Contents

Preface

This, the 9th edition of *Stockley's Drug Interactions*, continues to build on the experience gained by the editorial team, from a history of more than 30 years of analysing the literature on drug interactions. In the words of Ivan Stockley, from his original guidance to us: 'most readers want answers quickly, and therefore we have to write concisely and crisply to produce a picture which emerges very rapidly. We are not in the business of writing a discursive essay or great literature. Our business is bread-and-butter, rapid and unambiguous communication, for which we use direct and simple English, avoiding jargon wherever we can, recognising that our readers have varied backgrounds. Some may have forgotten (or never known) some of what we, with our familiarity with the subject, come to regard as basic pharmacology or medicine. At the same time we need to avoid patronising the well-informed reader by "mickey-mousing" it.' This is the philosophy we work with, and we hope to continue to pay due respect to Ivan Stockley's intentions by adhering to this fitting guidance.

In some areas we have become slightly more discursive, in the hope of better explaining the relevance of an interaction to specific patient groups. However, we have addressed the needs of those in a hurry by including a short summary of the interaction, with the advice on the management of the interaction discussed separately from the detailed clinical evidence and mechanism information. For those with more time, or those wishing to know the full picture, the clinical evidence and mechanism sections provide more detailed background on the interaction. Whichever approach is taken, the aim of *Stockley's Drug Interactions* is, as ever, to inform busy doctors, pharmacists, nurses and other healthcare professionals of the facts about drug interactions, without their having to do the time-consuming literature searches and full assessment of the papers for themselves. If you need some insight into the general philosophy underlying the way the information is handled in this publication, you should have a look at the section, 'Before using this book. . .'.

This publication is unique in the Stockley family of products by not including a symbol to rate the severity of the interaction. We continue to review this decision, but we currently believe that, in this fully comprehensive text, it is not always possible to simply assign one rating – certainly drug groups are often not identical in the way they interact, and to assign one symbol to the discussion of a group of drugs risks incorrectly implying that all members may interact similarly. Further, it overlooks the range of differences in the individual patient that a practitioner may need to consider. An otherwise fit and healthy patient will react very differently to a patient with a multitude of medical problems, and, in some instances, the interaction may only occur in the presence of certain disease states, for example renal impairment, or perhaps only in children. We therefore prefer to discuss these various risks and differences, where applicable, and allow the reader to make the decision on the severity of the interaction with the full knowledge of their particular patient. We believe that the ratings symbols have a useful place in our other products, such as *Stockley's Drug Interactions Pocket Companion*, where the interaction information is designed to be abridged, and summarised in a few lines: in this situation the symbol presents a worst-case scenario.

For this edition of *Stockley's Drug Interactions*, the concise and easy-to-read format of the monographs has been maintained. As with previous editions, all of the existing interactions monographs have been reviewed, revalidated and updated, and many new ones have been added, making a total in excess of 3700 monographs, representing at 20% increase in content on the previous edition. This serves to highlight the ever-increasing wealth of information on this topic. Indeed we now cite well over 22,000 references, more, we think, than any other reference text on this subject. We also review relevant information provided by regulatory bodies outside of the UK, in particular the EMEA in Europe and the FDA in the US, which continues to enhance the international flavour of the publication. In addition, we have created three new chapters, covering Nutritional agents, Supplements and Vitamins, Thyroid hormones, and Urological drugs, to reflect the increasing literature available on these particular topic areas.

Previous editions have found us struggling with the best way to deal with the interactions of herbal medicines in this reference, which is primarily an evidence-based text. As before, we have included the interactions of herbal medicines for which clinical evidence is available. However, we have long felt that the overwhelming numbers of theoretical and *in vitro* papers are worthy of analysis alongside the modest amount of clinical data on herbal medicines interactions. Our sister publication *Stockley's Herbal Medicines Interactions*, first published in 2009, has therefore been written to deal with this theoretical data, which does not fit with the philosophy of *Stockley's Drug Interactions*.

This edition has also seen a growth in our editorial team, which includes experienced clinical pharmacists and medical writers, and we have been pleased to have the advice and assistance of pharmacists with a greater knowledge of community pharmacy and specialist clinical subjects than those in our existing team. In particular, the advice of Rosy Weston, a specialist HIV pharmacist, has been of great help, and our thanks go out to her. The diverse practical experience of our team and advisors helps us to maintain the quality and realistic nature of the management advice given.

The Editorial team have also had assistance from many other people in developing this publication, and the Editor gratefully acknowledges the assistance and guidance that they have provided. The *Martindale* team continue to be a great source of advice and support, and particular thanks is due to the editor, Sean Sweetman, both for his direct assistance with producing the publication, and for allowing us access to the *Martindale* databases, from which we derive much of our nomenclature. We greatly appreciate the help of Chloë Hatwal in putting together the final typeset pages. Thanks are also due to Tamsin Cousins, for patiently handling the various aspects of producing our publications in print. We are also grateful for the support of both Paul Weller and Robert Bolick.

Stockley's Drug Interactions continues to be available on the Pharmaceutical Press electronic platform, *MedicinesComplete* (available at www.medicinescomplete.com), where it is updated quarterly; as well as being available on other platforms as an e-book. With the continued development of the integratable Alerts product and the *MedicinesComplete* platform, we remain indebted to Julie McGlashan, Elizabeth King, and all those involved in the technical aspects of these products, for their advice and support. For more details about these digital products please visit: www.pharmpress.com/Stockley

Finally, thanks are due to those who take the time to provide us with feedback, either directly, or in the form of questions about the publication. We continue to value this input to evolve the publication and to ensure it meets the needs of the users. We are particularly grateful to those who have taken the time to answer our questions about specific aspects of practice. Anyone who wishes to contact the Stockley team can do so at the following address: stockley@rpsgb.org

London, February 2010

Abbreviations

ACE—angiotensin-converting enzyme
ADP—adenosine diphosphate
AIDS—acquired immunodeficiency syndrome
ALT—alanine aminotransferase
am—*ante meridiem* (before noon)
aPTT—activated partial thromboplastin time
AST—aspartate aminotransferase
AUC—area under the time–concentration curve
$AUC_{0–12}$—area under the time–concentration curve measured over 0 to 12 hours
AV—atrioventricular
BCRP—breast cancer resistance protein (ABCG2)
BNF—British National Formulary
BP—blood pressure
BP—British Pharmacopoeia
BPC—British Pharmaceutical Codex
BPH—benign prostatic hyperplasia
bpm—beats per minute
BUN—blood urea nitrogen
CAPD—continuous ambulatory peritoneal dialysis
CDC—Centers for Disease Control (USA)
CNS—central nervous system
COMT—catechol-*O*-methyl transferase
COPD—chronic obstructive pulmonary disease
COX—cyclo-oxygenase
CSF—cerebrospinal fluid
CSM—Committee on Safety of Medicines (UK) (now subsumed within the Commission on Human Medicines)
DNA—deoxyribonucleic acid
ECG—electrocardiogram
ECT—electroconvulsive therapy
ED_{50}—the dose at which 50% of subjects respond
EEG—electroencephalogram
e.g.—*exempli gratia* (for example)
EMEA—European Agency for the Evaluation of Medicinal Products
FDA—Food and Drug Administration (USA)
$FEF_{25–75}$—maximum expiratory flow over the middle 50% of the vital capacity
FEV_1—forced expiratory volume in one second
FSH—follicle simulating hormone
FVC—forced vital capacity
g—gram(s)
GABA—gamma-aminobutyric acid
h—hour(s)
HAART—highly active antiretroviral therapy
HbA_{1c}—glycosylated (glycated) haemoglobin
HIV—human immunodeficiency virus
HRT—hormone replacement therapy
ibid—*ibidem*, in the same place (journal or book)
i.e.—*id est* (that is)
INR—international normalised ratio
ITU—intensive therapy unit
IU—International Units
IUD—intra-uterine device
kg—kilogram(s)
L—litre(s)
LDL—low-density lipoprotein
LFT—liver function test
LH—luteinising hormone
LMWH—low-molecular-weight heparin
MAC—minimum alveolar concentration
MAO—monoamine oxidase
MAOI—monoamine oxidase inhibitor
MAO-A—monoamine oxidase, type A
MAO-B—monoamine oxidase, type B
MCA—Medicines Control Agency (UK) (now MHRA)
MHRA—Medicines and Healthcare products Regulatory Agency (UK)
MIC—minimum inhibitory concentration
mEq—milliequivalent(s)
mg—milligram(s)
mL—millilitre(s)
mmHg—millimetre(s) of mercury
mmol—millimole
mol—mole
MRSA—methicillin resistant *Staphylococcus aureus*
NICE—National Institute for Health and Clinical Excellence (UK) (formerly the National Institute for Clinical Excellence)
nM—nanomole
nmol—nanomole
NNRTI—non-nucleoside reverse transcriptase inhibitor
NRTI—nucleoside reverse transcriptase inhibitor
NSAID—non-steroidal anti-inflammatory drug
NYHA—New York Heart Association
PABA—para-amino benzoic acid
PCP—pneumocystis pneumonia
pH—the negative logarithm of the hydrogen ion concentration
pm—*post meridiem* (after noon)
pO_2—plasma partial pressure (concentration) of oxygen
PPI—proton pump inhibitor
ppm—parts per million
RIMA—reversible inhibitor of monoamine oxidase type A
RNA—ribonucleic acid
sic—written exactly as it appears in the original
SNRI—serotonin and noradrenaline reuptake inhibitor
SSRI—selective serotonin reuptake inhibitor
SVT—supraventricular tachycardia
T3—Triiodothyronine
TPN—total parenteral nutrition
TSH—thyroid-stimulating hormone
UGT—uridine diphospho glucuronosyltransferase
UK—United Kingdom
US and USA—United States of America
USP—United States Pharmacopeia

Before using this book . . .

. . . you should read this short explanatory section so that you know how the drug interaction data have been set out here, and why – as well as the basic philosophy that has been followed in presenting it.

The monographs

This publication has over 3700 monographs with a common format, which are subdivided into sections like these:

- An abstract or summary for quick reading.
- **Clinical evidence**, detailing one, two or more illustrative examples of the interaction, followed by most or all of other supportive clinical evidence currently available.
- **Mechanism**, in brief.
- **Importance and management**, a short discussion designed to aid rapid clinical decision making. For example:
  – Is the interaction established or not?
  – What is its incidence?
  – How important is it?
  – How can it be managed?
  – And what, if any, are the non-interacting alternatives?
- **References**, a list of all of the relevant references. The length of the references list gives a very fair indication of the extent of the documentation. A long list indicates a well documented interaction, whereas a short list indicates poor documentation.

Some of the monographs have been compressed into fewer subsections instead of the more usual five, simply where information is limited or where there is little need to be more expansive.

The monographs do not carry the drug interaction Hazard/Severity ratings as used in the electronic *Stockley Interactions Alerts*, but what is written in each monograph should speak for itself.

Quality of information on interactions

The data on interactions are of widely varying quality and reliability. The best come from clinical studies carried out on large numbers of patients under scrupulously controlled conditions. The worst are anecdotal, uncontrolled, or based solely on *animal* studies. Sometimes they are no more than speculative and theoretical scaremongering guesswork, hallowed by repeated quotation until they become virtually set in stone.

The aim has been to filter out as much useless noise as possible, so wherever possible 'secondary' references are avoided, and 'primary' references which are available in good medical and scientific libraries are used instead – although sometimes unpublished, good quality, in-house reports on drug company files have been used where the drug company has kindly allowed access to the information. Product literature (for example, the Summary of Product Characteristics in the UK and the Prescribing Information in the US) rather than the research reports that lie behind them are also cited because they are the only source of published information about new drugs.

The quality of drug company literature is very variable. Some of it is excellent, helpful and very reliable, but regrettably a proportion contains a welter of speculative and self-protective statements, probably driven more by the company's medico-legal policy than anything else, and the nervousness of drug regulatory authorities. It is almost unbelievable (but true all the same) that drug companies that are scrupulous in the way they do their research, come out with statements about possible interactions that are little more than guesswork.

When drawing your own conclusions

The human population is a total mixture, unlike selected batches of laboratory animals (same age, weight, sex, and strain etc.). For this reason human beings do not respond uniformly to one or more drugs. Our genetic make up, ethnic background, sex, renal and hepatic functions, diseases and nutritional states, ages and other factors (the route of administration, for example) all contribute towards the heterogeneity of our responses. This means that the outcome of giving one or more drugs to any individual for the first time is never totally predictable because it is a new and unique 'experiment'. Even so, some idea of the probable outcome of using a drug or a pair of drugs can be based on what has been seen in other patients: the more extensive the data, the firmer the predictions.

The most difficult decisions concern isolated cases of interaction, many of which only achieved prominence because they were serious. Do you ignore them as 'idiosyncratic' or do you, from that moment onwards, contraindicate the use of the two drugs totally?

There is no simple 'yes' or 'no' answer to these questions, but one simple rule-of-thumb is that isolated cases of interaction with old and very well-tried pairs of drugs are unlikely to be of general importance, whereas those with new drugs may possibly be the tip of an emerging iceberg and should therefore initially be taken much more seriously until more is known. The delicate balance between these two has then to be set against the actual severity of the reaction reported and weighed up against how essential it is to use the drug combination in question.

When deciding the possible first-time use of any two drugs in any particular patient, you need to put what is currently known about these drugs against the particular profile of your patient. Read the monograph. Consider the facts and conclusions, and then set the whole against the backdrop of your patients unique condition (age, disease, general condition, and so forth) so that what you eventually decide to do is well thought out and soundly based. We do not usually have the luxury of knowing absolutely all the facts, so that an initial conservative approach is often the safest.

I

General considerations and an outline survey of some basic interaction mechanisms

Drug interactions overview

(a) What is a drug interaction?

An interaction is said to occur when the effects of one drug are changed by the presence of another drug, herbal medicine, food, drink or by some environmental chemical agent. Much more colourful and informal definitions by patients are that it is ". . . when medicines fight each other. . .", or ". . . when medicines fizz together in the stomach . . .", or ". . .what happens when one medicine falls out with another. . ."

The outcome can be harmful if the interaction causes an increase in the toxicity of the drug. For example, there is a considerable increase in risk of severe muscle damage if patients taking statins start taking azole antifungals (see 'Statins + Azoles', p.1321). Patients taking monoamine oxidase inhibitor antidepressants (MAOIs) may experience an acute and potentially life-threatening hypertensive crisis if they eat tyramine-rich foods such as cheese (see 'MAOIs or RIMAs + Tyramine-rich foods', p.1395).

A reduction in efficacy due to an interaction can sometimes be just as harmful as an increase: patients taking warfarin who are given rifampicin (rifampin) need more warfarin to maintain adequate anticoagulation (see 'Coumarins + Antibacterials; Rifamycins', p.424), while patients taking 'tetracyclines', (p.390) or 'quinolones', (p.374) need to avoid antacids and milky foods (or separate their ingestion) because the effects of these antibacterials can be reduced or even abolished if admixture occurs in the gut.

These unwanted and unsought interactions are adverse and undesirable but there are other interactions that can be beneficial and valuable, such as the deliberate co-prescription of antihypertensive drugs and diuretics in order to achieve antihypertensive effects possibly not obtainable with either drug alone (see 'Antihypertensives + Other drugs that affect blood pressure', p.1051). The mechanisms of both types of interaction, whether adverse or beneficial, are often very similar, but the adverse interactions are the focus of this publication.

Definitions of a drug interaction are not rigidly adhered to in this publication because the subject inevitably overlaps into other areas of adverse reactions with drugs. So you will find in these pages some 'interactions' where one drug does not actually affect another at all, but the adverse outcome is the simple additive effects of two drugs with similar effects (for example the combined effects of two or more CNS depressants, or two drugs which affect the QT interval). Sometimes the term 'drug interaction' is used for the physico-chemical reactions that occur if drugs are mixed in intravenous fluids, causing precipitation or inactivation. The long-established and less ambiguous term is 'pharmaceutical incompatibilities'. Incompatibilities are not covered by this publication.

(b) What is the incidence of drug interactions?

The more drugs a patient takes the greater the likelihood that an adverse reaction will occur. One hospital study found that the rate was 7% in those taking 6 to 10 drugs but 40% in those taking 16 to 20 drugs, which represents a disproportionate increase.[1] A possible explanation is that the drugs were interacting.

Some of the early studies on the frequency of interactions uncritically compared the drugs that had been prescribed with lists of possible drug interactions, without appreciating that many interactions may be clinically trivial or simply theoretical. As a result, an unrealistically high incidence was suggested. Most of the later studies have avoided this error by looking at only potentially clinically important interactions, and incidences of up to 8.8% have been reported.[2-4] Even so, not all of these studies took into account the distinction that must be made between the incidence of potential interactions and the incidence of those where clinical problems actually arise. The simple fact is that some patients experience quite serious reactions while taking interacting drugs, while others appear not to be affected at all.

A screening of 2 422 patients over a total of 25 005 days revealed that 113 (4.7%) were taking combinations of drugs that could interact, but evidence of interactions was observed in only 7 patients, representing an incidence of 0.3%.[2] In another study of 44 hospital inpatients taking 10 to 17 drugs over a 5-day period, 77 potential drug interactions were identified, but only one probable and four possible adverse reactions (6.4%) were detected.[5] A further study, among patients taking antiepileptic drugs, found that 6% of the cases of toxicity were due to drug interactions.[6] These figures are low compared with those of a hospital survey that monitored 927 patients who had received 1004 potentially interacting drug combinations. Changes in drug dose were made in 44% of these cases.[7] A review of these and other studies found that the reported incidence rates ranged from 2.2 to 70.3%, and the percentage of patients actually experiencing problems was less than 11.1%. Another review of 639 elderly patients found a 37% incidence of interactions.[8] Yet another review of 236 geriatric patients found an 88% incidence of clinically significant interactions, and a 22% incidence of potentially serious and life-threatening interactions.[9] A 4.1% incidence of drug interactions on prescriptions presented to community pharmacists in the US was found in a further survey,[10] whereas the incidence was only 2.9% in another American study,[11] and just 1.9% in a Swedish study.[12] An Australian study found that about 10% of hospital admissions were drug-related, of which 4.4% were due to drug interactions.[13] A very high incidence (47 to 50%) of potential drug interactions was found in a study carried out in an Emergency Department in the US.[14] One French study found that 16% of the prescriptions for a group of patients taking antihypertensive drugs were contraindicated or unsuitable,[15] whereas another study in a group of geriatric patients found only a 1% incidence.[16] The incidence of problems would be expected to be higher in the elderly because ageing affects the functioning of the kidneys and liver.[17,18]

These discordant figures need to be put into the context of the under-reporting of adverse reactions of any kind by medical professionals, for reasons that may include pressure of work or the fear of litigation. Both doctors and patients may not recognise adverse reactions and interactions, and some patients simply stop taking their drugs without saying why. None of these studies give a clear answer to the question of how frequently drug interactions occur, but even if the incidence is as low as some of the studies suggest, it still represents a very considerable number of patients who appear to be at risk when one thinks of the large numbers of drugs prescribed and taken every day.

(c) How seriously should interactions be regarded and handled?

It would be very easy to conclude after browsing through this publication that it is extremely risky to treat patients with more than one drug at a time, but this would be an over-reaction. The figures quoted in the previous section illustrate that many drugs known to interact in some patients, simply fail to do so in others. This partially explains why some quite important drug interactions remained virtually unnoticed for many years, a good example of this being the increase in serum digoxin levels seen with quinidine (see 'Digoxin and related drugs + Quinidine', p.1111).

Examples of this kind suggest that patients apparently tolerate adverse interactions remarkably well, and that many experienced physicians accommodate the effects (such as rises or falls in serum drug levels) without consciously recognising that what they are seeing is the result of an interaction.

One of the reasons it is often difficult to detect an interaction is that, as already mentioned, patient variability is considerable. We now know many of the predisposing and protective factors that determine whether or not an interaction occurs but in practice it is still very difficult to predict what will happen when an individual patient is given two potentially interacting drugs. An easy solution to this practical problem is to choose a non-interacting alternative, but if none is available, it is frequently possible to give interacting drugs together, if appropriate precautions are taken. If the effects of the interaction are well-monitored they can often be allowed for, often simply by adjusting the doses of the interacting drugs. Many interactions are dose-related so that if the dose of the causative drug is reduced, the effects on the other drug will be reduced accordingly. Thus a non-prescription dose of cimetidine may not inhibit the metabolism of phenytoin, whereas a larger dose may clearly increase phenytoin levels (see 'Phenytoin + H_2-receptor antagonists', p.637).

The dose of the affected drug may also be critical. For example, isoniazid causes the levels of phenytoin to rise, particularly in those individuals who are slow acetylators of isoniazid, and levels may become toxic. If the serum phenytoin levels are monitored and its dose reduced appropriately, the concentrations can be kept within the therapeutic range (see 'Phenytoin + Antimycobacterials', p.628). Some interactions can be accommodated by using another member of the same group of drugs. For example, the serum levels of doxycycline can become subtherapeutic if phenytoin, barbiturates or carbamazepine are given, but other tetracyclines do not seem to be affected (see 'Tetracyclines + Antiepileptics; Enzyme-inducing', p.389). Erythromycin causes serum lovastatin levels to rise because it inhibits its metabolism, but does not affect pravastatin levels because these two statins are metabolised in different ways (see 'Statins', (p.1313)). It is therefore clearly important not to uncritically extrapolate the interactions seen with one drug to all members of the same group.

It is interesting to note in this context that a study in two hospitals in Maryland, US, found that when interacting drugs were given with warfarin (but not theophylline) the length of hospital stay increased by a little over 3 days, with a rise in general costs because of the need to do more tests to get the balance right.[19] So it may be easier, quicker and cheaper to use a non-interacting alternative drug (always provided that its price is not markedly greater).

The variability in patient response has lead to some extreme responses among prescribers. Some clinicians have become over-anxious about interactions so that their patients are denied useful drugs that they might reasonably be given if appropriate precautions are taken. This attitude is exacerbated by some of the more alarmist lists and charts of interactions, which fail to make a distinction between interactions that are very well documented and well established, and those that have only been encountered in a single patient, and which in the final analysis are probably totally idiosyncratic. 'One swallow does not make a summer', nor does a serious reaction in a single patient mean that the drugs in question should never again be given to anyone else.

At the other extreme, there are some health professionals who, possibly because they have personally encountered few interactions, fail to consider drug interactions, so that some of their patients are potentially put at risk. An example of this is the fact that cisapride continued to be prescribed with known interacting drugs, even after the rare risk of fatal torsade de pointes arrhythmias, which can cause sudden death, was well established.[20] The responsible position lies between these two extremes, because a very substantial number of interacting drugs can be given together safely, if the appropriate precautions are taken. There are relatively few pairs of drugs that should always be avoided.

Table 1.1 Some drug absorption interactions

Drug affected	*Interacting drugs*	*Effect of interaction*
Ciclosporin (Cyclosporine)	Orlistat	Orlistat inhibits the absorption of dietary fats and therefore also lipophilic molecules such as ciclosporin
Digoxin	Metoclopramide Propantheline	Reduced digoxin absorption Increased digoxin absorption (due to changes in gut motility)
Digoxin Levothyroxine Warfarin	Colestyramine	Reduced absorption due to binding/complexation with colestyramine
Ketoconazole	Antacids H_2-receptor antagonists Proton pump inhibitors	Reduced ketoconazole absorption due to reduced dissolution
Penicillamine	Antacids (containing Al^{3+} and/or Mg^{2+}), iron compounds, food	Formation of less soluble penicillamine chelates resulting in reduced absorption of penicillamine
Methotrexate	Neomycin	Neomycin-induced malabsorption state
Quinolones	Antacids (containing Al^{3+} and/or Mg^{2+}), milk, Zn^{2+}(?), Fe^{2+}	Formation of poorly absorbed complexes
Tetracyclines	Antacids (containing Al^{3+}, Ca^{2+}, Mg^{2+}, and/or Bi^{2+}), milk, Zn^{2+}, Fe^{2+}	Formation of poorly soluble chelates resulting in reduced antibacterial absorption (see Fig. 1.1, p.3)

Mechanisms of drug interactions

Some drugs interact together in totally unique ways, but as the many examples in this publication amply illustrate, there are certain mechanisms of interaction that are encountered time and time again. Some of these common mechanisms are discussed here in greater detail than space will allow in the individual monographs, so that only the briefest reference need be made there.

Mechanisms that are unusual or peculiar to particular pairs of drugs are detailed within the monographs. Very many drugs that interact do so, not by a single mechanism, but often by two or more mechanisms acting in concert, although for clarity most of the mechanisms are dealt with here as though they occur in isolation. For convenience, the mechanisms of inter-

actions can be subdivided into those that involve the pharmacokinetics of a drug, and those that are pharmacodynamic.

Pharmacokinetic interactions

Pharmacokinetic interactions are those that can affect the processes by which drugs are absorbed, distributed, metabolised and excreted (the so-called ADME interactions).

Drug absorption interactions

Most drugs are given orally for absorption through the mucous membranes of the gastrointestinal tract, and the majority of interactions that go on within the gut result in reduced rather than increased absorption. A clear distinction must be made between those that decrease the *rate* of absorption and those that alter the *total amount* absorbed. For drugs that are given long-term, in multiple doses (e.g. warfarin) the rate of absorption is usually unimportant, provided the total amount of drug absorbed is not markedly altered. On the other hand for drugs that are given as single doses, intended to be absorbed rapidly (e.g. analgesics such as paracetamol (acetaminophen)), where a rapidly achieved high concentration is needed, a reduction in the rate of absorption may result in failure to achieve an adequate effect. 'Table 1.1', (p.2), lists some of the drug interactions that result from changes in absorption.

(a) Effects of changes in gastrointestinal pH

The passage of drugs through mucous membranes by simple passive diffusion depends upon the extent to which they exist in the non-ionised lipid-soluble form. Absorption is therefore governed by the pKa of the drug, its lipid-solubility, the pH of the contents of the gut and various other parameters relating to the pharmaceutical formulation of the drug. Thus the absorption of salicylic acid by the stomach is much greater at low pH than at high. On theoretical grounds it might be expected that alterations in gastric pH caused by drugs such as the H_2-receptor antagonists would have a marked effect on absorption, but in practice the outcome is often uncertain because a number of other mechanisms may also come into play, such as chelation, adsorption and changes in gut motility, which can considerably affect what actually happens. However, in some cases the effect can be significant. Rises in pH due to the proton pump inhibitors (see 'Azoles + Proton pump inhibitors', p.246), and the H_2-receptor antagonists (see 'Azoles + H_2-receptor antagonists', p.245), can markedly reduce the absorption of ketoconazole.

(b) Adsorption, chelation and other complexing mechanisms

Activated charcoal is intended to act as an adsorbing agent within the gut for the treatment of drug overdose or to remove other toxic materials, but inevitably it can affect the absorption of drugs given in therapeutic doses. Antacids can also adsorb a large number of drugs, but often other mechanisms of interaction are also involved. For example, the tetracycline antibacterials can chelate with a number of divalent and trivalent metallic ions, such as calcium, aluminium, bismuth and iron, to form complexes that are both poorly absorbed and have reduced antibacterial effects (see 'Figure 1.1', (see below)). These metallic ions are found in dairy products and antacids. Separating the doses by 2 to 3 hours goes some way towards reducing the effects of this type of interaction. The marked reduction in the bioavailability of penicillamine caused by some antacids seems also to be due to chelation, although adsorption may have some part to play. Colestyramine, an anionic exchange resin intended to bind bile acids and cholesterol metabolites in the gut, binds to a considerable number of drugs (e.g. digoxin, warfarin, levothyroxine), thereby reducing their absorption. 'Table 1.1', (p.2), lists some drugs that chelate, complex or adsorb other drugs.

(c) Changes in gastrointestinal motility

As most drugs are largely absorbed in the upper part of the small intestine, drugs that alter the rate at which the stomach empties can affect absorption. Propantheline, for example, delays gastric emptying and reduces paracetamol (acetaminophen) absorption, see 'Paracetamol (Acetaminophen) + Antimuscarinics', p.211, whereas metoclopramide, see 'Paracetamol (Acetaminophen) + Domperidone or Metoclopramide', p.212, has the opposite effect. However, the total amount of drug absorbed remains unaltered. Drugs with antimuscarinic effects decrease the motility of the gut, thus the tricyclic antidepressants can increase the absorption of other drugs, probably because they increase the time available for dissolution and absorption but in the case of levodopa (see 'Levodopa + Tricyclic antidepressants', p.806), they may reduce the absorption, possibly because the exposure time to intestinal mucosal metabolism is increased. The same reduced levodopa absorption has also been seen with 'homatropine', (p.796). These examples illustrate that what actually happens is sometimes very unpredictable because the final outcome may be the result of several different mechanisms.

