograms/mL in patients taking phenytoin and primidone, and just 9.9 micrograms/mL in patients taking primidone alone.[3] A further study found that primidone levels were lower in patients also taking carbamazepine, but there were no significant changes in primidone-derived phenobarbital levels. Carbamazepine-10,11-epoxide levels were increased by primidone.[4] In a retrospective study, the plasma level to dose ratio for primidone was lower in patients also taking carbamazepine than

in those taking primidone alone, and the primidone-derived phenobarbital levels were higher.[5]

Mechanism

When primidone was stopped in the single case cited, the clearance of carbamazepine decreased by about 60%.[1] This is consistent with the known enzyme-inducing effects of primidone (converted in the body to phenobarbital), which can increase the metabolism of other drugs by the liver. There is some evidence to suggest that carbamazepine may increase the metabolism of primidone to phenobarbital.

Importance and management

Direct information seems to be limited to these reports. It may be prudent to monitor combined treatment, and adjust the antiepileptic doses if necessary. Consider also 'Carbamazepine + Phenobarbital', p.609.

Carbamazepine + Probenecid

Probenecid appears to increase the metabolism of carbamazepine to carbamazepine-10,11-epoxide.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study, 10 healthy subjects were given probenecid 500 mg twice daily for 10 days with a single 200-mg dose of carbamazepine on day 6. The AUC of carbamazepine was decreased by about 19% and the AUC of carbamazepine-10,11-epoxide was increased by about 33%. Probenecid tended to decrease the formation of conjugated forms of both carbamazepine and its epoxide metabolite but this was not statistically significant. Probenecid increased the oral clearance of carbamazepine by 26%.

The increased metabolism of carbamazepine to carbamazepine-10,11-epoxide was thought to be due to induction of cytochrome P450 isoenzymes CYP3A4 and CYP2C8 by probenecid.[1] The clinical significance of the increase in levels of the active metabolite, carbamazepine-10,11-epoxide is unclear. This was a single-dose study, and it is known that following multiple doses, carbamazepine also induces its own metabolism by CYP3A4. The effect of carbamazepine on this isoenzyme would be expected to be much greater than any effect of probenecid, which does not usually cause clinically relevant interactions by this mechanism.

Carbamazepine + Proton pump inhibitors

Omeprazole markedly raises the levels of a single dose of carbamazepine, but has no significant effect on the levels of carbamazepine taken long-term. Some anecdotal reports suggest that carbamazepine levels may possibly be reduced by lansoprazole. Pantoprazole did not affect the pharmacokinetics of carbamazepine in one study.

Clinical evidence

(a) Lansoprazole

In 2001 the manufacturers of lansoprazole had on record 5 undetailed case reports of apparent interactions between lansoprazole and carbamazepine. One of them describes the development of carbamazepine toxicity when lansoprazole was added, but there is some doubt about this case because it is thought that the patient may have started to take higher doses of carbamazepine.

The other 4 cases are consistent, in that carbamazepine levels fell shortly after lansoprazole was added and/or the control of seizures suddenly worsened. One patient had a fall in carbamazepine serum levels from 11.5 mg/mL to 7.7 mg/L. The carbamazepine levels of another patient returned to normal when the lansoprazole was stopped.[1]

(b) Omeprazole

In a study in 7 patients, omeprazole 20 mg daily for 14 days was found to increase the AUC of a single 400-mg dose of carbamazepine by 75%. The clearance of carbamazepine was reduced by 40% and its elimination half-life was more than doubled (from 17.2 to 37.3 hours).[2] In a study in 10 healthy subjects, omeprazole 20 mg twice daily for 14 days increased the AUC, peak plasma level and elimination half-life of a single 400-mg dose of sustained-release carbamazepine (*Mazetol*) by about 90%, 31%, and 57%, respectively.[3] However, a retrospective study of the records of 10 patients who had been taking omeprazole 20 mg daily with long-term carbamazepine (rather than a single dose) found a non-significant reduction in carbamazepine serum levels.[4]

(c) Pantoprazole

In healthy subjects, pantoprazole 40 mg daily for 5 days had no effect on the AUC of carbamazepine or its metabolite, carbamazepine-10,11-epoxide, after a single 400-mg dose of carbamazepine.[5]

Mechanism

Omeprazole may inhibit the oxidative metabolism of single doses of carbamazepine. However, when carbamazepine is taken continuously it induces its own metabolism by the cytochrome P450 isoenzyme CYP3A4, thereby possibly opposing the effects of this interaction.[4]

Importance and management

It seems that in practice no clinically relevant interaction is likely to occur between omeprazole and carbamazepine. For lansoprazole, information seems to be limited to this handful of reports from which no broad general conclusions can be drawn. Pantoprazole appears not to affect the pharmacokinetics of carbamazepine.

Carbamazepine + Retinoids

An isolated report describes a patient who did not respond to etretinate until the carbamazepine she was taking was withdrawn. A study in one patient found that isotretinoin modestly reduced the plasma levels of both carbamazepine and its active metabolite.

Clinical evidence, mechanism, importance and management

(a) Etretinate

A girl taking carbamazepine and valproate and with pityriasis rubra pilaris did not respond to etretinate for a period of 2 months and had none of its characteristic mucocutaneous adverse effects. When the carbamazepine was withdrawn and the valproate dose increased, she had a good response to etretinate within 6 weeks. It was suggested that carbamazepine may have reduced the bioavailability or increased the metabolism of etretinate.[1] Note that etretinate is extensively metabolised to acitretin, and that acitretin use is now preferred to etretinate. This appears to be an isolated case, and its general relevance to the use of etretinate or acitretin is unknown.

(b) Isotretinoin

The AUC of carbamazepine in a patient with epilepsy taking carbamazepine 600 mg daily was reduced by 11% when isotretinoin

500 micrograms/kg daily was taken, and by 24% when isotretinoin 1 mg/kg daily was taken. The AUC of carbamazepine-10,11-epoxide (the active metabolite of carbamazepine) was reduced by 21% and 44% by the small and large doses of isotretinoin, respectively. The patient had no adverse effects.[2] Although the author of the report suggests that monitoring may be necessary in patients given both drugs, changes of this magnitude, especially those seen with the lower dose of isotretinoin, are not usually clinically significant.

Carbamazepine + SSRIs

Some, but not all, reports indicate that carbamazepine levels can be increased by fluoxetine and fluvoxamine. Toxicity may develop. Citalopram, paroxetine and sertraline do not normally affect carbamazepine, but there is an isolated case of raised carbamazepine levels with sertraline.
Citalopram, paroxetine and sertraline levels may be reduced by carbamazepine. The use of carbamazepine with an SSRI has, rarely, led to effects such as hyponatraemia, serotonin syndrome, and parkinsonism.

Clinical evidence

(a) Citalopram

In a study in 12 healthy subjects, citalopram 40 mg daily for 2 weeks did not affect the pharmacokinetics of carbamazepine 400 mg daily.[1] An approximate 30% decrease in citalopram levels occurred in 6 patients taking citalopram 40 to 60 mg daily when they were given carbamazepine 200 to 400 mg daily for 4 weeks. Despite this decrease, the combination was considered clinically useful.[2] Similarly, two patients with epilepsy, major depression, and panic disorder had increased citalopram levels (one had an improved antidepressant response, but the other patient experienced tremor and increased anxiety) when their treatment with carbamazepine was replaced by oxcarbazepine.[3]

(b) Fluoxetine

Two patients developed carbamazepine toxicity (diplopia, blurred vision, tremor, vertigo, nausea, tinnitus etc.) within 7 and 10 days of starting to take fluoxetine 20 mg daily. Their serum carbamazepine levels were found to have risen by about 33% and 60%, respectively. The problem was resolved in one of them by reducing the carbamazepine dose from 1 g to 800 mg daily, and in the other by stopping fluoxetine.[4] The effects seen in these cases are supported by a study in 6 healthy patients, where adding fluoxetine 20 mg daily to steady-state carbamazepine caused a rise in the AUC of carbamazepine and carbamazepine-10,11-epoxide (its active metabolite) of about 25 to 50%.[5]

In contrast, in 8 patients with epilepsy taking stable doses of carbamazepine, fluoxetine 20 mg daily for 3 weeks was found to have no effect on the serum levels of carbamazepine or carbamazepine-10,11-epoxide.[6]

Aside from these pharmacokinetic changes two cases of parkinsonism developed within 3 and 9 days of adding fluoxetine to carbamazepine treatment. In both cases carbamazepine levels were unaffected.[7] A case of serotonin syndrome (shivering, agitation, myoclonic-like leg contractions, diaphoresis, etc.) has also been seen in a woman taking carbamazepine 200 mg daily and fluoxetine 20 mg daily.[8]

(c) Fluvoxamine

Increased serum levels and signs of carbamazepine toxicity (nausea, vomiting) were seen in 3 patients taking long-term carbamazepine when they were given fluvoxamine. The carbamazepine level almost doubled in one of them within 10 days of starting fluvoxamine 50 to 100 mg daily. The interaction was accommodated by reducing the carbamazepine dose by 200 mg daily in all three (from 1 g to 800 mg in one of them, and from 800 to 600 mg daily in the other two).[9,10] An approximate doubling of carbamazepine levels has also been seen in other patients given fluvoxamine.[11-14]

In contrast, in 7 patients with epilepsy taking stable doses of carbamazepine, fluvoxamine 100 mg daily for 3 weeks was found to have no effect on the serum levels of carbamazepine or carbamazepine-10,11-epoxide.[6] Furthermore, a literature search[15] by the manufacturers of fluvoxamine only identified 8 cases of an interaction between fluvoxamine and carbamazepine up until 1995.

(d) Paroxetine

In patients with epilepsy, paroxetine 30 mg daily for 16 days did not affect the plasma levels or therapeutic effects of carbamazepine. Steady-state paroxetine plasma levels were lower in those taking carbamazepine (27 nanograms/mL) than in those taking sodium valproate (73 nanograms/mL).[16]

An elderly patient taking carbamazepine 200 mg daily then 400 mg daily for neuropathic pain associated with herpes zoster infection was given paroxetine 20 mg daily to treat depression. He developed vertigo, bradycardia and syncope and his plasma sodium was found to be low (120 mmol/L). Sodium levels returned to normal (135 mmol/L) over several weeks after carbamazepine was withdrawn.[17]

(e) Sertraline

A placebo-controlled study in 13 healthy subjects (7 taking sertraline, 6 taking placebo) found that sertraline 200 mg daily for 17 days had no effect on the pharmacokinetics of carbamazepine 200 mg twice daily or on its metabolite, carbamazepine-10,11-epoxide. In addition, sertraline did not potentiate the cognitive effects of carbamazepine.[18]

However, an isolated report describes a woman who had taken carbamazepine 600 mg and flecainide 100 mg daily for 2 years, who had a rise in her trough serum carbamazepine levels from 4.7 micrograms/mL to 8.5 micrograms/mL within 4 weeks of starting sertraline 100 mg daily. After 3 months of treatment, carbamazepine levels were 11.9 micrograms/mL. At the same time she developed pancytopenia (interpreted as a toxic bone marrow reaction to the increased carbamazepine levels), which improved when both carbamazepine and sertraline were stopped.[19]

An isolated report describes a woman with a schizoaffective disorder, successfully treated for 3 years with haloperidol and carbamazepine, who was given sertraline 50 mg daily for depression. When she failed to respond, the sertraline dose was progressively increased to 300 mg daily but her sertraline plasma levels remained low (about 17 to 25% of those predicted). Another patient taking carbamazepine similarly failed to respond to the addition of sertraline and had low sertraline levels.[20] In an analysis of plasma sertraline levels, the concentration to daily-dose ratio of sertraline was significantly lower in patients who had taken sertraline with carbamazepine compared with those who had taken sertraline without carbamazepine,[21] suggesting that carbamazepine lowered sertraline levels.

Mechanism

The evidence suggests that fluoxetine and fluvoxamine inhibit the metabolism of carbamazepine by the liver (presumably by inhibiting the cytochrome P450 isoenzyme CYP3A4) so that its loss from the body is reduced, leading to a rise in its serum levels.[5,12] However, fluoxetine usually only has weak effects on this isoenzyme.

Citalopram, sertraline and possibly paroxetine serum levels may be reduced because carbamazepine induces their metabolism by CYP3A4, which results in lower levels of these SSRIs. Oxcarbazepine appears not to interact. Carbamazepine and paroxetine may cause hyponatraemia so the reduced sodium levels in these two cases could be due to the combined adverse effects of these drugs.[17,22]

Importance and management

Information for fluoxetine and fluvoxamine appears to be limited to these reports. Not all patients appear to be affected, but because it is not possible to identify which patients are at risk, it would seem prudent to be alert for an increase in carbamazepine serum levels and toxicity (e.g. nausea, vomiting, ataxia and drowsiness) if fluoxetine or fluvoxamine is added. If toxicity is suspected, monitor carbamazepine levels and reduce the dose as necessary. The manufacturers of fluoxetine suggest that carbamazepine should be started at or adjusted towards the lower end of the dose range in those taking fluoxetine. They additionally suggest caution if fluoxetine has been taken during the previous 5 weeks.[23]

There would seem to be no particular need to monitor carbamazepine levels in patients taking citalopram, paroxetine, or sertraline. However, be aware that the SSRIs may be less effective in the presence of carbamazepine. Consider increasing the dose if necessary.

Note that SSRIs may increase seizure frequency and should therefore be

used with caution in patients with epilepsy, and avoided in those with unstable epilepsy.

Carbamazepine + Terfenadine

Carbamazepine toxicity, attributed to the use of terfenadine, has been described in one case report.

Clinical evidence, mechanism, importance and management

A 18-year-old woman taking carbamazepine after treatment for brain metastases, developed confusion, disorientation, visual hallucinations, nausea and ataxia shortly after starting to take terfenadine 60 mg twice daily for rhinitis. The symptoms were interpreted as carbamazepine toxicity. However, her total carbamazepine serum level of 8.9 mg/L was within the reference range. An interaction due to protein binding displacement was suspected and measurement of free carbamazepine revealed levels of 6 mg/L, almost three times the upper limit of normal. All the symptoms disappeared when the terfenadine was stopped. The authors speculate that the terfenadine had displaced the carbamazepine from its plasma protein binding sites, thereby increasing the levels of free and active carbamazepine.[1] The report is very brief and does not say whether any other drugs were being taken concurrently, so that this interaction is not established.

1. Hirschfeld S, Jarosinski P. Drug interaction of terfenadine and carbamazepine. *Ann Intern Med* (1993) 118, 907–8.

Carbamazepine + Ticlopidine

One case report suggests that ticlopidine may have increased carbamazepine levels, with associated toxicity.

Clinical evidence, mechanism, importance and management

A 67-year-old man taking carbamazepine 600 mg twice daily developed symptoms of carbamazepine toxicity (drowsiness, dizziness, ataxia) within a week of starting to take ticlopidine 250 mg twice daily. His carbamazepine level one week after starting the ticlopidine was 17.7 [micrograms/mL], but it had been only 10.1 [micrograms/mL] five weeks earlier. The carbamazepine dose was reduced to 500 mg twice daily, which resolved the symptoms, and resulted in a carbamazepine level of 12.5 [micrograms/mL] one week later. After stopping the ticlopidine, carbamazepine levels fell to 9.9 [micrograms/mL]. It was suggested that ticlopidine may interfere with carbamazepine metabolism.[1] However, carbamazepine is principally metabolised by the cytochrome P450 isoenzyme CYP3A4, and ticlopidine is not usually considered an inhibitor of this isoenzyme. This appears to be the only report of an interaction between carbamazepine and ticlopidine, and its general relevance is uncertain.

Carbamazepine + Trazodone

A single case report describes a moderate rise in carbamazepine levels in a patient given trazodone. Carbamazepine may moderately decrease trazodone levels.

Clinical evidence, mechanism, importance and management

A 53-year-old man who had been taking carbamazepine 700 mg daily for 7 months (serum levels 7.2 mg/L and 7.9 mg/L) started taking trazodone 100 mg daily. Two months later his serum carbamazepine levels were 10 mg/L and the concentration-to-dose ratio had increased by about 26%, but no signs or symptoms of carbamazepine toxicity were seen. The reasons for this interaction are not known but the authors suggest that it might occur because trazodone inhibits the cytochrome P450 isoenzyme CYP3A4, resulting in a reduction in the metabolism of carbamazepine.[1]

This seems to be the first and only report of raised carbamazepine levels with trazodone, and its general importance is unknown. The rise was only moderate and in this case was clinically irrelevant, but a carbamazepine serum rise of 26% might possibly be of importance in those patients with serum levels already near the top end of the therapeutic range. Therefore if carbamazepine adverse effects (e.g. nausea, vomiting, ataxia, drowsiness) develop in a patient taking trazodone, consider an interaction as a possible cause.

In 6 patients taking trazodone 150 or 300 mg daily, the addition of carbamazepine 400 mg daily for 4 weeks decreased the plasma levels of trazodone by 24%, and decreased the levels of the active metabolite of trazodone by 40%.[2] However, the combination was considered clinically useful in three of the cases.[2,3] In another study, when carbamazepine 400 mg daily was given with trazodone 100 to 300 mg daily, the plasma levels of trazodone and its active metabolite were reduced by 76% and 60%, respectively.[4,5] The FDA in the US and the manufacturers of trazodone recommend that patients should be closely monitored and trazodone doses increased if necessary when both drugs are given.[4-7]

Carbamazepine + Valnoctamide

Carbamazepine toxicity may develop if valnoctamide is also taken.

Clinical evidence

A study in 6 patients with epilepsy taking carbamazepine 800 to 1200 mg daily found that valnoctamide 200 mg three times daily for 7 days caused a 1.5- to 6.5-fold increase in the serum levels of carbamazepine-10,11-epoxide (an active metabolite of carbamazepine). Clinical signs of carbamazepine toxicity (drowsiness, ataxia, nystagmus) were seen in 4 patients. Two patients were also taking phenobarbital or phenytoin, and the serum levels of these drugs were unaffected by valnoctamide.[1] A further study in 6 healthy subjects found that valnoctamide 600 mg daily for 8 days increased the half-life of carbamazepine-10,11-epoxide, after a single 100-mg dose of carbamazepine, threefold (from 6.7 to 19.7 hours) and decreased its oral clearance fourfold.[2]

Mechanism

Valnoctamide inhibits the enzyme epoxide hydrolase, which is concerned with the metabolism and elimination of carbamazepine and its active epoxide metabolite.[1,2]

Importance and management

Information is limited but the interaction between carbamazepine and valnoctamide appears to be established. Patients taking carbamazepine who also take valnoctamide could rapidly develop carbamazepine toxicity because the metabolism of its major metabolite, carbamazepine-10,11-epoxide, is inhibited. This interaction is very similar to the interaction that occurs between carbamazepine and valpromide (an isomer of valnoctamide), see 'Carbamazepine + Valproate', below. Concurrent valnoctamide should be avoided unless the carbamazepine dose can be reduced appropriately.

Carbamazepine + Valproate

Carbamazepine levels are usually only slightly affected by sodium valproate, valproic acid or valpromide but a moderate to marked rise in the levels of its active metabolite, carbamazepine-10,11-epoxide, may occur.
Carbamazepine may reduce the serum levels of valproate by 60% or more. Concurrent use may possibly increase the incidence of sodium valproate-induced hepatotoxicity.

Clinical evidence

(a) Carbamazepine and carbamazepine-10,11-epoxide levels

1. Sodium valproate or Valproic acid. A study in 7 adult patients with epilepsy who had been taking carbamazepine 8.3 to 13.3 mg/kg for more than 2 months found that their steady-state serum carbamazepine levels fell by an average of 24% (range 3 to 59%) over a 6-day period when they were given sodium valproate 1 g twice daily. The carbamazepine levels were reduced in 6 of the patients and remained unchanged in one. The levels of the active metabolite of carbamazepine, carbamazepine-10,11-epoxide, increased by a mean of 38%, with small decreases or no change in 4 patients and 24 to 150% increases in the remaining 3 patients.[1,2]
Other reports state that falls,[3,4] no changes[3,5-7] and even a slight rise[4] in carbamazepine levels have been seen in some patients also taking sodium valproate or valproic acid. The serum levels of carbamazepine-10,11-epoxide are reported to be increased by about 50 to 100%.[6,8-10] This active metabolite may cause the development of marked adverse effects such as blurred vision, dizziness, vomiting, tiredness and even nystagmus.[6-8,11] Acute psychosis, tentatively attributed to elevated epoxide levels, occurred when carbamazepine was given to a patient taking sodium valproate.[12]

2. Valpromide. Symptoms of carbamazepine toxicity, without increases in carbamazepine levels, developed in 5 out of 7 patients with epilepsy taking carbamazepine when concurrent treatment with sodium valproate was replaced by valpromide. The toxicity appeared to be connected with a fourfold increase in the serum levels of the active metabolite of carbamazepine, carbamazepine-10,11-epoxide, which rose to 8.5 micrograms/mL.[13]
In another study in 6 patients with epilepsy the serum levels of carbamazepine-10,11-epoxide rose by 330% (range 110 to 864%) within a week of starting valpromide, and two of the patients developed confusion, dizziness and vomiting. The symptoms disappeared and serum carbamazepine-10,11-epoxide levels fell when the valpromide dose was reduced by one-third.[6]
A study in healthy subjects given a single 100-mg oral dose of carbamazepine-10,11-epoxide confirmed that valpromide 300 mg twice daily for 8 days reduced carbamazepine-10,11-epoxide clearance by 73%, and increased peak levels by 62%.[14]

(b) Valproate levels

A pharmacokinetic study in 6 healthy subjects found that carbamazepine, 200 mg daily, over a 17-day period, increased the valproic acid clearance by 30%.[15]

Other reports have described reductions in serum valproate levels of 34 to 38% when carbamazepine was added,[16-18] and rises of 50 to 65% when the carbamazepine was withdrawn.[19,20] The rise appears to reach a plateau after about 4 weeks.[20] A pharmacokinetic model has been devised to estimate valproate clearance when given with carbamazepine.[21]

(c) Other effects

Evidence from epidemiological studies suggests that the risk of fatal hepatotoxicity is higher when valproate is given with other antiepileptics than when it is given alone, especially in infants.[22,23] A single case report describes hepatocellular and cholestatic jaundice and a reversible Parkinsonian syndrome in a woman taking sodium valproate and carbamazepine, which reversed when the carbamazepine was withdrawn. Levels of both drugs did not exceed the therapeutic range at any stage. The Parkinsonian syndrome was attributed to a drug interaction, whereas the hepatotoxicity was considered most likely to be due to the carbamazepine, although the valproate may have contributed.[24]

Mechanism

The evidence suggests that carbamazepine increases the metabolism of valproate, so that it is cleared from the body more quickly. Carbamazepine may also possibly increase the formation of a minor but hepatotoxic metabolite of valproic acid (2-propyl-4-pentenoic acid or 4-ene-VPA).[25,26]

The latter stages of carbamazepine metabolism appear to be inhibited by both valproate and its amide derivative, valpromide.[27] The levels of the metabolite carbamazepine-10,11-epoxide increase during concurrent use, probably by inhibition of its metabolism to carbamazepine-10,11-trans-diol,[28-30] by epoxide hydrolase. Valpromide was found to be about 100 times more potent an inhibitor of this enzyme than valproic acid *in vitro*[31] and caused a threefold higher rise in epoxide levels than valproate in one study.[6] The carbamazepine-10,11-epoxide metabolite has anticonvulsant activity, but it may also cause toxicity if its serum levels become excessive.[6,32]

It has also been suggested that valproate is not a selective inhibitor of epoxide hydrolase but that it inhibits all the steps of the epoxide-diol pathway.[33] The trans-diol metabolite is then further converted by glucuronidation, and it seems that this step is also inhibited.[30]

Importance and management

Moderately well documented interactions, which are established. A minor to modest fall in carbamazepine levels may occur, but there may be a moderate to marked rise in the active epoxide metabolite. Therefore, be alert for signs of toxicity, which may indicate high levels of carbamazepine-10,11-epoxide and a need to reduce the carbamazepine dose.

Be alert for falls in the serum levels of valproate if carbamazepine is added, and rises if carbamazepine is withdrawn. Sodium valproate has been associated with serious hepatotoxicity, especially in children aged less than 3 years, and this has been more common in those receiving other antiepileptics. Sodium valproate monotherapy is to be preferred in this group.

There is also some debate about whether the combination of valproate (especially valpromide) and carbamazepine should be avoided, not only because of the risk of toxicity but also because inhibition of epoxide hydrolase may be undesirable.[13] This enzyme is possibly important for the

detoxification of a number of teratogenic, mutagenic and carcinogenic epoxides.[6,13] More study is needed.

Carbamazepine + Venlafaxine

The concurrent use of venlafaxine and carbamazepine led to hyponatraemia in one patient.

Clinical evidence, mechanism, importance and management

A case report describes a woman who was taking carbamazepine 800 mg at breakfast, and 400 mg at lunch and dinner, lamotrigine 100 mg twice daily and phenobarbital 100 mg twice daily who developed hyponatraemia following the addition of venlafaxine 150 mg daily and mirtazapine. Her sodium level fell from 142.5 mmol/L at the time when venlafaxine was added, to 124.8 mmol/L 2 years later, at which point she experienced syncope. The authors attribute this to the syndrome of inappropriate secretion of antidiuretic hormone caused by the combination of carbamazepine, lamotrigine and venlafaxine.[1] However, of these drugs, carbamazepine and venlafaxine are associated with this effect, whereas lamotrigine is not. Therefore an interaction between venlafaxine and carbamazepine seems a likely cause of the hyponatraemia. The clinical relevance of this isolated case is unclear.

Note that venlafaxine may cause seizures and should therefore be used with caution in patients with epilepsy.

Carbamazepine + Vigabatrin

Vigabatrin does not normally alter carbamazepine levels, although one study has found a modest increase, and one a modest decrease, in carbamazepine levels when vigabatrin was given.

Clinical evidence

In an early clinical study in 12 patients, vigabatrin 2 to 3 g daily did not change the serum levels of carbamazepine.[1] Similarly, other studies found that carbamazepine levels were not significantly altered by the addition of vigabatrin.[2,3] However, in one study, in which 59 patients taking carbamazepine received vigabatrin, 34 patients had an increase in carbamazepine levels, 3 had no change, and 22 had a decrease in carbamazepine levels, resulting in a mean overall increase of 6%, which was not significant.[4] Similarly, in another study 46 out of 66 patients had an increase in carbamazepine level of at least 10% (mean increase about 24%), and in 24 of these patients the carbamazepine level exceeded the reference range.[5] In this study, the increase in carbamazepine level was greater the lower the initial carbamazepine level.[5] In contrast, one study in 15 patients reported a mean 18% *decrease* in carbamazepine levels when vigabatrin was added.[6]

Mechanism

Not understood.

Importance and management

The studies seem to suggest that any change in carbamazepine levels with vigabatrin is of borderline clinical significance and therefore the majority of patients will not be affected. Any change is likely to be more important in patients at the top of the therapeutic carbamazepine range. It would therefore seem prudent to be alert for any increase in carbamazepine adverse effects (such as nausea and vomiting, ataxia, and drowsiness) and consider taking carbamazepine levels and reducing the carbamazepine dose if these develop.

Carbamazepine or Oxcarbazepine + Viloxazine

Viloxazine can cause a marked rise in carbamazepine levels and toxicity has been seen. Viloxazine does not appear to alter oxcarbazepine levels.

Clinical evidence

(a) Carbamazepine

The serum carbamazepine levels of 7 patients rose by 50% (from 8.1 micrograms/mL to 12.1 micrograms/mL) after they took viloxazine 100 mg three times daily for 3 weeks.[1] Signs of mild toxicity (dizziness, ataxia, fatigue, drowsiness) developed in 5 of the 7 patients. These symptoms disappeared and the serum carbamazepine levels fell when viloxazine was withdrawn.[1] Another report found a 2.5-fold increase in serum carbamazepine levels in one patient that occurred within 2 weeks of starting viloxazine 300 mg daily.[2] Another report found an average 55% rise in plasma carbamazepine levels and toxicity in 4 of 7 patients also taking viloxazine.[3] Yet another patient developed choreoathetosis and increased serum carbamazepine levels, which were attributed to the use of viloxazine.[4]

In one study, the pharmacokinetics of a single dose of viloxazine were reported to be unaffected by carbamazepine,[5] but in the case report cited above, which was at steady-state, the viloxazine levels were found to be reduced by carbamazepine.[2]

(b) Oxcarbazepine

In 6 patients with simple or partial seizures the steady-state serum levels of oxcarbazepine (average dose 1.5 g daily) were unaffected by the addition of viloxazine 100 mg twice daily for 10 days. No adverse effects were seen.[6]

Mechanism

Uncertain. What is known suggests that viloxazine inhibits the metabolism of carbamazepine, thereby reducing its clearance and raising its serum levels.

Importance and management

Information seems to be limited to the reports cited. If concurrent use is undertaken, serum carbamazepine levels should be monitored closely and suitable dose reductions made as necessary to avoid possible toxicity. No dose adjustment seems to be necessary with oxcarbazepine.

Ethosuximide + Isoniazid

A single report describes a patient who developed psychotic behaviour and signs of ethosuximide toxicity when isoniazid was also given.

Clinical evidence, mechanism, importance and management

An patient with epilepsy, who had been stable taking ethosuximide and sodium valproate for 2 years, developed persistent hiccuping, nausea, vomiting, anorexia and insomnia within a week of starting to take isoniazid 300 mg daily. Psychotic behaviour gradually developed over the next 5 weeks and so the isoniazid was stopped. The appearance of these symptoms appeared to be related to the sharp rise in serum ethosuximide levels (from about 50 micrograms/mL up to 198 micrograms/mL).[1] It is suggested that the isoniazid may have inhibited the metabolism of the ethosuximide, leading to accumulation and toxicity. The general importance of this case is uncertain. More study is needed to establish an interaction.

1. van Wieringen A, Vrijlandt CM. Ethosuximide intoxication caused by interaction with isoniazid. *Neurology* (1983) 33, 1227–8.

Ethosuximide + Other antiepileptics

Minor to modest falls in ethosuximide levels may occur if carbamazepine, primidone or phenytoin are also given, whereas methylphenobarbital or valproate may cause a rise in ethosuximide levels. Lamotrigine appears not to affect ethosuximide levels.
Ethosuximide is reported to have caused phenytoin toxicity in a few cases, and it appears that ethosuximide can reduce valproate levels.

Clinical evidence

(a) Barbiturates

In a retrospective analysis, the level-to-dose ratio of ethosuximide was 33% lower in 29 patients with epilepsy taking ethosuximide and **primidone** than in 39 patients taking ethosuximide alone,[1] suggesting that primidone reduces ethosuximide levels.

Similarly, in a study that compared the pharmacokinetics of a single dose of ethosuximide in 10 patients with epilepsy taking **phenobarbital**, phenytoin and/or carbamazepine with 12 healthy controls, the epileptic group had markedly shorter (about halved) ethosuximide half-lives.[2] Conversely, another report stated that ethosuximide levels tended to rise (amount not stated) when **methylphenobarbital** was given (the opposite effect to that which would be expected), but ethosuximide did not appear to be affected by **phenobarbital** or **primidone**.[3] Phenobarbital levels (derived from **primidone**) do not appear to be affected by ethosuximide.[4]

(b) Carbamazepine

A study in 6 healthy subjects taking ethosuximide 500 mg daily found that the mean plasma levels of ethosuximide were reduced by 17% (from 32 mg/mL to 27 mg/mL) by carbamazepine 200 mg daily for 18 days. One individual had a 35% reduction in ethosuximide levels.[5] Another study, which compared 10 patients with epilepsy taking enzyme-inducing antiepileptic drugs, including 4 taking carbamazepine, with 12 healthy controls found that the epileptic group had markedly shorter (about halved) ethosuximide half-lives.[2]

In contrast, the concurrent use of carbamazepine did not affect the correlation between ethosuximide dose and levels in another study.[3]

(c) Lamotrigine

Five children taking ethosuximide and various other antiepileptics had no change in their plasma ethosuximide levels when lamotrigine was also given.[6]

(d) Phenytoin

A study compared the pharmacokinetics of a single dose of ethosuximide in 10 patients with epilepsy taking phenobarbital, phenytoin and/or carbamazepine with 12 healthy controls. The epileptic group had markedly shorter (about halved) ethosuximide half-lives.[2] In contrast, the concurrent use of phenytoin did not affect the correlation between ethosuximide levels and dose in another study.[3]

Three cases have occurred in which ethosuximide appeared to have been responsible for increasing phenytoin levels,[7-9] leading to the development of phenytoin toxicity in 2 patients.[8,9]

(e) Valproate

Four out of 5 patients taking ethosuximide (average dose 27 mg/kg) had an increase in their serum levels of about 50% (from 73 micrograms/mL to 112 micrograms/mL), within 3 weeks of starting to take valproic acid (adjusted to the maximum tolerated dose). Sedation occurred and ethosuximide dose reductions were necessary.[10] In a single-dose study in 6 healthy subjects, the use of sodium valproate for 9 days was reported to have increased the ethosuximide half-life and reduced its clearance by 15%.[11] However, other studies have described no changes[12,13] or even lower serum ethosuximide levels (level to dose ratio reduced by 36%) when valproate was given.[1]

One study in 13 children found that ethosuximide can lower valproate serum levels. In the presence of ethosuximide the valproate levels were lower than with valproate alone (87 micrograms/mL versus 120 micrograms/mL). After stopping ethosuximide the valproate levels rose by about 40%.[14]

Mechanism

The most probable explanation for the fall in ethosuximide levels is that carbamazepine and the other enzyme-inducing antiepileptics increase the metabolism and clearance of ethosuximide, which is known to be metabolised by the cytochrome P450 subfamily CYP3A.[2]

Importance and management

The concurrent use of antiepileptics is common and often advantageous. Information on these interactions is sparse and even contradictory and their clinical importance is uncertain. Nevertheless, good monitoring would clearly be appropriate if these drugs are used with ethosuximide to monitor for potential toxicity and to ensure adequate seizure control.

Felbamate + Antacids

In one study, an aluminium/magnesium hydroxide-containing antacid had no effect on the absorption of felbamate.

Clinical evidence, mechanism, importance and management

Felbamate 2.4 g daily was given to 9 women with epilepsy for 2 weeks. For a third week the felbamate was taken with an antacid containing **aluminium/magnesium hydroxide** (*Maalox Plus*). No significant changes in the plasma levels or AUC of felbamate were seen.[1] No felbamate dose adjustments would seem to be needed if it is taken with this or any other similar antacid.

1. Sachdeo RC, Narang-Sachdeo SK, Howard JR, Dix RK, Shumaker RC, Perhach JL, Rosenberg A. Effect of antacid on the absorption of felbamate in subjects with epilepsy. *Epilepsia* (1993) 34 (Suppl 6), 79–80.

Felbamate + Erythromycin

Erythromycin does not alter the pharmacokinetics of felbamate.

Clinical evidence, mechanism, importance and management

In a randomised, crossover study, 12 patients with epilepsy were given felbamate 3 g or 3.6 g daily, either alone or with erythromycin 333 mg every 8 hours for 10 days. The pharmacokinetics of felbamate were unchanged by erythromycin.[1] There would therefore seem no need to adjust the dose of felbamate if erythromycin is given.

Felbamate + Gabapentin

There is some evidence that the half-life of felbamate may be prolonged by gabapentin.

Clinical evidence, mechanism, importance and management

In a retrospective examination of clinical data from patients taking felbamate, its half-life was found to be 24 hours in 40 patients taking felbamate alone, whereas in 18 other patients also taking gabapentin (including 7 taking a third drug), the half-life of felbamate was extended to 32.7 hours.[1] The practical clinical importance of this effect is uncertain. More study is needed.

Fosphenytoin + Miscellaneous

Fosphenytoin is a prodrug of phenytoin, which is rapidly and completely hydrolysed to phenytoin in the body. It is predicted to interact with other drugs in the same way as phenytoin.[1,2] No drugs are known to interfere with the conversion of fosphenytoin to phenytoin.[2]

2. Pro-Epanutin (Fosphenytoin sodium). Pfizer Ltd. UK Summary of product characteristics, December 2008.

Gabapentin + Antacids

Aluminium/magnesium hydroxide slightly reduces the absorption of gabapentin.

Clinical evidence, mechanism, importance and management

An **aluminium/magnesium hydroxide** antacid (*Maalox TC*) reduced the bioavailability of gabapentin 400 mg by about 20% when given either at the same time or 2 hours after gabapentin. When the antacid was given 2 hours before gabapentin, the bioavailability was reduced by about 10%.[1] These small changes are unlikely to be of clinical importance. Nevertheless, the manufacturers of gabapentin recommend that it is taken at least 2 hours after **aluminium/magnesium-containing antacids**.[2,3]

2. Neurontin (Gabapentin). Pfizer Ltd. UK Summary of product characteristics, December 2008.
3. Neurontin (Gabapentin). Pfizer Inc. US Prescribing information, April 2009.

Gabapentin + Cimetidine

A brief report notes that cimetidine decreased the renal clearance of gabapentin by 12%, which was not expected to be clinically important. No study details were given.[1]

1. Busch JA, Bockbrader HN, Randinitis EJ, Chang T, Welling PG, Reece PA, Underwood B, Sedman AJ, Vollmer KO, Türck D. Lack of clinically significant drug interactions with Neurontin (Gabapentin). 20th International Epilepsy Congress. Oslo, Norway, July 1993. Abstract 013958.

Gabapentin + Food

Food, including protein and enteral feeds, does not have a clinically important effect on the absorption of gabapentin.

Clinical evidence, mechanism, importance and management

A high-protein meal (80 g of total protein) increased the maximum serum levels of a single 800-mg dose of gabapentin by 36% in healthy subjects. The AUC was increased by 11%, which was not statistically significant.

These findings were the opposite of those expected, because L-amino acids compete for gabapentin intestinal transport *in vitro*.[1] Another study also reported no significant differences in the pharmacokinetics of gabapentin when a single 400- or 800-mg dose was given after a high protein meal rather than in the fasting state.[2]

In another single-dose study, the absorption of gabapentin from capsules did not differ when given intact or opened and mixed with either apple sauce or orange juice, but tended to be higher (AUC increased by 26%) when opened and mixed with a protein-containing vehicle (chocolate pudding).[3] Similarly, no change in absorption was found when gabapentin syrup was mixed with tap water, grape juice, or an **enteral feed** (*Sustacal*), but a modest 31% increase in the AUC was seen when the gabapentin was mixed with **chocolate milk**.[4]

These small changes are unlikely to be of clinical importance, so it does not matter when gabapentin is taken in relation to food.

4. Parnell J, Sheth R, Limdi N, Gidal BE. Oral absorption of gabapentin syrup is not impaired by concomitant administration with various beverages or enteral nutrition supplement. *Epilepsia* (2001) 42 (Suppl 7), 91.

Gabapentin + Other antiepileptics

Gabapentin does not normally affect the pharmacokinetics of carbamazepine, phenytoin, phenobarbital or valproate. However, isolated reports describe increased phenytoin levels and toxicity in two patients given gabapentin.

Clinical evidence, mechanism, importance and management

The pharmacokinetics of both **phenytoin** and gabapentin remained unchanged in 8 patients with epilepsy who were given gabapentin 400 mg three times daily for 8 days, in addition to **phenytoin**, which they had been taking for at least 2 months.[1] Other studies confirm that the steady-state pharmacokinetics of **phenytoin** are unaffected by gabapentin, and that the pharmacokinetics of gabapentin are similarly unaffected by **phenytoin**.[2,3] These reports contrast with an isolated report of a patient taking **phenytoin**, **carbamazepine** and **clobazam** whose serum **phenytoin** levels increased three to fourfold, with symptoms of toxicity, on two occasions when gabapentin 300 to 600 mg daily was given. **Carbamazepine** serum levels remained unchanged. The author suggests that this differing reaction may be because the patient was taking more than one antiepileptic, unlike previous studies where only single drugs had been used.[4] However, another case of **phenytoin** toxicity possibly attributable to gabapentin has been described in a patient who was not taking any other antiepileptics.[5]

Gabapentin does not affect **phenobarbital** levels, nor is it affected by **phenobarbital**.[2,3,6] Other studies confirm that the steady-state pharmacokinetics of **carbamazepine** and **valproate** are unaffected by gabapentin, and that the pharmacokinetics of gabapentin are similarly unaffected by these antiepileptics.[2,3,7]

It would seem therefore that no dose adjustments are normally needed if gabapentin is added to treatment with most of these antiepileptics. However, if gabapentin is added to **phenytoin** it may be wise to bear the possibility of raised **phenytoin** levels in mind. Be alert for phenytoin adverse effects (e.g. blurred vision, nystagmus, ataxia or drowsiness).

For mention that gabapentin may prolong the half-life of felbamate, see 'Felbamate + Gabapentin', p.616.

For mention of the lack of interaction between levetiracetam and gabapentin, see 'Levetiracetam + Other antiepileptics', p.621.

Gabapentin + Probenecid

A brief report notes that probenecid had no effect on the renal clearance of gabapentin. No study details were given.[1]

1. Busch JA, Bockbrader HN, Randinitis EJ, Chang T, Welling PG, Reece PA, Underwood B, Sedman AJ, Vollmer KO, Türck D. Lack of clinically significant drug interactions with Neurontin (Gabapentin). 20th International Epilepsy Congress. Oslo, Norway, July 1993. Abstract 013958.

Lacosamide + Miscellaneous

No clinically relevant pharmacokinetic interactions occur between lacosamide and digoxin, metformin or omeprazole. Food does not affect the pharmacokinetics of lacosamide. Potent enzyme inducers such as rifampicin (rifampin) are predicted to reduce the levels of lacosamide. Caution is required if class I antiarrhythmics are given with lacosamide because of the possibility of enhanced PR prolongation.

Clinical evidence, mechanism, importance and management

(a) Antiarrhythmics

Dose-dependent prolongation of the PR interval may occur with lacosamide.[1,2] The UK manufacturer advises that lacosamide should be used with caution in patients taking class I antiarrhythmics (see 'Table 9.1', (p.273)) or other drugs that prolong the PR interval. See also 'Lacosamide + Other antiepileptics', p.618.

(b) Enzyme inducers

The UK manufacturer notes that potent enzyme inducers (presumably CYP3A4 inducers as they name **rifampicin** (**rifampin**) and **St John's wort**) may moderately reduce the exposure to lacosamide and advises caution when starting or ending treatment with these drugs in patients taking lacosamide.[1] For a list of CYP3A4 inducers, see 'Table 1.4', (p.6).

(c) Food

In a study, 24 healthy subjects were given a single 300-mg dose of lacosamide in the fasted state or after a high-fat meal. Food did not affect lacosamide pharmacokinetics,[3] and it may therefore be taken without regard to food.[1,2]

(d) Omeprazole

Omeprazole 40 mg daily increased the AUC of lacosamide by 19%.[1] The US manufacturer notes that plasma levels of the (inactive[1]) *O*-desmethyl metabolite of lacosamide were decreased by about 60% in the presence of omeprazole,[2] possibly due to inhibition of lacosamide metabolism by cytochrome P450 isoenzyme CYP2C19.[1] These changes would not be expected to be clinically relevant. Lacosamide 600 mg daily did not affect the pharmacokinetics of a single 40-mg dose of omeprazole,[1,2] although the US manufacturer states that *in vitro* data suggest that lacosamide has the potential to inhibit CYP2C19.[2] However, one *in vitro* study suggests the interaction only occurs at levels 30-fold higher than therapeutic lacosamide plasma levels.[4]

(e) Other drugs

In studies in healthy subjects there were no pharmacokinetic interactions between lacosamide and digoxin or metformin.[1,2,5]

Available at: http://www.aesnet.org/go/publications/aes-abstracts/abstract-search/?mode=display&st=lacosamide&sy=all&sb=All&startrow=31&id=6674 (accessed 29/01/10).

Lacosamide + Other antiepileptics

No significant pharmacokinetic interaction appears to occur between lacosamide and carbamazepine, lamotrigine, oxcarbazepine, or valproate. Lacosamide does not affect plasma levels of phenytoin or phenobarbital, clonazepam, gabapentin, levetiracetam, topiramate and zonisamide. However, limited evidence suggests that the enzyme-inducing antiepileptics may reduce lacosamide exposure.

Clinical evidence, mechanism, importance and management

(a) Carbamazepine or Oxcarbazepine

In a study in 19 healthy subjects given lacosamide 200 mg twice daily, modified-release carbamazepine 200 mg twice daily had no clinically significant effect on the pharmacokinetics of lacosamide.[1] In a further study in 18 healthy subjects given modified-release carbamazepine 200 mg twice daily with lacosamide 200 mg twice daily, there were no significant changes in the pharmacokinetics of carbamazepine.[1] In studies in patients with uncontrolled partial seizures taking one or two antiepileptic drugs, the addition of lacosamide 100 mg to 600 mg daily did not affect the plasma levels of carbamazepine and its 10,11-epoxide metabolite or oxcarbazepine.[2,3] In placebo-controlled clinical studies in patients with partial-onset seizures, the plasma levels of carbamazepine and carbamazepine-10,11-epoxide or the active metabolite of oxcarbazepine, monohydroxyoxcarbazepine, were unaffected by the concurrent use lacosamide.[4] The manufacturers of lacosamide note that, in a population pharmacokinetic analysis, the concurrent use of lacosamide with other antiepileptic drugs known to be enzyme inducers (carbamazepine, phenytoin, phenobarbital) decreased the exposure of lacosamide by 15 to 25%.[4,5] This finding is expected to be of limited clinical relevance, and it would appear that, in general, no dose adjustment of either carbamazepine or lacosamide is likely to be needed on concurrent use. However, the manufacturers advise caution if lacosamide is given with drugs known to be associated with PR prolongation, and they name carbamazepine.[4,5] However, the UK manufacturer states that a subgroup analysis of clinical study results did not find an increase in PR prolongation in patients given lacosamide and carbamazepine.[5]

(b) Lamotrigine

In studies in patients with uncontrolled partial seizures taking one or two antiepileptic drugs, the addition of lacosamide in doses of 100 mg to 600 mg daily did not affect plasma levels of lamotrigine.[2,3] The manufacturers advise caution if lacosamide is given with drugs known to be associated with PR prolongation, and they name lamotrigine.[4,5] However, the UK manufacturer of lacosamide states that subgroup analysis of clinical study results did not find an increase in PR prolongation in patients given lacosamide and lamotrigine.[5]

(c) Phenobarbital or Phenytoin

In studies in patients with uncontrolled partial seizures taking one or two antiepileptic drugs, the addition of lacosamide in doses of 100 mg to 600 mg daily did not affect the plasma levels of phenytoin.[2,3] In clinical studies, lacosamide did not affect the plasma levels of phenobarbital.[4] The manufacturer of lacosamide notes that, in a population pharmacokinetic analysis in patients with partial-onset seizures, the concurrent use of lacosamide with other antiepileptic drugs known to be enzyme inducers (carbamazepine, phenytoin, phenobarbital) decreased the exposure of lacosamide by 15 to 25%.[4,5] However, this would be expected to be of little clinical relevance, and no dose adjustments would be expected to be needed if lacosamide is given with phenytoin or phenobarbital.

(d) Pregabalin

The manufacturers of lacosamide advise caution if lacosamide is given with drugs known to be associated with PR prolongation: they name pregabalin.[4,5]

(e) Valproate

Phase I studies in healthy subjects have found no pharmacokinetic interaction between lacosamide and valproate.[6] In studies in patients with uncontrolled partial seizures taking one or two antiepileptic drugs, the addition of lacosamide in doses of 100 mg to 600 mg daily did not affect the plasma levels of valproate.[2,3] Further, in clinical studies, the concurrent use of lacosamide did not affect the plasma levels of valproate.[4] No dose adjustment of lacosamide or valproate appears to be necessary on concurrent use.

(f) Other antiepileptics

In studies in patients with uncontrolled partial seizures taking one or two antiepileptic drugs, the addition of lacosamide in doses of 100 mg to 600 mg daily did not affect the plasma levels of **gabapentin**, **levetiracetam**, **topiramate**, or **zonisamide**.[2,3] In clinical studies, the concurrent use of lacosamide did not affect the steady-state levels of **clonazepam**.[4]

Lamotrigine + Antimycobacterials

Rifampicin markedly increased the clearance of lamotrigine in a pharmacokinetic study. A case report described a similar finding, and also included some limited evidence suggesting that isoniazid may inhibit lamotrigine metabolism.

Clinical evidence

In a pharmacokinetic study in 10 healthy subjects, **rifampicin** (**rifampin**) 600 mg daily for 5 days increased the clearance of a single 25-mg dose of lamotrigine by 97% and decreased its AUC by 44%. The amount of lamotrigine glucuronide recovered in the urine was increased by 36%.[1] Similarly, a case report describes a 56-year-old woman taking lamotrigine 150 mg daily who had unexpectedly low serum lamotrigine levels of 1.3 mg/L after starting **rifampicin**, **isoniazid** and pyrazinamide. The lamotrigine dose was therefore increased to 250 mg daily. After rifampicin and pyrazinamide were stopped, isoniazid continued and ethambutol started, the lamotrigine serum levels rose to 12.4 mg/L but no toxicity was seen.[2] It is unclear whether there is any relationship between lamotrigine plasma levels and toxicity.[3]

Mechanism

Rifampicin (rifampin) increases the loss of lamotrigine from the body, probably by inducing glucuronidation via glucuronyltransferases.[1] It was suggested that isoniazid may have inhibited lamotrigine metabolism.[2]

Importance and management

Information appears to be limited to these reports, but the interaction between lamotrigine and rifampicin (rifampin) would appear to be established. Be aware that rifampicin could reduce the efficacy of lamotrigine, and that increased lamotrigine doses are likely to be required.

The case report also raises the possibility of an interaction between lamotrigine and isoniazid. If isoniazid is added to or withdrawn from lamotrigine treatment, be alert for the need to adjust the lamotrigine dosage.

3. Chong E, Dupuis LL. Therapeutic drug monitoring of lamotrigine. *Ann Pharmacother* (2002) 36, 917–20.

Lamotrigine + Cimetidine

In a study in 10 healthy subjects, cimetidine 400 mg twice daily for 5 days had no effect on the pharmacokinetics of a single 25-mg

dose of lamotrigine. No lamotrigine dose adjustment appears to be needed during concurrent use.[1]

1. Ebert U, Thong NQ, Oertel R, Kirch W. Effects of rifampicin and cimetidine on pharmacokinetics and pharmacodynamics of lamotrigine in healthy subjects. *Eur J Clin Pharmacol* (2000) 56, 299–304.

Lamotrigine + Felbamate

Felbamate does not appear to affect the pharmacokinetics of lamotrigine.

Clinical evidence, mechanism, importance and management

In 21 healthy subjects, felbamate 1.2 g twice daily had minimal effects on the pharmacokinetics of lamotrigine 100 mg twice daily, when both drugs given together for 10 days. The AUC of lamotrigine was increased by 14%, which was not considered to be clinically relevant.[1] Similarly, there was no difference in lamotrigine pharmacokinetics in 6 patients receiving lamotrigine and felbamate and 5 patients taking lamotrigine alone.[2] Therefore the dose of lamotrigine does not need to be adjusted if felbamate is given.

1. Colucci R, Glue P, Holt B, Banfield C, Reidenberg P, Meehan JW, Pai S, Nomeir A, Lim J, Lin C-C, Affrime MB. Effect of felbamate on the pharmacokinetics of lamotrigine. *J Clin Pharmacol* (1996) 36, 634–8.
2. Gidal BE, Kanner A, Maly M, Rutecki P, Lensmeyer GL. Lamotrigine pharmacokinetics in patients receiving felbamate. *Epilepsy Res* (1997) 27, 1–5.

Lamotrigine + Fluconazole

An isolated case suggests that fluconazole does not affect lamotrigine levels.

Clinical evidence, mechanism, importance and management

A patient who had been taking carbamazepine, lamotrigine and barbexaclone for many years, was given fluconazole 150 mg with her morning dose of antiepileptics. Although she developed symptoms of carbamazepine toxicity and raised carbamazepine levels, her lamotrigine levels were not significantly affected by the concurrent use fluconazole.[1]

1. Ulivelli M, Rubegni P, Nuti D, Bartalini S, Giannini F, Rossi S. Clinical evidence of fluconazole-induced carbamazepine toxicity. *J Neurol* (2004) 251, 622–3.

Lamotrigine + Orlistat

Orlistat may reduce the absorption of lamotrigine.

Clinical evidence, mechanism, importance and management

An patient with epilepsy taking lamotrigine 200 mg daily had an increase in seizure frequency from one each month to more than one each week after starting orlistat 120 mg three times daily. It was suggested that orlistat, which is known to affect the absorption of lipophilic drugs, may have reduced the absorption of lamotrigine which is considered to be highly lipophilic.[1]

This appears to be the only report of an interaction between orlistat and lamotrigine, and therefore its clinical relevance is unclear.

1. Bigham S, McGuigan C, MacDonald BK. Reduced absorption of lipophilic anti-epileptic medications when used concomitantly with the anti-obesity drug orlistat. *Epilepsia* (2006) 47, 2207.

Lamotrigine + Phenobarbital or Primidone

Phenobarbital has been associated with reduced lamotrigine levels. Lamotrigine does not appear to affect phenobarbital and primidone levels.

Clinical evidence, mechanism, importance and management

In a retrospective study, the lamotrigine serum concentration-to-dose ratio was lower in patients also taking phenobarbital than in those taking lamotrigine alone (0.52 versus 0.99),[1] suggesting that phenobarbital lowers lamotrigine levels. Similar findings have been reported in another study.[2] No changes in the serum levels of phenobarbital or primidone were seen in a study in 12 patients also given lamotrigine 75 to 400 mg daily.[3]

Phenobarbital induces the metabolism of lamotrigine, and the recommended starting dose and long-term maintenance dose of lamotrigine in patients already taking phenobarbital or primidone is twice that of patients receiving lamotrigine monotherapy.[4,5] However, note that if patients are also taking valproate in addition to phenobarbital, the lamotrigine dose should be reduced, see ‘Lamotrigine + Valproate’, p.620. The lamotrigine dose may need to be reduced if phenobarbital is withdrawn.

Lamotrigine + Phenytoin

Phenytoin has been associated with reduced lamotrigine serum levels. Lamotrigine has no effect on phenytoin levels.

Clinical evidence, mechanism, importance and management

In a retrospective study, the lamotrigine serum concentration-to-dose ratio was much lower in patients also taking phenytoin than in those taking lamotrigine alone (0.32 versus 0.98),[1] suggesting that phenytoin lowers lamotrigine levels. Other studies in patients taking lamotrigine with phenytoin have reported similar findings.[2,3] In another study, the mean lamotrigine levels were approximately doubled when phenytoin was withdrawn.[4]

One study suggests that the serum level of phenytoin is unchanged in patients taking lamotrigine 75 to 400 mg daily.[5]

Phenytoin is a known hepatic enzyme inducer, which increases lamotrigine metabolism. The recommended starting dose and long-term maintenance dose of lamotrigine in patients already taking phenytoin is twice that of patients receiving lamotrigine monotherapy.[6,7] The lamotrigine dose may need to be reduced if phenytoin is withdrawn.

However, note that if patients are also taking valproate in addition to phenytoin, the lamotrigine dose should be reduced, see ‘Lamotrigine + Valproate’, p.620.

Lamotrigine + Sertraline

A report describes two cases in which sertraline appeared to increase lamotrigine levels and cause toxicity.

Clinical evidence, mechanism, importance and management

A patient’s lamotrigine levels were found to have doubled, and symptoms of toxicity were noted (confusion, cognitive impairment), 6 weeks after sertraline 25 mg daily was started.[1] The lamotrigine dose was halved, and the sertraline dose titrated to 50 mg daily. Symptoms of toxicity resolved, but the lamotrigine levels were still 24% higher than before sertraline was started. Another patient taking sertraline and lamotrigine had signs of lamotrigine toxicity. The sertraline dose was reduced by 33%, which resulted in a halving of the lamotrigine level even though the lamotrigine dose was increased by 33%.

The authors suggest that sertraline may competitively inhibit the glucuronidation of lamotrigine. Evidence so far appears limited to this report of 2 cases. In view of the increased risk of rash with increased lamotrigine levels, until more is known, it may be prudent to monitor the outcome of concurrent use.

1. Kaufman KR, Gerner R. Lamotrigine toxicity secondary to sertraline. *Seizure* (1998) 7, 163–5.

Lamotrigine + Topiramate

Although one study suggested that topiramate reduces lamotrigine levels, in general a clinically relevant interaction would not be expected. Lamotrigine has no effect on topiramate levels.

Clinical evidence, mechanism, importance and management

In the preliminary report of one study, it was found that serum lamotrigine levels of 4 of 7 patients who were stable taking lamotrigine 350 to 800 mg daily decreased by 40 to 50% when they were given topiramate, titrated to 800 mg daily.[1] In contrast, other authors reported that the addition of topiramate 75 to 800 mg daily had little effect on the steady-state serum levels of lamotrigine 100 to 950 mg daily in 24 patients. The mean lamotrigine level before topiramate was 10.4 mg/L and during topiramate was 9.7 mg/L. Only 2 of the patients had reductions of greater than 30% (40% and 43%).[2] A further study by the same research group confirmed the lack of effect of topiramate on lamotrigine pharmacokinetics.[3] The authors of the second study[2] note that there is some evidence that peak-to-trough variations of as much as 30 to 40% can occur during the use of lamotrigine, and therefore timing of blood sampling might be a factor in the findings of the first study.[1]

In one study in 13 patients lamotrigine had no effect on topiramate pharmacokinetics. The oral clearance of topiramate 400 mg daily was 2.6 L/hour when given alone, and 2.7 L/hour when given with lamotrigine, and the AUC and plasma levels of topiramate were also similar.[3]

The balance of the evidence suggests that there is no important pharmacokinetic interaction between topiramate and lamotrigine. No special precautions appear to be necessary during concurrent use.

Lamotrigine + Valproate

The serum levels of lamotrigine can be markedly increased by valproate. Concurrent use has been associated with skin rashes, tremor and other toxic reactions. Lamotrigine has been found to cause small increases, decreases or no changes in valproate levels.

Clinical evidence

(a) Effects on lamotrigine levels

In 6 healthy subjects sodium valproate 200 mg every 8 hours reduced the clearance of lamotrigine by 20% and increased its AUC by 30%.[1] In another study in 18 healthy subjects taking valproate 500 mg twice daily, the clearance of lamotrigine 50, 100 or 150 mg daily was also markedly reduced and its half-life increased.[2] In a retrospective study, the lamotrigine serum concentration-to-dose ratio was markedly higher in patients also taking valproate than in those taking lamotrigine monotherapy (3.57 versus 0.98), suggesting that valproate increases lamotrigine levels. In patients also taking phenytoin, the effects of valproate on lamotrigine were offset (0.99 versus 0.98). However, the effects of valproate on lamotrigine were not completely offset by either carbamazepine or phenobarbital (1.67 or 1.8, respectively versus 0.98).[3] Other studies have reported broadly similar findings.[4-6] Three studies have found that the effect of valproate on lamotrigine was independent of the valproate dose or serum level (that is, it is maximal within the usual therapeutic dose range of valproate).[6-8] Another study has shown that the inhibition of lamotrigine clearance by valproate begins at very low valproate doses (less than 125 mg daily), and is maximal at doses of about 500 mg daily.[9] A study in women found that valproate appears to reduce the induction of lamotrigine metabolism associated with pregnancy or the use of oral contraceptives thus resulting in higher lamotrigine plasma levels.[10] Consider also 'Combined hormonal contraceptives + Lamotrigine', p.1183.

(b) Effects on valproate levels

In one study, 18 healthy subjects taking valproate 500 mg twice daily were also given lamotrigine 50, 100 or 150 mg daily. The lamotrigine caused a 25% decrease in valproate serum levels and a 25% increase in valproate oral clearance.[2] A study in 11 children taking valproate and other antiepileptics noted that no clinically important changes in valproate serum levels occurred when lamotrigine was added.[11] A retrospective analysis found that lamotrigine was associated with only a 7% reduction in valproate levels, which would not be expected to be clinically significant.[12]

(c) Toxic reactions

1. Rash. A patient who had taken valproate for 3 years and whose seizures were not adequately controlled by 600 mg daily was also given lamotrigine 25 mg every other day for 2 weeks, then 25 mg daily. In the fourth week of treatment he mistakenly took lamotrigine 200 mg instead of 25 mg and within hours he developed fever, oral lesions and then skin lesions, diagnosed as the Stevens-Johnson syndrome. Lamotrigine was withdrawn, the valproate dose was increased to 750 mg daily and he was treated with prednisolone, fluids, cephalosporins and proton pump inhibitors and after one month he had no active skin or mucosal lesions. It was suggested that an interaction between lamotrigine and valproate may have contributed to the development of Stevens-Johnson syndrome.[13] The authors of another report suggest that the development of Stevens-Johnson syndrome in a patient whose daily lamotrigine dose was increased gradually from 25 mg to 150 mg daily occurred as a result of the concurrent use of valproic acid. The patient was also taking trifluoperazine and zuclopenthixol.[14]

In a survey of adult patients with epilepsy who had lamotrigine added to their existing treatment, 33 were also taking valproate. Of these, 10 patients (30%) developed a rash, whereas only 6 of the 70 (8%) not taking valproate did so.[15] In another analysis of skin rash in patients taking lamotrigine, 11 of 12 patients with serious rash were also taking sodium valproate, and all but one had a lamotrigine starting dose that is higher than currently recommended.[16] However, in another study in which patients taking valproate were given lower initial doses of lamotrigine, there was no difference in incidence of rash when compared with those taking lamotrigine and other antiepileptics (13% versus 14.2%).[17]

2. Tremor. In 3 patients severe and disabling tremor (sometimes preventing them from feeding themselves) occurred when they were given lamotrigine and sodium valproate. The problem resolved when the doses were reduced.[18] In a study of 13 adult patients, all developed upper limb tremor when given lamotrigine with valproate, which could be minimised by reducing the dose of either or both drugs.[19] Other studies have found similar effects.[7,20,21]

3. Other. Severe multiorgan dysfunction and disseminated intravascular coagulation was seen in 2 children when they took lamotrigine with valproate.[22] Three patients taking lamotrigine developed neurotoxicity (confusion, lethargy) after starting to take valproate (an intravenous bolus dose of valproic acid then oral therapy). Lamotrigine levels had risen 2.9- to 6.9-fold.[20] Confusion, disorientation, visual disturbances and behavioural changes were reported in another patient 4 days after valproate was added to her treatment with lamotrigine. Lamotrigine levels were found to be 22.9 micrograms/mL (reference range 1 to 13 micrograms/mL). She recovered within 2 days of the discontinuation of both drugs.[23]

One study reported that the formation of hepatotoxic metabolites of valproate was unaffected by lamotrigine.[2]

Mechanism

Not fully understood. It is thought that valproate reduces lamotrigine glucuronidation by competitive inhibition, which results in a decreased lamotrigine clearance.[1,2,24,25] Raised lamotrigine levels have been implicated in the development of rash and serious skin reactions including Stevens-Johnson syndrome; concurrent valproate appears to increase the risk.[13,14,17,26] If lamotrigine is given with valproate rather than as lamotrigine monotherapy in pregnancy, there is a possibility that the foetus will be exposed to greater levels of lamotrigine, as valproate may counter the decline in lamotrigine levels that occur in pregnancy.[10]

Increased valproate clearance may be due to enzyme induction. Tremor may be the result of a pharmacodynamic interaction.[7,19]

Importance and management

A well documented interaction. Concurrent use can be therapeutically valuable, but the lamotrigine dose should be reduced by about half when valproate is added to avoid possible toxicity (sedation, tremor, ataxia, fatigue, rash).[2,7-9,17,18,27] In patients already taking valproate, the manufacturer of lamotrigine recommends a lamotrigine starting dose that is half that of lamotrigine monotherapy, irrespective of whether they are also receiving enzyme-inducing antiepileptics, and a very gradual dose-escalation rate.[28] The outcome should be very well monitored. The CSM in the UK has suggested that the concurrent use of sodium valproate is one of the main risk factors for the development of serious skin reactions to lamotrigine, because it prolongs the half-life of lamotrigine.[26] Rashes are potentially serious and should be evaluated promptly.[17,28,29] The reports cited above[18,22] also suggest that sometimes other serious reactions (disabling tremor, multiorgan dysfunction) can occur.

Levetiracetam + Food

The oral absorption of levetiracetam is not significantly affected by food.

Clinical evidence, mechanism, importance and management

In a study, 10 healthy subjects were given a 500-mg tablet of levetiracetam with 120 mL of water or crushed and mixed with either 4 oz (about 113 g) of apple sauce or 120 mL of an enteral nutrition formulation (*Sustacal*). The overall rate and extent of absorption of oral levetiracetam were not significantly affected by crushing and mixing the tablet with either apple sauce or an enteral nutrition preparation, although the peak serum level of levetiracetam may be slightly reduced if it is mixed with enteral nutrition.[1] The clinical relevance of any effect seems likely to be small.

Levetiracetam + Other antiepileptics

There is some evidence that the enzyme-inducing antiepileptics (carbamazepine, phenobarbital, phenytoin and primidone) may modestly reduce levetiracetam levels. Levetiracetam does not usually alter the levels of these antiepileptics. However, some studies have found modestly raised phenytoin levels, and cases of possible carbamazepine toxicity have also been reported. There appears to be no pharmacokinetic interaction between levetiracetam and gabapentin, lamotrigine, topiramate, or valproate.

Clinical evidence, mechanism, importance and management

(a) Carbamazepine

Evidence from clinical studies suggests that levetiracetam does not affect the serum levels of carbamazepine.[1-3] A study in 187 children treated with antiepileptic drugs either alone or in combination found that levetiracetam did not significantly affect plasma levels of carbamazepine.[4] However, one report describes 4 patients who experienced disabling symptoms compatible with carbamazepine toxicity when levetiracetam was added. The symptoms resolved after a decrease in the carbamazepine dose or withdrawal of the levetiracetam. A pharmacodynamic interaction was suggested, because levels of carbamazepine and its metabolite, carbamazepine-10,11-epoxide, were not affected.[5]

Some evidence suggests that patients taking levetiracetam with enzyme-inducing antiepileptics such as carbamazepine had modestly (24%) lower levetiracetam levels than those also receiving antiepileptics not considered to be enzyme-inducers (gabapentin, lamotrigine, vigabatrin), but this was not considered clinically relevant.[6] Similarly, another retrospective analysis of patient data found that the serum levetiracetam level to dose ratio was modestly lower in patients also receiving carbamazepine than those receiving monotherapy (0.32 versus 0.52),[7] suggesting that carbamazepine moderately lowers levetiracetam levels.

In general, there is no need to modify the dose of either carbamazepine or levetiracetam when used together. However, the report of possible carbamazepine toxicity introduces a note of caution.

(b) Phenytoin

Some evidence suggests that patients taking levetiracetam with enzyme-inducing antiepileptics such as phenytoin had modestly (24%) lower levetiracetam levels than those taking other antiepileptics not considered to be enzyme inducers (gabapentin, lamotrigine, vigabatrin), but this was not considered clinically relevant.[6] A retrospective analysis of patient data found that the serum levetiracetam level-to-dose ratio was lower in patients also receiving phenytoin than those receiving monotherapy (0.32 versus 0.52),[7] suggesting that phenytoin modestly lowers levetiracetam levels.

Evidence from clinical studies suggests that levetiracetam does not affect the serum levels of phenytoin.[1-3] Similarly, in one study, levetiracetam 1.5 g twice daily for 12 weeks had no effect on the steady-state pharmacokinetics of phenytoin in 6 subjects with epilepsy who were taking stable doses of phenytoin.[8] However, in one clinical study the addition of levetiracetam increased phenytoin levels by 27% to 52% in 4 patients. A further patient had a 75% increase in phenytoin levels [estimated from figure] and experienced signs of toxicity (sedation, ataxia) and required a reduction in his phenytoin dose. Another patient with raised phenytoin levels [estimated increase of 47%] had the dose of levetiracetam reduced.[9]

In general therefore, there is no need to modify the dose of either phenytoin or levetiracetam when they are used together. However, the report of raised phenytoin levels suggests that some caution is warranted.

(c) Valproate

In healthy subjects, sodium valproate 500 mg twice daily for 8 days did not affect the pharmacokinetics of a single 1.5-g dose of levetiracetam. In addition, levetiracetam did not affect the pharmacokinetics of valproate.[10] In an analysis of clinical study data, the AUC of levetiracetam in 57 patients also taking valproic acid was slightly (11%) higher than in 28 patients also taking antiepileptics not thought to affect microsomal enzymes (gabapentin, lamotrigine, vigabatrin), but this was not thought to be clinically relevant.[6] In another retrospective analysis of patient data, the serum levetiracetam level-to-dose ratio was the same in patients also receiving valproic acid than those receiving monotherapy (0.53 versus 0.52),[7] suggesting that valproate does not alter levetiracetam levels. Furthermore, evidence from clinical studies suggests that levetiracetam does not affect the serum levels of valproate.[1,3,4] There appears to be no need to adjust the doses of either sodium valproate or levetiracetam if these drugs are used together.

(d) Other antiepileptics

The AUC of levetiracetam tended to be lower in 436 patients also taking enzyme-inducing antiepileptics (carbamazepine, phenobarbital, phenytoin, **primidone**) than in 28 patients also taking antiepileptics not thought to affect microsomal enzymes (**gabapentin**, **lamotrigine**, **vigabatrin**), but the difference was modest (24%).[6] Another retrospective analysis of patient data found that the serum levetiracetam level-to-dose ratio did not differ significantly between patients also taking **lamotrigine** and those taking levetiracetam alone (0.45 versus 0.52), but was modestly lower in those taking **oxcarbazepine** (0.34 versus 0.52).[7] A study in 187 children taking antiepileptic drugs either alone or in combination found that levetiracetam did not significantly affect plasma levels of **lamotrigine** or **topiramate**.[4]

Furthermore, evidence from clinical studies suggests that levetiracetam does not affect the serum levels of **gabapentin**, **lamotrigine**, **phenobarbital**, or **primidone**.[1-3] In general, therefore, no dose adjustments would seem to be needed if levetiracetam is used as add-on therapy with any of these drugs.

Levetiracetam + Probenecid

Probenecid increases the plasma levels of an inactive metabolite of levetiracetam.

Clinical evidence, mechanism, importance and management

One report suggests that probenecid 500 mg four times daily does not affect the renal excretion of levetiracetam. However, the renal excretion of the primary and pharmacologically inactive metabolite of levetiracetam, ucb L057, was reduced by 61%, and its plasma concentrations increased 2.5-fold,[1] although the manufacturer notes that these levels are still low.[2] The clinical relevance of elevated levels of ucb L057 is not known, therefore some have suggested caution is warranted in patients given both drugs.[1] The effect of levetiracetam on probenecid has not been studied.[2,3]

Mesuximide + Other antiepileptics

Phenobarbital, phenytoin, and possibly felbamate increase the levels of the active metabolite of mesuximide, *N*-desmethylmesuximide. Mesuximide increases the levels of phenobarbital and phenytoin, and decreases the levels of lamotrigine, and to a lesser extent, valproate.

Clinical evidence

(a) Felbamate

Three adolescent patients with epilepsy taking mesuximide developed mild adverse effects within 3 days of starting to take felbamate, which became more serious after one month (decreased appetite, nausea, weight loss, insomnia, dizziness, hiccups, slurred speech). During this time the levels of the active metabolite of mesuximide, *N*-desmethylmesuximide, rose by 26% and 46% in two patients, respectively. The adverse effects disappeared and *N*-desmethylmesuximide levels fell when the mesuximide dose was reduced. Other antiepileptics being taken were carbamazepine, ethotoin and valproate.[1]

(b) Lamotrigine

In 6 patients taking mesuximide, lamotrigine levels were 53% lower (range 36 to 72%), when compared with lamotrigine levels before starting or after stopping mesuximide. In some patients deterioration in seizure control was seen while taking mesuximide, and an improvement in seizure control occurred after mesuximide was stopped.[2] In another study, lamotrigine levels were about 70% lower in 13 patients also taking mesuximide than in 64 patients taking lamotrigine alone, when corrected for dose. Note that in patients also taking valproate, the reduction in lamotrigine levels caused by mesuximide was compensated for by the increase caused by valproate, see also 'Lamotrigine + Valproate', p.620.[3]

(c) Phenobarbital or Primidone

A study in hospitalised patients with petit mal epilepsy found that when mesuximide was given to 8 patients taking phenobarbital and 13 patients taking primidone, the mean serum levels of phenobarbital rose by 38% and 40%, respectively. Dose reductions were needed in 50% and 62% of patients, respectively. It was also found that the concurrent use of phenobarbital increased the serum levels of the active metabolite of mesuximide, *N*-desmethylmesuximide.[4]

(d) Phenytoin

Mesuximide was given to 17 patients taking phenytoin, which resulted in a 78% rise in the phenytoin serum levels requiring dose reductions in about 30% of the patients. It was also found that the concurrent use of phenytoin increased the serum levels of the active metabolite of mesuximide, *N*-desmethylmesuximide.[4]

(e) Valproate

A retrospective analysis of serum valproate levels was carried out in 17 patients who started and/or stopped taking mesuximide and whose concurrent medication remained unaltered. In the 14 patients starting mesuximide, a mean decrease in valproate levels of 32% was seen. In the 8 patients who stopped mesuximide a 30% increase in valproate levels occurred.[5] Note that the related drug, ethosuximide, has also been reported to lower valproate levels, see 'Ethosuximide + Other antiepileptics', p.615.

Mechanism

It has been suggested that phenobarbital, phenytoin and felbamate compete with mesuximide for the same metabolic mechanisms (hydroxylation) in the liver. As a result each one is metabolised more slowly and therefore their levels increase. Mesuximide appears to increase the clearance of valproate and lamotrigine (which principally occurs by glucuronidation).

Importance and management

Information about these interactions is limited. Nevertheless, concurrent use should be monitored. Anticipate the need to reduce the dose of phenytoin, phenobarbital or primidone if mesuximide is given. The dose of lamotrigine may need to be increased if mesuximide is given. There is also some evidence that the dose of valproate may need to be increased.

The activity of mesuximide is thought to be due to its active metabolite, *N*-desmethylmesuximide. Therefore, it has been suggested that levels of this metabolite should also be monitored. Anticipate the need to reduce the dose of mesuximide if felbamate is added. Other antiepileptics such as phenobarbital and phenytoin may also increase levels of *N*-desmethylmesuximide.[4]

Oxcarbazepine + Erythromycin

Erythromycin does not appear to affect the pharmacokinetics of oxcarbazepine.

Clinical evidence, mechanism, importance and management

In a study in 8 healthy subjects, the pharmacokinetics of a single 600-mg dose of oxcarbazepine were unaffected by erythromycin 500 mg twice daily for 7 days.[1] Erythromycin appears not to interact with oxcarbazepine, and no oxcarbazepine dose adjustments therefore seem to be necessary during concurrent use.

1. Keränen T, Jolkkonen J, Jensen PK, Menge GP, Andersson P. Absence of interaction between oxcarbazepine and erythromycin. *Acta Neurol Scand* (1992) 86, 120–3.

Oxcarbazepine + Felbamate

Felbamate has no clinically relevant effect on the pharmacokinetics of oxcarbazepine, but concurrent use appears to increase the incidence of adverse effects.

Clinical evidence, mechanism, importance and management

A double-blind, randomised study in 8 healthy subjects found that oxcarbazepine 300 to 600 mg every 12 hours, given with felbamate 600 to 1200 mg every 12 hours for 10 days had no effect on the plasma levels of the major active metabolite of oxcarbazepine (monohydroxyoxcarbazepine). However, the levels of dihydroxyoxcarbazepine (a minor, inactive metabolite) were reduced, and the maximum serum levels of oxcarbazepine were reduced, by about 20%. Although these changes were considered to be clinically irrelevant, the incidence of some adverse effects (dizziness, somnolence, nausea, diplopia) rose during concurrent use.[1] It may be prudent to consider this interaction as a possible cause if oxcarbazepine adverse effects become troublesome in a patient also taking felbamate.

1. Hulsman JARJ, Rentmeester TW, Banfield CR, Reidenberg P, Colucci RD, Meehan JW, Radwanski E, Mojaverian P, Lin C-C, Nezamis J, Affrime MB, Glue P. Effects of felbamate on the pharmacokinetics of the monohydroxy and dihydroxy metabolites of oxcarbazepine. *Clin Pharmacol Ther* (1995) 58, 383–9.

Oxcarbazepine + Other antiepileptics

Oxcarbazepine does not appear to affect the pharmacokinetics of carbamazepine, phenobarbital or valproate to a clinically relevant extent, but it may modestly reduce lamotrigine levels. High doses of oxcarbazepine increase phenytoin levels.
Phenytoin and phenobarbital can increase the loss of the active metabolite of oxcarbazepine, monohydroxyoxcarbazepine. Lamotrigine but not valproate, may increase levels of monohydroxyoxcarbazepine, although one study found no pharmacokinetic interaction.

Clinical evidence

(a) Effects of replacing carbamazepine with oxcarbazepine on other antiepileptics

A double-blind, crossover comparison of oxcarbazepine and carbamazepine in patients with epilepsy found that when carbamazepine was replaced by oxcarbazepine in 14 patients also taking **valproate**, the serum levels of **valproate** rose by 32%, and in 7 patients also **phenytoin**, the serum levels of **phenytoin** rose by 23%. In 18 patients taking carbamazepine, **valproate** and **phenytoin**, replacement of carbamazepine with oxcarbazepine caused a rise in the serum **valproate** and **phenytoin** levels of 21% and 25%, respectively. The study extended over 12 weeks to establish steady-state levels.[1] Another study in 4 patients with epilepsy (aged 13 to 17 years) found that the level to dose ratio of free **valproate** rose when the patients were switched from carbamazepine to oxcarbazepine, with an increase in valproate adverse effects, which resolved when the valproate dose was decreased.[2]

(b) Effects of oxcarbazepine on other antiepileptics

A study in 35 patients with epilepsy found that when oxcarbazepine 300 mg three times daily was added to treatment with **carbamazepine**, **sodium valproate** or **phenytoin** for 3 weeks there were no clinically relevant changes in the pharmacokinetics of any of these antiepileptics.[3] However, analysis of data from clinical studies found that oxcarbazepine decreased **carbamazepine** levels by about 15 to 22%, increased **phenobarbital** levels by about 14%, and at high doses increased **phenytoin** levels by up to 40%.[4,5]

In another analysis, **lamotrigine** levels were about 34% lower in 14 patients also taking oxcarbazepine than in 64 patients taking **lamotrigine** alone, when corrected for dose. In this study, the effect of oxcarbazepine was less than that of **carbamazepine** (34% versus 47%).[6] Similarly, in another analysis, the addition of oxcarbazepine to **lamotrigine** reduced **lamotrigine** levels by 15 to 75%.[7] However in contrast to these findings, one study in healthy subjects found that oxcarbazepine had no effect on the pharmacokinetics of **lamotrigine**, although adverse effects were reported to be more frequent and severe during concurrent use.[8]

(c) Effects of other antiepileptics on oxcarbazepine

1. Carbamazepine. In a study in patients given oxcarbazepine, the AUC of the metabolite monohydroxyoxcarbazepine was 40% lower in the presence of carbamazepine.[3] Similarly, in a study in children, carbamazepine was found to increase the apparent clearance of monohydroxyoxcarbazepine by 31 to 35%.[9]

2. Lamotrigine. A retrospective analysis found that monohydroxyoxcarbazepine levels to oxcarbazepine dose ratios were higher in 7 patients also taking lamotrigine than in those taking oxcarbazepine alone,[10] suggesting that lamotrigine decreased oxcarbazepine metabolism. However, in contrast to these findings, one study in healthy subjects found that lamotrigine had no effect on the pharmacokinetics of oxcarbazepine or its metabolite, monohydroxyoxcarbazepine, although adverse effects were reported to be more frequent and more severe during concurrent use.[8]

3. Phenobarbital. The AUCs of oxcarbazepine and its active metabolite, monohydroxyoxcarbazepine, were reduced by phenobarbital by 43% and 25%, respectively. There were no other significant effects on the pharmacokinetics of oxcarbazepine.[11] Similarly, in a study in children, phenobarbital was found to increase the apparent clearance of monohydroxyoxcarbazepine by 31 to 35%.[9] Another study found that the serum levels of monohydroxyoxcarbazepine were not affected by phenobarbital but its further conversion to dihydroxyoxcarbazepine was increased.[12] Since the conversion to dihydroxyoxcarbazepine is a minor step in the metabolism of monohydroxyoxcarbazepine, the overall antiepileptic action of oxcarbazepine is unlikely to be altered.

4. Phenytoin. A study found that phenytoin caused a 29% reduction in the AUC of monohydroxyoxcarbazepine.[3] Another study found that the serum levels of monohydroxyoxcarbazepine were not affected by phenytoin but its further conversion to dihydroxyoxcarbazepine was increased.[12] Since the conversion to dihydroxyoxcarbazepine is a minor step in the metabolism of monohydroxyoxcarbazepine, the overall antiepileptic action of oxcarbazepine is unlikely to be altered. Correspondingly, a study found that phenytoin 100 to 375 mg daily increased the clearance of the active metabolite, monohydroxyoxcarbazepine, by almost 40%.[13] Similarly, in a study in children, phenytoin was found to increase the apparent clearance of monohydroxyoxcarbazepine by 31 to 35%.[9]

5. Valproate. In a study in children given oxcarbazepine, valproic acid had no significant effect on the clearance of the monohydroxyoxcarbazepine metabolite of oxcarbazepine.[9]

Mechanism

Unlike carbamazepine, oxcarbazepine appears not to have marked enzyme-inducing properties so that it would not be expected to have as great an effect on the metabolism of other antiepileptics. However, oxcarbazepine does appear to act as an inhibitor of the cytochrome P450 isoenzyme CYP2C19 at high concentrations and therefore may raise phenytoin levels (see 'Phenytoin + Carbamazepine', p.632, for more on this mechanism). Other antiepileptics can increase the metabolism of the active metabolite of oxcarbazepine, monohydroxyoxcarbazepine. The situation with lamotrigine is not clear. In one study lamotrigine appeared to decrease the metabolism of oxcarbazepine but another study found no pharmacokinetic interaction.

Importance and management

Information about the concurrent use of oxcarbazepine and other antiepileptics is limited, but growing. The overall picture seems to be that oxcarbazepine is a less potent enzyme inducer than carbamazepine, and therefore it does not markedly affect the serum levels of other antiepileptics. If oxcarbazepine is substituted for carbamazepine, be aware that the drug levels of some other antiepileptics may rise. High oxcarbazepine doses may increase phenytoin levels, and the manufacturer notes that a decrease in the phenytoin dose may be required.[4] The clinical relevance of the modest reductions in lamotrigine levels is uncertain. For mention of modestly reduced levetiracetam levels in the presence of oxcarbazepine, see 'Levetiracetam + Other antiepileptics', p.621.

Any changes in the pharmacokinetics of oxcarbazepine brought about by other antiepileptics seem to be of minimal clinical relevance. However, the clinical relevance of the increase in the active metabolite monohydroxyoxcarbazepine with lamotrigine requires further study. In addition, there is the theoretical risk that monohydroxyoxcarbazepine levels might rise to toxic levels if carbamazepine or phenytoin were withdrawn.[3] For mention that there may be an increase in adverse effects if oxcarbazepine is used with felbamate, see 'Oxcarbazepine + Felbamate', p.623.

Paraldehyde + Disulfiram

***Animal* data suggest that disulfiram can increase paraldehyde levels and prolong its effects. There is a theoretical potential for a disulfiram reaction.**

Clinical evidence, mechanism, importance and management

It is thought that paraldehyde is depolymerised in the liver to acetaldehyde, and then oxidised by acetaldehyde dehydrogenase.[1] As disulfiram inhibits this enzyme, concurrent use would be expected to result in the accumulation of acetaldehyde and result in a modified disulfiram reaction.[2] However, studies in *animals* given disulfiram and paraldehyde found increases in the levels of paraldehyde and an increase in its hypnotic effect, with only small increases in acetaldehyde levels and no increase in toxicity.[2,3] In addition, there appear to be no reports of a disulfiram reaction involving paraldehyde in humans. However, three cases of mental confusion have been reported in patients receiving disulfiram and paraldehyde.[4] Note that, patients with liver disease are at greater risk of paraldehyde adverse effects, and the addition of disulfiram results in a further risk. Therefore it may be prudent to avoid concurrent use in this type of patient.

Phenobarbital or Primidone + Allopurinol

Allopurinol appears not to alter phenobarbital levels, including those derived from primidone.

Clinical evidence, mechanism, importance and management

In a study of add-on therapy, allopurinol (150 mg daily in those less than 20 kg, and 300 mg daily for other patients) for 4 months, had no effect on the phenobarbital levels in 46 patients taking antiepileptics including phenobarbital.[1] In another similar study, allopurinol 10 mg/kg increased to 15 mg/kg daily for 12 weeks had no effect on serum phenobarbital levels in 11 patients taking primidone or phenobarbital with or without other antiepileptics.[2] Therefore phenobarbital or primidone dose alterations are unlikely to be required if allopurinol is also given.

Phenobarbital + Azoles

Limited evidence suggests phenobarbital causes a marked decrease in itraconazole levels, and might decrease ketoconazole levels. Phenobarbital is also predicted to decrease posaconazole levels and markedly decrease voriconazole levels.

Clinical evidence, mechanism, importance and management

Note that primidone is metabolised to phenobarbital, and therefore **primidone** may also be expected to interact similarly with azole antifungals.

(a) Fluconazole

For a report that fluconazole does not significantly affect the levels of **barbexaclone** (a compound of levopropylhexedrine with phenobarbital), see 'Carbamazepine + Azoles', p.600.

(b) Itraconazole

The serum levels of itraconazole 200 mg daily were very low (0.01 to 0.03 mg/L, reference range 0.25 to 2 mg/L) in a patient taking phenobarbital. Two months after stopping the phenobarbital they were higher (0.15 mg/L), but still below the therapeutic range, apparently because carbamazepine had been recently started.[1] For mention of two other patients who had very low itraconazole levels while taking both phenytoin and phenobarbital, see 'Phenytoin + Azoles', p.630. Some manufacturers of itraconazole say that the concurrent use of potent enzyme inducers such as phenobarbital is not recommended.[2]

(c) Ketoconazole

Low ketoconazole levels in a patient with leukaemia receiving various antineoplastics was attributed to the concurrent use of phenytoin and pheno-

barbital.[3] It may be prudent to monitor the efficacy of ketoconazole if phenobarbital is also given.

(d) Posaconazole

Based on the evidence with 'phenytoin', (p.630), the manufacturer of posaconazole predicts that phenobarbital will reduce posaconazole levels, and therefore suggests avoiding the combination unless the benefits outweigh the risks.[4] If concurrent use is necessary monitor for posaconazole efficacy.

(e) Voriconazole

Based on the evidence with 'phenytoin', (p.630), the manufacturer of voriconazole predicts that phenobarbital will reduce voriconazole levels, and therefore contraindicates their concurrent use.[5,6] In the US, the manufacturer extends this contraindication to all long-acting barbiturates.[6]

Phenobarbital + Dextropropoxyphene (Propoxyphene)

When 4 patients with epilepsy took dextropropoxyphene 65 mg three times a day for a week there was an average 20% rise in their serum phenobarbital levels.[1] This rise is unlikely to be clinically significant in most patients.

1. Hansen BS, Dam M, Brandt J, Hvidberg EF, Angelo H, Christensen JM, Lous P. Influence of dextropropoxyphene on steady state serum levels and protein binding of three anti-epileptic drugs in man. *Acta Neurol Scand* (1980) 61, 357–67.

Phenobarbital or Primidone + Felbamate

Felbamate causes a moderate increase in phenobarbital levels (including those derived from primidone), which has resulted in phenobarbital toxicity.

Clinical evidence

When 24 healthy subjects taking phenobarbital 100 mg daily were also given felbamate 1.2 g twice daily for 10 days, the AUC and the maximum plasma levels of phenobarbital were raised by 22% and 24%, respectively. Concurrent use was said to be safe and well tolerated.[1] A 30% increase in phenobarbital plasma concentrations was seen in another 19 patients taking phenobarbital or primidone (which is metabolised to phenobarbital) when they were given felbamate (average dose 2458 mg daily).[2] A phenobarbital dose reduction of about 30% was needed in another 6 patients when they started to take felbamate.[3]

A man taking sodium valproate and phenobarbital had an almost 50% increase in phenobarbital serum levels over a 5-week period after felbamate 50 mg/kg was added, despite an initial phenobarbital dose reduction from 230 mg to 200 mg daily. He was hospitalised because of increased lethargy, anorexia and ataxia and was eventually discharged taking phenobarbital 150 mg daily.[4]

It has also been noted that felbamate levels are lower in patients taking phenobarbital than in historical control patients not taking phenobarbital.[1] The manufacturer notes that steady-state felbamate levels were 29% lower in patients also given phenobarbital, when compared with levels in newly diagnosed epileptics given felbamate 2.4 g daily.[5] However, in a modelling study, phenobarbital apparently had little or no effect on the pharmacokinetics of felbamate.[6]

Mechanism

Not established. It seems possible that the felbamate may inhibit more than one pathway in the metabolism of phenobarbital, resulting in a reduction in its loss from the body. The cytochrome P450 isoenzyme CYP2C19 may be involved.[1,7]

Importance and management

An established interaction. If felbamate is added to established treatment with phenobarbital or primidone, particularly in patients already taking substantial doses, monitor closely for any evidence of increased adverse effects (drowsiness, lethargy, anorexia, ataxia) and reduce the doses of phenobarbital or primidone if necessary.

Phenobarbital + Influenza vaccines

Influenza vaccine can cause a moderate rise in the levels of phenobarbital.

Clinical evidence, mechanism, importance and management

The serum levels of phenobarbital rose by about 30% in 11 out of 27 children who were given 0.5 mL of a whole virus influenza vaccine USP, types A and B, (Squibb). Levels remained elevated 28 days after vaccination.[1]

It was suggested that the vaccine inhibits the liver enzymes concerned with the metabolism of phenobarbital, thereby reducing its loss from the body. Information is very limited, but note that, a similar 30% increase in phenobarbital levels with felbamate has eventually required a dose adjustment after long-term concurrent use. However, as influenza vaccines are usually given as a single dose phenobarbital accumulation seems unlikely, and the increase in levels will eventually be self-limiting. Therefore it seems unlikely that this moderate increase in phenobarbital levels will be of clinical significance.

1. Jann MW, Fidone GS. Effect of influenza vaccine on serum anticonvulsant concentrations. *Clin Pharm* (1986) 5, 817–20.

Phenobarbital + Troleandomycin

Troleandomycin caused a modest fall in the phenobarbital levels of one patient.

Clinical evidence, mechanism, importance and management

A patient taking phenobarbital and carbamazepine had a modest reduction in plasma phenobarbital levels from about 40 micrograms/mL to 31 micrograms/mL when given troleandomycin.[1] The general importance of this single report is uncertain, but this 23% fall is probably of limited clinical importance.

Phenobarbital + Valproate

Serum phenobarbital levels can be increased by valproate, which may result in excessive sedation and lethargy. Small reductions in valproate levels have also been reported. Combined use of phenobarbital and valproate may cause an increase in serum liver enzymes.

Clinical evidence

A 6-month study in 11 patients with epilepsy taking phenobarbital 90 to 400 mg daily found that when they were also given valproic acid 11.2 to 42.7 mg/kg daily sedation developed. On average the dose of phenobarbital was reduced to 54% of the original dose with continued good seizure control. Another 2 patients who did not have their phenobarbital dose reduced had an increase in their phenobarbital levels of 12% and 48%, respectively, when valproic acid was added.[1]

Another study found that sodium valproate 1.2 g daily raised serum phenobarbital levels in 20 patients by an average of 27%. Signs of toxicity occurred in 13 patients, but the dose only needed to be reduced in 3 patients.[2] This interaction has been described in numerous other reports, and dose reductions of the phenobarbital were almost always necessary to avoid excessive drowsiness.[3-17] In one study the rise in phenobarbital levels was much greater in children (over 100%) than in adults (about 50%).[18]

A small reduction in sodium valproate levels (of about 25%) has also been reported, but the effect on seizure control was not mentioned.[19] A reduction in valproate levels caused by phenobarbital has also been reported elsewhere.[20]

The incidence of increased liver enzyme activity was found to be higher in 41 patients receiving phenobarbital with valproate than in 40 patients taking valproate alone (ALT 7.3% versus 0%). When phenytoin was also given an even greater incidence of increases (ALT 26.1% and AST 28.3% versus about 20%) occurred. However, the increases were mild and were not considered clinically important.[21]

Mechanism

The evidence indicates that valproate inhibits three steps in the metabolism of phenobarbital by the liver, leading to its accumulation in the body. The inhibited steps are the formation of *p*-hydroxyphenobarbital by the cytochrome P450 isoenzyme CYP2C9,[22] the *N*-glucosidation of phenobarbital[23] and the *O*-glucuronidation of *p*-hydroxyphenobarbital.[23]

Importance and management

An extremely well documented and well established interaction of clinical importance. The incidence seems to be high. The effects of concurrent use should be well monitored and suitable phenobarbital dose reductions made as necessary to avoid toxicity. The dose may need to be reduced by one-third to one-half.[1] The significance of the modest reduction in valproate levels is not clear, especially as valproate levels do not correlate well with efficacy of treatment. Valproate has been associated with serious hepatotoxicity, especially in children aged less than 3 years, and this has been more common in those receiving other antiepileptics. Valproate monotherapy is to be preferred in this group.

Phenytoin + Allopurinol

A case report describes phenytoin toxicity in a boy given allopurinol. Another study found that allopurinol may raise phenytoin levels but only in some patients.

Clinical evidence, mechanism, importance and management

A 13-year-old boy with Lesch-Nyhan syndrome who was taking phenobarbital, clonazepam, valproic acid and phenytoin 200 mg daily became somnolent within 7 days of starting to take allopurinol 150 mg daily. His serum phenytoin levels were found to have increased from 7.5 micrograms/mL to 20.8 micrograms/mL.[1] In a study, 2 patients had a marked increase in phenytoin levels when they were given allopurinol (150 mg daily in those less than 20 kg, and 300 mg daily for other patients) for 4 months, which in one case led to withdrawal from the study, and in the other to a phenytoin dose reduction. However, 16 other patients had no change in phenytoin levels while taking this dose of allopurinol.[2]

The reason for this reaction is not known. An *animal* study confirmed that 50 mg/kg, but not 20 mg/kg, of allopurinol reduced phenytoin elimination, but was unable to work out the mechanism.[3]

Although information is limited, it appears that allopurinol may raise phenytoin levels in some patients. It would therefore be prudent to monitor for phenytoin toxicity (e.g. blurred vision, nystagmus, ataxia or drowsiness) when allopurinol, particularly in high doses, is added.

Phenytoin + Amiodarone

Serum phenytoin levels can be raised by amiodarone, markedly so in some individuals, and phenytoin toxicity may occur. Amiodarone serum levels are reduced by phenytoin.

Clinical evidence

(a) Phenytoin serum levels increased

Three patients had a marked rise in serum phenytoin levels 10 days to 4 weeks after being given amiodarone 400 mg to 1.2 g daily. One patient developed phenytoin toxicity (ataxia, lethargy, vertigo) within 4 weeks of starting to take amiodarone and had a serum phenytoin level of 40 micrograms/mL, representing a three to fourfold increase. Levels restabilised when the phenytoin dose was withheld and then reduced from 300 to 200 mg daily. The serum phenytoin levels of the other 2 patients were approximately doubled by amiodarone.[1] Other case reports describe 3 patients who had two- to threefold rises in serum phenytoin levels, and toxicity, 2 to 6 weeks after starting amiodarone.[2-4]

A study in healthy subjects found that amiodarone 200 mg daily for 3 weeks increased the AUC of a single 5-mg/kg intravenous dose of phenytoin by 40%.[5] Another pharmacokinetic study found that amiodarone 200 mg daily for 6 weeks raised the AUC and steady-state peak serum

levels of phenytoin by 40% and 33%, respectively. In this study, phenytoin 2 to 4 mg/kg daily was given orally for 14 days before and during the last 2 weeks of amiodarone use.[6]

(b) Amiodarone serum levels reduced

A study in 5 healthy subjects given amiodarone 200 mg daily found that over a 5-week period the serum amiodarone levels gradually increased. When phenytoin 3 to 4 mg/kg daily was added for a period of 2 weeks, the serum amiodarone levels fell to concentrations that were between about 50% and 65% of those predicted.[7]

Mechanism

Uncertain. It seems possible that amiodarone inhibits the liver enzymes concerned with the metabolism of phenytoin, resulting in a rise in its serum levels.[6] It seems unlikely that drug displacement from protein binding sites had a part to play as free and bound levels of phenytoin remained constant.[6]

Phenytoin is an enzyme-inducing drug that possibly increases the metabolism of the amiodarone by the liver.

Importance and management

Information seems to be limited to the reports cited, but both interactions appear to be clinically important. Concurrent use should not be undertaken unless the effects can be well monitored.

Monitor phenytoin levels and for adverse effects (e.g. blurred vision, nystagmus, ataxia or drowsiness) and reduce the phenytoin dose as necessary. A 25 to 30% reduction has been recommended for those taking phenytoin 2 to 4 mg/kg daily, but it should be remembered that small alterations in phenytoin dose may result in a large change in phenytoin levels, as phenytoin kinetics are non-linear.[6,8,9] Note that the phenytoin levels in some individuals were doubled after only 10 days of concurrent use.[1] Amiodarone has a long half-life so that this interaction will persist for weeks after its withdrawal. Continued monitoring is important. Be aware that ataxia due to phenytoin toxicity may be confused with amiodarone-induced ataxia.[1,3]

It is not clear whether or not the amiodarone dose should be increased to accommodate this interaction because the metabolite of amiodarone (*N*-desethylamiodarone) also has important antiarrhythmic effects.[7]

Phenytoin + Antacids

Some studies have found that antacids can reduce phenytoin levels and this may have been responsible for some loss of seizure control in a few patients. However other studies have not found any interaction and it seems that usually no clinically important interaction occurs.

Clinical evidence

A review briefly mentions that 3 patients taking phenytoin were found to have low serum phenytoin levels of 2 to 4 micrograms/mL when they were given phenytoin at the same time as antacids (unnamed), but when antacid administration was delayed by 2 to 3 hours the serum phenytoin levels rose two to threefold.[1]

Elsewhere, 2 patients with epilepsy are reported to have had inadequate seizure control, which coincided with the ingestion of **aluminium/magnesium hydroxide** antacids for dyspepsia.[2]

In a study in 8 healthy subjects, the AUC of a single dose of phenytoin was reduced by a modest 25% by either **aluminium/magnesium hydroxide** or **calcium carbonate**.[3] A study in 6 healthy subjects given **aluminium** or **magnesium hydroxide** did not find any change in the rate or extent of absorption of a single dose of phenytoin,[2] and a similar study found that **calcium carbonate** also had no effect on the absorption of phenytoin.[4] A controlled study in 6 patients with epilepsy found that a **magnesium trisilicate** and **aluminium hydroxide** antacid (*Gelusil*) caused a slight 12% reduction in steady-state serum phenytoin levels, which would not be expected to be clinically significant. Seizure frequency was not affected.[4] A study in 2 subjects found that the absorption of phenytoin was not altered by a mixture of **aluminium/magnesium hydroxide** and **magnesium trisilicate**, or **calcium carbonate**.[5] In another study in 6 healthy subjects, no statistically significant decrease in absorption was seen when phenytoin was given with an antacid containing **simeticone**, **aluminium hydroxide** and **magnesium oxide** (*Asilone*).[6]

Mechanism

Not understood. One suggestion is that diarrhoea and a general increase in peristalsis caused by some antacids may cause a reduction in phenytoin absorption. Another is that antacids may cause changes in gastric acid secretion, which could affect phenytoin solubility.

Importance and management

This possible interaction is fairly well documented, but the results are conflicting. In practice it appears not to be important in most patients, although some loss of seizure control has been seen to occur in isolated cases. Concurrent use need not be avoided but if there is any hint that phenytoin levels are reduced, separation of the doses by 2 to 3 hours may, as with other interactions caused by antacids, minimise the effects.

Phenytoin + Antidiabetics

Large and toxic doses of phenytoin have been seen to cause hyperglycaemia, but normal therapeutic doses do not usually affect the control of diabetes. Two isolated cases of phenytoin toxicity have been attributed to the use of tolazamide or tolbutamide. Miglitol does not affect the bioavailability of phenytoin.

Clinical evidence

(a) Effects on phenytoin

In a study, tolbutamide 500 mg two or three times daily was given to 17 patients taking phenytoin 100 to 400 mg daily.[1] The patients had a transient 45% rise in the amount of non-protein-bound phenytoin by day 2, which had disappeared by day 4. The introduction to this report briefly mentions a man given phenytoin and **tolazamide** who developed phenytoin toxicity, which disappeared when **tolazamide** was replaced by **insulin**.[1] A woman previously uneventfully treated with phenytoin and **tolbutamide** developed toxicity on a later occasion when she took **tolbutamide** with twice the previous dose of phenytoin.[2] One study in healthy subjects found that **miglitol** 100 mg three times daily for 5 days did not affect the bioavailability of a single 400-mg dose of phenytoin.[3]

(b) Response to antidiabetics

Phenytoin has been found in a number of reports[4-9] to raise the blood glucose levels of both diabetics and non-diabetics. However, in all but one of these cases the phenytoin dose was large (at least 8 mg/kg) or even in the toxic range (70 to 80 mg/kg). There is little evidence that a hyperglycaemic response to usual doses of phenytoin is normally large enough to interfere with the control of diabetes, either with diet alone or with conventional antidiabetic drugs. In the one case where the interaction occurred with a therapeutic dose of phenytoin (1.2 g in the 24 hours follow-

ing status epilepticus), the situation was complicated by the use of many other drugs and by renal impairment.[5]

Mechanism

Studies in *animals* and man[10-13] suggest that phenytoin-induced hyperglycaemia occurs because the release of insulin from the pancreas is impaired. This implies that no interaction is possible without functional pancreatic tissue. Just why phenytoin appeared to interact with tolazamide and tolbutamide is uncertain, but it is possible that these antidiabetics competitively inhibit phenytoin hydroxylation[14,15] by the cytochrome P450 isoenzyme CYP2C9.[16]

Importance and management

The weight of evidence shows that no interaction of clinical importance normally occurs between phenytoin and the antidiabetic drugs (most of the studies involved sulfonylureas). No special precautions would generally be expected to be necessary.

Phenytoin + Antimycobacterials

Phenytoin levels are markedly reduced by rifampicin, but can be raised by isoniazid. Patients who are slow acetylators (slow metabolisers) of isoniazid may develop phenytoin toxicity. If rifampicin (rifampin) and isoniazid are given together, serum phenytoin levels may fall in patients who are fast acetylators of isoniazid, but may occasionally rise in those who are slow acetylators. Clofazimine may reduce serum phenytoin levels.

Clinical evidence

(a) Isoniazid

A study in 32 patients given phenytoin 300 mg daily found that within a week of starting to take isoniazid 300 mg daily and **aminosalicylic acid** 15 g daily, 6 of them had phenytoin levels almost 5 micrograms/mL higher than the rest of the group. On the following days, when the phenytoin levels of these 6 patients rose above 20 micrograms/mL, the typical signs of phenytoin toxicity were seen. All 6 patients with raised phenytoin levels had unusually high serum isoniazid levels and were identified as slow acetylators of isoniazid.[1]

Rises in serum phenytoin levels and toxicity induced by the concurrent use of isoniazid has been described in numerous other reports,[2-15] involving large numbers of patients, one of which describes a fatality.[8]

(b) Rifampicin (Rifampin)

A study in 6 patients found that the clearance of intravenous phenytoin 100 mg doubled (from 46.7 to 97.8 mL/minute), when rifampicin 450 mg daily was taken for 2 weeks.[16]

A man taking phenytoin 400 mg daily experienced a seizure 3 days after starting rifampicin 600 mg daily. His phenytoin level was low (5.1 micrograms/mL) so rifampicin was stopped and the phenytoin dose increased to 500 mg daily. His level increased slowly over the next 2 weeks, eventually ranging between 16 and 25 micrograms/mL.[17] Another man taking phenytoin needed a dose reduction from 375 to 325 mg daily to keep his serum phenytoin levels within the therapeutic range when he stopped taking rifampicin.[18] A man with AIDS taking a large number of drugs (rifampicin, clofazimine, ciprofloxacin, ethambutol, clarithromycin, diphenoxylate, bismuth, octreotide, co-trimoxazole, amphotericin, flucytosine, amikacin, zalcitabine) was also given phenytoin to control a right-sided seizure disorder. Despite taking phenytoin 1.6 g daily, and a trial of intravenous treatment, his trough phenytoin plasma levels remained almost undetectable until rifampicin was withdrawn, when they rose to 5 micrograms/mL with the oral dose. When **clofazimine** was withdrawn the levels rose even further to 10 micrograms/mL.[19]

(c) Rifampicin (Rifampin) and Isoniazid

A patient taking phenytoin 300 mg daily developed progressive drowsiness (a sign of phenytoin toxicity) during the first week of taking isoniazid, rifampicin and ethambutol. His serum phenytoin levels rose to 46.1 micrograms/mL. He slowly recovered when the phenytoin was stopped, and he was later stabilised taking phenytoin 200 mg daily. He proved to be a slow acetylator of isoniazid.[20] Another patient taking phenytoin 300 mg daily was also given isoniazid, rifampicin and ethambutol but, in anticipation of the response seen in the previous patient, his phenytoin dose was reduced to 200 mg daily. Within 3 days he developed seizures because his serum phenytoin levels had fallen to only 8 micrograms/mL. He needed to take phenytoin 400 mg daily to keep the serum levels within the therapeutic range. He was a fast acetylator of isoniazid.[20]

The clearance of phenytoin was doubled in 14 patients given rifampicin 450 mg, isoniazid 300 mg and ethambutol 900 mg to 1.2 g daily for 2 weeks. No further changes occurred in the pharmacokinetics of phenytoin after 3 months of antimycobacterial treatment. In this study, the interaction was of a similar magnitude in both the 8 slow acetylators and the 6 fast acetylators.[16]

Mechanism

Rifampicin (a known potent liver enzyme inducer) increases the metabolism and clearance of phenytoin from the body so that a larger dose is needed to maintain adequate serum levels. Isoniazid inhibits the liver microsomal enzymes that metabolise phenytoin, and as a result phenytoin accumulates and its serum levels rise.[21] Only patients who are slow acetylators (slow metabolisers) of isoniazid normally attain blood levels of isoniazid that are sufficiently high to cause extensive inhibition of phenytoin metabolism. Fast acetylators (fast metabolisers) remove the isoniazid too quickly for this to occur. Acetylator status is genetically determined. Thus some individuals will show a rapid rise in phenytoin levels, which eventually reaches toxic concentrations, whereas others will show only a relatively slow and unimportant rise to a plateau within, or only slightly above the therapeutic range.

If isoniazid and rifampicin are given together, the enzyme inhibitory effects of isoniazid may oppose the effects of rifampicin in patients who are slow acetylators of isoniazid, but in patients who are fast acetylators, the isoniazid will be cleared too quickly for it effectively to oppose the rifampicin effects. However, in one study isoniazid did not counter the effects of rifampicin in slow acetylators.[16]

The interaction involving clofazimine is not understood.

Importance and management

Direct information seems to be limited to these reports, but the interactions appear to be of clinical importance. Monitor the serum phenytoin levels and increase the dose appropriately if rifampicin alone is started. Reduce the phenytoin dose if rifampicin is stopped. If both rifampicin and isoniazid are given, the outcome may depend on the isoniazid acetylator status of the patient. Patients who are fast acetylators will probably also need an increased phenytoin dose, whereas patients who are slow acetylators may need a smaller phenytoin dose if toxicity is to be avoided. All patients

should be monitored very closely as, unless acetylator status is known, the outcome is unpredictable.

The interaction with phenytoin and isoniazid alone is well documented, well established, clinically important and potentially serious. About 50% of the population are slow or relatively slow metabolisers of isoniazid,[1] but not all of them develop serum phenytoin levels in the toxic range. The reports indicate that somewhere between 10 and 33% of patients are at risk.[1-4,10] This adverse interaction may take only a few days to develop fully in some patients, but several weeks in others. Therefore concurrent use should be very closely monitored (e.g. for evidence of phenytoin adverse effects, such as blurred vision, nystagmus, ataxia or drowsiness), making suitable dose reductions as necessary. One patient was reported to have had better seizure control with fewer adverse effects while taking both drugs than with phenytoin alone.[22]

Information about clofazimine seems to be limited to one report. Monitor concurrent use, anticipating the need to increase the phenytoin dose.

Phenytoin + Aspirin or NSAIDs

Phenytoin levels can be markedly increased by azapropazone and toxicity can develop rapidly. It is inadvisable for patients to take these drugs together. Phenytoin levels can also be increased by phenylbutazone, and phenytoin toxicity may occur. It seems likely that oxyphenbutazone will interact similarly.

Phenytoin toxicity has been seen in one patient taking ibuprofen, although no pharmacokinetic interaction was found in a study. Phenytoin toxicity occurred in a patient taking celecoxib. High-dose aspirin can cause protein-binding displacement of phenytoin, but this does not usually seem to be clinically important. No clinically significant interaction occurs between phenytoin and bromfenac, etodolac or tolfenamic acid.

Clinical evidence, mechanism, importance and management

(a) Aspirin

It has been suggested that if a patient has been taking large quantities of aspirin, phenytoin is 'potentiated'.[1] This comment remains unconfirmed, although a study in 10 healthy subjects did find that aspirin 975 mg every 4 hours caused protein binding displacement of phenytoin, resulting in a 16% rise in free salivary phenytoin levels and a 24% decrease in serum levels. However, these changes were considered unlikely to be clinically significant, and aspirin doses of 325 and 650 mg every 4 hours had no appreciable effect on phenytoin.[2] Similar effects on protein binding displacement have been seen in other studies.[3-7] However, although the ratios of free and bound phenytoin may change, there does not appear to be a clinical effect, possibly because the extra free phenytoin is metabolised by the liver.[6] A study in 10 patients with epilepsy taking phenytoin found that when they were also given aspirin 500 mg three times daily for 3 days, no significant changes in serum phenytoin levels or antiepileptic effects occurred.[8] The extremely common use of aspirin, and the almost total silence in the literature about an adverse interaction between phenytoin and aspirin implies that no special precautions are likely to be needed when both drugs are given.

(b) Azapropazone

A patient taking phenytoin developed phenytoin toxicity within 2 weeks of starting azapropazone 600 mg twice daily. Further study in 5 healthy subjects given phenytoin 125 to 250 mg daily found that azapropazone 600 mg twice daily, briefly decreased their mean serum phenytoin levels from 5 micrograms/mL to 3.7 micrograms/mL before they rose steadily over the next 7 days to 10.5 micrograms/mL.[9,10] An extension of this study is described elsewhere.[11] Another report describes phenytoin toxicity in a woman taking phenytoin and primidone when **fenclofenac** was replaced by azapropazone 1.2 g daily.[12]

The most likely explanation is that azapropazone inhibits the liver enzymes concerned with the metabolism of phenytoin, resulting in its accumulation. It also seems possible that azapropazone displaces phenytoin from its plasma protein binding sites so that levels of unbound (and active) phenytoin are increased. Information seems to be limited to the reports cited, but it appears to be a clinically important interaction. The incidence is uncertain, but an interaction occurred in all 5 of the subjects in the study cited.[9,11] The concurrent use of azapropazone and phenytoin has been contraindicated.[13]

(c) Bromfenac

Twelve healthy subjects were given bromfenac 50 mg three times daily for 4 days and then phenytoin 300 to 330 mg for up to 14 days (to achieve stable levels), and then both drugs for 8 days. It was found that the peak phenytoin serum levels and AUC were increased by 9% and 11%, respectively, while the bromfenac peak levels and AUC were reduced by 42%. The suggested reason for the reduction in bromfenac levels is that phenytoin increases its metabolism by the liver.[14] In practical terms these results indicate that there is no need to adjust the dose of phenytoin if bromfenac is added, nor any need to increase the bromfenac dose unless there is any evidence that its efficacy is diminished.

(d) Celecoxib

An elderly woman taking phenytoin 300 mg daily who had also been taking celecoxib for the previous 6 months, developed signs of phenytoin toxicity. She was found to have a phenytoin level of 42 micrograms/mL, and a very slow rate of elimination.[15] It was thought that celecoxib may have competed with phenytoin for elimination by the cytochrome P450 isoenzyme CYP2C9. The general relevance of this isolated report is unclear.

(e) Etodolac

A crossover study in 16 healthy subjects found that etodolac 200 mg every 12 hours for 3 days had no effect on the pharmacokinetics or the pharmacological effects of phenytoin (100 mg twice daily for 2 days and 100 mg on day three).[16] There would seem to be no reason for avoiding the concurrent use of these drugs.

(f) Ibuprofen or Dexibuprofen

Studies in healthy subjects found that the pharmacokinetics of single 300- or 900-mg doses of phenytoin were not significantly altered by ibuprofen 300 or 400 mg every 6 hours.[17,18] However, a report describes a woman stabilised on phenytoin 300 mg daily who developed phenytoin toxicity within a week of starting to take ibuprofen 400 mg four times daily.[19] Her serum phenytoin levels had risen to about 25 micrograms/mL. The phenytoin was stopped for 3 days and the ibuprofen withdrawn, and within 10 days the phenytoin level had dropped to about 17 micrograms/mL. Another report describes a patient stabilised taking phenytoin 300 mg daily (4.3 mg/kg daily) who developed symptoms of phenytoin toxicity 72 hours after starting dexibuprofen 800 mg daily. Phenytoin levels were found to be 30.6 micrograms/mL. Dexibuprofen was withdrawn and phenytoin was stopped for 3 days. Two weeks after

the re-introduction of phenytoin, symptoms of toxicity had resolved and levels had fallen to 17.3 micrograms/mL.[20] The reasons for this interaction are not understood.

Both phenytoin and ibuprofen have been available for many years. Dexibuprofen, the active enantiomer of ibuprofen, has been introduced more recently. These 2 cases, some 25 years apart, appear to be the only reports of an adverse interaction. No special precautions would normally seem to be necessary.

(g) Oxyphenbutazone or Phenylbutazone

Six patients with epilepsy taking phenytoin 200 to 350 mg daily who were then also given phenylbutazone 100 mg three times daily had a mean fall in their phenytoin serum levels from 15 micrograms/mL to 13 micrograms/mL over the first 3 days, after which the levels rose steadily to 19 micrograms/mL over the next 11 days. One patient developed symptoms of toxicity. His levels of free phenytoin more than doubled.[8] Another study found that phenylbutazone increased the steady-state half-life of phenytoin from 13.7 hours to 22 hours.[21]

The predominant effect of phenylbutazone seems to be the inhibition of the enzymes concerned with the metabolism of phenytoin,[21] leading to its accumulation in the body and a rise in its serum levels. The initial transient fall may possibly be related in some way to the displacement by phenylbutazone of phenytoin from its plasma protein binding sites.[22] This is an established interaction, although the documentation is very limited. Monitor the outcome of adding phenylbutazone and reduce the phenytoin dose as necessary. There is no direct evidence that oxyphenbutazone interacts like phenylbutazone, but as it is the main metabolic product of phenylbutazone in the body and has been shown to prolong the half-life of phenytoin in *animals*,[23] it would be expected to interact similarly.

(h) Tolfenamic acid

In a study in 11 patients, tolfenamic acid 300 mg daily for 3 days had no significant effect on the serum levels of phenytoin.[8] No special precautions seem necessary if these drugs are taken concurrently.

Phenytoin + Atovaquone

In 12 healthy subjects, atovaquone (1 g given twelve hours before and with a single 600-mg dose of phenytoin) did not affect the pharmacokinetics of phenytoin. It was concluded that a clinically important pharmacokinetic interaction is unlikely.[1]

1. Davis JD, Dixon R, Khan AZ, Toon S, Rolan PE, Posner J. Atovaquone has no effect on the pharmacokinetics of phenytoin in healthy male volunteers. *Br J Clin Pharmacol* (1996) 42, 246–8.

Phenytoin + Azoles

Phenytoin levels are raised by fluconazole (toxicity seen). Posaconazole, voriconazole and possibly miconazole interact similarly. Itraconazole (and therefore probably ketoconazole) have little effect on phenytoin levels.

Phenytoin decreases itraconazole and possibly ketoconazole levels (treatment failures seen). Posaconazole and voriconazole are similarly affected. Fluconazole levels are not usually affected by phenytoin, although there is one report of reduced efficacy.

Clinical evidence

(a) Fluconazole

In a randomised, placebo-controlled study, 10 subjects taking fluconazole 200 mg daily for 14 days with phenytoin 200 mg daily for the last 3 days were compared with 10 other subjects taking phenytoin alone. Fluconazole caused the phenytoin AUC to rise by 75%, and the trough phenytoin levels to rise by 128%.[1] Two other studies reported similar findings,[2,3] and there are reports describing at least 7 cases of phenytoin toxicity caused by fluconazole.[4-7]

Some studies suggest that phenytoin does not alter fluconazole levels;[1,3] however, a brief report noted that 3 of 9 patients taking fluconazole and phenytoin required an increase in their fluconazole dose or the substitution of another antifungal due to a lack of efficacy. It was suggested that phenytoin may reduce fluconazole levels in some patients.[8]

(b) Itraconazole

In a study in 13 healthy subjects, oral phenytoin 300 mg daily for 15 days reduced the AUC of a single 200-mg dose of itraconazole by more than 90%. The half-life of itraconazole fell from 22.3 hours to 3.8 hours.[9] A parallel study in 15 healthy subjects found that itraconazole 200 mg for 15 days increased the phenytoin AUC by 10%.[9]

Two patients taking phenytoin and two taking phenytoin with carbamazepine either did not respond to treatment with itraconazole 400 mg daily for aspergillosis, coccidioidomycosis or cryptococcosis, or suffered a relapse. All of them had undetectable or substantially reduced serum itraconazole levels compared with other patients taking itraconazole alone.[10] Two other patients also had very low itraconazole serum levels while taking phenytoin and phenobarbital.[11]

(c) Ketoconazole

A study in 9 healthy subjects found that ketoconazole 200 mg twice daily for 6 days did not significantly alter the AUC_{0-48} of a single 250-mg dose of phenytoin.[2]

A man being treated for coccidioidal meningitis with ketoconazole 400 mg daily relapsed when he was given phenytoin 300 mg daily. A pharmacokinetic study found that his peak serum ketoconazole levels and AUC were reduced, when compared with the values seen before the phenytoin was started. Even though the ketoconazole dose was increased to 600 mg, and later 1.2 g, his serum levels remained low compared with other patients taking only 400 or 600 mg of ketoconazole.[12] Coccidioidomycosis progressed in another patient taking phenytoin despite the use of ketoconazole.[10] Low serum ketoconazole levels were seen in one patient taking phenytoin and phenobarbital.[13]

(d) Miconazole

A man with epilepsy, well controlled with phenytoin, developed symptoms of phenytoin toxicity within one day of starting *intravenous* miconazole 500 mg every 8 hours and flucytosine. After one week of concurrent use his serum phenytoin levels had risen by 50% (from 29 micrograms/mL to 43 micrograms/mL). He had some very mild symp-

toms of phenytoin toxicity before the antifungal treatment was started.[14] Another patient developed symptoms of phenytoin toxicity (nystagmus, ataxia) within 5 days of starting to take oral miconazole 500 mg daily. His serum phenytoin level rose to 40.8 micrograms/mL. After discontinuation of the miconazole the same dose of phenytoin resulted in a level of 14.5 micrograms/mL.[15]

(e) Posaconazole

In a study in healthy subjects the concurrent use of posaconazole 200 mg daily and phenytoin 200 mg daily for 10 days decreased the AUC of posaconazole by 50%, when compared with controls. Although there was no statistically significant change in phenytoin pharmacokinetics, some subjects had increases in phenytoin levels, which the authors thought could be clinically relevant.[16]

(f) Voriconazole

Studies in healthy subjects found that phenytoin 300 mg daily decreased the maximum serum levels and AUC of voriconazole by 49% and 69%, respectively. Also, voriconazole 400 mg twice daily increased the maximum serum levels and AUC of phenytoin 300 mg daily by 67% and 81%, respectively.[17] A patient with systemic lupus erythematosus presented with seizures, and multiple brain lesions were found on imaging. She was given phenytoin 400 mg daily for seizure control and oral voriconazole 300 mg twice daily for possible CNS *Aspergillus* infection. After one month, because voriconazole trough levels were low (0.2 micrograms/mL) and clinical improvement had not occurred, the dose of voriconazole was increased to 400 mg twice daily. Nine days later trough levels of voriconazole had increased to 0.68 micrograms/mL, but 6 weeks later the patient developed oral candidiasis. Voriconazole was increased to 400 mg three times daily. At steady-state her serum levels were 4.08 micrograms/mL and the candidiasis improved.[18]

Mechanism

Fluconazole inhibits the cytochrome P450 isoenzymes responsible for phenytoin metabolism (probably CYP2C9).[2] Voriconazole and miconazole probably act similarly, but ketoconazole and itraconazole do not affect this isoenzyme and therefore do not significantly affect phenytoin levels. Phenytoin is an enzyme inducer, and appears to induce the metabolism of these azoles to varying degrees.