(d) Induction or inhibition of drug transporter proteins

The oral bioavailability of some drugs is limited by the action of drug transporter proteins, which eject drugs that have diffused across the gut lining back into the gut. At present, the most well characterised drug transporter is 'P-glycoprotein', (p.8). Digoxin is a substrate of P-glycoprotein, and drugs that induce this protein, such as rifampicin (rifampin), may reduce the bioavailability of digoxin (see 'Digoxin and related drugs + Rifampicin (Rifampin)', p.1113.

(e) Malabsorption caused by drugs

Neomycin causes a malabsorption syndrome, similar to that seen with non-tropical sprue. The effect is to impair the absorption of a number of drugs including 'digoxin', (p.1080), and 'methotrexate', (p.745).

Drug distribution interactions

(a) Protein-binding interactions

After absorption, drugs are rapidly distributed around the body by the circulation. Some drugs are totally dissolved in the plasma water, but many others are transported with some proportion of their molecules in solution and the rest bound to plasma proteins, particularly the albumins. The extent of this binding varies enormously but some drugs are extremely highly bound. For example, dicoumarol has only four out of every 1000 molecules remaining unbound at serum concentrations of 0.5 mg%. Drugs can also become bound to albumin in the interstitial fluid, and some, such as digoxin, can bind to the heart muscle tissue.

The binding of drugs to the plasma proteins is reversible, an equilibrium being established between those molecules that are bound and those that are not. Only the unbound molecules remain free and pharmacologically active, while those that are bound form a circulating but pharmacologically inactive reservoir which, in the case of drugs with a low-extraction ratio, is temporarily protected from metabolism and excretion. As the free molecules become metabolised, some of the bound molecules become unbound and pass into solution to exert their normal pharmacological

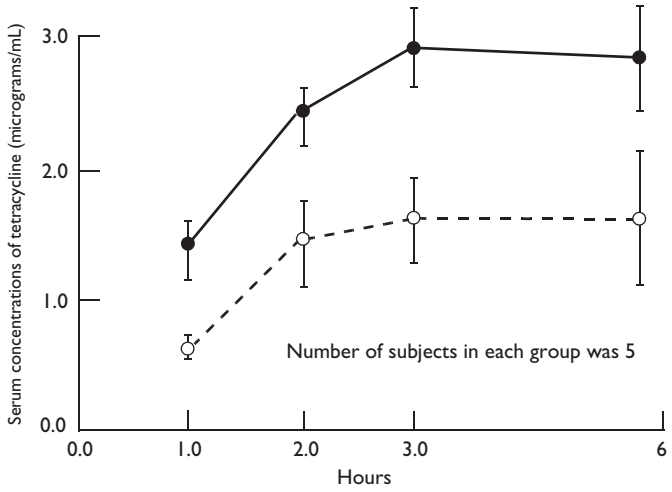

Fig. 1.1 A drug chelation interaction. Tetracycline forms a less-soluble chelate with iron if the two drugs are allowed to mix within the gut. This reduces the absorption and depresses the serum levels and the antibacterial effects (after Neuvonen PJ, *BMJ* (1970) 4, 532, with permission). The same interaction can occur with other ions such as Al^{3+}, Ca^{2+}, Mg^{2+}, Bi^{2+} and Zn^{2+}.

actions, before they, in their turn are metabolised and excreted.

Depending on the concentrations and their relative affinities for the binding sites, one drug may successfully compete with another and displace it from the sites it is already occupying. The displaced (and now active) drug molecules pass into the plasma water where their concentration rises. So for example, a drug that reduces the binding from 99% to 95% would increase the unbound concentration of free and active drug from 1% to 5% (a fivefold increase). This displacement is only likely to raise the number of free and active molecules significantly if the majority of the drug is within the plasma rather than the tissues, so that only drugs with a low apparent volume of distribution (V_d) will be affected. Examples include the sulfonylureas, such as tolbutamide (96% bound, V_d 10 litres), oral anticoagulants, such as warfarin (99% bound, V_d 9 litres), and phenytoin (90% bound, V_d 35 litres). However, another important factor is clearance. Clinically important protein-binding interactions are unlikely if only a small proportion of the drug is eliminated during a single-passage through the eliminating organ (low-extraction ratio drugs), as any increase in free fraction will be effectively cleared. Most drugs that are extensively bound to plasma proteins and subject to displacement reactions (e.g. warfarin, sulfonylureas, phenytoin, methotrexate, and valproate) have low-extraction ratios, and drug exposure is therefore independent of protein-binding.

An example of displacement of this kind happens when patients stabilised on warfarin are given cloral hydrate because its major metabolite, trichloroacetic acid, is a highly bound compound that successfully displaces warfarin. This effect is only very short-lived because the now free and active warfarin molecules become exposed to metabolism as the blood flows through the liver, and the amount of drug rapidly falls. This transient increase in free warfarin levels is unlikely to change the anticoagulant effect of warfarin because the clotting factor complexes that are produced when warfarin is taken have a very long half-life, and thus take a long time to reach a new steady state. Normally no change in the warfarin dose is needed (see 'Coumarins + Cloral hydrate and related drugs', p.449).

In vitro many commonly used drugs are capable of being displaced by others but in the body the effects seem almost always to be buffered so effectively that the outcome is not normally clinically important. It would therefore seem that the importance of this interaction mechanism has been grossly over-emphasised.[1-3] It is difficult to find an example of a clinically important interaction due to this mechanism alone. It has been suggested that this interaction mechanism is likely to be important only for drugs given intravenously that have a high-extraction ratio, a short pharmacokinetic-pharmacodynamic half-life and a narrow therapeutic index. Lidocaine has been given as an example of a drug fitting these criteria.[3] Some drug interactions that were originally assumed to be due to changes in protein binding have subsequently been shown to have other interaction mechanisms involved. For example, inhibition of metabolism has subsequently been shown to be important in the interactions between 'warfarin and phenylbutazone', (p.488), and 'tolbutamide and sulfonamides', (p.574).

However, knowledge of altered protein binding is important in therapeutic drug monitoring. Suppose for example a patient taking phenytoin was given a drug that displaced phenytoin from its binding sites. The amount of free phenytoin would rise but this would be quickly eliminated by metabolism and excretion thereby keeping the amount of free active phenytoin the same. However, the total amount of phenytoin would now be reduced. Therefore if phenytoin was monitored using an assay looking at total phenytoin levels it may appear that the phenytoin is subtherapeutic and that the dose may therefore need increasing. However, as the amount of free active phenytoin is unchanged this would not be necessary and may even be dangerous.

Basic drugs as well as acidic drugs can be highly protein bound, but clinically important displacement interactions do not seem to have been described. The reasons seem to be that the binding sites within the plasma are different from those occupied by acidic drugs (alpha-1-acid glycoprotein rather than albumin) and, in addition, basic drugs have a large V_d with only a small proportion of the total amount of drug being within the plasma.

(b) Induction or inhibition of drug transporter proteins

It is increasingly being recognised that distribution of drugs into the brain, and some other organs such as the testes, is limited by the action of drug transporter proteins such as P-glycoprotein. These proteins actively transport drugs out of cells when they have passively diffused in. Drugs that are inhibitors of these transporters could therefore increase the uptake of drug substrates into the brain, which could either increase adverse CNS effects, or be beneficial. For more information, see 'Drug transporter proteins', (p.8).

Table 1.2 Drugs affecting or metabolised by the cytochrome P450 isoenzyme CYP1A2

Inhibitors	Cimetidine	Oestrogens
	Fluoroquinolones	Rofecoxib
	Ciprofloxacin	Tacrine
	Enoxacin	Tiabendazole
	Fluvoxamine	Ticlopidine
	Methoxsalen	Zileuton

Drug metabolism (biotransformation) interactions

Although a few drugs are cleared from the body simply by being excreted unchanged in the urine, most are chemically altered within the body to less lipid-soluble compounds, which are more easily excreted by the kidneys. If this were not so, many drugs would persist in the body and continue to exert their effects for a long time. This chemical change is called 'metabolism', 'biotransformation', 'biochemical degradation' or sometimes 'detoxification'. Some drug metabolism goes on in the serum, the kidneys, the skin and the intestines, but the greatest proportion is carried out by enzymes that are found in the membranes of the endoplasmic reticulum of the liver cells. If liver is homogenised and then centrifuged, the reticulum breaks up into small sacs called microsomes which carry the enzymes, and it is for this reason that the metabolising enzymes of the liver are frequently referred to as the 'liver microsomal enzymes'.

Drugs are metabolised by two major types of reaction. The first, so-called phase I reactions (involving oxidation, reduction or hydrolysis), turn drugs into more polar compounds, while phase II reactions involve coupling drugs with some other substance (e.g. glucuronic acid, known as glucuronidation) to make compounds that are usually inactive.

The majority of phase I oxidation reactions are carried out by the haem-containing enzyme cytochrome P450. Cytochrome P450 is not a single entity, but is in fact a very large family of related isoenzymes. However, in practice, only a few specific subfamilies seem to be responsible for most (about 90%) of the metabolism of the commonly used drugs. The most important isoenzymes are CYP1A2, CYP2B6, CYP2C8, CYP2C9, CYP2C19, CYP2D6, CYP2E1 and CYP3A4. Other enzymes involved in phase I metabolism include monoamine oxidases and epoxide hydrolases.

Less is known about the enzymes responsible for phase II conjugation reactions. However, UDP-glucuronyltransferases (UGT), methyltransferases, and N-acetyltransferases (NAT) are examples. UGTs are the sub-

ject of much study and look to become increasingly important in explaining the mechanisms behind a number of interactions.

Although metabolism is very important for the body to remove drugs, it is increasingly recognised that drugs can be adsorbed, distributed, or eliminated by transporters, the most well understood at present being 'P-glycoprotein', (p.8).

(a) Changes in first-pass metabolism

1. Changes in blood flow through the liver. After absorption in the intestine, the portal circulation takes drugs directly to the liver before they are distributed by the blood flow around the rest of the body. A number of highly lipid-soluble drugs undergo substantial biotransformation during this first-pass through the gut wall and liver and there is some evidence that some drugs can have a marked effect on the extent of first pass metabolism by altering the blood flow through the liver. However, there are few clinically relevant examples of this, and many can be explained by other mechanisms, usually altered hepatic metabolism (see *Inhibition or induction of first-pass metabolism*, below). One possible example is the increase in rate of absorption of dofetilide with verapamil, which has resulted in an increased incidence of torsade de pointes (see 'Dofetilide + Verapamil', p.288).

Another is the increase in bioavailability of high-extraction beta blockers with hydralazine, possibly caused by altered hepatic blood flow, or altered metabolism (see 'Beta blockers + Hydralazine', p.1010).

2. Inhibition or induction of first-pass metabolism. The gut wall contains metabolising enzymes, principally cytochrome P450 isoenzymes. In addition to the altered metabolism caused by changes in hepatic blood flow (see *Changes in blood flow through the liver*, above) there is evidence that some drugs can have a marked effect on the extent of first-pass metabolism by inhibiting or inducing the cytochrome P450 isoenzymes in the gut wall or in the liver. An example is the effect of grapefruit juice, which seems to inhibit the cytochrome P450 isoenzyme CYP3A4, mainly in the gut, and therefore reduces the metabolism of oral calcium-channel blockers. Although altering the amount of drug absorbed, these interactions are usually considered drug metabolism interactions. The effect of grapefruit on the metabolism of other drugs is discussed further under 'Drug-food interactions', (p.11).

(b) Enzyme induction

When barbiturates were widely used as hypnotics it was found necessary to keep increasing the dose as time went by to achieve the same hypnotic effect, the reason being that the barbiturates increase the activity of the microsomal enzymes so that extent of metabolism and excretion increases. This phenomenon of enzyme stimulation or induction not only accounts for the need for an increased barbiturate dose but if another drug that is metabolised by the same range of enzymes is also present, its enzymatic metabolism is similarly increased and larger doses are needed to maintain the same therapeutic effect. However, note that not all enzyme-inducing drugs induce their own metabolism (a process known as auto-induction).

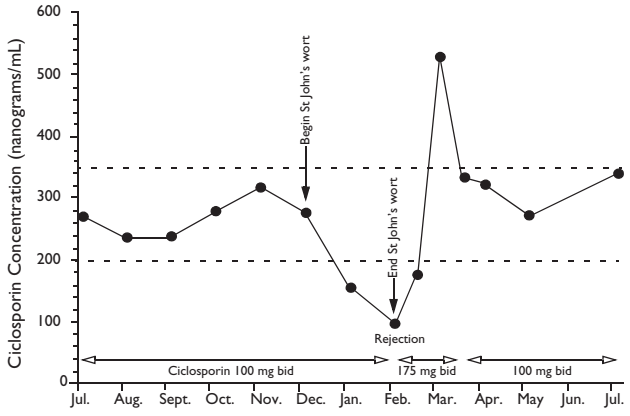

Fig. 1.2 An enzyme induction interaction. Chronology of ciclosporin trough concentrations (—●—) in a patient self-medicating with St John's wort. ---------- = desired ciclosporin therapeutic range (after Barone GW, Gurley BJ, Ketel BL, Lightfoot ML, Abul-Ezz SR. Drug interaction between St. John's Wort and Cyclosporine. *Ann Pharmacother* (2000) 34: 1013–16, with permission).

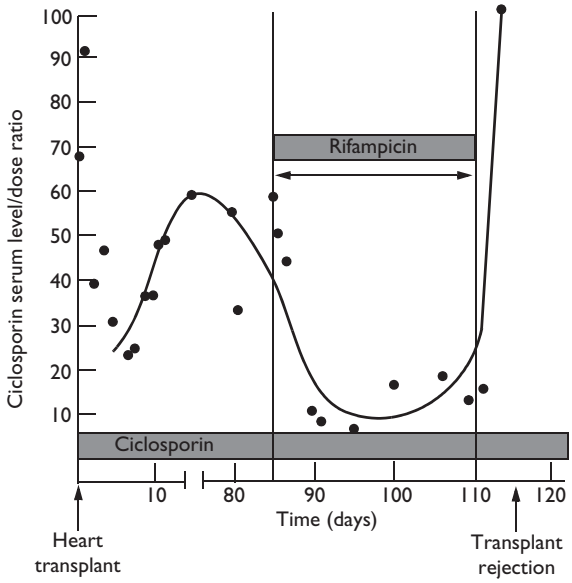

Fig. 1.3 An enzyme induction interaction. Rifampicin (600 mg daily plus isoniazid) increased the metabolism of ciclosporin in this patient, thereby reducing the trough serum levels. He subsequently died because his heart transplant was rejected (after *Transplant Proc*, 16, Van Buren D, Wideman CA, Ried M, Gibbons S, Van Buren CT, Jarowenko M, Flechner SM, Frazier OH, Cooley DA, Kahan BD. The antagonistic effect of rifampicin upon cyclosporine bioavailability. 1642–5, Copyright Elsevier (1984)).

The metabolic pathway that is most commonly induced is phase I oxidation mediated by the cytochrome P450 isoenzymes. The main drugs responsible for induction of the most clinically important cytochrome P450 isoenzymes are listed in 'Table 1.2', (p.4), 'Table 1.3', (p.6), and 'Table 1.4', (p.6). 'Figure 1.2', (see below) shows the reduction in trough ciclosporin levels when it is given with the enzyme inducer, St John's wort. This herb induces the metabolism of ciclosporin by induction of CYP3A4 and possibly also P-glycoprotein (consider also 'Ciclosporin + St John's wort (*Hypericum perforatum*)', p.1253). 'Figure 1.3', (see above), shows the effects of another enzyme inducer, rifampicin (rifampin) on the serum levels of ciclosporin presumably by its effects on CYP3A4 (consider also 'Ciclosporin + Antimycobacterials', p.1224). Phase II glucuronidation can also be induced. An example is when rifampicin induces the glucuronidation of 'zidovudine', (p.942).

The extent of the enzyme induction depends on the drug and its dose, but it may take days or even 2 to 3 weeks to develop fully, and may persist for a similar length of time when the enzyme inducer is stopped. This means that enzyme induction interactions are delayed in onset and slow to resolve. Enzyme induction is a common mechanism of interaction and is not confined to drugs; it is also caused by the chlorinated hydrocarbon insecticides such as dicophane and lindane, and smoking tobacco.

If one drug reduces the effects of another by enzyme induction, it may be possible to accommodate the interaction simply by raising the dose of the drug affected, but this requires good monitoring, and there are obvious hazards if the inducing drug is eventually stopped without remembering to reduce the dose again. The raised drug dose may be an overdose when the drug metabolism has returned to normal.

(c) Enzyme inhibition

More common than enzyme induction is the inhibition of enzymes. This results in the reduced metabolism of an affected drug, so that it may begin to accumulate within the body, the effect usually being essentially the same as when the dose is increased. Unlike enzyme induction, which may take several days or even weeks to develop fully, enzyme inhibition can occur within 2 to 3 days, resulting in the rapid development of toxicity. The metabolic pathway that is most commonly inhibited is phase I oxidation by cytochrome P450 isoenzymes. The main drugs responsible for inhibition of the most clinically important cytochrome P450 isoenzymes are listed in 'Table 1.2', (p.4), 'Table 1.3', (p.6), and 'Table 1.4', (p.6). For example a marked increase occurred in the plasma levels of a single dose of sildenafil after ritonavir had also been taken for 7 days, probably

Table 1.3 Drugs affecting or metabolised by the CYP2 family of cytochrome P450 isoenzymes

because ritonavir inhibits the metabolism of sildenafil by CYP3A4 (see 'Phosphodiesterase type-5 inhibitors + Protease inhibitors', p.1539).

An example of inhibition of phase I hydrolytic metabolism, is the inhibition of epoxide hydrolase by valpromide, which increases the levels of 'carbamazepine', (p.613). Phase II conjugative metabolism can also be inhibited. Examples are the inhibition of carbamazepine glucuronidation by 'sodium valproate', (p.613), and the inhibition of methyltransferase by aminosalicylates causing raised levels of 'azathioprine', (p.774).

The clinical significance of many enzyme inhibition interactions depends on the extent to which the serum levels of the drug rise. If the serum levels remain within the therapeutic range the interaction may not be clinically important.

(d) Genetic factors in drug metabolism

An increased understanding of genetics has shown that some of the cytochrome P450 isoenzymes are subject to 'genetic polymorphism', which simply means that some of the population have a variant of the isoenzyme with different (usually poor) activity. The best known example is CYP2D6, for which a small proportion of the population have a variant with low activity and are described as being poor or slow metabolisers (about 5 to 10% in white Caucasians, 0 to 2% in Asians and black people). Which group any particular individual falls into is genetically determined. The majority who possess the isoenzyme are called fast or extensive metabolisers. It is possible to find out which group any particular individual falls into by looking at the way a single dose of a test or probe drug is metabolised. This varying ability to metabolise certain drugs may explain why some patients develop toxicity when given an interacting drug while others remain symptom free. CYP2D6, CYP2C9 and CYP2C19 also show polymorphism, whereas CYP3A4 does not, although there is still some broad variation in the population without there being distinct groups. The effects of CYP2C19 polymorphism are discussed in more detail in 'Gastrointestinal drugs', (p.1142). At present, genotyping of cytochrome P450 isoenzymes is primarily a research tool and is not widely used clinically. In the future, it may become standard clinical practice and may be used to individualise drug therapy.[1]

(e) Cytochrome P450 isoenzymes and predicting drug interactions

It is interesting to know which particular isoenzyme is responsible for the metabolism of drugs because by doing *in vitro* tests with human liver enzymes it is often possible to explain why and how some drugs interact. For example, ciclosporin is metabolised by CYP3A4, and rifampicin (rifampin) is a known, potent inducer of this isoenzyme, whereas ketoconazole inhibits its activity, so that it comes as no surprise that rifampicin reduces the levels of ciclosporin and ketoconazole increases them.

What is very much more important than retrospectively finding out why two drugs interact, is the knowledge such *in vitro* tests can provide about forecasting which other drugs may possibly also interact. This may reduce the numbers of expensive clinical studies in subjects and patients and avoids waiting until significant drug interactions are observed in clinical use. A lot of effort is being put into this area of drug development.[2-6] However, at present such prediction is, like weather forecasting, still a somewhat hit-and-miss business because all of the factors that may modify or interfere with metabolism are not known. It is far too simplistic to think that we have all the answers just because we know which liver isoenzymes are concerned with the metabolism of a particular drug, but it is a very good start.

'Table 1.2', (p.4), 'Table 1.3', (p.6), and 'Table 1.4', (p.6), are lists of drugs that are inhibitors, inducers, or substrates of the clinically important cytochrome P450 isoenzymes, and each drug has a cross reference to a monograph describing a drug interaction thought to occur by that mechanism. If a new drug is shown to be an inducer, or an inhibitor, and/or a substrate of a given isoenzyme, these tables could be used to predict likely drug interactions. However, what may happen *in vitro* may not necessarily work in clinical practice because all of the many variables which can come into play are not known (such as how much of the enzyme is available, the concentration of the drug at the site of metabolism, and the affinity of the drug for the enzyme). Remember too that some drugs can be metabolised by more than one cytochrome P450 isoenzyme (meaning that this other isoenzyme may be able to 'pick up' more metabolism to compensate for the inhibited pathway); some drugs (and their metabolites) can both induce a particular isoenzyme and be metabolised by it; and some drugs (or their metabolites) can inhibit a particular isoenzyme but not be metabolised by it. With so many factors possibly impinging on the outcome of giving two or more drugs together, it is very easy to lose sight of one of the factors (or not even know about it) so that the sum of 2 plus 2 may not turn out to be the 4 that you have predicted.

For example, ritonavir and other protease inhibitors are well known potent inhibitors of CYP3A4, and in clinical use increase the levels of many drugs that are substrates of this isoenzyme. Methadone is a substrate of CYP3A4, and some *in vitro* data show that ritonavir (predictably) increased methadone levels. However, unexpectedly, in clinical use the protease inhibitors seem to decrease methadone levels, by a yet unknown mechanism (see, 'Opioids; Methadone + Protease inhibitors', p.200).

Another factor complicating the understanding of metabolic drug interactions is the finding that there is a large overlap between the inhibitors or inducers and substrates of P-glycoprotein (a 'drug transporter protein', (p.8)) and those of CYP3A4. Therefore, both mechanisms may be involved in many of the drug interactions previously thought to be due to effects on CYP3A4.

Drug excretion interactions

With the exception of the inhalational anaesthetics, most drugs are excreted either in the bile or in the urine. Blood entering the kidneys along the renal arteries is, first of all, delivered to the glomeruli of the tubules where molecules small enough to pass through the pores of the glomerular membrane (e.g. water, salts, some drugs) are filtered through into the lumen of the tubules. Larger molecules, such as plasma proteins, and blood cells are retained within the blood. The blood flow then passes to the remaining parts of the kidney tubules where active energy-using transport systems are able to remove drugs and their metabolites from the blood and secrete them into the tubular filtrate. The renal tubular cells additionally possess active and passive transport systems for the reabsorption of drugs. Interference by drugs with renal tubular fluid pH, with active transport systems and with blood flow to the kidney can alter the excretion of other drugs.

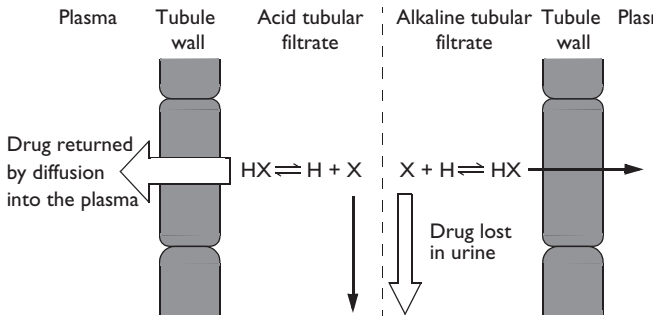

Fig. 1.4 An excretion interaction. If the tubular filtrate is acidified, most of the molecules of weakly acid drugs (HX) exist in an un-ionised lipid-soluble form and are able to return through the lipid membranes of the tubule cells by simple diffusion. Thus they are retained. In alkaline urine most of the drug molecules exist in an ionised non-lipid soluble form (X). In this form the molecules are unable to diffuse freely through these membranes and are therefore lost in the urine.

(a) Changes in urinary pH

As with drug absorption in the gut, passive reabsorption of drugs depends upon the extent to which the drug exists in the non-ionised lipid-soluble form, which in its turn depends on its pKa and the pH of the urine. Only the non-ionised form is lipid-soluble and able to diffuse back through the lipid membranes of the tubule cells. Thus at high pH values (alkaline),

weakly acid drugs (pKa 3 to 7.5) largely exist as ionised lipid-insoluble molecules, which are unable to diffuse into the tubule cells and will therefore remain in the urine and be removed from the body. The converse will be true for weak bases with pKa values of 7.5 to 10.5. Thus pH changes that increase the amount of drug in the ionised form (alkaline urine for acidic drugs, acid urine for basic drugs) will increase the loss of the drug, whereas moving the pH in the opposite direction will increase their retention. 'Figure 1.4', (p.7), illustrates the situation with a weakly acidic drug. The clinical significance of this interaction mechanism is small, because although a very large number of drugs are either weak acids or bases, almost all are largely metabolised by the liver to inactive compounds and few are excreted in the urine unchanged. In practice, therefore, only a handful of drugs seem to be affected by changes in urinary pH (possible exceptions include changes in the excretion of 'quinidine', (p.313), or 'analgesic-dose aspirin', (p.151), due to alterations in urinary pH caused by antacids, and the increase in the clearance of 'methotrexate', (p.758), with urinary alkalinisers). In cases of overdose, deliberate manipulation of urinary pH has been used to increase the removal of drugs such as methotrexate and salicylates.

Table 1.5 Examples of interactions probably due to changes in renal transport

Drug affected	*Interacting drug*	*Result of interaction*
Cephalosporins Dapsone Methotrexate Penicillins Quinolones	Probenecid	Serum levels of drug affected raised; possibility of toxicity with some drugs
Methotrexate	Salicylates and some other NSAIDs	Methotrexate serum levels raised; serious methotrexate toxicity possible
Pramipexole	Cimetidine	Serum levels of drug affected raised

(b) Changes in active renal tubular excretion

Drugs that use the same active transport systems in the renal tubules can compete with one another for excretion. For example, probenecid reduces the excretion of penicillin and other drugs. With the increasing understanding of drug transporter proteins in the kidneys, it is now known that probenecid inhibits the renal secretion of many other anionic drugs by organic anion transporters (OATs).[1] Probenecid possibly also inhibits some of the ABC transporters in the kidneys. The ABC transporter, P-glycoprotein, is also present in the kidneys, and drugs that alter this may alter renal drug elimination. See, 'Drug transporter proteins', (p.8), for further discussion. Some examples of drugs that possibly interact by alterations in renal transport are given in 'Table 1.5', (see above).

(c) Changes in renal blood flow

The flow of blood through the kidney is partially controlled by the production of renal vasodilatory prostaglandins. If the synthesis of these prostaglandins is inhibited the renal excretion of some drugs may be reduced. An interaction where this is the suggested mechanism is the rise in serum lithium seen with some NSAIDs, see 'Lithium + NSAIDs', p.1360.

(d) Biliary excretion and the entero-hepatic shunt

1. Enterohepatic recirculation. A number of drugs are excreted in the bile, either unchanged or conjugated (e.g. as the glucuronide) to make them more water soluble. Some of the conjugates are metabolised to the parent compound by the gut flora and are then reabsorbed. This recycling process prolongs the stay of the drug within the body, but if the gut flora are diminished by the presence of an antibacterial, the drug is not recycled and is lost more quickly. This may possibly explain the rare failure of the hormonal contraceptives that can be brought about by the concurrent use of penicillins or tetracyclines, but see *Mechanism* in 'Combined hormonal contraceptives + Antibacterials; Penicillins', p.1170. Antimicrobial-induced reductions in gut bacteria may reduce the activation of 'sulfasalazine', (p.1163).