Importance and management

The increase in serum phenytoin levels with **fluconazole** is established and clinically important. Toxicity can develop within 2 to 7 days unless the phenytoin dose is reduced. Monitor serum phenytoin levels closely and reduce the dose appropriately. Also be alert for any evidence of reduced fluconazole effects. Evidence for increased phenytoin levels with **miconazole** is limited, even so it would be prudent to monitor serum phenytoin levels. Note that, a large proportion of miconazole oral gel (both prescription and non-prescription doses) may be swallowed and therefore adequate systemic absorption may occur to produce an interaction.

The decrease in **itraconazole** levels with phenytoin is established, clinically important and its incidence appears to be high. Because such a marked fall in itraconazole levels occurs, it is difficult to predict by how much its dose should be increased, and indeed, dose increases may not be effective. The authors of one report advise using another antifungal instead,[9] and this seems prudent. The small rise in serum phenytoin levels caused by itraconazole is unlikely to be clinically important.

Information on the interaction between **ketoconazole** and phenytoin appears to be limited to these reports, but be alert for any signs of a reduced antifungal response. It may be necessary to increase the dose of the ketoconazole, but note that this may not be wholly successful. Ketoconazole probably does not have an important effect on phenytoin levels.

Phenytoin halves **posaconazole** levels, and posaconazole might increase phenytoin levels. The manufacturer of posaconazole suggests that concurrent use should be avoided unless the benefits outweigh the risks.[19] If used together it would seem sensible to consider increasing the posaconazole dose, and increase monitoring of phenytoin adverse effects (e.g. blurred vision, nystagmus, ataxia or drowsiness), taking levels as necessary, and adjusting the phenytoin dose as appropriate.

The interaction between phenytoin and **voriconazole** is established. The UK manufacturers say that concurrent use of voriconazole and phenytoin should be avoided unless the benefits outweigh the risks.[20] If used together, the manufacturers recommend careful monitoring of phenytoin levels and adverse effects, and doubling the dose of oral voriconazole (from 200 to 400 mg twice daily and from 100 mg to 200 mg twice daily in patients less than 40 kg) or increasing the dose of intravenous voriconazole (from 4 to 5 mg/kg twice daily).[20,21] However, note that, in the case report described above,[18] doses of voriconazole 50% greater than those recommended were required to treat breakthrough infection.

Phenytoin + Bile-acid binding resins

The absorption of phenytoin does not appear to be affected by colestyramine or colestipol.

Clinical evidence, mechanism, importance and management

In a study in 6 healthy subjects, colestyramine 5 g or colestipol 10 g did not have a significant effect on the absorption of a single 500-mg dose of phenytoin. Colestyramine and colestipol were given 2 minutes before and 6 and 12 hours after the phenytoin.[1] Another study in 6 healthy subjects found that colestyramine 4 g four times daily for 5 days had no significant effect on the extent of the absorption of a single 400-mg dose of phenytoin (given on day 3, two minutes after the colestyramine).[2] No special precautions would seem to be necessary if either of these drugs and phenytoin is taken concurrently.

Phenytoin + Calcium-channel blockers

Diltiazem can increase phenytoin levels. A single case report describes phenytoin toxicity with nifedipine and another case report describes neurological toxicity when a patient taking phenytoin (with carbamazepine) was given isradipine.

The levels of felodipine and nisoldipine are very markedly reduced by phenytoin. Case reports suggest that nimodipine and verapamil levels may be reduced by phenytoin.

Clinical evidence

(a) Diltiazem

Elevated serum phenytoin levels and signs of toxicity developed in 2 out of 14 patients taking phenytoin when they were also given diltiazem.[1] A patient taking phenytoin 250 mg twice daily developed signs of toxicity within 2 weeks of starting to take diltiazem 240 mg every 8 hours.[2]

(b) Felodipine

After taking felodipine 10 mg daily for 4 days, 10 patients with epilepsy (including 2 taking phenytoin alone and 3 taking phenytoin with carbamazepine) had markedly reduced plasma felodipine levels (peak levels of 1.6 nanomol/L compared with 8.9 nanomol/L in 12 control subjects). The felodipine bioavailability was reduced to 6.6%.[3]

(c) Isradipine

A man taking carbamazepine and phenytoin developed neurological toxicity while also taking isradipine, which the authors attributed to a pharmacokinetic or pharmacodynamic interaction between the phenytoin and isradipine.[4] However, a commentator considered that an interaction between carbamazepine and isradipine was more plausible.[5]

(d) Nifedipine

An isolated report describes phenytoin toxicity in a man taking phenytoin, 3 weeks after he started to take nifedipine 30 mg daily. His serum phenytoin level was 30.4 micrograms/mL. The nifedipine was stopped, and over the next 2 weeks his serum phenytoin levels fell to 10.5 micrograms/mL. A further 2 weeks later all the symptoms had resolved.[6] However, a retrospective study of 8 patients suggested that nifedipine does not usually interact with phenytoin.[1]

One of the manufacturers of nifedipine notes that the bioavailability of nifedipine may be reduced by phenytoin.[7]

(e) Nimodipine

A study in 8 patients with epilepsy, one of whom was taking phenytoin with carbamazepine, found that the AUC of a single 60-mg oral dose of nimodipine was only about 15% of that obtained in a group of healthy subjects.[8]

(f) Nisoldipine

Twelve patients with epilepsy receiving long-term phenytoin and 12 healthy subjects were given single 40- or 20-mg doses of nisoldipine. The mean nisoldipine AUCs (normalised for a 20-mg dose) were 1.6 micrograms/L per hour for the patients, and 15.2 micrograms/L per hour for the healthy subjects.[9]

(g) Verapamil

A woman taking phenytoin who was then also given verapamil had persistently subtherapeutic plasma verapamil levels (less than 50 nanograms/mL) despite increases in the verapamil dose from 80 mg twice daily to 160 mg three times daily. When the phenytoin was stopped, her plasma verapamil levels rose to the expected concentrations.[10]

Mechanism

Diltiazem may inhibit the metabolism of phenytoin. In contrast, the antiepileptics are well recognised as enzyme inducers, which can increase the metabolism of the calcium-channel blockers by the liver, resulting in a very rapid loss from the body.

Importance and management

Information about the effects of calcium-channel blockers on phenytoin is limited, but what is known indicates that if diltiazem is given with phenytoin, the dose of phenytoin may possibly need to be reduced to avoid toxicity; however, it should be noted that there are only 3 case reports describing this interaction and not all patients appear to be affected, so any effect appears to be rare. The case report of phenytoin toxicity with nifedipine is isolated, and of unknown importance.

Phenytoin markedly reduces felodipine, verapamil, and possibly nifedipine levels. Although not all calcium-channel blockers have been studied, most would be expected to interact with phenytoin similarly, as they are metabolised by the same isoenzymes (see 'Calcium-channel blockers', (p.1025)). A considerable increase in the dose of any calcium-channel blocker will probably be needed in the presence of phenytoin. In some cases the decreases in levels are so large, that dose increases may not be effective, and alternatives to the calcium-channel blocker may be necessary.

Note that the manufacturers of nimodipine[11] and nisoldipine[12] contraindicate the concurrent use of phenytoin because of the possibility of a large reduction in their levels.

Phenytoin + Carbamazepine

Some reports describe rises in phenytoin levels, with toxicity, whereas others describe falls in phenytoin levels, when carbamazepine is given. Falls in carbamazepine levels, sometimes with rises in carbamazepine-10,11-epoxide levels, have also been described.

Clinical evidence

(a) Reduced serum phenytoin levels

Carbamazepine 600 mg daily for 4 to 14 days reduced the serum phenytoin levels of 3 out of 7 patients, from 15 to 7 micrograms/mL, from 18 to 12 micrograms/mL and from 16 to 10 micrograms/mL, respectively. Phenytoin serum levels rose again 10 days after carbamazepine was withdrawn.[1]

Reduced serum phenytoin levels in patients given carbamazepine have been described in other reports.[2-5]

(b) Raised serum phenytoin levels

A study in 6 patients with epilepsy taking phenytoin 350 to 600 mg daily found that over a 12-week period the addition of carbamazepine 600 to 800 mg daily increased the phenytoin serum levels by 35%, increased its half-life by 41% and reduced its clearance by 37%. Neurotoxicity increased by 204%, with additional symptoms of toxicity (sedation, ataxia, nystagmus, etc.) developing in 5 of the 6 patients. The phenytoin dose remained unchanged throughout the period of the study.[6]

Other reports have also described increases in serum phenytoin levels,[7-12] which were as large as 81%, and even up to 100% in some cases.[8,10] One study found that carbamazepine increased the free fraction of phenytoin by 39%.[13]

(c) Reduced serum carbamazepine levels

A series of multiple regression analyses on data from a large number of patients [the precise number is not clear from the report] found that phenytoin reduced plasma carbamazepine levels by, on average, 0.9 micrograms/mL for each 2 mg/kg per day of phenytoin.[7]

Reduced serum carbamazepine levels have been described in other studies and reports.[3,11,14-17] Two studies found that phenytoin markedly increased the levels of the active metabolite of carbamazepine, carbamazepine-10,11-epoxide.[18,19]

Mechanism

Not understood. Both carbamazepine and phenytoin are enzyme inducers, and might therefore be expected to increase the metabolism of each other. However, more recently it has been shown that carbamazepine can inhibit the cytochrome P450 isoenzyme CYP2C19, which is one of the enzymes involved in phenytoin metabolism.[20] Carbamazepine might therefore

cause increases in phenytoin levels by this mechanism. Moreover, CYP2C19 shows genetic polymorphism (that is, different patients have different amounts of this isoenzyme), so an interaction by this mechanism would not occur in all patients.

Importance and management

Phenytoin may decrease carbamazepine levels, but carbamazepine has a variable effect on phenytoin levels, with both increases and decreases described. Monitor antiepileptic levels during concurrent use (where possible including the active metabolite of carbamazepine, carbamazepine-10,11-epoxide) so that steps can be taken to avoid the development of toxicity or lack of efficacy. Not all patients appear to have an adverse interaction, and, at present, it does not seem possible to identify those potentially at risk. The risk of carbamazepine-induced water intoxication is reported to be reduced in patients also taking phenytoin.[15]

Phenytoin + Chloramphenicol

Phenytoin levels can be raised by intravenous chloramphenicol and phenytoin toxicity may occur. Other evidence indicates that phenytoin may increase or decrease chloramphenicol levels in children.

Clinical evidence

(a) Effect on chloramphenicol

A child given a 6-week course of intravenous chloramphenicol 100 mg/kg daily in four divided doses had a reduction in chloramphenicol peak and trough serum levels of 46% and 74%, respectively, within 2 days of starting phenytoin 4 mg/kg daily.[1] In contrast, 6 children (aged 1 month to 12 years) developed raised, toxic chloramphenicol levels while receiving phenytoin.[2]

(b) Effect on phenytoin

A man taking phenytoin 100 mg four times daily developed signs of phenytoin toxicity within a week of starting intravenous chloramphenicol (1 g every 6 hours for 4 doses then 2 g every 6 hours). His serum phenytoin levels had risen by about threefold, from about 7 to 24 micrograms/mL.[3]

This interaction has been described in a number of other reports.[4-12] One study found that intravenous chloramphenicol more than doubled the half-life of phenytoin.[4] The AUC of phenytoin after a single intravenous dose of **fosphenytoin** was 23% higher (not significant) in children also given intravenous chloramphenicol, when compared with those given intravenous cefotaxime. In addition, the phenytoin half-life was significantly prolonged by chloramphenicol (23.7 hours versus 15.5 hours).[13]

Mechanism

It seems probable that chloramphenicol, a known enzyme inhibitor,[14] affects the liver enzymes (possibly cytochrome P450 isoenzyme CYP2C19[15]) concerned with the metabolism of phenytoin thereby reducing its rate of clearance from the body. The changes in the pharmacokinetics of chloramphenicol in children are not understood.

Importance and management

The rise in serum phenytoin levels with intravenous chloramphenicol in adults is well documented and clinically important. A two to fourfold rise can occur within a few days. Concurrent use should be avoided unless the effects can be closely monitored and appropriate phenytoin dose reductions made as necessary. The use of a single prophylactic dose of phenytoin or fosphenytoin may be an exception to this.[13] It seems very doubtful if enough chloramphenicol is absorbed from eye drops or ointments for an interaction to occur.

The general clinical importance of the changes in serum chloramphenicol levels in children is uncertain, but the effects of concurrent use should certainly be monitored. More study is needed.

Phenytoin + Chlorphenamine

Phenytoin toxicity was attributed to the concurrent use of chlorphenamine in two patients.

Clinical evidence, mechanism, importance and management

A woman taking phenytoin and phenobarbital developed phenytoin toxicity with serum phenytoin levels of about 65 micrograms/mL about a week after starting to take chlorphenamine 4 mg three times daily. The toxic symptoms disappeared and phenytoin levels fell when chlorphenamine was withdrawn.[1] Another woman taking antiepileptics, including phenytoin, developed slight grimacing of the face and involuntary jaw movements (but no speech slurring, ataxia or nystagmus) within 12 days of starting to take chlorphenamine 12 to 16 mg daily. Her serum phenytoin level had risen to 30 micrograms/mL but it fell when chlorphenamine was withdrawn.[2]

The reason for these reactions is not clear but it has been suggested that

chlorphenamine may have inhibited the metabolism of phenytoin by the liver; however, chlorphenamine is not usually associated with enzyme inhibition. These are isolated cases, and their general relevance is uncertain, but it seems likely to be small.

Phenytoin + Coumarins and related drugs

Phenytoin levels can be increased by dicoumarol (toxicity seen) and phenprocoumon, but they are usually unchanged by warfarin and phenindione. However, a single case of phenytoin toxicity has been seen with warfarin. Phenytoin would be expected to reduce the anticoagulant effects of coumarin anticoagulants, and this has been seen with dicoumarol and warfarin. However, cases of increased effects of warfarin have been reported, and one study found that the effects of phenprocoumon were generally unaltered. A single case of severe bleeding has been described in a patient taking acenocoumarol and phenytoin.

Clinical evidence

The reports of interactions between phenytoin and various anticoagulants are summarised in 'Table 14.2', (below), and discussed in further detail below.

(a) Acenocoumarol

A 68-year-old woman with a double mitral valve lesion, atrial fibrillation and hypertension, taking digoxin and diuretics, was stabilised taking acenocoumarol 17 mg per week in divided doses and paroxetine. Phenytoin 400 mg daily for 3 days then 300 mg daily was started because of a seizure, and 11 days later she developed ataxia, lethargy and nystagmus (free phenytoin level 12.5 micromol/L). At the same time her INR was found to have risen from a range of 2 to 4, up to 14.5 and a huge retroperitoneal haematoma was discovered. After appropriate treatment she was discharged taking acenocoumarol 13 mg per week in divided doses and half the phenytoin dose.[1]

(b) Dicoumarol

Phenytoin 300 mg daily was given to 6 subjects taking dicoumarol 40 to 160 mg daily for a week. No significant changes in the prothrombin-proconvertin concentration occurred until 3 days after stopping the phenytoin. In the following 5 days it climbed from 20 to 50%, with an accompanying drop in the serum dicoumarol levels.[2] Four other subjects taking dicoumarol 60 mg daily were also given phenytoin 300 mg daily for the first week of treatment, and then 100 mg daily for 5 more weeks. The prothrombin-proconvertin concentration had risen from 20 to 70% after 2 weeks of concurrent use, representing an antagonism of the anticoagulant effect, and only fell to previous levels 5.5 weeks after stopping phenytoin.[2]

A study in 6 subjects taking phenytoin 300 mg daily found that when they were also given dicoumarol (doses adjusted to give prothrombin values of about 30%) their serum phenytoin levels rose on average by almost 10 micrograms/mL (126%) over 7 days.[3] In another study in 3 patients the half-life of phenytoin increased by about fivefold during dicoumarol use.[4]

A patient taking dicoumarol developed phenytoin toxicity within a few days of starting to take phenytoin 300 mg daily (dose based on a weight of 62 kg). Phenytoin was withdrawn, and re-introduced at 200 mg daily, which gave satisfactory phenytoin levels.[5]

(c) Phenindione

A study in 4 patients taking phenytoin 300 mg daily found that phenindione did not affect their serum phenytoin levels.[4]

(d) Phenprocoumon

An investigation in patients taking long-term phenprocoumon found that in the majority of cases phenytoin had no significant effect on either serum phenprocoumon levels or the anticoagulant control, although a few patients had a fall and others a rise in serum anticoagulant levels, with consequent decreased or increased effects.[6]

A study in 4 patients taking phenytoin 300 mg daily found that when they were given phenprocoumon their serum phenytoin levels rose from about 10 micrograms/mL to 14 micrograms/mL over 7 days.[4] The phenytoin half-life increased from 9.9 hours to 14 hours.

(e) Warfarin

The prothrombin time of a patient taking warfarin increased from 21 to 32 seconds over a month when phenytoin 300 mg daily was also given, despite a 22% reduction in the warfarin dose. He was restabilised on the original warfarin dose when phenytoin was withdrawn. Six other reports

Table 14.2 Summary of interactions between phenytoin and anticoagulants

Concurrent treatment with phenytoin and anticoagulant	*Effect on anticoagulant*	*Effect on serum phenytoin levels*
Acenocoumarol	Single case of increase[1]	Uncertain
Dicoumarol	Reduced[2]	Markedly increased[3-5]
Phenindione	Not documented	Usually unchanged[3,4]
Phenprocoumon	Usually unchanged[6]	Increased[4]
Warfarin	Increased[7-12,13] Single case of increase followed by decrease[10]	Usually unchanged[4] Increased in two cases[12,14]

describe this interaction.[7-12] One of them describes a patient who had an increased anticoagulant response to warfarin for the first 6 days after phenytoin was added. The anticoagulant effect then declined to less than the level seen before the addition of phenytoin.[10] Conversely, a population pharmacokinetic analysis reported that the clearance of warfarin was *increased* by 30% in 6 patients taking phenytoin or phenobarbital.[13] However, the findings were not reported separately for the two drugs, and are therefore difficult to interpret (phenobarbital is a known inducer of warfarin clearance, see 'Coumarins + Barbiturates', p.440).

A study in 2 patients taking phenytoin 300 mg daily found that their serum phenytoin levels were unaffected by warfarin given for 7 days, and the half-life of phenytoin in 4 other patients was unaffected.[4] However, a patient taking phenytoin 300 mg daily developed symptoms of toxicity shortly after starting to take warfarin.[14] Another patient developed phenytoin toxicity 6 months after starting to take phenytoin with warfarin.[12]

Mechanism

Multiple, complex and poorly understood. Dicoumarol and phenprocoumon (but not normally warfarin) appear to inhibit the metabolism of phenytoin by the liver, so that its loss from the body is reduced. Phenytoin is an inducer of the cytochrome P450 isoenzyme CYP2C9, which is involved (to varying degrees) in the metabolism of the coumarin anticoagulants. Phenytoin would therefore be expected to decrease the levels and effect of some coumarins, and this has been shown for dicoumarol. However, increased effects of warfarin have been noted, suggesting reduced metabolism of warfarin. Why this occurs is uncertain, but poor CYP2C9 metaboliser phenotype (that is, those patients genetically lacking this isoenzyme) may provide an explanation.[15] Phenytoin possibly also has a diverse depressant effect on the liver, which lowers blood clotting factor production.[16]

Importance and management

None of these interactions has been extensively studied nor are they well established, but what is known suggests that the use of dicoumarol with phenytoin should be avoided or monitored very closely. Similarly, serum phenytoin levels and anticoagulant control should be well monitored if acenocoumarol, phenprocoumon or warfarin is given with phenytoin. Dose adjustments may be needed to accommodate any interactions. Information about other anticoagulants (apart from phenindione, which had no effect on phenytoin levels) appears to be lacking, but it would clearly be prudent to monitor the effects of concurrent use.

Phenytoin + Dextromethorphan

Dextromethorphan appears not to affect phenytoin levels.

Clinical evidence, mechanism, importance and management

A double-blind, crossover study in 4 patients with severe complex partial seizures found that dextromethorphan 120 mg daily in liquid form (*Delsym*) over 3 months had no effect on their serum phenytoin levels. There was a non-significant alteration in the complex partial seizure and tonic-clonic seizure frequency.[1] This suggests that the dose of phenytoin does not need to be adjusted in patients also given dextromethorphan.

Phenytoin + Dextropropoxyphene (Propoxyphene)

Although no interaction generally appears to occur between phenytoin and dextropropoxyphene, a case report describes phenytoin toxicity in a patient given both drugs.

Clinical evidence, mechanism, importance and management

In a study, 6 patients taking phenytoin were given dextropropoxyphene 65 mg three times daily for 6 to 13 days. Dextropropoxyphene caused only a very small rise in phenytoin levels.[1] In contrast, a review briefly mentions one patient who developed toxic serum phenytoin levels while taking dextropropoxyphene in doses of up to 600 mg daily on an as-required basis.[2]

Concurrent use need not be avoided, but as rises in the serum levels of phenytoin can occur it would be prudent to monitor the outcome, especially if large doses of dextropropoxyphene are being taken. It is probably sufficient to monitor for increased phenytoin adverse effects (blurred vision, nystagmus, ataxia or drowsiness).

Phenytoin + Diazoxide

Three children and one adult had very marked reductions in their phenytoin levels when diazoxide was given, and in one case seizures developed. There is some evidence that the effects of diazoxide may be reduced by phenytoin.

Clinical evidence

A child taking phenytoin 29 mg/kg daily and an adult taking phenytoin 1 g daily were unable to achieve therapeutic phenytoin serum levels while taking diazoxide. When the diazoxide was withdrawn, satisfactory serum phenytoin levels were achieved with doses of only 6.6 mg/kg and 400 mg daily, in the child and the adult, respectively. When diazoxide was restarted experimentally in the adult, the serum phenytoin levels became undetectable after 4 days, and seizures occurred.[1] Two other reports describe this interaction.[2,3]

Limited evidence suggests that the half-life and effects of the diazoxide can be reduced by phenytoin.[2,4]

Mechanism

What is known suggests that diazoxide increases the metabolism and the clearance of phenytoin from the body.[1,2]

Importance and management

Information is limited to these reports, but the interaction would appear to be established. Given the rapid development of seizures in one case, it would seem prudent to avoid concurrent use where possible. If both drugs must be given, monitor the effects of concurrent use, being alert for the need to increase the phenytoin dose. The clinical importance of the reduced diazoxide effects is uncertain.

4. Pruitt AW, Dayton PG, Patterson JH. Disposition of diazoxide in children. *Clin Pharmacol Ther* (1973) 14, 73–82.

Phenytoin + Dichloralphenazone

There is some evidence that phenytoin levels may be reduced by dichloralphenazone.

Clinical evidence, mechanism, importance and management

In 5 healthy subjects, dichloralphenazone 1.3 g each night for 13 nights doubled the total body clearance of a single intravenous dose of phenytoin.[1] The phenazone component of dichloralphenazone is a known enzyme inducer and the increased clearance of phenytoin is probably due to an enhancement of its metabolism by the liver. There seem to be no additional reports of adverse effects in patients given both drugs, so that the clinical importance of this interaction is uncertain. However, it would seem prudent to be alert for a reduction in serum phenytoin levels if dichloralphenazone is also given.

1. Riddell JG, Salem SAM, McDevitt DG. Interaction between phenytoin and dichloralphenazone. *Br J Clin Pharmacol* (1980) 9, 118P.

Phenytoin + Felbamate

Felbamate causes a moderate increase in phenytoin levels. Felbamate levels are reduced by phenytoin.

Clinical evidence

A pilot study in 4 patients noted that felbamate increased plasma phenytoin levels.[1] Therefore, in a further study in 5 patients, the phenytoin dose was automatically reduced by 20% when felbamate was given. One patient needed a slight increase in phenytoin dose, whereas 2 other patients needed a further reduction in their phenytoin dose.[2] In a later full report of this study, it was noted that phenytoin dose decreases of 10 to 30% were required to maintain stable levels in the presence of felbamate.[3] Another study in patients with epilepsy found that felbamate 1.2 or 1.8 g daily increased the maximum plasma phenytoin levels by 31% and 69%, respectively. Higher felbamate doses necessitated phenytoin dose reductions of 20 to 40%.[4]

Studies in children and adults have found that phenytoin increased the clearance of felbamate by about 40%,[5,6] and decreased maximum felbamate levels by 56 to 60%, when compared with patients taking felbamate alone.[4] Another report suggested that this effect was dose-dependent.[7]

Mechanism

Uncertain but felbamate probably acts as a competitive inhibitor of phenytoin metabolism, thereby reducing its loss from the body and increasing its serum levels,[2,8] whereas phenytoin induces felbamate metabolism, thereby increasing its clearance.[7]

Importance and management

Established interactions. The phenytoin dose may need to be reduced (a 20 to 40% reduction seems to be about right[2,4,8]) if felbamate is added, and increased if felbamate is withdrawn. However, note that, as phenytoin pharmacokinetics are non-linear, any dose adjustments will need to be assessed in individual patients. The importance of the reduced felbamate levels is uncertain, but they are probably less important because felbamate has a wide therapeutic range.[4]

Phenytoin + Food

The absorption of phenytoin can be affected by some foods. A very marked reduction in phenytoin absorption has been described when it was given with enteral feeds (e.g. *Isocal*, *Osmolite*), by nasogastric or jejunostomy tubes.

Clinical evidence

(a) Food by mouth

A study found that serum drug levels were lower than expected when phenytoin was disguised in **vanilla pudding** and given to children. However, when the phenytoin was mixed with **apple sauce**, 3 out of 10 patients developed serum phenytoin levels within the toxic range, and the mean levels were twice those seen when the tablets were mixed with the **vanilla pudding**.[1] The absorption of phenytoin as the acid in a micronised form (*Fenantoin*, ACO, Sweden) was faster and the peak serum levels were on average 40% higher when it was given after a **standardised breakfast**.[2] In a further study to investigate the effects of component parts of the **standardised breakfast**, the same authors found that **fat** had no measurable effect, but **carbohydrate** may enhance, and **protein** reduce, the absorption of phenytoin.[3]

Another study in 5 subjects found that the bioavailability of a single dose of phenytoin was enhanced when it was given immediately after a '**balanced**' **meal**. Administration after a **high-lipid meal** resulted in large inter-patient variability in phenytoin bioavailability.[4] One single-dose study found that, when taken with a **high-protein meal**, the total absorption of phenytoin was not affected, although it was slightly delayed.[5]

A patient with epilepsy had a marked fall in his serum phenytoin levels accompanied by an increased seizure frequency when phenytoin was given at bedtime with 8 oz of a food supplement (***Ensure***).[6] Another patient had reduced phenytoin serum levels when phenytoin was given as an oral suspension with oral ***Fresubin liquid food concentrate***.[7]

However, in contrast, a study in 10 healthy subjects found that when ***Ensure*** or ***Vivonex TEN*** was given every 4 hours for 24 hours, the absorption of a single 400-mg dose of phenytoin was unaffected.[8] Similarly, a single-dose study in healthy subjects found that the bioavailability of phenytoin sodium 400 mg in a capsule formulation (*Dilantin Kapseals*) was not affected by ***Ensure***.[9]

A study in healthy subjects found that phenytoin levels were reduced by enteral feeds, but that it was easier to attain therapeutic levels of phenytoin in those also receiving a **meat-based** formulation (***Compleat Modified***) rather than a **protein hydrolysate** formulation (***Osmolite***).[10]

(b) Food by nasogastric tube

A patient taking phenytoin 300 mg daily who was being fed with ***Fortison*** through a nasogastric tube, following a brain injury sustained in a road traffic accident, had a phenytoin serum level of only 1 mg/L. When phenytoin 420 mg was given diluted in water and separated from the food by 2 hours, a serum level of 6 mg/L was achieved.[11] This report describes a similar reaction in another patient with a cerebral tumour.[11]

A study in 20 patients and 5 healthy subjects found that phenytoin absorption was reduced by about 70% when it was given by nasogastric tube with an **enteral feed** product (***Isocal***) at a rate of 100 to 125 mL/hour.[12] Other reports describe the same interaction in patients given ***Ensure***,[13] ***Isocal***,[14,15] or ***Osmolite***.[13,16-18] However, another study in healthy subjects found that the absolute bioavailability of phenytoin suspension or phenytoin sodium solution given by nasogastric tube was not affected by an enteral feed product (***Isocal***).[19]

(c) Food by jejunostomy tube

A woman with a history of seizures had acceptable serum phenytoin levels when phenytoin was given intravenously, but they fell from 19.1 micrograms/mL to less than 2.5 micrograms/mL when a comparable dose of phenytoin suspension was given in the presence of an **enteral feed** product (***Jevity***), given by jejunostomy tube.[20]

Mechanism

Not fully resolved. Phenytoin can bind to some food substances, which reduces its absorption.[21,22] One study in healthy subjects failed to find any difference in phenytoin bioavailability after fasting or with *Ensure* (given hourly or every 4 hours), suggesting that factors other than direct contact of phenytoin and feed contribute to decreased phenytoin bioavailability.[23] Phenytoin can also become bound to the nasogastric tubing[24] and may also be poorly absorbed if the tubing empties into the duodenum rather than the stomach.[24] Delivery into the jejunum appears to have an even greater detrimental effect on phenytoin absorption, because there is even less time for adequate absorption.[20] Other factors that could contribute to the interaction are gastrointestinal transit time, the nitrogen source in the feed, the calcium content and pH of the feed, the dose form of phenytoin or its dilution before administration.[25]

Importance and management

Phenytoin is often taken orally with food to reduce gastric irritation. This normally appears not to have a marked effect on absorption, but the studies cited above show that some formulations and some foods can interact. If there are problems with the control of seizures or evidence of toxicity, review how and when the patient is taking the phenytoin.

Some studies in healthy subjects failed to find an interaction between phenytoin and enteral feeding.[8,9,19,23] However, many studies in patients have found a clinically important interaction between phenytoin and enteral feeds given orally or by nasogastric tube. The markedly reduced bioavailability associated with the nasogastric route has been successfully managed by giving the phenytoin diluted in water 2 hours after stopping the feed, flushing with 60 mL of water, and waiting another 2 hours before restarting the feed,[11,12] However, one limited study failed to confirm that this method is successful,[13] and some sources suggest waiting 1 hour[26] or 6 hours[14] after the phenytoin dose before restarting the feed. Some increase in the phenytoin dose may also be needed. Monitor concurrent use closely. The same problem can clearly also occur when enteral feeds are given by jejunostomy tube. Approaches on how to minimise any potential interaction have been reported,[25,27] including the development and use of an algorithm.[25] In patients requiring phenytoin and enteral nutrition, the initial use of intravenous phenytoin to establish therapeutic levels has been suggested. It may also be considered if therapeutic levels cannot be maintained without compromising nutritional intake. Stopping continuous feed 1 hour rather than 2 hours before and after phenytoin administration and the use of twice daily phenytoin rather than three times daily administration have also been suggested as methods of maintaining adequate caloric intake as well as phenytoin levels in some patients.[27]

Phenytoin + H_2-receptor antagonists

Phenytoin levels are raised by the use of cimetidine and toxicity has occurred. Limited evidence suggests that low doses of cimetidine may not interact. Very rarely bone marrow depression develops on concurrent use. Famotidine, nizatidine and ranitidine do not normally interact with phenytoin, although, rarely, cases of elevated phenytoin levels have been reported.

Clinical evidence

(a) Cimetidine

The serum phenytoin levels of 9 patients rose by 60% (from 5.7 micrograms/mL to 9.1 micrograms/mL) when they were given cimetidine 200 mg three times daily and 400 mg at night for 3 weeks. The serum phenytoin level returned to its former levels within 2 weeks of stopping the cimetidine.[1]

This interaction has been described in many reports and studies involving patients[2-7] and healthy subjects.[8-11] Phenytoin toxicity has developed in some individuals. The extent of the rise in serum levels is very variable being quoted as 13 to 33% over about 6 days in one report[2] and 22 to 280% over 3 weeks in others.[4,12] There is some evidence that the effect may be dependent on the dose of cimetidine. One study found that the effect of cimetidine 2.4 g daily was greater than that of 1.2 g daily or 400 mg daily; the effect of the lower two doses did not differ from each other.[9] In another study, cimetidine 200 mg twice daily for 2 weeks had no effect on serum phenytoin levels in 9 patients taking stable doses of phenytoin.[13]

Severe and life-threatening agranulocytosis in 2 patients[14,15] and thrombocytopenia in 6 other patients[16-18] has been attributed to the concurrent use of phenytoin and cimetidine. Severe skin reactions have also been reported in 3 patients taking phenytoin, cimetidine, and dexamethasone after resection of brain tumours, which resolved on discontinuing phenytoin.[19]

(b) Famotidine

A study in 10 subjects found that famotidine 40 mg daily for 7 days did not alter the pharmacokinetics of a single dose of phenytoin.[20] However, a single case report describes phenytoin toxicity and an almost doubled serum level (increase from 18 to 33 micrograms/mL) in a patient given famotidine. This was managed by a reduction in the phenytoin dose.[21]

(c) Nizatidine

In a study in 18 healthy subjects, nizatidine 150 mg twice daily for 9 doses had no effects on the pharmacokinetics of a single dose of phenytoin.[22]

(d) Ranitidine

A study in 4 patients found that ranitidine 150 mg twice daily for 2 weeks did not alter phenytoin levels.[4,12] Similarly, a double-blind, crossover study in healthy subjects found that ranitidine 150 mg twice daily for 6 days had no significant effect on steady-state phenytoin levels.[23] However, one patient had a 40% increase in serum phenytoin levels over a month when ranitidine 150 mg twice daily was given,[24] and two others also developed elevated serum phenytoin levels and signs of toxicity,

which were attributed to the use of ranitidine.[25,26] Another patient developed a severe skin reaction when treated with phenytoin, ranitidine and dexamethasone after resection of a brain tumour, which resolved on discontinuing phenytoin.[19]

Mechanism

Cimetidine inhibits the activity of the liver enzymes concerned with the metabolism of phenytoin, thus allowing it to accumulate in the body and, in some instances, to reach toxic concentrations. Famotidine, nizatidine and ranitidine normally do not affect these enzymes. Agranulocytosis and thrombocytopenia are relatively rare manifestations of bone marrow depression caused by both phenytoin and the H_2-receptor antagonists.

Importance and management

The interaction between phenytoin and cimetidine is well documented and clinically important. It is not possible to identify individuals who will show the greatest response, but those with serum levels at the top end of the therapeutic range are most at risk. Do not give cimetidine to patients already taking phenytoin unless the serum levels can be monitored and suitable phenytoin dose reductions made as necessary. The results from one small study suggest that low doses of cimetidine (such as those available without a prescription in the UK) may not interact.[13] As there are only rare cases of an interaction with phenytoin reported for famotidine, nizatidine, and ranitidine, extra monitoring beyond that usually carried out in patients receiving phenytoin does not appear to be warranted but be alert for signs of phenytoin toxicity (e.g. blurred vision, nystagmus, ataxia or drowsiness) when these H_2-receptor antagonists are first added to established treatment with phenytoin.

Phenytoin + Immunoglobulins

An isolated report describes a patient taking phenytoin who died, probably from hypersensitivity myocarditis, two days after receiving immunoglobulins for Guillain-Barré syndrome.

Clinical evidence, mechanism, importance and management

A man who had been taking phenytoin for 8 years was diagnosed as having Guillain-Barré syndrome for which intravenous immunoglobulin was started at 400 mg/kg daily. On day 2 the patient complained of abdominal pain, aching shoulders and backache. He subsequently developed hypotension and died, despite resuscitation attempts. A post-mortem suggested that he had died from hypersensitivity myocarditis, which the authors of the report suggest might have resulted from the long-term use of phenytoin.[1] This hypersensitivity with phenytoin has been reported before.[2] Because this complication is so serious, the authors of this report suggest that leukocyte counts, in particular eosinophils, should be monitored if immunoglobulins and phenytoin are given concurrently.[1] The general importance of this alleged interaction is not known. However, note that, subsequent to this report, intravenous immunoglobulin has successfully been used to treat a few cases of a hypersensitivity syndrome to phenytoin,[3-5] one including eosinophilia.[3] Furthermore, intravenous immunoglobulin alone has also been associated with causing myocarditis.[6] An interaction is therefore by no means established.

Phenytoin + Influenza vaccines

Influenza vaccination is reported to increase, decrease or to have no effect on phenytoin serum levels. The efficacy of the vaccine remains unchanged.

Clinical evidence

The serum phenytoin levels of 8 children with epilepsy were increased by about 50% (from 9.5 to 15.16 micrograms/mL) 7 days after they were given 0.5 mL of an influenza virus vaccine USP, types A and B, whole virus (Squibb). The phenytoin levels returned to baseline over the following 7 days.[1] Temporary rises in the serum phenytoin levels of 3 patients, apparently caused by influenza vaccination, are briefly described in another report.[2]

In contrast, another study in 16 patients given 0.5 mL of an inactivated whole-virion trivalent influenza vaccine found that 7 and 14 days later their mean serum phenytoin levels were not significantly altered, although 4 of them showed a trend towards raised levels. Subsequently, these 4 patients had serum phenytoin increases ranging from 46 to 170%, which returned to baseline between week 4 and 17 after immunisation.[3]

In yet another study, within 4 days of receiving 0.5 mL of a subvirion, trivalent influenza vaccine, the serum phenytoin levels of 7 patients were reduced by 11 to 14%, which is unlikely to have much clinical significance.[4] A further study[5] measured both free and total phenytoin levels in 8 patients receiving phenytoin. Two days after receiving 0.5 mL of a trivalent influenza vaccine, the total phenytoin level had increased by 10%, and this then returned to baseline levels by day 7. However, the free phenytoin level gradually decreased after vaccination, reaching a maximum decrease of 25% below baseline at day 14.

The efficacy of influenza vaccine is reported to be unchanged by phenytoin.[6]

Mechanism

Where an interaction occurs it is suggested that it may be due to the inhibitory effect of the vaccine on the liver enzymes concerned with the metabolism of the phenytoin, resulting in a reduced clearance from the body.[1]

Importance and management

The outcome of immunisation with influenza vaccine on phenytoin levels is uncertain. Concurrent use need not be avoided but it would be prudent to monitor the effects closely. Be aware that any alteration in levels may take a couple of weeks to develop and usually resolves spontaneously.

Phenytoin + Isotretinoin

A study in 7 healthy subjects taking phenytoin 300 mg daily found that the addition of isotretinoin 40 mg twice daily for 11 days had no effect on the steady-state pharmacokinetics of phenytoin.[1] No phenytoin dose adjustments would seem to be needed if these drugs are given concurrently.

1. Oo C, Barsanti F, Zhang R. Lack of effect of isotretinoin on the pharmacokinetics of phenytoin at steady-state. *Pharm Res* (1997) 14 (11 Suppl), S-561.

Phenytoin + Loxapine

A single case report describes decreased serum phenytoin levels in a patient given loxapine.

Clinical evidence, mechanism, importance and management

The serum phenytoin levels of a patient with epilepsy were reduced by loxapine: when loxapine was withdrawn, the phenytoin levels rose markedly.[1] The general importance of this case is uncertain, but bear this interaction in mind, particularly as loxapine can lower the convulsive threshold.

1. Ryan GM, Matthews PA. Phenytoin metabolism stimulated by loxapine. *Drug Intell Clin Pharm* (1977) 11, 428.

Phenytoin + Macrolides

Erythromycin appears not to interact with phenytoin. Limited evidence suggests that clarithromycin may possibly raise phenytoin levels. Phenytoin is predicted to reduce telithromycin levels.

Clinical evidence

(a) Clarithromycin

A retrospective study of serum phenytoin levels in a group of 21 patients with AIDS and a large control group of 557 subjects suggested that the concurrent use of clarithromycin (a total of 22 samples from at least 10 patients) was associated with higher serum phenytoin levels. The concentration-to-dose ratio of the phenytoin was 1.6 without clarithromycin and 3.9 with clarithromycin.[1]

(b) Erythromycin

A single-dose study in 8 healthy subjects found that the mean clearance of phenytoin was unchanged by erythromycin 333 mg every 8 hours for 7 days. However, there were occasional large changes in phenytoin clearance.[2] Similarly, in another study in 8 healthy subjects, erythromycin 250 mg every 6 hours for 7 days had no effect on the pharmacokinetics of a single dose of phenytoin.[3]

Mechanism

Not known, but it could be that clarithromycin inhibits the metabolism of phenytoin by the liver.

Importance and management

This seems to be the first and only evidence that clarithromycin possibly interacts like this. Given that the effect was identified retrospectively any interaction seems unlikely to cause an acute problem. Erythromycin appears not to interact with phenytoin, but nevertheless caution has been recommended,[2] because of the occasional large changes in clearance that were seen.

Other macrolides appear not to have been studied. However, based on an interaction with the known enzyme inducer rifampicin (rifampin) (see 'Macrolides + Rifamycins', p.357), the manufacturers of **telithromycin** predict that its levels will be reduced by phenytoin, possibly making them sub-therapeutic. They advise avoiding telithromycin use during and for up to 2 weeks after phenytoin has been taken.[4]

Phenytoin + Methylphenidate

Although two small studies found that methylphenidate did not alter phenytoin levels, case reports describe raised phenytoin levels and phenytoin toxicity in patients also given methylphenidate.

Clinical evidence

A 5-year-old hyperkinetic boy with epilepsy taking phenytoin 8.9 mg/kg and **primidone** 17.7 mg/kg daily, developed ataxia without nystagmus when he was also given methylphenidate 40 mg daily. Serum levels of both of the antiepileptics were found to be toxic and only began to fall when the methylphenidate dose was reduced.[1] A further case also describes phenytoin toxicity in a child given methylphenidate.[2]

Only one other case has been reported, but this patient was later re-challenged with the two drugs and phenytoin toxicity was not seen.[3] Furthermore, this interaction has not been seen in clinical studies and observations in 3 healthy subjects[3] and more than 11 patients[4] taking phenytoin and methylphenidate.

Mechanism

Not fully understood. The suggestion is that methylphenidate acts as an enzyme inhibitor, slowing the metabolism of the phenytoin by the liver and leading to its accumulation in those individuals whose drug metabolising system is virtually saturated by phenytoin.

Importance and management

These appear to be the only reports of a possible interaction between phenytoin and methylphenidate, and an interaction is not established. The concurrent use of both drugs need not be avoided but be alert for any evidence of toxicity, particularly if the phenytoin dose is high. It would seem prudent to monitor for symptoms of phenytoin toxicity (e.g. blurred vision, nystagmus, ataxia or drowsiness) and take levels if necessary.

Phenytoin + Metronidazole

One study found that the half-life of intravenous phenytoin was modestly prolonged by metronidazole, whereas another found

that metronidazole did not affect the pharmacokinetics of oral phenytoin. An anecdotal report describes a few patients who developed toxic phenytoin levels when given metronidazole.

Clinical evidence, mechanism, importance and management

A pharmacokinetic study in 7 healthy subjects found that metronidazole 250 mg three times daily increased the half-life of a single 300-mg intravenous dose of phenytoin by about 40% (from 16 to 23 hours) and reduced its clearance by 15%.[1] In contrast, another study in 5 healthy subjects found that the pharmacokinetics of a single 300-mg oral dose of phenytoin were unaffected by metronidazole 400 mg twice daily for 6 days.[2] An anecdotal report describes several patients (exact number not stated) who developed toxic phenytoin serum levels when given metronidazole.[3] These appear to be the only reports of this potential interaction, and the reason for their discordant findings is not clear. It seems that few patients are likely to experience a clinically significant interaction.

Phenytoin + Nefazodone

Nefazodone did not affect the pharmacokinetics of phenytoin in healthy subjects.

Clinical evidence, mechanism, importance and management

Nefazodone 200 mg twice daily for 7 days had no effect on the pharmacokinetics of a single 300-mg dose of phenytoin in healthy subjects, and no changes in vital signs, ECGs or other physical measurements were seen. There was no evidence that a clinically significant interaction was likely.[1]

Phenytoin + Nitrofurantoin

An isolated report describes a reduction in phenytoin levels and poor seizure control in a patient given nitrofurantoin.

Clinical evidence, mechanism, importance and management

A man with seizures due to a brain tumour was taking phenytoin 300 mg daily. He had a seizure within one day of starting nitrofurantoin 200 mg daily for a urinary-tract infection and, despite a recent increase in the phenytoin dose to 350 mg, his serum phenytoin levels were found to be modestly reduced (from about 9 to 7.6 micrograms/mL). They continued to fall, and were 6.3 micrograms/mL despite a further increase in the phenytoin dose to 400 mg daily. When the nitrofurantoin was stopped the patient was restabilised on his original dose of phenytoin. The reasons for this effect are not understood but, on the basis of a noted rise in serum gamma glutamyltransferase levels during the use of the nitrofurantoin, the authors speculate that it increased the metabolism of the phenytoin by the liver.[1] The general importance of this interaction is uncertain, but probably small.

Phenytoin + Orlistat

Orlistat does not alter the pharmacokinetics of phenytoin.

Clinical evidence, mechanism, importance and management

In a placebo-controlled, randomised study, 12 healthy subjects were given orlistat 120 mg three times daily for 7 days, with a single 300-mg dose of phenytoin on day 4. The pharmacokinetics of phenytoin were unchanged by orlistat,[1] and no phenytoin dose adjustments are therefore thought to be needed if these two drugs are given concurrently.

Phenytoin + Penicillins

An isolated case describes a marked reduction in serum phenytoin levels, resulting in seizures, which was attributed to the use of oxacillin.

Clinical evidence, mechanism, importance and management

An woman with epilepsy taking phenytoin 400 mg daily, hospitalised for second degree burns sustained during a generalised seizure, experienced brief clonic seizures and was found to have an marked reduction in her serum phenytoin levels, from 16.3 micrograms/mL to 3.5 micrograms/mL, which was attributed to the concurrent use of oral **oxacillin** 500 mg every 6 hours. The phenytoin dose was increased, but seizures continued and progressed to status epilepticus, and intravenous phenytoin was given. Doses of oral phenytoin of about 600 mg daily were required to maintain minimum therapeutic levels, sometimes with supplementation of small intravenous doses. Just before the **oxacillin** was withdrawn the serum phenytoin level was 22.3 micrograms/mL, but 6 months later it had risen to 39.9 micrograms/mL, and the phenytoin dose was reduced.[1] Other studies have shown that penicillins such as **oxacillin**, **cloxacillin** and **dicloxacillin** can displace phenytoin from plasma protein binding, decreasing total serum levels but increasing the free fraction of phenytoin. If anything, this would be predicted to increase phenytoin toxicity,[2,3] rather than decrease its levels, as seen in the case. This seems to be only report of an adverse interaction between phenytoin and a penicillin. Its general importance is probably small.

Phenytoin + Pheneturide

Phenytoin levels can be increased by about 50% by pheneturide.

Clinical evidence, mechanism, importance and management

In 9 patients, the steady-state half-life of phenytoin was prolonged from 32 hours to 47 hours by pheneturide. Mean serum levels were raised by about 50% but fell rapidly over the 2 weeks after pheneturide was withdrawn.[1] This study confirms a previous report of this interaction.[2] However, the reason for this interaction is uncertain, but as the two drugs have a similar structure it is possible that they compete for the same metabolising enzymes in the liver, thereby resulting, at least initially, in a reduction in the metabolism of the phenytoin. If concurrent use is undertaken the outcome should be well monitored. Reduce the phenytoin dose as necessary.

Phenytoin + Phenobarbital

The concurrent use of phenytoin and phenobarbital is normally advantageous and uneventful. Changes in phenytoin levels (often decreases but sometimes increases) can occur if phenobarbital is added, but seizure control is not usually affected. Phenytoin toxicity following phenobarbital withdrawal has been seen. Increased phenobarbital levels and possibly toxicity may result if phenytoin is given to patients taking phenobarbital.

Clinical evidence

A study in 10 patients with epilepsy taking phenytoin 2.8 to 6.8 mg/kg daily found that while taking phenobarbital 1.1 to 2.5 mg/kg daily their serum phenytoin levels were reduced. Five patients had a mean reduction of about 65% (from 15.7 to 5.7 micrograms/mL). In most cases phenytoin levels rose when phenobarbital was withdrawn. In one patient this was so rapid and steep that he developed ataxia and a cerebellar syndrome with phenytoin levels of up to 60 micrograms/mL, despite a reduction in the phenytoin dose.[1]

This reduction in phenytoin levels by phenobarbital has been described in other reports.[2-7] Some of these reports also described a very transient and small rise[4] or no alteration[4,5] in serum phenytoin levels in individual patients. Three other studies have found that phenobarbital does not alter phenytoin levels.[8-10]

Elevated serum phenobarbital levels occurred in children with epilepsy when they were also given phenytoin. In 5 patients the phenobarbital levels were approximately doubled. In some cases mild ataxia was seen but the relatively high barbiturate levels were well tolerated.[1] A long-term study in 6 adults with epilepsy found that when phenytoin was added to phenobarbital, the level-to-dose ratio of phenobarbital gradually rose by about 60% over one year, and then gradually fell again over the next 2 years.[11] This suggests that initially, phenytoin reduces phenobarbital metabolism.

In a patient taking phenobarbital 100 mg and phenytoin 160 mg daily, the serum levels of phenobarbital increased by about 53% within about 2 days when the dose of phenytoin was increased to 490 mg daily.[12]

Mechanism

Phenobarbital can have a dual effect on phenytoin metabolism: it may cause enzyme induction, which results in a more rapid clearance of the phenytoin from the body, or with large doses it may inhibit metabolism by competing for enzyme systems. The total effect will depend on the balance between the two drugs. The reason for the elevation of serum phenobarbital levels is not fully understood, but the extent of the effect may be dependent on the serum level of phenytoin.[12,13]

Importance and management

Concurrent use can be therapeutically valuable. Changes in dose or the addition or withdrawal of either drug needs to be monitored to ensure that toxicity does not occur, or that seizure control is not worsened. The contradictory reports cited here do not provide a clear picture of what is likely to happen. Consider also 'Primidone + Phenytoin', p.649.

Phenytoin + Phenothiazines

Phenytoin levels can be raised or lowered by the use of chlorpromazine, prochlorperazine or thioridazine. Phenytoin may reduce levels of the active metabolite of thioridazine.

Clinical evidence

(a) Chlorpromazine

The serum phenytoin levels of a patient taking phenytoin, primidone and sultiame doubled after chlorpromazine 50 mg daily was taken for a month.[1] However, another 4 patients taking chlorpromazine 50 to 100 mg daily showed no interaction.[1] In another report, one out of 3 patients taking phenytoin and phenobarbital had a fall in their serum phenytoin levels when they were also given chlorpromazine.[2] A further very brief report states that in rare instances chlorpromazine has been noted to impair phenytoin metabolism.[3]

In a large study in patients taking phenytoin with various phenothiazines (chlorpromazine, **thioridazine** or **mesoridazine**), phenytoin levels were decreased by 44% when the phenothiazines were started, and decreased by 33% when the phenothiazine dose was increased. A number of patients experienced an increased frequency of seizures. In patients who had these phenothiazines discontinued or the dose *decreased*, the phenytoin levels increased by 55% and 71%, respectively, and toxic levels occurred in some patients.[4]

(b) Prochlorperazine

A single very brief report states that in rare instances prochlorperazine has been noted to impair phenytoin metabolism.[3]

(c) Thioridazine

One out of 6 patients taking phenytoin and phenobarbital had a marked rise in serum phenytoin levels when thioridazine was added, whereas 4 others had a fall in phenytoin levels.[2] Phenytoin toxicity has also been described in 2 patients after about 2 weeks of the concurrent use of thioridazine.[5] A retrospective study in 27 patients taking phenytoin found that when they were given thioridazine their serum phenytoin levels were increased by at least 4 micrograms/mL (4 patients), decreased by at least 4 micrograms/mL (2 patients), or were unchanged (21 patients).[6] Another retrospective study comparing 28 patients taking both phenytoin and thioridazine with patients taking either drug alone found no evidence that thioridazine increased the risk of phenytoin toxicity.[7] A further study found no changes in serum phenytoin or thioridazine levels in patients given both drugs, but the serum levels of mesoridazine (the active metabolite of thioridazine) were reduced, suggesting that higher doses of thioridazine may be necessary to achieve the same effect.[8] See also the study[4] in section (a), which found a decrease in phenytoin levels and an increase in seizure frequency when patients took phenothiazines including thioridazine.

Mechanism

Uncertain. Phenothiazines such as thioridazine are said to be inhibitors of the cytochrome P450 isoenzyme CYP2D6, and as such would not be expected to affect phenytoin metabolism, at least by this mechanism.

Importance and management

A confusing situation as the results are inconsistent. The concurrent use of phenytoin and these phenothiazines need not be avoided, but it would be prudent to watch for any signs of changes in serum phenytoin levels that would affect antiepileptic control. It is also worth remembering that phenothiazines may decrease the seizure threshold. In one study a trend towards increased seizure frequency was noted after phenothiazines were added, or doses increased.[4] Also note that phenytoin may reduce levels of some phenothiazines. Whether all phenothiazines interact similarly is uncertain.

Phenytoin + Proton pump inhibitors

Studies have found that omeprazole either does not affect phenytoin levels, or may raise phenytoin levels: the differences may be due to the different doses and subjects involved in these studies. A study with esomeprazole suggests it may cause a minor rise in phenytoin levels. Lansoprazole does not normally affect phenytoin levels, but an isolated case report of toxicity is tentatively attributed to an interaction. Pantoprazole and rabeprazole appear not to affect the pharmacokinetics of phenytoin.

Clinical evidence

(a) Esomeprazole

The manufacturer of esomeprazole reports that, in patients with epilepsy, esomeprazole 40 mg increases the trough plasma levels of phenytoin by 13%.[1]

(b) Lansoprazole

In a group of 12 healthy subjects lansoprazole 60 mg daily for 7 days caused only a very small and clinically irrelevant rise (less than 3%) in the AUC of a single intravenous dose of phenytoin.[2,3] In contrast the manufacturer has received an isolated report of the development of blurred vision, diarrhoea, muscle pain, dizziness, abdominal pain, salivary hypersecretion, increased sweating and incoordination in a man taking phenytoin, which occurred within a day of stopping sustained-release propranolol 80 mg and starting lansoprazole.[4] The phenytoin serum levels were not measured but the symptoms might possibly have been due to phenytoin toxicity, although it should be said that if an interaction with lansoprazole was responsible, it developed unusually quickly.

(c) Omeprazole

In 8 patients with epilepsy, omeprazole 20 mg daily for 3 weeks caused no changes in the mean steady-state serum phenytoin levels.[5] Four patients had unchanged levels, 2 had falls and 2 had rises, but none of them was adversely affected by the use of omeprazole.[5]

In 10 healthy subjects, omeprazole 40 mg daily for 7 days increased the AUC of a single 300-mg dose of phenytoin by 25%.[6] In another study the clearance of a 250-mg intravenous dose of phenytoin was reduced by 15% by omeprazole 40 mg given for 7 days.[7] A further study found that 3 doses of omeprazole 40 mg had no effect on the pharmacokinetics of a single dose of phenytoin.[8]

(d) Pantoprazole

A randomised, crossover study in 23 healthy subjects found that pantoprazole 40 mg daily for 7 days did not alter the pharmacokinetics (AUC, maximum serum levels, half-life) of a single 300-mg dose of phenytoin.[9] This study has also been published elsewhere.[10]

(e) Rabeprazole

A preliminary report, which gives no details, states that when rabeprazole was used with phenytoin, no significant changes in the pharmacokinetics of phenytoin were seen.[11]

Mechanism

Not understood. A possible explanation is that if the dose of omeprazole is high enough, it may possibly reduce the metabolism of phenytoin by CYP2C19. Esomeprazole may have similar effects. However, CYP2C19 has only a minor role in phenytoin metabolism,[12] and so the effects are usually small. With lansoprazole, the overall picture is that it does not act as an enzyme inducer or inhibitor[13] (or it is only very weak) so that it would not be expected to interact with phenytoin to a clinically relevant extent (confirmed by the study cited above[2]). The same appears to be true for pantoprazole and rabeprazole.

Importance and management

Information is very limited but it seems that omeprazole 20 mg daily does not affect serum phenytoin levels, whereas 40 mg daily may possibly cause a slight increase, although this is probably of no clinical relevance in most patients. However, multiple dose studies are ideally needed to confirm this. No special precautions would normally seem necessary if lansoprazole or omeprazole is given with phenytoin.

The manufacturers of esomeprazole suggest that the concurrent use of phenytoin should be monitored,[1] although the elevation in levels seen in the study would almost certainly not be clinically significant. No special precautions would seem to be necessary if rabeprazole or pantoprazole and phenytoin are given concurrently.

Phenytoin + *Shankhapushpi* (*SRC*)

A case report, and an *animal* study, indicate that an antiepileptic Ayurvedic herbal preparation, *Shankhapushpi* (*SRC*), can markedly reduce phenytoin levels, leading to an increased seizure frequency.

Clinical evidence

An man with epilepsy taking **phenobarbital** 120 mg daily and **phenytoin** 500 mg daily developed an increase in seizure frequency when *Shankhapushpi* (*SRC*) three times daily was given. His plasma **phenytoin** levels were found to have fallen from 18.2 micrograms/mL to 9.3 micrograms/mL, whereas his **phenobarbital** levels were little changed. When the *SRC* was stopped the **phenytoin** plasma levels rose to 30.3 micrograms/mL, and toxicity was seen. A reduction in the dose of **phenytoin** to 400 mg daily resulted in levels of 16.2 micrograms/mL. Another possible case of this interaction has also been reported.[1,2]

Subsequent studies in *rats* found that *SRC* reduces the plasma levels of **phenytoin** by about half.[3] These pharmacokinetic effects were only seen after multiple doses, not single doses of **phenytoin**. A pharmacodynamic interaction, resulting in reduced antiepileptic activity was also noted.[1,3,4]

Mechanism

Not understood. There is evidence from *animal* studies that *SRC* may affect the pharmacokinetics of the phenytoin and possibly its pharmacodynamics as well,[1,3] thereby reducing its antiepileptic activity. It is also suggested that one of the ingredients of *SRC* may have some antiepileptic activity.[3]

Importance and management

Information about this interaction appears to be limited to these reports. *Shankhapushpi* (*SRC*) is given because it has some antiepileptic activity (demonstrated in *animal* studies[3,4]), but there is little point in combining it with phenytoin if the outcome is a fall in plasma phenytoin levels, accompanied by an increase in seizure frequency. For this reason concurrent use should be avoided. *SRC* is a syrup prepared from *Convolvulus pluricaulis* leaves, *Nardostachys jatamansi* rhizomes, *Onosma bracteatum* leaves and flowers and the whole plant of *Centella asiatica*, *Nepeta hindostana* and *Nepeta elliptica*.[3] The first two of these plants appear to contain compounds with antiepileptic activity.[5]

It has been suggested that adulteration of traditional medicines with various antiepileptics[6,7] may be an unexpected factor in these interactions.

Phenytoin + SSRIs

Phenytoin levels can be increased in some patients by fluoxetine and toxicity may occur. There are also isolated reports of phenytoin toxicity in patients taking fluvoxamine. Phenytoin and sertraline do not normally interact, but rarely patients have developed increased phenytoin levels.
Sertraline and possibly paroxetine levels may be reduced by phenytoin.