2. Drug transporter proteins. Increasing research shows that numerous drug transporter proteins (both from the ABC family and SLC family, see 'Drug transporter proteins', (p.8)) are involved in the hepatic extraction and secretion of drugs into the bile.[2] The relevance of many of these to drug interactions is still unclear, but the bile salt export pump (ABCB11) is known to be inhibited by a variety of drugs including ciclosporin, glibenclamide, and bosentan. Inhibition of this pump may increase the risk of cholestasis, and the manufacturer of bosentan states that they should be avoided in patients taking bosentan (see 'Sulfonylureas + Bosentan', p.586, and 'Ciclosporin + Endothelin receptor antagonists', p.1238).

Drug transporter proteins

Drugs and endogenous substances are known to cross biological membranes, not just by passive diffusion, but by carrier-mediated processes, often known as transporters. Significant advances in the identification of various transporters have been made, although the contribution of many of these to drug interactions in particular, is still unclear.[1,2] The most well known is P-glycoprotein, which is a product of the MDR1 gene (ABCB1 gene) and a member of the ATP-binding cassette (ABC) family of efflux transporters.[1] Its involvement in drug interactions is discussed below.

Another ABC transporter is sister P-glycoprotein, otherwise called the bile salt export pump (BSEP or ABCB11).[1] It has been suggested that inhibition of this pump may increase the risk of cholestasis, see *Drug transporter proteins* under 'Drug excretion interactions', (p.7).

Other transporters that are involved in some drug interactions are the organic anion transporters (OATs), organic anion-transporting polypeptides (OATPs) and organic cation transporters (OCTs), which are members of the solute carrier superfamily (SLC) of transporters.[1] The best known example of an OAT inhibitor is probenecid, which affects the renal excretion of a number of drugs, see *Changes in active kidney tubule excretion*, under 'Drug excretion interactions', (p.7).

Table 1.6 Drugs affecting or transported by P-glycoprotein

Inhibitors	*Inducers*	*Substrates*
Ciclosporin	Protease inhibitors	Digoxin*
Clarithromycin	Ritonavir	Loperamide
Itraconazole	Tipranavir	Talinolol
Quinidine	Rifampicin (Rifampin)	
Ranolazine	St John's wort (*Hypericum perforatum*)	
Valspodar		
Verapamil		

* Considered the preferred *in vivo* substrate.

P-glycoprotein interactions

Some drug interactions occur because they interfere with the activity of P-glycoprotein. This is an efflux pump found in the membranes of certain cells, which can push metabolites and drugs out of the cells and have an impact on the extent of drug absorption (in the intestine), distribution (to the brain, testis, or placenta) and elimination (in the urine and bile). So, for example, the P-glycoprotein in the cells of the gut lining can eject some already-absorbed drug molecules back into the intestine resulting in a reduction in the total amount of drug absorbed. In this way P-glycoprotein acts as a barrier to absorption. The activity of P-glycoprotein in the endothelial cells of the blood-brain barrier can also eject certain drugs from the brain, limiting CNS penetration and effects.

The pumping actions of P-glycoprotein can be induced or inhibited by some drugs. So, for example, the induction (or stimulation) of the activity of P-glycoprotein by rifampicin (rifampin), that occurs within the lining cells of the gut causes digoxin to be ejected into the gut more vigorously. This results in a fall in the plasma levels of digoxin (see 'Digoxin and related drugs + Rifampicin (Rifampin)', p.1113). In contrast, verapamil appears to inhibit the activity of P-glycoprotein, and is well known to increase digoxin levels (see 'Digoxin and related drugs + Calcium-channel blockers; Verapamil', p.1091). Ketoconazole also has P-glycoprotein inhibitory effects, and has been shown to increase the CSF levels of ritonavir, possibly by preventing the efflux of ritonavir from the CNS (see 'Protease inhibitors + Azoles; Ketoconazole', p.964). Thus the induction or inhibition of P-glycoprotein can have an impact on the pharmacokinetics

of some drugs. Note that there is evidence that P-glycoprotein inhibition may have a greater impact on drug distribution (e.g. into the brain) than on drug absorption (e.g. plasma levels).[2]

There is an overlap between CYP3A4 and P-glycoprotein inhibitors, inducers and substrates. Therefore, both mechanisms may be involved in many of the drug interactions traditionally thought to be due to changes in CYP3A4. 'Table 1.6', (p.8), lists some P-glycoprotein inhibitors and inducers. Many drugs that are substrates for CYP3A4 (see 'Table 1.4', (p.6)) are also substrates for P-glycoprotein. Digoxin and talinolol are examples of the few drugs that are substrates for P-glycoprotein but not CYP3A4, and they are therefore useful in studying some interactions that may occur by this mechanism.

P-glycoprotein is also expressed in some cancer cells (where it was first identified). This has led to the development of specific P-glycoprotein inhibitors, such as valspodar, with the aim of improving the penetration of cytotoxic drugs into cancer cells.

Pharmacodynamic interactions

Pharmacodynamic interactions are those where the effects of one drug are changed by the presence of another drug at its site of action. Sometimes the drugs directly compete for particular receptors (e.g. beta$_2$ agonists, such as salbutamol, and beta blockers, such as propranolol) but often the reaction is more indirect and involves interference with physiological mechanisms. These interactions are much less easy to classify neatly than those of a pharmacokinetic type.

Additive or synergistic interactions

If two drugs that have the same pharmacological effect are given together the effects can be additive. For example, alcohol depresses the CNS and, if taken in moderate amounts with normal therapeutic doses of any of a large number of drugs (e.g. anxiolytics, hypnotics, etc.), may cause excessive drowsiness. Strictly speaking (as pointed out earlier) these are not interactions within the definition given in 'What is a drug interaction?', (p.1). Nevertheless, it is convenient to consider them within the broad context of the clinical outcome of giving two drugs together.

Additive effects can occur with both the main effects of the drugs as well as their adverse effects, thus an additive interaction can occur with antimuscarinic antiparkinson drugs (main effect) or butyrophenones (adverse effect) that can result in serious antimuscarinic toxicity (see 'Antipsychotics + Antimuscarinics', p.833).

Sometimes the additive effects are solely toxic (e.g. additive ototoxicity, nephrotoxicity, bone marrow depression, QT interval prolongation). Examples of these reactions are listed in 'Table 1.7', (see below). It is common to use the terms 'additive', 'summation', 'synergy' or 'potentiation' to describe what happens if two or more drugs behave like this. These words have precise pharmacological definitions but they are often used rather loosely as synonyms because in practice it is often very difficult to know the extent of the increased activity, that is to say whether the effects are greater or smaller than the sum of the individual effects.

Serotonin syndrome

In the 1950s a serious and life-threatening toxic reaction was reported in patients taking iproniazid (an MAOI) when they were given pethidine (meperidine). For further information about this interactions, see under 'MAOIs or RIMAs + Opioids; Pethidine (Meperidine)', p.1381. The reasons were then not understood and even now we do not have the full picture. What happened is thought to have been due to over-stimulation of the 5-HT$_{1A}$ and 5-HT$_{2A}$ receptors and possibly other serotonin receptors in the central nervous system (in the brain stem and spinal cord in particular) due to the combined effects of these two drugs. It can occur exceptionally after taking only one drug, which causes over-stimulation of these 5-HT receptors, but much more usually it develops when two or more drugs (so-called serotonergic or serotomimetic drugs) act in concert. The characteristic symptoms (now known as serotonin syndrome) fall into three main areas, namely altered mental status (agitation, confusion, mania), autonomic dysfunction (diaphoresis, diarrhoea, fever, shivering) and neuromuscular abnormalities (hyperreflexia, incoordination, myoclonus, tremor). These are the 'Sternbach diagnostic criteria' named after Dr Harvey Sternbach who drew up this list of clinical features and who suggested that at least three of them need to be seen before classifying this toxic reaction as serotonin syndrome rather than neuroleptic malignant syndrome.[1]

The syndrome can develop shortly after one serotonergic drug is added to another, or even if one is replaced by another without allowing a long enough washout period in between, and the problem usually resolves within about 24 hours if both drugs are withdrawn and supportive measures given. Non-specific serotonin antagonists (cyproheptadine, chlorpromazine, methysergide) have also been used for treatment. Most patients recover uneventfully, but there have been a few fatalities.

Table 1.7 Additive, synergistic or summation interactions

Drugs	*Result of interaction*
Antipsychotics + Antimuscarinics	Increased antimuscarinic effects; heat stroke in hot and humid conditions, adynamic ileus, toxic psychoses
Antihypertensives + Drugs that cause hypotension (e.g. Phenothiazines, Sildenafil)	Increased antihypertensive effects; orthostasis
Beta-agonist bronchodilators + Potassium-depleting drugs	Hypokalaemia
CNS depressants + CNS depressants Alcohol + Antihistamines Benzodiazepines + Anaesthetics, general Opioids + Benzodiazepines	Impaired psychomotor skills, reduced alertness, drowsiness, stupor, respiratory depression, coma, death
Drugs that prolong the QT interval + Other drugs that prolong the QT interval Amiodarone + Disopyramide	Additive prolongation of QT interval, increased risk of torsade de pointes
Methotrexate + Co-trimoxazole	Bone marrow megaloblastosis due to folic acid antagonism
Nephrotoxic drugs + Nephrotoxic drugs (e.g. Aminoglycosides, Ciclosporin, Cisplatin, Vancomycin)	Increased nephrotoxicity
Neuromuscular blockers + Drugs with neuromuscular blocking effects (e.g. Aminoglycosides)	Increased neuromuscular blockade; delayed recovery, prolonged apnoea
Potassium supplements + Potassium-sparing drugs (e.g. ACE inhibitors, Angiotensin II receptor antagonists, Potassium-sparing diuretics)	Hyperkalaemia

Following the first report of this syndrome, many other cases have been described involving 'tryptophan and MAOIs', (p.1393), the 'tricyclic antidepressants and MAOIs', (p.1391), and, more recently, the 'SSRIs', (p.1384), but other serotonergic drugs have also been involved and the list continues to grow.

It is still not at all clear why many patients can take two, or sometimes several serotonergic drugs together without problems, while a very small number develop this serious toxic reaction, but it certainly suggests that there are other factors involved that have yet to be identified. The full story is likely to be much more complex than just the simple additive effects of two drugs.

1. Sternbach H. The serotonin syndrome. *Am J Psychiatry* (1991) 148, 705–13.

Antagonistic or opposing interactions

In contrast to additive interactions, there are some pairs of drugs with activities that are opposed to one another. For example the coumarins can prolong the blood clotting time by competitively inhibiting the effects of dietary vitamin K. If the intake of vitamin K is increased, the effects of the coumarin are opposed and the prothrombin time can return to normal,

thereby cancelling out the therapeutic benefits of anticoagulant treatment (see 'Coumarins and related drugs + Food; Vitamin K_1-rich', p.464). Other examples of this type of interaction are listed in 'Table 1.8', (see below).

Table 1.8 Opposing or antagonistic interactions

Drug affected	*Interacting drugs*	*Results of interaction*
ACE inhibitors or Loop diuretics	NSAIDs	Antihypertensive effects opposed
Anticoagulants	Vitamin K	Anticoagulant effects opposed
Antidiabetics	Glucocorticoids	Blood glucose-lowering effects opposed
Antineoplastics	Megestrol	Antineoplastic effects possibly opposed
Levodopa	Antipsychotics (those with dopamine antagonist effects)	Antiparkinsonian effects opposed

Drug or neurotransmitter uptake interactions

A number of drugs with actions that occur at adrenergic neurones can be prevented from reaching those sites of action by the presence of other drugs. The tricyclic antidepressants prevent the re-uptake of noradrenaline (norepinephrine) into peripheral adrenergic neurones. Thus patients taking tricyclics and given parenteral noradrenaline have a markedly increased response (hypertension, tachycardia); see 'Tricyclic and related antidepressants + Inotropes and Vasopressors', p.1507. Similarly, the uptake of guanethidine (and related drugs guanoclor, betanidine, debrisoquine, etc.) is blocked by 'chlorpromazine, haloperidol, tiotixene', (p.1059), a number of 'amfetamine-like drugs', (p.1058), and the 'tricyclic antidepressants', (p.1060), so that the antihypertensive effect is prevented. The antihypertensive effects of clonidine are also prevented by the tricyclic antidepressants, one possible reason being that the uptake of clonidine within the CNS is blocked (see 'Clonidine and related drugs + Tricyclic and related antidepressants', p.1054). Some of these interactions at adrenergic neurones are illustrated in 'Figure 1.5', (see below).

Drug-herb interactions

The market for herbal medicines and supplements in the Western world has markedly increased in recent years, and, not surprisingly, reports of interactions with 'conventional' drugs have arisen. The most well known and documented example is the interaction of St John's wort (*Hypericum perforatum*) with a variety of drugs, see below. There have also been isolated reports of other herb-drug interactions, attributable to various mechanisms, including additive pharmacological effects.

Based on these reports, there are a growing number of reviews of herbal medicine interactions, which seek to predict likely interactions based on the, often hypothesised, actions of various herbs. Many of these predictions seem tenuous at best.

Rather than add to the volume of predicted interactions, at present, *Stockley's Drug Interactions* includes only those interactions for which there are published reports. Our sister publication, *Stockley's Herbal Medicines Interactions*, attempts to deal with these interactions in much greater depth, assessing the theoretical as well as the clinical evidence for the interactions of herbal medicines, dietary supplements and nutraceuticals.

To aid collection of data in this area, health professionals should routinely ask patients about their use of herbal medicines and supplements, and report any unexpected responses to treatment.

An additional problem in interpreting these interactions, is that the interacting constituent of the herb is usually not known and is therefore not

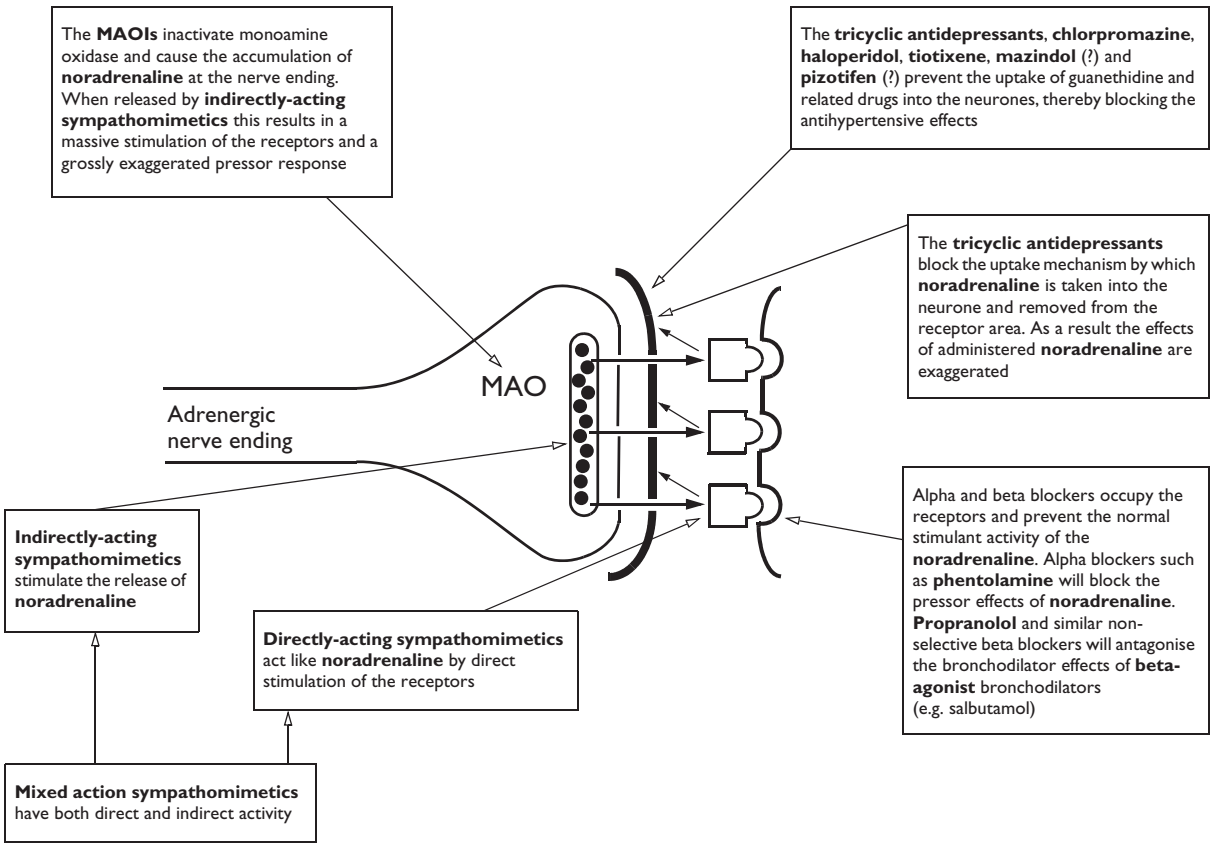

Fig. 1.5 Interactions at adrenergic neurones. A highly simplified composite diagram of an adrenergic neurone (molecules of noradrenaline (norepinephrine) indicated as (●) contained in a single vesicle at the nerve-ending) to illustrate in outline some of the different sites where drugs can interact. More details of these interactions are to be found in individual monographs.

standardised for. It could vary widely between different products, and batches of the same product.

St John's wort (Hypericum perforatum)

An increasing number of reports have implicated St John's wort (*Hypericum perforatum*) in drug interactions. Evidence has shown that the herb can induce the cytochrome P450 isoenzyme CYP3A4, and can also induce 'P-glycoprotein', (p.8). Hence St John's wort decreases the levels of 'ciclosporin', (p.1253) and 'digoxin', (p.1115), respectively. Other less certain evidence suggests that CYP2E1 and CYP1A2 may also be induced. St John's wort has serotonergic properties, and this has resulted in a pharmacodynamic interaction with the 'SSRIs', (p.1492), namely the development of serotonin syndrome. St John's wort contains many possible constituents that could be responsible for its pharmacological effects. The major active constituents are currently considered to be hyperforin (a phloroglucinol) and hypericin (a naphthodianthrone). Hypericin is the only constituent that is standardised for, and then only in some St John's wort preparations.

Drug-food interactions

It is well established that food can cause clinically important changes in drug absorption through effects on gastrointestinal motility or by drug binding, see 'Drug absorption interactions', (p.3). In addition, it is well known that tyramine (present in some foodstuffs) may reach toxic concentrations in patients taking 'MAOIs', (p.1395). With the growth in understanding of drug metabolism mechanisms, it has been increasingly recognised that some foods can alter drug metabolism. Currently, grapefruit juice causes the most clinically relevant of these interactions, see *Grapefruit juice*, below.

(a) Cruciferous vegetables and charcoal-broiled meats

Cruciferous vegetables, such as brussels sprouts, cabbage, and broccoli, contain substances that are inducers of the cytochrome P450 isoenzyme CYP1A2. Chemicals formed by 'burning' meats additionally have these properties. These foods do not appear to cause any clinically important drug interactions in their own right, but their consumption may add another variable to drug interaction studies, so complicating interpretation. In drug interaction studies where alteration of CYP1A2 is a predicted mechanism, it may be better for patients to avoid these foods during the study.

(b) Grapefruit juice

By chance, grapefruit juice was chosen to mask the taste of alcohol in a study of the effect of alcohol on felodipine, which led to the discovery that grapefruit juice itself markedly increased felodipine levels, see 'Calcium-channel blockers + Grapefruit juice', p.1034. In general, grapefruit juice inhibits intestinal CYP3A4, and only slightly affects hepatic CYP3A4. This is demonstrated by the fact that intravenous preparations of drugs that are metabolised by CYP3A4 are not much affected, whereas oral preparations of the same drugs are. These interactions result in increased drug levels.

Some drugs that are not metabolised by CYP3A4 show decreased levels with grapefruit juice, such as 'fexofenadine', (p.670). The probable reason for this is that grapefruit juice is an inhibitor of some drug transporters (see 'Drug transporter proteins', (p.8)), and possibly affects organic anion-transporting polypeptides (OATPs), although inhibition of P-glycoprotein has also been suggested.

The active constituent of grapefruit juice is uncertain. Grapefruit contains naringin, which degrades during processing to naringenin, a substance known to inhibit CYP3A4. Because of this, it has been assumed that whole grapefruit will not interact, but that processed grapefruit juice will. However, subsequently some reports have implicated the whole fruit. Other possible active constituents in the whole fruit include bergamottin and dihydroxybergamottin.

Conclusions

It is now quite impossible to remember all the known clinically important interactions and how they occur, which is why this publication has been produced, but there are some broad general principles that need little memorising:

- Be on the alert with any drugs that have a narrow therapeutic window or where it is necessary to keep serum levels at or above a suitable level (e.g. certain anticoagulants, antidiabetic drugs, antiepileptics, antihypertensives, anti-infectives, antineoplastic cytotoxics, digitalis glycosides, immunosuppressants, etc.).
- Remember some of those drugs that are key enzyme inducers (e.g. phenytoin, barbiturates, rifampicin (rifampin), etc) or enzyme inhibitors (e.g. azole antifungals, HIV-protease inhibitors, erythromycin, SSRIs).
- Think about the basic pharmacology of the drugs under consideration so that obvious problems (additive CNS depression for example) are not overlooked, and try to think of what might happen if drugs that affect the same receptors are used together. Don't forget that many drugs affect more than one type of receptor.
- Keep in mind that the elderly are at risk because of reduced liver and renal function on which drug clearance depends.

2

ACE inhibitors and Angiotensin II receptor antagonists

ACE inhibitors (angiotensin-converting enzyme inhibitors) prevent the production of angiotensin II from angiotensin I. The angiotensin II receptor antagonists are more selective, and target the angiotensin II type I (AT_1) receptor, which is responsible for the pressor actions of angiotensin II.

Angiotensin II is involved in the renin-angiotensin-aldosterone system, which regulates blood pressure, sodium and water homoeostasis by the kidneys, and cardiovascular function. Angiotensin II stimulates the synthesis and secretion of aldosterone and raises blood pressure via a direct vasoconstrictor effect.

Angiotensin converting enzyme (ACE) is identical to bradykinase, so ACE inhibitors may additionally reduce the degradation of bradykinin and affect enzymes involved in the production of prostaglandins.

Many of the interactions of the ACE inhibitors and angiotensin II receptor antagonists involve drugs that affect blood pressure. Consequently in most cases the result is either an increase in the hypotensive effect (e.g. 'alcohol', (p.51)) or a decrease in the hypotensive effect (e.g. 'indometacin', (p.32)).

In addition, due to their effects on aldosterone, the ACE inhibitors and angiotensin II antagonists may increase potassium concentrations and can therefore have additive hyperkalaemic effects with other drugs that cause elevated potassium levels. Furthermore, drugs that affect renal function may potentiate the adverse effects of ACE inhibitors and angiotensin II antagonists on the kidneys.

Most ACE inhibitor and angiotensin II receptor antagonist interactions are pharmacodynamic, that is, interactions that result in an alteration in drug effects rather than drug disposition, so in most cases interactions of individual drugs will be applicable to the group. *In vitro* experiments suggest that the role of cytochrome P450 isoenzymes in the metabolism and interactions of the angiotensin II receptor antagonists (candesartan, eprosartan, irbesartan, losartan and valsartan) is small, although losartan, irbesartan, and to a minor extent, candesartan, are metabolised by CYP2C9. Only losartan and irbesartan were considered to have a theoretical potential for pharmacokinetic drug interactions involving CYP2C9.[1] See 'Angiotensin II receptor antagonists + Azoles', p.39. The ACE inhibitors do not appear to undergo interactions via cytochrome P450 isoenzymes.

'Table 2.1', (see below) lists the ACE inhibitors and the angiotensin II receptor antagonists. Although most of the interactions of the ACE inhibitors or angiotensin II receptor antagonists are covered in this section, if the ACE inhibitor or angiotensin II receptor antagonist is the affecting drug, the interaction is dealt with elsewhere.

Table 2.1 ACE inhibitors and Angiotensin II receptor antagonists

Group	*Drugs*
ACE inhibitors	Alacepril, Benazepril, Captopril, Cilazapril, Delapril, Enalapril, Fosinopril, Imidapril, Lisinopril, Moexipril, Perindopril, Quinapril, Ramipril, Spirapril, Temocapril, Trandolapril, Zofenopril
Angiotensin II receptor antagonists	Candesartan, Eprosartan, Irbesartan, Losartan, Olmesartan, Telmisartan, Valsartan

ACE inhibitors + Aliskiren

The concurrent use of ramipril and aliskiren does not result in a clinically significant pharmacokinetic interaction, although additive blood pressure-lowering effects occur. However, the concurrent use of aliskiren and ACE inhibitors may increase the risk of hyperkalaemia.

Clinical evidence, mechanism, importance and management

In a study, 17 healthy subjects were given **ramipril** 2.5 mg daily, titrated to 10 mg daily by day 3, and aliskiren 300 mg daily, either alone or together for periods of 6 or 7 days. **Ramipril** increased the peak levels and AUC of aliskiren by 31% and 12%, respectively. Aliskiren increased the AUC of **ramipril** by 22%, but did not affect its plasma levels. The AUC of the active metabolite of **ramipril**, ramiprilat was unchanged, but its peak plasma levels decreased by 15%. These pharmacokinetic changes are unlikely to be clinically relevant and dose adjustments are not needed on concurrent use.[1] However, the concurrent use of **ramipril** with aliskiren results in additive blood pressure reduction.[2]

In one study, where aliskiren was given with an ACE inhibitor to patients with diabetes, increases in serum potassium were more frequent (5.5%) compared with an incidence of 0.9% that had been reported in hypertensive patients.[3]

The concurrent use of aliskiren and ramipril does not appear to result in a clinically significant pharmacokinetics interaction: no such interaction would be expected with other ACE inhibitors, but this ideally needs confirmation. However, as would be expected, concurrent use appears to result in an increased blood pressure-lowering effect, which would generally be considered desirable. Nevertheless, be alert for a greater than desired hypotensive effect. Also note that, the manufacturer of aliskiren warns that patients receiving other drugs that inhibit the renin-angiotensin system, and/or those with reduced renal function and/or diabetes are at an increased risk of hyperkalaemia during the use of aliskiren.[3] An increased frequency of monitoring potassium levels may be prudent.

ACE inhibitors + Allopurinol

A case of hypersensitivity has been attributed to the use of captopril with allopurinol. Anaphylaxis and myocardial infarction occurred when one man taking enalapril was given allopurinol. The concurrent use of ACE inhibitors and allopurinol may increase the risk of leucopenia and serious infection, especially in renal impairment.

Clinical evidence

No significant pharmacokinetic changes were seen in 12 healthy subjects given allopurinol and **captopril** alone and in combination.[1] A report describes fever, arthralgia and myalgia in a diabetic man with chronic renal failure who was also given **captopril** and allopurinol. He improved when the **captopril** was withdrawn.[2] A man taking **enalapril** had an acute anaphylactic reaction with severe coronary spasm, culminating in myocardial infarction, within 20 minutes of taking allopurinol 100 mg. He recovered and continued to take **enalapril** without allopurinol.[3]

The UK manufacturer of **captopril** also warns that neutropenia and agranulocytosis, resulting in serious infection, have occurred in patients taking **captopril** and other ACE inhibitors, and that the concurrent use of allopurinol may be a complicating factor, especially in those with renal impairment.[4]

Mechanism

Not understood. It is uncertain whether these are interactions because allopurinol alone can cause severe hypersensitivity reactions, particularly in the presence of renal failure. Captopril can also induce a hypersensitivity reaction.

Importance and management

These interactions are not clearly established, and the reaction appears to be rare and unpredictable. All that can be constructively said is that patients taking both drugs should be very closely monitored for any signs of hypersensitivity (e.g. skin reactions) or a low white cell count (e.g. sore throat, fever), especially if they have renal impairment. The UK manufacturer of captopril recommends that differential white blood cell counts should be performed before adding allopurinol, then every 2 weeks during the first 3 months of treatment, and periodically thereafter.[4] Similar caution and advice is given by the UK manufacturers of several other ACE inhibitors. For other possible interactions with ACE inhibitors that might result in an increased risk of leucopenia see also 'ACE inhibitors + Azathioprine', p.18 and 'ACE inhibitors + Procainamide', p.37.

ACE inhibitors + Angiotensin II receptor antagonists

The concurrent use of ACE inhibitors and angiotensin II receptor antagonists increases the risk of hypotension, renal impairment and hyperkalaemia.