Clinical evidence

(a) Fluoxetine

A woman taking phenytoin 370 mg, diazepam 4 mg, and clonazepam 6 mg daily was given fluoxetine 20 mg for depression. Five days later her serum phenytoin levels had risen from 18 micrograms/mL to 26.5 micrograms/mL, and a further 9 days later to 30 micrograms/mL, accompanied by signs of toxicity (tremor, headache, abnormal thinking, increased partial seizure activity). Seven days after stopping the phenytoin the serum levels had fallen to 22 micrograms/mL.[1]

Two other patients, taking phenytoin 300 and 400 mg daily, respectively, had marked rises in serum phenytoin levels (from 15 to 35 micrograms/mL and from 11.5 to 47 micrograms/mL), accompanied by signs of phenytoin toxicity, within 5 to 10 days of starting fluoxetine 20 or 40 mg daily. The problem resolved when the fluoxetine was stopped or the phenytoin dose reduced.[2] Another patient only developed this interaction after taking fluoxetine for about 9 months.[3] Another case describes raised phenytoin levels with improved efficacy when fluoxetine was started, and reduced levels and possible loss of efficacy when fluoxetine was stopped.[4]

A review initiated by the FDA in the US and the manufacturers of fluoxetine briefly describes another 23 anecdotal observations of suspected interactions between phenytoin and fluoxetine (most of them incompletely documented). These suggest that a 50% increase in serum phenytoin levels, with accompanying toxicity, can occur within 1 to 42 days (mean onset time of 2 weeks) after starting fluoxetine.[5] Conversely, a retrospective review of 7 patients taking phenytoin and fluoxetine found no cases of an interaction.[6]

(b) Fluvoxamine

About one month after starting to take fluvoxamine 50 mg daily, a woman taking phenytoin 300 mg daily experienced ataxia and was found to have a threefold increase in her phenytoin levels (from 16.6 to 49.1 micrograms/mL). Fluvoxamine was subsequently discontinued, and the phenytoin dose reduced, with gradual recovery.[7] Another report describes phenytoin toxicity (serum levels of 48 micrograms/mL) in an 86-year-old woman after she took fluvoxamine 100 to 200 mg daily for 10 days.[8] However the fluvoxamine was started only 2 days after phenytoin 200 mg twice daily had been started, and the serum phenytoin levels were not checked until the toxicity had actually developed. Both drugs were then stopped and the phenytoin later successfully reinstated without the fluvoxamine. A worldwide analysis of data up to 1995 by the manufacturers of fluvoxamine identified only 2 reported cases of interactions (clinical symptoms only) between phenytoin and fluvoxamine.[9]

(c) Paroxetine

In a group of patients with epilepsy, paroxetine 30 mg daily for 16 days caused no changes in the plasma levels or therapeutic effects of phenytoin. Steady-state paroxetine plasma levels were lower in those also taking phenytoin (16 nanograms/mL) than in those taking valproate (73 nanograms/mL).[10]

The US manufacturer of paroxetine notes that phenytoin 300 mg daily for 14 days decreased the AUC and half-life of a single 30-mg dose of paroxetine by 50% and 35%, respectively. In another study, paroxetine 30 mg daily for 14 days had minimal effects on a single 300-mg dose of phenytoin (AUC reduced by 12%).[11]

(d) Sertraline

A randomised, placebo-controlled study in 30 healthy subjects taking phenytoin 100 mg three times daily, found that sertraline 50 to 200 mg daily did not affect the steady-state trough serum levels of phenytoin, nor was there any evidence that concurrent use impaired cognitive function.[12] However, another report describes 2 elderly patients whose serum phenytoin levels rose when they were given sertraline, but there was no evidence of toxicity. One of them had an almost fourfold rise in serum phenytoin levels whereas the other had a rise of only about one-third.[13]

In an analysis of plasma sertraline levels the concentration to daily dose ratio of sertraline was significantly lower in patients who had taken sertraline with phenytoin compared with those who had taken sertraline without phenytoin,[14] which suggested that phenytoin increases sertraline metabolism

Mechanism

An *in vitro* investigation found that fluoxetine and fluvoxamine inhibited the metabolism of phenytoin by the cytochrome P450 isoenzyme CYP2C9 in human liver tissue.[15] This would presumably lead to a rise in serum phenytoin levels. In this study, sertraline was a weaker inhibitor of CYP2C9, and was considered less likely to interact with phenytoin.[15] A similar study also suggested that the risk of interaction was greatest for fluoxetine, and less likely with sertraline and paroxetine.[16] Sertraline plasma levels may be reduced because of enzyme induction by phenytoin which would increase its metabolism and clearance from the body.[14]

Importance and management

The interaction between phenytoin and fluoxetine appears to be established but its incidence is not known. Because of the unpredictable nature of this interaction, if fluoxetine is added to treatment with phenytoin in any patient, be alert for the need to reduce the phenytoin dose. Ideally the phenytoin serum levels should be monitored. Similarly, to be on the safe side phenytoin levels should be monitored when fluvoxamine is first added to treatment with phenytoin so that any patient affected can be quickly identified. Although an interaction with sertraline appears less likely, be alert for any evidence of an increase in phenytoin adverse effects (e.g. blurred vision, nystagmus, ataxia or drowsiness) if sertraline is given. The clinical relevance of the reduction in paroxetine levels caused by phenytoin is unknown, but it would seem prudent to be alert for a reduction in the effects of paroxetine, and increase its dose as necessary. More study of these interactions is needed.

Note that SSRIs should be avoided in patients with unstable epilepsy, and the use of SSRIs in those with controlled epilepsy should be carefully monitored, because of the potential increased seizure risk.

Phenytoin + Sucralfate

The absorption of single-dose phenytoin can be modestly reduced by sucralfate, but this effect was not seen in a multiple-dose study.

Clinical evidence

In 8 healthy subjects, sucralfate 1 g was found to reduce the absorption (measured over a 24-hour period) of a single 300-mg dose of phenytoin by 20%.[1] Peak serum phenytoin levels were also reduced, but this was not statistically significant. Another single-dose study found a mean reduction in phenytoin absorption of up to 9.5%.[2] In a study in 6 healthy subjects, sucralfate 1 g four times daily for 7 days had no effect on the steady-state levels of phenytoin 5 to 7 mg/kg daily. The fourth daily dose of sucralfate was taken simultaneously with the daily phenytoin dose at bedtime. After 7 days, all phenytoin levels were within 15% of the baseline values (range, 6% decrease to 15% increase).[3]

Mechanism

Uncertain. Reduced bioavailability has been demonstrated in a single-dose study in *dogs* when the drugs were given simultaneously, and this did not occur if the phenytoin was given 2 hours after the sucralfate.[4]

Importance and management

Information about an interaction between sucralfate and phenytoin is limited. The reduction in phenytoin absorption found in single-dose studies was quite small, and was not seen in a multiple-dose study, suggesting it is unlikely to be clinically relevant.

Phenytoin + Sulfinpyrazone

Phenytoin levels may be markedly increased by sulfinpyrazone.

Clinical evidence

A review of the drug interactions of sulfinpyrazone identified two studies that found interactions with phenytoin.[1] In the first, the serum phenytoin levels of 2 out of 5 patients taking phenytoin 250 to 350 mg daily were doubled (from about 10 micrograms/mL to 20 micrograms/mL) within 11 days of starting to take sulfinpyrazone 800 mg daily. One of the remaining patients had a small increase in phenytoin levels, but the other two had no changes at all. When the sulfinpyrazone was withdrawn, the serum phenytoin concentrations fell to their former levels. The second study was a clinical study in patients with epilepsy, which found that sulfinpyrazone 800 mg daily for a week increased the phenytoin half-life from 10 hours to 16.5 hours and reduced the metabolic clearance by 46% (from 59 mL/minute to 32 mL/minute).

Mechanism

Uncertain. It seems probable that sulfinpyrazone inhibits the metabolism of phenytoin by the liver, thereby allowing it to accumulate in the body and leading to a rise in its serum levels. Displacement of phenytoin from its plasma protein binding sites may also have a small part to play.

Importance and management

Information seems to be limited to these studies. A similar interaction with phenytoin has been reported with phenylbutazone, which has a very close chemical relationship with sulfinpyrazone. Thus, what is known suggests that concurrent use should be monitored and suitable phenytoin dose reductions made if necessary.

Phenytoin + Sulfonamides and/or Trimethoprim

Phenytoin levels can be raised by co-trimoxazole, sulfamethizole, sulfamethoxazole, sulfadiazine and trimethoprim. Phenytoin toxicity may develop in some cases. A single case of liver failure has been described in a patient taking phenytoin with co-trimoxazole. Sulfamethoxypyridazine and sulfadimethoxine are reported not to interact with phenytoin.

Clinical evidence

(a) Co-trimoxazole or Trimethoprim

A patient taking phenytoin 400 mg daily developed signs of toxicity (ataxia, nystagmus, loss of balance) within 2 weeks of starting to take co-trimoxazole 960 mg twice daily. His serum levels were found to have risen to about 38 micrograms/mL (reference range 10 to 20 micrograms/mL).[1]

A child who was stable taking phenytoin and sultiame developed phenytoin toxicity within 48 hours of starting co-trimoxazole. Toxicity resolved when the antibacterial was changed to amoxicillin.[2] A clinical study found that co-trimoxazole and trimethoprim can increase the phenytoin half-life by 39% and 51%, respectively, and decrease the mean metabolic clearance of phenytoin by 27% and 30%, respectively.[3] Sulfamethoxazole alone had only a small effect on the half-life of phenytoin, and did not affect its clearance.[3] A case report describes fatal acute hepatic failure in a 60-year-old woman 10 days after she started taking co-trimoxazole and 14 days after she started taking phenytoin.[4] This patient was also given cimetidine, which may raise phenytoin levels (see 'Phenytoin + H_2-receptor antagonists', p.637).

(b) Sulfadiazine

In a study in 8 patients, sulfadiazine 4 g daily for a week increased the half-life of a single intravenous dose of phenytoin by 80%. The mean metabolic clearance of phenytoin decreased by 45%.[3]

(c) Sulfamethizole

The development of phenytoin toxicity in a patient taking sulfamethizole prompted a study of this interaction in 8 patients. After the concurrent use of phenytoin and sulfamethizole 1 g four times daily for 7 days the phenytoin half-life had increased from 11.8 hours to 19.6 hours. Of the 4 patients receiving long-term treatment with phenytoin, 3 had rises in serum phenytoin levels from 22 micrograms/mL to 33 micrograms/mL, from 19 micrograms/mL to 23 micrograms/mL and from 4 micrograms/mL to 7 micrograms/mL, respectively. The phenytoin levels of the fourth patient were not affected.[5,6] Another single-dose study found that the half-life of phenytoin was increased and its mean metabolic clearance reduced by 36% by sulfamethizole.[3]

(d) Other sulfonamides

Pretreatment for one week with **sulfamethoxypyridazine** or **sulfadimethoxine** did not significantly alter the pharmacokinetics of a single dose of phenytoin.[3]

Mechanism

The sulfonamides that interact appear to do so by inhibiting the metabolism of the phenytoin by the liver (possibly by the cytochrome P450 isoenzyme CYP2C9)[7], resulting in its accumulation in the body. This would also seem to be true for trimethoprim. Depletion of glucuronic acid by phenytoin may have increased the hepatotoxicity of co-trimoxazole.[4]

Importance and management

The documentation seems to be limited to the reports cited, but the interaction is established. Co-trimoxazole, sulfamethizole, sulfadiazine and trimethoprim can increase serum phenytoin levels. The interaction probably occurs in most patients, but the small number of adverse reaction reports suggests that the risk of toxicity is small. It is clearly most likely in those with serum phenytoin levels at the top end of the range. If concurrent use is thought appropriate, serum phenytoin levels should be closely monitored and the phenytoin dose reduced if necessary. Alternatively, if appropriate, use a non-interacting antibacterial (in some circumstances 'penicillins', (p.640), or 'macrolides', (p.639), may be appropriate). There seems to be little information about other sulfonamides. Limited data suggests that sulfamethoxypyridazine or sulfadimethoxine may not interact, but until more is known it may be prudent to be alert for this interaction with any of them.

Phenytoin + Sultiame

Serum phenytoin levels can be approximately doubled by sultiame and phenytoin toxicity may occur.

Clinical evidence

The serum phenytoin levels in 6 out of 7 patients with epilepsy approximately doubled within about 5 to 25 days of starting to take sultiame 400 mg daily. All experienced an increase in adverse effects and definite phenytoin toxicity occurred in 2 patients. In most of the patients, phenytoin serum levels fell back to baseline over the 2 months following the withdrawal of sultiame.[1] All of the patients were also taking **phenobarbital** and although greater variations in serum **phenobarbital** levels were seen, they were not considered to be clinically significant.[1]

A number of other reports confirm this interaction,[2-8] some of which describe the development of phenytoin toxicity.

Mechanism

The evidence suggests that sultiame interferes with the metabolism of the phenytoin by the liver, leading to its accumulation in the body.

Importance and management

A reasonably well-documented, established and clinically important interaction. The incidence seems to be high. If sultiame is added to established treatment with phenytoin, increases in serum phenytoin levels of up to 75% or more may be expected.[3,7] Phenytoin serum levels should be closely monitored and appropriate dose reductions made to prevent the development of toxicity. The changes in phenobarbital levels appear to be unimportant.

Phenytoin + Tamoxifen

Some preliminary evidence suggests that high-dose tamoxifen can cause increase phenytoin levels, causing toxicity. Phenytoin may lower tamoxifen levels.

Clinical evidence, mechanism, importance and management

A man who had undergone an operation 10 years previously for a brain tumour and had since remained seizure-free while taking phenytoin 200 mg twice daily began to have breakthrough seizures. It was established that his brain tumour had recurred and so tamoxifen was started as experimental treatment. The dose of tamoxifen was slowly titrated to 200 mg daily over a 6-week period. He continued to receive phenytoin and was also given **carbamazepine** as his seizures were not controlled, but when the maximum dose of tamoxifen (200 mg daily) was reached he began to develop symptoms of phenytoin toxicity with a serum level of 28 micrograms/mL. The toxicity disappeared and the phenytoin levels decreased when the phenytoin dose was reduced. The **carbamazepine** serum levels remained unchanged throughout.[1] The authors of this report say that other patients similarly treated with tamoxifen also developed phenytoin toxicity, which disappeared when the phenytoin dose was reduced by 15 to 20%.

Another study of the pharmacokinetics of high-dose tamoxifen in patients with brain tumours found that the mean tamoxifen levels in 15 patients taking phenytoin were about 60% lower than in patients not taking phenytoin, although this did not reach statistical significance due to high inter-patient variability.[2]

The reasons for these possible interactions are not known, but it could be that tamoxifen and phenytoin both compete for the same metabolising enzymes.

The evidence for this interaction is very slim indeed and it may possibly only occur with high-dose tamoxifen. Consider monitoring phenytoin levels if high-dose tamoxifen is added and monitor the efficacy of the tamoxifen. More study is needed to establish an interaction.

Phenytoin + Terfenadine

In 12 patients with epilepsy, a one-day and a 2-week course of terfenadine 60 mg twice daily had no effect on the pharmacokinetics of phenytoin.[1] No phenytoin dose adjustments seem likely to be needed if both drugs are used.

1. Coniglio AA, Garnett WR, Pellock JH, Tsidonis O, Hepler CD, Serafin R, Small RE, Driscoll SM, Karnes HT. Effect of acute and chronic terfenadine on free and total serum phenytoin concentrations in epileptic patients. *Epilepsia* (1989) 30, 611–16.

Phenytoin + Ticlopidine

Ticlopidine reduces the metabolism of phenytoin. A number of case reports describe patients who developed phenytoin toxicity when ticlopidine was also taken.

Clinical evidence

A 65-year-old man taking phenytoin 200 mg daily and clobazam developed signs of phenytoin toxicity (vertigo, ataxia, somnolence) within a week of starting ticlopidine 250 mg daily. His serum phenytoin levels had risen from 18 mg/L to 34 mg/L. When the phenytoin dose was reduced to 200 mg daily the toxic symptoms disappeared within a few days and his serum phenytoin levels fell to 18 mg/L. To test whether an interaction had occurred, ticlopidine was stopped, whereupon the serum phenytoin levels fell, within about 3 weeks, to 8 mg/L, during which time the patient experienced his first seizure in 2 years. When ticlopidine was restarted, his serum phenytoin levels rose again, and within a month had reached 19 mg/L.[1] A number of other case reports describe phenytoin toxicity, which occurred within 2 to 6 weeks of starting ticlopidine 250 mg once or twice daily.[2-7] These were usually managed by reducing the phenytoin

dose. One patient then experienced breakthrough seizures after the ticlopidine was stopped without re-adjusting the phenytoin dose.[6] One case in a patient also taking **phenobarbital** reported that no change in **phenobarbital** levels occurred.[4]

A study in 6 patients taking phenytoin found that ticlopidine 250 mg twice daily approximately halved the steady-state phenytoin clearance.[8]

Mechanism

The metabolism of phenytoin to 5-(4-hydroxyphenyl)-5-phenylhydantoin (HPPH) by the cytochrome P450 isoenzyme CYP2C19, and to a lesser extent by CYP2C9, in the liver is inhibited by ticlopidine.[1,3,4,9] Further metabolism of HPPH to dihydroxylated products is mediated mainly by CYP2C19 and this may also be inhibited by ticlopidine.[9]

Importance and management

The interaction is established and clinically important, but its incidence is unknown. It would seem prudent to monitor for phenytoin adverse effects (blurred vision, nystagmus, ataxia or drowsiness) and consider monitoring phenytoin levels in any patient if ticlopidine is added to established treatment, being alert for the need to reduce the phenytoin dose. If ticlopidine is discontinued, the phenytoin dose may need to be increased.

Phenytoin + Tizanidine

An isolated report describes a modest increase in serum phenytoin levels in a patient also taking tizanidine.

Clinical evidence, mechanism, importance and management

An isolated report describes a 59-year-old man whose phenytoin levels rose by one-third, from about 19 micrograms/mL to 25.5 micrograms/mL, and who experienced drowsiness within a week of starting to take tizanidine 6 mg daily. The phenytoin was stopped for 3 days and restarted at a reduced dose, but the drowsiness recurred in 3 weeks (phenytoin level 20.5 micrograms/mL). Therefore, the tizanidine was withdrawn.[1] The general importance of this interaction is unclear, but it would seem prudent to remain aware of this interaction in case of otherwise unexplained phenytoin adverse effects.

1. Ueno K, Miyai K, Mitsuzane K. Phenytoin-tizanidine interaction. *DICP Ann Pharmacother* (1991) 25, 1273.

Phenytoin + Trazodone

An isolated case report describes phenytoin toxicity in a patient given trazodone.

Clinical evidence, mechanism, importance and management

A patient taking phenytoin 300 mg daily developed progressive signs of phenytoin toxicity after taking trazodone 500 mg daily for 4 months. His serum phenytoin levels had risen from 17.8 micrograms/mL to 46 micrograms/mL.[1] Therapeutic phenytoin serum levels were restored by reducing the phenytoin dose to 200 mg daily and the trazodone dose to 400 mg daily. The reasons for this apparent interaction are not understood, and this appears to be the only reported case of an interaction. No general conclusions can be drawn.

1. Dorn JM. A case of phenytoin toxicity possibly precipitated by trazodone. *J Clin Psychiatry* (1986) 47, 89–90.

Phenytoin + Tricyclic antidepressants

Evidence from two patients suggests that imipramine can raise serum phenytoin levels, but nortriptyline and amitriptyline appear not to do so. Phenytoin possibly reduces serum desipramine levels.

Clinical evidence

(a) Phenytoin levels

The serum phenytoin levels of 2 patients rose over a 3-month period when they were given **imipramine** 75 mg daily. One patient had an increase in phenytoin levels from about 7.6 micrograms/mL to 15 micrograms/mL and developed mild toxicity (drowsiness and uncoordination). These signs disappeared and the phenytoin serum levels of both patients fell when **imipramine** was withdrawn. One of them was also taking nitrazepam and clonazepam, and the other was also taking sodium valproate and carbamazepine, but both patients were stable on these combinations before the addition of **imipramine**.[1]

Other studies have found that **nortriptyline** 75 mg daily had an insignificant effect on the serum phenytoin levels of 5 patients,[2] and that **amitriptyline** had no effect on the elimination of phenytoin in 3 subjects.[3]

(b) Tricyclic antidepressant levels

A report describes 2 patients who had low serum **desipramine** levels, despite taking standard doses, while they were also taking phenytoin.[4]

Mechanism

One suggestion is that imipramine inhibits the metabolism of phenytoin by the liver, which results in its accumulation in the body. An *in vitro* study[5] has shown that the tricyclics can inhibit the cytochrome P450 isoenzyme CYP2C19, but this isoenzyme usually has only a minor role in phenytoin metabolism (see 'Antiepileptics', (p.592)). The reduced desipramine levels may be a result of enzyme induction by phenytoin.

Importance and management

The documentation is very limited indeed and none of these interactions is adequately established. The results of the *in vitro* study suggest that the interaction may only assume importance in those subjects that are deficient in CYP2C9, the enzyme usually responsible for phenytoin metabolism.[5] The tricyclic antidepressants as a group lower the seizure threshold, which suggests that extra care should be taken if deciding to use them in patients with epilepsy. If concurrent use is undertaken the effects should be very well monitored.

Phenytoin + Valproate

The concurrent use of phenytoin and valproate is common and usually uneventful. Initially total phenytoin levels may fall but this is offset by a rise in the levels of free (and active) phenytoin, which may very occasionally cause some toxicity. After continued use the total phenytoin levels rise, and there might be sustained increases in free phenytoin levels. There is also some very limited evidence to suggest that concurrent use possibly increases the incidence of valproate hepatotoxicity.

Clinical evidence

(a) Phenytoin levels

A number of reports clearly show that the total serum levels of phenytoin fall during the early concurrent use of valproate, while the concentrations of free phenytoin rise.[1-5] In one report it was noted that within 4 to 7 days the total serum phenytoin levels had fallen from 19.4 micrograms/mL to 14.6 micrograms/mL.[1] A study extending over a year in 8 patients taking phenytoin and valproate found that by the end of 8 weeks the total serum phenytoin levels of 6 of them had fallen by almost as much as 50%, but had returned to their original levels in all but one patient by the end of the year.[6] Similar results were found in another study.[7] However, in a further study, some patients had a sustained increase in the free fraction of phenytoin.[4] Another regression analysis showed that valproate increased the free fraction of phenytoin.[8] The occasional patient may have symptoms of phenytoin toxicity.[9] Delirium and an increased seizure frequency were seen in one patient taking valproic acid with phenytoin.[10]

(b) Valproate levels

Studies have found that valproate levels are reduced by the presence of phenytoin.[11,12] Another study reported that valproate levels were increased by 30 to 200% when phenytoin was discontinued in 12 patients taking both drugs, which allowed dose reductions in 6 patients. In these patients, there was no change in seizure control when phenytoin was stopped.[13]

(c) Hepatotoxicity

Epidemiological studies suggest that the risk of fatal hepatotoxicity is higher when valproate is given as polytherapy with enzyme inducers such as phenytoin than when it is given as monotherapy, especially in infants.[14,15] For mention of raised liver enzymes with concurrent use of valproate, phenobarbital and phenytoin, see 'Phenobarbital + Valproate', p.625.

Mechanism

The initial fall in total serum phenytoin levels appears to result from the displacement of phenytoin from its protein binding sites by valproate,[1-5,10] the extent being subject to the diurnal variation in valproate levels.[16] This allows more of the unbound drug to be exposed to metabolism by the liver and the total phenytoin levels fall. After several weeks the metabolism of phenytoin is inhibited by valproate and phenytoin levels rise.[2,4] This may result in sustained elevation of free (active) phenytoin levels.[17] Phenytoin reduces valproate levels, probably because it increases its metabolism by the liver. Because phenytoin is an enzyme inducer it may also possibly increase the formation of a minor but hepatotoxic metabolite of valproate (2-propyl-4-pentenoic acid or 4-ene-VPA).[18]

Importance and management

An extremely well-documented interaction (only a selection of the references being listed here). Concurrent use is common and usually advantageous, the adverse effects of the interactions between the drugs usually being of only minor practical importance. However, the outcome should still be monitored. A few patients may experience mild toxicity if valproate is started, but most patients taking phenytoin do not need a dose change. During the first few weeks total serum phenytoin levels may fall by 20 to 50%, but usually no increase in the dose is needed, because it is balanced by an increase in the levels of free (active) phenytoin levels. In the following period, the total phenytoin levels may rise again. This may result in a sustained rise in free phenytoin levels.

When monitoring concurrent use it is important to understand fully the implications of changes in 'total' and 'free' or 'unbound' serum phenytoin concentrations. Where monitoring of free phenytoin levels is not available, various nomograms have been designed for predicting unbound phenytoin concentrations during the use of valproate.[17,19] Bear in mind the evidence that the incidence of valproate-induced liver toxicity may be increased when it is given with phenytoin, especially in infants.

Phenytoin + Vigabatrin

Vigabatrin causes a small to moderate reduction in phenytoin levels.

Clinical evidence

In one early clinical study in 19 patients, the mean plasma phenytoin levels were about 30% lower when they were given vigabatrin 2 to 3 g daily: in 2 patients phenytoin levels fell below the therapeutic range. However, the change in phenytoin levels was not correlated with the change in seizure frequency.[1] Another clinical study found that vigabatrin reduced the mean serum phenytoin levels by 20% in 53 patients; 41 patients had a decrease in phenytoin levels and 12 had an increase. In this study, some of the patients (number not stated) with decreased phenytoin levels had an increase in seizure frequency and required a phenytoin dose increase.[2,3] In another analysis, the decrease in phenytoin levels did not occur until the fifth week of vigabatrin use.[4] Three other studies have shown roughly similar decreases in phenytoin levels when vigabatrin was added.[5-7]

Mechanism

Not understood. Studies in patients found that decreases in phenytoin levels do not appear to be due to reduced metabolism or altered plasma protein binding.[4] Similarly, it is not due to altered bioavailability, as the interaction occurred with intravenous phenytoin.[5]

Importance and management

The interaction between phenytoin and vigabatrin would appear to be established. Vigabatrin causes a modest decrease in phenytoin levels in some patients, which takes a number of weeks to become apparent. A small increase in the dose of phenytoin may possibly be needed in some patients.

Phenytoin + Viloxazine

Viloxazine can raise phenytoin levels, and signs of toxicity have developed in some patients. Phenytoin does not appear to affect the pharmacokinetics of viloxazine.

Clinical evidence

The serum phenytoin levels of 10 patients with epilepsy rose by 37% (from 18.8 micrograms/mL to 25.7 micrograms/mL) over the 3 weeks following the addition of viloxazine 150 to 300 mg daily. The increase ranged from 7 to 94%. Signs of toxicity (ataxia, nystagmus) developed in 4 of the patients 12 to 16 days after starting viloxazine. Their serum phenytoin levels had risen to between 32.3 and 41 micrograms/mL. When viloxazine was withdrawn the symptoms disappeared and phenytoin levels fell.[1] The pharmacokinetics of viloxazine were unaffected by phenytoin.[2]

Mechanism

Uncertain. What is known suggests that viloxazine inhibits the metabolism of phenytoin, thereby reducing its clearance and raising its serum levels.

Importance and management

Information seems to be limited to the reports cited. If concurrent use is undertaken, serum phenytoin levels should be monitored closely and suitable dose reductions made as necessary to avoid possible toxicity.

Phenytoin + Zidovudine

Although one study found that zidovudine did not alter the pharmacokinetics of phenytoin, there is other evidence suggesting that some changes possibly occur, although these may actually be due to HIV infection.

Clinical evidence, mechanism, importance and management

Although there are said to have been 13 cases of a possible interaction between zidovudine and phenytoin, the details are not described in the report.[1] No significant changes in the pharmacokinetics of phenytoin 300 mg daily were seen in 12 asymptomatic HIV-positive patients who were taking zidovudine 200 mg every 4 hours.[1] Another study found that the mean phenytoin dose was higher in HIV-positive patients, when compared with subjects with epilepsy without the virus, while the mean phenytoin levels in the HIV-positive group were lower (i.e. a higher phenytoin dose resulted in lower serum levels in HIV-positive subjects). Zidovudine did not appear to affect the levels.[2,3] The current evidence would suggest that it is HIV infection, rather than zidovudine, that affects phenytoin levels, but more study is needed to confirm this.

Phenytoin + Zileuton

The pharmacokinetics of phenytoin are not affected by zileuton.

Clinical evidence, mechanism, importance and management

A controlled study in 20 healthy subjects found that the pharmacokinetics of a single 300-mg dose of phenytoin were unaltered by zileuton 600 mg every 6 hours for 5 days.[1] An *in vitro* study found that zileuton had little effect on the isoenzymes responsible for the metabolism of phenytoin.[2] These studies suggest that zileuton is unlikely to affect phenytoin levels in clinical use.

Piracetam + Other antiepileptics

Piracetam does not appear to alter the levels of sodium valproate or primidone. No interaction has been found between piracetam and carbamazepine, clonazepam, phenobarbital, or phenytoin.

Clinical evidence, mechanism, importance and management

The addition of piracetam (2 to 4 g three times daily, increased to a maximum of 18 to 24 g daily) did not affect plasma levels of **sodium valproate** or **primidone** in patients with myoclonus. The exact number of patients taking these drugs is unclear, as the report just states that 28 patients were taking **clonazepam**, **sodium valproate**, or **primidone**, alone or in combination.[1] Another similar report, briefly noted the same findings.[2] The manufacturer of piracetam notes that no interaction has been found between piracetam and **clonazepam**, **carbamazepine**, **phenytoin**, **phenobarbital** and **sodium valproate**, although this is based on a small number of patients.[3] No dose adjustments appear to be required if piracetam is used with these antiepileptics.

Pregabalin + Miscellaneous

Carbamazepine, oxcarbazepine, and phenytoin may decrease serum levels of pregabalin. Levetiracetam does not affect the pharmacokinetics of pregabalin, and there appears to be no pharmacokinetic interaction between pregabalin and gabapentin, lamotrigine, phenobarbital, topiramate, valproate, alcohol, lorazepam, or oxycodone. However, the impairment of cognitive and gross motor function caused by oxycodone was additive with pregabalin, and pregabalin may potentiate the effects of alcohol and lorazepam.

Clinical evidence, mechanism, importance and management

(a) Alcohol or Lorazepam

The manufacturer notes that there was no clinically relevant pharmacokinetic interaction between pregabalin and lorazepam or alcohol, and that concurrent use caused no clinically important effect on respiration. However, they note that pregabalin may potentiate the effects of lorazepam and alcohol.[1]

(b) Other antiepileptics

Pregabalin 200 mg three times daily for 7 days was added to monotherapy with various antiepileptics in patients with partial epilepsy. Pregabalin did not alter the steady-state levels of **phenytoin**, **carbamazepine** (or its active metabolite, carbamazepine-10,11-epoxide), **valproate** or **lamotrigine**. In addition, the steady-state pharmacokinetics of pregabalin were not different to those seen previously in healthy subjects taking pregabalin

alone, suggesting that these antiepileptics do not alter pregabalin pharmacokinetics.[2] Similarly, population pharmacokinetic analyses of clinical studies found no important changes in the pharmacokinetics of **lamotrigine**, **phenobarbital**, **phenytoin**, **topiramate** or **valproate** when they were given with pregabalin, and the pharmacokinetics of pregabalin were unaffected by these drugs.[3] However, this sort of analysis gives only the broadest impression of whether or not a drug interacts, and another study in patients with epilepsy found that pregabalin levels were 30%, 22%, and 23% lower when it was given with the enzyme-inducing drugs **carbamazepine**, **oxcarbazepine**, and **phenytoin**, respectively. In this study **levetiracetam** had no effect on the serum concentrations of pregabalin.[4] The manufacturer also notes that there is no pharmacokinetic interaction between pregabalin and **gabapentin**.[1]

(c) Oxycodone

The manufacturer notes that there was no clinically relevant pharmacokinetic interaction between pregabalin and oxycodone, and that there was no clinically important effect on respiration. However, pregabalin appeared to cause an additive impairment in cognitive and gross motor function when given with oxycodone.[1] This suggests caution is warranted during combined use.

Primidone + Isoniazid

A single case report describes elevated primidone levels and reduced levels of its phenobarbital metabolite when primidone was given with isoniazid.

Clinical evidence, mechanism, importance and management

A patient taking primidone had raised serum primidone levels and reduced serum phenobarbital levels. This was attributed to the concurrent use of isoniazid, which inhibited the metabolism of primidone by the liver. The half-life of primidone rose from 8.7 hours to 14 hours and the steady-state primidone levels rose by 83% in the presence of isoniazid.[1] The importance of this interaction is uncertain, but prescribers should bear this interaction in mind in case of an unexpected response to primidone.

1. Sutton G, Kupferberg HJ. Isoniazid as an inhibitor of primidone metabolism. *Neurology* (1975) 25, 1179–81.

Primidone + Miscellaneous

Primidone is substantially converted to phenobarbital within the body and it is therefore expected to interact with other drugs in the same way as phenobarbital. Some drugs may increase the conversion of primidone to phenobarbital.

Clinical evidence, mechanism, importance and management

Primidone is substantially converted to phenobarbital within the body. For example, a group of patients taking long-term primidone developed serum primidone levels of 9 micrograms/mL and serum phenobarbital levels of 31 micrograms/mL.[1] Primidone would therefore be expected to interact with other drugs in the same way as phenobarbital. Some enzyme-inducing drugs might increase the conversion of primidone to phenobarbital, and this has been demonstrated for 'phenytoin', (below), and 'carbamazepine', (p.609). Some patients have been treated with a combination of phenobarbital and primidone. In this situation higher phenobarbital levels might be expected.

1. Booker HE, Hosokowa K, Burdette RD, Darcey B. A clinical study of serum primidone levels. *Epilepsia* (1970) 11, 395–402.

Primidone + Phenytoin

Primidone-derived serum phenobarbital levels are increased by phenytoin. This is normally an advantageous interaction, but phenobarbital toxicity occasionally occurs.

Clinical evidence

A study in 44 patients with epilepsy taking primidone and phenytoin found that their serum phenobarbital to primidone ratio was high (4.35) when compared with that in 15 other patients who were only taking primidone (1.05).[1] This suggests that in the presence of phenytoin, primidone-derived phenobarbital levels are higher than when primidone is given alone. Similar results are described in other studies.[2-7] A few patients may develop barbiturate toxicity.[8]

An initial marked decrease in phenytoin levels, then an increase to half the initial phenytoin level, was seen in the first few weeks after withdrawing primidone in an infant. Primidone-derived phenobarbital levels before discontinuing the primidone were very high, and were associated with marked sedation.[9]

Mechanism

Phenytoin increases the metabolic conversion of primidone to phenobarbital, while possibly reducing the subsequent metabolism (hydroxylation) of the phenobarbital. The net effect is a rise in phenobarbital levels.[10] Phenobarbital may increase or decrease phenytoin levels, see 'Phenytoin + Phenobarbital', p.640.

Importance and management

Well documented. This is normally an advantageous interaction because phenobarbital is itself an active antiepileptic. However, it should be noted that phenobarbital serum levels could sometimes reach toxic concentrations,[8] even if only a small dose of phenytoin is added. Changes in phenytoin levels may also occur (see 'Phenytoin + Phenobarbital', p.640).

Primidone + Valproate

Valproate has been reported to cause increases, decreases, and no change in primidone levels. Primidone-derived phenobarbital levels appear to be increased by valproate.

Clinical evidence

In a number of cases, patients taking primidone required a decrease in the primidone dose after valproate was added.[1-4] In 6 cases this was due to an increase in the primidone-derived phenobarbital level,[1] and in the other cases phenobarbital levels were not measured, but the dose reduction was needed to overcome the sedation that occurred when valproate was added.[2-4] Primidone levels were not measured in any of these cases.[1-4] In two other studies, primidone levels either decreased,[5] or did not change when valproate was added.[6] However, phenobarbital levels, where measured, had increased.[6]

In 7 children the serum levels of primidone 10 to 18 mg/kg daily rose two- to threefold when valproate (dose not stated) was also given. After

1 to 3 months of concurrent use the serum primidone levels fell in 3 of the patients but persisted in one. Follow-up primidone levels were not taken in the other 3 patients, and none of the patients had phenobarbital levels measured.[7]

In contrast, in a further study, neither phenobarbital levels nor primidone levels were significantly altered when valproate was given.[8]

Mechanism

It has been suggested that valproate decreases the conversion of primidone to phenobarbital, and decreases the metabolism of phenobarbital (see also 'Phenobarbital + Valproate', p.625). This would result in increased primidone and phenobarbital levels. However, increased renal clearance of primidone may also occur, resulting in no overall change to primidone levels. Depending on the balance between these various effects a variety of levels may result.[8] The results of one study suggest that the proposed inhibition of primidone metabolism caused by valproate may diminish over the first few months of concurrent use.[7]

Importance and management

There seems to be little consistency about the effect of valproate on primidone levels. However, in the majority of cases phenobarbital levels seem to be raised (see also 'Phenobarbital + Valproate', p.625). It would therefore seem prudent not to act on primidone levels without considering the corresponding phenobarbital levels. Monitor the patient for increased signs of sedation, which may be resolved by a reduction in the primidone dose.

Progabide + Other antiepileptics

Progabide may raise phenytoin levels and alter the levels of carbamazepine. Clonazepam, phenobarbital and valproate levels are minimally affected by progabide.

Clinical evidence

(a) Phenytoin

Marked increases in serum phenytoin levels have been seen in a few patients also given progabide,[1-4] while smaller changes have been described in some studies,[5,6] and negligible changes in others.[7]

In one study, 17 out of 26 patients with epilepsy needed a reduction in their phenytoin dose to keep the levels within 25% of the serum levels achieved in the absence of progabide. Over half the patients needed a dose reduction within 4 weeks of starting concurrent use. Most of those needing a dose reduction had a maximum increase in the serum level of 40% or more, which was sometimes accompanied by toxicity.[2,8] In a later report of this study, of a total of 32 patients with epilepsy taking carbamazepine with phenytoin and then given progabide, 22 needed a reduction in their phenytoin dose to maintain serum levels within 25% of those achieved in the absence of progabide. In addition, it appeared this effect on phenytoin serum levels continued for a while after progabide was withdrawn.[4]

(b) Other antiepileptics

Information about antiepileptics other than phenytoin is limited, but progabide is reported to minimally reduce,[1,9,10] minimally increase[1] or not to change[2,3,5-7] **carbamazepine** serum levels. An increase of up to 24% in the levels of carbamazepine-10-11-epoxide (the active metabolite of **carbamazepine**) has also been reported.[6,10] **Valproate**[3,5-7] and **clonazepam**[11] serum levels do not seem to be significantly affected by progabide. Progabide appears to cause a small increase in serum **phenobarbital** levels, which is of little clinical importance.[1,5-7]

Mechanism

Uncertain.

Importance and management

Some small to moderate changes in the serum levels of carbamazepine, clonazepam, phenobarbital, and valproate can apparently occur in the presence of progabide, but only the interaction with phenytoin appears to be clinically relevant. Be alert for evidence of phenytoin adverse effects (e.g. blurred vision, nystagmus, ataxia or drowsiness) and consider reducing the dose of phenytoin if progabide is used concurrently.

Remacemide + Other antiepileptics

Remacemide causes modest increases in carbamazepine and phenytoin serum levels. Carbamazepine, phenobarbital and phenytoin moderately reduce remacemide serum levels. Valproate and lamotrigine do not appear to interact with remacemide.

Clinical evidence

(a) Carbamazepine

When a group of 10 patients taking carbamazepine were also given up to 300 mg of remacemide twice daily for 2 weeks the minimum serum levels and the AUC of carbamazepine were increased by 20% and 22%, respectively. None of the patients had symptoms of carbamazepine toxicity.[1] Another study in 11 patients taking carbamazepine found that remacemide caused a similar 20 to 30% increase in the AUC of carbamazepine, again without signs of toxicity. No consistent changes in the AUC of carbamazepine-10,11-epoxide, the main metabolite of carbamazepine, were seen.[2] Another study has reported a slight inhibitory effect of remacemide on carbamazepine metabolism, which is in line with these other findings.[3] One of these studies also reported that the AUC of remacemide was decreased by 40 to 50% and the AUC of its main metabolite by about 70% in the presence of carbamazepine, when compared with healthy subjects (presumably not taking carbamazepine).[2]

However, a further study of the efficacy of remacemide and carbamazepine in combination found that about two-thirds of the 120 patients treated needed 14 to 50% reductions in their carbamazepine dose, to ensure levels remained in the therapeutic range.[4]

(b) Lamotrigine

In a study in healthy subjects there was no clinically relevant pharmacokinetic interaction between remacemide (200 mg daily increased to 200 mg

three times daily) and lamotrigine (200 mg twice daily decreased to 100 mg daily).[5]

(c) Phenobarbital

In a study in healthy subjects, phenobarbital 30 mg daily increased to 90 mg daily increased the clearance of remacemide 200 mg twice daily by 67%, and slightly increased the plasma levels of phenobarbital (by 9%).[6]

(d) Phenytoin

A group of 10 patients taking phenytoin were also given up to 300 mg remacemide twice daily for 2 weeks. On average remacemide did not affect phenytoin pharmacokinetics but 5 patients had an increase in minimum serum levels of 30% or more. None of the patients had symptoms of phenytoin toxicity.[1] In another study 10 patients with epilepsy, who had been taking phenytoin for at least 3 months, were given remacemide 300 mg twice daily for 12 days. Phenytoin maximum plasma levels were increased by 14% and the AUC was raised by 12%. Average concentrations of remacemide and its main metabolite were around only 40% and 30%, respectively, of those achieved in healthy subjects taking remacemide alone, at the same dose.[7] Another study reported a slight inhibitory effect of remacemide on phenytoin metabolism, which is in line with these other findings.[3]

(e) Valproate

A group of 10 patients taking valproate were also given remacemide up to 300 mg twice daily for 14 days. The pharmacokinetics of valproate remained unchanged.[1] Another study in 17 patients confirmed these findings,[8] and an earlier study by the same authors also noted no effect of remacemide on valproate metabolism.[3]

Mechanism

Not fully understood, but *in vitro* studies indicate that remacemide inhibits the cytochrome P450 isoenzyme CYP3A4, which in practice would be expected to result in a reduction in the metabolism of the carbamazepine resulting in an increase in its serum levels. Remacemide appears to inhibit CYP2C9 to a lesser extent, which is reflected in a smaller interaction with phenytoin. Valproate is metabolised by glucuronidation and is therefore unaffected.[1]

Carbamazepine and phenytoin, known enzyme inducers, also seem to increase the metabolism of the remacemide.[7]

Importance and management

Information is limited, but the interactions of remacemide with carbamazepine, phenobarbital and phenytoin appear to be established, but so far only the carbamazepine interaction seems to have been shown to be of clinical importance. Even so, it may be prudent to monitor the effects of concurrent use with phenytoin or phenobarbital. No interaction occurs between remacemide and valproate or lamotrigine.

Retigabine + Other antiepileptics

The clearance of retigabine is increased by carbamazepine and phenytoin, but not affected by phenobarbital, topiramate, or valproate. Retigabine does not alter the pharmacokinetics of any of these antiepileptics. There is a modest pharmacokinetic interaction between retigabine and lamotrigine.

Clinical evidence, mechanism, importance and management

(a) Enzyme-inducing antiepileptics

The preliminary report of a study in patients with epilepsy notes that the clearance of retigabine was increased (amount not stated) by **carbamazepine** and **phenytoin**, whereas retigabine did not alter **carbamazepine** or **phenytoin** pharmacokinetics.[1] This is consistent with the known enzyme-inducing properties of **carbamazepine** and **phenytoin**, and the fact that retigabine has not been shown to induce hepatic enzymes. In contrast, in a study in healthy subjects, **phenobarbital** 90 mg daily did not affect the pharmacokinetics of retigabine 200 mg every 8 hours, and the pharmacokinetics of **phenobarbital** were not altered by retigabine.[2] The clinical relevance of the effect of **carbamazepine** and **phenytoin** on retigabine remains to be assessed. No dose adjustments seem to be necessary with **phenobarbital**.

(b) Lamotrigine

In a study in 14 healthy subjects, lamotrigine 25 mg daily for 5 days increased the AUC of a single 200-mg dose of retigabine by 15% and decreased its clearance by 13%.[3] In another 15 subjects, retigabine (200 mg twice daily increased to 300 mg twice daily over 15 days) decreased the AUC of a single 200-mg dose of lamotrigine by 18% and increased its clearance by 22%. It was suggested that lamotrigine competes for renal elimination with retigabine, but the mechanism behind the decreased lamotrigine levels is unknown.[3] These modest changes are unlikely to be clinically important for most patients, but the authors suggest that the effects need to be assessed at the upper recommended dose ranges, and therefore advise caution.

(c) Topiramate

The preliminary report of a study notes that the pharmacokinetics of retigabine and topiramate were not altered by concurrent use in patients with epilepsy.[1] No special dosing precautions are necessary.

(d) Valproate

The preliminary report of a study notes that the pharmacokinetics of retigabine and valproic acid were not altered by concurrent use in patients with epilepsy.[1] No special dosing precautions are necessary.

Rufinamide + Food

Food increases the rate and extent of absorption of rufinamide.

Clinical evidence, mechanism, importance and management

In a study to investigate the effect of food on the pharmacokinetics of rufinamide, 12 healthy subjects were given a single 600-mg dose of rufinamide after an overnight fast, or with a fat- and protein-rich breakfast. The AUC of rufinamide was increased by 44% by food, when compared with the fasted state, and the maximum plasma level was increased twofold. The time to reach the maximum plasma level was shortened from 8 hours to 6 hours in the group that took rufinamide with food. Headache was reported more frequently in the fed group, but the use of analgesics was not different between the two groups.[1] The manufacturer recommends that rufinamide is taken with food,[2] to maximise absorption.

1. Cardot J-M, Lecaillon J-B, Czendlik C, Godbillon J. The influence of food on the disposition of the antiepileptic rufinamide in healthy volunteers. *Biopharm Drug Dispos* (1998) 19, 259–62.
2. Inovelon (Rufinamide). Eisai Ltd. UK Summary of product characteristics, October 2009.

Rufinamide + Miscellaneous

Rufinamide may increase the clearance of drugs that are substrates of CYP3A4, such as triazolam. Other cytochrome P450 isoenzymes are unlikely to be affected.

Clinical evidence and mechanism

(a) CYP3A4

Rufinamide has been shown to induce the cytochrome P450 isoenzyme CYP3A4 to a moderate degree. A study found that rufinamide 400 mg twice daily for 11 days increased the clearance of **triazolam**, a substrate of CYP3A4, by 55% and reduced its exposure by 36%.[1]

(b) CYP1A2

Rufinamide 400 mg twice daily did not affect the pharmacokinetics of **olanzapine**, a substrate of CYP1A2.[1]

Importance and management

Evidence about CYP3A4 substrates is limited, but is in line with the *in vitro* effects of rufinamide, and the way in which triazolam is known to be metabolised. The manufacturers recommend that any patient taking a drug that is a substrate of CYP3A4 should be monitored for 2 weeks after starting, stopping, or changing the dose of rufinamide, and dose adjustments made as appropriate. Note that the effects of CYP3A4 substrates are likely to be diminished. For a list of known substrates of this isoenzyme, see 'Table 1.4', (p.6).

The manufacturer[1] also advises that similar precautions should be taken when rufinamide is given with drugs with a narrow therapeutic margin, and specifically mentions **warfarin** and **digoxin**. However, warfarin is only metabolised to a limited extent by this isoenzyme, and moderate CYP3A4 inhibitors do not generally interact with warfarin (see 'diltiazem', (p.445), and 'erythromycin', (p.417)), although cases of bleeding may occur. The prediction with digoxin, a P-glycoprotein substrate, appears to be based on the fact that an effect of rufinamide on P-glycoprotein has not been excluded. Further study is needed.

No pharmacokinetic interaction would be expected with substrates of CYP1A2. For a list of known substrates of this isoenzyme, see 'Table 1.2', (p.4).

1. Inovelon (Rufinamide). Eisai Ltd. UK Summary of product characteristics, October 2009.

Rufinamide + Other antiepileptics

The clearance of rufinamide is increased by phenytoin, phenobarbital and primidone. Valproate may raise rufinamide levels in some patients, particularly children. No pharmacokinetic interaction appears to occur between rufinamide and carbamazepine, clobazam, lamotrigine, oxcarbazepine or topiramate. Vigabatrin does not appear to alter the pharmacokinetics of rufinamide, and rufinamide does not alter the trough levels of clonazepam.

Clinical evidence

(a) Carbamazepine or Oxcarbazepine

Preliminary evidence suggests that the pharmacokinetics of rufinamide are not affected by the concurrent use of carbamazepine or oxcarbazepine.[1] Furthermore, rufinamide does not cause a clinically relevant alteration in the trough concentrations of carbamazepine[1,2] or oxcarbazepine.[1]

(b) Clobazam or Clonazepam

Preliminary evidence suggests that the pharmacokinetics of rufinamide are not affected by the concurrent use of clobazam, and rufinamide does not alter the trough concentrations of clobazam or clonazepam.[1]

(c) Lamotrigine

The pharmacokinetics of rufinamide and lamotrigine do not appear to be affected by concurrent use.[2,3]

(d) Phenobarbital, Phenytoin, and Primidone

It has been reported that any combination of phenobarbital, phenytoin, and primidone increased the clearance of rufinamide by about 25%, but that rufinamide had no effect on the trough concentrations of these drugs.[1] However, the manufacturer suggests that the plasma levels of phenytoin may be increased by rufinamide, and that the dose of phenytoin may need to be reduced.[3]

(e) Topiramate

The pharmacokinetics of topiramate and rufinamide do not appear to be affected by concurrent use.[2,3]

(f) Valproate

Valproate has been found to reduce the clearance of rufinamide: one paper reports a modest reduction of 22%.[1] Based on predicted plasma levels, valproate was found to increase rufinamide levels by 55 to 70% in children, 23 to 26% in adolescents, and less than 16% in adults,[4] which suggests that the magnitude of the effects depends upon the age of the patient. Rufinamide has not been found to have any effect on the trough concentrations of valproate.[1]

(g) Vigabatrin

Vigabatrin is reported not to affect the pharmacokinetics of rufinamide.[1]

Mechanism, importance and management

Evidence is limited; however, the interaction between valproate and rufinamide appears to be established. In patients taking valproate, and weighing less than 30 kg, the manufacturer advises starting rufinamide at 200 mg daily, and increasing the dose by no more than 200 mg every 2 days (according to clinical response and efficacy) until a maximum dose of 600 mg daily is achieved.[3] No dose adjustment is recommended for patients weighing more than 30 kg.

It would seem prudent to monitor the plasma levels and clinical effects of rufinamide when it is started or stopped in patients taking phenobarbital, phenytoin, and primidone. Furthermore, monitor for phenytoin adverse effects (e.g. blurred vision, nystagmus, ataxia or drowsiness) and consider taking phenytoin levels if these occur. Note that fosphenytoin is a prodrug of phenytoin, and in the absence of direct evidence it would seem prudent to follow the same precautions described for phenytoin.

4. Eisai Ltd. Personal communication, July 2008.

Stiripentol + Miscellaneous

Stiripentol inhibits the metabolism of caffeine and is therefore expected to inhibit the metabolism of other similarly metabolised drugs (e.g. theophylline).
Stiripentol may inhibit the metabolism of drugs by CYP2C19 (e.g. omeprazole) and CYP3A4 (e.g. ciclosporin, simvastatin, ergot derivatives). Stiripentol has no significant effect on the pharmacokinetics of dextromethorphan and an interaction with other CYP2D6 substrates is not expected. Food may protect stiripentol from degradation by gastric acid.

Clinical evidence, mechanism, importance and management

(a) CYP1A2 substrates

In a study, 12 healthy subjects were given **caffeine** before and after stiripentol (500 mg twice daily on day one, 1 g twice daily on day 2, and 1.5 g twice daily from day 3 to day 13) found that the AUC of a metabolite of caffeine expired in the breath was almost 8-fold lower after treatment with stiripentol.[1] Caffeine can be used as a probe drug to assess the activity of the cytochrome P450 isoenzyme CYP1A2 and this study therefore suggests that stiripentol may inhibit this isoenzyme. The manufacturer of stiripentol therefore does not recommend that **theophylline** (and therefore probably **aminophylline**) or **caffeine** are taken with stiripentol. They extend this warning to foodstuffs containing **caffeine** or **chocolate**, and specifically name **cola** drinks.[2] Clinical evidence regarding an interaction appears to be lacking. If a patient taking stiripentol develops adverse effects such as headache, jitteriness, restlessness, insomnia, consider the inadvertent intake of caffeine as a possible cause. Note that, other drugs that are potent CYP1A2 inhibitors can usually be given with caffeine, if adverse effects are appropriately monitored, see 'Caffeine + SSRIs', p.1422.

(b) CYP2C19 substrates

An *in vitro* study has shown that stiripentol is an inhibitor of the cytochrome P450 isoenzyme CYP2C19.[1] The manufacturer of stiripentol predicts that there may be an increased risk of adverse effects when drugs metabolised by this enzyme are also taken, and that dose adjustment may be required. They specifically name **citalopram** and **omeprazole**, and suggest caution if these drugs are required.[2] For a full list of substrates of this enzyme see 'Table 1.3', (p.6). Note that the clinical relevance of any interaction does not appear to have been established.

(c) CYP2D6 substrates

In vitro studies have found that stiripentol is an inhibitor of the isoenzyme CYP2D6,[1,2] and the manufacturers predict that there may be an increased risk of adverse effects when drugs metabolised by this isoenzyme are also taken, and that dose adjustment may be required. They specifically name **propranolol**, **carvedilol**, **timolol**, **fluoxetine**, **paroxetine**, **sertraline**, **imipramine**, **clomipramine**, **haloperidol**, **codeine**, **dextromethorphan**, and **tramadol**.[2] However, in a study in 12 healthy subjects, stiripentol (500 mg twice daily on day one, 1 g twice daily on day 2, and 1.5 g twice daily from day 3 to 13) did not affect the metabolism of dextromethorphan.[1] Dextromethorphan is used as a probe drug to assess the activity of CYP2D6, and this study therefore suggests that stiripentol does not have a clinically relevant effect on drugs metabolised by this isoenzyme.

(d) CYP3A4 substrates

A study, 12 healthy subjects were given **dextromethorphan** before and after stiripentol (500 mg twice daily on day one, 1 g twice daily on day 2, and 1.5 g twice daily on days 3 to 13). Although dextromethorphan is usually used as a probe drug for the cytochrome P450 isoenzyme CYP2D6, its metabolism by *N*-demethylation can be used as a measure of CYP3A4 activity. This study found that stiripentol does inhibit dextromethorphan N-demethylation, and therefore suggests that stiripentol may inhibit CYP3A4.[1] The manufacturer therefore predicts that there may be an increased risk of adverse effects when drugs metabolised by this isoenzyme are also taken, and that dose adjustment may be required. They specifically name the **protease inhibitors**, **astemizole**, **chlorphenamine**, **calcium-channel blockers**, **atorvastatin**, **simvastatin**, and **oral** [**hormonal**] **contraceptives**, and suggest caution if these drugs are required.

The manufacturer also advises caution if drugs that have a narrow therapeutic index and are metabolised by CYP3A4 are given with stiripentol. They name **tacrolimus**, **ciclosporin** and **sirolimus**.

The manufacturer also suggests that ergotism may occur if **ergot derivatives** are taken with stiripentol, with the possibility of necrosis of the extremities, and recommend that ergot preparations are not taken with stiripentol unless strictly necessary.

It is suggested that there may be an increase in the plasma levels of benzodiazepines that are substrates of this enzyme (they name **alprazolam**, **midazolam** and **triazolam**), resulting in excessive sedation. Caution is recommended when these drugs are used with stiripentol.[2]

For a list of CYP3A4 substrates, see 'Table 1.4', (p.6).

(e) Food

Stiripentol is known to degrade in an acidic environment, and the manufacturer therefore advises that stiripentol is taken with food to avoid exposure to gastric acid. Additionally they advise avoiding milk or dairy products, carbonated drinks, and fruit juice at the same time as stiripentol,[2] but state that they have no evidence of any interaction with milk or dairy products, but have predicted this interaction based on the known ability of dairy products to complex with other drugs.[3]

Stiripentol + Other antiepileptics

Stiripentol causes marked rises in the levels of carbamazepine, clobazam, phenobarbital and phenytoin. Stiripentol causes only a small rise in the levels of valproate. Levetiracetam and topiramate do not appear to interact with stiripentol.

Clinical evidence

(a) Carbamazepine

The clearance of carbamazepine in one subject fell by 39% when stiripentol 1.2 g daily was taken and by 71% when stiripentol 2.4 g daily was taken.[1] Three other studies in adults and children confirmed that stiripentol reduces the clearance of carbamazepine by about 50 to 65%,[2-4] and significantly increases carbamazepine levels.[5] Another study found that the formation of carbamazepine-10,11-epoxide, the active metabolite of carbamazepine, was markedly reduced in children taking carbamazepine with stiripentol.[6]

In 11 patients no adverse effects on motor, perceptual or attention tests were seen when stiripentol was given with other antiepileptic drugs (carbamazepine, **clobazam**, **phenobarbital**, **phenytoin**, and **valproate**) but the doses of carbamazepine, **phenobarbital**, **phenytoin** were reduced before the combination was taken.[7]

(b) Clobazam

In a study, 41 children with myoclonic epilepsy were given valproate and clobazam for one month with stiripentol 50 mg/kg daily or placebo added for a further 2 months. The dose of clobazam was reduced from 0.5 to 0.38 mg/kg daily in those also given stiripentol because of adverse effects. Plasma levels of clobazam and norclobazam were significantly increased, and levels of hydroxynorclobazam significantly decreased, by stiripentol.[8,9]

For a small study suggesting a lack of adverse effects, see under *Carbamazepine*, above.

(c) Phenobarbital

Phenobarbital clearance in 2 subjects fell by about 30 to 40% when they took stiripentol 2.4 g daily.[1] For a further study, see under *Carbamazepine*, above.

(d) Phenytoin

Patients with epilepsy taking two or three antiepileptics (phenytoin, phenobarbital, carbamazepine, clobazam, primidone, nitrazepam) were also given stiripentol, increasing from 600 mg to 2.4 g daily. The 5 patients taking phenytoin had an average 37% reduction in the phenytoin clearance when they took stiripentol 1.2 g daily, and a 78% reduction when they took stiripentol 2.4 g daily. These changes in clearance were reflected in marked rises in the steady-state serum levels of phenytoin: for example the serum phenytoin levels of one patient rose from 14.4 mg/L to 27.4 mg/L over 30 days while he was taking stiripentol, despite a 50% reduction in his phenytoin dose. Phenytoin toxicity was seen in another two subjects.[1] For a further study, see under *Carbamazepine*, above.

(e) Valproate

In a study, 41 children with myoclonic epilepsy were given valproate and clobazam for one month with stiripentol 50 mg/kg daily or placebo for a further 2 months. The dose of valproate did not change from a baseline maximum of 30 mg/kg daily when given with stiripentol.[8,9]

Valproate 1 g daily was given to 8 subjects with or without stiripentol 1.2 g daily. The stiripentol caused a 14% increase in the peak serum levels of valproate.[10] For a small study suggesting a lack of adverse effects, see under *Carbamazepine*, above.

(f) Other antiepileptics

There is no evidence to suggest that a pharmacokinetic interaction will occur between **levetiracetam** or **topiramate** and stiripentol.[11]

Mechanism

Stiripentol inhibits the activity of various cytochrome P450 isoenzymes in the liver, including CYP1A2, CYP2C9, CYP2C19, CYP2D6 and CYP3A4, some of which are concerned with the metabolism of other antiepileptics. As a result the loss of the antiepileptic from the body is reduced and the serum levels rise accordingly.[3,9,12] In the case of valproate, cytochrome P450 is only involved in minor valproate metabolic pathways and therefore only a small rise in serum levels occurs.[10] However, there is evidence that stiripentol may reduce the formation of a minor but hepatotoxic metabolite of valproate (2-propyl-4-pentenoic acid or 4-ene-VPA).[13]

Importance and management

Established and clinically important interactions. The carbamazepine, clobazam, phenobarbital and phenytoin doses should be reduced to avoid the development of elevated serum levels and possible toxicity during the

concurrent use of stiripentol. One study[3] suggests that the carbamazepine dose should be decreased incrementally over 7 to 10 days, beginning as soon as the stiripentol is started and, regardless of age, the maintenance dose of carbamazepine should aim to give serum levels of 5 to 10 micrograms/mL.

Stiripentol causes only small changes in the serum levels of valproate and dose adjustments are unlikely to be needed with this combination.

No dose adjustment is needed when stiripentol is given with levetiracetam or topiramate.

Tiagabine + Cocaine

Tiagabine does not affect the cardiovascular effects of cocaine, but may attenuate some of its subjective effects.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study, 7 cocaine-users were given two oral doses of tiagabine 4 mg, ten hours apart. Two hours after the second dose they were given an injection of sodium chloride 0.9%, then two doses of cocaine (0.15 mg/kg, and then, 30 minutes later, 0.3 mg/kg). Tiagabine did not affect the cocaine-induced changes in blood pressure and heart rate, but was reported to attenuate some of the subjective effects (stimulation and craving) of cocaine.[1]

The clinical relevance of this findings is unclear, but is does suggest that concurrent use is unlikely to result in adverse cardiac effects.

1. Sofuoglu M, Poling J, Mitchell E, Kosten TR. Tiagabine affects the subjective responses to cocaine in humans. *Pharmacol Biochem Behav* (2005) 82, 569–73.

Tiagabine + Miscellaneous

The pharmacokinetics of tiagabine were not altered by cimetidine or erythromycin. No clinically relevant pharmacokinetic interactions occur between tiagabine and theophylline or warfarin.

Clinical evidence, mechanism, importance and management

In a study in 12 healthy subjects, **cimetidine** 400 mg twice daily for 5 days increased the steady-state AUC of tiagabine 4 mg twice daily by just 5%.[1,2]

In a study in 14 healthy subjects, **erythromycin** 500 mg twice daily had no clinically relevant effect on the steady-state pharmacokinetics of tiagabine 4 mg twice daily.[3]

Multiple dose studies in healthy subjects have also excluded any clinically relevant pharmacokinetic interactions between tiagabine and **theophylline** or **warfarin** but no further study details were given.[1]

Tiagabine + Other antiepileptics

Tiagabine plasma levels are reduced by enzyme-inducing antiepileptics (carbamazepine, phenytoin, phenobarbital and primidone). Tiagabine may cause a slight reduction in valproate levels, but has no effect on carbamazepine, phenytoin or vigabatrin levels.

Clinical evidence, mechanism, importance and management

In an early clinical study, tiagabine was reported to have no significant effect on the plasma levels of **carbamazepine**, **phenytoin**, **valproate**, and **vigabatrin**.[1] Similarly, in 12 patients with epilepsy, tiagabine (titrated from 8 mg up to a maximum of 48 mg daily over 18 days) did not alter the steady-state pharmacokinetics of **phenytoin** or **carbamazepine**.[2] However, in another similar study, tiagabine reduced the AUC of **valproate** by 10%, but this reduction is not expected to be clinically significant.[3]

A study in patients taking 1 to 3 other enzyme-inducing antiepileptics (**phenobarbital**, **phenytoin**, **carbamazepine**, **primidone**) found that tiagabine half-lives were shorter (3.8 to 4.9 hours) when compared with historical values in healthy subjects taking tiagabine alone (7.1 hours).[4] The manufacturers say that the plasma concentrations of tiagabine may be reduced 1.5- to 3-fold by these enzyme-inducing antiepileptics.[5] Based on this, they recommend that the initial maintenance dose of tiagabine in patients *not* taking enzyme-inducing drugs should be lower (15 to 30 mg daily) than in those taking these drugs (30 to 45 mg daily).[5]

Topiramate + Carbamazepine

Topiramate levels may be reduced by carbamazepine. Carbamazepine levels are not affected by topiramate. However, one report suggests that the toxicity seen when topiramate is added to maximum tolerated doses of carbamazepine may respond to a reduction in the carbamazepine dose.

Clinical evidence

(a) Carbamazepine levels

In a study in 12 patients with epilepsy, topiramate titrated up to a maximum of 400 mg twice daily had no effect on the steady-state plasma levels of carbamazepine 300 to 800 mg every 8 hours or on its main metabolite, carbamazepine-10,11-epoxide.[1] An earlier study in patients with epilepsy also reported that topiramate does not affect the pharmacokinetics of carbamazepine.[2] In contrast, another report describes 2 patients taking a maximum tolerated dose of carbamazepine who started treatment with topiramate and subsequently developed symptoms suggestive of carbamazepine toxicity. In both these cases, the symptoms resolved when the carbamazepine dose was reduced, and this enabled continued titration of

the topiramate dose in one patient. A review of the clinical use of these two drugs found another 23 cases that fitted this pattern. Carbamazepine levels were not reported.[3]

(b) Topiramate levels

In a study in 12 patients with epilepsy, the topiramate plasma levels and AUC were found to be about 40% lower in the presence of carbamazepine.[1] A population pharmacokinetic study reported that patients taking carbamazepine had 32% lower morning topiramate level than patients not taking enzyme-inducing antiepileptics.[4] In a study in healthy subjects, carbamazepine 600 mg daily was found to cause a twofold increase in the clearance of a single 200-mg dose of topiramate. The mean half-life of topiramate decreased from 29 hours to 19 hours. There was also a two- to threefold increase in the formation of the 2 major metabolites of topiramate (2,3-diol-topiramate and 10-hydroxy-topiramate), although 41% of topiramate was excreted unchanged in the urine in the presence of carbamazepine.[5] The same group have reported similar results in a study in patients.[6] In contrast, an earlier study reported that carbamazepine did not have a major effect on the pharmacokinetics of topiramate.[2]

Mechanism

Carbamazepine appears to induce the metabolism of topiramate. Although topiramate can weakly induce CYP3A4 this does not usually appear to have a clinically relevant effect on carbamazepine metabolism, unless carbamazepine is already at the maximum tolerated dose. The increase in topiramate clearance by carbamazepine may be partly due to the stimulation of oxidative pathways resulting in the formation of 2,3-diol-topiramate and 10-hydroxy-topiramate.[6]

Importance and management

Carbamazepine possibly results in a moderate reduction in topiramate plasma levels, but this is probably of limited clinical importance. There is some evidence that the toxicity seen when topiramate is added to maximum tolerated doses of carbamazepine may respond to a reduction in the carbamazepine dose.

Topiramate + Phenobarbital or Primidone

Topiramate appears not to alter the pharmacokinetics of phenobarbital or primidone. Phenobarbital modestly reduces topiramate levels.

Clinical evidence, mechanism, importance and management

A review of data from double-blind, placebo-controlled studies found that over periods of 8 to 12 weeks the plasma levels of phenobarbital or primidone in patients (number not stated) with partial seizures remained unchanged when they were also given topiramate.[1]

A population pharmacokinetic study reported that patients taking phenobarbital had 31% lower morning topiramate levels than patients not taking enzyme-inducing antiepileptics.[2] Another study that grouped carbamazepine, phenobarbital and phenytoin reported that patients taking one or more of these drugs had a 50% greater topiramate clearance than patients taking lamotrigine or valproate.[3]

Phenobarbital probably induces the metabolism of topiramate thereby reducing its levels. When topiramate is added to existing treatment with phenytoin or phenobarbital its dose should be titrated to effect and therefore any interaction is automatically accounted for. If phenobarbital or primidone are withdrawn or added to established treatment with topiramate, be aware that the dose of topiramate may need adjustment.

Topiramate + Phenytoin

In some patients the plasma levels of phenytoin are slightly raised by topiramate, and topiramate plasma levels may be reduced by phenytoin.

Clinical evidence

Topiramate, titrated to a maximum of 400 mg twice daily, was given to 12 patients with epilepsy taking phenytoin 260 to 600 mg daily. When the maximum tolerated dose of topiramate was reached, the phenytoin dose was then reduced, and in some cases phenytoin was subsequently discontinued. Topiramate clearance was assessed in 2 patients and was found to be increased two- to threefold by phenytoin.[1] Similarly, a population pharmacokinetic study reported that patients taking phenytoin and topiramate had 50% lower morning topiramate levels than patients not taking enzyme-inducing antiepileptics.[2]

In the first study above, 3 of the 12 patients had a decrease in phenytoin clearance and an increase of 25 to 55% in the AUC of phenytoin when taking topiramate: the other 9 had no changes.[1] This slight increase is said not to be clinically significant based on analyses from six add-on studies.[3]

Mechanism

An *in vitro* study using human liver microsomes found that topiramate does not inhibit most hepatic cytochrome P450 isoenzymes, except for CYP2C19 at high concentrations.[1] This isoenzyme plays a minor role in phenytoin metabolism, but it has been suggested this may become important at high doses of topiramate in patients who are CYP2C9 poor metabolisers,[1] (that is, those lacking this isoenzyme). Phenytoin appears to induce the metabolism of topiramate.

Importance and management

The interaction between topiramate and phenytoin appears to be established, and topiramate dose adjustments may be required if phenytoin is added or discontinued. No reduction in the phenytoin dose seems necessary in the majority of patients, but be aware that a few patients may have increased phenytoin levels, particularly at high topiramate doses. Monitor for phenytoin adverse effects (e.g. blurred vision, nystagmus, ataxia or drowsiness), take phenytoin levels if these occur, and adjust the dose of phenytoin accordingly.

Topiramate + Valproate

Encephalopathy has been reported in patients given topiramate with valproate. Two studies found no clinically relevant pharmacokinetic interaction between topiramate and valproate.

Clinical evidence, mechanism, importance and management

Five patients with severe epilepsy developed stuporous encephalopathy with marked cognitive impairment when taking topiramate with valproate. A further patient experienced this effect when taking topiramate alone.

Four of the patients had hyperammonaemia which resolved when topiramate or valproate was withdrawn. The toxicity was possibly due to a synergistic effect of valproate and topiramate on liver ornithine metabolism resulting in hyperammonaemia. It was also possible that the encephalopathy was due to topiramate toxicity in at-risk patients, such as those with pre-existing chronic encephalopathy.[1]

In a study in 12 patients with epilepsy, the pharmacokinetics of both topiramate, titrated to 400 mg twice daily, and valproate 1 to 4.5 g daily were slightly changed by concurrent use. The topiramate AUC was raised by about 18%, and the valproate AUC was reduced by about 11%, but these changes were not considered to be clinically relevant.[2] However, the proportion of various metabolites of valproate was altered by topiramate: metabolism to 4-ene-valproate (a putative hepatotoxin) and metabolism by oxidation increased, whereas conjugation decreased.[2] Similar changes have been seen with other enzyme-inducing antiepileptics (see *Mechanism* in 'Phenytoin + Valproate', p.646). Another study in patients with epilepsy found that valproate did not have any clinically significant effects on topiramate pharmacokinetics and metabolism.[3]

The pharmacokinetic studies suggest that dose adjustments are not required during concurrent use.[2] However, the report of encephalopathy with topiramate and valproate indicates that, particularly for at-risk patients such as those with pre-existing encephalopathy, careful monitoring is advisable.[1]

Valproate + Acarbose

An isolated case report describes reduced valproate levels in a patient taking acarbose.

Clinical evidence, mechanism, importance and management

A patient with epilepsy taking sodium valproate for 10 years had a 40% reduction in his normally stable valproate levels, from 67 micrograms/mL to 40.5 micrograms/mL, when acarbose was added. No other drugs were being taken. When the acarbose was stopped and then restarted, the valproate levels rose and then fell once again. The reason for this effect is not understood but the authors of the report suggest that acarbose possibly reduces the absorption of valproate.[1] This is an isolated report and its general importance is unknown, but it would seem prudent to be alert for any evidence of reduced effects if acarbose is given to a patient taking valproate.

1. Serrano JS, Jiménez CM, Serrano MI, Garrido H, Balboa B. May acarbose impair valproate bioavailability? *Methods Find Exp Clin Pharmacol* (1996) 18 (Suppl C), 98.

Valproate + Allopurinol

Allopurinol appears not to alter the levels of valproate.

Clinical evidence, mechanism, importance and management

A study investigating allopurinol in refractory epilepsy found that allopurinol (150 mg daily in those less than 20 kg, and 300 mg daily for other patients), given for 4 months, had no effect on valproate levels in 28 patients taking antiepileptics including valproate.[1] In another similar study, allopurinol 10 mg/kg increased to 15 mg/kg daily for 12 weeks had no effect on serum valproate levels in 6 patients taking antiepileptics including valproate.[2] Therefore valproate dose alterations are unlikely to be required if allopurinol is used.

2. Coppola G, Pascotto A. Double-blind, placebo-controlled, cross-over trial of allopurinol as add-on therapy in childhood refractory epilepsy. *Brain Dev* (1996) 18, 50–2.

Valproate + Antacids

The absorption of valproate was slightly, but not significantly, increased by an aluminium/magnesium hydroxide suspension, but was not affected by magnesium trisilicate or a calcium carbonate suspension.

Clinical evidence, mechanism, importance and management

In 7 healthy subjects the AUC of a single 500-mg dose of valproic acid, given one hour after breakfast, was increased by 12% (range 3 to 28%) by 62 mL of an **aluminium/magnesium hydroxide** suspension (*Maalox*) given with and 2 hours after valproate. Neither **magnesium trisilicate** suspension (*Trisogel*) nor **calcium carbonate** suspension (*Titralac*) had a significant effect on valproate absorption.[1] No special precautions would seem necessary during concurrent use.

1. May CA, Garnett WR, Small RE, Pellock JM. Effects of three antacids on the bioavailability of valproic acid. *Clin Pharm* (1982) 1, 244–7.

Valproate + Aspirin or NSAIDs

Valproate toxicity developed in several young patients given large and repeated doses of aspirin and in an elderly patient taking low-dose aspirin. Increased levels of free valproate were found in a number of children within hours of them taking aspirin. Conversely, a slightly reduced valproate level was reported in one patient who took ibuprofen. Modestly altered protein binding has been shown when sodium valproate was given with diflunisal or naproxen.

Clinical evidence, mechanism, importance and management

(a) Aspirin

A 17-year-old girl taking valproate 21 mg/kg daily was prescribed aspirin 18 mg/kg daily for lupus arthritis. Within a few days she developed a disabling tremor which disappeared when the aspirin was stopped. Total serum valproate levels were not significantly changed, but the free fraction fell from 24% to 14% when the aspirin was withdrawn. Similar toxic reactions (tremor, nystagmus, drowsiness, ataxia) were seen in 2 children, aged 6 and 4 years, given 12 and 20 mg/kg aspirin every 4 hours while taking valproate.[1] In 5 children with epilepsy taking valproate, free valproate levels increased by 31 to 66% (average 49%) 17 hours after starting aspirin 11.5 to 16.9 mg/kg four times daily.[2]

A 76-year-old man given valproate semisodium 750 mg daily had a total valproate blood level of 13.5 nanograms/mL, which rose to 19.3 nanograms/mL after aspirin 325 mg daily was added. The valproate semisodium dose was increased over a period of 2 months in an attempt to increase levels to the reference range. Two weeks after the dose of valproate semisodium was increased to 2.5 g daily he experienced dizziness and incoordination with difficulty standing and transferring from a bed to a wheelchair and he experienced a fall. It was found that his trough total valproate level was 64 nanograms/mL (reference range 50 to 70 nanograms/mL), but his trough free valproate level was 24.7 nanograms/mL (reference range 4.8 to 17.3 nanograms/mL). Aspirin was discontinued and 5 days later total and free trough valproate levels were 36 nanograms/mL and 3.9 nanograms/mL, respectively. Dizziness and incoordination resolved when the dose of valproate semisodium was reduced to 1.25 g daily..[3]

One case report of fatal hyperammonaemia was speculated to have been induced by valproate, and the authors also considered that concurrent use of aspirin and 'cimetidine', (p.659), may have contributed.[4]

Aspirin displaces valproate from its protein binding sites[2,3,5] and also alters its metabolism by the liver[6] so that the levels of free (and pharmacologically active) valproate rise. This could temporarily increase both the therapeutic and toxic effects of the valproate. However, there is evidence that increased hepatic elimination of valproate counterbalances this effect.

Direct information seems to be limited to the studies and case reports cited. Clinically relevant interactions appear rare, probably because in most cases the effects of aspirin on free valproate levels cancel each other out.

The combination need not necessarily be avoided, but it would seem prudent to be aware of this interaction if valproate and high-dose aspirin are used.

(b) Diflunisal

In 7 healthy subjects, diflunisal 250 mg twice daily for 7 days given with sodium valproate 200 mg twice daily caused a 20% increase in the unbound fraction of valproate. There was a 35% increase in the AUC of one of the oxidation metabolites of valproate, and a small decrease in the AUC of some of the diflunisal glucuronide metabolites. This was due to changes in the renal clearance of these metabolites.[7] Whether any of these modest changes have any clinical relevance remains to be seen, but it appears unlikely.

(c) Ibuprofen

A 15-year-old boy was found to have a subtherapeutic valproate level (43 micrograms/mL) 3 days after starting to take ibuprofen 600 mg every 6 hours for post-fracture analgesia. The ibuprofen was stopped, and after one week the valproate levels were within the therapeutic range (60 micrograms/mL).[8] The general importance of this isolated case is unknown. More study is needed.

(d) Naproxen

A study in 6 healthy subjects found that naproxen 500 mg twice daily moderately decreased the AUC of a single 800-mg dose of sodium valproate by 11%.[9] Similarly, in another study, when naproxen 500 mg twice daily was given with sodium valproate 500 mg twice daily, the AUC of valproate was decreased by 20% and the AUC of naproxen was increased by 7%.[10] It is suggested that naproxen and sodium valproate displace each other from their protein binding sites.[9,10] The clinical relevance of these modest changes is uncertain, but is likely to be small.[9]

Valproate + Bile-acid binding resins

Colestyramine causes a small reduction in the absorption of valproate. No interaction occurs if administration of the drugs is separated by 3 hours. Colesevelam does not interact with valproate.

Clinical evidence

(a) Colesevelam

In a study in 26 healthy subjects, colesevelam 4.5 g had no effect on the pharmacokinetics of a single 250-mg dose of valproic acid.[1]

(b) Colestyramine

In a study, 6 healthy subjects were given a single 250-mg dose of valproic acid either alone, at the same time as colestyramine 4 g twice daily, or 3 hours before colestyramine. The bioavailability of valproate taken alone and when separated from the colestyramine by 3 hours remained the same. When the valproate was taken at the same time as the colestyramine, the valproate AUC fell by 15% and its maximum serum levels fell by 21%.[2]

Mechanism

Colestyramine is an ion-exchange resin intended to bind with bile acids in the gut, but it can also bind with drugs, leading to a reduction in their absorption. This apparently occurs to a limited extent with valproate.

Importance and management

Direct information about an interaction between colestyramine and valproate appears to be limited to this single study. The fall in the bioavailability is small and probably of very limited clinical importance, but the interaction can apparently be totally avoided by separating administration by 3 hours so that admixture in the gut is minimised. Colesevelam does not appear to interact with valproate.

Valproate + Carbapenems

Panipenem with betamipron dramatically reduces valproate serum levels. Ertapenem, imipenem and meropenem have similar effects and seizures have occurred when they were given to patients taking valproate. All carbapenems are expected to interact similarly.

Clinical evidence

(a) Ertapenem

A report describes a patient taking valproate semisodium 2 g daily who had recurring tonic-clonic seizures after starting ertapenem. His serum valproic acid levels had decreased from 130 micrograms/mL (measured about 3 months earlier) to 70 micrograms/mL on day 7 of treatment with ertapenem 1 g daily when the seizures occurred. He was given intravenous valproic acid 750 mg and the dose of valproate semisodium was increased to 2.75 g daily. Four days later he presented with recurrent seizures and serum valproic acid levels of 10.7 micrograms/mL. He was given intravenous valproic acid 1 g followed by oral valproate semisodium 100 mg. Ertapenem was discontinued and the next day his serum valproic acid was 55 micrograms/mL. An increase in his valproate semisodium dose followed by a gradual decrease allowed therapeutic levels to be achieved and he had no further seizures.[1]

In another case report, total valproate levels in a patient taking valproic acid solution 1.1 g daily in divided doses (separated from enteral nutrition she was receiving) fell from 72 micrograms/mL to 36.4 micrograms/mL about 4 days after she was also given ertapenem 1 g daily. The valproic acid dose was increased to 1.6 g daily, but 2 days later valproate levels had further decreased to 18.4 micrograms/mL. The dose of valproic acid was further increased to 2 g daily and levels 4 days later had decreased to about 1 microgram/mL. Ertapenem was discontinued and intravenous valproic acid was given as a loading dose of 800 mg then 400 mg every 6 hours. Once valproate levels returned to the therapeutic range she was given valproic acid solution 1.4 g daily.[2]

(b) Imipenem

A report describes a reduction in valproate levels from 80 micrograms/mL to 24 micrograms/mL then 33 micrograms/mL in a patient with epilepsy 4 and 11 days after imipenem was given to treat a *Pseudomonas aeruginosa* infection.[3] In another report, a patient taking valproate 800 mg daily had a 57% reduction in plasma valproate levels during treatment with imipenem 500 mg twice daily for 5 days. A second patient taking valproate 600 mg daily had a reduction in plasma valproate levels of 49% when given imipenem 500 mg twice daily for 7 days.[4] Decreased valproate levels and recurrence of tonic-clonic convulsions occurred in another patient during concurrent treatment with imipenem.[5]

(c) Meropenem

A report describes 2 patients whose valproate levels fell when meropenem and amikacin were given. The first patient had been maintained on intravenous valproate 1.2 to 1.6 g daily with valproate levels of between 50 and 100 micrograms/mL. Two days after the addition of the antibacterials the levels had halved, and after 3 days of subtherapeutic levels, phenytoin was substituted for valproate. The other patient experienced a drop in valproate levels from 44 micrograms/mL to 5 micrograms/mL within 24 hours of being given meropenem, despite being given greater doses of valproic acid.[6] Other reports[3,7-14] describe reductions in valproate levels in several other patients when they were also given meropenem: 4 of them developed seizures.[3,11-13] A retrospective study of an 18-month period identified 39 patients who had been treated with valproate and meropenem. Plasma

valproate levels fell in all patients by an average of 66% (range 34 to 92%) within 24 hours of concurrent use. Clinical assessment of the interaction in 20 of the patients found worsening seizures or epileptic activity on EEG or both in 11 patients (55%).

(d) Panipenem

A report describes 3 cases of Japanese children taking antiepileptic drugs who had marked reductions in valproate serum levels while receiving panipenem with betamipron for serious chest infections.[15] An increased seizure frequency occurred in 2 of the patients. In one case the serum valproate levels fell from 30.1 micrograms/mL to 1.53 micrograms/mL within 4 days of starting panipenem, and rose again when it was stopped. All 3 patients were also taking carbamazepine but its serum levels were unchanged by the antibacterial. In a further 3 cases, 60 to 100% reductions in valproate levels were reported, which occurred within 2 days of starting concurrent treatment: increased seizure frequency occurred in 2 cases.[16]

Mechanism

Unknown, but the speed of the interaction is said to be inconsistent with enzyme induction, and accelerated renal excretion has been suggested.[6] Altered protein binding has been shown in *animal* and *in vitro* studies.[17] Enhanced glucuronidation of valproate, by up-regulation of the catalysing cofactor, is reported to increase hepatic intrinsic clearance and renal excretion of valproate.[18] Decreased hydrolysis of glucuronidated valproate due to inhibition of the hydrolytic enzyme by carbapenems may also be involved.[18,19] It has been suggested that decreased plasma valproate levels may partly be due to an increase in the distribution of valproate into erythrocytes.[4]

Importance and management

Although there are few reports of an interaction between valproate and imipenem or ertapenem, there are now several reports of the interaction between valproate and meropenem or panipenem. Seizures or increased seizure frequency as well as significant decreases in valproate levels have been reported. It would therefore seem prudent to monitor the valproate levels in any patient also given a carbapenem, being alert for the need to increase the valproate dose, or to use another antibacterial, or an alternative to valproate. Carbamazepine[15] and phenytoin[6] did not interact in the above reports.

Valproate + Chlorpromazine

Valproate levels are slightly raised in patients given chlorpromazine, but this appears to be of minimal clinical importance. An isolated report describes severe hepatotoxicity in a patient taking chlorpromazine and valproate.

Clinical evidence, mechanism, importance and management

When 6 patients taking valproate 400 mg daily were given chlorpromazine 100 to 300 mg daily, their steady-state trough valproate serum levels rose by 22%. The half-life increased by 14% and the clearance fell by 14% (possibly due to some reduction in its liver metabolism).[1] However, these changes are modest, and this interaction would normally seem to be of minimal importance. Severe hepatotoxicity occurred in another patient given both drugs,[2] which could have been due to the combined hepatotoxic effects of both drugs.

Valproate + Erythromycin

Two isolated reports describe valproate toxicity in a woman and a child given erythromycin. Another report describes vitamin K deficiency in a child given valproate and erythromycin.

Clinical evidence, mechanism, importance and management

A child taking valproic acid developed a deficiency of prothrombin complex after taking erythromycin 300 mg three times daily. This resolved when the patient was given oral vitamin K. It was suggested that the effect was because the numbers of vitamin-K producing intestinal bacteria were reduced.[1] A woman taking lithium and valproate 3.5 g daily developed fatigue and walking difficulties a day after starting to take erythromycin 250 mg four times daily. Within a week she had also developed slurred speech, confusion, difficulty in concentrating and a worsening gait. Her serum valproate levels had risen from 88 mg/L (measured 2 months before) to 260 mg/L. She recovered within 24 hours of the valproate and erythromycin being withdrawn. Her serum lithium levels remained unchanged.[2] In another case, a child taking sodium valproate had a threefold increase in serum valproate levels after taking erythromycin 150 mg every 8 hours and aspirin 250 mg every 6 hours for 3 days.[3]

These case reports contrast with another study in a 10-year-old boy taking valproic acid 375 mg twice daily who had only very small and clinically unimportant changes in the pharmacokinetics of valproate, consistent with inhibition of cytochrome P450 metabolism, when given erythromycin 250 mg four times daily.[4]

The general relevance of these isolated reports is unclear, but probably small.

Valproate + Felbamate

Felbamate can raise valproate serum levels causing toxicity. Valproate may slightly decrease the clearance of felbamate.

Clinical evidence

(a) Effect on sodium valproate

The average steady-state valproate serum levels in 7 patients with epilepsy were raised by 28% (from 66.9 micrograms/mL to 85.4 micrograms/mL) by felbamate 1.2 g daily, and by 54% (from 66.9 micrograms/mL to 103 micrograms/mL) by felbamate 2.4 g daily. In addition, the AUC of valproate was raised by 28% and 54% by felbamate 1.2 g and 2.4 g, respectively. Valproate clearance was correspondingly reduced by felbamate.[1] Similar effects were seen in another study,[2,3] and one of these studies suggested that in children the interaction may be more marked.[3] Many of the patients experienced nausea. Other toxic effects included lethargy, drowsiness, headaches, cognitive disturbances and low platelet counts.[1,2]

(b) Effect on felbamate

The clearance of felbamate was decreased by 21% by valproate in one study,[4] and another study reported a significantly lower felbamate clearance in the presence of valproate.[5] However, a further study noted only a minimal effect of valproate on felbamate clearance.[6]

Mechanism

Uncertain. Altered plasma protein binding of valproate is unlikely to be important.[7] Felbamate may cause inhibition of the oxidative pathway of valproate metabolism.[8]

Importance and management

An established interaction. It may be necessary to reduce the valproate dose to avoid toxicity if felbamate is given. The authors of one report suggest a 30 to 50% reduction. It may also be necessary to reduce the felbamate dose, although the effects appear modest. If both drugs are given monitor the outcome closely, being alert for valproate adverse effects (e.g. nausea, vomiting and dizziness) particularly during the initial stages of treatment.

Valproate + Fluoxetine

Isolated reports describe marked increases or modest decreases in valproate levels in a small number of patients given fluoxetine. Valproate toxicity occurred in one patient.

Clinical evidence

A woman with an atypical bipolar disorder and 'severe mental retardation' taking semisodium valproate (divalproex sodium) 3 g daily had a rise in her serum valproic acid levels from 93.5 mg/L to 152 mg/L within 2 weeks of starting to take fluoxetine 20 mg daily. The valproate dose was reduced to 2.25 g daily and 2 weeks later the serum valproic acid levels had fallen to 113 mg/L. No adverse effects were seen.[1] Another woman taking valproic acid developed elevated serum valproate levels (a rise from 78 mg/L to 126 mg/L) without any accompanying clinical symptoms within one month of starting to take fluoxetine 20 mg daily. Valproate levels fell again when the fluoxetine was stopped.[2] Similarly, a 17-year-old taking valproic acid and felbamate developed drowsiness and difficulty in being roused 2 weeks after starting fluoxetine 20 mg daily. His valproate level had increased to 141 micrograms/mL from a previous range of 100 to 110 micrograms/mL. His valproate dose was reduced by about 15%, and his consciousness improved.[3]

In contrast 2 cases of *reduced* valproate levels have also been reported in patients taking fluoxetine. In the first case, a 67-year-old woman taking valproic acid 2 g daily and fluoxetine 20 mg daily had a serum valproate level of 51.9 mg/L. This increased to 64.9 mg/L 9 days after fluoxetine was discontinued and fell to 32.6 mg/L 6 days after fluoxetine was restarted. In the second case, an 81-year-old woman was taking valproic acid 1 g with fluoxetine 20 mg daily and had serum valproate levels of 41.9 mg/L. The fluoxetine was stopped, and 6 days later valproate serum levels had risen to 56.2 mg/L. After re-introduction of fluoxetine her valproate levels fell to 45.6 mg/L.[4]

Mechanism

Not understood.

Importance and management

These reports are somewhat confusing and inconsistent. The overall picture is that concurrent use need not be avoided, but that the outcome should probably be monitored. Indicators of valproate toxicity include nausea, vomiting, and dizziness. More study is needed to establish an interaction.

Valproate + Food

Food appears not to affect the bioavailability of valproate, although in one study, the rate of absorption was increased.

Clinical evidence, mechanism, importance and management

In a study in 12 healthy subjects, the absorption of a single dose of a sustained-release formulation containing sodium valproate 333 mg and valproic acid 145 mg (*Depakine Chrono*) was increased when it was given with a standard breakfast rather than in the fasting state. However, the extent of absorption, the AUC, the mean residence time and the elimination half-life were not changed.[1] Similarly, in another study in healthy subjects, the bioavailability of a single 300-mg dose of sustained-release sodium valproate (*Orfiril long*) was not affected when it was given with a high-energy, high-fat breakfast.[2] A further study in 12 healthy subjects found that dietary fibre (citrus pectin 14 g) did not affect the rate or extent of absorption of a single 500-mg dose of valproate.[3]

Valproate + H_2-receptor antagonists

Aside from one tentative case report, cimetidine and ranitidine do not appear to have a clinically significant interaction with valproate.

Clinical evidence, mechanism, importance and management

In 6 patients, the clearance of a single oral dose of sodium valproate was reduced by 2 to 17% after a 4-week course of **cimetidine**, but was not affected by **ranitidine**.[1] It seems doubtful if the interaction between valproate and **cimetidine** is of clinical importance. However, a case of fatal hyperammonaemia in a patient with systemic lupus erythematosus was

speculated to have been induced by valproate, and the authors also considered that the concurrent use of **cimetidine** and aspirin (see 'Valproate + Aspirin or NSAIDs', p.656) may have contributed.[2] The general importance of this case is unknown.

Valproate + Isoniazid

An isolated report describes the development of raised serum valproate levels and toxicity in a child given isoniazid while taking valproate. Another report describes raised liver enzymes and drowsiness in a patient taking both drugs.

Clinical evidence, mechanism, importance and management

A 5-year-old girl with left partial seizures, successfully treated with valproate 600 mg daily and clonazepam for 7 months, developed signs of valproate toxicity (drowsiness, asthenia) shortly after starting to take isoniazid 200 mg daily because of a positive tuberculin reaction. Her serum valproate levels were found to have risen to around 121 to 139 mg/L (reference range 50 to 100 mg/L).[1] Over the next few months various changes were made in her treatment, the most significant being a 62% reduction in the dose of valproate, which was needed to maintain satisfactory therapeutic valproate levels. Later when the isoniazid was stopped her valproate levels fell below the reference range and seizures recurred. It was then found necessary to increase the valproate to its former dose. The suggested explanation for this interaction is that isoniazid inhibited the metabolism (oxidation) of valproate by the liver so that it accumulated. The child was found to be a very slow acetylator of isoniazid.[1]

Another child who had been treated with valproate for several years was given isoniazid for the treatment of tuberculosis. At the same time, seizures recurred, and the valproate was stopped and primidone 750 mg daily started. Seven months later seizures persisted, and she was admitted to hospital. Liver enzyme values were normal. She was given valproate 300 mg daily increased to 600 mg daily, and within 2 days she was vomiting and drowsy. After 5 days she had increased liver enzymes and her prothrombin time had fallen, so the valproate was stopped. Valproate levels were 81 micrograms/mL. It was speculated that the CNS effects and hepatic impairment were due to an interaction between valproate and isoniazid.[2]

The general importance of these cases is uncertain, but bear them in mind in the event of an unexpected response to treatment.

2. Dockweiler U. Isoniazid-induced valproic-acid toxicity, or vice versa. *Lancet* (1987) ii, 152.

Valproate + Methylphenidate

Two children taking valproic acid rapidly developed severe dyskinesias and bruxism (teeth grinding and jaw clenching) after the first and second dose of methylphenidate, respectively. Valproate appears to potentiate the effects of methylphenidate, possibly by a pharmacokinetic mechanism, or because of additive dopaminergic effects. The authors of the report advise clinical observation while the dose of methylphenidate is being established.[1]

1. Gara L, Roberts W. Adverse response to methylphenidate in combination with valproic acid. *J Child Adolesc Psychopharmacol* (2000) 10, 39–43.

Valproate + Propranolol

One patient had a reduction in valproate clearance when propranolol was also given, but 12 other patients had no change in valproate clearance when taking propranolol.

Clinical evidence, mechanism, importance and management

An isolated report describes a 28% reduction in valproate clearance in a patient taking valproate semisodium with propranolol 40 mg, and a 35% reduction in valproate clearance with propranolol 80 mg. However, 12 other patients taking valproate had no changes in the clearance, serum levels or half-life of valproate when they were given propranolol 60 or 120 mg daily for 3 weeks.[1] This interaction would therefore not appear to be of general importance. No special precautions would seem necessary if propranolol is given to patients taking valproate.

1. Nemire RE, Toledo CA, Ramsay RE. A pharmacokinetic study to determine the drug interaction between valproate and propranolol. *Pharmacotherapy* (1996) 16, 1059–62.

Valproate + Theophylline

A study in 6 healthy subjects found that oral aminophylline 200 mg every 6 hours for 3 doses did not affect the pharmacokinetics of a single 400-mg dose of sodium valproate.[1] No dose adjustment of sodium valproate appears to be needed with concurrent use of aminophylline, and therefore theophylline.

1. Kulkarni C, Vaz J, David J, Joseph T. Aminophylline alters pharmacokinetics of carbamazepine but not that of sodium valproate — a single dose pharmacokinetic study in human volunteers. *Indian J Physiol Pharmacol* (1995) 39, 122–6.

Vigabatrin + Clomipramine

An isolated case report describes mania in an patient with epilepsy taking vigabatrin and clomipramine.

Clinical evidence, mechanism, importance and management

An isolated report describes an man with epilepsy, taking carbamazepine and clobazam, who started taking clomipramine 35 mg daily for depression. About one month later, vigabatrin 2 g daily was added to improve seizure control. After about a week, the patient progressively developed signs of mania, which required him to be hospitalised after about 10 weeks. The clomipramine was stopped, the vigabatrin continued (because of its efficacy), and haloperidol started. Within a week the patient's mood had stabilised. The authors of the report attributed the mania to an interaction between the vigabatrin and the clomipramine.[1,2] Note that both clomipramine and vigabatrin can cause psychiatric disorders including mania, and vigabatrin should be used with caution in patients with depression. No general conclusions can be based on this single report.

2. Sastre-Garau P, Thomas P, Beaussart M, Goudemand M. Accès maniaque consécutif à une association vigabatrin-clomipramine. *Encephale* (1994) 20, 363.

Vigabatrin + Felbamate

No clinically relevant pharmacokinetic interactions appear to occur between vigabatrin and felbamate.

Clinical evidence, mechanism, importance and management

In a study in 16 healthy subjects, felbamate 2.4 g daily increased the AUC of vigabatrin 2 g daily by 13%, which is unlikely to be clinically significant. In a second study, in a further 18 healthy subjects, vigabatrin did not affect felbamate pharmacokinetics.[1] It therefore appears that concurrent use can be undertaken without the need to adjust the dose of either drug.

1. Reidenberg P, Glue P, Banfield C, Colucci R, Meehan J, Rey E, Radwanski E, Nomeir A, Lim J, Lin C, Guillaume M, Affrime MB. Pharmacokinetic interaction studies between felbamate and vigabatrin. *Br J Clin Pharmacol* (1995) 40, 157–60.

Vigabatrin + Phenobarbital or Primidone

Vigabatrin causes a small decrease in phenobarbital and primidone levels. There is some evidence that phenobarbital may reduce the efficacy of vigabatrin in infantile spasms.

Clinical evidence

In an early clinical study in 26 patients, vigabatrin 2 to 3 g daily did not change the serum levels of phenobarbital.[1] Similarly, another study found that phenobarbital levels were not significantly altered by vigabatrin.[2] A further study found that vigabatrin caused serum level reductions of 7% with phenobarbital and 11% with primidone.[3,4] Alterations of this size would not be expected to be clinically relevant.

There is some evidence that the efficacy of vigabatrin for infantile seizures may be reduced in those taking phenobarbital. The median time to response after starting vigabatrin was 3 days in 3 infants not taking phenobarbital and 34 days in 6 patients taking phenobarbital. Three patients did not respond to vigabatrin until after phenobarbital was withdrawn.[5]

Mechanism

Not understood.

Importance and management

There appears to be no change in phenobarbital levels with vigabatrin, but some suggestion that vigabatrin may be less effective for infantile spasms in the presence of phenobarbital. Bear this possibility in mind.

Vigabatrin + Valproate

No pharmacokinetic interaction appears to occur between vigabatrin and valproate, but one retrospective study found a correlation between valproate levels and vigabatrin levels.

Clinical evidence, mechanism, importance and management

In 11 children, vigabatrin 40 to 80 mg/kg daily did not change the serum levels of sodium valproate.[1] The combined use of vigabatrin and sodium valproate in 16 children with refractory epilepsy was found not to affect the steady-state serum levels of either drug and the combination reduced the frequency of seizures.[2] However, a retrospective analysis of serum samples from 53 patients found that the vigabatrin concentration-to-dose ratio was increased as the valproate trough steady-state levels increased,[3] suggesting that valproate slightly raises vigabatrin levels. Nevertheless, no dose adjustments usually appear to be necessary on concurrent use.

Zonisamide + Miscellaneous

Cimetidine does not alter zonisamide pharmacokinetics. Food has no effect on the absorption of zonisamide. A case of reduced zonisamide levels possibly caused by risperidone has been described.
Potent inhibitors of CYP3A4 are predicted to modestly decrease zonisamide clearance.

Clinical evidence, mechanism, importance and management

(a) Cimetidine

In a study in healthy subjects, cimetidine 300 mg four times daily for 13 days did not affect the clearance, half-life, apparent volume of distribution or the amount of drug recovered from the urine after a single 300-mg oral dose of zonisamide. The drugs were well tolerated.[1,2] No special precautions would seem to be needed if both drugs are used.

(b) CYP3A4 inhibitors

In vitro studies have shown that the cytochrome P450 isoenzyme CYP3A4 is the principal isoenzyme involved in the metabolism of zonisamide.[3] Based on *in vitro* data, it is predicted that **ketoconazole**, **ciclosporin**, **miconazole** and **fluconazole** may cause a modest to minor decrease in the clearance of zonisamide. Conversely, **itraconazole** and **triazolam** were not predicted to have an effect.[3] This casts some doubt on these findings as *in vivo*, **ketoconazole** and **itraconazole** usually interact similarly. *In vitro* predictions do not always mirror what happens in clinical use, and therefore further study is needed to establish an effect.

(c) Food

In a study in healthy subjects there was no difference in the pharmacokinetics of a single 300- or 400-mg dose of zonisamide when given in the fasted state or when it was given after breakfast. Zonisamide may be taken without regard to the timing of meals.[4]

(d) Risperidone

A 57-year-old man taking zonisamide was given risperidone 2 mg daily, which was gradually increased to 10 mg daily. About 2 months after starting the risperidone, the zonisamide level had fallen from 23.7 micrograms/mL to 10.7 micrograms/mL. The risperidone was stopped, and the zonisamide level had slightly increased again to 12.4 micrograms/mL about one month later. It was suggested that a metabolic interaction occurred.[5] More study is needed to establish any interaction.

Zonisamide + Other antiepileptics

Phenobarbital, phenytoin and carbamazepine can cause a small to moderate reduction in the levels of zonisamide, while lamotrigine may increase zonisamide levels. Clonazepam and valproate have little or no effect.
Zonisamide has variable effects (a modest decrease, an increase, or no effect) on carbamazepine serum levels, but has no important effect on lamotrigine, phenobarbital, primidone or valproate levels. Most studies also suggest that zonisamide has no effect on phenytoin levels, but two showed a modest increase. In theory, the combination of zonisamide and topiramate may increase the risk of renal calculi.

Clinical evidence

(a) Carbamazepine

In one study the ratio of plasma level to zonisamide dose was 39% lower in 17 patients taking carbamazepine than in 28 patients taking zonisamide alone, suggesting that carbamazepine modestly reduces zonisamide levels.[1] Similarly, in another study in 12 children with epilepsy taking zonisamide 8.6 to 13.6 mg/kg daily, carbamazepine 12.1 to 18.1 mg/kg daily reduced zonisamide plasma levels by about 35 to 37%.[2] In an early study in 2 groups of patients, one taking carbamazepine and the other phenytoin, it was noted that the zonisamide AUC following a single 400-mg dose was 40% higher in the carbamazepine group than the phenytoin group.[3] However, in the first study, the plasma concentration-to-dose ratio was the same in patients taking carbamazepine as in those taking phenytoin.[1] Therefore the comparative effects of carbamazepine and phenytoin on zonisamide levels are unclear.

In one study, the ratio of carbamazepine-10,11-epoxide (the major active metabolite of carbamazepine) to carbamazepine in the plasma was 50% lower in patients also taking zonisamide, suggesting that zonisamide reduces carbamazepine metabolism. However, the plasma concentration-to-dose ratio of carbamazepine was only 20% higher, which was not signifi-

cant.[1] An early pilot study in 7 patients noted a consistent rise in carbamazepine plasma levels (range 26 to 270%) after zonisamide was started.[4] The opposite effect was seen in a study of 16 paediatric patients in whom zonisamide reduced the ratio of carbamazepine serum levels to dose by up to 22% and increased the relative amount of its major metabolite in the serum by up to 100%, suggesting that zonisamide increases the metabolism of carbamazepine. However, the free fraction of carbamazepine remained unaltered.[5]

Contrasting with these three studies are four others that found no changes in the serum levels of carbamazepine or carbamazepine-10,11-epoxide when zonisamide was used,[2,6-8] although in one of the studies, the renal clearance of carbamazepine-10,11-epoxide was reduced by zonisamide.[8] A further study similarly found no change in the plasma level of carbamazepine in 41 patients also given zonisamide (7.5 micrograms/mL versus 7.4 micrograms/mL).[9]

(b) Clonazepam

In one study the ratio of plasma level to dose ratio of zonisamide did not differ between 8 patients also taking clonazepam and 28 patients taking zonisamide alone, suggesting clonazepam has no effect on zonisamide levels.[1]

(c) Lamotrigine

In 18 patients, zonisamide 100 mg daily increased to 200 mg twice daily did not alter the steady-state pharmacokinetics of lamotrigine.[10,11] Further, the pharmacokinetics of zonisamide were unaffected by lamotrigine.[11] However, in 2 patients who were stable taking zonisamide 600 mg daily or 800 mg daily, the addition of lamotrigine (incremental doses up to 400 mg daily) caused roughly twofold increases in their zonisamide levels, with symptoms of toxicity that were maximal 40 to 60 minutes after taking a zonisamide dose.[12]

(d) Phenobarbital or Primidone

In one study the ratio of plasma level to dose ratio of zonisamide was 29% lower in 11 patients also taking phenobarbital than in 28 patients taking zonisamide alone, suggesting that phenobarbital reduces zonisamide levels.[1] Similarly, another study in healthy subjects found that pretreatment with phenobarbital roughly doubled the clearance of a single dose of zonisamide.[13] A further study found no changes in the serum levels of phenobarbital or primidone in 34 and 13 patients, respectively, who were also given zonisamide.[9]

(e) Phenytoin

In one study the ratio of plasma level to dose ratio of zonisamide was 39% lower in 14 patients also taking phenytoin than in 28 patients taking zonisamide alone, suggesting phenytoin modestly reduces zonisamide levels.[1] In an early study in two groups of patients, one taking carbamazepine and the other phenytoin, it was noted that the zonisamide AUC following a single 400-mg dose was 40% higher in the carbamazepine group than the phenytoin group.[3] However, in the first study, the reduction in zonisamide level-to-dose ratio was the same for phenytoin as for carbamazepine.[1] Therefore the comparative effect of phenytoin and carbamazepine on zonisamide levels is unclear.

Other studies in both adults and children suggest that zonisamide does not affect phenytoin levels.[6,9,14] However, in a population pharmacokinetic analysis, the clearance of phenytoin at a given dose was 14% lower and the serum level 16% higher in 39 patients also taking zonisamide.[15] Similarly, the preliminary results from 9 patients in another study showed that there was a 28% increase in the steady-state AUC of phenytoin when zonisamide 100 mg daily increased to 200 mg twice daily was given,[16] although a later study by the same authors, in 19 patients, found that zonisamide did not affect the pharmacokinetics of phenytoin to a clinically relevant extent.[17]

(f) Topiramate

Zonisamide and topiramate are both weak inhibitors of carbonic anhydrase and either may increase the risk of renal calculi. However, a study in children with epilepsy found that giving either topiramate or zonisamide with a ketogenic diet (high-fat, adequate protein, low-carbohydrate used in difficult to control epilepsy) did not increase the risk of renal calculi that occurred with a ketogenic diet alone.[18] In a retrospective study including 10 patients taking zonisamide and topiramate, there were no reports of renal calculi.[19]

(g) Valproate

In one study the ratio of plasma level to dose of zonisamide was about 20% lower in 24 patients also taking valproate than in 28 taking zonisamide alone, suggesting that valproate has little effect on zonisamide levels.[1] Similarly, another study in 16 patients found that valproate did not affect the pharmacokinetics of zonisamide.[20] Further, the steady-state pharmacokinetics of valproate did not change when zonisamide 100 mg daily increased to 200 mg twice daily was given 16 patients taking valproate.[20,21]

Another study found that zonisamide did not affect the serum levels of sodium valproate in 12 children.[14] A further study similarly found no marked changes in the plasma level of valproic acid in 7 patients also given zonisamide.[9]

Mechanism

Uncertain. It seems possible that phenobarbital, phenytoin and carbamazepine can induce the metabolism of zonisamide thereby reducing its serum levels. The plasma protein binding of zonisamide is unaffected by other antiepileptics (phenobarbital, phenytoin, carbamazepine, valproate).[22]

Importance and management

None of these studies reported any major problems during concurrent use of zonisamide and these other antiepileptic drugs. Zonisamide serum levels are lower with phenobarbital, phenytoin and carbamazepine, and there is the possibility of carbamazepine or phenytoin level changes, so it would be prudent to monitor patients taking any of these combinations.

There appears to be a theoretical risk of a pharmacodynamic interaction between zonisamide and topiramate, but the limited evidence available suggests the interaction is unlikely to be of importance.

Antihistamines

Antihistamines (histamine H_1-antagonists) vary in their interaction profiles by sedative potential, route of metabolism, and cardiotoxicity (QT interval prolongation).

(a) Additive sedative effects

The older antihistamines (e.g. chlorphenamine, diphenhydramine and hydroxyzine) are also referred to as sedating antihistamines or first-generation antihistamines. As the former name suggests they have the potential to cause additive sedative effects with other sedating drugs. This type of interaction is discussed elsewhere, see 'CNS depressants + CNS depressants', p.1553. The sedating antihistamines also tend to have antimuscarinic (also called anticholinergic) adverse effects and so therefore may interact additively with other antimuscarinic-type drugs. This is also discussed elsewhere, see 'Antimuscarinics + Antimuscarinics', p.786.

The newer (non-sedating antihistamines or second-generation antihistamines) have a low potential to cause sedative effects. This appears to be because they are substrates for P-glycoprotein, an efflux transporter found in many organs, which would have the effect of actively ejecting any drug molecules that crossed the blood-brain barrier. Nevertheless, sedation may occur on rare occasions and patients should be advised to be alert to the possibility of drowsiness if they have not taken the drug before. Any drowsiness is likely to become apparent after the first few doses, and would indicate that additive sedative effects with other sedating drugs might be expected. The antihistamines are listed, by sedative potential, in 'Table 15.1', (below).

(b) Metabolism

Some of the sedating antihistamines, such as diphenhydramine, are inhibitors of the cytochrome P450 isoenzyme CYP2D6. None of the non-sedating antihistamines are known to inhibit cytochrome P450 isoenzymes, but some are substrates for CYP3A4 including astemizole, desloratadine, ebastine, loratadine, mizolastine, rupatadine and terfenadine, see 'Table 15.2', (p.664). This has important consequences for the potential cardiotoxicity of astemizole and terfenadine, see below. Loratadine and desloratadine are also substrates for CYP2D6, and mizolastine is also metabolised by glucuronidation. Cetirizine, levocetirizine and fexofenadine are minimally metabolised. Where pharmacokinetic interactions occur with fexofenadine, these appear to be mediated via drug transporters such as P-glycoprotein and/or organic anion transport polypeptide (OATP). For more information about the effects of drug transporters, see 'Drug transporter proteins', (p.8).

(c) QT interval prolongation and cardiac arrhythmias

Important drug interactions occur with the non-sedating antihistamines, astemizole and terfenadine. Raised serum levels of these two antihistamines can block potassium channels, lengthening the QT interval and increasing the risk of potentially fatal cardiac arrhythmias (torsade de pointes). Therefore, dangerous interactions may result when other drugs reduce the metabolism of astemizole or terfenadine, usually by inhibition of the cytochrome P450 isoenzyme CYP3A4. Such drugs include the 'macrolides', (p.671) and the 'azoles', (p.665). Adverse interactions are also predicted when astemizole or terfenadine are used with drugs that prolong the QT interval, see 'Antihistamines + Drugs that prolong the QT interval', p.669. Due to these potentially fatal interactions, astemizole and terfenadine have been withdrawn from many countries. Apart from possibly ebastine, loratadine and mizolastine, where information is inconclusive, none of the other non-sedating antihistamines have been clearly shown to be associated with QT prolongation (see 'Table 15.2', (p.664)). Therefore, even when pharmacokinetic interactions result in increased levels, these are unlikely to be clinically important in terms of cardiotoxicity.

Table 15.1 Systemic antihistamines (classified by sedative potential) and topical antihistamines

Sedative potential	*Antihistamine*
Non-sedating	Acrivastine, Astemizole,* Cetirizine, Desloratadine, Ebastine,* Fexofenadine, Levocetirizine, Loratadine, Mizolastine,* Rupatadine, Terfenadine*
Sedating	Azatadine, Brompheniramine, Buclizine, Chlorphenamine, Cinnarizine, Clemastine, Cyclizine, Cyproheptadine, Dexchlorpheniramine, Flunarizine, Meclozine, Mepyramine, Mequitazine, Pheniramine, Tripelennamine, Triprolidine
Significantly sedating	Alimemazine, Bromazine, Carbinoxamine, Dimenhydrinate, Diphenhydramine, Doxylamine, Hydroxyzine, Promethazine, Trimeprazine
Topical use (mainly)	Antazoline, Azelastine, Emedastine, Epinastine, Levocabastine, Olopatadine

*Important QT prolongation known to occur (astemizole, terfenadine), or may possibly occur (ebastine, mizolastine), see Table 15.2

Table 15.2 Metabolism and cardiac effects of non-sedating antihistamines

Antihistamines + Azoles

The azole antifungals raise the levels of astemizole and terfenadine, which can result in life-threatening arrhythmias; this has been seen in a number of cases. Mizolastine, ebastine and acrivastine either are, or are predicted to be, similarly affected. The situation with loratadine is unclear as one study found that the concurrent use of ketoconazole caused a small increase in the QT interval.

Ketoconazole raises the levels of desloratadine, emedastine, fexofenadine and rupatadine but no adverse cardiac effects were seen. No interaction occurs between ketoconazole and azelastine, cetirizine, intranasal levocabastine, and none is expected with levocetirizine.

Clinical evidence

The effect of various azole antifungals on the plasma levels of the non-sedating antihistamines, and their cardiac effects from controlled studies are summarised in 'Table 15.3', (p.666). The subsections below include data from case reports and further studies.

(a) Astemizole

A 63-year old woman developed torsade de pointes and was found to have a prolonged QT interval after taking astemizole and **ketoconazole**. These two drugs were withdrawn and she was successfully treated with a temporary pacemaker, magnesium sulphate and lidocaine. She was later discharged with a normal ECG.[1]

(b) Desloratadine

A patient undergoing chemotherapy developed severe pruritus and was given desloratadine and clemastine. Because of pyrexia of unknown origin she was treated with meropenem and then 48 hours later **fluconazole** was added. After about 36 hours severe hepatotoxicity was detected, and apart from the anti-infectives the other drugs were stopped. Liver parameters recovered over the following week. Because the patient had previously received clemastine and **fluconazole** without problems, this case was attributed to a possible interaction between **fluconazole** and desloratadine.[2]

(c) Ebastine

A review of the safety of ebastine cites two studies assessing the potential interaction between ebastine and **ketoconazole**. A single-dose study, found that the combination did not affect the QTc interval, whereas a multiple-dose study found that the QTc interval was prolonged by 18.1 milliseconds by the combination.[3]

(d) Fexofenadine

1. Itraconazole. In a single-dose study, giving itraconazole 200 mg one hour before fexofenadine 180 mg increased the AUC of fexofenadine 2.3-fold, and 3-fold in two groups of subjects with different genotypes for the gene encoding P-glycoprotein. Itraconazole pretreatment increased the effect of fexofenadine on histamine-induced wheal and flare reaction.[4]

2. Ketoconazole. Fexofenadine has no effect on the pharmacokinetics of ketoconazole, but fexofenadine levels are increased by ketoconazole.[5]

(e) Loratadine

In one study the cardiac effects of loratadine were found to be similar to those of ebastine (see above), which caused a small increase in the QTc interval.[6] However, loratadine alone, given at 4 times the recommended dose for 90 days, had no effect on the QTc interval when compared with placebo.[7] See also 'Table 15.2', (p.664), for the potential effects of loratadine on the QT interval.

(f) Rupatadine

A review reports a study in which the systemic exposure to rupatadine 20 mg was increased 10-fold by **ketoconazole** 200 mg daily for 7 days. The pharmacokinetics of **ketoconazole** were unaffected by rupatadine. There were no clinically relevant changes in the QTc interval, vital signs or adverse effects.[8]

(g) Terfenadine

1. Fluconazole. The US manufacturer of fluconazole reports that fluconazole 400 mg or 800 mg daily significantly increased plasma levels of terfenadine (magnitude not stated).[9] In an interaction study, 6 healthy subjects were given fluconazole 200 mg daily with terfenadine 60 mg twice daily for about 6 days. Although fluconazole increased the AUC of terfenadine by 34%, there was no statistically significant prolongation of the QTc interval.[10]

2. Itraconazole. A 26-year-old woman taking terfenadine 60 mg twice daily began to have fainting episodes on the third evening after starting to take itraconazole 100 mg twice daily for vaginitis. When admitted to hospital the next morning her ECG showed a QT interval of 580 milliseconds and her heart rate was 67 bpm. Several episodes of torsade de pointes were recorded, and she fainted during two of them. No arrhythmias were seen 20 hours after the last itraconazole dose, and her QT interval returned to normal after 3 days. She was found to have terfenadine levels of 28 nanograms/mL in the first sample of serum taken (normally less than 5 nanograms/mL) and she still had levels of 12 nanograms/mL about 60 hours after taking the last tablet.[11,12] Two other similar cases have been reported,[13,14] and the FDA has received four well-documented cases of severe cardiac complications due to this interaction.[15]

3. Ketoconazole. A 39-year-old woman taking terfenadine 60 mg twice daily developed a number of episodes of syncope and light-headedness, preceded by palpitations, dyspnoea and diaphoresis, within 2 days of starting to take ketoconazole 200 mg twice daily. ECG monitoring revealed torsade de pointes and a QTc interval of 655 milliseconds. Her terfenadine serum levels were 57 nanograms/mL (levels expected to be 10 nanograms/mL or less). Other drugs being taken were cefaclor (stopped 3 to 4 days before the problems started) and medroxyprogesterone acetate. She had taken terfenadine and cefaclor on two previous occasions in the absence of ketoconazole without problems.[16,17] Other cases of an interaction between terfenadine and ketoconazole have also been reported.[18,19]

4. Oxiconazole. A 25-year-old woman complained of palpitations and chest pain radiating down her left arm, and was also found to be having frequent ventricular premature beats in a pattern of bigeminy. On questioning it turned out that she was taking terfenadine and using topical oxiconazole for ringworm on her arm. Both drugs were stopped and her symptoms disappeared the following week.[20]

Mechanism

Astemizole and terfenadine are known to be metabolised by the cytochrome P450 isoenzyme CYP3A4. The azole antifungals are known inhibitors of this isoenzyme, with ketoconazole having potent effects, and fluconazole in low doses having modest effects. Concurrent use of these antihistamines and the azoles therefore leads to increased antihistamine levels. High serum levels of astemizole and terfenadine (but not its metabolites) block cardiac potassium channels leading to prolongation of the QT interval, which may precipitate the development of torsade de pointes (see 'Table 15.2', (p.664)). The risk of cardiac arrhythmias with other non-sedating antihistamines appears to be non-existent or very much lower (see 'Table 15.2', (p.664)), so any pharmacokinetic interactions do not result in clinically relevant cardiac toxicity. In fact, studies have shown that desloratadine at nine times the recommended dose,[21] fexofenadine in overdose,[5,22] and mizolastine at four times the recommended dose[23] do not affect the QT interval. However, some questions remain about loratadine and ebastine. Additionally, some studies have reported that ketoconazole alone is associated with a small increase in QT interval,[6] and at least one case of torsade de pointes has been reported for ketoconazole alone.[24] Therefore the cardiac effects of ketoconazole may be additive with those of the antihistamines, and this may be important for ebastine and loratadine.

In vitro studies have suggested that rupatadine is mainly metabolised by CYP3A4.[25] Therefore its levels are raised by the azoles. Fexofenadine is not metabolised by CYP3A4, but it is a substrate for P-glycoprotein and OATP,[26] therefore azole antifungals may increase its levels by inhibiting drug transporter proteins.