Clinical evidence, mechanism, importance and management

Both ACE inhibitors and angiotensin II receptor antagonists can have adverse renal effects and can cause hyperkalaemia. These effects might be expected to be additive when they are used together. In one randomised clinical study in patients with heart failure taking ACE inhibitors (74% taking **enalapril**, **lisinopril**, **captopril**, or **ramipril**), the addition of **candesartan** resulted in higher rates of withdrawals for renal impairment (increase in creatinine 7.8% versus 4.1% with placebo) and hyperkalaemia (3.4% versus 0.7% with placebo).[1]

In another double-blind study in patients with heart failure, the concurrent use of **valsartan** and **captopril** resulted in a higher incidence of adverse events leading to a dose reduction or a discontinuation of study treatment than either drug alone. For hypotension, treatment was discontinued in 90 patients (1.9%) taking both drugs, 70 patients (1.4%) taking **valsartan**, and 41 patients (0.8%) taking **captopril**. For renal causes treatment was discontinued in 61 patients (1.3%) taking both drugs, 53 patients (1.1%) taking **valsartan** and 40 patients (0.8%) taking **captopril**; and for hyperkalaemia treatment was discontinued in 12 patients (0.2%) taking both drugs, 7 patients (0.1%) taking **valsartan** and 4 patients (0.1%) taking **captopril**.[2]

A placebo-controlled study in 24 patients with diabetic nephropathy taking **enalapril** 40 mg daily found that the addition of **irbesartan** 300 mg daily had a greater effect on reduction of albuminuria and blood pressure than **enalapril** alone. Plasma potassium levels of greater than 5.2 mmol/L occurred in one patient taking **enalapril** alone and in one patient taking **irbesartan** with **enalapril**. Six patients taking both drugs experienced transient hypotension or tiredness.[3]

Another study in patients with hypertension not controlled with **lisinopril** 20 mg daily found that either an increase in the **lisinopril** dose to 40 mg daily, or the addition of **candesartan** 16 mg daily for 2 weeks then 32 mg daily, controlled hypertension in 37% and 43% of patients, respectively. Eleven patients taking **lisinopril** and 9 patients taking **lisinopril** with **candesartan** developed hyperkalaemia resulting in discontinuation in 4 patients taking **lisinopril** with **candesartan**.[4]

In the ONTARGET study, patients with vascular disease or high-risk diabetes without heart failure were given either **ramipril** 10 mg daily (8 576 patients), **telmisartan** 80 mg daily (8 542 patients), or both drugs

(8 502 patients). The use of **ramipril** with **telmisartan** reduced the average systolic blood pressure by up to 5 mmHg, but did not have an additive effect on the renin-angiotensin system. The combination was associated with more adverse effects including hypotensive symptoms, syncope, renal impairment and hyperkalaemia without an increase in benefit. Discontinuation of treatment because of hypotensive symptoms occurred in 406 patients taking both drugs, compared with 149 taking **ramipril** alone and 229 taking **telmisartan** alone. In patients at high vascular risk, the use of both drugs reduced proteinuria to a greater extent than **ramipril** alone, but overall worsened major renal outcomes.[5-7]

Monitor blood pressure, renal function and serum potassium carefully if the concurrent use of an ACE inhibitor and an angiotensin II receptor antagonist is considered desirable.

ACE inhibitors + Antacids

Aluminium/magnesium hydroxide-containing antacids reduce the bioavailability of captopril by 40% and fosinopril by about one-third. An antacid did not affect ramipril pharmacokinetics.

Clinical evidence

In 10 healthy subjects an antacid containing **aluminium/magnesium hydroxide** and **magnesium carbonate** reduced the AUC of a single 50-mg dose of **captopril** by about 40%, when compared with the fasting state. However, this did not alter the extent of the reduction in blood pressure.[1]

Another study found that *Mylanta* [**aluminium/magnesium hydroxide** and simeticone[2]] reduced the bioavailability of **fosinopril** 20 mg by about one-third.[3]

It is briefly noted in a review that antacid use did not affect the pharmacokinetics of ramiprilat, the active metabolite of **ramipril**.[4]

Mechanism

The mechanism of this interaction is uncertain, but is unlikely to be due to elevated gastric pH as cimetidine did not have a similar effect.[3]

Importance and management

Evidence about interactions between ACE inhibitors and antacids it limited. Greater decreases in captopril bioavailability (caused by 'food', (p.28)) were found not to be clinically relevant, therefore, it is unlikely the change seen with antacids will be clinically important. However, with fosinopril, the manufacturers[2,5] suggest separating administration of antacids by at least 2 hours.

The UK manufacturers of **quinapril**[6] and **trandolapril**[7] also warn that antacids may reduce the bioavailability of ACE inhibitors, quite possibly based on the way that captopril and fosinopril interact, but there seems to be no evidence of a clinically significant interaction in practice.

ACE inhibitors + Antipsychotics

Marked postural hypotension occurred in a patient given chlorpromazine and captopril. The hypotensive adverse effects of antipsychotics such as the phenothiazines may be additive with the effects of ACE inhibitors.

Clinical evidence, mechanism, importance and management

A patient fainted and developed marked postural hypotension (standing blood pressure 66/48 mmHg) when given **captopril** 6.25 mg twice daily and **chlorpromazine** 200 mg three times daily. He had previously taken **chlorpromazine** with nadolol, prazosin and hydrochlorothiazide without any problems, although his blood pressure was poorly controlled on these drugs. As the patient's blood pressure was elevated when taking **chlorpromazine** or **captopril** alone, there appeared to be a synergistic hypotensive effect between the two drugs.[1]

The manufacturers of several ACE inhibitors warn that ACE inhibitors may enhance the hypotensive effects of certain antipsychotics, and that postural hypotension may occur. Some of these warnings are based, not unreasonably, on the adverse reactions seen with other ACE inhibitors or antihypertensives, but not necessarily on direct observations.[2] If postural hypotension occurs advise patients to lay down and elevate their legs if they feel faint or dizzy, and, when recovered, to get up slowly. Dose adjustments may be necessary to accommodate this interaction.

ACE inhibitors + Aprotinin

A retrospective study in patients undergoing cardiopulmonary bypass surgery found that pre-operative ACE inhibitor use with intra-operative aprotinin use increased the risk of renal failure.

Clinical evidence

The effects of preoperative ACE inhibitor use and/or intra-operative use of aprotinin were studied in a retrospective analysis of risk factors for acute renal failure in 1209 patients who underwent coronary artery bypass graft, valve, or combined procedures. Patients with preoperative renal impairment were excluded from the study, and only those with a low baseline risk of renal complications and no immediately identifiable cause of acute renal failure were included. Multivariate analysis indicated that risk factors for acute renal failure in the study patients were increasing age, valve procedures, red blood cell and platelet transfusions, lowest haematocrit during cardiopulmonary bypass, and the combination of ACE inhibitor and aprotinin use. The use of either an ACE inhibitor alone or aprotinin alone was not a significant predictor of acute renal failure.[1]

Mechanism

Aprotinin is a proteolytic enzyme inhibitor that has many actions including antagonism of the kallikrein-kinin system, which in turn affects bradykinins and renin. It would therefore be expected to have complex interactions with the ACE inhibitors,[2] which also affect these proteins.

It has been suggested that ACE inhibitors promote vasodilation of the efferent arteriole of the glomerulus, which reduces glomerular perfusion pressure. This can be compensated by vasodilation of the afferent arteriole to preserve glomerular perfusion pressure. Aprotinin may counter this compensatory response by causing vasoconstriction of the afferent arteriole, which reduces glomerular perfusion pressure and reduces renal excretory function. It was also suggested that this may not be generally clinically relevant, but in a situation such as cardiopulmonary bypass sur-

gery, where there are altered haemodynamics, there is the theoretical possibility of affecting renal haemodynamics.[1]

Importance and management

Patients taking ACE inhibitors may potentially be at increased risk of renal failure following cardiac surgery if aprotinin is used intra-operatively. The authors suggest more study is needed, but do advise the avoidance of aprotinin in such patients. They suggest that consideration should be given to stopping the ACE inhibitor for 2 to 3 days before surgery.[1] For information about the peri-operative use of ACE inhibitors, consider also 'Anaesthetics, general + ACE inhibitors or Angiotensin II receptor antagonists', p.102.

ACE inhibitors + Aspirin

The antihypertensive efficacy of captopril and enalapril may be reduced by high-dose aspirin in about 50% of patients. Low-dose aspirin (less than or equal to 100 mg daily) appears to have little effect. It is unclear whether aspirin attenuates the benefits of ACE inhibitors in heart failure. The likelihood of an interaction may depend on disease state and its severity.
Renal failure has been reported in a patient taking captopril and aspirin.

Clinical evidence

A. Effects on blood pressure

(a) Captopril

In 8 patients with essential hypertension, aspirin 600 mg every 6 hours for 5 doses did not significantly alter the blood pressure response to a single 25 to 100-mg dose of captopril. However, the prostaglandin response to captopril was blocked and the blood pressure response to captopril was blunted in 4 of the 8 patients.[1] In another study, in 15 patients with hypertension, aspirin 75 mg daily did not alter the antihypertensive effects of captopril 25 mg twice daily.[2]

(b) Enalapril

Two groups of 26 patients, one with mild to moderate hypertension taking enalapril 20 mg twice daily and the other with severe primary hypertension taking enalapril 20 mg twice daily (with nifedipine 30 mg and atenolol 50 mg daily), were given test doses of aspirin 100 mg and 300 mg daily for 5 days. The 100-mg dose of aspirin did not alter the efficacy of the antihypertensive drugs, but the 300-mg dose reduced the antihypertensive efficacy in about half the patients in both groups. In these patients, the antihypertensive effects were diminished by 63% in those with mild to moderate hypertension and by 91% in those with severe hypertension.[3] In contrast, another study in 7 patients with hypertension taking enalapril (mean daily dose 12.9 mg) found that aspirin 81 mg or 325 mg daily for 2 weeks did not have any significant effect on blood pressure.[4] A further study in 18 patients also found that aspirin 100 mg daily for 2 weeks did not alter the antihypertensive effect of enalapril 20 or 40 mg daily.[5]

(c) Unspecified ACE inhibitors

In a randomised study, the use of low-dose aspirin 100 mg daily for 3 months did not alter blood pressure control in patients taking ACE inhibitors, when compared with placebo.[6] Similarly, in a re-analysis of data from the Hypertension Optimal Treatment (HOT) study, long-term low-dose aspirin 75 mg daily did not interfere with the blood pressure-lowering effects of the antihypertensive drugs studied, when compared with placebo. Of 18 790 treated hypertensive patients, 41% received an ACE inhibitor, usually in combination with felodipine.[7]

B. Effects in coronary artery disease and heart failure

Various pharmacological studies have looked at the *short-term* effects of the combination of ACE inhibitors and aspirin on haemodynamic parameters. In one study in 40 patients with decompensated heart failure, aspirin 300 mg given on the first day and 100 mg daily thereafter antagonised the short-term haemodynamic effects of **captopril** 50 mg given every 8 hours for 4 days. The **captopril**-induced increase in cardiac index and the reduction in peripheral vascular resistance and pulmonary wedge pressure were all abolished.[8] A placebo-controlled study in 9 patients with chronic heart failure found that aspirin 75 mg daily for 7 days inhibited both the arterial and venous dilator responses to a single 25-mg dose of **captopril**.[9] In another study, in 15 patients with chronic heart failure receiving treatment with ACE inhibitors (mainly **enalapril** 10 mg twice daily), aspirin in doses as low as 75 mg impaired vasodilatation induced by arachidonic acid.[10] In yet another study, aspirin 325 mg daily worsened pulmonary diffusion capacity and made the ventilatory response to exercise less effective in patients taking **enalapril** 10 mg twice daily, but did not exert this effect in the absence of ACE inhibitors.[11] However, results from studies are inconsistent. In a review,[12] five of 7 studies reported that aspirin did not alter the haemodynamic effects of ACE inhibitors whereas the remaining two did. In one of these studies showing an adverse interaction between aspirin and **enalapril**, **ticlopidine** did not interact with **enalapril**.[13]

A number of large clinical studies of ACE inhibitors, mostly post-myocardial infarction, have been re-examined to see if there was a difference in outcome between those receiving aspirin at baseline, and those not. The results are summarised in 'Table 2.2', (p.16). However, in addition to the problems of retrospective analysis of non-randomised parameters, the studies vary in the initiation and duration of aspirin and ACE inhibitor treatment and the length of follow-up, the degree of heart failure or ischaemia, the prognosis of the patients, and the final end point (whether compared with placebo or with the benefits of aspirin or ACE inhibitors). The conclusions are therefore conflicting, and, although two meta-analyses of these studies found no interaction, an editorial[14] disputes the findings of one of these analyses.[15]

In addition to these sub-group analyses, there have been a number of retrospective cohort studies. A retrospective study involving 576 patients with heart failure requiring hospitalisation, found a trend towards an increased incidence of early readmissions (within 30 days after discharge) for heart failure among subjects taking ACE inhibitors and aspirin, compared with those taking ACE inhibitors without aspirin (16% versus 10%). In patients without coronary artery disease the increase in readmissions was statistically significant (23% versus 10%).[16] However, long-term survival in heart failure was not affected by the use of aspirin with ACE inhibitors. Furthermore, among patients with coronary artery disease, there was a trend towards improvement in mortality in patients receiving the combination, compared with an ACE inhibitor without aspirin (40% versus 56%).[17] A lack of adverse interaction was also found in a retrospective study involving 14 129 elderly patients who survived an acute myocardial infarction, for which they had been hospitalised. However, the added benefit of the combination over patients who received either aspirin or ACE inhibitors alone was not statistically significant.[18] Similarly, in another cohort of patients discharged after first hospitalisation for heart failure, there was no increase in mortality rates or readmission rates in those taking aspirin and ACE inhibitors.[19] A study in elderly patients with heart failure and resident in nursing homes included 12 703 who were taking an ACE inhibitor (51% were taking **captopril**; 33% **enalapril**; 9% **lisinopril**; with the rest taking **benazepril**, **fosinopril**, **quinapril**, or **ramipril**) and of these, 2046 also took aspirin (mostly 325 mg daily). The mortality rate, hospitalisation rate, or rate of decline in physical function after one year in patients taking ACE inhibitors, were not decreased by the use of aspirin. The findings were not affected by the presence of ischaemic heart disease and did not vary with the type or dose of ACE inhibitor used.[20] In another retrospective analysis in patients with stable left ventricular systolic dysfunction, no decrease in survival was seen in patients receiving ACE inhibitors, when comparing those also receiving aspirin (mean dose 183 mg daily; 74% of patients received 200 mg or less) and those not receiving aspirin.[21] Conversely, another study found that, compared with patients not taking aspirin, the use of high-dose aspirin (325 mg daily or more) with an ACE inhibitor was associated with a small but statistically significant 3% increase in the risk of death, whereas low-dose aspirin (160 mg daily or less) was not.[22]

C. Effects on renal function

Acute renal failure developed in a woman taking **captopril** when she started to take aspirin for arthritis. Renal function improved when both were stopped.[23] However, in a re-analysis of data from the Hypertension Optimal Treatment (HOT) study, long-term low-dose aspirin 75 mg daily had no effect on changes in serum creatinine, estimated creatinine clearance or the number of patients developing renal impairment, when compared with placebo. Of 18 790 treated hypertensive patients, 41% received an ACE inhibitor.[7] A study in 10 patients with chronic congestive heart failure, due

Table 2.2 Sub-group analyses of clinical studies assessing the interaction between aspirin and ACE inhibitors

Study and patients	*Aspirin dose*	*ACE inhibitor*	*Follow-up*	*Finding*	*Refs*
Evidence of an interaction					
SOLVD 6512 patients treated for heart failure or prevention of heart failure	Not reported	Enalapril	37 to 41 months	Combined treatment associated with reduced benefits compared with enalapril alone.	1
CONSENSUS II 6090 patients with acute MI	Not reported	Enalapril	6 months	Effect of enalapril less favourable in those taking aspirin at baseline.	2
GUSTO-I 31622 post-MI patients without heart failure	Not reported	Not reported	11 months (starting 30 days post MI)	Combined use associated with higher mortality than aspirin alone (mortality rates 3.3% vs 1.6%).	3
EPILOG 2619 patients undergoing coronary angioplasty	325 mg daily	Not reported	12 months	Combined use associated with higher mortality than aspirin alone (mortality rates 3.7% vs 1.2%).	3
AIRE 1986 patients after acute MI, with heart failure	Not reported	Ramipril 2.5 to 5 mg twice daily started 3 to 10 days after MI	15 months (average)	Trend towards greater benefit of ramipril in those not receiving aspirin.	4
No evidence of an interaction					
BIP Secondary prevention of MI in 1197 patients with coronary artery disease	250 mg daily	Captopril or enalapril	5 years (average)	Lower death rate in those on combined therapy than those on ACE inhibitor alone (19% vs 27%).	5
SAVE 2231 patients with left ventricular dysfunction after MI	Not reported	Captopril 75 to 150 mg daily	42 months (average)	Trend towards greater benefits of captopril when taken with aspirin.	6
HOPE Prevention of cardiovascular events in 9297 patients without left ventricular dysfunction or heart failure	Not reported	Ramipril 10 mg daily	About 4.5 years	Benefits of ramipril not affected by aspirin.	7
CATS Early treatment of acute MI in 298 patients	80 to 100 mg daily	Captopril	1 year	Benefits of captopril not affected by aspirin. Better prognosis in those on aspirin.	8
ISIS-4 Early treatment of acute MI in 58050 patients	Not reported	Captopril 100 mg daily	At 5 weeks and 1 year	Benefits of captopril not affected by aspirin.	9
Meta-analysis of AIRE, SAVE, SOLVD and TRACE 12763 patients with left ventricular dysfunction or heart failure with or without MI	Not reported	Captopril, enalapril, ramipril, trandolapril	35 months (average)	Benefits of ACE inhibitors observed even if aspirin given.	10
Meta-analysis of CCS-1, CONSENSUS II, GISSI-3, and ISIS-4 Early treatment of MI in 96712 patients	160 to 325 mg daily	Captopril, enalapril, lisinopril	30 days	ACE inhibitor reduced 30-day mortality from 15.1% to 13.8%. ACE inhibitor plus aspirin reduced 30-day mortality from 6.7% to 6.3%.	11
TRACE 1749 patients with left ventricular dysfunction after acute MI	Not reported	Trandolapril 1 to 4 mg daily	24 to 50 months	Trend towards greater benefit of trandolapril in those receiving aspirin (mortality of 45% with ACE inhibitor, and 34% with ACE inhibitor plus aspirin).	12
SMILE 1556 patients with acute MI	Not reported	Zofenopril 7.5 mg increasing to 30 mg twice daily for 6 weeks	At 6 weeks and 1 year	Benefits of zofenopril not significantly affected by aspirin.	13

to ischaemic heart disease, taking ACE inhibitors (**captopril**, **cilazapril**, **enalapril**, **ramipril**) and aspirin 75 to 125 mg daily found that when they were given a single 50-mg dose of diclofenac or placebo, after aspirin had been discontinued for at least one week, diclofenac caused a significant deterioration in renal function compared with placebo or aspirin. Compared with placebo, both aspirin and diclofenac caused slight but significant increases in serum creatinine. However, there was no overall change in renal function (determined by glomerular filtration rate, urine flow, osmolality clearance, and sodium and potassium excretion) between placebo and low-dose aspirin. Long-term, low-dose aspirin appeared not to worsen renal function in patients with heart failure taking ACE inhibitors.[24]

D. Pharmacokinetic studies

A single-dose study in 12 healthy subjects found that the pharmacokinetics of **benazepril** 20 mg and aspirin 325 mg were not affected by concurrent use.[25]

Mechanism

Some, but not all the evidence suggests that prostaglandins may be involved in the hypotensive action of ACE inhibitors, and that aspirin, by inhibiting prostaglandin synthesis, may partially antagonise the effect of ACE inhibitors on blood pressure. This effect appears to depend on the dose of aspirin and may also be dependent on sodium status and plasma renin, and therefore it does not occur in all patients.

The beneficial effects of ACE inhibitors in heart failure and ischaemic heart disease are thought to be due, in part, to the inhibition of the breakdown of kinins, which are important regulators of prostaglandin and nitric oxide synthesis. Such inhibition promotes vasodilatation and afterload reduction. Aspirin may block these beneficial effects by inhibiting cyclo-oxygenase and thus prostaglandin synthesis, causing vasoconstriction, decreased cardiac output and worsening heart failure.[12,26]

Importance and management

Low-dose aspirin (less than or equal to 100 mg daily) does not alter the **antihypertensive efficacy** of captopril and enalapril. No special precautions would therefore seem to be required with ACE inhibitors and these low doses of aspirin. A high dose of aspirin (2.4 g daily) has been reported to interact in 50% of patients in a single study. Aspirin 300 mg daily has been reported to interact in about 50% of patients in another study, whereas 325 mg daily did not interact in further study. Thus, at present, it appears that if an ACE inhibitor is used with aspirin in doses higher than 300 mg daily, blood pressure should be monitored more closely, and the ACE inhibitor dose raised if necessary. Intermittent use of aspirin should be considered as a possible cause of erratic control of blood pressure in patients taking ACE inhibitors.

Both ACE inhibitors and aspirin are often taken by patients with **coronary artery disease**, and ACE inhibitors are used in **chronic heart failure**, which is often associated with coronary heart disease. The information about a possible interaction between ACE inhibitors and aspirin in heart failure is conflicting. This may be due to much of the clinical data being obtained from retrospective non-randomised analyses.[26] It may

also be a factor of different disease states. For example, an interaction may be less likely to be experienced in patients with heart failure of ischaemic aetiology than those with non-ischaemic causes, because of the added benefits of aspirin in ischaemic heart disease.[27] The available data, and its implications, have been extensively reviewed and commented on.[12,14,26-35] Some commentators have advised that, if possible, aspirin should be avoided in patients requiring long-term treatment for heart failure, particularly if heart failure is severe.[14,30] Others suggest avoiding aspirin in heart failure unless there are clear indications, such as atherosclerosis.[12,26,31,32] The use of lower doses of aspirin (80 to 100 mg daily rather than greater than or equal to 325 mg daily) in those with heart failure taking ACE inhibitors has also been suggested.[27,28,31]

US guidelines from 2005 on chronic heart failure[36] state that, "Many physicians believe the data justify prescribing aspirin and ACE inhibitors together when there is an indication for use of aspirin", while recognising that not all physicians agree. The guidelines say that further study is needed. The 2005 update of the European Society of Cardiology (ESC) guidelines stated that there was little evidence to support using ACE inhibitors and aspirin together in heart failure. The guidelines said aspirin could be used as prophylaxis after myocardial infarction, but that it should be avoided in patients with recurrent hospitalisation for worsening heart failure.[37] However, the ESC guidelines published in 2008 do not comment on the use of ACE inhibitors and aspirin. They note that antiplatelet agents are not as effective as warfarin in reducing the risk of thromboembolism in patients with atrial fibrillation and that there is no evidence that antiplatelet drugs reduce atherosclerotic risk in patients with heart failure.[38] NICE guidelines in the UK say that all patients with heart failure due to left ventricular systolic dysfunction should be considered for treatment with an ACE inhibitor, and that aspirin (75 to 150 mg daily) should be prescribed for patients with the combination of heart failure and atherosclerotic arterial disease (including coronary heart disease).[39] Data from ongoing randomised studies may provide further insight. Until these are available, low-dose aspirin and ACE inhibitors may continue to be used where there is a clear indication for both.

An increased risk of deterioration in **renal function** or **acute renal failure** appears to occur rarely with the combination of aspirin and ACE inhibitors. The routine monitoring of renal function, which is advised with ACE inhibitors, should be sufficient to detect any interaction.

ACE inhibitors + Azathioprine

Anaemia has been seen in patients given azathioprine with enalapril or captopril. Leucopenia occasionally occurs when captopril is given with azathioprine.

Clinical evidence

(a) Anaemia

Nine out of 11 kidney transplant patients taking ACE inhibitors (**enalapril** or **captopril**) had a fall in their haematocrit from 34% to 27%, and a fall in their haemoglobin from 11.6 g/dL to 9.5 g/dL when ciclosporin was replaced by azathioprine. Two patients were switched back to ciclosporin, and had a prompt rise in their haematocrit. Another 10 patients taking both

drugs similarly developed a degree of anaemia when compared with 10 patients not taking an ACE inhibitor (haematocrit of 33% compared with 41%, and a haemoglobin of 11.5 g/dL compared with 13.9 g/dL).[1] A later study by the same group of workers (again in patients taking **enalapril** or **captopril**) confirmed these findings; however, no pharmacokinetic interaction was found between **enalapril** and azathioprine.[2]

(b) Leucopenia

A patient whose white cell count fell sharply when taking both **captopril** 50 mg daily and azathioprine 150 mg daily, did not develop leucopenia when each drug was given separately.[3] Another patient who was given **captopril** (increased to 475 mg daily [sic] then reduced to 100 mg daily) immediately after discontinuing azathioprine, developed leucopenia. She was later successfully treated with **captopril** 4 to 6 mg daily [sic].[4] Other patients have similarly developed leucopenia when given both drugs:[5,6] in one case this did not recur when the patient was rechallenged with **captopril** alone (at a lower dose).[6]

Mechanism

The anaemia appears to be due to suppression of erythropoietin by the ACE inhibitors, and azathioprine may cause patients to be more susceptible to this effect.[2] The cause of the leucopenia is unknown. It may just be due to the additive effects of both drugs.

Importance and management

Anaemia caused by captopril and enalapril has been seen in kidney transplant patients and in dialysis patients (see 'ACE inhibitors or Angiotensin II receptor antagonists + Epoetins', p.26). The evidence that this effect can be potentiated by azathioprine is limited, but it would be prudent to monitor well if these drugs are used together.

The evidence that the concurrent use of ACE inhibitors and azathioprine increases the risk of leucopenia is also limited. However, the UK manufacturer of captopril recommends that it should be used with extreme caution in patients receiving **immunosuppressants**, especially if there is renal impairment. They advise that in such patients differential white blood cell counts should be performed before starting captopril, then every 2 weeks in the first 3 months of treatment, and periodically thereafter.[7] The UK manufacturers of a number of other ACE inhibitors also state that the use of ACE inhibitors with **cytostatic** or **immunosuppressive drugs** may lead to an increased risk of leucopenia. For other potential interactions with ACE inhibitors that might lead to an increased risk of leucopenia, see also 'ACE inhibitors + Allopurinol', p.13, and 'ACE inhibitors + Procainamide', p.37.

ACE inhibitors + Beta blockers

The combination of an ACE inhibitor with a beta blocker is in established clinical use. Enhanced blood pressure-lowering effects occur, as would be expected. Although not all combinations have been studied, no clinically significant pharmacokinetic interactions appear to occur between the ACE inhibitors and beta blockers.

Clinical evidence

(a) Atenolol

In a double-blind, crossover study in hypertensive subjects, the combination of atenolol 50 mg daily and **enalapril** 20 mg daily increased the hypotensive effect of either drug alone, but the effect was 30 to 50% less than additive.[1]

(b) Bisoprolol

In a single-dose, placebo-controlled, crossover study in 16 healthy men, bisoprolol 5 mg given with **imidapril** 10 mg did not significantly influence the pharmacokinetics of its active metabolite imidaprilat, and the pharmacodynamic effects, including blood pressure and heart rate reductions, were mainly additive.[2]

(c) Propranolol

In 10 healthy subjects propranolol 80 mg three times daily did not affect the pharmacokinetics of a single 20-mg dose of **quinapril**.[3] In another study the pharmacokinetics of **ramipril** 5 mg daily were unaffected by propranolol 40 mg twice daily.[4] Similarly, the manufacturer of **fosinopril** reports that the bioavailability of fosinoprilat, its active metabolite, was not altered by propranolol.[5,6] Another study found no significant pharmacokinetic interaction between **cilazapril** 2.5 mg daily and propranolol 120 mg daily in healthy subjects, but the reductions in blood pressure were roughly doubled and long-lasting in 6 healthy subjects and in 13 patients with hypertension.[7,8] A later report by the same authors found similar results in 17 patients.[9]

Mechanism, importance and management

Both ACE inhibitors and beta blockers lower blood pressure by different mechanisms, and therefore the enhanced blood pressure-lowering effects of the combination would be expected. No pharmacokinetic interactions have been demonstrated. The combination of an ACE inhibitor and a beta blocker is clinically useful in a number of cardiovascular disorders.

ACE inhibitors + Calcium-channel blockers

The combination of an ACE inhibitor and a dihydropyridine calcium-channel blocker is in established clinical use for hypertension, and, although only certain combinations have been studied, no clinically significant pharmacokinetic interactions appear to occur between these groups of drugs.