Importance and management

The interactions of astemizole and terfenadine with the azoles are established and clinically important, although much of the evidence for particular pairs of these antihistamines and the azoles is indirect. The incidence of an interaction is probably low, but because of the potential severity and unpredictability of this interaction, the concurrent use of astemizole and terfenadine is contraindicated with all azole antifungals in all patients. Note that a large proportion of **miconazole** oral gel (both prescription and

Table 15.3 Summary of the effects of azoles on the pharmacokinetics and cardiovascular effects of non-sedating antihistamines

Antihistamine (Oral unless specified)	*Azole (Oral unless specified)*	*Duration of combined use (days)*	*Subjects*	*Cmax increase‡*	*AUC increase*	*Effect on QTc*	*Refs*
Astemizole* 10 mg single dose	Itraconazole 200 mg twice daily	Single dose	12 healthy subjects	No change	82%	No change	1

non-prescription doses) may be swallowed and therefore adequate systemic absorption may occur to produce an interaction. A similar effect was seen in one case with topical oxiconazole. Note that, the UK manufacturer of terfenadine extended this contraindication to the concurrent use of topical azoles.[27] However, the US manufacturer of fluconazole contraindicates the concurrent use of terfenadine with daily doses of fluconazole 400 mg or greater, but only advises careful monitoring with fluconazole doses below 400 mg.[9]

The use of azole antifungals with mizolastine is also contraindicated,[28] and the manufacturer of ebastine advises against the concurrent use of ketoconazole and itraconazole.[29] Similarly, the manufacturer of rupatadine[25] advises that it should be used with caution with ketoconazole, and other inhibitors of CYP3A4, which would include all the azoles. Because there are no data on **acrivastine** with ketoconazole, the manufacturer advises caution.[30]

Ketoconazole markedly raises loratadine levels. In one study, this was associated with a small increase in QT interval, but no obvious alteration in adverse event profile. No special precautions appear to have been recommended for the use of loratadine with azoles.

Desloratadine, emedastine and fexofenadine levels are raised by ketoconazole but because this does not result in adverse cardiac effects concurrent use is considered safe. Azelastine, cetirizine (and therefore probably its isomer **levocetirizine**) and levocabastine seem to be free from clinically significant pharmacokinetic interactions, and have no cardiac effects, and so may therefore provide suitable alternatives if a non-sedating antihistamine is needed in a patient taking azole antifungals.

Antihistamines + Benzodiazepines and related drugs

Benzodiazepines impair psychomotor performance, but astemizole, ebastine, mizolastine and terfenadine (non-sedating antihistamines) do not further impair this. An enhanced sedative effect would be expected if known sedative antihistamines are given with benzodiazepines. Diphenhydramine does not alter the pharmacokinetics of zaleplon, but it did enhance the sedative effects of diazepam in one study.

Clinical evidence

(a) Astemizole

A study in 32 healthy subjects found that a single 10-mg dose of astemizole did not enhance the effects of a single 10-mg dose of **diazepam**.[1]

(b) Diphenhydramine

1. Diazepam. A study in 13 healthy subjects who took diphenhydramine 50 mg twice daily for 5 days, with a single 300-microgram/kg dose of diazepam on day 5 found no additive effects on sedation or the performance of a number of psychomotor tests. The plasma levels of diazepam measured 100 minutes after administration were increased by 39%, but this was not statistically significant. It was suggested that the subjects may have developed tolerance to the sedative effects of the antihistamine.[2]
Oral administration of diazepam 10 mg with diphenhydramine 100 mg impaired psychomotor performance compared with diazepam alone, up to 4 hours after the two drugs had been taken. Subjects noted a significant feeling of drunkenness after taking diazepam and diphenhydramine together which persisted for 4 hours. This feeling persisted for about 2 hours after taking diazepam alone.[3]

2. Zaleplon. A randomised, single-dose study in healthy subjects found that diphenhydramine 50 mg had no significant effect on the pharmacokinetics of a single 10-mg dose of zaleplon, despite the fact diphenhydramine is a moderate inhibitor of the primary metabolic pathway [aldehyde oxidase] of zaleplon.[4]

(c) Ebastine

In 12 healthy subjects ebastine 20 mg daily did not impair the performance of a number of psychomotor tests, although body sway and flicker fusion tests were altered. When ebastine was given with a single 15-mg dose of **diazepam**, it did not further impair performance, when compared with diazepam alone, and did not alter plasma **diazepam** levels.[5]

(d) Mizolastine

Mizolastine appears to lack sedative effects, and does not have a detrimental effect on psychomotor performance.[6] A single 2-mg dose of oral **lorazepam** was found to impair the performance of psychomotor tests in 16 healthy subjects, and caused some sedation and amnesia, but these effects were not changed when the subjects also took mizolastine 10 mg daily for 8 days.[6]

(e) Terfenadine

A study in 20 healthy subjects found that the concurrent use of **diazepam** 10 mg with terfenadine 120 mg had no effect on psychomotor performance.[3]

Mechanism, importance and management

A number of older antihistamines cause sedation, and this would be expected to be increased by some of the benzodiazepines by the simple addition of their CNS depressant effects. Non-sedating antihistamines would not be expected to have this effect (but see also ‘Antihistamines’, (p.663)), and this has been confirmed for astemizole, ebastine, mizolastine and terfenadine.

Antihistamines + Drugs that prolong the QT interval

Astemizole and terfenadine should generally not be used with other drugs that can also prolong the QT interval. The manufacturer of mizolastine issues the same advice. One early study found that hydroxyzine caused ECG abnormalities in high doses. The authors suggested that its use with other drugs that can cause cardiac abnormalities might increase the likelihood of arrhythmias and sudden death, but there is no published evidence of this. A retrospective review has confirmed that patients taking astemizole or terfenadine with inhibitors of CYP3A4 are exposed to an increased risk of ventricular arrhythmias.

Clinical evidence, mechanism, importance and management

(a) Non-sedating antihistamines

A review of data on the use of five non-sedating antihistamines (**acrivastine**, **astemizole**, **cetirizine**, **loratadine** and **terfenadine**) from the UK General Practice Research Database showed a relative risk of ventricular arrhythmias of 4.2 compared to non-use. It did not identify a higher risk of ventricular arrhythmias following terfenadine use than following use of the other non-sedating antihistamines. The relative risk of developing a ventricular arrhythmia was highest during astemizole use (19). Within the data used for this study there were no cases of ventricular arrhythmias in patients taking terfenadine and CYP3A4 inhibitors.[1] The authors concluded that the absolute risk of ventricular arrhythmias with the use of one of these drugs alone, was quite small. However, in the presence of other drugs that prolong the QT interval, the risk may be larger. The manufacturers of **astemizole**[2] and **terfenadine**[3] contraindicated the concurrent use of any other drugs that can also prolong the QT interval (for a list, see 'Table 9.2', (p.290)). However, the primary risk of QT prolongation and torsade de pointes with **astemizole** and **terfenadine** appears to be from drugs that significantly inhibit their metabolism (e.g. 'azoles', (p.665) and 'macrolides', (p.671)). Clinically relevant QT prolongation has not yet been shown conclusively for any of the other antihistamines (see 'Table 15.2', (p.664)), although the manufacturers of **mizolastine**[4] still contraindicate its use with drugs that prolong the QT interval. Isolated cases have been described with other antihistamines: a case report of torsade de pointes with sotalol and '**terfenadine**', (p.1024) was attributed solely to additive effects of QT prolongation with these drugs; and a small additional QT-prolonging effect has also been shown when **terfenadine** was given with 'sparfloxacin', (p.676). A case report describes a 73-year-old woman taking amiodarone for atrial fibrillation, who was given **loratadine**, and developed syncope and multiple episodes of torsade de pointes.[5] In a review of torsade de pointes in patients taking amiodarone long-term, two elderly female patients taking amiodarone 200 mg daily developed torsade de pointes 2 days and 7 days, respectively, after **loratadine** 10 mg daily was added.[6] Amiodarone may have inhibited the metabolism of **loratadine** by the cytochrome P450 isoenzyme CYP3A4; however, even in high-dose **loratadine** dose not appear to affect the QT interval. The general clinical relevance of these cases is uncertain, but the authors consider that the QT interval should be monitored if **loratadine** is given with other drugs that may potentially prolong the QT interval.[5]

A retrospective review of a cohort of 14 638 patients with urinary incontinence diagnosed between January 1991 and June 1995, identified that there was a significant association between the use of non-sedating antihistamines (**terfenadine** and **astemizole**) with drugs that are inhibitors of cytochrome P450 isoenzyme CYP3A4 and the incidence of ventricular arrhythmias, with an adjusted relative risk of 5.47. This combination was also shown to carry a significant risk of sudden death (relative risk 21.5).[7]

Consider also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290.

(b) Sedating antihistamines

A study, conducted in 1958, in 25 elderly patients with psychoses, taking high-dose **hydroxyzine** 300 mg daily over a 9-week period, found that ECG changes were mild, except for an alteration in T waves, which were definite in 9 patients. In each case the T waves were lower in altitude, broadened and flattened and sometimes notched. The QT interval was usually prolonged. A repeat of the study in a few patients, at least one given **hydroxyzine** 400 mg, found similar effects, the most pronounced change being a marked attenuation of cardiac repolarisation. On the basis of these observations the authors suggest that other drugs that cause ECG abnormalities such as thioridazine might aggravate and exaggerate these **hydroxyzine**-induced changes and increase the risk of sudden death.[8] However, note that in the decades of use of **hydroxyzine** since this study was conducted there appear to be only a few isolated reports of arrhythmias (tachycardia) associated with its use.[9,10] Note also that some manufacturers do not give any warnings regarding the use of **hydroxyzine** in patients with cardiac disorders, nor are any cardiac adverse effects mentioned, even for overdose.[11,12] However, one manufacturer does suggest that caution is necessary in patients pre-disposed to arrhythmias, or taking drugs that may cause arrhythmias.[13]

Antihistamines + Food

The pharmacokinetics of cetirizine, desloratadine, loratadine and rupatadine are not affected to a clinically relevant extent by food.

Clinical evidence, mechanism, importance and management

(a) Cetirizine

The manufacturer of cetirizine notes that the extent of absorption of cetirizine is unaffected by food, but the rate of absorption is decreased.[1] This is not expected to be clinically relevant.

(b) Desloratadine

A study in 18 healthy subjects found no difference in the pharmacokinetics of a single 7.5-mg dose of desloratadine taken after a 10-hour fast, or after a high-fat, high-calorie breakfast.[2]

(c) Loratadine

In a study, 24 healthy subjects were given a single 10-mg dose of extended-release loratadine after a 10-hour fast, or with a high-fat, high-calorie breakfast. Food increased the maximum plasma levels of loratadine by 53% and the AUC by 76%. However, this was not considered to be clinically significant, and there was no significant difference in the reporting of adverse effects between the two groups.[3] The UK manufacturer of an immediate-release preparation of loratadine notes that food can slightly delay the absorption of loratadine, but that this has no clinical effect.[4]

(d) Rupatadine

In a crossover study, 24 healthy subjects were given a single 20-mg dose of rupatadine after a high-fat breakfast, or when fasting. When taken with food, the AUC and half-life of rupatadine increased by 26% and 72%, respectively. The time to reach maximum plasma levels increased by 133%, although the maximum plasma levels were not significantly affected. The pharmacokinetics of desloratadine and 3-hydroxydesloratadine, two active metabolites of rupatadine, were not significantly affected by the presence of food. There was no apparent difference in the prevalence or

severity of adverse effects between the two groups.[5] The UK manufacturer states that rupatadine may be taken without regard to food.[6]

Antihistamines + Grapefruit and other fruit juices

Grapefruit juice raises terfenadine levels, increasing the risk of QT interval prolongation and torsade de pointes. Grapefruit juice does not appear to alter the pharmacokinetics of astemizole and desloratadine. The absorption of fexofenadine is modestly reduced by grapefruit juice, orange juice and apple juice.

Clinical evidence

(a) Astemizole

In a study in 12 healthy subjects the steady-state pharmacokinetics of astemizole 30 mg daily for 4 days, then 10 mg daily for the next 20 days, were unaffected by 200 mL of **grapefruit juice** given every 4 hours.[1]

(b) Desloratadine

The bioavailability of a single 5-mg dose of desloratadine was unaffected by 8 oz (240 mL) of double-strength **grapefruit juice**, which was given three times daily for 2 days before the desloratadine and then 5 minutes before and 2 hours after the dose.[2]

(c) Fexofenadine

A study in 12 healthy subjects found that a single 300-mL dose of normal strength **grapefruit juice** reduced the AUC of a single 120-mg dose of fexofenadine by 42% when they were given simultaneously.[3] An effect was apparent for 300 mL of **grapefruit juice** given up to 10 hours before fexofenadine 120 mg in at least some of the subjects involved in this study.[4] In a study in 23 healthy subjects the AUC of fexofenadine 60 mg was reduced by 30% by 8 oz (about 240 mL) of double-strength **grapefruit juice**, which was given three times daily for 2 days before the fexofenadine and then 5 minutes before and 2 hours after the dose.[2] Similarly, another study found that **grapefruit juice** at normal strength decreased the AUC of a single 120-mg dose of fexofenadine by 67%. Dilute **grapefruit juice** (25%) caused a smaller reduction in the AUC of fexofenadine of 23%. Normal strength **orange juice** and **apple juice** similarly decreased the AUC of fexofenadine by 72% and 77% respectively.[5] In this study, 300 mL of juice was given with the fexofenadine, followed by 150 mL every 30 minutes to a total volume of 1.2 litres.

(d) Rupatadine

The manufacturer of rupatadine notes that the concurrent use of grapefruit juice increases the systemic exposure of rupatadine 3.5-fold.[6]

(e) Terfenadine

Terfenadine 60 mg was given to 6 healthy subjects every 12 hours for 14 days, simultaneously with 240 mL of double-strength **grapefruit juice** every 12 hours for the final 7 days. Terfenadine was only detectable in the plasma when **grapefruit juice** was taken. The mean QTc interval was found to have risen from 420 to 434 milliseconds,[7] which is not of a magnitude usually considered to be clinically significant. The effects were less pronounced in a further 6 subjects who took the **grapefruit juice** 2 hours after the terfenadine.[7] Several other reports confirm these pharmacokinetics findings, although some did not find any changes in the QTc interval.[8-10]

Mechanism

Not fully understood, but it seems likely that some component of grapefruit juice inhibits the metabolism of the terfenadine to its active metabolite (by the cytochrome P450 isoenzyme CYP3A4), so that the parent drug accumulates.[9] Terfenadine, but not its metabolite, causes QTc prolongation. Increased QTc intervals are associated with the development of torsade de pointes and ventricular tachycardia, which is potentially life-threatening.

Fexofenadine is a substrate for P-glycoprotein, and organic anion transporting polypeptide (OATP), and changes in their function may affect fexofenadine uptake. OATP in particular may be inhibited by grapefruit juice, apple juice, and orange juice, so these juices may reduce fexofenadine levels by preventing its absorption.[5]

Importance and management

The interaction between terfenadine and grapefruit juice is established and potentially clinically important. However, the serious cardiac effects may only occur in a small subset of individuals. As of 1996 neither the FDA nor the CSM appeared to have reports of problems in patients that were attributable to the use of antihistamines and grapefruit juice,[8,11] although in 1997 the CSM had one report of a probable interaction with terfenadine.[12] Nevertheless because of the risk of serious cardiotoxicity (however small) it would be prudent for all patients taking terfenadine to avoid grapefruit juice: the UK manufacturer contraindicated concurrent use.[13] The manufacturer of rupatadine advises that grapefruit juice should not be taken simultaneously,[6] and the manufacturer of acrivastine advises caution but notes that there are no data to demonstrate an interaction.[14]

The evidence from healthy subjects suggests that astemizole does not interact with grapefruit juice, but it is possible that individuals predisposed to cardiac conduction disorders are at risk.

Further study is required to determine the clinical relevance, if any, of the reductions in fexofenadine bioavailability in the presence of grapefruit juice, orange juice, and apple juice. Consider this interaction as the cause if fexofenadine seems less effective than expected. Note that the amounts of fruit juice consumed in the study were quite large (1.2 litres). Desloratadine appears to be a safe alternative.

Antihistamines + H_2-receptor antagonists

No pharmacokinetic interaction appears to occur when cimetidine is given with cetirizine, desloratadine, ebastine or terfenadine, or when ranitidine is given with terfenadine or chlorphenamine. However, an isolated case report describes torsade de pointes in one patient taking terfenadine with cimetidine. Cimetidine moderately raises hydroxyzine levels and considerably raises loratadine levels. The renal clearance of fexofenadine was reduced by cimetidine in one study.

Clinical evidence

A. Non-sedating antihistamines

(a) Cetirizine

Cetirizine 10 mg was given to 8 patients with chronic urticaria before and after they took **cimetidine** 600 mg every 12 hours for 10 days. The pharmacokinetics of cetirizine were statistically unaltered and its effects remained unchanged.[1]

(b) Desloratadine

In a parallel study in 18 healthy subjects, **cimetidine** 600 mg every 12 hours had little effect on the pharmacokinetics of desloratadine 5 mg daily. The desloratadine AUC was increased by about 20% and its maximum level was increased by about 10%,[2,3] but there was no change in ECG parameters, including the QTc interval.[2]

(c) Ebastine

In a study in 12 healthy subjects, **cimetidine** had no significant effect on the conversion of single 20-mg doses of ebastine to its active metabolite, carebastine, and there was no evidence of sedation or other adverse effects. In this study **cimetidine** was given as 2 g in divided doses the day before the ebastine dose and 400 mg four times daily both on the day of, and the day after, the ebastine dose.[4]

(d) Fexofenadine

In 12 healthy subjects, **cimetidine** 400 mg twice daily for 6 days did not cause any changes in the plasma pharmacokinetics of a single 120-mg dose of fexofenadine. However, the renal clearance of fexofenadine was decreased by 39%.[5]

(e) Loratadine

In a study, 24 healthy subjects were given loratadine 10 mg and **cimetidine** 300 mg every 6 hours, alone and together for 10 days. The AUCs of loratadine and its metabolite were increased by 103% and 6%, respectively, but the safety profile of loratadine (clinical laboratory tests, vital signs and adverse events) was unchanged. Cardiac repolarisation and all other ECG measurements were unaltered, and no sedation or syncope were seen.[6]

(f) Terfenadine

In 12 healthy subjects, **cimetidine** 1.2 g daily for 5 days had no effect on the pharmacokinetics of a single 120-mg dose of terfenadine.[7] Another study in two groups of 6 healthy subjects found that **cimetidine** 600 mg every 12 hours or **ranitidine** 150 mg every 12 hours had no effect on the pharmacokinetics of terfenadine 60 mg every 12 hours. No adverse ECG changes were seen.[8] However, an isolated case report describes a 63-year-old woman who had 8 episodes of syncope (later identified as being due to torsade de pointes) and a convulsion 2 days after starting to take terfenadine 60 mg twice daily and **cimetidine** 400 mg twice daily. She was also taking chlorphenamine and co-proxamol (paracetamol (acetaminophen) and dextropropoxyphene (propoxyphene)).[9]

B. Sedating antihistamines

(a) Chlorphenamine

A study in healthy subjects found that the pharmacokinetics of a single 4-mg dose of chlorphenamine were unaffected by **ranitidine** 75 mg twice daily for 6 days.[10]

(b) Hydroxyzine

In one study, 8 patients with chronic urticaria were given hydroxyzine 25 mg before and after taking **cimetidine** 600 mg every 12 hours for 10 days. The **cimetidine** increased the AUC of hydroxyzine by 33% and also increased its suppression of the wheal and flare response (although this was not statistically significant).[1] A previous study in 7 patients found that **cimetidine** raised serum hydroxyzine levels.[11]

Mechanism

Cimetidine is a non-specific cytochrome P450 isoenzyme inhibitor, but it would seem that in most cases, with the exception of loratadine, these enzyme inhibitory effects do not significantly affect the metabolism of antihistamines. More recent evidence has shown that cimetidine can also affect drug transporter proteins, in particular it may inhibit organic cation transporters. However, it probably does not affect anion transporter proteins since it does not affect the plasma pharmacokinetics of fexofenadine, which is a substrate of these transporters.[5]

Importance and management

There would seem to be no good reason for avoiding the concurrent use of either cetirizine, ebastine, fexofenadine, hydroxyzine, or loratadine with cimetidine, or chlorphenamine with ranitidine, nor would any of the other H_2-receptor antagonists be expected to interact with any of these antihistamines.

The situation with terfenadine and cimetidine is not totally clear because of the isolated case report of toxicity cited here, but currently there is not enough evidence to advise against the concurrent use of these two drugs. The manufacturer of **mizolastine** recommends caution on the concurrent use of cimetidine,[12] with the implication that cimetidine might increase mizolastine levels and prolong the QT interval. This is a cautious approach because a link between mizolastine and cardiac arrhythmias has not been proven.

Antihistamines + Macrolides

Erythromycin causes terfenadine and astemizole to accumulate in a few individuals, which can prolong the QT interval and lead to life-threatening torsade de pointes arrhythmias. Other macrolides are believed to interact similarly, with the exception of azithromycin and possibly dirithromycin.

Erythromycin markedly raised ebastine levels, which caused a modest prolongation of the QT interval. Erythromycin also raises mizolastine and rupatadine levels, without affecting the QT interval. Acrivastine may interact similarly. The situation with erythromycin and loratadine is unclear as one study found that the combination caused a very slight increase in QT interval.

Both azithromycin and erythromycin raise fexofenadine levels, but this has no effect on the QT interval, or on adverse events. Azelastine, cetirizine, desloratadine, and intranasal levocabastine seem to be free of clinically relevant interactions with macrolides. An isolated case describes torsade de pointes possibly due to the use of spiramycin with mequitazine.

Clinical evidence

The effect of various macrolides on the plasma levels of the non-sedating antihistamines, and their cardiac effects from controlled studies are summarised in 'Table 15.4', (p.672). The subsections below include data from case reports and other studies.

(a) Astemizole

An 87-year-old woman collapsed suddenly in her kitchen 4 days after starting to take astemizole 10 mg daily and **erythromycin** twice daily [dose unknown]. An ECG showed her to be having multiple episodes of torsade de pointes, the longest of which lasted 17 seconds. Her QTc was 720 milliseconds and she was mildly hypokalaemic. She was given a temporary pacemaker and when she was eventually discharged with a normal sinus rhythm, her QTc had fallen to 475 milliseconds.[1] A second case report describes a 30-year-old woman who took

Table 15.4 Summary of the effect of macrolides on the pharmacokinetics and cardiovascular effects of non-sedating antihistamines

Antihistamine	*Macrolide*	*Duration of combined use (days)*	*Subjects*	*Cmax increase*[†]	*AUC increase*	*Effect on QTc*	*Refs*
Astemizole* 30 mg single dose	Dirithromycin 500 mg daily	Single dose of antihistamine	18 healthy subjects	No change	36%	No change	1
Astemizole 200 micrograms/kg daily	Erythromycin 50 mg/kg per day	14	10 patients aged 5 to 12 years			No significant change with Bazett's correction	2
Azelastine* 4 mg twice daily	Erythromycin 500 mg three times daily	7	8 healthy subjects	No change	No change	No change	3
Cetirizine 20 mg daily	Azithromycin 500 mg day 7 and 250 mg daily days 8 to 11	5	14 healthy subjects	No change	No change	No change	4
Cetirizine 20 mg daily	Erythromycin 500 mg three times daily	10	Healthy subjects	No change	No change	No change	3
Cetirizine 10 mg daily in children over 30 kg	Erythromycin 50 mg/kg per day	14	10 patients aged 5 to 12 years	No change	No change	No significant change with Bazett's correction	2
Desloratadine 5 mg daily	Azithromycin 500 mg, then 250 mg daily	5	18 healthy subjects	No change	No change	No change	4
Desloratadine 7.5 mg daily	Erythromycin 500 mg three times daily	10	24 healthy subjects	20%	10%	No change	5
Ebastine 20 mg daily	Erythromycin 2.4 g daily	10	30 healthy subjects	119% Similar changes found for carebastine	164% Similar changes found for carebastine	Mean increase of 19.6 milliseconds	6
Fexofenadine 60 mg twice daily	Azithromycin 500 mg, then 250 mg daily	5	18 healthy subjects	69%	67%	No change	4
Fexofenadine 120 mg twice daily	Erythromycin 500 mg three times daily	7	24 healthy subjects	82%	109%	No change	7
Levocabastine 200 micrograms twice daily intranasal	Erythromycin 333 mg single dose	Single dose of macrolide	38 healthy subjects	No change	No change	No change	8
Loratadine 10 mg daily	Clarithromycin 500 mg twice daily	10	24 healthy subjects	36% loratadine 69% descarbo-ethoxyloratadine	76% loratadine 49% descarbo-ethoxyloratadine	Mean increase of 4 milliseconds. Maximum QTc 439 milliseconds	9
Loratadine 10 mg daily	Erythromcyin 500 mg three times daily	10	24 healthy subjects	53% loratadine 61% descarbo-ethoxyloratadine	40% loratadine 46% descarbo-ethoxyloratadine	No change	10
Loratadine 5 mg daily for children less than 30 kg; 10 mg daily for children greater than or equal to 30 kg	Erythromcyin 50 mg/kg per day	14	10 patients aged 5 to 12 years			No significant change with Bazett's correction	2
Mizolastine 10 mg daily	Erythromycin 1 g twice daily	6	12 healthy subjects	40%	53%	No change	11
Terfenadine* 60 mg twice daily	Azithromycin 500 mg, then 250 mg daily	5	Healthy subjects	Terfenadine undetectable. No change in terfenadine acid metabolite	No change in terfenadine acid metabolite	No change	12, 13

astemizole 10 mg twice daily with **erythromycin** 250 mg every 6 hours for 3 days and developed syncope, which was shown to be due to torsade de pointes.[2] This patient was known to have congenital long QT syndrome, and had previously experienced syncope when taking astemizole, and therefore in this case an interaction is not established.

(b) Mequitazine

A 21-year-old woman with congenital long QT syndrome had several syncopal attacks, at least one of which was caused by torsade de pointes. This was attributed to the concurrent use of mequitazine and **spiramycin** over a 2-day period. The problem resolved when the drugs were withdrawn.[3]

(c) Rupatadine

1. Azithromycin. In a study, 24 healthy subjects were given rupatadine 10 mg daily for 6 days with azithromycin, 500 mg on day 2 and 250 mg daily thereafter. There were no clinically significant changes in the pharmacokinetics of rupatadine or its metabolites.[4]

2. Erythromycin. The systemic exposure to rupatadine was increased two- to threefold when rupatadine 20 mg was taken with erythromycin 500 mg three times daily for 7 days. There were no clinically relevant changes in the QT interval, vital signs or adverse effects.[5]

(d) Terfenadine

1. Erythromycin. An 18-year-old girl who was taking terfenadine 60 mg twice daily and erythromycin 250 mg every 6 hours, fainted while at school and, when later hospitalised, was seen to have repeated episodes of ventricular tachycardia and ventricular fibrillation requiring resuscitation. Later she was also noted to have torsade de pointes. Her QTc interval was found to be prolonged at 630 milliseconds. The drugs were withdrawn and 9 days later, after a period in intensive care, she was discharged symptom-free with a normal QTc interval.[6] A further case describes a 63-year-old man who had taken terfenadine 240 mg each day and erythromycin 2 g each day for 3 days, and subsequently experienced three syncopal episodes in one day. An ECG showed a prolonged QT interval and torsade de pointes, which resolved after intravenous magnesium sulphate was given.[7] In contrast, a retrospective report found no documented cardiac adverse events in 92 patients who had received erythromycin and terfenadine.[8]

2. Troleandomycin. A woman taking terfenadine 60 mg three times daily developed torsade de pointes and a prolonged QTc interval when troleandomycin 500 mg three times daily was added. She recovered when both were stopped, but again developed a significantly prolonged QTc interval when both were restarted.[9]

Mechanism

Some macrolides (particularly erythromycin and clarithromycin) appear to reduce the metabolism of terfenadine and astemizole by inhibition of the cytochrome P450 isoenzyme CYP3A4.[10,11] High serum levels of astemizole and terfenadine cause a prolongation of the QT interval and may precipitate the development of torsade de pointes, see 'Table 15.2', (p.664). The risk of cardiac arrhythmias with other non-sedating antihistamines appears to be non-existent or very much lower (see 'Table 15.2', (p.664)), so any pharmacokinetic interactions do not result in clinically relevant cardiac toxicity. In fact, studies have shown that fexofenadine in overdose,[12,13] and mizolastine at four times the recommended dose[14] do not affect the QT interval. However, some questions remain about mizolastine and ebastine. Erythromycin may increase the absorption and decrease the biliary secretion of fexofenadine[13] by an effect on drug transporters: this leads to an increase in fexofenadine levels. *In vitro* studies have suggested that rupatadine is mainly metabolised by CYP3A4.[15]

Importance and management

The interactions of **terfenadine** with erythromycin, clarithromycin, and troleandomycin; and **astemizole** with erythromycin are established, clinically important and potentially hazardous. From the reports above it does seem that only a very few individuals develop a clinically important adverse interaction with these macrolides, but identifying them in advance is not often practical or possible. Because of the unpredictability and potential severity of this interaction, the FDA in the US,[8] the CSM in the UK,[16] and the manufacturers of terfenadine[17] and astemizole[18] contraindicated macrolides in anyone taking terfenadine or astemizole. The only exception to this was azithromycin with astemizole.[18] The manufacturer of terfenadine extended this contraindication to the concurrent use of topical macrolides.[17]

The manufacturer of **mizolastine** also contraindicates the concurrent use of the macrolides,[19] although evidence of a clinically significant interaction appears to be lacking. Erythromycin markedly raises **ebastine** levels causing a modest increase in QT interval. The manufacturer of ebastine advises against concurrent use of the macrolides erythromycin, clarithromycin and josamycin.[20] The manufacturer of **rupatadine**[15] advises that it should be used with caution with erythromycin, and other inhibitors of CYP3A4, which would include a number of the macrolides. Because there are no data on **acrivastine** with erythromycin, the manufacturer advises caution.[21] Erythromycin also raises **loratadine** levels, which caused a very slight increase in QTc interval in one study. However, no special precautions appear to have been recommended for the use of loratadine with macrolides; high levels of loratadine are usually considered to be safe.

Fexofenadine levels are raised by both azithromycin and erythromycin but because this does not result in adverse cardiac effects concurrent use is considered safe. **Azelastine**, **cetirizine** (and therefore probably its isomer **levocetirizine**) **desloratadine** and **levocabastine** seem to be free from clinically significant pharmacokinetic interactions, and have no cardiac effects, and so may therefore provide suitable alternatives if a non-sedating antihistamine is needed in a patient taking macrolides.

The isolated case with **mequitazine** is unlikely to be of general importance, as this sedating antihistamine is not usually associated with causing ventricular arrhythmias.

Antihistamines + Nefazodone

Nefazodone inhibits the metabolism of terfenadine and thereby prolongs the QT interval. Astemizole may interact similarly. There is also some evidence that the combination of nefazodone and loratadine increases the QT interval, although to a lesser extent than terfenadine.

Clinical evidence, mechanism, importance and management

(a) Astemizole

The manufacturers of nefazodone and astemizole noted that an *in vitro* study suggests that nefazodone may increase astemizole levels. The UK manufacturer contraindicated concurrent use.[1,2] This seems prudent because raised levels of astemizole with other inhibitors of the cytochrome P450 isoenzyme CYP3A4 such as the macrolides (see 'Antihistamines + Macrolides', p.671), have been rarely associated with life-threatening torsade de pointes.

(b) Loratadine

A randomised, placebo-controlled study in healthy subjects found that when they were given nefazodone 300 mg twice daily with loratadine 20 mg daily, the loratadine AUC was increased by 39%. Similarly, the QTc interval was increased by 21.6 milliseconds by the combination, which was about half the increase seen with terfenadine 60 mg twice daily given with the same dose of nefazodone. Neither nefazodone or loratadine alone prolonged the QTc interval.[3] The findings for loratadine in this study were unexpected, as this antihistamine was considered to have no clinically relevant effect on the QT interval (but see also 'Table 15.2', (p.664)). The use of the Bazett formula to calculate QTc has been questioned,[4] but this is the most commonly used formula, and any overestimation would also apply to terfenadine. This appears to be the only study to have directly compared loratadine with terfenadine, and although it shows that loratadine at twice the recommended dose has half the QT-prolonging effect of terfenadine (at the maximum recommended dose), it nevertheless raises questions about the cardiac safety of loratadine.[4,5] Further study is needed.

(c) Terfenadine

In a randomised, placebo-controlled study, healthy subjects were given nefazodone 300 mg twice daily and terfenadine 60 mg twice daily, alone and in combination. Nefazodone increased the AUC of terfenadine about fivefold, which was associated with a mean increase in the QTc interval of 42.4 milliseconds. This was considered to result in a clinically significant increase in the risk of torsade de pointes.[3] This effect probably occurred because nefazodone inhibits the cytochrome P450 isoenzyme by which terfenadine is metabolised. Both nefazodone and terfenadine have largely been withdrawn from the market, but the combination was commonly contraindicated,[1,6] and it has been suggested that this contraindication explains the lack of clinical reports.[7]

Antihistamines + Protease inhibitors

Nelfinavir markedly increases terfenadine levels, which is expected to increase the risk of QT prolongation and torsade de pointes arrhythmias. Other protease inhibitors are predicted to interact similarly with terfenadine, astemizole and mizolastine. Ritonavir modestly increases cetirizine levels. Ritonavir and ritonavir-boosted lopinavir raise the levels of fexofenadine. Nelfinavir and hydroxyzine have been used together without adverse effects.

Clinical evidence, mechanism, importance and management

(a) Astemizole

Protease inhibitors are inhibitors of the cytochrome P450 isoenzyme CYP3A4, by which astemizole is metabolised. On the basis of the interaction of astemizole with other CYP3A4 inhibitors, such as the 'azoles', (p.665), the concurrent use of astemizole with any protease inhibitor was contraindicated.[1] This seems a sensible precaution.

(b) Cetirizine

In a study in 16 healthy subjects the concurrent use of cetirizine 10 mg daily and **ritonavir** 600 mg twice daily for 4 days (after reaching steady-state **ritonavir** levels), increased the AUC of cetirizine by 42% with a slight 9% increase in maximum plasma levels. It was suggested that **ritonavir** may have decreased the renal excretion of cetirizine. The increase in cetirizine levels was not considered to be clinically relevant. **Ritonavir** pharmacokinetics were minimally affected by cetirizine.[2]

(c) Fexofenadine

In a study, 12 healthy subjects took **ritonavir** in increasing doses up to 400 mg twice daily for 2 weeks, followed by a single 60-mg dose of fexofenadine. The maximum plasma levels of fexofenadine were increased by 60% and its AUC was increased 2.8-fold after the subjects took **ritonavir** 200 mg three times a day for one day, but after steady-state was attained, **ritonavir** increased the AUC of fexofenadine by 40%, and the increase in its plasma levels was not significant.[3] Similarly in a study in 8 healthy subjects the median AUC and maximum plasma levels of fexofenadine were increased 2.7-fold and 2.2-fold, respectively by **ritonavir**.[4] An extension to this study in 16 healthy subjects who took a single 120-mg dose of fexofenadine before, and after taking **ritonavir**-boosted **lopinavir** 100/400 mg daily for 11 days found that the median AUC and maximum plasma level of fexofenadine were increased 3.5-fold and 3-fold, respectively. The pharmacokinetics of fexofenadine were evaluated in 8 of the subjects in this study after a single dose of **ritonavir**-boosted **lopinavir**: the increase in median AUC and maximum plasma level was 4-fold and 3.8-fold, respectively.[4]

However, the marked increases in fexofenadine levels seen in studies with 'erythromycin', (p.671), and 'ketoconazole', (p.665), did not increase the adverse effects of fexofenadine and were not associated with any prolongation of the QT interval. This suggests that a clinically relevant interaction between **ritonavir** or **ritonavir**-boosted **lopinavir** and fexofenadine is unlikely.

(d) Hydroxyzine

A report describes the uneventful use of hydroxyzine in 10 HIV-positive children, who had developed a rash thought to be related to **nelfinavir** use.[5]

(e) Mizolastine

The manufacturers of mizolastine suggest that, because of the effects of ketoconazole and erythromycin, which raise mizolastine levels, the concurrent use of other potent inhibitors of the cytochrome P450 isoenzyme CYP3A4 with mizolastine should be approached with caution.[6] Although not specifically named, this would be expected to include the protease inhibitors.

(f) Terfenadine

Nelfinavir 750 mg every 8 hours for 5 days raised the levels of a single 60-mg dose of terfenadine from less than 5 nanograms/mL to a range of 5 to 15 nanograms/mL. The pharmacokinetics of **nelfinavir** were unaffected.[7] This rise in terfenadine levels is predicted to prolong the QT interval, and to increase the risk of torsade de pointes. On the basis of what is known about interactions with other inhibitors of the cytochrome P450 isoenzyme CYP3A4 such as the 'azoles', (p.665), all protease inhibitors (which inhibit CYP3A4 to a greater or lesser extent) are predicted to raise

terfenadine levels. Although terfenadine has been widely withdrawn from the market, concurrent use with protease inhibitors was contraindicated.[8] Because of the seriousness of this reaction, and the fact that it is not possible to predict which individuals will be affected, this seems a sensible precaution.

Antihistamines + Quinolones

Studies in healthy subjects found that there was a small additive effect on the QT interval when terfenadine was given with sparfloxacin.

Clinical evidence, mechanism, importance and management

In a single-dose, placebo-controlled study in 8 healthy subjects, **sparfloxacin** 400 mg increased the QT interval by 14 milliseconds, **terfenadine** 60 mg increased the QT interval by 7.5 milliseconds (not statistically significant), and the combination caused an increase of 24.7 milliseconds. The effects of the combination in this study were shown to be purely additive.[1]

Similarly, in a placebo-controlled study 22 patients were given **sparfloxacin** 400 mg on day one and 200 mg on days 2 to 4 with **terfenadine** 60 mg twice daily for 7 doses. The increase in the QT interval when the two drugs were given together was additive, and no pharmacokinetic interaction was found.[2]

As the effects of therapeutic doses of **terfenadine** on the QT interval are minimal, any additional effect with **sparfloxacin** would be small. Nevertheless, because torsade de pointes can cause sudden death, the combination of two drugs with the potential to prolong the QT interval is generally considered to be contraindicated (see 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290). Note that the UK manufacturer of **terfenadine** specifically contraindicated **sparfloxacin**.[3]

If an antihistamine is required in a patient taking **sparfloxacin**, one that has no effect on the QT interval should be used, for example, **cetirizine**, see 'Table 15.2', (p.664). Other quinolones that cause QT prolongation include **gatifloxacin** and **moxifloxacin**, see 'Table 9.2', (p.290), and it would also be prudent to avoid use of antihistamines that prolong the QT interval (e.g. **astemizole** and **terfenadine**) with these quinolones.

Antihistamines + SSRIs

Two isolated reports describe cardiotoxicity, which was attributed to the concurrent use of terfenadine and fluoxetine, although other evidence suggests that an interaction is unlikely. Terfenadine does not appear to interact with paroxetine or sertraline. A case report describes prolonged delirium in a patient who took an overdose of promethazine with fluvoxamine. There does not appear to be a significant interaction between desloratadine and fluoxetine.

Clinical evidence

(a) Desloratadine

In a placebo-controlled study in healthy subjects, the concurrent use of desloratadine 5 mg daily and **fluoxetine** 20 mg daily for 7 days (after attainment of **fluoxetine** steady-state) had no clinically relevant effects on the pharmacokinetics of either drug (changes in maximum levels and AUC were less than 15%). There was no change in ECG parameters including the QTc interval, and the combination did not increase the incidence of adverse effects.[1]

(b) Promethazine

A case report describes a 14-year-old girl taking **fluvoxamine** 150 mg daily who took an overdose of promethazine 1150 mg and cyproheptadine 200 mg. She developed an anticholinergic delirium, which lasted for 6 days. The authors suggest that this effect was prolonged because both promethazine and **fluvoxamine** are inhibitors and metabolites of CYP2D6, and thus the clearance of both drugs may have been impaired. However, other factors such as her small size, and the use of olanzapine to control the delirium may have been contributing factors.[2]

(c) Terfenadine

1. Fluoxetine. A 41-year-old man with no previous history of heart disease awoke one night short of breath, with a sensation of his heart missing beats and beating irregularly. He also experienced orthostatic hypotension on a number of occasions. However, a later ECG showed a normal sinus rhythm. He was taking daily doses of terfenadine 120 mg, fluoxetine 20 mg (started a month previously), ibuprofen 2.4 g, misoprostol 400 micrograms, *Midrin* (paracetamol (acetaminophen), dichloralphenazone, isometheptene mucate) and ranitidine 300 mg. This reaction was attributed to an interaction between fluoxetine and terfenadine. However, a few days after stopping the terfenadine, and 12 days after this episode, his cardiac rhythm as recorded by a 24-hour Holter monitor showed some minor abnormalities (intermittent sinus tachycardia, isolated premature beats), although nothing approaching the previous alarming episode.[3] A woman taking several drugs (topical aciclovir, beclometasone, pseudoephedrine, ibuprofen) had a prolonged QTc interval of 550 milliseconds 2 weeks after starting to take terfenadine and fluoxetine, but she remained asymptomatic. Within a week of stopping terfenadine her QTc interval had returned to normal.[4]

In contrast, 12 healthy subjects who were given a single 60-mg dose of terfenadine before and after taking fluoxetine 60 mg daily for 8 days showed no significant changes in the pharmacokinetics of terfenadine or its acid metabolite.[5]

2. Paroxetine. A two-period crossover study in 11 healthy subjects given terfenadine 60 mg twice daily found that paroxetine 20 mg daily for 8 days had no effect on the AUC of terfenadine or the QTc interval. A small, clinically unimportant reduction in the levels of carboxyterfenadine was seen. It was concluded that there is no clinically relevant interaction between terfenadine and paroxetine.[6]

Mechanism

Not understood. Terfenadine is metabolised by the cytochrome P450 isoenzyme CYP3A4, but fluoxetine usually has only weak effects on this isoenzyme. The case reports suggest that this may be significant in some patients.

Importance and management

The interaction between the SSRIs and terfenadine is not adequately established, and there seems to be no evidence regarding interactions between the SSRIs and astemizole, although it is possible that the contraindication with astemizole contributed to minimal usage of the combination and therefore a lack of reported interactions. In addition to fluoxetine and paroxetine, the manufacturers of terfenadine listed **fluvoxamine** and **citalopram** as drugs that were expected to increase terfenadine serum levels and therefore concurrent use was contraindicated.[7] Although the CSM in the UK initially stated that terfenadine should not be used with **sertraline**, they subsequently reviewed the data and suggested that an interaction is unlikely.[8]

There seems to be no reason to suspect a pharmacokinetic interaction between the SSRIs and other antihistamines, and this has been demonstrated with desloratadine and fluoxetine.

Antihistamines + Statins

Atorvastatin does not appear to alter the pharmacokinetics of terfenadine. The manufacturers suggest that rupatadine could exacerbate the muscle toxicity caused by the statins.

Clinical evidence, mechanism, importance and management

(a) Rupatadine

The UK manufacturer of rupatadine[1] reports that in clinical studies asymptomatic rises in creatine phosphokinase levels have occurred. As rupatadine is a substrate of the cytochrome P450 isoenzyme CYP3A4, by which some of the statins are also metabolised, the manufacturer advises caution on concurrent use, on the basis that the risk of interactions is unknown. However, it seems unlikely that a pharmacokinetic interaction will result in muscle disorders, because muscle disorders usually develop because of a several fold rise in the levels of the statin, which is unlikely to occur as a result of competition for metabolism by the same isoenzyme. For more information on the metabolism of individual statins, and monitoring for muscle disorders, see under 'Lipid regulating drugs', (p.1313)).

(b) Terfenadine

A group of healthy subjects were given a single 120-mg dose of terfenadine on day 8 of a 10-day course of atorvastatin 80 mg daily. It was found that atorvastatin caused some small to moderate changes in the pharmacokinetics of terfenadine and its metabolite fexofenadine (AUC increased by 35% and decreased by 2%, respectively, maximum serum levels decreased by 8% and decreased by 16%, respectively), none of which reached statistical significance. More importantly there were no changes in the QTc interval, which indicates that atorvastatin does not increase the cardiotoxicity of terfenadine.[2] There would therefore appear to be no reason for avoiding concurrent use.

2. Stern RH, Smithers JA, Olson SC. Atorvastatin does not produce a clinically significant effect on the pharmacokinetics of terfenadine. *J Clin Pharmacol* (1998) 38, 753–7.

Antihistamines + Terbinafine

Terbinafine does not interact with astemizole or terfenadine to a clinically relevant extent.

Clinical evidence, mechanism, importance and management

In a large-scale post-marketing survey of 25,884 patients taking terbinafine, over 40% were taking at least one other drug. From amongst this group, an unknown number of patients were taking **astemizole** or **terfenadine**. No adverse interactions were reported.[1] A crossover study in 26 healthy subjects given terbinafine 250 mg daily or placebo, with **terfenadine** 60 mg twice daily for 7 days, found that terbinafine reduced the trough levels of terfenadine acid metabolite by about 20% on the last day of concurrent use. Other **terfenadine** acid metabolite pharmacokinetic parameters were not affected. The AUC, and peak and trough plasma levels of terbinafine were increased by about 16%, 7%, and 22%, respectively, after 7 days of concurrent use. Although the incidence of ECG abnormalities was not significantly higher in any group, a 10% prolongation of the QT interval was found in those receiving **terfenadine** either alone or with terbinafine. However, concurrent use was well-tolerated and it was concluded that terbinafine could safely be given with **terfenadine**.[2]

Antihistamines; Ocular + Miscellaneous

No specific interaction studies have been performed with eye-drop formulations of the antihistamines azelastine, emedastine, epinastine, or olopatadine. However, interactions are not anticipated because very little drug is expected to reach the systemic circulation.

Clinical evidence, mechanism, importance and management

The UK manufacturer of **azelastine** eye drops notes that interaction studies with high oral doses of **azelastine** bear no relevance to the eye drops, as systemic levels are only in the picogram range after administration of eye drops.[1] Similarly, the manufacturer of **epinastine** eye drops notes that no drug interactions are anticipated as systemic **epinastine** levels are extremely low after ocular use. They note that **epinastine** is also excreted mostly unchanged.[2] The manufacturer of **olopatadine** eye drops notes that *in vitro* studies showed that it was not an inhibitor of the common cytochrome P450 isoenzymes.[3] No drug interactions would be anticipated between these, or any other, antihistamine eye drops and systemically administered drugs.

The manufacturer of **emedastine** eye drops notes that an interval of 10 minutes should be allowed after the administration of the eye drops and other ophthalmically administered medicines,[4] which is good practice for any ocular drugs.

Antihistamines; Astemizole + Quinine

Quinine causes a marked but transient increase in plasma astemizole levels, which potentially increases the risk of cardiac arrhythmias. Three case reports confirm that this is a clinically important interaction.

Clinical evidence

In a study, 12 healthy subjects were given astemizole 30 mg daily for 4 days followed by 10 mg daily for the next 20 days. The steady-state pharmacokinetics of astemizole were then examined after the subjects took quinine 20 mg every 4 hours for 12 hours (a total of 80 mg quinine), and after a single 430-mg dose of quinine. The smaller dose of quinine caused only a slight increase in the maximum plasma astemizole levels and AUC, but the larger single dose of quinine resulted in a transient threefold increase in both the maximum plasma levels and AUC of both astemizole and particularly desmethylastemizole, the metabolite of astemizole.[1]

A patient who had been taking astemizole 10 mg daily for 10 months with fluoxetine, alprazolam, isradipine, and diuretics with potassium had a syncopal episode one hour after taking the first dose of quinine sulphate 260 mg for leg cramp. The ECG showed recurrent episodes of torsade de pointes with a QT interval of greater than 680 milliseconds. The only electrolyte abnormality was slight hypomagnesaemia. Intravenous magnesium was given and the patient's QT interval shortened to 420 milliseconds over 3 days.[2] The manufacturers have on record two other case reports[3] of cardiac arrhythmias possibly attributable to an interaction between astemizole and quinine.

Mechanism

Uncertain. One suggestion is that the interaction is not primarily due to inhibition of the metabolism of astemizole by the quinine, but rather to a

transient quinine-induced displacement of both astemizole and its metabolite from its tissue binding sites.[1] Note that the desmethyl metabolite of astemizole causes QTc prolongation.

Importance and management

Information is very limited, but on the basis of the evidence cited above the manufacturer of astemizole contraindicated the concurrent use of quinine in order to avoid the risk of cardiac arrhythmias.[4] The case report that is cited here confirms that this is a potentially clinically hazardous drug combination.[2]

The larger single 430-mg dose of quinine used in the study approached the dose used for the treatment of malaria, whereas the smaller dose of 80 mg was equivalent to the amount contained in 2 litres of a quinine-containing soft drink.[1] There would therefore appear to be no reason for those taking astemizole to avoid moderate quantities of quinine-containing drinks. For more information about QT prolongation, see 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290.

Antihistamines; Cinnarizine + Phenylpropanolamine

In 12 healthy subjects, phenylpropanolamine 50 mg counteracted the mild sedation caused by cinnarizine 25 or 50 mg, and improved the performance of some skills related to driving.[1]

1. Savolainen K, Mattila MJ, Mattila ME. Actions and interactions of cinnarizine and phenylpropanolamine on human psychomotor performance. *Curr Ther Res* (1992) 52, 160–8.

Antihistamines; Fexofenadine + Antacids or Omeprazole

An aluminium/magnesium hydroxide-containing antacid modestly reduced fexofenadine levels in one study. Fexofenadine does not appear to affect the pharmacokinetics of omeprazole.

Clinical evidence, mechanism, importance and management

(a) Antacids

The manufacturer[1] notes that when a single 120-mg dose of fexofenadine was given within 15 minutes of an **aluminium/magnesium hydroxide** antacid (*Maalox*), the fexofenadine AUC was decreased by 41% and the maximum level was decreased by 43%. Although the effect of these reductions on possible efficacy has not been assessed, the manufacturer recommends that it is advisable to leave 2 hours between the administration of fexofenadine and antacids containing **aluminium** and **magnesium hydroxide**.[2]

(b) Omeprazole

A study in 8 healthy subjects found that fexofenadine 60 mg twice daily for 6 days had no effect on the pharmacokinetics of a single 40-mg dose of omeprazole given on day 6. In addition, there was no significant change in the pharmacokinetics of the metabolites of omeprazole.[3]

Antihistamines; Fexofenadine + Probenecid

Probenecid reduces the renal clearance of fexofenadine and raises its AUC.

Clinical evidence

In a study, 8 healthy subjects and 8 patients with cystic fibrosis were given two doses of probenecid 1 g, 12 hours apart, with a single 180-mg dose of fexofenadine one hour after the first dose of probenecid. The AUC of fexofenadine was increased by 53% and its renal clearance was reduced by 70% by probenecid.[1] Similarly, a further study in 12 healthy subjects who took a single 120-mg dose of fexofenadine alone, or after probenecid 1 g twice daily for 6 days found the renal clearance of fexofenadine was reduced by 63% and the AUC of fexofenadine was increased by 50% by probenecid. There was marked interindividual variation in the findings.[2]

Mechanism

An *in vitro* study has demonstrated that fexofenadine is a substrate for the human organic anion transporter-3 (OAT3), which probenecid inhibits. Therefore concurrent use results in decreased clearance and an increase in exposure to fexofenadine.[3]

Importance and management

Evidence for an interaction between fexofenadine and probenecid appears to be limited to these two studies, neither of which found that probenecid increased the adverse effects of fexofenadine. Note that much greater increases in the exposure to fexofenadine are not considered harmful (see 'Antihistamines + Azoles', p.665). Therefore this interaction is unlikely to be clinically significant.

Antihistamines; Fexofenadine + Rifampicin (Rifampin)

Rifampicin increases the oral clearance of fexofenadine.

Clinical evidence, mechanism, importance and management

A single 60-mg dose of fexofenadine was given to 24 healthy subjects 2 days before and on the last day of a 6-day course of rifampicin 600 mg daily. The oral clearance of fexofenadine was increased 1.3- to 5.3-fold, with no effect on renal clearance or half-life. This was thought to be due to the effect of rifampicin on P-glycoprotein, which is involved in the uptake of fexofenadine.[1] The clinical significance of this interaction is unclear, but until more is known it would seem prudent to monitor the efficacy of fexofenadine if it is given in combination with rifampicin.

1. Hamman MA, Bruce MA, Haehner-Daniels BD, Hall SD. The effect of rifampin administration on the disposition of fexofenadine. *Clin Pharmacol Ther* (2001) 69, 114–21.

Antihistamines; Fexofenadine + St John's wort (*Hypericum perforatum*)

Pretreatment with St John's wort (*Hypericum perforatum*) had no clinically relevant effect on the plasma levels of single-dose fexofenadine in one study, but markedly reduced fexofenadine levels in two others.

Clinical evidence

In a study in 12 healthy subjects a single 900-mg dose of St John's wort (*Hypericum perforatum*) increased the maximum plasma level and AUC of a single 60-mg dose of fexofenadine by 45% and 31%, respectively. Conversely, St John's wort 300 mg three times daily for 14 days caused a slight 5 to 10% decrease in the maximum level and AUC of a single 60-mg dose of fexofenadine in the same subjects.[1] In contrast, in another study in healthy subjects, 12 days of pretreatment with St John's wort increased the oral clearance of a single dose of fexofenadine by about 60%.[2] Similarly, a study in 30 healthy subjects found that 10 days of pretreatment with St

John's wort 300 mg 3 times daily, almost doubled the oral clearance of a single 60-mg dose of fexofenadine.[3]

Mechanism

In these studies St John's wort was thought to be interacting via its effects on P-glycoprotein.

Importance and management

The findings from these multiple-dose studies suggest that St John's wort either has no clinically relevant effect on fexofenadine, or that a decrease occurs that is possibly clinically important. It may be prudent to monitor closely for signs of reduced fexofenadine efficacy in a patient taking regular St John's wort, and if this is the case, consider St John's wort as a possible cause. Further study is needed.

Antihistamines; Flunarizine + Antiepileptics

Limited evidence suggests that phenytoin and carbamazepine can reduce serum flunarizine levels. Flunarizine does not appear to alter phenytoin or carbamazepine levels.

Clinical evidence, mechanism, importance and management

A study found that flunarizine levels were lower in patients taking multiple antiepileptics than in those taking only one antiepileptic (statistically significant only for flunarizine 10 mg). The antiepileptics taken were **carbamazepine**, **phenytoin**, and **sodium valproate**. Flunarizine did not affect the serum levels of these antiepileptics.[1] In another study, involving 12 patients, four of whom were taking **phenytoin**, four **carbamazepine** and four both **phenytoin** and **carbamazepine**, there was no difference in the pharmacokinetics of a single 30-mg dose of flunarizine or of multiple-dose flunarizine between the three groups. However, the apparent clearance values of flunarizine were several fold greater in these patients than in historical data from healthy subjects. There were no differences identified in the mean steady-state levels of the antiepileptics before and during flunarizine use.[2]

Although not conclusive, these data suggest that enzyme-inducing antiepileptics increase the metabolism of flunarizine and may reduce its steady-state serum level. There would seem to be no reason for avoiding concurrent use, but the outcome should be monitored as an increase in the dose of flunarizine may possibly be required.

Antihistamines; Meclozine + Metaxalone

A case report describes a patient who experienced auditory hallucinations when he took the maximum doses of both meclozine and metaxalone together. This effect disappeared when the drugs were stopped, but recurred on re-challenge. Note that this is an isolated report, and its clinical significance is unclear.[1]

1. Kuykendall JR, Rhodes RS. Auditory hallucinations elicited by combined meclizine and metaxalone use at bedtime. *Ann Pharmacother* (2004) 38, 1968–9.

Antihistamines; Terfenadine + Paracetamol (Acetaminophen)

An isolated report describes the development of torsade de pointes in an elderly man taking very large doses of paracetamol (acetaminophen) and amitriptyline when he began to take terfenadine.

Clinical evidence, mechanism, importance and management

An 86-year-old man taking **amitriptyline** 25 mg at night, prednisone 3 mg daily and excessive amounts of paracetamol (up to 1 g every 2 hours over a 6-month period) developed breathlessness and bradycardia shortly after starting to take terfenadine 60 mg twice daily. In hospital he became unconscious and was initially pulseless but recovered spontaneously. An ECG showed that he had AV block and a prolonged QT interval, which resulted in runs of self-limiting torsade de pointes.[1] The reasons for this reaction are not known, but a suggested explanation is that overdosage with paracetamol produced large amounts of a metabolite (*N*-acetyl-p-benzoquinoneimine). This metabolite could have inhibited the metabolism of the terfenadine by the cytochrome P450 isoenzyme CYP3A4, thereby resulting in terfenadine accumulation and the development of its cardiotoxic effects.[1] The **amitriptyline** may additionally have had some part to play because it can also (although rarely) cause torsade de pointes.

This is an isolated case and unlikely to be of general importance. There would seem to be little reason on the basis of this report for patients on terfenadine to avoid normal therapeutic doses of paracetamol. There appear to be no other reports of this interaction.

1. Matsis PP, Easthope RN. Torsades de pointes ventricular tachycardia associated with terfenadine and paracetamol self medication. *N Z Med J* (1994) 107, 402–403.

Antihistamines; Terfenadine + Venlafaxine

Venlafaxine does not appear to affect the pharmacokinetics of terfenadine to a clinically relevant extent.

Clinical evidence, mechanism, importance and management

A study in 24 subjects given a single 120-mg oral dose of terfenadine before and after taking venlafaxine 75 mg every 12 hours for 9 days found that the pharmacokinetic profile of terfenadine was unchanged, although its acid metabolite concentrations were slightly decreased by about 25%.[1] This study was undertaken to confirm that venlafaxine lacks inhibitory activity on the cytochrome P450 isoenzyme CYP3A4, but at the same time it also indicates that venlafaxine does not raise the serum levels of terfenadine, which are associated with serious cardiotoxicity. There would therefore seem to be no reason for avoiding concurrent use.

1. Amchin J, Zarycranski W, Taylor K, Albano D, Klockowski PM. Effect of venlafaxine on the pharmacokinetics of terfenadine. *Psychopharmacol Bull* (1998) 34,383–9.

Antihistamines; Terfenadine + Zileuton

In one study zileuton modestly increased terfenadine levels, without altering the QTc interval.

Clinical evidence, mechanism, importance and management

Terfenadine 60 mg every 12 hours for 7 days was given to 15 healthy subjects with either zileuton 600 mg every 6 hours or a placebo. The mean $AUC_{0\text{-}6}$ and the maximum plasma concentrations of terfenadine increased by 35% in the presence of zileuton, but the levels were still very low (less than 5 nanograms/mL). The maximum plasma concentration and AUC of carboxyterfenadine (a terfenadine metabolite) were increased by about 15% by zileuton. ECG measurements showed that the addition of zileuton did not increase the QTc interval nor cause any other significant changes.[1] The authors concluded that the interaction was unlikely to be of clinical significance. However, any drug that inhibits terfenadine metabolism may result in accumulation of terfenadine and prolongation of the QT interval with the risk of life-threatening arrhythmias. Note that the UK manufacturer contraindicated the concurrent use of terfenadine and zileuton.[2]

Antimigraine drugs

The drugs dealt with in this section are the ergot derivatives and the triptans (or more properly the serotonin 5-HT_1 agonists), whose main use is in the treatment of migraine. 'Table 16.1', (below) lists some of the drugs commonly used in migraine. Drugs such as propranolol, which are more commonly used in other conditions, are discussed elsewhere in this publication.

(a) Ergot derivatives

The main problem with the use of the ergot derivatives is that of ergotism. Drug interactions may result in additive effects, or cause raised levels of ergot derivatives, which may result in the symptoms of ergot poisoning. This can include severe circulatory problems e.g. the extremities may become numb, cold to the touch, tingle, and muscle pain may result. In extreme cases there may be no palpable pulse. Ultimately gangrene may develop, and amputation may be required. Chest pain can also occur, and in some cases myocardial infarction has been reported. Since dihydroergotamine, ergotamine and methysergide are metabolised in the liver by the isoenzyme CYP3A4, drugs which inhibit this isoenzyme, particularly potent inhibitors, such as some 'protease inhibitors', (p.684), should be avoided due to the risk of precipitating ergotism.

(b) Triptans

Although the triptans would be expected to share a number of pharmacodynamic drug interactions, due to their differing metabolic pathways they will not all necessarily share the same pharmacokinetic interactions. For example, sumatriptan, which is metabolised mainly by monoamine oxidase A, is unlikely to interact with macrolide antibacterials, which are inhibitors of the cytochrome P450 isoenzyme CYP3A4. However, eletriptan, which is mainly metabolised by CYP3A4 does interact (see 'Triptans + Macrolides', p.688). Frovatriptan and zolmitriptan are substrates for CYP1A2, and their metabolism is affected by CYP1A2 inhibitors such as fluvoxamine. However, the picture with zolmitriptan is more complicated, because it is also metabolised by monoamine oxidase A. Naratriptan appears unlikely to undergo significant pharmacokinetic interactions because half the dose is excreted unchanged and the rest is metabolised by a variety of isoenzymes. A summary of the enzymes involved in the metabolic pathways of the triptans can be found in 'Table 16.2', (below).