Clinical evidence

(a) Amlodipine

A study in 12 healthy subjects indicated that there was no pharmacokinetic interaction between single doses of amlodipine 5 mg and **benazepril** 10 mg.[1]

(b) Felodipine

In healthy subjects, no pharmacokinetic interaction occurred between single doses of felodipine 10 mg and **ramipril** 5 mg. The blood pressure-lowering effect of the combination was greater, and **ramipril** attenuated the reflex tachycardia caused by felodipine.[2]

(c) Manidipine

In a single-dose crossover study in 18 healthy subjects, the concurrent use of manidipine 10 mg and **delapril** 30 mg did not significantly alter the pharmacokinetics of either drug or their main metabolites.[3]

(d) Nicardipine

In a study in 12 patients with hypertension taking **enalapril** 20 mg daily, the addition of nicardipine 30 mg three times daily for 2 weeks did not alter the pharmacokinetics of **enalapril**.[4] The manufacturer of **spirapril** briefly noted in a review that the concurrent use of spirapril and nicardipine increased **spirapril** plasma levels by about 25% and increased the levels of its active metabolite, spiraprilat, by about 45%. The bioavailability of nicardipine was reduced by 30%. It was assumed that the interaction took place at the absorption site. However, the changes were not considered clinically relevant.[5]

(e) Nifedipine

No evidence of either a pharmacokinetic or adverse pharmacodynamic interaction was seen in 12 healthy subjects given single doses of slow-release nifedipine 20 mg and **lisinopril** 20 mg; the effects on blood pressure were additive.[6] Similarly, in healthy subjects, there was no pharmacokinetic interaction between single doses of slow-release nifedipine 20 mg and **benazepril** 10 mg; the effects on blood pressure were additive and the tachycardic effect of nifedipine was attenuated by benazepril.[7] The manufacturer of **fosinopril** notes that the bioavailability of fosinoprilat, the active metabolite of **fosinopril**, was not altered by nifedipine.[8,9] Similarly, the manufacturer of **moexipril** notes that in healthy subjects no clinically important pharmacokinetic interaction occurred between **moexipril** and nifedipine.[10]

(f) Nilvadipine

In a single-dose, placebo-controlled study in 16 healthy subjects, no pharmacokinetic interaction occurred between nilvadipine 8 mg and **imidapril** 10 mg, and the pharmacodynamic effects, including the reduction in blood pressure and the decrease in total peripheral resistance, were mostly additive.[11]

Mechanism

No pharmacokinetic interactions are expected. Enhanced blood pressure-lowering effects occur, as would be expected.

Importance and management

No important pharmacokinetic interactions have been demonstrated. The combination of an ACE inhibitor and a dihydropyridine calcium-channel blocker is clinically useful in the treatment of hypertension. A number of products combining an ACE inhibitor with a calcium-channel blocker are available. It is generally advised that these combination products are only used in patients who have already been stabilised on the individual components in the same proportions.

ACE inhibitors + Capsaicin

An isolated report describes a woman taking an ACE inhibitor who developed a cough each time she used a topical cream containing capsaicin.

Clinical evidence, mechanism, importance and management

A 53-year-old woman who had been taking an unnamed ACE inhibitor for several years, complained of cough each time she applied *Axsain*, a cream containing capsaicin 0.075%, to her lower extremities. Whether this reaction would have occurred without the ACE inhibitor was not determined,[1] but cough is a recognised adverse effect of ACE inhibitors and pre-treatment with an ACE inhibitor has been shown to enhance the cough caused by *inhaled* capsaicin.[1] Topical application of capsaicin may rarely result in coughing due to irritation of the mucous membranes of the respiratory tract.[2] This potential interaction is probably of little general clinical importance.

2. Axsain Cream (Capsaicin). Cephalon Ltd. UK Summary of product characteristics, July 2009.

ACE inhibitors + Cefradine

No clinically significant pharmacokinetic interaction appears to occur between captopril and cefradine.

Clinical evidence, mechanism, importance and management

No clinically significant pharmacokinetic interaction was noted in a single-dose study in 9 healthy subjects given captopril 25 mg and cefradine 500 mg.[1] Captopril and cefradine are both thought to be absorbed through common transport pathways, by intestinal peptide transporters, and as such it was considered that they might impair or delay the absorption of each other.[1] However, an *in vitro* study found that peptide transporters do not control intestinal absorption and renal reabsorption of ACE inhibitors and therefore other proteins or other mechanisms might be involved in the intestinal transport of ACE inhibitors.[2] No particular precautions seen necessary on concurrent use.

ACE inhibitors + Clonidine

Potentiation of the antihypertensive effect of clonidine by ACE inhibitors can be clinically useful.[1] However, limited evidence suggests that the effects of captopril may be delayed when patients are switched from clonidine.[2] Note that sudden withdrawal of clonidine may cause rebound hypertension.

ACE inhibitors + Colloids

Acute hypotension has been seen in a few patients taking enalapril when they were given a rapid infusion of albumin-containing stable plasma protein solution (SPPS). Another case occurred in an infant taking captopril when given albumin 4%. A few other cases have been described with gelatin-type colloids in patients taking ACE inhibitors (cilazapril, enalapril, lisinopril).

Clinical evidence

(a) Albumin

A woman taking **enalapril** 10 mg in the morning, underwent surgery for groin lymph node resection under spinal and general anaesthesia. When she was given a rapid infusion of 500 mL of the albumin solution, stable plasma protein solution (SPPS, *Commonwealth Serum Laboratories, Melbourne, Australia*), her pulse rose to 90 to 100 bpm and systolic blood pressure fell from 100 mmHg to 60 mmHg and a red flush was noted on all exposed skin. The blood pressure was controlled at 90 to 95 mmHg

with metaraminol 4.5 mg, given over 10 minutes. When the SPPS was finished, the blood pressure and pulse rate spontaneously restabilised.[1] SPPS is a 5% plasma protein solution prepared by the cold ethanol fractionation process and pasteurisation from human plasma (volunteer donors). It contains sodium octanoate as a stabiliser.[1] Two very similar cases have been recorded in patients taking **enalapril** when given SPPS.[2,3] The manufacturer of SPPS notes that **captopril** has also been involved in this hypotensive interaction.[4]

A 20-month-old infant taking **captopril** was haemodynamically stable for 35 minutes after induction of anaesthesia while awaiting a donor kidney, but then developed hypotension after a bolus dose of 20 mL of albumin 4% (*Albumex*) was given. This was reversed with dopamine infusion.[5]

(b) Gelatin-based colloids

A report describes 3 cases of severe hypotension in patients taking ACE inhibitors (**lisinopril**, **enalapril**) while undergoing joint replacement surgery, and after they had been given a gelatin-based plasma expander (*Gelofusin*), which contains 4% succinylated gelatin in saline. The hypotension was resistant to ephedrine and methoxamine, and responded to adrenaline (epinephrine) or dobutamine, which was required for 24 hours and 3 days, respectively, in two cases. Anaphylactoid reactions were excluded as a cause of the hypotension.[6] In another similar case, a patient taking **cilazapril** developed hypotension refractory to sodium chloride 0.9% after induction of anaesthesia, and this worsened when a gelatin-type colloid (*Gelafundina*) was given.[7]

Mechanism

Not fully established, but it is believed that SPPS contains low levels of pre-kallikrein activator, which stimulates the production of bradykinin, which can cause vasodilatation and hypotension. Normally the bradykinin is destroyed by kininase II (ACE), but this is delayed by the ACE inhibitor so that the hypotensive effects are exaggerated and prolonged.[3,8] In the case with albumin 4%, a sample of the albumin used was analysed, and it was found to contain less prekallikrein activating factor than maximum permissible levels.[5] It was suggested that the infusion of gelatin-based colloids somehow resulted in raised plasma kinin levels associated with inhibition of ACE.[6]

Importance and management

The interaction with SPPS would appear to be established and of clinical importance, and would apply to all ACE inhibitors. The author of one report suggested that if rapid expansion of intravascular volume is needed in patients taking ACE inhibitors, an artificial colloid might be a safer choice than SPPS.[1] The manufacturer of SPPS also recommended using an alternative plasma volume expander, including other albumin solutions.[4] It should be noted that following these reports SPPS was withdrawn from the Australasian market.[9] However, note that a case has also occurred with albumin 4%, and cases have also been attributed to synthetic colloid solutions containing gelatin. It may be that this is just an unpredictable effect of colloids in patients taking ACE inhibitors.

For discussion of the marked hypotension sometimes seen during induction of anaesthesia in patients taking ACE inhibitors, see also 'Anaesthetics, general + ACE inhibitors or Angiotensin II receptor antagonists', p.102.

ACE inhibitors + Co-trimoxazole or Trimethoprim

Two reports describe serious hyperkalaemia, apparently caused by the use of trimethoprim with sulfamethoxazole, and enalapril or quinapril in association with renal impairment.

Clinical evidence

A 40-year-old woman with a lung transplant (taking ciclosporin, azathioprine, prednisolone, **enalapril**, gentamicin inhalation, salbutamol and acetylcysteine) developed life-threatening hyperkalaemia of 6.8 mmol/L when she was given high-dose co-trimoxazole 120 mg/kg daily for suspected pneumocystis pneumonia. The co-trimoxazole (sulfamethoxazole with trimethoprim) and **enalapril** were stopped and she was treated with sodium chloride 0.9%, mannitol and furosemide. After 12 hours her serum potassium had decreased to 4.6 mmol/L and she began to recover over a period of a week, but she then developed fatal septic shock with multi-organ failure.[1]

In another case, an elderly man taking **quinapril** 20 mg daily for essential hypertension was found to have hyperkalaemia (serum potassium 7 to 7.4 mmol/L) and azotaemia 20 days after starting to take co-trimoxazole for mild acute pyelonephritis. Co-trimoxazole and **quinapril** were stopped, and nifedipine was given to control blood pressure. The patient was given dextrose, insulin, sodium polystyrene sulfonate and calcium gluconate, and the azotaemia and hyperkalaemia resolved over 36 hours.[2]

Mechanism

Hyperkalaemia has been reported in patients receiving co-trimoxazole alone.[3] This is attributed to the trimethoprim component, which can have a potassium-sparing effect on the distal part of the kidney tubules. ACE inhibitors reduce aldosterone synthesis, which results in reduced renal loss of potassium. The interaction is probably due to the additive effects of these two mechanisms, compounded by impaired renal function.[1,2]

Importance and management

Clinical examples of this interaction seem to be few, but the possibility of hyperkalaemia with either trimethoprim or ACE inhibitors alone, particularly with other factors such as renal impairment, is well documented. Thus it may be prudent to monitor potassium levels if this combination is used. It has been suggested that trimethoprim should probably be avoided in elderly patients with chronic renal impairment taking ACE inhibitors, and that patients with AIDS taking an ACE inhibitor for associated nephropathy should probably discontinue the ACE inhibitor during the use of high-dose co-trimoxazole.[2]

ACE inhibitors or Angiotensin II receptor antagonists + Dialysis or Transfusion membranes

An anaphylactoid reaction can occur in patients taking ACE inhibitors and possibly angiotensin II receptor antagonists within a few minutes of starting haemodialysis using high-flux polyacrylonitrile membranes ('AN69') or modified ST-AN69 membranes. Anaphylactoid reactions have also been reported in patients taking ACE inhibitors undergoing low-density lipoprotein apheresis.

Hypotensive reactions associated with blood transfusions through leucoreduction filters have occurred in patients taking ACE inhibitors.

Clinical evidence, mechanism, importance and management

(a) Apheresis

1. Low-density lipoprotein (LDL) apheresis. Anaphylactoid reactions occurred in 2 patients taking **captopril** or **enalapril** during removal of low-density lipoproteins (LDL apheresis) with dextran sulfate adsorption.[1] Further reactions were reported in 6 patients taking either **captopril** or **enalapril** and undergoing dextran sulfate apheresis. When the interval between the last dose of the ACE inhibitor and the apheresis was prolonged to 12 to 30 hours no further adverse reactions occurred.[2] However, other workers found lengthening the interval to be ineffective in one patient.[3]
A patient who experienced an anaphylactoid reaction while taking **ramipril** and undergoing dextran sulfate LDL apheresis took **losartan** 12.5 mg daily instead of ramipril without any reaction during the next four LDL apheresis procedures.[4] Another patient given **imidapril** had blurred vision and lacrimation with hypotension during dextran sulfate apheresis. Further study in this patient when given **losartan** 50 mg daily instead of **imidapril** found that during LDL apheresis, blood pressure reduction was mild and the patient did not experience noticeable adverse effects. The blood pressure reduction was attributed to the effect of **losartan** on angiotensin receptors, but as bradykinin levels were increased (by the **losartan**) this may also have contributed.[5] The authors concluded that low-dose **losartan** appears to be safe in patients undergoing LDL apheresis with dextran sulfate,[4,5] despite an increase in bradykinin levels.[5]
The manufacturer of **enalapril** suggests temporarily withholding the ACE inhibitor before each apheresis,[6] but other manufacturers of ACE inhibitors recommend using a different class of antihypertensive drug[7,8] or changing the method of lipoprotein reduction.[7,9]

2. Therapeutic plasma exchange. In a review of 299 patients undergoing therapeutic plasma exchange, all 14 patients taking ACE inhibitors experienced hypotension and/or flushing. The ACE inhibitors taken were **enalapril** (8 patients), **captopril** (6 patients); 2 of the patients also received **lisinopril** or **benazepril**. In addition, 20 of 285 patients not receiving ACE inhibitors experienced similar adverse effects. Therefore the patients taking ACE inhibitors accounted for 14 of 34 (41%) of patients experiencing these reactions. The 14 patients taking ACE inhibitors underwent 186 apheresis procedures. In 53 of these procedures an ACE inhibitor was given in the 24 hours before the procedure and hypotension and/or flushing occurred in 41 of the 53 procedures. Six of the 14 patients also underwent apheresis while not receiving an ACE inhibitor. One patient experienced transient hypotension; no reactions occurred in the other 5 patients. The authors recommended that ACE inhibitors should be withheld for at least 24 hours before apheresis.[10]

(b) High-flux dialysis

1. ACE inhibitors. In a retrospective study, 9 of 236 haemodialysis patients treated with high-flux polyacrylonitrile membranes ('AN69') were found to have had anaphylactoid reactions (severe hypotension, flushing, swelling of face and/or tongue, and dyspnoea) within 5 minutes of starting haemodialysis. Treatment with an ACE inhibitor had been recently started in all 9 patients (7 taking **enalapril**, the other 2 taking **captopril** or **lisinopril**). The anaphylactoid reactions resolved in all 6 patients who discontinued the ACE inhibitor. Two other patients were given a filter rinsing procedure (the 'Bioprime' rinse method) and a new dialysis membrane, and in the final patient further anaphylactoid reactions were prevented by cellulose-triacetate haemofiltration while the ACE inhibitor was continued.[11] Similar reactions have been reported elsewhere and are thought to be bradykinin mediated.[12-14]
The CSM in the UK has advised that the combination of ACE inhibitors and such membranes should be avoided, either by substituting an alternative membrane or an alternative antihypertensive drug.[15] Modified AN69 membranes (surface-treated AN69 membranes; ST-AN69) which reduce the generation of bradykinin have been developed and used in patients taking ACE inhibitors. However, there are reports of anaphylactoid reactions in 5 patients taking ACE inhibitors during haemodialysis with these modified membranes.[16,17]

2. Angiotensin II receptor antagonists. In a multicentre study, 324 of 406 haemodialysis patients who were given an initial dose of **losartan** 25 mg daily, increased after one week to 50 mg daily for 6 months completed the study. Ninety-six patients were dialysed with AN69 membranes. Two of these patients had possible anaphylactoid reactions. One of them became hypotensive 13 minutes after the start of a haemodialysis session and developed malaise, nausea, vomiting, dysaesthesia and generalised heat sensation, severe enough to stop the dialysis session. The second patient had mild generalised heat sensation and dysaesthesia within one minute of the start of haemodialysis but did not require discontinuation of the dialysis. The symptoms did not occur on subsequent haemodialysis even though **losartan** was continued and an AN69 membrane was used. Neither patient developed signs of hypersensitivity such as oedema, bronchospasm, pruritus, or urticaria. Also, 9 of the patients who had an anaphylactoid reaction while taking ACE inhibitors during haemodialysis with AN69 membranes did not have anaphylactoid reactions when taking **losartan** and dialysed with these membranes.[18] Another patient taking **losartan** and undergoing haemodialysis developed breathlessness and became agitated with profuse sweating about one hour after the start of his first dialysis after changing from a *Haemophan* (COBE 400) membrane to an **AN69 membrane** in an attempt to improve the efficacy of dialysis.[19] However, it has been suggested that in this latter case, the adverse effects were not the result of an anaphylactoid reaction mediated by bradykinin.[20]
There are few reports of anaphylactoid-like reactions involving angiotensin II receptor antagonists and the use of AN69 membranes. The authors of one report found **losartan** to be a safe drug in haemodialysis patients and its use with AN69 was not associated with an increase in anaphylactoid reactions.[18] However, other authors advise caution.[19,20]

(c) Transfusion reactions

A report describes 8 patients receiving ACE inhibitors and blood transfusions through bedside **leucoreduction filters** who experienced severe hypotensive reactions. The reactions were attributed to bradykinin generation during blood filtration and prevention of bradykinin breakdown due to the ACE inhibitors. Six of the patients tolerated subsequent transfusions, but 3 patients had discontinued their medication the day before the planned transfusion and one received washed (plasma-depleted) components. One patient experienced a second reaction, but then received washed red cells and had no reaction.[21]

ACE inhibitors + Diuretics; Loop, Thiazide and related

The combination of captopril or other ACE inhibitors with loop or thiazide diuretics is normally safe and effective, but first-dose hypotension (dizziness, lightheadedness, fainting) can occur, particularly if the dose of diuretic is high, and often in association with various predisposing conditions. Renal impairment, and even acute renal failure, have been reported. Diuretic-induced hypokalaemia may still occur when ACE inhibitors are used with these potassium-depleting diuretics.

Clinical evidence

(a) First dose hypotensive reaction

The concurrent use of **captopril** or other ACE inhibitors and loop or thiazide diuretics is normally safe and effective, but some patients experience first-dose hypotension (i.e. dizziness, lightheadedness, fainting) after taking the first one or two doses of the ACE inhibitor. This appears to be associated with, and exaggerated by, certain conditions (such as heart failure, renovascular hypertension, haemodialysis, high levels of renin and angiotensin, low-sodium diet, dehydration, diarrhoea or vomiting) and/or hypovolaemia and sodium depletion caused by diuretics, particularly in high doses. A study describes one woman whose blood pressure of 290/150 mmHg did not respond to a 10-mg intravenous dose of **furosemide**. After 30 minutes she was given **captopril** 50 mg orally and within 45 minutes her blood pressure fell to 135/60 mmHg and she required an infusion of saline to maintain her blood pressure.[1] In another study, a man taking **captopril** developed severe postural hypotension shortly after **furosemide** given.[2]

Starting with a low dose of the ACE inhibitor reduces the risk of first-dose hypotension. In a study in 8 patients with hypertension who had been taking a diuretic (mainly **furosemide** or **hydrochlorothiazide**) for at least 4 weeks, **captopril** was started in small increasing doses from 6.25 mg. Symptomatic postural hypotension was seen in 2 of the 8 patients, but it was only mild and transient.[3]

Hypotension is more common in patients with heart failure who are taking large doses of diuretics. In a study in 124 patients with severe heart failure, all taking **furosemide** (mean dose 170 mg daily; range 80 to 500 mg daily) and 90 also receiving the potassium-sparing diuretic spironolactone, the addition of **captopril** caused transient symptomatic hypotension in 44% of subjects. The **captopril** dose had to be reduced, and in 8 patients it was later discontinued. In addition, 4 patients developed symptomatic hypotension after one to 2 months of concurrent use, and **captopril** was also discontinued in these patients.[4]

There is some evidence that in patients with heart failure the incidence of marked orthostatic hypotension requiring treatment discontinuation in the first 36 hours was lower with **perindopril** 2 mg daily than **captopril** 6.25 mg three times daily (6 of 357 cases versus 16 of 368 cases, respectively).[5] However, the effect of other drugs, such as antihypertensives, vasodilators and diuretics, taken by the patients was not assessed in this study.

(b) Hypokalaemia

In one study, the reduction in plasma potassium was greater with **hydrochlorothiazide** 25 mg daily than with **hydrochlorothiazide** given with **cilazapril** 2.5 mg daily, showing that cilazapril reduced the potassium-depleting effect of **hydrochlorothiazide**.[6] In a placebo-controlled study in hypertensive patients given **quinapril** 2.5 mg, 10 mg or 40 mg daily, **hydrochlorothiazide** 6.25 mg, 12.5 mg, or 25 mg daily, or one of nine possible combinations of **quinapril** and **hydrochlorothiazide** with these doses, minimal changes in serum potassium occurred with **quinapril** or placebo alone. The percentage of patients with decreases in serum potassium of 0.5 mmol or more increased with dose of **hydrochlorothiazide** alone. The degree of attenuation of the hypokalaemic effect of **hydrochlorothiazide** was related to the dose of **quinapril**, with the 2.5-mg dose attenuating the hypokalaemic effect of **hydrochlorothiazide** 6.25 or 12.5 mg, but not that of **hydrochlorothiazide** 25 mg. At doses of **quinapril** 40 mg daily, dose-related decreases in serum potassium were not apparent.[7]

In one analysis, 7 of 21 patients taking potassium-depleting diuretics given ACE inhibitors for heart failure developed hypokalaemia. This was corrected by potassium supplementation in 2 cases, an increase in the ACE inhibitor dose in 3 cases, and the use of a potassium-sparing diuretic in the remaining 2 cases.[8] In another report, a woman taking **furosemide** 80 to 120 mg daily remained hypokalaemic despite also taking **ramipril** 10 mg daily and spironolactone 50 to 200 mg daily.[9] However, note that the addition of spironolactone to ACE inhibitors and loop or thiazide diuretics has generally resulted in an increased incidence of hyperkalaemia. For further information on this effect, see 'ACE inhibitors + Diuretics; Potassium-sparing', p.25.

(c) Hyponatraemia

An isolated report describes a patient taking **enalapril** 20 mg daily and atenolol 100 mg daily who developed severe hyponatraemia 3 days after **bendroflumethiazide** 10 mg daily was started. However, on two other occasions she only developed mild hyponatraemia when given **bendroflumethiazide** alone.[10] An earlier study reported changes in sodium balance due to **captopril** in all 6 patients with renovascular hypertension and in 11 of 12 patients with essential hypertension: sodium loss occurred in 12 of the 18 patients.[1]

(d) Renal impairment

The risk of ACE inhibitor-induced renal impairment in patients with or without renovascular disease can be potentiated by diuretics.[11-14] In an analysis of 74 patients taking **captopril** or **lisinopril**, reversible acute renal failure was more common in those who were also taking a diuretic (**furosemide** and/or **hydrochlorothiazide**) than those who were not (11 of 33 patients compared with 1 of 41 patients).[13] Similarly, in a prescription-event monitoring study, **enalapril** was associated with raised creatinine or urea in 75 patients and it was thought to have contributed to the deterioration in renal function and subsequent deaths in 10 of these patients. However, 9 of these 10 were also receiving loop or thiazide diuretics, sometimes in high doses.[15] Retrospective analysis of a controlled study in patients with hypertensive nephrosclerosis identified 8 of 34 patients who developed reversible renal impairment when given **enalapril** and various other antihypertensives including a diuretic (**furosemide** or **hydrochlorothiazide**). In contrast, 23 patients given placebo and various other antihypertensives did not develop renal impairment. Subsequently, **enalapril** was tolerated by 7 of the 8 patients without deterioration in renal function and 6 of these patients later received diuretics.[16] One patient was subsequently given **enalapril** with recurrence of renal impairment, but discontinuation of the diuretics (**furosemide**, **hydrochlorothiazide**, and triamterene) led to an improvement in renal function despite the continuation of **enalapril**.[17]

Renal impairment in patients taking ACE inhibitors and diuretics has also been described in patients with heart failure. A patient with congestive heart failure and pre-existing moderate renal impairment developed acute non-oliguric renal failure while taking **enalapril** 20 mg daily and **furosemide** 60 to 80 mg daily, which resolved when the sodium balance was restored.[18] In a study involving 90 patients with severe congestive heart failure who were receiving **furosemide** and spironolactone, a decline in renal function occurred in 18 patients during the first month after initiation of **captopril**; mean serum creatinine levels rose from 220 to 300 micromol/L. All the patients were receiving high daily doses of **furosemide** and all had renal impairment before receiving the first dose of **captopril**.[4]

Acute, fatal, renal failure developed in 2 patients with cardiac failure within 4 weeks of starting to take **enalapril** with **furosemide**, and in 2 similar patients renal impairment developed over a longer period.[19] Reversible renal failure developed in a patient with congestive heart failure when **captopril** and **metolazone** were given.[20]

(e) Pharmacokinetic and diuresis studies

1. Furosemide. A study in healthy subjects given single doses of **enalapril** and furosemide found no evidence of any pharmacokinetic interaction between these drugs.[21] Another study in hypertensive patients found that **captopril** did not affect the urinary excretion of furosemide, nor its subsequent diuretic effects.[22] However, a further study in healthy subjects found that, although **captopril** did not alter urinary excretion of furosemide, it did reduce diuresis.[23] Yet another study in healthy subjects found that **captopril** reduced the urinary excretion of furosemide, and halved the diuretic response during the first 20 minutes and decreased the natriuretic response to almost 30%, whereas **enalapril** and **ramipril** did not significantly alter

the diuretic effects of furosemide.[24] In one single-dose study in healthy subjects the concurrent use of **benazepril** and furosemide reduced the urinary excretion of furosemide by 10 to 20%, whereas **benazepril** pharmacokinetics were unaffected.[25] In one study, **lisinopril** did not alter the plasma levels or urinary excretion of furosemide, nor did it alter urinary electrolyte excretion.[26] Similarly, furosemide did not affect the pharmacokinetics of **lisinopril** either in single-dose or multiple-dose regimens.[27]

2. Hydrochlorothiazide. In a single-dose, randomised, crossover study in 19 elderly patients the pharmacokinetics of **enalapril** 10 mg were unaffected by hydrochlorothiazide 25 mg. However, there was a significant reduction in renal clearance and a significant increase in the AUC of its metabolite, enalaprilat, resulting in higher serum levels of the active drug. This acute interaction was not thought to be clinically significant for long-term use.[28]

No pharmacokinetic interaction occurred between **cilazapril** and hydrochlorothiazide in healthy subjects or patients with hypertension.[6] Similarly, no significant pharmacokinetic interaction occurred between **imidapril** and hydrochlorothiazide in healthy subjects[29] and neither **captopril** nor **ramipril** altered the diuresis induced by hydrochlorothiazide.[24]

The manufacturer of **spirapril** briefly noted in a review that there was no clinically relevant pharmacokinetic interaction between spirapril and hydrochlorothiazide.[30] Furthermore no pharmacokinetic interaction was found when **spirapril** and hydrochlorothiazide were given together as a bi-layer tablet.[31] In a single-dose study in healthy subjects there was no clinically important pharmacokinetic interaction when **moexipril** was given with hydrochlorothiazide.[32]

Mechanism

The first dose hypotension interaction is not fully understood. One suggestion is that if considerable amounts of salt and water have already been lost as a result of using a diuretic, the resultant depletion in the fluid volume (hypovolaemia) transiently exaggerates the hypotensive effects of the ACE inhibitor.

The cases of hypokalaemia are simply a result of the potassium-depleting effects of the diuretics outweighing the potassium-conserving effects of the ACE inhibitor. The converse can also occur.

Thiazides can cause hyponatraemia, but the enhanced effect may have been due to an alteration in renal haemodynamics caused by the ACE inhibitor: sustained angiotensin-converting enzyme blockade can produce natriuresis.[1]

Marked decreases in blood pressure may affect renal function, and in addition, the renin-angiotensin system plays an important role in the maintenance of the glomerular filtration rate when renal artery pressure is diminished.[12] However, diuretic-induced sodium depletion may also be an important factor in the renal impairment sometimes observed with ACE inhibitors.

Importance and management

The **first-dose hypotension** interaction between ACE inhibitors and diuretics is well established. The BNF in the UK notes that the risk is higher when the dose of diuretic is greater than furosemide 80 mg daily or equivalent,[33] and suggests that, in patients taking these doses of diuretics, ACE inhibitors should be initiated under close supervision, and consideration should be given to temporarily stopping the diuretic or reducing its dose at least 24 hours before the ACE inhibitor is added. If this is not considered clinically appropriate, the response to the first dose of the ACE inhibitor should be monitored for at least 2 hours, or until blood pressure has stabilised. In all patients taking diuretics, an ACE inhibitors should be started at a very low dose, even in patients at low risk (e.g. those with uncomplicated essential hypertension taking low-dose thiazides). To be on the safe side, all patients should be given a simple warning about what can happen and what to do when they first start concurrent use. The immediate problem (dizziness, lightheadedness, faintness), if it occurs, can usually be solved by the patient lying down. Taking the first dose of the ACE inhibitor just before bedtime is also preferable. Any marked hypotension is normally transient, but if problems persist it may be necessary temporarily to reduce the diuretic dose. There is usually no need to avoid the combination just because an initially large hypotensive response has occurred. A number of products combining an ACE inhibitor with a thiazide diuretic are available for the treatment of hypertension. These products should be used only in those patients who have been stabilised on the individual components in the same proportions.

The use of ACE inhibitors in patients taking potassium-depleting diuretics does not always prevent **hypokalaemia** developing. Serum potassium should be monitored.

There is only one isolated report of **hyponatraemia**, but be aware that ACE inhibitors may affect the natriuresis caused by diuretics.

The cases of **renal impairment** cited emphasise the need to monitor renal function in patients taking ACE inhibitors and diuretics. If increases in blood urea and creatinine occur, a dose reduction and/or discontinuation of the diuretic and/or ACE inhibitor may be required. In a statement, the American Heart Association comments that acute renal failure complicating the use of an ACE inhibitor is almost always reversible and repletion of extracellular fluid volume and discontinuation of the diuretic is the most effective approach. In addition, withdrawing the interacting drugs, supportive management of fluid and electrolytes, and temporary dialysis, where indicated, are the mainstays of treatment.[14] The concurrent use of ACE inhibitors, diuretics and NSAIDs may be particularly associated with an increased risk of renal failure, see 'ACE inhibitors + NSAIDs', p.32. The possibility of undiagnosed renal artery stenosis should also be considered.

None of the **pharmacokinetic** changes observed appear to be clinically significant.

ACE inhibitors + Diuretics; Potassium-sparing

The concurrent use of ACE inhibitors and potassium-sparing diuretics (e.g. amiloride), including the aldosterone antagonists (eplerenone, spironolactone) can result in clinically relevant or severe hyperkalaemia, particularly if other important risk factors are present.

Clinical evidence

(a) Amiloride

The serum potassium levels of 2 patients taking furosemide and unnamed potassium-sparing diuretics and potassium supplements rose by 18% and 24%, respectively, when they were given **captopril** 37.5 to 75 mg daily. The rises occurred within one or two days. No clinical signs or symptoms of hyperkalaemia were seen, but one of the patients had an increase in serum potassium to above the upper limits of normal.[1] In a post-marketing survey, 2 patients who had **enalapril**-associated renal impairment and died were also receiving amiloride and furosemide; one was also taking potassium supplements.[2] Four patients with diabetes, with some renal impairment, developed life-threatening hyperkalaemia with severe cardiac arrhythmias and deterioration of renal function, within 8 to 18 days of starting to take amiloride with hydrochlorothiazide and **enalapril**. Two suffered fatal cardiac arrests. Potassium levels were between 9.4 and 11 mmol/L. A fifth diabetic patient with normal renal function developed hyperkalaemia soon after receiving amiloride with hydrochlorothiazide and **captopril**.[3] A further case of hyperkalaemia and cardiac arrest was associated with **enalapril** and furosemide with amiloride.[4] In a brief report, the manufacturers of **enalapril** noted that, of 47 serious cases of hyperkalaemia, 25 patients were taking one or more (unnamed) potassium-sparing drugs.[5]

However, a retrospective comparison of 35 patients with congestive heart failure found no differences in the serum potassium levels of 16 patients taking furosemide, amiloride and **enalapril**, when compared with another group of 19 patients taking furosemide and amiloride alone. Patients were excluded from the comparison if they had significant renal impairment or were taking other drugs likely to affect serum potassium.[6]

(b) Eplerenone

In the large Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study (EPHESUS)[7] the rate of serious hyperkalaemia (defined as serum potassium 6 mmol/L or greater) was 5.5% in patients randomised to eplerenone 25 mg to 50 mg daily (mean 43 mg daily[8]) compared with 3.9% in those receiving placebo: this represented a 1.4-fold increase. More eplerenone recipients required hospitalisation for serious hyperkalaemia than placebo recipients (12 versus 3). The risk of serious hyperkalaemia was increased in those with a baseline creatinine clearance of less than 50 mL/minute (10.1% in the eplerenone group and 5.9% in the placebo group). Eplerenone reduced the risk of serious hypokalaemia (defined as serum potassium 3.5 mmol/L or less) by 60% (8.4% versus 13.1%). About 86% of patients in this study were also receiving an ACE inhibitor or an angiotensin II receptor antagonist, and about 60% were receiving a (loop[8]) diuretic.[7] However, the US manufacturer states that the rate of maximum potassium levels greater than 5.5 mmol/L were similar in EPHESUS regardless of the use of ACE inhibitor or angiotensin II receptor antagonist.[8] Nevertheless, they mention another study in diabetics with microalbuminuria, where a higher dose of eplerenone 200 mg given with **enalapril** 10 mg increased the frequency of hyperkalaemia (defined as serum potassium greater than 5.5 mmol/L) from 17% with enalapril alone to 38% with the combination: this represented a 2.2-fold increase.[8]

In another study in 153 patients with left ventricular hypertrophy given eplerenone 200 mg daily, **enalapril** 40 mg daily, or eplerenone 200 mg with **enalapril** 10 mg daily, serious hyperkalaemia (maximum plasma potassium level 6 mmol/L or greater) occurred in 7 patients taking eplerenone (10.9%), 2 taking **enalapril** (2.8%) and 3 patients taking eplerenone with **enalapril** (4.5%). Three patients in the eplerenone group, but none in the **enalapril** or **enalapril** with eplerenone groups were withdrawn because of hyperkalaemia. Some patients were also given hydrochlorothiazide at week 8, but any contribution of the thiazide to the effects on potassium levels was not noted.[9] Consider also 'ACE inhibitors + Diuretics; Loop, Thiazide and related', p.23.

(c) Spironolactone

Twenty-five of 262 patients taking ACE inhibitors and spironolactone, and admitted to hospital for medical emergencies, were found to have serious hyperkalaemia (defined as serum potassium levels greater than 6 mmol/L: 11 patients had levels of at least 8 mmol/L). These 25 patients were elderly (mean age 74 years) and being treated for hypertension, heart failure, diabetic nephropathy, proteinuria, or nephrotic syndrome; 22 had associated renal impairment and 12 had signs of volume depletion. Concurrent use of the ACE inhibitor and spironolactone had been started an average of 25 weeks before admission. The ACE inhibitors involved were **enalapril**, **captopril**, **lisinopril** or **perindopril,** and the average dose of spironolactone used was 57 mg daily; 10 patients were also receiving a loop or thiazide diuretic. Nineteen patients had ECG changes associated with hyperkalaemia; 2 of them died, another 2 required temporary pacing for third-degree heart block, and 2 others survived after sustained ventricular tachycardia and fibrillation. Of the 19 patients with ECG changes, 17 required at least one haemodialysis session and 12 were admitted to intensive care.[10] Other authors reported a higher 36% incidence of hyperkalaemia (serum potassium levels greater than 5 mmol/L) in 42 patients hospitalised for heart failure and prescribed spironolactone. It was suggested that this may be due to the excessively large doses of spironolactone prescribed,[11] although the specific doses were not mentioned.

Similar risk factors were found in an analysis of 44 patients with congestive heart failure who were taking spironolactone and ACE inhibitors or angiotensin II receptor antagonists, and were admitted for treatment of life-threatening hyperkalaemia. Their mean age was 76 years, the mean dose of spironolactone was 88 mg daily (range 25 to 200 mg daily) and 40 patients also received loop diuretics. In addition, 35 patients had type 2 diabetes. Haemodialysis was given to 37 patients, but in 6 patients renal function did not recover and 2 patients developed fatal complications.[12] A prospective 3-month study of patients who developed hyperkalaemia (potassium levels at least 6 mmol/L) while in hospital identified 112 patients; 40 of these cases (36%) were considered to be drug-related. Eight patients were receiving spironolactone with an ACE inhibitor.[13] A study in patients with chronic heart failure taking spironolactone 25 or 50 mg daily, furosemide and either **enalapril**, candesartan, or losartan, for 12 months, found that hyperkalaemia occurred in about 9% of patients and hypokalaemia in about 5% of patients.[14] A number of other cases of serious hyperkalaemia have been described in patients taking ACE inhibitors (**captopril**, **enalapril**, **lisinopril**), spironolactone, and loop (furosemide or bumetanide) or thiazide (hydroflumethiazide) diuretics.[2,15-19] Many of the patients were elderly and were receiving spironolactone 50 to 100 mg daily,[2,15,18] but one diabetic patient with moderate renal impairment was receiving just 25 mg of spironolactone daily.[17] In one report, the 4 cases had associated **enalapril**-induced deterioration in renal function and died.[2] Another patient died from complete heart block.[15]

One of the factors that affects the incidence of hyperkalaemia appears to be the dose of spironolactone. In a preliminary investigation for the Randomised Aldactone Evaluation Study (RALES), 214 patients with congestive heart failure taking an ACE inhibitor and a loop diuretic with or without digitalis, were randomised to receive placebo or various doses of spironolactone for 12 weeks. The incidence of hyperkalaemia (defined as serum potassium level of 5.5 mmol/L or greater) was 5% for the placebo group, whereas it was 5%, 13%, 20%, and 24% when spironolactone was given in single daily doses of 12.5 mg, 25 mg, 50 mg, or 75 mg, respectively.[20] The main RALES study involving 1663 patients found a 30% reduction in the risk of mortality in patients with severe heart failure when they were given spironolactone in addition to treatment including an ACE inhibitor, a loop diuretic and in most cases digoxin. During the first year of follow-up, the median creatinine concentration in the spironolactone group increased by about 4 to 9 micromol/L and the median potassium level increased by 0.03 mmol/L, but there was a low incidence of serious hyperkalaemia (2% in the spironolactone group compared with 1% in the placebo group). However, the dose of spironol-

actone was fairly low (mean dose 26 mg daily; range 25 mg every other day to 50 mg daily depending on serum potassium levels and response). In addition, patients with a serum creatinine of more than 221 micromol/L or a serum potassium of more than 5 mmol/L were excluded.[21] In a Canadian population-based time-series analysis, the increase in use of spironolactone for heart failure in patients taking ACE inhibitors after publication of the RALES study was found be associated with 50 additional hospitalisations for hyperkalaemia for every 1000 additional prescriptions for spironolactone, and there was a 6.7-fold increase in the number of patients dying from hyperkalaemia. The authors say that spironolactone-related hyperkalaemia is a much greater problem in every day practice than in the setting of a clinical study, and give a number of reasons for this including, less frequent monitoring of potassium levels, the presence of conditions predisposing to hyperkalaemia, failure to detect subsequent development of renal impairment, inappropriately high doses of spironolactone, increase in dietary potassium intake, and the use of spironolactone in heart failure with causes not included in the RALES study.[22] In another study, the use of spironolactone with ACE inhibitors in patients with class IV chronic heart failure was associated with a 14.6 odds ratio for developing hyperkalaemia when compared with ACE inhibitors alone. Predictors for hyperkalaemia included increases in creatinine following treatment, and diabetes.[23]

(d) Triamterene

A retrospective analysis found that **captopril**, given to 6 patients taking *Dyazide* (hydrochlorothiazide with triamterene), had not increased the potassium levels.[24]

Mechanism

ACE inhibitors reduce the levels of aldosterone, which results in the retention of potassium. This would be expected to be additive with the potassium-retaining effects of amiloride and triamterene and aldosterone antagonists such as spironolactone and eplerenone, leading to hyperkalaemia, but usually only if other risk factors are present (see *Importance and management* below).

Importance and management

Hyperkalaemia with ACE inhibitors and potassium-sparing diuretics, and particularly the aldosterone antagonist spironolactone, is well documented and well established. If it occurs it can be serious and potentially life threatening. Its incidence depends on the presence of other risk factors, and clinically important hyperkalaemia usually only appears to develop if one or more of these are also present, particularly renal impairment. Other risk factors in patients with heart failure include advanced age[18] and diabetes[12,25] (hyperkalaemia has been found to be relatively common in both non-insulin-dependent and insulin-dependent diabetics).[26] In addition, spironolactone in doses greater than 25 mg daily increase the risk of hyperkalaemia. A 7-year, case-control study in elderly patients found that patients treated with ACE inhibitors, and admitted to hospital with hyperkalaemia, were about 20 times more likely to have also been taking a potassium-sparing diuretic (adjusted odds ratio, 20.3) in the previous week, compared with control patients receiving ACE inhibitors who were not admitted for hyperkalaemia.[27]

A retrospective study in hospitalised patients who developed hyperkalaemia found that risk factors associated with a rapid rate of increase in serum potassium levels in decreasing order of importance were: the use of potassium supplements, severe renal impairment, the use of ACE inhibitors or angiotensin II receptor antagonists, the use of potassium-sparing diuretics, diabetes mellitus. Further, the presence of two or more of these risk factors is associated with an even faster development of hyperkalaemia. As the speed at which hyperkalaemia develops is also correlated with its severity, the authors recommend close monitoring in patients with two or more risk factors, and that a rapid increase in serum potassium (greater than 0.5 mmol/L per day) should prompt the identification and possible removal of any risk factors for hyperkalaemia.[28]

Because ACE inhibitors have potassium-sparing effects, potassium-sparing diuretics such as amiloride and triamterene should normally not be given concurrently. If, however, the use of both drugs is thought to be appropriate the serum potassium levels should be closely monitored so that any problems can be quickly identified. Note that the concurrent use of a potassium-depleting diuretic (a loop or thiazide diuretic) with the potassium-sparing diuretic may not necessarily prevent the development of hyperkalaemia. The combination of an ACE inhibitor and spironolactone can be beneficial in some types of heart failure, but close monitoring of serum potassium and renal function is needed, especially with any changes in treatment or the patient's clinical condition. The combination should be avoided in patients with renal impairment with a glomerular filtration rate of less than 30 mL/min.[25] In addition, the dose of spironolactone should not exceed 25 mg daily.[25] Similarly, the UK manufacturer of eplerenone says that caution is required when it is given with ACE inhibitors, especially in renal impairment, and that potassium levels and renal function should be monitored.[29]

ACE inhibitors or Angiotensin II receptor antagonists + Epoetins

Epoetins may cause hypertension and thereby reduce the effects of antihypertensive drugs. An additive hyperkalaemic effect is theoretically possible with ACE inhibitors or angiotensin II receptor antagonists and epoetins. It is not entirely clear whether ACE inhibitors or angiotensin II receptor antagonists affect the efficacy of epoetins or not, but any interaction may take many months to develop.

Clinical evidence

A. Antihypertensive effects

The most frequent adverse effect of epoetins is an increase in blood pressure, so it is important to control any existing hypertension before epoetin is started (the manufacturers contraindicate epoetin in uncontrolled hypertension). Blood pressure should be monitored before and during the use of epoetins, and if necessary antihypertensives should be started or increased if the pressure rises.[1-3]

B. Epoetin efficacy

(a) Decreased epoetin effects

In a retrospective analysis of 43 haemodialysis patients given epoetin regularly for about 10 months, the dose of epoetin was not significantly different between patients taking **captopril** (20 patients) and a control group (23 patients) who did not receive any ACE inhibitors (116.7 units/kg per week versus 98.3 units/kg per week, respectively). However, the haemoglobin and haematocrit values were significantly less at about 10 g/dL and 29.3%, respectively, in the **captopril** group than the values of 11.4 g/dL and 33.3% in the control group.[4] Another study in 108 patients who had been receiving haemodialysis for an average of 7 years found that those taking an ACE inhibitor (**enalapril**, **imidapril**, **captopril**, **cilazapril**, **benazepril**, or **temocapril**) required higher maintenance doses of epoetin than those not taking ACE inhibitors.[5] A retrospective study of 40 dialysis patients found that the 20 patients taking an ACE inhibitor (**captopril** 12.5 to 75 mg daily, **enalapril** 2.5 to 5 mg daily or **fosinopril** 10 to 20 mg daily) had some evidence of increased epoetin requirements after one year, when compared with the control group. However, this was not significant until 15 months when the cumulative epoetin dose requirements were about doubled (12 092 units/kg versus 6 449 units/kg).[6] Similarly, a prospective study with a 12-month follow-up period found that 20 patients receiving **enalapril** 5 to 20 mg daily required significantly higher doses of epoetin compared with 20 patients receiving nifedipine or 20 patients receiving no antihypertensive.[7] Another study in 49 haemodialysis patients given epoetin found that higher doses were required in those patients also taking **lisinopril** 2.5 to 20 mg daily (16 patients), **captopril** 12.5 to 37.5 mg daily (4 patients), **perindopril** 4 mg daily (one patient) or **ramipril** 2.5 mg daily (one patient) than in those patients not taking an ACE inhibitor.[8] A further study in 47 haemodialysis patients also found that 17 of 22 patients taking an ACE inhibitor (**enalapril** 20 to 40 mg daily or **captopril** 25 to 75 mg daily, for at least 3 months) did not respond to epoetin, compared with 6 of the 25 patients not taking ACE inhibitors. Furthermore, haematocrit and erythropoietin levels were lower and epoetin doses were higher in the patients taking an ACE inhibitor.[9] In another prospective study, 15 patients in whom ACE inhibitors (**enalapril**, **captopril**, or **perindopril**) were withdrawn and replaced with amlodipine, felodipine or doxazosin, had an increase in their mean haematocrit level and a decrease in their mean epoetin dose requirement.[10]

Higher epoetin requirements with ACE inhibitors were also reported in studies in peritoneal dialysis patients,[11-13] and in patients receiving haemodialysis.[14]

In a prospective study, hypertensive patients undergoing haemodialysis for more than 12 months and receiving epoetin were given either **losartan** 50 mg daily increased to 100 mg daily (20 patients) or amlodipine (20 patients) for 12 months. Twenty normotensive haemodialysis patients receiving epoetin were included as controls. It was found that patients in the **losartan** group, but not those in the amlodipine or control groups, required higher doses of epoetin to maintain the same haemoglobin levels. This was apparent at 6 months and at 12 months the epoetin dose had increased from the pre-study level of 90 units/kg per week to 129.5 units/kg per week.[15]

(b) No interaction

A prospective study carried out over a 6-month period in more than 10 000 patients found that ACE inhibitors did not interfere with the haemoglobin level and epoetin dose, in haemodialysis patients. The findings did not exclude the possibility that individual patients may need more epoetin during the use of an ACE inhibitor or that haemoglobin levels may rise after withdrawal of the ACE inhibitor.[13]

A cross-sectional study that included 515 haemodialysis patients receiving epoetin found that the mean epoetin dose and prevalence of epoetin resistance was similar in patients also taking ACE inhibitors, angiotensin II receptor antagonists, both ACE inhibitors and angiotensin II receptor antagonists, other antihypertensive drugs, or those who received no antihypertensives. However, the length of treatment with ACE inhibitors or other drugs was not known.[16] Another study also found that neither ACE inhibitors nor angiotensin II receptor antagonists could be considered as independent factors for increasing epoetin requirements and they did not significantly affect haemoglobin levels. This study did find an association between the number of antihypertensives given to a patient and epoetin dose requirement, as well as female gender, diabetes, age and systolic blood pressure.[17]

A retrospective review of 14 haemodialysis patients receiving epoetin, compared the haematocrit and dose of epoetin for 16 weeks before, and 16 weeks after, starting ACE inhibitors (8 taking **captopril**, mean dose 35 mg daily and 6 taking **enalapril**, mean dose 7.85 mg daily). This study did not find any evidence of a clinically significant interaction when ACE inhibitors were added.[18] Another study involving 17 chronic haemodialysis patients found that ACE inhibitors (5 taking **captopril** and 12 taking **enalapril**) for 3 and 12 months did not increase the epoetin dose requirements or reduce the haematocrits.[19]

In a retrospective study, the response to epoetin in haemodialysis patients who had taken ACE inhibitors (mainly **lisinopril** 5 to 40 mg daily, with some taking **enalapril** 2.5 to 40 mg daily or **fosinopril** 10 to 20 mg daily) for at least 4 months was found to be similar to that in patients who had not been taking ACE inhibitors.[20] Another study by the same authors, which was completed by 33 of 51 eligible haemodialysis patients, those taking an ACE inhibitor (mainly **lisinopril**, with some taking **enalapril** or **captopril**) at the start of the study continued with this drug for 4 months and were then switched to another antihypertensive (usually amlodipine) for a further 4 months. Patients not initially taking an ACE inhibitor were switched to an ACE inhibitor, usually **lisinopril** (mean daily dose 25 mg), at 4 months. Dose requirements of epoetin and haematocrit values were similar in each treatment period.[21] A short report of a study in 252 haemodialysis patients receiving epoetin found no reduction in the response to epoetin in 48 of the patients who were also taking ACE inhibitors.[22] A retrospective analysis of haemodialysis patients taking either moderately low doses of ACE inhibitors and epoetin (329 patients) or with epoetin alone (1884 patients), over a 12-week period, was evaluated by comparing haematocrit values. The ACE inhibitors were **enalapril** (113 patients), **captopril** (96 patients), or **alacepril**, **benazepril**, **cilazapril**, **delapril**, **imidapril**, or **lisinopril** (120 patients) and it was found that these ACE inhibitors had no effect on epoetin treatment.[23] Another retrospective analysis of 175 patients undergoing dialysis and receiving epoetin, also found that there was no change in the response to epoetin in 32 of the patients who were also taking **enalapril** for at least 3 months.[24]

A prospective study in 15 haemodialysis patients found that **losartan** 50 to 100 mg daily for 3 months did not significantly affect endogenous erythropoietin levels or affect the dose requirements of epoetin.[25] Another study in 14 haemodialysis patients found no difference in epoetin requirements between patients receiving **losartan** 25 mg daily or placebo,[26] but again the **losartan** was only given for 3 months.

However, given the results of the studies[6,15] reported under *Decreased epoetin effects*, above, it is possible that these studies were not continued for long enough to detect an effect. Further, the lack of effect in one of the studies[23] may also reflect the relatively low doses or low target haematocrit.

(c) ACE inhibitors compared with Angiotensin II receptor antagonists

In one retrospective analysis of dialysis patients, 18 of 24 receiving losartan had decreases in haemoglobin, and 14 of these were using epoetin. A three to fourfold increase in the epoetin dose was required in these patients to restore the haemoglobin levels.[27] This study suggests that angiotensin II receptor antagonists can behave similarly to ACE inhibitors. However, in a prospective study in 25 patients who had been undergoing haemodialysis for more than one year, 12 patients were given **temocapril** 2 mg daily and 13 patients were given **losartan** 25 to 50 mg daily for 12 months. **Temocapril** decreased haemoglobin levels from 9.8 g/dL to 9.1 g/dL at 3 months and reached a minimum of 9 g/dL at 6 months; haemoglobin levels recovered to 9.7 g/dL at the end of the study by increasing the dose of epoetin. In contrast, no change was found in haemoglobin levels in the patients receiving **losartan**. The dose of epoetin was gradually increased from 76 to 121 units/kg per week in the **temocapril** group, but in the **losartan** group the epoetin dose was not significantly increased (94 versus 101 units/kg per week).[28] Similar results were found in a study with **captopril** and **losartan**.[29]

A follow-up to a retrospective study found that the use of ACE inhibitors did not affect haemoglobin response rates or the epoetin dose. Similarly, the use of angiotensin II receptor antagonists did not affect haemoglobin response rates or the epoetin dose in patients from countries where more

than 70% of patients had haemoglobin levels greater than or equal to 11 g/dL (epoetin doses tended to be higher in these countries). However, patients taking angiotensin II receptor antagonists, who were from countries where only 60 to 70% of patients had a haemoglobin level of greater than or equal to 11 g/dL, had a reduced response to epoetin (higher epoetin doses and lower haemoglobin response rates).[30]

A survey of anaemia in more than 4000 kidney transplant recipients in 16 European countries found an association between post-transplant anaemia and the use of ACE inhibitors or angiotensin II receptor antagonists. However, haemoglobin levels in patients taking ACE inhibitors were not significantly different to levels in patients who had not received these drugs, whereas haemoglobin levels were lower in patients taking angiotensin II receptor antagonists.[31]

C. Hyperkalaemia

The manufacturers of epoetin alfa and beta comment that increased potassium levels have been reported in a few patients with chronic renal failure receiving epoetin, and that serum potassium levels should be monitored regularly.[1-3] An additive hyperkalaemic effect is therefore theoretically possible with patients also receiving ACE inhibitors or angiotensin II receptor antagonists.

Mechanism

Epoetin can cause hypertension, possibly associated with haemodynamic changes produced by the increase in haematocrit.[32]

It has been argued that ACE inhibitors might possibly reduce the efficacy of epoetin in haemodialysis patients for several reasons. A dose-dependent decrease in haematocrit is regularly observed when patients are given ACE inhibitors or angiotensin II receptor antagonists. In most patients this decrease is small and not clinically important. However, in conditions such as erythrocytosis associated with renovascular hypertension or renal transplantation, the haematocrit-lowering effects of these drugs may be marked.[33] Furthermore, ACE inhibitors may reduce polycythaemia that occurs following renal transplantation, and ACE inhibitors reduce the plasma levels of endogenous erythropoietin.[4,18,34] Another suggestion is that ACE inhibitors and angiotensin II receptor antagonists may reduce testosterone levels in men receiving haemodialysis, but not in women, and this may be associated with resistance to epoetin.[35] As suppression of angiotensin II levels has been found in dialysis patients receiving epoetin, it has been suggested that the effect of ACE inhibitors on erythropoietin may be associated with a feedback loop between erythropoietin and the renin-angiotensin system.[36] Many other factors have also been proposed.[36,37]

Drugs that block angiotensin II cause reduced levels of aldosterone, which results in the retention of potassium. This would be expected to be additive with other drugs that cause hyperkalaemia.

Importance and management

Blood pressure should be routinely monitored in patients receiving epoetin, and this monitoring would seem sufficient to detect any interaction that affects the blood pressure-lowering effects of the ACE inhibitors or angiotensin II receptor antagonists. The dose of ACE inhibitor may need to be increased, but if blood pressure rises cannot be controlled, a transient interruption of the use of epoetin is recommended. Similarly, serum electrolytes, including potassium, should be routinely monitored in patients using epoetin. If potassium levels rise, consider withholding epoetin until the level is corrected.[1,2]

The overall picture of the effect of ACE inhibitors on epoetin resistance is unclear, and it would seem that an interaction, if it happens, takes a long time to develop. The dose of ACE inhibitor and also of epoetin may be important factors for the development of epoetin resistance with the effect possibly being most apparent with high doses of ACE inhibitor, particularly if the patient is given low-dose epoetin. It has been suggested that any epoetin resistance due to high-dose ACE inhibitor should be able to be counteracted by increased dose of epoetin.[38] There is even less evidence regarding any interaction with angiotensin II antagonists, although one study suggests epoetin resistance may develop in patients given high-dose losartan for 6 months or more.[15] As epoetin dose is governed by response, no immediate intervention is generally necessary. More long-term study is needed.

ACE inhibitors + Food

Food has little or no effect on the extent of absorption of cilazapril, enalapril, fosinopril, lisinopril, quinapril, ramipril, spirap-

ril, and trandolapril although the rate of absorption may be decreased. Food reduced the absorption of imidapril and moexipril, reduced the conversion of perindopril to perindoprilat, and may reduce the absorption of captopril.