Early in the development of triptans it was theorised that they might present a high risk of excess serotonergic activity and increase the risk of 'serotonin syndrome', (p.9), especially when used with other drugs with serotonergic actions. Therefore sumatriptan was contraindicated in patients taking drugs such as the SSRIs and lithium. However, with more experience of the triptans it appears that interactions resulting in serotonin syndrome are rare, and so concurrent use with these other serotonergic drugs may now be undertaken, with an appropriate awareness of the potential problems.

Table 16.1 Antimigraine drugs

Group	*Drugs*
Antihistamines	Flunarizine, Pizotifen
Beta blockers	Atenolol, Metoprolol, Nadolol, Propranolol, Timolol
Ergot derivatives	Codergocrine, Ergotamine, Dihydroergocryptine, Dihydroergotamine, Methysergide
Triptans (Serotonin (5-HT_1) agonists)	Almotriptan, Eletriptan, Frovatriptan, Naratriptan, Rizatriptan, Sumatriptan, Zolmitriptan

Table 16.2 Principal enzymes involved in the metabolism of the triptans†

	MAO-A	*CYP1A2*	*CYP2C9*	*CYP2C19*	*CYP2D6*	*CYP3A4*
Almotriptan	Substrate				Substrate (minor)	Substrate
Eletriptan					Substrate (minor)	Substrate
Frovatriptan		Substrate			Substrate (minor)	
Naratriptan		Substrate (minor)	Substrate (minor)	Substrate (minor)	Substrate (minor)	Substrate (minor)
Rizatriptan	Substrate	Substrate (minor)				
Sumatriptan	Substrate					
Zolmitriptan	Substrate	Substrate				Substrate

†Other isoenzymes have been implicated, but not at clinically relevant concentrations of the triptans

Ergot derivatives + Antidepressants

One isolated report describes three cases in which patients developed symptoms indicative of serotonin syndrome when they took dihydroergotamine with amitriptyline, paroxetine and imipramine, or sertraline. Some antidepressants such as fluoxetine, fluvoxamine or nefazodone may increase the levels of the ergot derivatives.

Clinical evidence

A woman taking **imipramine**, **paroxetine** and lithium, who had a 3-week continuous headache, was given 300 micrograms and then 500 micrograms of **dihydroergotamine** intravenously. Within 5 minutes of the 500-microgram dose she developed dysarthria, dilated pupils, diaphoresis, diffuse weakness, and barely responded to commands. She was diffusely hyperreflexic and showed occasional myoclonic jerks. She recovered after 90 minutes.[1]

A woman with a history of migraine headaches responded well to **amitriptyline**, metoclopramide and **dihydroergotamine**. Six weeks after the **amitriptyline** was replaced by **sertraline**, she was again successfully treated for acute migraine with 10 mg of intravenous metoclopramide and 1 mg of intravenous **dihydroergotamine**. However, 2 hours later she developed nausea, emesis, agitation, weakness, diaphoresis, salivation, chills, and fever. All of the symptoms subsided after 24 hours.[1]

A woman with a history of migraines (treated prophylactically with **amitriptyline** and propranolol) was admitted to hospital in status migrainosus. She was given 1 mg of **dihydroergotamine**, 10 mg of prochlorperazine and 10 mg of metoclopramide (all intravenously). Within 20 minutes she became diaphoretic, tachycardic, diffusely hyperreflexic, agitated, confused, and briefly lost consciousness twice. Diazepam 8 mg given intramuscularly calmed her agitation, and all the symptoms resolved after 6 hours. A year later she was given 6 mg of subcutaneous sumatriptan while taking **nortriptyline** daily with no ill effects.[1]

Mechanism

Not understood. All of these patients appeared to have developed symptoms similar to those of 'serotonin syndrome', (p.9), which is thought to be due to hyperstimulation of 5-HT receptors in the brain. Dihydroergotamine is a 5-HT agonist while paroxetine and sertraline are both serotonin (5-HT) reuptake inhibitors, all of which might be expected to increase 5-HT concentrations in the CNS, and thereby increase receptor stimulation.

Importance and management

These appear to be isolated cases and not of general importance, nevertheless they illustrate the potential for the development of serotonin syndrome in patients given multidrug regimens that affect 5-HT receptors. The syndrome is rare and it may (so it has been suggested[1]) sometimes be an idiosyncratic reaction.

Note that some antidepressants e.g. **fluoxetine**, **fluvoxamine** and **nefazodone** can inhibit the cytochrome P450 isoenzyme CYP3A4, which is involved in the metabolism of ergot derivatives. This may result in reduced metabolism and therefore possibly ergot toxicity. The manufacturers of dihydroergotamine[2] and **ergotamine**[3,4] suggest giving these particular antidepressants with caution. Note that **methysergide** is also metabolised by CYP3A4 and therefore may be expected to interact similarly.

The manufacturer of **reboxetine** warns that its concurrent use with ergot derivatives might result in increased blood pressure, although no clinical data are quoted.[5]

Ergot derivatives + Beta blockers

The use of beta blockers with ergot derivatives in the management of migraine is not uncommon, but concurrent use has, rarely, resulted in severe peripheral vasoconstriction and hypertension.

Clinical evidence

A man with recurrent migraine headaches, reasonably well-controlled over a 6-year period with *Cafergot* suppositories (containing **ergotamine tartrate**), developed progressively painful and purple feet a short while after starting to take **propranolol** 30 mg daily. When he eventually resumed taking the *Cafergot* alone there was no further evidence of peripheral vasoconstriction.[1]

A similar case has been reported elsewhere, although an interaction is inconclusive in this patient, as neither the **ergotamine** nor the **propranolol** were taken alone.[2] Another case occurred in a woman who had been taking **oxprenolol** and **ergotamine tartrate** (dosages unknown) for some considerable time. Arteriography showed severe spasm in a number of arteries, which responded eventually to an intra-arterial infusion of glyceryl trinitrate and heparin.[3] Severe pain in the legs and feet occurred in another man after he took **methysergide** 3 mg and **propranolol** 120 mg daily for 2 weeks. He did not respond to various therapies, and in 6 days it was necessary to amputate both his legs below the knee because of gangrene.[3] A woman taking **propranolol** for migraine prophylaxis became hypertensive (BP 180/120 mmHg) with a crushing substernal pain immediately after being given oxygen, prochlorperazine 5 mg and intravenous **dihydroergotamine** 750 micrograms for an acute migraine headache. She recovered uneventfully. She was later found to be hyperthyroid, which, it was suggested, may have contributed to the interaction.[4]

These reports contrast with another stating that the use of **propranolol** with **ergotamine** was both effective and uneventful in 50 patients.[5]

Mechanism

Uncertain. One suggestion is that additive vasoconstriction occurs.[1,3] Ergot derivatives cause vasoconstriction, and the beta blockers do the same by blocking the normal ($beta_2$-stimulated) sympathetic vasodilatation. Beta blockers also reduce blood flow by reducing cardiac output.

Importance and management

Concurrent use is usually safe and effective, and there are only a handful of reports of adverse interactions. It was suggested that the disease state may have contributed to the interaction in one case,[4] and at least one of the other cases could have been due to the ergotamine alone (i.e. ergotism).[5] However, it would clearly be prudent to be extra alert for any signs of an adverse response, particularly those suggestive of reduced peripheral circulation (coldness, numbness or tingling of the hands and feet).

Ergot derivatives + CYP3A4 inducers

CYP3A4 inducers such as nevirapine and rifampicin would be expected to reduce the clinical effect of ergot derivatives. Efavirenz may increase or decrease the levels of ergot derivatives.

Clinical evidence, mechanism, importance and management

Drugs that induce the cytochrome P450 isoenzyme CYP3A4 would be expected to increase the metabolism of ergot alkaloids and decrease their plasma levels. This type of interaction may result in reduced efficacy, but

is unlikely to cause serious adverse effects. The manufacturer of **nevirapine** suggests that, although specific drug interaction studies have not been conducted, there could be a potential drug interaction with ergot alkaloids such as **ergotamine**, and additional clinical monitoring may be warranted when giving these drugs together.[1] It may be prudent to consider an alternative antimigraine treatment, such as one of the triptans not metabolised by CYP3A4, see 'Table 16.2', (p.680).

Note that **rifampicin** has been used as a potent enzyme inducer to reduce **ergotamine** levels in a patient with ergotism, and was said to play a key role in reducing ergotamine levels.[2]

A list of CYP3A4 inducers is given in 'Table 1.4', (p.6).

Efavirenz also induces CYP3A4, and therefore would also be expected to reduce the levels of ergot derivatives. However, the manufacturers[3,4] advise that, due to competition for metabolism by CYP3A4, **efavirenz** may possibly *increase* the levels of ergot derivatives, leading to ergot toxicity. For this reason they contraindicate concurrent use.[3,4] See 'Ergot derivatives + CYP3A4 inhibitors', below. However, there appear to be no published reports of the outcome of this interaction.

4. Sustiva Film-coated Tablets (Efavirenz). Bristol-Myers Squibb Pharmaceuticals Ltd. UK Summary of product characteristics, June 2009.

Ergot derivatives + CYP3A4 inhibitors

The azole antifungals are predicted to raise the levels of ergot derivatives, which may lead to ergotism. Other CYP3A4 inhibitors, such as cimetidine, delavirdine, grapefruit juice and quinupristin/dalfopristin are expected to interact similarly, although possibly to a lesser extent.

Clinical evidence, mechanism, importance and management

The ergot alkaloids are mainly metabolised by the cytochrome P450 isoenzyme CYP3A4. The manufacturers of **ergotamine**, **dihydroergotamine** and **methysergide** therefore logically predict that their levels will be raised by CYP3A4 inhibitors, which may lead to ergotism: this has been seen with the 'macrolides', (p.683), and the 'protease inhibitors', (p.684).

Drugs such as the **azole antifungals** would be expected to interact similarly, although there appear to be no studies or case reports describing an interaction. Note that, of the azoles, **ketoconazole** and **itraconazole** are the most potent CYP3A4 inhibitors, and would therefore be expected to interact to the greatest extent; their use, as well as the use of **posaconazole**[1] or **voriconazole**[1,2] is generally contraindicated.[3-6] Other CYP3A4 inhibitors that are contraindicated with ergot derivatives include **delavirdine**[2] and **efavirenz**;[1] however, note that **efavirenz** also typically *induces* CYP3A4 in clinical practice, and may therefore also *reduce* the levels of ergot derivatives, consider 'Ergot derivatives + CYP3A4 inducers', p.681. However, there appear to be no published reports of the outcome of this interaction.

The concurrent use of less potent CYP3A4 inhibitors such as **cimetidine**,[1,2] **clotrimazole**,[3-6] **fluconazole**,[3-6] **grapefruit juice**,[3-6] **quinupristin**/**dalfopristin**[1] and **zileuton**,[4,6] should either be avoided if possible, or used with caution. Not all of the manufacturers mention all combinations, but these are all reasonable predictions, and it would therefore seem appropriate to apply them to all ergot derivatives used in the management of migraine. Therefore if any of these less potent CYP3A4 inhibitors is given with an ergot derivative it would be prudent to be aware that raised levels may occur. Strongly advise patients not to take any further doses and seek medical advice if early symptoms of increased levels, such as a decreased sensitivity to touch or pain, numbness or tingling in the fingers and toes, nausea and vomiting (unrelated to the migraine) develop.

Ergot derivatives + Ergot derivatives

The concurrent use of methysergide and other ergot derivatives can increase the risk of severe and persistent spasm of major arteries in some patients.

Clinical evidence

A man developed loss of temperature sensitivity over the right side of his face and arm, as well as vertigo, dysphagia and hoarseness, 7 days after starting to take methysergide 2 mg three times daily and 500 micrograms of subcutaneous **ergotamine tartrate** at night. Continued use resulted in impaired pain, touch and temperature sensation over the right side of his face, shoulder and arm. Arteriography demonstrated left vertebral artery occlusion and right vertebral arterial spasm. These symptoms, apart from the loss of temperature sensitivity, resolved when the drugs were stopped.[1] Another man treated for cluster headaches with methysergide 2 mg, intramuscular **ergotamine tartrate** and pizotifen developed ischaemia of the right foot, with impalpable popliteal and pedal pulses. Arteriography showed that blood flow to the arteries of the right leg was reduced.[1]

Another report describes prolonged myocardial ischaemia in a patient with cluster headaches when a single 2-mg dose of **ergotamine tartrate** was added to methysergide 2 mg three times daily. Sublingual glyceryl trinitrate relieved the pain.[2]

A further case report describes a woman who developed gangrene of both big toes following surgical treatment of bilateral hallux valgus (bone swellings). Before the time of operation, and for 20 days afterwards, she took 6 tablets of *Bellergal* (total of **ergotamine tartrate** 1.8 mg, alkaloids of belladonna 600 micrograms, phenobarbital 120 mg daily) and methysergide maleate 6 mg daily. One toe was subsequently removed by amputation, the other recovered slowly following cessation of the **ergotamine** and methysergide.[3]

Mechanism

Cluster headaches are associated with abnormal dilatation of the carotid arteries, which can be constricted by ergot derivatives. In the cases cited it would seem that combined vasoconstrictor effects caused arterial spasm elsewhere in the body, resulting in serious tissue ischaemia. Parenteral ergotamine increases the risk of arterial spasm.

Importance and management

Direct information seems to be limited to these cases. Cardiovascular complications can occur with ergot derivatives given alone, but these cases suggest that their concurrent use may unpredictably increase the risk in some patients. Clearly they should be used together with great caution, or avoided.

The manufacturer of methysergide contraindicates its use with vasoconstrictive drugs including ergot alkaloids.[4] Many manufacturers of other ergot alkaloids (**dihydroergotamine**, ergotamine) say that they should not be used with other ergot alkaloids (including **methysergide**). In addition, the manufacturers of dihydroergotamine[5,6] suggest that it should not be used within 24 hours of ergot-type medications.

Note that drugs such as bromocriptine are also ergot derivatives, and it is similarly recommended that their use with other ergot derivatives should be avoided, see 'Bromocriptine and other dopamine agonists + Ergot derivatives', p.791.

Ergot derivatives + Glyceryl trinitrate (Nitroglycerin)

The ergot derivatives such as dihydroergotamine would be expected to oppose the anti-anginal effects of glyceryl trinitrate. Nevertheless, an *animal* study has not borne out this expectation.

Clinical evidence, mechanism, importance and management

There seem to be no clinical reports of adverse interactions between the ergot derivatives and glyceryl trinitrate, but as **ergot** causes vasoconstriction and can provoke angina it would be expected to oppose the effects of glyceryl trinitrate when used as a vasodilator for the treatment of angina.[1] Nevertheless, a study in *animals* suggested that **dihydroergotamine** would not worsen exercise-induced angina pectoris, and that the antianginal efficacy of glyceryl trinitrate would not be neutralised by pretreatment with **dihydroergotamine**.[2]

However, glyceryl trinitrate has been shown to increase the bioavailability of **dihydroergotamine** (by up to 370% in one case) in subjects with orthostatic hypotension, which would increase its vasoconstrictor effects.[1] The clinical outcome of concurrent use is therefore uncertain, especially as glyceryl trinitrate has been successfully used to relieve pain and arterial spasm related to the use of ergot derivatives (see 'Ergot derivatives + Ergot derivatives', p.682, and 'Ergot derivatives + Beta blockers', p.681). Note that ergot derivatives are generally regarded as contraindicated in those with ischaemic heart disease.

Ergot derivatives + Macrolides

Ergot toxicity can develop rapidly in patients taking ergotamine or dihydroergotamine if they are given erythromycin or troleandomycin. Cases of toxicity have also been reported with clarithromycin, josamycin, and oleandomycin; midecamycin and telithromycin are predicted to interact similarly. No cases of toxicity appear to have been described with azithromycin, dirithromycin, or spiramycin, and none would be expected.

Clinical evidence

(a) Clarithromycin

A 59-year-old woman took **ergotamine tartrate** 2 mg for a typical migraine headache. After 2 hours her tongue became swollen, painful and bluish in colour. She was moderately hypertensive (BP 200/110 mmHg), and her fingers and toes were cold and cyanotic (blue); this was diagnosed as ergotism. She had taken this dose of **ergotamine** many times previously without problems, but on this occasion she had been taking clarithromycin 500 mg twice daily for the previous 5 days. Other evidence suggests that this patient may possibly have been unusually sensitive to vascular occlusion.[1] The authors of this report briefly quote another case, originating from the manufacturers of clarithromycin, of a possible interaction with **dihydroergotamine**, although this was complicated by the concurrent use of other medications (not named) used in the management of AIDS.[1] A woman who had previously uneventfully taken *Cafergot* (**ergotamine tartrate** 1 mg, caffeine 100 mg) for migraine developed ergotism (leg pain, cold and cyanosed limbs, and impalpable pulses) within 3 days of starting to take clarithromycin (dosage not stated). The authors postulated that smoking and the use of oxymetazoline (both of which have vasoconstrictor effects) may also have had some part to play.[2]

(b) Erythromycin

A woman who had regularly and uneventfully taken *Migral* (**ergotamine tartrate** 2 mg, cyclizine hydrochloride 50 mg, caffeine 100 mg) on a number of previous occasions, took one tablet during a course of treatment with erythromycin 250 mg every 6 hours. Within 2 days she developed severe ischaemic pain in her arms and legs during exercise, with a burning sensation in her feet and hands. When admitted to hospital 10 days later, her extremities were cool and cyanosed. Her pulse could not be detected in the lower limbs.[3]

Eight other cases of acute ergotism have been reported[4-11] in which patients were taking **ergotamine tartrate** or **dihydroergotamine** and erythromycin. The reaction has been reported to develop within a few hours,[7] but it may take several days to occur.[10] One case appeared to occur when the erythromycin was started 3 days after the last dose of **dihydroergotamine**.[5]

A study involving 9 healthy subjects found that erythromycin increased the mean maximum plasma level and AUC of α-**dihydroergocryptine** by 9.5-fold and greater than 13-fold, respectively.[12]

(c) Josamycin

An isolated report describes a 33-year-old woman who developed severe ischaemia of the legs within 3 days of starting to take josamycin 2 g daily and **ergotamine tartrate** 300 micrograms. Her legs and feet were cold, white and painful, and most of her peripheral pulses were impalpable.[13]

(d) Midecamycin diacetate

After 12 healthy subjects took midecamycin diacetate 800 mg twice daily for 8 days, the peak level of a single 9-mg dose of **dihydroergotamine** were raised 3 to 40-fold.[14]

(e) Oleandomycin

A case of ergotism has been reported in a 45-year-old woman who had been taking **ergotamine** 4 mg daily for 5 years and recently also oleandomycin.[15]

(f) Troleandomycin

A 40-year-old woman who had been taking **dihydroergotamine**, 90 drops daily, for 3 years without problems, developed cramp in her legs within a few hours of starting to take troleandomycin 250 mg four times a day. Five days later she was admitted to hospital as an emergency, with severe ischaemia of her arms and legs. Her limbs were cold and all her peripheral pulses were impalpable.[16]

There are reports of several other patients who had taken normal doses of **ergotamine tartrate** or **dihydroergotamine** for months or years without problems, who then developed severe ergotism within hours or days of starting to take normal doses of troleandomycin.[17-24] This resulted in a myocardial infarction in one patient.[25]

Mechanism

Erythromycin and troleandomycin are potent inhibitors of the cytochrome P450 isoenzyme CYP3A4, an enzyme involved in the metabolism of ergot derivatives.[26,27] Clarithromycin and oleandomycin are also known to inhibit CYP3A4. As a result the ergot is poorly metabolised and accumulates in the body. This leads to increased vasoconstriction and ultimately ischaemia. Josamycin, midecamycin and **roxithromycin** have a lower affinity for CYP3A4 than erythromycin or troleandomycin and are therefore less likely to interact,[26,27] although interactions have been reported. **Azithromycin**, **dirithromycin** and **spiramycin** have little or no effect on CYP3A4.[27]

Importance and management

The interactions of ergot derivatives with erythromycin and troleandomycin are well documented, well established, and clinically important. Although information about clarithromycin and oleandomycin appears to be confined to case reports, they would be expected to interact similarly. The concurrent use of all of these macrolides and ergot derivatives should be avoided. Some of the cases cited were effectively treated with sodium nitroprusside or naftidrofuryl oxalate.[1,5,7-9,22] Note that **telithromycin**, is also a relatively potent inhibitor of CYP3A4 and the UK manufacturer contraindicates, and the US manufacturer advises against its use with ergot derivatives such as ergotamine and dihydroergotamine.[28,29]

Josamycin, midecamycin, and roxithromycin are less likely to interact because they have a much lower affinity for CYP3A4. Nevertheless, there has been a report of ergotism with josamycin, and the rise in dihydroergotamine levels seen with midecamycin would be expected to be clinically relevant.

Azithromycin, dirithromycin and spiramycin would not be expected to interact because they do not inhibit CYP3A4. Nevertheless, ergot alkaloids are contraindicated with azithromycin,[30,31] because clinically important interactions have been seen between ergot derivatives and other

macrolide antibacterials.[32,33] However, there seems so far to be no direct evidence of any adverse interactions between ergot alkaloids and azithromycin, and the US manufacturer says that concurrent use can be undertaken with careful monitoring.[34]

Ergot derivatives + Protease inhibitors

A patient receiving indinavir rapidly developed ergotism after taking normal doses of ergotamine. Several other patients taking ritonavir (sometimes with another protease inhibitor) and ergotamine have developed the same interaction. A patient taking nelfinavir developed peripheral arterial vasoconstriction after also taking ergotamine. Other ergot derivatives and protease inhibitors are expected to interact similarly.

Clinical evidence

(a) Indinavir

An HIV-positive man who had been taking lamivudine, stavudine, co-trimoxazole and indinavir (2.4 g daily) for more than a year was given *Gynergene caféiné* (**ergotamine tartrate** 1 mg with caffeine 100 mg) for migraine. He took two doses on two consecutive days, and 5 days later presented with numbness and cyanosis of the toes of his left foot. The next day he complained of intermittent claudication of his left leg, and 6 days later was admitted to hospital because of worsening symptoms and night cramps. Examination showed a typical picture of ergotism, with vasospasm and reduced blood flow in the popliteal, tibial and femoral arteries. He was given heparin and buflomedil (a vasodilator), and recovered after 3 days.[1]

See *Ritonavir with other protease inhibitors*, below, for details regarding a fatality involving the use of indinavir and ritonavir with ergotamine.

(b) Nelfinavir

A 40-year-old HIV-positive woman twice took **ergotamine** 2 mg for a migraine while also taking nelfinavir, zidovudine and lamivudine. On the first occasion she developed pain and cyanosis in her toes, and on the second occasion she developed cyanosis and oedema in her hands and feet, causing pain so severe that she was unable to walk. On both occasions peripheral arterial pulses were not palpable. Although she recovered spontaneously on both occasions, the authors caution concurrent use due to the extremely severe potential effects.[2]

See also *Ritonavir with other protease inhibitors*, below.

(c) Ritonavir

A 63-year-old man with AIDS, who had taken **ergotamine tartrate** 1 to 2 mg daily for migraine headaches over the last 5 years, had his treatment with zidovudine, zalcitabine and co-trimoxazole changed to zidovudine, didanosine and ritonavir 600 mg every 12 hours. Within 10 days he developed paraesthesias, coldness, cyanosis and skin paleness of both arms, and when admitted to hospital his axillary, brachial, radial and ulnar pulses were found to be absent. An arterial doppler test showed the absence of blood flow in both his radial and ulnar arteries and he was diagnosed as having ergotism. The **ergotamine** and ritonavir were stopped, and he recovered when given prostaglandin E1 and calcium nadroparin.[3]

A case report describes irreversible coma in a 34-year-old woman who was taking ritonavir 600 mg twice daily, lamivudine and stavudine. She presented with dizziness, loss of vision, headache, vomiting, diarrhoea and a feeling of cold in her left foot after having taken three tablets of **ergotamine** 1 mg in the preceding 4 days. Peripheral pulses were absent in her extremities. After an initial period of recovery she again experienced a loss of consciousness, with signs of stenosis and vasospasm with cerebral hypoperfusion. Despite treatment with alprostadil, and discontinuation of ritonavir her condition deteriorated, and 2 years after the initial presentation, she remained in coma vigil (a state of altered consciousness).[4]

At least 4 other cases of ergotism have been reported in patients taking ritonavir after taking ergot derivatives:[5-8] one required surgical amputation of the toes.[6] Ergotism developed in two of the patients within a few hours to 24 hours of taking a single 1- or 2-mg dose of **ergotamine tartrate**,[5,7] and in the others within about 4 to 15 days.[6,8] One was taking a combination drug (**ergotamine tartrate** 300 micrograms, belladonna extract 200 micrograms and phenobarbital 20 mg) twice daily for gastric discomfort,[6] and another received 10 mg of ergotamine rectally over 4 days.[8]

(d) Ritonavir with other protease inhibitors

A 49-year-old man taking ritonavir 200 mg twice daily and **indinavir** 800 mg twice daily (with stavudine and lamivudine) took 3 *Cafergot* tablets (**ergotamine tartrate** 1 mg and caffeine 100 mg) for a headache. However, his headache worsened, he developed progressive lower extremity weakness, severe peripheral vasoconstriction, labile hypertension and livedo reticularis (skin discoloration due to underlying capillary changes). He lapsed into coma and on day 5 was declared brain dead.[9]

A 31-year-old man, taking ritonavir 400 mg twice daily (and also taking pizotifen, **nelfinavir**, stavudine, lamivudine, co-trimoxazole and venlafaxine), developed severe burning and numbness in both feet, and paraesthesias in his hands, after taking 4 tablets of **ergotamine** 1 mg and caffeine 100 mg over 10 days. He was diagnosed as having ergotism. The drugs were stopped and he was treated effectively with intravenous alprostadil and heparin.[10]

Another man receiving ritonavir and **saquinavir** experienced numbness in his hands and feet, cyanosis of his extremities, and nausea and vomiting after taking **ergotamine** [4 mg]. Four days after taking the ergotamine he was found to have no pulses (by Doppler) in any extremity and ergot toxicity was diagnosed. He was given heparin, rifampicin (rifampin), nitrate vasodilators, calcium-channel blockers and prostaglandins; pulses re-

turned in his hands after 24 hours and in his feet after 48 hours. The patient recovered with gangrene of all his toes, one of which required amputation. Treatment included rifampicin to induce liver enzymes and therefore increase the metabolism of the ergotamine.[11]

At least two other cases of ergotism have been reported in patients taking ergot derivatives with ritonavir and another protease inhibitor (**amprenavir**,[12] unspecified[13]).

Mechanism

Protease inhibitors can, to varying degrees, reduce the metabolism of ergotamine (and other ergot derivatives) by inhibiting the cytochrome P450 isoenzyme CYP3A4. Therefore ergotamine levels are increased, which may result in toxicity. Ergotamine poisoning causes arterial spasm, which reduces and even shuts down the flow of blood in arteries.

Importance and management

Information appears to be limited to these reports, but what happened is consistent with the way other drugs that are CYP3A4 inhibitors can interact with ergot derivatives (see 'Ergot derivatives + Macrolides', p.683). This interaction would appear to be established, and is clearly clinically important. It would be prudent for any patient taking indinavir or ritonavir, and probably nelfinavir, to avoid the concurrent use of ergotamine or any other ergot derivative, such as **dihydroergotamine** or **methysergide**.

Information about possible interactions between ergot derivatives and other protease inhibitors seems to be limited, but as the protease inhibitors all inhibit CYP3A4 they would be expected to interact similarly, particularly if ritonavir is given as a pharmacokinetic enhancer. The manufacturers of protease inhibitors (including amprenavir, **atazanavir**, **darunavir**, **fosamprenavir**, indinavir, **lopinavir**, nelfinavir, ritonavir, saquinavir, **tipranavir**) generally contraindicate their use with ergot derivatives.

Ergot derivatives + Tetracyclines

Five patients taking ergotamine or dihydroergotamine developed ergotism when they also took doxycycline or tetracycline.

Clinical evidence

A woman who had previously taken **ergotamine tartrate** successfully and uneventfully for 16 years was given **doxycycline** and **dihydroergotamine** 30 drops three times a day. Five days later her hands and feet became cold and reddened, and she was diagnosed as having a mild form of ergotism.[1]

Other cases of ergotism, some of them more severe, have been described in two patients taking **ergotamine tartrate** and **doxycycline**,[2,3] and in 3 patients taking **tetracycline**-containing preparations.[4,5]

Mechanism

Unknown. One suggestion is that these antibacterials may inhibit the metabolism and clearance of ergotamine in the liver, thereby prolonging its stay in the body and enhancing its activity.[1] One of the patients had a history of alcoholism[2] and two of them were in their eighties,[5] so impaired liver function may have played a part.

Importance and management

Information is very limited indeed. The incidence and general importance of this interaction is uncertain, but it seems likely to be small. However, note that one of the manufacturers of ergotamine[6] actually recommends that the concurrent use of 'tetracycline' should be avoided. Impaired liver function may possibly be a contributory factor in this interaction and it may be prudent to monitor patients with this risk factor more closely.

Ergot derivatives; Dihydroergotamine + Heparin

The use of dihydroergotamine with heparin has resulted in ergotism. In some cases, amputation of the affected limb was necessary. The rate of absorption and peak levels of subcutaneous dihydroergotamine are reduced by heparin.

Clinical evidence, mechanism, importance and management

There have been several reports of ergotism following the combined use of **dihydroergotamine** and heparin for thromboembolic prophylaxis. In a retrospective review of 61 092 Austrian patients attending trauma units who received **dihydroergotamine** and heparin prophylaxis, complications attributable to ergotism were seen in 142 patients. In 7 patients amputation was necessary and in a further 7 cases immediate opening of the vessel and catheter dilatation was successful.[1] Other published reports support this interaction,[2,3] including a report of two patients who experienced fatal myocardial infarctions, attributed to coronary artery spasm as a complication of prophylaxis with **dihydroergotamine** and heparin.[4]

It has been found that the use of heparin results in a 25% increase in the AUC of subcutaneous **dihydroergotamine**. Giving the two drugs at the same injection site reduced the rate of dihydroergotamine absorption by 63%, delayed the time to peak levels by 110%, and reduced the peak levels by 15%. **Dihydroergotamine** had no effect on the pharmacokinetics of heparin.[5]

Because of the risk of peripheral ischaemia, the combination of **dihydroergotamine** and heparin is no longer widely used for thromboembolic prophylaxis. If the combination is used, the patient must be closely observed for any sign of vascular spasm.

Triptans + Azoles

Ketoconazole and fluconazole increase the AUC of eletriptan by about sixfold and twofold, respectively. Almotriptan is less affected; ketoconazole raises its AUC by about 60%. Itraconazole is predicted to interact in the same way as ketoconazole.

Clinical evidence

(a) Almotriptan

In a randomised, crossover study, 16 healthy subjects were given **ketoconazole** 400 mg daily on days 1 to 3, with a single 12.5-mg dose of almotriptan on day 2. Ketoconazole increased the AUC and maximum plasma levels of almotriptan by 57% and 61%, respectively. The renal clearance of almotriptan was also reduced, by approximately 16%.[1]

(b) Eletriptan

A pharmacokinetic study by the manufacturers of eletriptan found that **ketoconazole** 400 mg increased the maximum serum levels and AUC of eletriptan 2.7-fold, and 5.9-fold, respectively, and prolonged its half-life from 4.8 to 8.3 hours. **Fluconazole** caused a lesser 40% increase in the maximum serum levels of eletriptan, and doubled its AUC.[2,3]

Mechanism

Ketoconazole is a potent inhibitor of the cytochrome P450 isoenzyme CYP3A4, by which eletriptan is metabolised. Ketoconazole therefore inhibits the metabolism of eletriptan, which results in raised eletriptan levels. Fluconazole is a less potent inhibitor of CYP3A4 than ketoconazole, and therefore has a more modest effect. Almotriptan is also metabolised by CYP3A4, but this is not its only route of metabolism, and therefore inhibition of CYP3A4 by ketoconazole has a less dramatic effect on its levels.

Importance and management

Although studies are limited, these interactions are established. In the study with almotriptan and ketoconazole adverse events were not significantly altered, and so no almotriptan dosage adjustment is considered necessary when using this combination.[1] Ketoconazole dramatically raises eletriptan levels, and therefore the manufacturers advise that concurrent use should be avoided.[2,3] In addition, the US manufacturer recommends that eletriptan should not be given within 72 hours of ketoconazole.[2]

Itraconazole is expected to interact in the same way as ketoconazole, and therefore the same precautions should be taken.

Fluconazole is a less potent inhibitor of CYP3A4 and therefore may be used with caution. Other triptans would be expected to have little or no interaction with the azoles as they are not predominantly metabolised by CYP3A4 (see 'Table 16.2', (p.680)).

Triptans + Beta blockers

The plasma levels of rizatriptan are almost doubled by propranolol. No clinically important interaction occurs between other triptans and beta blockers.

Clinical evidence, mechanism, importance and management

(a) Almotriptan

Twelve healthy subjects were given **propranolol** 80 mg twice daily for 7 days followed by a single 12.5-mg dose of almotriptan. Although some small changes were noted in the pharmacokinetics of almotriptan (e.g. AUC increased by 7%), these were not considered to be clinically significant and concurrent use of the combination was well tolerated.[1]

(b) Eletriptan

In an interaction study, 12 healthy subjects were given a single 80-mg dose of eletriptan after taking **propranolol** 80 mg twice daily for 7 days. It was found that the eletriptan AUC was increased by 30%, and the half-life increased from 4.9 to 5.2 hours. However, these changes were not considered to be clinically significant, and no significant blood pressure changes or any adverse events were seen, when compared with taking eletriptan alone.[2,3]

The UK manufacturer reports that no evidence of an interaction was seen in clinical studies where eletriptan was taken with beta blockers.[3]

(c) Frovatriptan

A single 2.5-mg oral dose of frovatriptan was given to 12 healthy subjects after they had taken **propranolol** 80 mg twice daily for 7 days. The AUC and maximum levels of frovatriptan were increased by 25% and 23%, respectively. However, these changes are small, and no changes occurred in the ECGs and vital signs of the subjects. Therefore the pharmacokinetic interaction was not thought to be of clinical significance.[4]

(d) Naratriptan

The US manufacturer of naratriptan reports that, from population pharmacokinetic analyses, beta blockers did not affect the clearance of naratriptan, and the efficacy of naratriptan was unaffected by the concurrent use of beta blockers.[5] The UK manufacturer similarly says that there is no evidence of interactions with beta blockers (none specifically named).[6]

(e) Rizatriptan

A series of double-blind, placebo-controlled studies were conducted in a total of 51 healthy subjects who were given a single 10-mg dose of rizatriptan after they had taken **propranolol** 60 or 120 mg twice daily, **nadolol** 80 mg daily, or **metoprolol** 100 mg daily, for 7 days.[7] **Nadolol** and **metoprolol** had no effect on the pharmacokinetics of rizatriptan. However, **propranolol** raised the AUC and the maximum plasma concentration of rizatriptan by 1.67 and 1.75-fold, respectively; in one subject there was a fourfold increase in the AUC. Adjusting the dose of **propranolol** and separating the administration by 2 hours had little effect on this interaction.[7] The AUC of the active *N*-monodesmethyl metabolite of rizatriptan was not affected by **propranolol**.[7]

In vitro studies have similarly shown that **propranolol** markedly inhibits the metabolism of rizatriptan, whereas **atenolol**, **nadolol** and **timolol** do not affect the metabolism of rizatriptan.[7]

The manufacturers recommend that a 5-mg dose of rizatriptan (rather than the more usual 10 mg) should be used in the presence of **propranolol**, with a maximum of two[8] or three doses in 24 hours.[9] In the UK, they also state that administration should be separated by at least 2 hours,[8] although the rationale for this is less clear given that the above study found that such a dose separation did not appear to modify the interaction. No reduction in the rizatriptan dosage would seem to be needed in the presence of **atenolol**, **metoprolol**, **nadolol** or **timolol**.

(f) Sumatriptan

In a study in 10 healthy subjects, **propranolol** 80 mg twice daily for 7 days did not alter the pharmacokinetics of a single 300-mg dose of sumatriptan given on day 7. There was no significant effect on pulse rate or blood pressure.[10] The manufacturer says that the efficacy of sumatriptan was unaffected by the concurrent use of beta blockers.[11]

(g) Zolmitriptan

In a randomised, crossover study, 12 healthy subjects were given **propranolol** 160 mg or a placebo daily for 7 days, with a single 10-mg oral dose of zolmitriptan on day 7. **Propranolol** increased the maximum serum levels and the AUC of zolmitriptan by 56% and 37%, respectively, and reduced the extent of its conversion to its active metabolite, probably due to inhibition of, or competition for, metabolism by cytochrome P450 isoenzymes. However, the higher zolmitriptan levels were not associated with a greater rise in blood pressure and it was concluded that no clinically important changes in the therapeutic effects of zolmitriptan are likely, nor are any adjustments in its dosage needed.[12]

The manufacturer says there is no evidence that the concurrent use of beta blockers, has any effect on the efficacy or unwanted effects of zolmitriptan.[13]

Triptans + Ergot derivatives

Theoretically additive vasoconstriction may occur when ergot derivatives and triptans are given together, although this has been demonstrated only in one study with sumatriptan. However, one isolated case report describes myocardial infarction in a woman taking sumatriptan and methysergide.
No important additive effect has been seen in pharmacodynamic studies with ergot derivatives and almotriptan, eletriptan, frovatriptan, naratriptan, rizatriptan or zolmitriptan, although minor increases in blood pressure were reported with eletriptan.

Clinical evidence

(a) Almotriptan

The manufacturer of almotriptan says that no additive vasospastic effects were seen in a clinical study in 12 healthy subjects given almotriptan and **ergotamine**.[1] However, they do note that such effects are theoretically possible.

(b) Eletriptan

The manufacturer reports that when oral **ergotamine** with caffeine was given 1 hour and 2 hours after eletriptan, minor additive increases in blood pressure were seen.[2]

(c) Frovatriptan

In a randomised, crossover study, 12 healthy subjects were given a single 5-mg dose of oral frovatriptan, a single 2-mg sublingual dose of **ergotamine**, or both drugs together. **Ergotamine** reduced the maximum levels and AUC of frovatriptan by about 25%, which was modest. However, frovatriptan had no effect on **ergotamine** pharmacokinetics, and no clinically significant changes in the haemodynamics or the ECGs of the subjects were noted.[3]

(d) Naratriptan

A study in 12 healthy subjects found that 1 mg of intramuscular **dihydroergotamine** reduced the AUC and the maximum serum levels of a single 2.5-mg dose of naratriptan by 15% and 20%, respectively, but this was not considered to be clinically relevant. Concurrent use was well tolerated and no clinically significant blood pressure, heart rate or ECG effects were seen.[4]

(e) Rizatriptan

In a pharmacodynamic study in 16 healthy subjects additive vasospastic effects were not observed when oral rizatriptan 10 mg was given with intravenous **ergotamine** 250 micrograms.[5,6]

(f) Sumatriptan

A study in 38 migraine sufferers found that 1 mg of intravenous **dihydroergotamine** caused a maximum increase in blood pressure of 13/9 mmHg, while 2 or 4 mg of subcutaneous sumatriptan caused a smaller rise in blood pressure of 7/6 mmHg. When both drugs were given together the blood pressure rises were no greater than with **dihydroergotamine** alone.[7] A clinical study found that the adverse event profile of subcutaneous sumatriptan was not affected by the concurrent use of oral **dihydroergotamine**.[8] However, another pharmacodynamic study found that subcutaneous sumatriptan and intravenous **ergotamine** had additive vasoconstrictive effects (as assessed by decreases in toe-arm systolic blood pressure gradients).[9]

Myocardial infarction has been reported in a 43-year-old woman after she took two 2-mg doses of **methysergide** 12 hours apart, followed by sumatriptan 6 mg subcutaneously. Severe chest pain and tightness with breathlessness began 15 minutes later, and results of various tests were consistent with 'coronary spasm on an area of atherosclerosis'.[10]

(g) Zolmitriptan

In a randomised, placebo-controlled study, 12 healthy subjects were given 5 mg of oral **dihydroergotamine** twice daily for 10 days, with oral zolmitriptan 10 mg (four times the usual dose) on day 10. No significant changes in blood pressure, ECGs, or zolmitriptan pharmacokinetics were seen, and concurrent use was well tolerated.[11] Another randomised, placebo-controlled study in 12 healthy subjects looked at the effects of oral zolmitriptan 20 mg (eight times the usual dose) given with oral **ergotamine** 2 mg (contained in *Cafergot* tablets; **ergotamine** 1 mg with caffeine 100 mg). Using a very detailed and thorough range of techniques, no clinically relevant cardiovascular changes were found, even at this large dose of zolmitriptan, and concurrent use was generally well tolerated. No important changes in zolmitriptan pharmacokinetics were seen.[12]

Mechanism

Vasoconstriction is a well known adverse effect of ergot derivatives, and coronary vasoconstriction may also occur rarely with the triptans. (Note that in 1992, soon after the marketing of sumatriptan, the CSM in the UK had received 34 reports of chest pain or tightness caused by sumatriptan, possibly due to coronary vasoconstriction.[13]) It is therefore theoretically possible that the drugs may have additive vasoconstrictive effects, although there is little evidence of this in practice.

Importance and management

Due to the theoretical risk of additive vasoconstriction, and possible significant coronary vasoconstriction ergot derivatives are generally contraindicated with the triptans.

The UK manufacturer of sumatriptan says that ergotamine should not be given less than 6 hours after taking the triptan, and recommends that the triptan should not be taken less than 24 hours after taking ergotamine.[14] The same recommendations are made by the UK manufacturers of almotriptan,[1] rizatriptan,[5] and zolmitriptan.[15] The UK manufacturers of eletriptan,[2] and frovatriptan,[16] recommend that ergot derivatives are not given for a minimum of 24 hours (not just 6 hours) after these triptans, and in general, in the US, it is recommended that triptans and ergotamine or ergot-type medication should not be taken within 24 hours of each other. In the absence of specific guidance for individual triptans, it would seem prudent to follow this advice.

Triptans + Flunarizine

Flunarizine did not alter the pharmacokinetics or pharmacodynamics of sumatriptan in one study. Flunarizine does not appear to interact with eletriptan.

Clinical evidence, mechanism, importance and management

(a) Eletriptan

The manufacturer notes that although no formal interaction studies have been carried out, there was no evidence of an interaction between eletriptan and flunarizine in clinical studies.[1]

(b) Sumatriptan

A double-blind study in healthy subjects found that flunarizine 10 mg daily for 8 days had no effect on the pharmacokinetics of a single dose of sumatriptan, and the combination caused no significant changes in blood pressure, ECG or heart rate.[2]

1. Relpax (Eletriptan hydrobromide). Pfizer Ltd. UK Summary of product characteristics, February 2008.
2. Van Hecken AM, Depré M, De Schepper PJ, Fowler PA, Lacey LF, Durham JM. Lack of effect of flunarizine on the pharmacokinetics and pharmacodynamics of sumatriptan in healthy volunteers. *Br J Clin Pharmacol* (1992) 34, 82–4.

Triptans + Macrolides

Erythromycin markedly raises the plasma levels of eletriptan; clarithromycin, josamycin and troleandomycin are predicted to interact similarly. Erythromycin is predicted to raise almotriptan levels. Clarithromycin does not significantly alter the pharmacokinetics of sumatriptan.

Clinical evidence

(a) Eletriptan

A clinical pharmacokinetic study by the manufacturer of eletriptan[1] found that **erythromycin** 1 g increased the maximum serum levels and AUC of eletriptan twofold and 3.6-fold, respectively, and prolonged its half-life from 4.6 to 7.1 hours.

(b) Sumatriptan

A study in which 24 healthy subjects were given sumatriptan 50 mg on the morning of the fourth day of a course of **clarithromycin** 500 mg twice daily, found that **clarithromycin** did not significantly affect the pharmacokinetics of sumatriptan.[2]

Mechanism

The macrolides are, to varying degrees, inhibitors of the cytochrome P450 isoenzyme CYP3A4, by which eletriptan is metabolised. Therefore erythromycin reduces eletriptan metabolism and raises its plasma levels. Sumatriptan is not metabolised by CYP3A4 and therefore does not interact with clarithromycin.

Importance and management

Information is limited but an interaction between eletriptan and erythromycin appears to be established. Because of the elevated levels seen, the UK manufacturer advises against their concurrent use.[1] Similarly, other drugs that are moderate to potent CYP3A4 inhibitors, including **clarithromycin**[1,3] **josamycin**,[1] and troleandomycin,[3] are predicted to raise serum eletriptan levels, and should also not be used with eletriptan. The US manufacturer recommends that eletriptan should not be given within 72 hours of potent CYP3A4 inhibitors, and they specifically name **clarithromycin** and **troleandomycin**.[3] Note that the macrolides differ in their ability to inhibit CYP3A4, see 'Ergot derivatives + Macrolides', p.683.

Almotriptan is also metabolised, at least in part, by CYP3A4. The US manufacturer therefore reasonably predicts that its levels may be raised by erythromycin.[4] However, note that, based on its interaction with 'ketoconazole', (p.685), dosage adjustments would not be expected to be necessary.

Other triptans would be expected to have little or no interaction with the macrolides as they are not predominantly metabolised by CYP3A4 (see 'Table 16.2', (p.680)).

Triptans + MAOIs

Moclobemide (a RIMA) markedly inhibits the metabolism of rizatriptan, modestly inhibits the metabolism of zolmitriptan, and approximately doubles the bioavailability of sumatriptan. Moclobemide has no clinically significant pharmacokinetic effect on almotriptan, and is not expected to affect the pharmacokinetics of eletriptan, frovatriptan, or naratriptan. Non-selective MAOIs (e.g. phenelzine) would be expected to behave similarly.
Selegiline (an MAO-B inhibitor) does not alter the pharmacokinetics of sumatriptan or zolmitriptan, and would not be expected to alter the pharmacokinetics of the other triptans.
Some have suggested that there may be a pharmacodynamic interaction between MAOIs (both selective and non-selective) and triptans, which may result in serotonin syndrome.

Clinical evidence

(a) Almotriptan

In a study, 12 healthy subjects were given **moclobemide** 150 mg twice daily for 8 days with a single 12.5-mg dose of almotriptan on day 8. The AUC of almotriptan was increased by 37%, its clearance was decreased by 27% and its half-life was increased by 24%, but this was not considered to be clinically significant.[1]

(b) Frovatriptan

A study in 9 healthy subjects given a single 2.5-mg oral dose of frovatriptan after taking **moclobemide** 150 mg twice daily for 7 days did not find any pharmacokinetic changes, or any alterations in the vital signs and ECGs of the subjects.[2]

(c) Rizatriptan

In a randomised, placebo-controlled study, 12 healthy subjects were given **moclobemide** 150 mg three times daily for 4 days, with a single 10-mg dose of rizatriptan on day 4. **Moclobemide** increased the AUCs of rizatriptan and its active (but minor) metabolite by 2.2- and 5.3-fold, respectively, and increased their maximum serum levels by 1.4- and 2.6-fold, respectively. Despite these rises, the concurrent use of these drugs was well tolerated and any adverse effects were mild and similar to those seen when rizatriptan was given with placebo.[3]

(d) Sumatriptan

Three groups of 14 subjects were given placebo, **moclobemide** 150 mg three times daily, or **selegiline** 5 mg twice daily for 8 days, with subcutaneous sumatriptan 6 mg on day 8. No statistically significant differences in pulse rates or blood pressures were seen between any of the groups. However, the AUC of sumatriptan in the **moclobemide**-treated group was approximately doubled (129% increase), its clearance was reduced by 56%, and its half-life increased by 52%. The pharmacokinetic changes seen in the **selegiline** group were not consistent. There were no differences in the adverse events experienced by any of the three groups.[4]

A comprehensive search of the literature, and reports from proprietary manufacturers, identified published reports of 31 patients taking sumatriptan and MAOIs concurrently, but no adverse events were reported.[5] Furthermore, a patient taking **moclobemide** 300 mg three times daily had no adverse effects when given oral sumatriptan 100 mg on six occasions.[6] However, a patient who had taken an overdose of **moclobemide**, together with sumatriptan, sertraline, and citalopram developed serotonin syndrome.[7]

(e) Zolmitriptan

In a series of randomised studies, 12 healthy subjects were given **selegiline** 10 mg daily or **moclobemide** 150 mg twice daily for 7 days, with a single 10-mg oral dose of zolmitriptan on day 7.[8] **Moclobemide** increased

the AUCs of zolmitriptan and its active metabolite, by 26% and threefold, respectively.[9]

In another study, **selegiline** had no effect on the pharmacokinetics of zolmitriptan or its metabolites, apart from a small (7%) reduction in its renal clearance.[8]

Mechanism

Almotriptan, rizatriptan, sumatriptan and zolmitriptan are substrates of MAO-A. Therefore moclobemide, an inhibitor of MAO-A, can reduce their metabolism, resulting in raised levels. The effect differs between the triptans as less than half of a dose of almotriptan is metabolised by MAO-A,[10] whereas MAO-A is the principal enzyme concerned with the metabolism of rizatriptan[3] and sumatriptan.[11] Frovatriptan is not metabolised by MAO-A, and therefore its pharmacokinetics are not affected by moclobemide.

Importance and management

The interactions of moclobemide with **rizatriptan** or **sumatriptan** are established, and clinically relevant. The UK and US manufacturers contraindicate their use both during, and for 2 weeks after, the use of both non-selective MAOIs (e.g. phenelzine) and moclobemide because of the risks of coronary vasospasm.[12-15]

The interaction with **zolmitriptan** is modest, although levels of its active metabolite are more markedly raised. The US manufacturer contraindicates its use both during, and for 2 weeks after, the use of moclobemide,[16] whereas the UK manufacturer restricts the dose of zolmitriptan to 5 mg in 24 hours.[9] In the absence of any direct information it would seem prudent to apply these warnings to the use of non-selective MAOIs.

The interaction of moclobemide with **almotriptan** is slight, and no dosage adjustments would be expected to be necessary with any selective or non-selective MAOI.

Moclobemide did not affect the pharmacokinetics of **frovatriptan**, and would not be expected to affect the pharmacokinetics of **eletriptan** or **naratriptan**, as they, like frovatriptan, are not metabolised by MAO-A, see 'Table 16.2', (p.680). Similarly, non-selective inhibitors of MAO would not be expected to interact.

Selegiline, a selective inhibitor of MAO-B, does not affect the pharmacokinetics of sumatriptan or zolmitriptan, and would not be expected to alter the metabolism of any other triptan. Other MAO-B inhibitors, such as rasagiline, would also therefore not be expected to interact. However, note that the MAO-B selectivity of selegiline is lost at doses above 10 mg daily.

One isolated UK manufacturer of selegiline contraindicates its use with triptans and recommends a time interval of 24 hours between discontinuation of selegiline and initiation of serotonin agonists.[17] This is possibly because of a theoretical possibility of 'serotonin syndrome', (p.9), developing on concurrent use. The manufacturers of almotriptan,[18] and frovatriptan,[19] also warn of the possibility of serotonin syndrome with MAOIs. The syndrome is rare and it may (so it has been suggested[20]) sometimes be an idiosyncratic reaction.

Triptans + Paracetamol (Acetaminophen)

Paracetamol causes a slight increase in zolmitriptan levels and zolmitriptan causes a slight reduction in the rate and extent of paracetamol absorption, but this does not appear to be clinically relevant. Sumatriptan also delays paracetamol absorption.

Clinical evidence, mechanism, importance and management

In a randomised, crossover study, 15 healthy subjects were given a single 10-mg dose of **zolmitriptan**, alone or with 1 g of paracetamol. Paracetamol increased the maximum plasma levels and AUC of **zolmitriptan** by 11%, while reducing its renal clearance by 9%. The paracetamol maximum plasma levels and AUC were reduced by 31% and 11%, respectively, and absorption was delayed (time to achieve maximum plasma levels increased from 45 minutes to 3 hours). The presence of oral metoclopramide 10 mg did not affect the interaction between **zolmitriptan** and paracetamol.[1] The authors considered that the small changes in pharmacokinetics seen were of no clinical relevance.[1]

Similarly, in a study in 9 migraine patients, pretreatment with oral **sumatriptan** 100 mg delayed paracetamol absorption and reduced its maximum plasma concentration by 50%, but the total absorption of paracetamol over 8 hours was not significantly altered.[2] It has been suggested that **sumatriptan** and **zolmitriptan** might have some inhibitory effect on gastric emptying thereby slowing the absorption of paracetamol,[1,2] and although this appears to occur, it does not appear to be clinically relevant.

Triptans + Pizotifen

Pizotifen does not alter the pharmacokinetics or pharmacodynamics of sumatriptan or zolmitriptan, and does not alter the efficacy of acute sumatriptan for migraine. It seems unlikely that any of the other triptans will interact with pizotifen.

Clinical evidence

(a) Sumatriptan

Pizotifen 500 micrograms three times daily for 8 days was found to have no significant effect on the pharmacokinetics of sumatriptan in 14 healthy subjects. In addition, no significant changes in blood pressure or heart rate occurred.[1] In a clinical study, pizotifen prophylaxis did not alter the efficacy of acute sumatriptan for migraine relief. In this study, the combination was associated with more weight gain than sumatriptan alone, an effect that was attributed solely to the pizotifen.[2]

(b) Zolmitriptan

In a placebo-controlled, randomised study, 12 healthy subjects were given pizotifen 1.5 mg daily for 8 days, with oral zolmitriptan 10 mg on day 8. Pizotifen did not significantly alter the pharmacokinetics of zolmitriptan, and no clinically relevant changes in heart rates or ECGs or blood pressures were seen as a result of concurrent use.[3]

Mechanism, importance and management

Although the information is limited, it shows that no sumatriptan or zolmitriptan dosage adjustments are expected to be needed if used with pizo-

tifen, and concurrent use appears safe. On the basis of the information about sumatriptan and zolmitriptan it seems unlikely that any of the other triptans will interact.

Triptans + Protease inhibitors

Protease inhibitors such as ritonavir, indinavir or nelfinavir would be expected to markedly increase the levels of eletriptan. Ritonavir is also expected to increase the levels of almotriptan.

Clinical evidence, mechanism, importance and management

The manufacturers state that the concurrent use of eletriptan and ritonavir, indinavir, or nelfinavir should be avoided, because these protease inhibitors are potent inhibitors of the cytochrome P450 isoenzyme CYP3A4, an enzyme involved in the metabolism of eletriptan. Concurrent use would therefore be expected to markedly increase eletriptan levels.[1,2] In addition, the US manufacturer recommends that eletriptan should not be given within 72 hours of ritonavir and nelfinavir.[2] This predicted interaction is based on the known interaction with 'erythromycin', (p.688), and 'ketoconazole', (p.685). Similar predictions are made by the manufacturer of almotriptan; they advise that increased exposure to almotriptan may be expected with the use of ritonavir.[3] It is unclear what the clinical significance of this effect may be.

Triptans + SSRIs or SNRIs

The SSRIs normally appear not to interact with the triptans, but there are a few rare cases of dyskinesias when sumatriptan was given with an SSRI, and there is some evidence to suggest that serotonin syndrome may occasionally develop. The SNRIs venlafaxine, duloxetine and milnacipran are predicted to interact similarly. Fluvoxamine modestly inhibits the metabolism of frovatriptan, and may inhibit the metabolism of zolmitriptan.

Clinical evidence

The FDA in the US has reviewed 27 reports of serotonin syndrome associated with the concurrent use of an SSRI or SNRI (e.g. **duloxetine** or **venlafaxine**) and a triptan. Two reports described life-threatening events and 13 reports stated that the patients required hospitalisation. Some of the cases occurred in patients who had previously taken an SSRI or SNRI with a triptan without experiencing serotonin syndrome. In 8 cases, recent dose increases or the addition of another serotonergic drug had occurred around the time of symptom onset: the median time to onset was one day, with a range of 10 minutes to 6 days.[1] Reports describing interactions with specific triptans are outlined in the subsections below.

(a) Almotriptan

Fluoxetine 60 mg daily was given to 14 healthy subjects for 8 days, with a single 12.5-mg dose of almotriptan on day 8. **Fluoxetine** raised the maximum plasma levels of almotriptan by about 18%. The combination was well tolerated and caused no ECG changes, so no dose alterations were considered necessary.[2]

(b) Eletriptan

The manufacturer notes that although no formal interaction studies have been done, there was no evidence of an interaction between eletriptan and SSRIs in clinical studies, and that in population pharmacokinetic studies SSRIs appeared unlikely to alter the pharmacokinetics of eletriptan.[3] A retrospective review of seven double-blind studies identified 253 patients who had received eletriptan with an SSRI and 3908 patients who received eletriptan alone. There were no clinically significant differences with respect to the incidence of adverse effects between the two groups.[4]

(c) Frovatriptan

Fluvoxamine has been shown to increase the blood levels of frovatriptan by 27 to 49%.[5]

(d) Naratriptan

The UK manufacturer of naratriptan notes that there is no evidence of interactions with SSRIs.[6]

(e) Rizatriptan

In a placebo-controlled study, 12 healthy subjects were given a single 10-mg dose of rizatriptan after they took **paroxetine** 20 mg daily for 14 days. The plasma levels of rizatriptan and its active metabolite were not altered by **paroxetine**, and no adverse effects were seen. Safety evaluations included blood pressure, heart rate, temperature and a visual analogue assessment of mood. There was no evidence of serotonin syndrome.[7]

(f) Sumatriptan

A study in 11 healthy subjects found that **paroxetine** 20 mg daily for 16 days had no effect on the response to a 6-mg dose of subcutaneous sumatriptan, as measured by prolactin levels. The sumatriptan levels remained unaltered, its cardiovascular effects were unchanged and no clinically significant adverse effects occurred.[8] Other studies report that the concurrent use of sumatriptan and SSRIs (**fluoxetine** 20 to 60 mg daily, **fluvoxamine** 200 mg daily, **paroxetine** 20 to 50 mg daily, **sertraline** 50 to 100 mg daily) was successful and uneventful.[9,10] No adverse effects have been noted in 148 other patients.[11]

A prospective study of 12 339 individuals receiving sumatriptan by injection identified 14.5% of these (1784) who were also taking SSRIs (**fluoxetine** 8.3%, **sertraline** 5.5%, **paroxetine** 3.9%, other 0.4%) or **venlafaxine** 1.7%. Patients taking SSRIs were found to have a higher absolute frequency of adverse neurological effects, when compared with those not taking antidepressants (0.8% and 0.25%, respectively). Nevertheless, the authors concluded that there was no evidence of an interaction as the adverse events occurred more than 24 hours after sumatriptan was given.[12]

However, a case report describes a 65-year-old woman who had been taking **paroxetine** 20 mg [daily] for a number of years, who developed confusion, strange behaviour, sinus tachycardia, hypertension and hyperthermia shortly after starting sumatriptan. Serotonin syndrome was diagnosed, and she recovered completely when both drugs were withdrawn.[13]

Additionally, in Canada, post-marketing surveillance of the voluntary reports received by the manufacturers of **fluoxetine** identified 2 cases that showed good evidence, and another 4 cases that showed some, but not strong evidence, of reactions consistent with serotonin syndrome in patients also taking sumatriptan.[14] Other cases describe a decrease in the efficacy of sumatriptan with **fluoxetine**,[15] dyskinesias and dystonias with sumatriptan and **paroxetine**,[16] and twenty possible cases of serotonin syndrome with sumatriptan and SSRIs.[11,17]

The manufacturers of sumatriptan also say that they have rare post-marketing reports of weakness, hyperreflexia and incoordination following the use of sumatriptan and SSRIs.[18]

(g) Zolmitriptan

A placebo-controlled, crossover study in 20 subjects given **fluoxetine** 20 mg daily for 28 days, with zolmitriptan 10 mg on day 28, found that the pharmacokinetics of zolmitriptan were unaffected by **fluoxetine**.[19] Only very slight changes were seen in the pharmacokinetics of its active metabolite.[19] **Sertraline**, **paroxetine**, and **citalopram** are also not expected to alter the pharmacokinetics of zolmitriptan. However, **fluvoxamine**, a potent CYP1A2 inhibitor, is predicted to increase levels of zolmitriptan,[20] based on the known interaction with cimetidine (see 'Triptans; Zolmitriptan + Cimetidine', p.692).