Clinical evidence, mechanism, importance and management

(a) Captopril

Although food reduced the AUC of captopril 25 to 100 mg by up to 56%[1-4] this had no effect on the maximum decrease in blood pressure.[1,3,4] One study in 10 healthy subjects reported that food caused a one-hour delay in the maximum hypotensive effect of captopril.[1] Another study, in 10 hypertensive patients, found that the extent and duration of the antihypertensive efficacy of captopril 50 mg twice daily for one month was not affected by whether it was taken before or after food.[5] However, decreasing the dose of an ACE inhibitor might reduce the duration of the hypotensive effect and it has been suggested that these results should be confirmed with lower doses of captopril.[5]

(b) Moexipril

In one study, food reduced the AUC of the active metabolite of moexipril (moexiprilat) by 40 to 50%.[6] Food did not reduce moexipril-induced ACE-inhibition and therefore the reduced bioavailability was not expected to be clinically relevant.[7]

(c) Perindopril

Although food did not significantly affect the pharmacokinetics of a single 4-mg dose of perindopril, the AUC of its active metabolite perindoprilat was reduced by 44%.[8] The blood pressure-lowering effects were not assessed, but it seems possible that they would not be affected (see *Captopril*, above). Nevertheless, the UK manufacturer recommends that perindopril should be taken in the morning before a meal.[9]

(d) Other ACE inhibitors

Single-dose studies have found that food has no statistically significant effect on the pharmacokinetics of **lisinopril**,[10] or **enalapril**, and its active metabolite, enalaprilat.[11] Similarly, food had minimal effects on the pharmacokinetics of **cilazapril** (AUC decreased by only 14%).[12] Food caused small increases in the time to reach maximum plasma levels of **quinapril** and its active metabolite. However, as the increase was less than 30 minutes this is not expected to alter the therapeutic effect.[13] Likewise, the manufacturers of **spirapril** briefly mention in a review that food delayed its absorption by one hour, but it did not affect the bioavailability of **spirapril** or spiraprilat, its active metabolite.[14] The US manufacturers of **fosinopril**,[15] **ramipril**,[16] and **trandolapril**[17] state that food may slow their absorption, but both the UK[18-20] and US[15-17] manufacturers state that the extent of absorption is unaffected.

The UK manufacturer of **imidapril** states that a fat-rich meal significantly reduces the absorption of **imidapril**, and recommends that the drug be taken at the same time each day, about 15 minutes before a meal.[21]

ACE inhibitors + Garlic

In a single report, a patient taking lisinopril developed marked hypotension and became faint after taking garlic capsules.

Clinical evidence, mechanism, importance and management

A man whose blood pressure was 135/90 mmHg while taking **lisinopril** 15 mg daily began to take garlic 4 mg daily (*Boots odourless garlic oil capsules*). After 3 days he became faint on standing and was found to have a blood pressure of 90/60 mmHg. Stopping the garlic restored his blood pressure to 135/90 mmHg within a week. The garlic on its own did not lower his blood pressure. The reasons for this interaction are not known, although garlic has been reported to cause vasodilatation and reduce blood pressure.[1] This seems to be the first and only report of this reaction, so its general importance is small. There seems to be nothing documented about garlic and any of the other ACE inhibitors.

ACE inhibitors + Gold

Peripheral vasodilatation has occurred in some patients given ACE inhibitors and gold. Isolated cases of loss of consciousness, cardiovascular collapse and cerebrovascular accident have been reported. In some patients the reaction occurred soon after the ACE inhibitor was started, while in others there appeared to be a lag time of several months or more.

Clinical evidence

A retrospective analysis of patients given gold compounds at one clinic from 1996 to 2000 identified 8 patients who had experienced a nitritoid reaction (adverse effects associated with the use of gold compounds, consisting of facial flushing, nausea, dizziness, and occasionally, hypotension, as a result of peripheral vasodilatation) of which one was considered serious. They had been given weekly doses of **sodium aurothiomalate** 25 to 50 mg for between 13 months and 13 years before the reaction occurred. However, in 2 of the patients who had been receiving gold for 2 years and 13 years, respectively, the nitritoid reaction occurred one to 4 weeks after starting the ACE inhibitor (**ramipril** in one patient; not specified in the other).[1]

A report describes 4 patients receiving long-term gold for rheumatoid arthritis who developed nitritoid reactions. These reactions occurred soon after starting an ACE inhibitor (**captopril**, **enalapril**, or **lisinopril**). All the patients had been receiving a monthly injection of **sodium aurothiomalate** 50 mg for at least 2 years and none had ever had such a reaction before. The reactions were controlled by changing treatment to **aurothioglucose**, discontinuing the ACE inhibitor, or reducing the dose of **sodium aurothiomalate** to 25 mg.[2]

Another report notes 2 further cases observed by one of the authors of the earlier report[2] and also describes a patient given a weekly and then monthly intramuscular injection of **sodium aurothiomalate** 50 mg for 4 months before she started taking **lisinopril** 20 mg daily. Seven months later she experienced paraesthesiae in her hands and tongue and palpitations a few minutes after the **sodium aurothiomalate** injection; mild paraesthesiae occurred again after her next injection. The following four injections were without any adverse effects, but then within 5 to

10 minutes of the next injection she became dizzy and flushed with nausea and vomiting and collapsed, requiring cardiopulmonary resuscitation. One day later she developed bloody diarrhoea and, the following day, a peeling erythematous rash, which gradually resolved over a few weeks; these were possible adverse effects of the gold. **Sodium aurothiomalate** was replaced with hydroxychloroquine and **lisinopril** was continued.[3]

Two patients who had been receiving **sodium aurothiomalate** 50 mg/month for over 20 years without adverse effects developed nitritoid reactions. One of the patients who had been taking **ramipril** 10 mg daily for about 15 months, experienced nausea, angina, and hypotension 10 minutes after an injection of **sodium aurothiomalate**. Although it was concluded that the reaction was due to a vasovagal episode, secondary to the injection and possibly exaggerated by atenolol, on review of the case, it was considered that an interaction with **ramipril** was also a possibility. About 10 months after the second patient had started taking **perindopril** 2 mg daily gradually increased to 6 mg daily, he lost consciousness whilst driving his car 20 minutes after an injection of **sodium aurothiomalate**. On admission to hospital it was concluded that he had experienced a vasovagal attack secondary to ischaemic heart disease. A month later he developed chest pain 10 minutes after the gold injection and he remained conscious but was hypotensive with a heart rate of 40 bpm. Both patients had been receiving **sodium aurothiomalate** for many years, and the possibility of an interaction occurring several months after starting an ACE inhibitor was suggested.[4] There is a further report of a patient who had taken **enalapril** for 3 years and **sodium aurothiomalate** for 6 years who experienced mild nitritoid symptoms following two successive injections of **sodium aurothiomalate** and then a cerebrovascular accident within several hours of her next injection.[5]

Mechanism

Not understood. The nitritoid reaction is a recognised reaction that can occur in patients receiving gold compounds. Most reactions are associated with sodium aurothiomalate (incidence of about 5%), but they have also been reported with auranofin and sodium aurothioglucose.[5,6] It has been suggested that the difference in frequency with sodium aurothiomalate compared with other gold compounds may be related to differences in bioavailability, with the aqueous sodium aurothiomalate being rapidly absorbed, whereas the oil-based aurothioglucose or auranofin are absorbed more slowly.[1,5]

ACE inhibitors prevent bradykinin breakdown, so patients may have higher bradykinin levels.[1] It has been suggested that ACE inhibitors may 'unmask' a hypersensitivity reaction, possibly by potentiation of kinins, resulting in an exaggerated inflammatory response.[3] However, reactions involving bradykinin, may be delayed for several months after starting an ACE inhibitor.[4] An *in vitro* study found that captopril binds strongly with gold, ejecting thiomalate into solution.[7]

Importance and management

Although the nitritoid reaction is an established adverse effect of gold compounds, patients also taking ACE inhibitors may be at an increased risk. A possible interaction should be borne in mind if a patient experiences these reactions and is also taking an ACE inhibitor. The cases reported indicate that reactions may occur soon after starting an ACE inhibitor or there may be a lag time of several months or more. It has been recommended that patients taking ACE inhibitors who require gold compounds should, if possible, be given aurothioglucose. If this is not available, a 50% reduction in the sodium aurothiomalate dose is recommended, with the patient in the recumbent position, and under observation for 20 minutes following the next few injections.[1]

ACE inhibitors + H_2-receptor antagonists

In general, no clinically significant interactions appear to occur between the H_2-receptor antagonists (including cimetidine) and the ACE inhibitors. However, note that cimetidine modestly reduces the bioavailability of temocapril.

Clinical evidence, mechanism, importance and management

In studies in healthy subjects, **cimetidine** did not appear to alter the pharmacokinetics or pharmacological effects of **captopril**[1] or **enalapril**,[2] or the pharmacokinetics of **fosinopril**[3] or **quinapril**.[4] The manufacturers of **cilazapril** say that no clinically significant interactions have occurred with H_2-receptor antagonists (not specifically named)[5] and the manufacturers of **benazepril**,[6] **moexipril**,[7] **ramipril**,[8] and **trandolapril**[9] say that no important pharmacokinetic interaction occurred with **cimetidine**. The manufacturers of **spirapril** briefly note in a review that **cimetidine** did not alter the plasma concentrations of **spirapril** or its active metabolite spiraprilat.[10] None of these pairs of drugs appears to interact to a clinically relevant extent, and no special precautions appear to be necessary.

Preliminary findings in 18 healthy subjects suggest that **cimetidine** 400 mg twice daily had no effect on the metabolism of **temocapril** 20 mg daily, but the AUC was reduced by 26% on the fifth day of concurrent use.[11] The clinical relevance of this is uncertain, but changes of this magnitude with other ACE inhibitors have often not been clinically relevant.

ACE inhibitors or Angiotensin II receptor antagonists + Heparins

Heparin may increase the risk of hyperkalaemia with ACE inhibitors or angiotensin II receptor antagonists.

Clinical evidence, mechanism, importance and management

An extensive review of the literature found that heparin (both **unfractionated** and **low-molecular-weight heparins**) and **heparinoids** inhibit the secretion of aldosterone, and this can cause hyperkalaemia.[1] The CSM in the UK suggests that plasma potassium levels should be measured in all patients with risk factors (including those taking potassium-sparing drugs) before starting heparin, and monitored regularly thereafter, particularly if heparin is to be continued for more than 7 days.[2] Note that ACE inhibitors and angiotensin II receptor antagonists are potassium sparing, via their effects on aldosterone. Some workers[1] have suggested that the monitoring interval should probably be no greater than 4 days in patients at a relatively high risk of hyperkalaemia. Other risk factors include renal impairment, diabetes mellitus, pre-existing acidosis or raised plasma potassium.[2]

If hyperkalaemia occurs, the offending drugs should be stopped (although this may not be practical in the case of heparin). When the hy-

perkalaemia has been corrected (by whatever medical intervention is deemed appropriate) the drugs can cautiously be reintroduced.

ACE inhibitors + Insect allergen extracts

There are a few case reports of severe anaphylactoid reactions in patients receiving ACE inhibitors during desensitisation with bee or wasp venom.

Clinical evidence

A report describes 2 cases of anaphylactoid reactions during **wasp venom immunotherapy** in patients taking **enalapril**. In one patient, generalised pruritus and severe hypotension occurred within a few minutes of the first venom injection. Desensitisation was achieved after the **enalapril** was stopped, and then the immunotherapy was maintained by discontinuing the **enalapril** 24 hours before the monthly venom injection. However, on one occasion, when the **enalapril** had not been stopped, the patient experienced a severe anaphylactoid reaction 30 minutes after the venom injection. In the other patient, an anaphylactoid reaction occurred after the second dose of venom. The ACE inhibitor was replaced with nifedipine so that venom immunotherapy could be continued. However, **enalapril** was reintroduced a few months later and subsequent venom administration induced an anaphylactoid reaction. **Enalapril** was stopped again so that desensitisation could be maintained.[1]

In another report, a 43-year-old man who had been taking ACE inhibitors for 2 years (**lisinopril** 40 mg daily for the previous 5 months) had a hypotensive reaction to an insect sting. After skin testing, he received venom immunotherapy. About 4 months later, he had a severe anaphylactic reaction 5 minutes after being given a maintenance dose of **wasp venom** and **mixed vespid venom**. The ACE inhibitor was replaced with a calcium-channel blocker, and he subsequently tolerated full-strength venom immunotherapy injections.[2]

A retrospective review of patients evaluated for **Hymenoptera venom** allergy, at a single medical centre from 2000 to 2005, identified 79 patients undergoing venom immunotherapy. ACE inhibitors (**lisinopril**, **ramipril**, or **benazepril**) were taken by 17 patients (21%): 7 patients continued to take the ACE inhibitor when immunotherapy was started and 10 began to take an ACE inhibitor after starting immunotherapy. None of the patients receiving ACE inhibitors had systemic reactions during venom immunotherapy (compared with 13 of 62 patients not taking an ACE inhibitor). However, the patients taking ACE inhibitors were older (mean age 56 years versus 36 years) and had received immunotherapy for longer (mean 72 months versus 30 months) than those who were not taking an ACE inhibitor. Twelve of the 17 patients (71%) taking an ACE inhibitor reported having field stings, but none of these patients had a systemic reaction. One patient did have a reaction to a field sting early in his venom immunotherapy treatment, before he started to take an ACE inhibitor, but he did not experience a reaction on rechallenge while taking an ACE inhibitor.[3]

Mechanism

ACE inhibitors might potentiate the hypotension associated with anaphylactic reactions by inhibiting the breakdown of bradykinin and decreasing concentrations of the vasoconstrictor angiotensin II.[4] It has also been suggested that similar reactions may occur after an insect sting.[4] This is supported by a case report that describes a woman who had generalised angioedema in response to bee stings on at least three occasions while taking captopril and then cilazapril, but experienced only localised swelling before and after treatment with an ACE inhibitor.[5]

Importance and management

One retrospective review[3] suggested that ACE inhibitors do not increase the risk of anaphylaxis to venom immunotherapy; however, isolated reactions, especially following reintroduction of an ACE inhibitor in two cases mentioned above,[1] suggest that in some patients ACE inhibitors may increase the risk of anaphylaxis. On the basis of these few reports, it cannot be said with certainty that an interaction occurs; but it is possible that ACE inhibitors could exacerbate the response to insect venoms and insect venom immunotherapy.

The use of ACE inhibitors in patients with **Hymenoptera venom** allergy (bee, wasp or stinging ant allergy) or those undergoing venom immunotherapy requires caution because of the potential severity of the reaction. If an ACE inhibitor is considered necessary, appropriate measures should be put in place. These include minimising the risk of exposure to insect stings e.g. by physical protection, and ensuring the patient carries adrenaline (epinephrine) [such as an *EpiPen*] for emergency self-treatment.[4] Some authors[1,2,4] and manufacturers advise temporarily withholding the ACE inhibitor before each desensitisation (24 hours was sufficient in one case), while others suggest temporary substitution of a different antihypertensive e.g. a calcium-channel blocker. ACE inhibitors with active metabolites with prolonged terminal half-lives (including **benazepril**, **quinapril**, and **ramipril**) may require discontinuation for longer periods.[4,6] Note that some evidence suggests that anaphylactic shock in patients taking beta blockers may be resistant to treatment with adrenaline (epinephrine), see 'Beta blockers + Inotropes and Vasopressors', p.1011. Therefore beta blockers are probably not a suitable alternative.

ACE inhibitors + Interleukin-3

Marked hypotension occurred when three patients taking ACE inhibitors were given interleukin-3.

Clinical evidence, mechanism, importance and management

Twenty-six patients with ovarian or small-cell undifferentiated cancers were given chemotherapy followed by recombinant human interleukin-3. Three of the 26 were taking ACE inhibitors (not named) and all three developed marked hypotension (WHO toxicity grade 2 or 3) within one to 4 hours of the first interleukin-3 injection. Their blood pressures returned to normal while continuing the interleukin-3 when the ACE inhibitors were stopped. When the interleukin-3 was stopped, they once again needed the ACE inhibitors to control their blood pressure. None of the other 23 patients had hypotension, except one who did so during a period of neutropenic fever.[1] The authors of the report suggest (and present some supporting evidence) that the drugs act synergistically to generate large amounts of nitric oxide in the blood vessel walls. This relaxes the smooth muscle in the blood vessel walls causing vasodilatation and consequent hypotension.[1] Information seems to be limited to this single report, but it would be prudent to monitor blood pressure even more closely if patients taking ACE inhibitors are given interleukin-3.

1. Dercksen MW, Hoekman K, Visser JJ, ten Bokkel Huinink WW, Pinedo HM, Wagstaff J. Hypotension induced by interleukin-3 in patients on angiotensin-converting enzyme inhibitors. *Lancet* (1995) 345, 448.

ACE inhibitors + Iron compounds

Serious systemic reactions occurred when three patients taking enalapril were given infusions of ferric sodium gluconate; however, there was no increase in the incidence of such adverse reactions in patients taking ACE inhibitors in a very large clinical study. Oral ferrous sulfate may decrease the absorption of captopril, but this is probably of little clinical importance.

Clinical evidence

(a) Intravenous iron

A man with iron-deficiency anaemia taking furosemide and digoxin was given 125 mg of **ferric sodium gluconate** (*Ferlixit*[1]) intravenously in 100 mL of saline daily. Four days later, **enalapril** 5 mg daily was started. After the infusion of only a few drops of his next dose of **ferric sodium**

gluconate, he developed diffuse erythema, abdominal cramps, hypotension, nausea and vomiting. He recovered after being given hydrocortisone 200 mg. Three days later, in the absence of the **enalapril**, he restarted the iron infusions for a further 10 days without problems, and was later treated uneventfully with **enalapril**.[2] Two other patients taking **enalapril** reacted similarly when given intravenous infusions of **ferric sodium gluconate**. Neither was given any more intravenous iron and later had no problems while taking **enalapril** alone. During the same 13-month period in which these three cases occurred, 15 other patients, who were not taking ACE inhibitors, also received intravenous iron with no adverse reactions.[2] In contrast, an interim report of a randomised, crossover study involving 1117 dialysis patients given a placebo or a single intravenous dose of 125 mg of **ferric sodium gluconate complex** (*Ferrlecit*) in sucrose, found no evidence of any significant difference in the incidence of immediate allergic reactions or other adverse reactions to the iron in the 308 patients also taking ACE inhibitors.[3] The findings of the full study, which included 707 patients taking ACE inhibitors, were the same.[4] Similarly, the longer-term follow-up of patients from this study who continued to receive intravenous **ferric sodium gluconate complex**, found that there was no difference in the incidence or severity of adverse events in the 372 patients taking ACE inhibitors, when compared with the 949 patients who were not taking ACE inhibitors.[5]

(b) Oral iron

A double-blind study in 7 healthy subjects, given a single 300-mg dose of **ferrous sulfate** or placebo with **captopril** 25 mg, found that the AUC of unconjugated plasma **captopril** (the active form) was reduced by 37% although the maximum plasma levels were not substantially changed. The AUC of total plasma **captopril** was increased by 43%, although this was not statistically significant. There were no significant differences in blood pressure between treatment and placebo groups.[6]

Mechanism

Uncertain. Intravenous iron may cause a variety of systemic reactions including fever, myalgia, arthralgia, hypotension, and nausea and vomiting, which are believed to be due to the release of various inflammatory mediators such as bradykinin, caused by iron-catalysed toxic free radicals. The authors of the report suggest that ACE inhibitors like enalapril decrease the breakdown of kinins so that the toxic effects of the iron become exaggerated.[2]

The reduced levels of unconjugated captopril seen in the presence of oral iron are probably due to reduced absorption resulting from a chemical interaction between ferric ions and captopril in the gastrointestinal tract producing a captopril disulfide dimer and ferrous iron.[6]

Importance and management

The interaction with intravenous iron is not firmly established because up to 25% of all patients given iron by this route develop a variety of systemic reactions, ranging from mild to serious anaphylactoid reactions. In addition, information from the large clinical study indicates that there is no increased risk in patients taking ACE inhibitors. This suggests that no extra precautions are required if intravenous iron is given to patients taking any ACE inhibitor.

There is limited evidence that oral iron may reduce the absorption of captopril. The clinical relevance of this is unknown, but probably small. Information about the effect of oral iron on other ACE inhibitors is lacking.

ACE inhibitors + Moracizine

Moracizine causes some moderate alterations in the pharmacokinetics of captopril, but these are unlikely to be clinically important.

Clinical evidence, mechanism, importance and management

In a pharmacokinetic study, 19 healthy subjects were given moracizine 250 mg or **captopril** 50 mg, both every 8 hours, either alone or together, for 22 doses. When taken together the pharmacokinetics of the moracizine and total **captopril** remained unchanged, but the maximum blood levels of the free **captopril** and its AUC decreased by 32% and 14%, respectively. The half-life of the free **captopril** was reduced by 44%.[1] These modest changes are unlikely to be clinically relevant.

ACE inhibitors + NSAIDs

There is evidence that most NSAIDs can increase blood pressure in patients taking antihypertensives, including ACE inhibitors, although some studies have not found the increase to be clinically relevant. Some variation between drugs possibly occurs, with indometacin appearing to have the most significant effect. The combination of an NSAID and an ACE inhibitor can increase the risk of renal impairment and hyperkalaemia.

Clinical evidence

A. Effects on blood pressure

Various large epidemiological studies and meta-analyses of clinical studies have been conducted to assess the effect of NSAIDs on blood pressure in patients taking antihypertensives, and the findings of these are summarised in 'Table 23.2', (p.1027). In these studies, NSAIDs were not always associated with an increase in blood pressure, and the maximum increase was 6.2 mmHg. The effect has been shown for both coxibs and non-selective NSAIDs. In two meta-analyses,[1,2] the effects were evaluated by NSAID. The confidence intervals for all the NSAIDs overlapped, showing that there was no statistically significant difference between them, with the exception of the comparison between **indometacin** and **sulindac** in one analysis.[2] Nevertheless, an attempt was made at ranking the NSAIDs based on the means. In one analysis,[1] the effect was said to be greatest for **piroxicam**, **indometacin**, and **ibuprofen**, intermediate for **naproxen**, and least for **sulindac** and **flurbiprofen**. In the other meta-analysis,[2] the effect was said to be greatest for **indometacin** and **naproxen**, intermediate for **piroxicam**, and least for **ibuprofen** and **sulindac**. An attempt was also made to evaluate the effect by antihypertensive.[1] The mean effect was greatest for beta blockers, intermediate for vasodilators (this group included ACE inhibitors and calcium-channel blockers), and least for diuretics. However, the differences between the groups were not significant.

The findings of individual studies that have studied the effects of specific NSAIDs on ACE inhibitors are outlined in the subsections below.

(a) Celecoxib

In a double-blind study in hypertensive patients taking **lisinopril** 10 to 40 mg daily, celecoxib did not have a clinically or statistically significant effect on blood pressure. The 24-hour blood pressure increased by 2.6/1.5 mmHg in 91 patients taking celecoxib 200 mg twice daily for 4 weeks compared with 1/0.3 mmHg in 87 patients taking placebo.[3] In another large study in 810 elderly patients with osteoarthritis and controlled hypertension given either celecoxib 200 mg or rofecoxib 25 mg daily for 6 weeks, approximately 40% of the patients randomised to the celecoxib group were receiving ACE inhibitors. Systolic blood pressure increased by a clinically significant amount (greater than 20 mmHg) in 11% of patients receiving celecoxib,[4] while in another study, only 4 of 87 (4.6%) of hypertensive patients taking ACE inhibitors had clinically significant increases in blood pressure after taking celecoxib 200 mg twice daily for 4 weeks.[5] A further study in 25 hypertensive patients with osteoarthritis taking **trandolapril** (with or without hydrochlorothiazide) found that the 24-hour blood pressure was not significantly increased by celecoxib 200 mg daily, but, at its peak activity, celecoxib increased blood pressure

by about 5/4 mmHg.[6] In another randomised study, 16% of 138 patients given celecoxib 200 mg daily developed hypertension within 6 weeks (defined as a 24-hour systolic blood pressure greater than 135 mmHg). These patients had well-controlled hypertension at baseline; 83% were receiving an ACE inhibitor and 64% an additional antihypertensive.[7] The proportion of patients who developed hypertension was similar to that with naproxen (19%) and less than that with rofecoxib (30%).

(b) Ibuprofen

In 90 patients taking ACE inhibitors, giving ibuprofen for 4 weeks resulted in clinically significant increases in blood pressure in 15 of the patients. For the group as a whole, diastolic blood pressure was increased by 3.5 mmHg.[5] In one single-dose study in 8 healthy subjects, ibuprofen 800 mg or indometacin 50 mg abolished the hypotensive effect of **captopril** 50 mg when they received a high sodium diet, but not when they received a low sodium diet.[8] A case report describes attenuation of the antihypertensive effects of **captopril** by ibuprofen in an elderly woman.[9] However, two studies in African women found that ibuprofen 800 mg three times daily for one month did not alter the antihypertensive effect of either **fosinopril** 10 to 40 mg daily or **lisinopril** 10 to 40 mg daily (given with hydrochlorothiazide 25 mg daily).[10,11] It was thought that the diuretic might have enhanced salt depletion and renin stimulation making the antihypertensive action of the combination less prostaglandin dependent.[10]

(c) Indometacin

1. Captopril. In a randomised, double-blind study, 105 patients with hypertension were given captopril 25 to 50 mg twice daily for 6 weeks, which reduced their blood pressure by a mean of 8.6/5.6 mmHg. Indometacin 75 mg daily was then added for one week, which caused a rise in blood pressure in the group as a whole of 4.6/2.7 mmHg (an attenuation of the effect of captopril of about 50%). Clear attenuation was seen in 67% of the patients, and occurred regardless of baseline blood pressure.[12] This same interaction has been described in numerous earlier studies, in both patients with hypertension and healthy subjects, given indometacin.[8,13-20] A man whose blood pressure was well controlled with captopril 75 mg daily had a rise in his blood pressure from 145/80 mmHg to 220/120 mmHg when he started using indometacin suppositories 200 mg daily.[21] In contrast, a randomised, placebo-controlled, crossover study in 11 patients found that indometacin 50 mg twice daily did not alter the antihypertensive efficacy of captopril 50 mg twice daily.[22]

2. Enalapril. In 9 patients with hypertension, indometacin 50 mg twice daily for one week significantly reduced the antihypertensive effect of enalapril 20 to 40 mg daily by about 18 to 22%.[23] In another study in 18 patients, indometacin 25 mg three times daily attenuated the antihypertensive effect of enalapril 20 to 40 mg daily. The reduction in hypotensive effect was about 42% when assessed by 24-hour ambulatory blood pressure monitoring (9.4/4.1 mmHg increase in blood pressure with indometacin), and 12 to 23% when assessed by clinic blood pressure monitoring.[24] Similar results were found in other studies.[25-28] A further study in 10 normotensive subjects receiving a fixed sodium intake and enalapril 20 mg daily, with or without indometacin 50 mg twice daily for one week, found that indometacin reduced the natriuretic response to the ACE inhibitor.[29] A single case report describes a patient taking enalapril 10 mg daily whose hypertension was not controlled when indometacin 100 mg daily in divided doses was added.[30] However, other studies found that indometacin did not significantly alter the blood pressure response to enalapril.[19,22,31]

3. Lisinopril. In a placebo-controlled, crossover study in 56 patients taking lisinopril 10 to 20 mg daily, indometacin 50 mg twice daily for 2 weeks produced mean blood pressure increases of 5.5/3.2 mmHg.[32] Similarly, results of an earlier study suggested that indometacin increased the blood pressure of 9 patients taking lisinopril.[26] In contrast in a placebo-controlled study in 16 patients, indometacin 50 mg twice daily for 4 weeks was found to have little effect on the antihypertensive efficacy of lisinopril 40 mg daily.[33]

4. Other ACE inhibitors. A placebo-controlled, randomised, crossover study in 16 hypertensive patients found that indometacin 50 mg twice daily reduced the blood pressure-lowering effects of **cilazapril** 2.5 mg daily. The reduction was greater when **cilazapril** was added to indometacin than when indometacin was added to **cilazapril** (approximately 60% versus 30% reduction in hypotensive effect measured 3 hours after the morning dose).[34] In 10 hypertensive patients the antihypertensive effects of **perindopril** 4 to 8 mg daily were also found to be reduced by about 30% by indometacin 50 mg twice daily.[35] A brief mention is made in a review that, in healthy subjects, the pharmacodynamics of **ramipril** were unaffected by indometacin (dose not stated) given for 3 days.[36] Indometacin 25 mg three times daily did not alter the hypotensive effects of **trandolapril** 2 mg daily in 17 hypertensive patients.[37]

(d) Naproxen

In a randomised study, 19% of 130 patients given naproxen 500 mg twice daily developed hypertension within 6 weeks (defined as a 24-hour systolic blood pressure greater than 135 mmHg). These patients had well-controlled hypertension at baseline; 83% were receiving an ACE inhibitor and 66% an additional antihypertensive.[7] The proportion of patients who developed hypertension was similar to that with celecoxib (16%) and less than that with rofecoxib (30%).