Mechanism

Not understood. SSRIs increase the levels of 5-HT (serotonin) at post-synaptic receptors. In theory the triptans (5-HT_1 agonists) might possibly add to the effects of these increased levels of serotonin, but in practice it is questionable whether this is normally clinically relevant. Fluvoxamine probably inhibits the metabolism of frovatriptan[21] by cytochrome P450 isoenzyme CYP1A2, and is predicted to interact with zolmitriptan[20] by the same mechanism.

Importance and management

The weight of evidence suggests that the concurrent use of the triptans and SSRIs is normally uneventful, but adverse reactions do occur occasionally. SSRIs have frequently been prescribed with triptans and a drug interaction causing the serotonin syndrome appears to be extremely rare.[22,23] The authors of some of the references above concluded that their findings do not imply that concurrent use should be avoided, but that caution and close monitoring should be used.[11,14] Signs of serotonin syndrome include agitation, hyperthermia, tachycardia, weakness, hyperreflexia, and incoordination. Monitoring is particularly advisable during treatment initiation and dose increases. The FDA in the US recommends that patients given a triptan with an SSRI or SNRI should be informed of the possibility of serotonin syndrome and be carefully observed.[1] Similar advice is given by most US and UK manufacturers of SSRIs, SNRIs, and triptans; the exception being the UK manufacturers of sertraline, who cautiously state that, until further data are available, serotonergic drugs such as sumatriptan should not be used concurrently, due to a possible enhancement of 5-HT associated effects.[24,25] The manufacturer of **milnacipran** similarly states that it should not be used with triptans, and that one week should elapse after stopping milnacipran before starting a triptan.[26]

Fluvoxamine is predicted to have a pharmacokinetic interaction with zolmitriptan and therefore the manufacturer recommends a maximum dosage of 5 mg in 24 hours in the presence of fluvoxamine.[20] A similar pharmacokinetic interaction may also occur between fluvoxamine and frovatriptan, and the manufacturer advises caution and strict adherence to the recommended dose.[21]

Triptans + St John's wort (*Hypericum perforatum*)

Serotonin syndrome has been reported in a patient taking eletriptan and St John's wort.

Clinical evidence

A 28-year-old woman who had been taking fluoxetine 60 mg daily for one year for an eating disorder, and St John's wort (dose and frequency not stated) for one month, suffered a loss of consciousness, convulsions, and mental confusion after **eletriptan** 40 mg daily was started 3 days earlier for a recurrent migraine. Previous use of **eletriptan** and fluoxetine had not resulted in any reported adverse effects. After admission to hospital, the patient developed acute rhabdomyolysis and transient mild acute renal failure. Serotonin syndrome was diagnosed, all medications were stopped, and the symptoms gradually resolved over 10 days.[1]

Mechanism

Additive serotonergic effects are the likely explanation for the case report above as serotonin syndrome has been reported with both St John's wort[2] and with the triptans alone.

Importance and management

The CSM/MCA in the UK note that potentiation of serotonergic effects have been identified between the triptans and St John's wort leading to an increased risk of adverse effects. They advise that patients taking triptans should not take St John's wort preparations.[3,4] However, most UK manufacturers of triptans simply warn about the potential increase in undesirable effects. The possible concern is that concurrent use may result in the development of serotonin syndrome. For more information on serotonin syndrome, see under 'Additive or synergistic interactions', (p.9).

Triptans + Tobacco

The clearance of naratriptan, and possibly frovatriptan, is modestly increased by smoking. However, this is unlikely to be clinically relevant. One large study found no evidence of an interaction between smoking and sumatriptan.

Clinical evidence

(a) Frovatriptan

In a retrospective analysis of pharmacokinetic data from phase I studies, there was a trend for a lower frovatriptan AUC and maximum plasma level in smokers, when compared with non-smokers. The clearance tended to be higher but the half-life did not differ.[1]

(b) Naratriptan

The manufacturer notes that smoking increases the clearance of naratriptan by 30%.[2]

(c) Sumatriptan

A prospective study of 12 339 individuals receiving sumatriptan by injection identified 18.3% of these (2262) who were current smokers. There was no evidence of an interaction between sumatriptan and tobacco smoking.[3]

Mechanism

Tobacco smoke is known to induce the cytochrome P450 isoenzyme CYP1A2, which metabolises both naratriptan and frovatriptan to some extent. **Zolmitriptan** is also a substrate of CYP1A2, but the effect of smoking does not appear to have been studied.

Importance and management

Although data are limited, the possible small changes in the pharmacokinetics of frovatriptan and naratriptan with smoking are unlikely to be clinically relevant.

Triptans + Verapamil

Verapamil markedly raises the plasma levels of eletriptan, but only slightly increases the plasma levels of almotriptan.

Clinical evidence, mechanism, importance and management

(a) Almotriptan

In a crossover study, 12 healthy subjects were given a single 12.5-mg dose of almotriptan, either alone or after they had taken sustained-release verapamil 120 mg twice daily for 7 days. Verapamil increased the AUC and maximum plasma level of almotriptan by about 20% and 24%, respectively. However, the only effect this caused was a slight increase in systolic BP (8 mmHg), which occurred 2 hours after the dose. It was suggested that verapamil might inhibit the metabolism of almotriptan by the cytochrome P450 isoenzyme CYP3A4.[1] The pharmacokinetic changes are slight, and no dosage adjustments or particular precautions would appear to be necessary on concurrent use.

(b) Eletriptan

In a clinical study, verapamil 480 mg markedly raised the maximum plasma levels and AUC of eletriptan by 2.2-fold and 2.7-fold, respectively.[2,3] The UK manufacturer states that these increases are not considered to be clinically significant as there were no associated increases in blood pressure or adverse events, when compared with eletriptan alone.[2]

Triptans; Sumatriptan + Butorphanol

Sumatriptan given by injection appears not to interact with butorphanol nasal spray, but if both drugs are given sequentially by nasal spray a modest reduction in butorphanol absorption may occur.

Clinical evidence, mechanism, importance and management

No pharmacokinetic interactions or change in adverse effects were found to occur when 24 healthy subjects were given a single 1-mg dose of butorphanol tartrate nasal spray and a 6-mg subcutaneous dose of sumatriptan succinate. It was concluded that concurrent use during acute migraine attacks need not be avoided.[1]

In another study, 19 healthy subjects were given a 1-mg dose of butorphanol nasal spray either 1 or 30 minutes after a 20-mg dose of sumatriptan nasal spray. When butorphanol was given 1 minute after sumatriptan the AUC and maximum plasma levels of butorphanol were reduced by about 29% and 38%, respectively. When butorphanol was given 30 minutes after sumatriptan no significant pharmacokinetic interaction was noted. It was suggested that sumatriptan may cause a transient vasoconstriction of nasal blood vessels, leading to reduced butorphanol absorption. It would therefore seem wise to separate administration to ensure that the full effects of butorphanol are achieved.[2]

Triptans; Sumatriptan + Loxapine

An isolated report describes a woman taking loxapine who developed a severe dystonic reaction when she was given sumatriptan.

Clinical evidence, mechanism, importance and management

A woman was taking loxapine 10 mg twice daily for psychotic target symptoms, benzatropine for the prophylaxis of extrapyramidal effects, carbamazepine for mood stabilisation, and *Fiorcet* (paracetamol (acetaminophen), caffeine, and butalbital) for migraine headaches. Two days after the loxapine dosage was raised to 35 mg daily she was given a single 6-mg subcutaneous dose of sumatriptan for a migraine headache. Within 15 minutes she developed torticollis, which was treated with intramuscular benzatropine and intravenous diphenhydramine.

The authors of the report suggest that this reaction was possibly caused by the additive dystonic effects of the loxapine and sumatriptan, despite the presence of the benzatropine. Dystonia is not an uncommon extrapyramidal reaction associated with antipsychotics, and neck stiffness and dystonia are recognised adverse effects of sumatriptan, but of low incidence.[1] This seems to be the first and only report of this apparent interaction, and therefore its general significance is unclear.

Triptans; Sumatriptan + Naproxen

A study in 12 healthy subjects found that a single 500-mg dose of naproxen had no significant effect on the pharmacokinetics of a single 100-mg oral dose of sumatriptan.[1] A 12-month tolerability study found that a tablet containing both sumatriptan and naproxen was well tolerated for the treatment of acute migraine attacks, and the adverse events did not differ from those expected for the individual components alone.[2]

1. Srinivasu P, Rambhau D, Rao BR, Rao YM. Lack of pharmacokinetic interaction between sumatriptan and naproxen. *J Clin Pharmacol* (2000) 40, 99–104.
2. Winner P, Cady RK, Ruoff GE, Frishberg BM, Alexander WJ, Zhang Y, Kori SH, Lener SE. Twelve-month tolerability and safety of sumatriptan-naproxen sodium for the treatment of acute migraine. *Mayo Clin Proc* (2007) 82, 61–8.

Triptans; Sumatriptan + Topiramate

Topiramate does not affect the pharmacokinetics of oral or subcutaneous sumatriptan to a clinically relevant extent.

Clinical evidence, mechanism, importance and management

In a study, 24 healthy subjects were given topiramate 50 mg every 12 hours increased to 100 mg every 12 hours for a total of 7 days, with a single 100-mg oral dose of sumatriptan on day 7. It was found that topiramate reduced the AUC of sumatriptan by 10%, but this was not considered to be clinically relevant. Topiramate had no effect on the AUC of a 6 mg subcutaneous dose of sumatriptan. The clearance of topiramate appeared to be reduced, when data from this study was compared with that from historical controls, but the magnitude of the effect was not stated.[1] The clinical significance of this effect is unclear.

1. Bialer M, Doose DR, Murthy B, Curtin C, Wang S-S, Twyman RE, Schwabe S. Pharmacokinetic interactions of topiramate. Clin Pharmacokinet. (2004) 43, 763–80.

Triptans; Zolmitriptan + Cimetidine

Cimetidine moderately raises the plasma levels of zolmitriptan.

Clinical evidence, mechanism, importance and management

The manufacturer of zolmitriptan notes that the half-life of zolmitriptan was increased by 44% and the AUC was increased by 48% when it was

given after cimetidine.[1] They suggest that this may be because of the inhibitory effect of cimetidine on the cytochrome P450 isoenzyme CYP1A2, an enzyme involved in the metabolism of zolmitriptan. The UK manufacturer recommends a maximum dose of zolmitriptan of 5 mg in 24 hours in patients taking cimetidine.[1] The US manufacturer makes no recommendation on dose.[2]

1. Zomig Tablets (Zolmitriptan). AstraZeneca UK Ltd. UK Summary of product characteristics, January 2008.

2. Zomig (Zolmitriptan). AstraZeneca Pharmaceuticals LP. US Prescribing information, October 2008.

Triptans; Zolmitriptan + Metoclopramide

Metoclopramide does not affect the pharmacokinetics of zolmitriptan.

Clinical evidence, mechanism, importance and management

In a randomised, crossover study, 15 healthy subjects were given a single 10-mg dose of zolmitriptan, alone or with metoclopramide 10 mg. Metoclopramide had no effect on the pharmacokinetics of zolmitriptan,[1] so dosage adjustments would not appear to be necessary when giving these two drugs.

1. Seaber EJ, Ridout G, Layton G, Posner J, Peck RW. The novel anti-migraine compound zolmitriptan (Zomig 311C90) has no clinically significant interactions with paracetamol or metoclopramide. *Eur J Clin Pharmacol* (1997) 53, 229–34.

Triptans; Zolmitriptan + Quinolones

The quinolone antibacterials are predicted to increase levels of zolmitriptan by inhibiting the cytochrome P450 isoenzyme CYP1A2, an enzyme involved in its metabolism.[1] This is based on the known interaction of zolmitriptan with 'cimetidine', (p.692). The UK manufacturer recommends a maximum dose of zolmitriptan of 5 mg in 24 hours in patients taking quinolone antibacterials such as ciprofloxacin. Note that the quinolones differ in their ability to inhibit CYP1A2; their effects on caffeine may give a useful guide to their potency in this respect, see 'Caffeine + Quinolones', p.1422.

1. Zomig Tablets (Zolmitriptan). AstraZeneca UK Ltd. UK Summary of product characteristics, January 2008.

Triptans; Zolmitriptan + Xylometazoline

In a clinical study in 18 healthy subjects, the rate or extent of absorption of intranasal zolmitriptan 5 mg was not affected when it was given 30 minutes after xylometazoline nasal spray.[1] This suggests that nasal vasoconstriction does not affect absorption of intranasal zolmitriptan.

1. Nairn K, Kemp JV, Dane AL, Roberts DW, Dixon R. Evaluation of the effect of xylometazoline on the absorption of zolmitriptan nasal spray. *Clin Drug Invest* (2002) 22, 703–7.

Antineoplastics

The antineoplastic drugs (also called cytotoxics or sometimes cytostatics) are used in the treatment of malignant disease, alone or in conjunction with radiotherapy, surgery, or immunosuppressants. They also find application in the treatment of a number of autoimmune disorders such as rheumatoid arthritis and psoriasis, and a few are used with other immunosuppressant drugs (ciclosporin, corticosteroids) to prevent transplant rejection. These other drugs are dealt with under the section on 'immunosuppressants', (p.1209).

Of all the drugs discussed in this publication, the antineoplastic drugs are amongst the most toxic and have a narrow therapeutic index. This means that quite small increases in their levels can lead to the development of serious and life-threatening toxicity. A list of the antineoplastics and other drugs that are used in the treatment of malignancy that are featured in this section appear in 'Table 17.1', (p.695), grouped by their primary mechanism of action. This table also includes a number of hormone antagonists that are used in the treatment of cancer.

Unlike most of the other interaction monographs in this publication, some of the information on the antineoplastic drugs is derived from *animal* experiments and *in vitro* studies, so that confirmation of their clinical relevance is still needed. The reason for including these data is that the antineoplastic drugs as a group do not lend themselves readily to the kind of clinical studies that can be undertaken with many other drugs, and there would seem to be justification in this instance for including indirect evidence of this kind. The aim is not to make definite predictions, but to warn users of the interaction possibilities.

Table 17.1 Antineoplastics and other drugs used in the treatment of cancer

Action	*Drugs*
Alkylating agents, and drugs that appear to have an alkylating action	
Nitrosoureas	Carmustine, Lomustine, Streptozocin
Platinum compounds	Carboplatin, Cisplatin, Oxaliplatin
Others	Altretamine, Busulfan, Chlorambucil, Chlormethine (Mechlorethamine), Cyclophosphamide, Dacarbazine, Estramustine, Ifosfamide, Melphalan, Temozolomide, Thiotepa
Antimetabolites	
Folate antagonists	Methotrexate, Pemetrexed, Raltitrexed
Podophylotoxin derivatives	Etoposide, Teniposide
Purine analogues	Azathioprine, Cladribine, Clofarabine, Fludarabine, Mercaptopurine, Nelarabine, Tioguanine
Pyridmidine analogues	Capecitabine, Carmofur, Cytarabine, Fluorouracil, Gemcitabine, Tegafur
Mitotic inhibitors	
Taxanes	Docetaxel, Paclitaxel
Topoisomerase I inhibitors	Irinotecan, Topotecan
Vinca alkaloids	Vinblastine, Vincristine, Vindesine, Vinorelbine
Cytotoxic antibiotics	
Anthracyclines	Aclarubicin, Amrubicin, Daunorubicin, Doxorubicin, Epirubicin, Idarubicin, Mitoxantrone
Others	Bleomycin, Dactinomycin, Mitomycin
Anti-androgens	Bicalutamide, Flutamide, Nilutamide
Anti-oestrogens	
Aromatase inhibitors	Aminoglutethimide, Anastrozole, Exemestane, Formestane, Letrozole
Oestrogen-receptor antagonists	Fulvestrant, Tamoxifen, Toremifene
Tyrosine kinase inhibitors	Dasatinib, Erlotinib, Gefitinib, Imatinib, Lapatinib, Nilotinib, Sorafenib, Sunitinib
Monoclonal antibodies	Alemtuzumab, Bevacizumab, Cetuximab, Panitumumab, Rituximab, Trastuzumab
Photosensitisers	5-Aminolevulinic acid, Porfimer sodium, Temoporfin
Miscellaneous	Amsacrine, Asparaginase (Colaspase, Crisantaspase, Pegaspargase), Bexarotene, Bortezomib, Enzastaurin, Hydroxycarbamide, Lenalidomide, Mitotane, Pentostatin, Procarbazine, Thalidomide, Tipifarnib, Trabectedin, Tretinoin, Vorinostat

Alemtuzumab + Miscellaneous

Six infection-related deaths occurred in a study of consolidation therapy with alemtuzumab after induction therapy with fludarabine and rituximab. After alemtuzumab, at least 12 months should elapse before live vaccines are given.

Clinical evidence, mechanism, importance and management

(a) Fludarabine with Rituximab

In a clinical study in patients with chronic lymphocytic leukaemia, there were six infection-related deaths out of 51 patients given consolidation alemtuzumab therapy after an induction regimen of **fludarabine** and **rituximab**.[1,2] In this study, patients received up to 6 cycles of intravenous fludarabine 25 mg/m^2 with intravenous rituximab (escalated to 375 mg/m^2) daily for 5 days every 4 weeks. Four months after their last dose of fludarabine, patients with a complete response or stable disease started subcutaneous alemtuzumab (escalated to 30 mg) three times weekly for 6 weeks. Of the six patients who died, five had achieved a complete remission after induction therapy. The infections occurred both during the use of alemtuzumab and for up to 16 months afterwards. The study was subsequently amended to restrict the use of alemtuzumab to those with a partial response to **fludarabine** and **rituximab**, with close monitoring for infection.

It is thought that the immunosuppressive properties of these drugs were additive, and that there was insufficient time allowed before alemtuzumab was given for recovery from immunosuppression from the induction therapy.[1] Note that this use of alemtuzumab is outside the current licensed indications, and this combination should not be given to patients outside the context of a clinical study.[1,2]

(b) Vaccines, live

The manufacturer advises that vaccination with live viral vaccines should not be undertaken within at least 12 months of the use of alemtuzumab, although there are no specific data on this.[3]

Altretamine (Hexamethylmelamine) + Antidepressants

Severe orthostatic hypotension has been described in patients given altretamine with either phenelzine, amitriptyline or imipramine.

Clinical evidence, mechanism, importance and management

Four patients experienced very severe orthostatic hypotension (described by the authors as potentially life-threatening) when they were given altretamine 150 to 250 mg/m^2 with either **phenelzine** 60 mg daily, **amitriptyline** 50 mg daily or **imipramine** 50 to 150 mg daily.[1] They experienced incapacitating dizziness, severe lightheadedness, and/or fainting within a few days of taking both drugs. Standing blood pressures as low as 50/30 mmHg and 60/40 mmHg were recorded. The reasons for this hypotensive effect are not known. One of the patients had no problems when **imipramine** was replaced by **nortriptyline** 50 mg daily. One other patient who had also taken altretamine with antidepressants reported dizziness, while another noted non-specific discomfort. The incidence of this interaction is unknown, but it is clear that the concurrent use of altretamine and **tricyclics** or **MAOIs** should be closely monitored.

1. Bruckner HW, Schleifer SJ. Orthostatic hypotension as a complication of hexamethylmelamine antidepressant interaction. *Cancer Treat Rep* (1983) 67, 516.

Altretamine (Hexamethylmelamine) + Pyridoxine (Vitamin B_6)

Pyridoxine reduced the neurotoxicity associated with altretamine, but also reduced its effectiveness.

Clinical evidence, mechanism, importance and management

In a large randomised study in women with advanced ovarian cancer the neurotoxicity associated with altretamine and cisplatin chemotherapy was reduced by pyridoxine, but the response duration was also reduced.[1] In this study, cisplatin was given on day 1 (37.5 or 75 mg/m^2) and altretamine 200 mg/m^2 daily was given on days 8 to 21, and half the patients also received pyridoxine 100 mg three times daily on days 1 to 21. It is unclear how pyridoxine reduced the activity of this regimen, but the use of pyridoxine should probably be avoided in patients receiving altretamine.

Hexamethylmelamine and low or moderate dose cisplatin with or without pyridoxine for treatment of advanced ovarian carcinoma: a study of the Eastern Cooperative Oncology Group. *Cancer Invest* (1992) 10, 1–9.

9-Aminocamptothecin + Antiepileptics; Enzyme-inducing

Carbamazepine, phenobarbital, and phenytoin can lower the levels of 9-aminocamptothecin.

Clinical evidence, mechanism, importance and management

A study in 59 patients with glioblastoma multiforme or recurrent high grade astrocytomas found that the steady-state plasma levels of 9-aminocamptothecin were reduced to about one-third in 29 of the patients also taking antiepileptics (**carbamazepine**, **phenobarbital**, **phenytoin**, sodium valproate). The incidence of myelosuppression was greater in those not taking antiepileptics.[1] A further study also found that the clearance of 9-aminocamptothecin was increased by **carbamazepine** and **phenytoin**.[2] The reason for the reduced 9-aminocamptothecin levels is not known, but it seems likely that it was due to the enzyme-inducing activity of **carbamazepine**, **phenobarbital** and **phenytoin**. These results suggest that higher than usual doses of 9-aminocamptothecin are possibly needed in the presence of these antiepileptics. **Fosphenytoin** and **primidone**, which are metabolised to phenytoin and phenobarbital, respectively, would be expected to interact similarly.

Aminoglutethimide + Danazol

Danazol may reduce the efficacy of aminoglutethimide.

Clinical evidence, mechanism, importance and management

In a randomised study, giving danazol with aminoglutethimide in women with breast cancer, reduced the response rate compared with the use of aminoglutethimide alone. It was found that danazol suppresses sex hormone-binding globulin leading to increased free oestradiol, which counteracts the oestradiol suppressive effect of aminoglutethimide.[1] Danazol should probably not be given with anti-oestrogenic treatments.

1. Dowsett M, Murray RML, Pitt P, Jeffcoate SL. Antagonism of aminoglutethimide and danazol in the suppression of serum free oestradiol in breast cancer patients. *Eur J Cancer Clin Oncol* (1985) 21, 1063–8.

Aminoglutethimide + Diuretics

A single case report describes hyponatraemia, which occurred after a patient had taken aminoglutethimide and bendroflumethiazide for 10 months.

Clinical evidence, mechanism, importance and management

A woman who had been taking **bendroflumethiazide** 10 mg daily and potassium chloride 578 mg for several years for hypertension and mild cardiac decompensation, was given aminoglutethimide 1 g daily, and hydrocortisone 60 mg daily, for breast cancer. After 10 months of treatment she was hospitalised with severe hyponatraemia, which resolved when all the drugs were withdrawn. No significant change in electrolytes occurred over 3 months when the aminoglutethimide and hydrocortisone were used alone, but serum sodium fell again when the diuretic was restarted. The serum sodium levels were subsequently maintained by the addition of fludrocortisone 100 micrograms daily.[1] The hyponatraemia was thought to be caused by the combined inhibitory effect of the aminoglutethimide on aldosterone production (which normally retains sodium in the body) and the sodium loss caused by the diuretic. Plasma electrolytes should be monitored when aminoglutethimide is used, and this would seem particularly important if it is given with any diuretic.

1. Bork E, Hansen M. Severe hyponatremia following simultaneous administration of aminoglutethimide and diuretics. *Cancer Treat Rep* (1986) 70, 689–90.

5-Aminolevulinic acid + St John's wort (*Hypericum perforatum*)

An isolated case report describes a severe phototoxic reaction attributed to a synergistic effect of oral 5-aminolevulinic acid and St John's wort.

Clinical evidence

A 47-year-old woman who was taking St John's wort (*Hyperiforce*, dose not stated) experienced a phototoxic reaction on skin areas exposed to light 6 hours after receiving oral 5-aminolevulinic acid 40 mg/kg. She developed a burning erythematous rash and severe swelling of the face, neck and hands. Treatment with oral corticosteroids resulted in complete resolution after skin desquamation.[1]

Mechanism

It was suggested that there was a synergistic photosensitivity reaction between the two drugs.

Importance and management

This appears to be the only report of such an effect, but bear it in mind in the event of an unexpected adverse reaction to oral 5-aminolevulinic acid. Note that this photosensitiser and its derivative methyl aminolevulinate are more usually applied topically, and in this situation, any interaction is unlikely to be important.

1. Ladner DP, Klein SD, Steiner RA, Walt H. Synergistic toxicity of <delta>-aminolaevulinic acid-induced protoporphyrin IX used for photodiagnosis and hypericum extract, a herbal antidepressant. *Br J Dermatol* (2001) 144, 901–22.

Anastrozole + Miscellaneous

Cimetidine and quinapril do not affect anastrozole levels. Anastrozole does not appear to interact with aspirin, digoxin or oral antidiabetics. It also appears to have no effect on cytochrome P450 enzymes, so it is unlikely to interact with drugs that are affected by inducers or inhibitors of this enzyme system.

Clinical evidence, mechanism, importance and management

In a pharmacokinetic study, 10 elderly women with breast cancer were given anastrozole 1 mg daily for 10 weeks and 5 of them who also had hypertension were additionally given **quinapril**, after week 4, for 28 days. **Quinapril** did not affect plasma anastrozole levels and dose adjustment is not required during concurrent use.[1]

A clinical study with **cimetidine** found that it does not affect the pharmacokinetics of anastrozole.[2] This provides some evidence that anastrozole might not be affected by other drugs that inhibit cytochrome P450 isoenzymes, although cimetidine is only a weak non-specific inhibitor of this enzyme system. Another clinical study found that anastrozole does not affect the pharmacokinetics of **antipyrine** (**phenazone**),[3] a non-specific marker of cytochrome P450 induction or inhibition. This suggests that anastrozole is probably unlikely to interact with those drugs that are known to be affected by inducers and inhibitors of this enzyme system.

The UK manufacturer of anastrozole notes that in clinical studies there was no evidence of any interactions between anastrozole and commonly used drugs;[4] **aspirin**, **digoxin**, and **oral antidiabetics** were specifically mentioned in the early product information.[5]

Anthracyclines + Ciclosporin

High-dose ciclosporin increases the serum levels and the myelotoxicity of doxorubicin. An isolated report describes severe neurotoxicity and coma in a patient who had taken ciclosporin and was subsequently given doxorubicin. Ciclosporin can also increase the levels of daunorubicin, epirubicin, idarubicin and mitoxantrone.

Clinical evidence

(a) Daunorubicin

In a randomised study in patients receiving daunorubicin, ciclosporin significantly reduced the frequency of resistance to induction therapy (31% versus 47%) and increased relapse-free and overall survival. Ciclosporin recipients had higher steady-state serum levels of daunorubicin and its active metabolite, daunorubicinol.[1]

(b) Doxorubicin

Eight patients with small cell lung cancer were given an initial course of doxorubicin (25 to 70 mg/m^2 over one hour) and a subsequent ciclosporin-modulated doxorubicin course (ciclosporin 6 mg/kg bolus, then 16 mg/kg daily for 2 days) for multidrug-resistant tumour modulation. All of the patients were also given cyclophosphamide and vincristine. Ciclosporin increased the AUC of doxorubicin by 48%, and increased the AUC of its active metabolite, doxorubicinol, by 443%. The myelotoxicity was increased by concurrent use: the leucocyte count fell by 84% after doxorubicin and by 91% after doxorubicin with ciclosporin, and the platelet counts fell by 36% and 73%, respectively. The patients had significant weight loss and severe myalgias.[2]

Three preliminary phase I studies[3-5] are consistent with this report. In these studies, ciclosporin was found to increase the doxorubicin AUC by 40 to 73%, and the doxorubicinol AUC by 250 to 285%. However, no evidence of increased cardiotoxicity was found in a study of 23 patients given ciclosporin and doxorubicin.[6]

A heart transplant patient was given ciclosporin 2 mg/kg daily for 22 months. The ciclosporin was stopped and he was given doxorubicin 60 mg, vincristine 2 mg, cyclophosphamide 600 mg and prednisone 80 mg to treat Burkitt's lymphoma stage IVB. Eight hours later he developed disturbances of consciousness, which lead to stage I coma, from which he spontaneously recovered 12 hours later. A week later a similar course of chemotherapy was started, and 10 to 15 minutes later he lost consciousness and generalised tonic clonic seizures progressively developed. He died 8 days later without recovering consciousness.[7]

(c) Epirubicin

Preliminary evidence suggests that ciclosporin can markedly increase the AUC of epirubicin (up to about fourfold) and increase bone marrow suppression in response to epirubicin.[5] In one study in 20 patients ciclosporin did not increase the cardiotoxicity of epirubicin .[6]

(d) Idarubicin

In 9 patients the concurrent use of ciclosporin and idarubicin increased the AUC of idarubicin and its active metabolite, idarubicinol, by 77% and 181%, respectively, when compared with 11 patients receiving idarubicin alone.[8] Unacceptable toxicity occurred when idarubicin 9 or 12 mg/m^2 daily was given with ciclosporin 16 mg/kg daily, when compared with idarubicin 12 mg/m^2 alone: 3 of 7 patients given the combination died. Increases in the AUC of idarubicin and idarubicinol produced by ciclosporin have also been reported elsewhere.[9]

(e) Mitoxantrone

The pharmacokinetics of mitoxantrone 10 mg/m^2 daily were compared with mitoxantrone 6 mg/m^2 (a 40% reduction in dose) with high-dose ciclosporin in children. The ciclosporin recipients had a 42% reduction in mitoxantrone clearance, a 12% increase in mitoxantrone AUC, and similar toxicity.[10]

Mechanism

Uncertain. One reason may be that ciclosporin affects P-glycoprotein in the biliary tract so that the clearance of these anthracyclines in the bile is reduced. An additional reason may be that ciclosporin inhibits the metabolism of anthracycline metabolites, such as doxorubicinol, so that they accumulate.[2] The increased levels of both would explain the increases in toxicity. It is not clear why such severe neurotoxicity was seen in one patient.

Importance and management

An established and clinically important interaction. Ciclosporin alters the pharmacokinetics of the anthracyclines resulting in increased levels. This pharmacokinetic interaction has complicated study into the value of using ciclosporin to modulate multidrug resistance in tumours and thereby improve the response to chemotherapy. In the case of anthracyclines and 'etoposide', (p.724), any benefit could simply be attributed to dose intensification. Consequently, some have suggested reducing the dose of the anthracycline.[10] The use of high-dose ciclosporin for multidrug-resistant tumour modulation remains experimental and should only be used in clinical studies. Concurrent use should be very well monitored. More study is needed to find out the possible effects of low-dose ciclosporin.

Anthracyclines + Taxanes

Toxicity associated with combinations of paclitaxel with doxorubicin or epirubicin depends on the order of administration. Some modest pharmacokinetic changes may occur when paclitaxel and epirubicin are given together. The combination of doxorubicin and paclitaxel is more cardiotoxic than doxorubicin alone: paclitaxel increases doxorubicin levels but doxorubicin does not alter paclitaxel levels. Docetaxel may modestly affect the pharmacokinetics of epirubicin and doxorubicin.

Clinical evidence

(a) Doxorubicin

1. Docetaxel. The pharmacokinetics of doxorubicin 50 mg/m^2, given as a 30-minute infusion, were unaffected when it was given immediately before or one hour before a one-hour infusion of docetaxel 75 mg/m^2 when compared with administration alone. However, the AUC of docetaxel was increased, both when given immediately before and one hour after doxorubicin, by 50% and 75%, respectively.[1] A retrospective review of patients who were given doxorubicin followed one hour later by docetaxel found that the clearance of docetaxel was about 20% lower than in patients who had received docetaxel alone, whereas the clearance of doxorubicin did not differ when given with docetaxel.[2]

In a study, 627 patients with breast cancer were given doxorubicin 50 mg/m^2 with docetaxel 75 mg/m^2, or doxorubicin 60 mg/m^2 with cyclophosphamide 600 mg/m^2, postoperatively for 4 courses to assess disease-free survival at 5 years. The study was terminated prematurely because of the high risk of life-threatening complications in the patients given doxorubicin with docetaxel (2 deaths associated with drug toxicity and one case of perforated peritonitis in a patient with febrile neutropenia). The incidence of febrile neutropenia was 41% and 7% in the doxorubicin with docetaxel, and doxorubicin with cyclophosphamide groups, respectively.[3]

A woman with recurrence of breast cancer developed pseudomembranous colitis (non-*Clostridium difficile*) and cholestatic jaundice 6 days after completing her first cycle of treatment with doxorubicin and docetaxel and again 4 days after the second cycle, about one month later.[4]

2. Paclitaxel. Early studies in patients with breast cancer found a higher frequency of toxicity (particularly mucositis) when paclitaxel was given immediately before doxorubicin (given as 24-hour and 48-hour infusions, respectively) rather than the other way around.[5] A subsequent study with similar effects revealed that doxorubicin clearance was reduced by one-third if paclitaxel was given first.[6] In another study the peak plasma levels of doxorubicin were increased when it was given by bolus injection 15 minutes after a 3-hour infusion of paclitaxel rather than the other way around. The effect was non-linear and dependent on the dose of paclitaxel.[7] The same authors had already found that this regimen produced a higher than expected incidence of cardiac toxicity, which was not affected by sequence with the short interval between administration.[8] Subsequent studies[9,10] have found that this schedule results in unacceptable cardiotoxicity when the total cumulative doxorubicin dose exceeds 340 to 380 mg/m^2. When a bolus dose of doxorubicin was given 15 or 30 minutes before a 3-hour infusion of paclitaxel, the levels of doxorubicin were higher than when the interval was 24 hours.[7,11] Moreover, when paclitaxel and doxorubicin were given together as a 3-hour infusion the levels of doxorubicin were lower than when a bolus dose of doxorubicin was given 15 minutes before a 3-hour paclitaxel infusion.[7] Similarly, in another study, the pharmacokinetics of each drug were found to be unchanged when they were given simultaneously as a 72-hour infusion.[12]

(b) Doxorubicin, liposomal

In 10 patients the AUC of intravenous pegylated liposomal doxorubicin (*Caelyx*) 30 to 35 mg/m^2 was increased by a mean of 80% when it was given immediately before intravenous **paclitaxel** 70 or 175 mg/m^2 compared with when it was given alone. Peak plasma levels of doxorubicin were also increased and clearance was reduced by 71%. In 9 other patients given *Caelyx* then **docetaxel** 30 or 60 mg/m^2, the AUC of doxorubicin was increased by 12% and clearance reduced by only 16%.[13]

(c) Epirubicin

The pharmacokinetics of epirubicin were compared in 4 patients with breast cancer given intravenous epirubicin 90 mg/m^2 alone and in 16 patients given the same dose of epirubicin followed immediately by either **paclitaxel** 175 mg/m^2 as a 3-hour infusion or **docetaxel** 70 mg/m^2 as a one-hour infusion. No effect on epirubicin levels was detected, but the concentrations of epirubicin metabolites (epirubicinol and deoxydoxorubicinone) were increased by both **paclitaxel** and **docetaxel**.[14] In a subsequent study, 21 patients were given the same regimen of epirubicin followed immediately by **paclitaxel** and 18 patients were given the drugs in the reverse order. Non-haematological toxicity was unaffected by the order of administration, but when **paclitaxel** was given first the neutrophil

and platelet nadir was lower and neutrophil recovery was slower. The AUC for epirubicin was also higher when **paclitaxel** was given first, but the pharmacokinetics of **paclitaxel** were unaffected.[15]

In one study, 21 women with breast cancer were given intravenous epirubicin 90 mg/m^2 followed 15 minutes later by a 3-hour intravenous infusion of **paclitaxel** 175 mg/m^2 (6 patients), 200 mg/m^2 (9 patients), or 225 mg/m^2 (6 patients). Six women were given **paclitaxel** 200 mg/m^2 30 hours after epirubicin. A significant increase in the AUC of epirubicin occurred with **paclitaxel** 200 mg/m^2 (23%) and 225 mg/m^2 (34%) and increases in the AUC of the metabolite of epirubicin (epirubicinol) occurred at all dose levels of **paclitaxel**, compared with those found when epirubicin was given 30 hours before **paclitaxel**.[16] In another study, exposure to epirubicin metabolites, but not epirubicin itself, was increased when it was given 15 minutes before a 3-hour infusion of **paclitaxel**, when compared with a regimen using a 24-hour interval between the two drugs. In addition, the neutrophil nadir was lower, and the clearance of **paclitaxel** was 30% slower with the former regimen, but cardiac toxicity was uncommon.[17]

Conversely, a study of the concurrent use of **docetaxel** and epirubicin did not find that the sequence of drug administration affected the pharmacokinetics of epirubicin, nor was there any difference in toxicity.[18] In another study, 16 patients with breast cancer had a transient but significant increase in epirubicin plasma levels during the subsequent infusion (after an interval of one hour) of **docetaxel** 75 mg/m^2, which was not seen if the **docetaxel** was given within 10 minutes of epirubicin.[19] A study in 43 patients who received **docetaxel**, cyclophosphamide and epirubicin found an increase in the plasma levels of epirubicinol, but this was only seen during the **docetaxel** infusion, after which levels returned to normal. The pharmacokinetics of **docetaxel** were not significantly different from historical data on its use alone.[20]

Mechanism

Studies in *mice* have found that the taxanes docetaxel and paclitaxel, and the vehicle used for paclitaxel, *Cremophor*, may all modify the distribution and metabolism of doxorubicin increasing its levels in the heart, liver and kidneys. This may contribute to the cardiac toxicity seen during use with paclitaxel.[21] Similarly, *in vitro* studies in human myocardial tissue found that paclitaxel and docetaxel increased the conversion of doxorubicin to doxorubicinol, the metabolite that is thought to be responsible for cardiotoxicity.[22] An *in vitro* study on the effect of paclitaxel and *Cremophor* on epirubicin metabolism in human blood found that paclitaxel slightly decreased the production of epirubicinol. A marked inhibition of epirubicinol production occurred in the presence of *Cremophor*, but because of the low volume of distribution of *Cremophor* this is not likely to be of clinical significance.[16] In addition, *in vitro* studies have shown that the taxanes may reduce the biliary excretion of doxorubicin and epirubicin by inhibiting P-glycoprotein,[7] and inhibition of epirubicinol excretion via competition for P-glycoprotein by paclitaxel and *Cremophor* may be significant.[16]

The case of pseudomembranous colitis and cholestatic jaundice in one patient was attributed to the combination of docetaxel and doxorubicin, but the patient was also receiving long-term treatment with erythromycin and omeprazole which may have contributed to the interaction by inhibiting docetaxel metabolism by the cytochrome P450 isoenzyme CYP3A.[4]

Importance and management

The effect of paclitaxel on doxorubicin appears to be established, and various strategies have been suggested to reduce the cardiotoxicity of this combination. These include giving doxorubicin at least 24 hours before paclitaxel; reducing the cumulative dose of doxorubicin; or adding the cytoprotective drug dexrazoxane.[23] Epirubicin is considered less cardiotoxic than doxorubicin, and may be an alternative in some situations. However, it still appears preferable to give the anthracycline before the taxane. Docetaxel appears to have little clinically relevant effect on doxorubicin or epirubicin pharmacokinetics, but doxorubicin might increase docetaxel levels. Further study is needed on the optimum scheduling of anthracyclines and taxanes to maximise efficacy and minimise toxicity.

Anthracyclines; Aclarubicin + Other antineoplastics

Myelosuppression is among the adverse effects of aclarubicin. The concurrent use of other drugs with similar myelosuppressant actions may be expected to have additive effects. Previous treatment with nitrosoureas (not specifically named) or mitomycin has been shown to increase the severity of the myelosuppression.[1,2]

Anthracyclines; Daunorubicin + Protease inhibitors

The pharmacokinetics of liposomal daunorubicin did not appear to be affected by ritonavir- or indinavir-based antiretroviral regimens.

Clinical evidence, mechanism, importance and management

In a study of the effects of the protease inhibitors **ritonavir** or **indinavir** on the pharmacokinetics of liposomal daunorubicin 40 mg/m^2 twice weekly in patients with Kaposi's sarcoma, the AUC of daunorubicin and its active metabolite, daunorubicinol, did not differ between 6 patients taking a **ritonavir**-based regimen or 9 patients taking an **indinavir**-based regimen, when compared with 6 other patients not taking a protease inhibitor. In patients for whom data were available before starting the protease inhibitor, the daunorubicin AUC was unchanged by **indinavir** in 3 patients, but was reduced by 30% after starting the **ritonavir** in 2 patients. The antiretroviral regimens used were **indinavir** 800 mg three times daily plus dual NRTIs or **ritonavir** 400 mg or 600 mg twice daily plus NRTIs. The protease inhibitors had been taken for at least a month before the pharmacokinetics of daunorubicin were assessed. The potential impact of daunorubicin on the pharmacokinetics of the antiretrovirals was not assessed. Two patients in this study were taking **ritonavir-boosted saquinavir** 600 mg three times daily with the same schedule of liposomal daunorubicin, however the number of patients was considered too small to draw any conclusions about a possible interaction.[1]

These data suggest that indinavir and ritonavir do not alter the pharmacokinetics of liposomal daunorubicin to a clinically relevant extent, and therefore no daunorubicin dose adjustment is needed on concurrent use.

For mention that protease inhibitor regimens have been associated with an increased risk of infection when used with various antineoplastic regimens, see 'Antineoplastics + Protease inhibitors', p.703.

Anthracyclines; Doxorubicin + Barbiturates

The effects of doxorubicin may be reduced by the barbiturates.

Clinical evidence, mechanism, importance and management

A comparative study in patients given doxorubicin found that those also taking barbiturates had a doxorubicin plasma clearance that was 50% higher than those who were not taking barbiturates (318 mL/minute compared with 202 mL/minute).[1] This clinical study is in agreement with previous studies in *mice*.[2] A possible explanation is that the barbiturate increases the metabolism of the doxorubicin. It seems possible that the dose of doxorubicin will need to be increased in barbiturate-treated patients to achieve maximal therapeutic effects.

Anthracyclines; Doxorubicin + Tamoxifen

Tamoxifen appears to have no significant effect on the pharmacokinetics of doxorubicin.

Clinical evidence, mechanism, importance and management

A pharmacokinetic study in patients with non-Hodgkin's lymphoma receiving CHOP (cyclophosphamide, vincristine, prednisone and doxorubicin 37.5 to 50 mg/m^2) found that the addition of tamoxifen 480 mg daily for 5 days had no significant effect on the AUC or total clearance of doxorubicin.[1]

For the possible additive thromboembolic effect of doxorubicin and tamoxifen, see 'Antineoplastics + Tamoxifen', p.704.

1. El-Yazigi A, Berry J, Ezzat A, Wahab FA. Effect of tamoxifen on the pharmacokinetics of doxorubicin in patients with non-Hodgkin's lymphoma. *Ther Drug Monit* (1997) 19, 632–6.

Anthracyclines; Doxorubicin + Toremifene

In a study, 6 patients were given high-dose oral toremifene 600 mg daily for 5 days, with doxorubicin 60 mg/m^2 intravenously on day 5. The pharmacokinetics of doxorubicin were not affected by toremifene when compared with a single intravenous dose of doxorubicin 60 mg/m^2 given alone.[1] Usual doses of toremifene would not be expected to interact with doxorubicin.

1. Wurz GT, Soc L, Emshoff VD, Cadman TB, DeGregorio MW. Pharmacokinetics analysis of high-dose toremifene in combination with doxorubicin. *Cancer Chemother Pharmacol* (1998) 42, 363–6.

Anthracyclines; Epirubicin + Cimetidine

Cimetidine can increase the exposure to epirubicin.

Clinical evidence, mechanism, importance and management

In a study in 8 patients, cimetidine 400 mg twice daily increased the AUC of epirubicin by 50%. At the same time the AUCs of two metabolites of epirubicin, epirubicinol and 7-deoxydoxorubicinol aglycone, increased by 41% and 357%, respectively. Liver blood flow also increased by 17%.[1] The mechanism for this effect is unknown. More study of this interaction is needed but be aware of the possibility that cimetidine may increase the exposure to epirubicin; monitor the patient closely and adjust the epirubicin dose if needed. Cimetidine is available without a prescription in some countries so that patients may unwittingly increase the toxicity of epirubicin.

1. Murray LS, Jodrell DI, Morrison JG, Cook A, Kerr DJ, Whiting B, Kaye SB, Cassidy J. The effect of cimetidine on the pharmacokinetics of epirubicin in patients with advanced breast cancer: preliminary evidence of a potentially common drug interaction. *Clin Oncol* (1998) 10, 35–8.

Antineoplastics + Amphotericin B

Amphotericin B may delay the clearance of methotrexate, and there may be an increased risk of renal impairment. Similarly, the use of conventional amphotericin B with nephrotoxic antineoplastics such as cisplatin and ifosfamide may increase the risk of renal impairment.

Clinical evidence

Two children had delayed clearance of pulse **methotrexate** (1 g/m^2 over 24 hours) while they were receiving amphotericin B. **Methotrexate** levels were about 300 to 500% higher 48 hours after **methotrexate** when they were receiving amphotericin B, compared with **methotrexate** alone.[1] In a study, **methotrexate** clearance in 18 children given high-dose **methotrexate** (1 g/m^2 intravenously) was significantly correlated with the glomerular filtration rate (GFR). Concurrent amphotericin B in 6 of the children significantly decreased the GFR.[2] A history of heavy amphotericin B treatment (greater than 30 mg/kg) correlated with decreased **methotrexate** clearance in 24 children with relapsed leukaemia.[3]

A multivariate analysis in patients receiving high-dose **cisplatin** with saline hydration and mannitol diuresis found that the concurrent use of amphotericin B was a predictor of renal failure.[4]

Mechanism

Amphotericin B may cause renal impairment, which can result in delayed methotrexate clearance. Both cisplatin and amphotericin B are nephrotoxic, and their effects might be expected to be additive.

Importance and management

Evidence regarding an interaction between amphotericin B and methotrexate appears to be limited. Nevertheless, the adverse effects of methotrexate should be carefully monitored (e.g. patient reported symptoms, LFTs, renal function, blood counts) in patients taking amphotericin B or those previously extensively treated with the drug. In patients taking large doses of methotrexate (i.e. not the weekly doses given for conditions such as rheumatoid arthritis), the monitoring of methotrexate levels is recommended.

Similarly, evidence for an interaction between cisplatin and amphotericin B is limited, but what happens is in line with the known nephrotoxic effects of both drugs. The manufacturer of conventional amphotericin B states that nephrotoxic antineoplastics should not be given concurrently except with great caution.[5] Of the antineoplastics, cisplatin, **ifosfamide** and methotrexate are well known for their nephrotoxicity. Liposomal amphotericin B is licensed for use in the empirical treatment of presumed fungal infections in febrile neutropenic patients. It is therefore likely to be used in patients who have received antineoplastics and who may have antineoplastic-induced renal impairment. The manufacturer notes that it has been used successfully in a large number of patients with pre-existing renal impairment. Nevertheless, renal function should still be closely monitored in these patients.[6]

Antineoplastics + Aprepitant

Aprepitant had no effect on the pharmacokinetics of single intravenous doses of docetaxel or vinorelbine. The activation of cyclophosphamide and thiotepa was slightly lower in patients receiving aprepitant. Etoposide and paclitaxel have been commonly used with aprepitant without any dose adjustment. Fosaprepitant is rapidly converted to aprepitant after intravenous administration, and is therefore expected to share the same interactions.

Clinical evidence

(a) Cyclophosphamide

The rate of auto-induction of cyclophosphamide was 23% lower and exposure to the active metabolite, 4-hydroxycyclophosphamide, was 5% lower in 6 patients receiving aprepitant with a 4-day course of high-dose CTC (cyclophosphamide, thiotepa, carboplatin) when compared with 49 patients receiving high-dose CTC without aprepitant.[1]

(b) Docetaxel

Aprepitant 125 mg given one hour before docetaxel on day one, then 80 mg daily on days 2 and 3 had no effect on the pharmacokinetics of a single 60- to 100-mg/m^2 infusion of docetaxel in 10 patients with cancer, and did not alter the toxicity profile. Each subject acted as their own control.[2]

(c) Thiotepa

The formation clearance of thiotepa was 33% lower and exposure to the active metabolite, TEPA (triethylenephosphamide), was 20% lower in 6 patients receiving aprepitant with a 4-day course of high-dose CTC (cyclophosphamide, thiotepa, carboplatin) when compared with 49 patients receiving high-dose CTC without aprepitant.[1]

(d) Vinorelbine

In a pharmacokinetic study, in 12 patients with cancer, aprepitant 125 mg on day one and 80 mg daily on days 2 and 3 had no effect on the pharmacokinetics of intravenous vinorelbine 25 mg/m^2 given on day one or day 8.[3]

Mechanism

In the short-term, aprepitant is an inhibitor of the cytochrome P450 isoenzyme CYP3A4, and might therefore reduce the activation of antineoplastics activated by this isoenzyme (cyclophosphamide, thiotepa), or increase the toxicity of antineoplastics metabolised by this enzyme (docetaxel, irinotecan). There is some evidence that aprepitant has a greater effect on CYP3A4 substrates when they are given orally rather than intravenously (see 'midazolam', (p.840)), so this might explain the findings with the intravenous antineoplastics studied.[2]

Importance and management

The studies cited above suggest that clinically relevant pharmacokinetic interactions between aprepitant and intravenous cyclophosphamide, docetaxel, thiotepa and vinorelbine are unlikely: in each case the effects found were modest. However, a degree of caution may be warranted if any of these antineoplastics are given orally, as greater effects may result (see *Mechanism*). These findings suggest that, despite aprepitant being an inhibitor of CYP3A4, it is unlikely to have any clinically relevant effect on the pharmacokinetics of intravenously antineoplastics that are substrates of this isoenzyme. Nevertheless, the manufacturers of aprepitant and fosaprepitant recommend caution when these drugs are used with antineoplastics that are metabolised by CYP3A4.[4-7] In the UK they limit this to antineoplastics given orally (**etoposide** and vinorelbine are named);[4,6] however, in addition, they particularly caution use with **irinotecan** (given intravenously), because of the possibility of increased toxicity with this drug.[4,6] In the US, the manufacturer mentions that **etoposide**, **paclitaxel** and vinorelbine were commonly given with aprepitant without dose adjustment for potential interactions. They recommend particular caution with **vinblastine**, **vincristine** and **ifosfamide**, as only a few patients have received these drugs with aprepitant, and with other antineoplastics principally metabolised by CYP3A4 that have not yet been studied (**imatinib** and **irinotecan** are named).[5,7]

Antineoplastics + Calcium-channel blockers

Verapamil can increase the efficacy of doxorubicin in tissue culture systems and increase doxorubicin levels in patients. D-verapamil can alter the pharmacokinetics of epirubicin and possibly increase its bone marrow depressant effects.

The absorption of verapamil can be modestly reduced by antineoplastic regimens containing cyclophosphamide, vincristine and procarbazine, or vindesine, doxorubicin and cisplatin.

Clinical evidence, mechanism, importance and management

(a) Antineoplastic regimens

A study in 9 patients with a variety of malignant diseases found that treatment with antineoplastics reduced the absorption of a single 160-mg oral dose of **verapamil**. The **verapamil** AUC in 8 patients was reduced by 40% (range 7 to 58%), but one patient conversely had a 26% increase. Five patients received a modified COPP regimen (**cyclophosphamide**, **vincristine**, **procarbazine**, prednisone) and 4 patients received VAC (**vindesine**, **doxorubicin**, **cisplatin**).[1]

It is believed that these antineoplastics damage the lining of the upper part of the small intestine, which impairs the absorption of **verapamil**. The clinical relevance of this reduction does not appear to have been studied but it seems likely that at least some patients will be affected. Therefore it would seem prudent to monitor concurrent use for verapamil efficacy.

(b) Doxorubicin

The efficacy of doxorubicin was increased by **verapamil** and **nicardipine** in doxorubicin-resistant tissue culture systems, while **nifedipine** had only minimal activity.[2] A study in 5 patients with small cell lung cancer given doxorubicin, vincristine, etoposide and cyclophosphamide found that when they were given **verapamil** 240 to 480 mg daily the AUC of doxorubicin was doubled, its peak serum levels were raised and its clearance was reduced. No increased toxicity was seen in this study.[3] However, although another study found no increase in doxorubicin acute toxicities, intravenous **verapamil** caused an unacceptable degree of cardiac adverse effects (heart block, hypotension, and/or heart failure) when given in doses to attain plasma levels four times the normal upper limit.[4]

(c) Epirubicin

When used to reduce multidrug resistance in patients with advanced colorectal cancer receiving epirubicin, the D-isomer of **verapamil** appears to increase the bone marrow depressant toxicity of epirubicin.[5] Another study found that **D-verapamil** halved the AUC and half-life of epirubicin, and increased its clearance,[6] while yet another study did not find these changes but found that the production of the metabolites of epirubicin was increased.[7] These changes should be taken into account if both drugs are used. More study is needed to evaluate the possible advantages and disadvantages of giving these drugs together.

Antineoplastics + Colony-stimulating factors

Because of the increased risk of myelosuppression, colony-stimulating factors such as filgrastim and lenograstim should not be given at the same time as myelosuppressive cytotoxic antineoplastics.

Clinical evidence, mechanism, importance and management

Colony-stimulating factors such as filgrastim and lenograstim promote the growth of myeloid cell lines. Because rapidly dividing myeloid cells have increased sensitivity to cytotoxic chemotherapy, the manufacturers have advised that these drugs should not be used from 24 hours before until 24 hours after cytotoxic chemotherapy.[1-3] In support of this, the manufacturer of filgrastim notes that preliminary evidence confirmed that the severity of neutropenia could be exacerbated when patients were given **fluorouracil** and filgrastim concurrently.[2]

Note also that there is some evidence that colony-stimulating factors may potentiate the pulmonary toxicity of 'bleomycin', (p.707), and 'cyclophosphamide', (p.716).

Antineoplastics + 5-HT$_3$-receptor antagonists

Ondansetron does not appear to affect the pharmacokinetics of cyclophosphamide and cisplatin to a clinically relevant extent. Ondansetron does not appear to affect the pharmacokinetics of carmustine or the *in vitro* activity of epirubicin, bleomycin, cisplatin or estramustine. Cisplatin and fluorouracil do not affect the pharmacokinetics of ondansetron. In *in vitro* studies granisetron potentiated the cytotoxic effects of epirubicin, had an additive effect on bleomycin and estramustine activity and appeared not to affect the metabolism of docetaxel and paclitaxel.

Clinical evidence, mechanism, importance and management

(a) Granisetron

1. Cytotoxicity. In an *in vitro* study, granisetron significantly potentiated the cytotoxic effects of **epirubicin** on fibroblasts, and the effect of granisetron on the cytotoxic effects of **bleomycin** and **estramustine** in lung cancer cells appeared to be additive. The clinical relevance of the effects of granisetron on **epirubicin** is not known.[1]

2. Electrocardiac effects. A review of the ECGs of 30 patients who had received granisetron and **doxorubicin** or **epirubicin** found that the antineoplastics did not cause any further change in the PR interval above that which was caused by granisetron alone. There were no clinically significant cardiac effects reported.[2]

3. Pharmacokinetics. An *in vitro* study found that granisetron did not affect the metabolism of **docetaxel** or **paclitaxel**,[3] nor did a study in 6 patients demonstrate any change in the pharmacokinetics or bone-marrow suppressant effect of **docetaxel** when given with granisetron.[4]

(b) Ondansetron

1. Cytotoxicity. An *in vitro* study found that ondansetron did not affect the cytotoxic effects of **bleomycin**, **epirubicin**, **estramustine** or **cisplatin** in fibroblasts and lung cancer cells.[1]

2. Nephrotoxicity. In a small retrospective review of patients who had received cisplatin, there was a decreased incidence of nephrotoxicity (an increase in serum creatinine of about 44 micromol/L or more) in those patients who had also received ondansetron.[5] The mechanism for this association is unclear. The data from these sorts of analyses require confirmation in a controlled study, because it is possible that the findings are due to chance alone. The general relevance of this report is therefore uncertain.

3. Pharmacokinetics. The pharmacokinetics of high-dose **cyclophosphamide**, **cisplatin** and **carmustine** in 23 patients given ondansetron, lorazepam and diphenhydramine as antiemetics were compared with those in 129 patients who received prochlorperazine instead of ondansetron. It was found that the AUCs of **cyclophosphamide** and **cisplatin**, but not that of **carmustine**, were lower (by 15% and 19%, respectively) in the ondansetron group.[6] Similarly, in another study, the pharmacokinetics of antineoplastics were analysed in 54 patients with breast cancer who were receiving high-dose **cyclophosphamide**, **cisplatin** and **carmustine** with lorazepam and ondansetron, with or without prochlorperazine, and compared with 75 matched control patients whose had been given prochlorperazine and lorazepam. In those given ondansetron the median AUC of **cyclophosphamide** was 17% lower, the **cisplatin** AUC was about 10% higher and the **carmustine** AUC was unchanged.[7]

In a crossover study in 10 patients, who received intravenous **cyclophosphamide** 600 mg/m^2 and **epirubicin** 90 mg/m^2 and either oral ondansetron 16 mg or placebo, found that the pharmacokinetic parameters of **cyclophosphamide** or its metabolite were not significantly altered by ondansetron although there was considerable variation between subjects. It was concluded that ondansetron can be safely given with **cyclophosphamide**.[8]

No significant changes in the pharmacokinetics of ondansetron occurred in 20 patients with cancer taking **cisplatin** 20 to 40 mg/m^2 and/or **fluorouracil** 1 g/m^2 for 5 days but the clearance was lower than in healthy subjects.[9]

Information seems to be limited to these studies, but any pharmacokinetic effects appear to be small, and unlikely to be clinically relevant.

Antineoplastics + Megestrol

In one clinical study megestrol reduced the response rates to etoposide with cisplatin but in another had no effect on response rates to alternating cycles of cyclophosphamide, doxorubicin and vincristine, and etoposide with cisplatin.

Clinical evidence

A study in 243 patients with advanced small-cell lung cancer (SCLC) given **etoposide** and **cisplatin** found that patients who also received megestrol acetate 800 mg daily had increased non-fluid body-weight and significantly less nausea and vomiting. Although the one-year survival rate was similar in both groups patients who received megestrol had a significantly worse response rate to **cisplatin** (68% compared with 80%) and a higher incidence of thromboembolic events. However the megestrol recipients did have poorer quality of life (a prognostic factor) at the beginning of the study and this may have influenced the findings.[1] In a similar study, megestrol acetate had no effect on response rates, symptom profile or overall survival in patients with SCLC receiving chemotherapy (alternating cycles of **cyclophosphamide**, **doxorubicin** and **vincristine**, and **etoposide** with **cisplatin** for a maximum of 6 cycles). In this study, megestrol acetate was given at a dose of 160 mg three times daily for 8 days starting 3 days before each cycle of chemotherapy.[2]

Mechanism

An *in vitro* study found that megestrol may antagonise the antineoplastic activity of cisplatin by up-regulating cellular detoxification mechanisms.[3]

Importance and management

The authors of the first study suggest that megestrol acetate should not be used routinely at the time of chemotherapy.[1] Be aware that the use of megestrol may antagonise the antitumour activity of cisplatin. More study is needed.

Antineoplastics + Propofol

There are two isolated reports of severe pain occurring when patients who had previously received intravenous chemotherapy were given intravenous propofol via hand veins, and one report of excessive bradycardia after a bolus dose of propofol in a child receiving cytarabine.

Clinical evidence

Although pain on injection of propofol is well known, one group of workers noted that, on a number of occasions, patients previously given intravenous chemotherapy had marked pain, both at the site of injection and up the arm, when given propofol via hand veins.[1] This would seem to link with a report of a 15-year-old girl with acute lymphoblastic leukaemia who had been given several injections of **cyclophosphamide**, **methotrexate** and **vincristine** during the previous 6 months, and who was cannulated in her hand and given an infusion of *Plasmalyte B*. An injection of 60 micrograms of fentanyl via this cannula was painful and 20 mg of lidocaine helped, but 20 mg of propofol caused extreme pain. A further 20 mg of lidocaine was given and the propofol administration was stopped, but the pain continued. The whole hand became blue and congested, and blood began to move backwards up the drip tubing. The venous congestion gradually subsided over the next 15 minutes.[2] The authors recommended that propofol should be avoided in patients who have recently had intravenous chemotherapy.[2]