(e) Rofecoxib

The manufacturer of rofecoxib noted that in patients with mild-to-moderate hypertension, rofecoxib 25 mg daily, taken with **benazepril** 10 to 40 mg daily, for 4 weeks, was associated with a small attenuation of the antihypertensive effect (average increase in mean arterial pressure of 2.8 mmHg).[38] Similarly, a case report describes a patient taking **lisinopril** 10 mg daily whose blood pressure rose from 127/78 mmHg to 143/89 mmHg when he was given rofecoxib 25 mg daily. His blood pressure was controlled by increasing the dose of **lisinopril** to 20 mg daily.[39]

In another study, in 810 elderly patients with osteoarthritis and controlled hypertension given either celecoxib 200 mg or rofecoxib 25 mg daily for 6 weeks, approximately 29% of the patients randomised to the rofecoxib group were receiving ACE inhibitors. Systolic blood pressure increased by a clinically significant amount (greater than 20 mmHg) in 17% of the patients receiving rofecoxib.[4] In another similar randomised study, 30% of 138 patients given rofecoxib 25 mg daily developed hypertension within 6 weeks (defined as a 24-hour systolic blood pressure greater than 135 mmHg). These patients had well-controlled hypertension at baseline; 84% were receiving an ACE inhibitor and 62% an additional antihypertensive.[7] The proportion of patients who developed hypertension was greater than with celecoxib (16%) or naproxen (19%).

(f) Sulindac

In one study, sulindac 200 mg twice daily given to patients taking **captopril** 100 to 200 mg twice daily caused only a small rise in blood pressure (from 132/92 mmHg to 137/95 mmHg).[15] Sulindac 150 mg twice daily did not attenuate the blood pressure response to **captopril** when it was substituted for ibuprofen in an elderly woman.[9] Similarly, sulindac 200 mg twice daily did not blunt the antihypertensive effect of **enalapril** in 9 patients with hypertension.[31] Two studies in black women also found that sulindac 200 mg twice daily for one month did not alter the antihypertensive effect of **fosinopril** 10 to 40 mg daily or **lisinopril** 10 to 40 mg daily (given with hydrochlorothiazide 25 mg daily).[10,11]

(g) Other NSAIDs

In 6 hypertensive patients taking **enalapril**, a single 8-mg dose of **lornoxicam** was found to have no effect on systolic blood pressure, but a small rise in diastolic pressure (from 88.2 mmHg to 93.3 mmHg) occurred after 2 hours.[25] In 29 patients with hypertension **oxaprozin** 1.2 g daily for 3 weeks did not affect the pharmacodynamics of **enalapril** 10 to 40 mg daily.[40]

Twenty-five hypertensive patients with osteoarthritis taking **trandolapril** 2 to 4 mg daily (with or without hydrochlorothiazide) had an increase in blood pressure of about 3/4 mmHg when they were given **diclofenac** 75 mg twice daily.[6] However, **diclofenac** 75 mg twice daily for one month did not alter the antihypertensive effect of **lisinopril** 10 to 40 mg daily (given with hydrochlorothiazide).[11]

A study found that only 5 of 91 (5.5%) hypertensive patients stable taking ACE inhibitors had clinically significant increases in blood pressure when they were given **nabumetone** 1 g twice daily for 4 weeks.[5] A study in 17 black women found that **nabumetone** 1 g twice daily for one month did not alter the antihypertensive effect of **fosinopril** 10 to 40 mg daily (given with hydrochlorothiazide).[10]

B. Effects on renal function

A case report describes a patient with heart failure treated intermittently with **ibuprofen** and later with **naproxen** and **indometacin** for gout, who developed acute renal failure when also given **captopril**. Treatment with an NSAID alone was without adverse effects on renal function and treatment with **captopril** alone appeared to improve his renal function.[41] In a retrospective analysis, 3 of 162 patients who had been taking ACE inhibitors and NSAIDs developed reversible renal failure, compared with none of 166 patients taking ACE inhibitors alone and none of 2116 patients tak-

ing NSAIDs alone. One patient was taking **naproxen** or **salsalate** and had a progressive decline in renal function over 19 months after **captopril** was started. Another man taking unnamed NSAIDs developed reversible renal failure 4 days after starting to take **captopril**.[42] In another similar analysis, in patients aged over 75 years, 2 out of 12 patients given an ACE inhibitor and an NSAID developed acute renal failure (one died) and a further 4 patients had a deterioration in their renal function. All of these 6 patients were also taking diuretics (see 'ACE inhibitors + Diuretics; Loop, Thiazide and related', p.23), but of the 6 with unaffected renal function, only two were taking diuretics.[43] A randomised, crossover study in 17 black patients receiving **fosinopril** with hydrochlorothiazide and NSAIDs for a month, found that acute renal failure (a decrease in glomerular filtration rate of greater than or equal to 25%) occurred in 4 of the 17 patients when receiving **ibuprofen**, 1 of 17 when receiving **sulindac** and 0 of 17 when receiving **nabumetone**.[10]

In a multivariate analysis, the use of ACE inhibitors or angiotensin II receptor antagonists with NSAIDs or diuretics was associated with significant renal impairment when two or more drugs from these groups was taken.[44] In a nested case-control study using the UK General Practice Research Database, the relative risk of acute renal failure was 3.2 with NSAID use, 3.5 with ACE inhibitor use, and 10.6 with NSAIDs and a cardiovascular drug. The risk was not more than additive with NSAIDs and ACE inhibitors.[45] In a case-control study, recently starting an NSAID was associated with a 2.2-fold increased risk of hospitalisation for renal impairment in patients taking ACE inhibitors.[46] In 2002, 28 of 129 reports to the Australian Adverse Drug Reactions Advisory Committee of acute renal failure were associated with the concurrent use of ACE inhibitors (or angiotensin II receptor antagonists), diuretics, and NSAIDs (including coxibs), and these cases had a fatality rate of 10%. In patients taking this triple combination, renal failure appeared to be precipitated by mild stress such as diarrhoea or dehydration. In other patients, the addition of a third drug (usually an NSAID) to a stable combination of the other two, resulted in acute renal failure.[47]

A placebo-controlled study in 10 patients with chronic congestive heart failure taking an ACE inhibitor (**captopril**, **cilazapril**, **enalapril**, **ramipril**), and aspirin 75 to 125 mg daily (for ischaemic heart disease) found that when they were given a single 50-mg dose of **diclofenac** after aspirin had been discontinued for at least one week, there was a significant deterioration in renal function compared with placebo or aspirin. Compared with placebo, both aspirin and **diclofenac** caused slight but significant increases in serum creatinine.[48]

In contrast, a retrospective analysis found no evidence that the adverse effects of ACE inhibitors on renal function were greater in those taking NSAIDs.[49] A further study in 17 hypertensive patients with normal baseline renal function, found that **indometacin** 25 mg three times daily did not adversely affect renal function when it was given with **trandolapril** 2 mg daily for 3 weeks.[50]

C. Hyperkalaemia

Hyperkalaemia, resulting in marked bradycardia, was attributed to the use of **loxoprofen** in an elderly woman taking **imidapril**.[51] A 77-year-old woman with mild hypertension and normal renal function taking **enalapril** 2.5 mg daily arrested and died 5 days after starting to take **rofecoxib** for leg pain. Her potassium was found to be 8.8 mmol/L. Infection and dehydration could have contributed to the hyperkalaemia in this patient.[52]

D. Pharmacokinetic studies

The manufacturer of **spirapril** briefly noted in a review that there was no relevant pharmacokinetic interaction between spirapril and **diclofenac**.[53] In 29 patients with hypertension, **oxaprozin** 1.2 g daily for 3 weeks did not affect the pharmacokinetics of **enalapril** 10 to 40 mg daily.[40] A brief mention is made in a review that, in healthy subjects, the pharmacokinetics of **ramipril** were unaffected by **indometacin** [dose not stated] given for 3 days.[36]

Mechanism

Some, but not all the evidence suggests that prostaglandins may be involved in the hypotensive action of ACE inhibitors, and that NSAIDs, by inhibiting prostaglandin synthesis, may partially antagonise the effect of ACE inhibitors. Another suggestion is that NSAIDs promote sodium retention and so blunt the blood pressure lowering effects of several classes of antihypertensive drugs, including ACE inhibitors. This interaction may be dependent on sodium status and on plasma renin, and so drugs that affect sodium status e.g. diuretics may possibly influence the effect. Therefore, the interaction does not occur in all patients. It may also depend on the NSAID, with indometacin being frequently implicated, and sulindac less so, as well as on the dosing frequency.[6]

Both NSAIDs and ACE inhibitors alone can cause renal impairment. In patients whose kidneys are under perfused, they may cause further deterioration in renal function when used together.[54] Impaired renal function is a risk factor for hyperkalaemia with ACE inhibitors.

Importance and management

The interaction between indometacin and ACE inhibitors is well established, with several studies showing that indometacin can reduce the **blood pressure-lowering** effect of a number of ACE inhibitors. The interaction may not occur in all patients. If indometacin is required in a patient taking any ACE inhibitor, it would be prudent to monitor blood pressure. In a few small comparative studies, indometacin has been shown to have less effect on the calcium-channel blockers amlodipine, felodipine, and nifedipine, than on enalapril.[24,27,28] Therefore, a calcium-channel blocker may sometimes be an alternative to an ACE inhibitor in a patient requiring indometacin. Consider also, 'Calcium-channel blockers + Aspirin or NSAIDs', p.1027.

Limited information suggests that sulindac has little or no effect on ACE inhibitors, and may therefore be less likely to cause a problem, but further study is needed. The coxibs appear to have similar or greater effects on ACE inhibitors than conventional NSAIDs.

Although information about other NSAIDs is limited, the mechanism suggests that all of them are likely to interact similarly. Until more is known, it may be prudent to increase blood pressure monitoring when any NSAID is added or discontinued in a patient taking any ACE inhibitor, and intermittent use of NSAIDs should be considered as a possible cause of erratic control of blood pressure. In addition, sodium status and therefore diuretic use may affect any interaction. However, some consider that the clinical importance of an interaction between NSAIDs and antihypertensives is less than has previously been suggested.[55] While their findings do not rule out a 2/1 mmHg increase in blood pressure with NSAIDs in treated hypertensives, they suggest that if patients in primary care have inadequate control of blood pressure, other reasons may be more likely than any effect of concurrent NSAIDs.[55] Further study is needed. For the effects of NSAIDs on other antihypertensive drug classes see 'Beta blockers + Aspirin or NSAIDs', p.997, 'Calcium-channel blockers + Aspirin or NSAIDs', p.1027, and 'Thiazide diuretics + NSAIDs', p.1138.

There is an increased risk of **deterioration in renal function** or acute renal failure with the combination of NSAIDs and ACE inhibitors, especially if poor renal perfusion is present. Renal function should be monitored periodically in patients taking ACE inhibitors with NSAIDs, particularly in volume depleted patients. In a statement, the American Heart Association comments that acute renal failure complicating the use of an ACE inhibitor is almost always reversible and repletion of extracellular fluid volume and discontinuation of any diuretic is the best approach. In addition, withdrawal of interacting drugs, supportive management of fluid and electrolytes, and temporary dialysis, where indicated, are the mainstays of treatment.[56] The Australian Adverse Drug Reactions Advisory Committee consider that the triple combination of ACE inhibitors, diuretics and NSAIDs (including coxibs) should be avoided if possible, and that great care should be taken when giving ACE inhibitors and NSAIDs to patients with renal impairment.[47] Deterioration in renal function increases the risk of **hyperkalaemia**.

ACE inhibitors and other antihypertensives + Orlistat

In a handful of cases, patients taking enalapril and/or losartan and other antihypertensive drugs (amlodipine, atenolol, hydrochlorothiazide) had marked increases in blood pressure, hypertensive crises and, in one case, intracranial haemorrhage, within 7 to 60 days of starting orlistat.

Clinical evidence

The Argentinian System of Pharmacovigilance identified the following 3 cases of a possible interaction of orlistat with antihypertensives. An obese man whose hypertension was controlled at 120/80 mmHg with daily doses of **losartan** 100 mg, **atenolol** 100 mg, and **hydrochlorothiazide** 12.5 mg developed a hypertensive crisis (BP 260/140 mmHg) 7 days after starting to take orlistat 120 mg three times daily. The orlistat was stopped and the crisis was controlled. When later rechallenged with orlistat, his diastolic blood pressure rose to 100 to 110 mmHg after 5 days, but the systolic blood pressure increased only slightly. His blood pressure returned to baseline values 3 days after stopping the orlistat.[1] Two other patients reacted similarly. One whose blood pressure was controlled at 130/85 mmHg with **enalapril** 20 mg daily and **losartan** 50 mg daily developed an intracranial haemorrhage and hypertension (BP 160/100 mmHg) with occasional systolic peaks of around 200 mmHg one week after starting orlistat 120 mg three times daily. The other patient who was taking **enalapril** 20 mg daily and **amlodipine** 5 mg daily began to develop hypertensive peaks (BP 180/120 mmHg) 60 days after starting orlistat 120 mg twice daily. The hypertension responded when his medication was changed to **losartan** with **hydrochlorothiazide**, but 20 days later new hypertensive peaks developed (BP 180/110 to 120 mmHg). When the orlistat was withdrawn, the hypertension was controlled within 48 hours.[1]

The Uppsala Adverse Drug Reaction database has two reports of aggravated hypertension in women taking antihypertensives and orlistat.[1] Hypertension has also been reported in previously normotensive individuals taking orlistat, which, in one case, responded to stopping orlistat.[2,3]

However, the manufacturer has found no evidence of an association between orlistat and hypertension. In clinical studies, orlistat use was associated with a small reduction in blood pressure compared with placebo, which was as a result of weight reduction. Moreover, the incidence of hypertension of new onset and hypertensive crisis did not differ between orlistat and placebo (1.2% versus 1.3%, and 0% versus 0.1%, respectively).[4] In studies in healthy subjects, orlistat had no effect on steady-state **losartan** pharmacokinetics,[5] and no clinically significant effect on the pharmacokinetics of single-dose **captopril**, **atenolol**, **furosemide** or **nifedipine**.[6]

Mechanism

Not understood. Suggestions include a decrease in the absorption of the drugs due to accelerated gastrointestinal transit, increased defaecation, diarrhoea, or an increase in the amount of fat in the chyme.[1] An explanation for the difference between the clinical cases and pharmacokinetic studies may be that the latter tended to be single-dose studies in healthy subjects. Alternatively, these cases could just be idiosyncratic and not related to orlistat treatment.

Importance and management

The interactions between the antihypertensives and orlistat seem to be confined to the reports cited here, and their general significance is unclear. Given that the manufacturers report that specific drug interaction studies have not found any evidence of an interaction, the incidence seems likely to be small.

ACE inhibitors + Potassium compounds

ACE inhibitors maintain serum potassium levels. Hyperkalaemia is therefore possible if potassium supplements or potassium-containing salt substitutes are given, particularly in those patients where other risk factors are present.

Clinical evidence

(a) Potassium levels increased by concurrent use

1. Potassium supplements. The serum potassium levels of a patient taking a potassium supplement rose by 66% when **captopril** was added, with signs of a deterioration in renal function. Four other patients taking potassium supplements and furosemide (2 also taking unnamed potassium-sparing diuretics) had rises in their potassium levels of only 8 to 24% when given **captopril**. The rises occurred within one or 2 days. No clinical signs or symptoms of hyperkalaemia were seen, but 3 of the 5 patients had rises to above the upper limits of normal.[1] A post-marketing survey identified 10 patients in whom **enalapril** appeared to have been associated with renal impairment and death. Eight of them were also taking potassium supplements and/or potassium-sparing diuretics, and hyperkalaemia appeared to have been the immediate cause of death in two of them.[2] In a review of 47 patients taking **enalapril** for heart failure, and who experienced serious hyperkalaemia, 8 had also received potassium supplements.[3]
In another survey of 53 patients taking ACE inhibitors who had hyperkalaemia in the absence of significant renal impairment, less than 5% were taking a potassium supplement, but 30% were using a potassium-containing salt substitute (see *Dietary potassium*, below).[4]

2. Dietary potassium. Two patients with renal impairment, one taking **lisinopril** and the other taking **enalapril**, developed marked hyperkalaemia shortly after starting to take '*Lo salt*' (a salt substitute containing 34.6 g potassium in every 100 g). One developed a life-threatening arrhythmia.[5] A similar report describes a man taking **captopril** who developed hyperkalaemia and collapsed 2 weeks after starting to use a salt substitute containing potassium.[6] In a further report, severe hyperkalaemia occurred in a patient receiving a very-low-calorie diet with a protein supplement who was taking **lisinopril** 10 mg daily. The protein supplement contained 48 mmol of potassium, and salad topped with lemon juice and potassium chloride salt added at least another 72 mmol of potassium daily.[7] In 53 patients taking ACE inhibitors who had hyperkalaemia in the absence of significant renal impairment, 30% were using a salt substitute, and 72% were eating a moderate-to-high potassium diet, consisting of 2 or more servings of a potassium-rich food daily.[4] Hyperkalaemia and acute renal failure has also been reported in a diabetic patient taking **lisinopril** 20 mg twice daily following the use of a potassium-based water softener.[8]

(b) Potassium levels unaltered by concurrent use

A retrospective analysis of 14 patients without renal impairment taking potassium supplements and either furosemide or hydrochlorothiazide, found that the levels of serum potassium, during a 4-year period, had not significantly increased after the addition of **captopril**.[9] Another study in 6 healthy subjects found that intravenous potassium chloride caused virtually the same rise in serum potassium levels in those given **enalapril** as in those given a placebo.[10]

Mechanism

The potassium-retaining effects of the ACE inhibitors (due to reduced aldosterone levels) are additive with an increased intake of potassium, particularly when there are other contributory factors such as poor renal function or diabetes.

Importance and management

The documentation of this interaction appears to be limited, but it is well established. In practice, a clinically relevant rise in potassium levels usually occurs only if other factors are also present, the most important of which is impaired renal function. In general, because ACE inhibitors have potassium-sparing effects, potassium supplements should not routinely be given concurrently. If a supplement is needed, serum potassium should be closely monitored. This is especially important where other possible contributory risk factors are known to be present. A retrospective study in hospitalised patients who developed hyperkalaemia found that risk factors associated with a rapid rate of increase in serum potassium levels in decreasing order of importance were: the use of potassium supplements, severe renal impairment, the use of ACE inhibitors or angiotensin II receptor antagonists, the use of potassium-sparing diuretics, and then diabetes mellitus. Further, the presence of two or more of these risk factors (e.g. the use of an ACE inhibitor and a potassium supplement) was associated with an even faster rate of development of hyperkalaemia. As the rate of development of hyperkalaemia is also correlated with its severity, the authors recommend close monitoring in patients with two or more risk factors, and that a rapid increase in serum potassium (greater than 0.5 mmol/L per day) should prompt the identification and possible removal of any risk factors for hyperkalaemia.[11]

Other sources of dietary potassium should also be borne in mind. Patients with heart disease and hypertension are often told to reduce their salt (sodium) intake. One way of doing this is to use potassium-containing salt substitutes. However, it appears that there is some risk associated with excess use of these substitutes, especially in patients taking ACE inhibitors.

ACE inhibitors + Probenecid

Probenecid decreases the renal clearance of captopril and enalapril.

Clinical evidence, mechanism, importance and management

In 4 healthy subjects the steady-state levels of unchanged and total **captopril**, given by intravenous infusion, were slightly increased (by 14% and 36%, respectively) by the use of probenecid. Renal clearance of unchanged **captopril** decreased by 44%, but total clearance was reduced by only 19%.[1] These moderate changes are unlikely to be clinically important.

In 12 healthy subjects probenecid 1 g twice daily for 5 days increased the AUC of a single 20-mg oral dose of **enalapril** and its active metabolite, enalaprilat by about 50%. The renal clearance of **enalapril** was decreased

by 73%.[2] A moderate increase in the hypotensive effects might be expected, but there do not appear to be any reports of adverse effects.

ACE inhibitors + Procainamide

The combination of captopril or other ACE inhibitors and procainamide possibly increases the risk of leucopenia. No pharmacokinetic interaction occurs between captopril and procainamide.

Clinical evidence, mechanism, importance and management

In 12 healthy subjects the concurrent use of **captopril** 50 mg twice daily and procainamide 250 mg every 3 hours did not affect the pharmacokinetics of either drug.[1] A study in 9 patients undergoing treatment for heart failure (including 8 who were taking ACE inhibitors) found that the pharmacokinetics of a single intravenous dose of procainamide 750 mg and its metabolite *N*-acetylprocainamide were not significantly different to the pharmacokinetics in 7 matched control subjects without left ventricular dysfunction (one taking an ACE inhibitor). However, there was wider interpatient variation in pharmacokinetic parameters in the patients with heart failure.[2] The US manufacturer of **captopril** noted that in patients with heart failure who developed neutropenia, about 50% had a serum creatinine of about 140 micromol/L or greater, and more than 75% were also receiving procainamide.[3] Similarly, the UK manufacturer of **captopril** notes that neutropenia or agranulocytosis and serious infection have occurred in patients taking **captopril**, and that the concurrent use of procainamide may be a complicating factor. They recommend that the combination should be used with caution, especially in patients with renal impairment. They suggest that differential white blood cell counts should be performed before concurrent use, then every 2 weeks in the first 3 months of treatment and periodically thereafter.[4] The UK manufacturers of a number of other ACE inhibitors suggest that the concurrent use of ACE inhibitors and procainamide may lead to an increased risk of leucopenia.

For reports of other possible interactions with ACE inhibitors that might result in an increased risk of leucopenia see also 'ACE inhibitors + Allopurinol', p.13 and 'ACE inhibitors + Azathioprine', p.18.

ACE inhibitors + Rifampicin (Rifampin)

An isolated report describes a rise in blood pressure in one hypertensive patient, which was attributed to an interaction between enalapril and rifampicin. Rifampicin may reduce the plasma levels of the active metabolites of imidapril and spirapril.

Clinical evidence

A man taking **enalapril** and a variety of other drugs (warfarin, acebutolol, bendroflumethiazide, dipyridamole, metoclopramide and *Gaviscon*) developed a fever. He was given streptomycin, oxytetracycline and rifampicin, because of a probable *Brucella abortus* infection, whereupon his blood pressure rose from 164/104 mmHg to 180/115 mmHg over the next 5 to 6 days. It was suspected that an interaction with the rifampicin was possibly responsible. Subsequent studies in the same patient found that rifampicin, reduced the $AUC_{0\text{-}7}$ of enalaprilat, the active metabolite of **enalapril**, by 31%, although the AUC of **enalapril** was unchanged.[1] There is also the hint of this interaction in another report, where **enalapril** did not control blood pressure in a patient taking rifampicin.[2]

The manufacturer of **spirapril** briefly noted in a review that the use of rifampicin with **spirapril** modestly decreased plasma levels of **spirapril** and its active metabolite, spiraprilat.[3] The manufacturer of **imidapril** notes that rifampicin reduces the plasma levels of imidaprilat, the active metabolite of **imidapril**.[4]

Mechanism

The mechanism of this interaction is not clear, because rifampicin is a potent liver enzyme inducer, which might have been expected to cause the production of more, rather than less, of the active metabolites of these ACE inhibitors. However, the authors of one of the reports postulated that the rifampicin might have increased the loss of the enalaprilat in the urine,[1] and others suggested that rifampicin causes a non-specific stimulation of the elimination of spiraprilat.[3]

Importance and management

The general importance of these interactions is uncertain. The isolated reports with enalapril suggest minor clinical relevance. The manufacturers of spirapril did not consider the modest pharmacokinetic changes to be clinically relevant.[3] However, the manufacturers of imidapril state that rifampicin might reduce the antihypertensive efficacy of imidapril,[4] but this awaits clinical assessment.

ACE inhibitors + Sevelamer

Sevelamer did not alter the pharmacokinetics of enalapril in one study.

Clinical evidence, mechanism, importance and management

In 28 healthy subjects the concurrent use of a single 2.418-g dose of sevelamer hydrochloride (equivalent to 6 capsules) did not alter the AUC of a single 20-mg dose of **enalapril** or its active metabolite, enalaprilat.[1] Thus it appears that sevelamer does not bind to **enalapril** within the gut to reduce its absorption. Other ACE inhibitors would not be expected to interact with sevelamer, but this needs confirmation.

1. Burke SK, Amin NS, Incerti C, Plone MA, Lee JW. Sevelamer hydrochloride (Renagel®), a phosphate-binding polymer, does not alter the pharmacokinetics of two commonly used antihypertensives in healthy volunteers. *J Clin Pharmacol* (2001) 41, 199–205.

ACE inhibitors + Sibutramine

Sibutramine has only a minimal effect on blood pressure control with ACE inhibitors.

Clinical evidence, mechanism, importance and management

In a randomised, double-blind study over 52 weeks in 220 obese, hypertensive patients, whose hypertension was well controlled with an ACE inhibitor (**benazepril**, **enalapril** or **lisinopril**) with or without a thiazide diuretic, two-thirds of the patients were also given sibutramine and one-third were given placebo. Sibutramine 20 mg daily caused small increases in mean blood pressure compared with placebo (133.1/85.5 mmHg compared with 130.4/82.8 mmHg, at 52 weeks, respectively), but overall, hypertension remained well controlled.[1] Another double-blind, placebo-controlled study in 86 obese patients taking ACE inhibitors and/or other antihypertensives, found that sibutramine 10 mg daily for 6 months reduced ventricular mass, but caused no significant alterations in blood pressure, although average heart rate increased from 78 to 82 bpm.[2] No

particular precautions therefore seem necessary if patients taking ACE inhibitors are given sibutramine.

Angiotensin II receptor antagonists + Aliskiren

The concurrent use of irbesartan, or valsartan with aliskiren does not result in clinically significant pharmacokinetic interactions. However, the concurrent use of aliskiren and angiotensin II receptor antagonists may increase the risk of hyperkalaemia. The concurrent use of irbesartan or valsartan with aliskiren results in a greater reduction in blood pressure.

Clinical evidence, mechanism, importance and management

In a study, 11 patients with mild to moderate renal impairment and 17 healthy subjects were given aliskiren 300 mg daily for 7 days. **Irbesartan** 300 mg daily was then started, and both drugs were given for a further 7 days. The steady-state pharmacokinetics of aliskiren were not affected by the concurrent use of **irbesartan**.[1]

In a study in 23 patients with hypertension, the addition of aliskiren 75 or 150 mg daily to **irbesartan** 150 mg for 3 weeks resulted in lower night-time blood pressures, when compared with **irbesartan** alone, and there was a non-significant reduction in daytime blood pressure with aliskiren 75 mg daily. There was a trend for both daytime and night-time blood pressures to rise rather than fall when the dose of aliskiren was increased from 75 to 150 mg daily, but these changes were not statistically significant. The plasma levels of aliskiren were not affected by **irbesartan**.[2]

In another study, 18 healthy subjects were given **valsartan** 320 mg daily with aliskiren 300 mg daily for 4 days. When compared with the use of either drug alone, **valsartan** decreased the AUC and peak plasma levels of aliskiren by 26% and 28%, respectively, and aliskiren decreased the AUC and peak plasma levels of **valsartan** by 14% and 12%, respectively.[3] These pharmacokinetic changes were not considered to be clinically relevant.[3]

The concurrent use of aliskiren and angiotensin II receptor antagonists does not appear to result in clinically significant pharmacokinetics interactions (seen with **valsartan** and **irbesartan**). However, as would be expected, concurrent use does appear to result in an increased blood pressure-lowering effect, which would generally be considered desirable. Nevertheless, be alert for a greater than desired hypotensive effect. Also note that, the manufacturer of aliskiren warns that patients receiving other drugs that inhibit the renin-angiotensin system, and/or those with reduced renal function and/or diabetes are at an increased risk of hyperkalaemia during the use of aliskiren.[4] This is presumably based on the results of a study with ramipril, see 'ACE inhibitors + Aliskiren', p.13.

Angiotensin II receptor antagonists + Antacids

Aluminium/magnesium hydroxide-containing antacids slightly reduce irbesartan and olmesartan absorption.

Clinical evidence, mechanism, importance and management

(a) Irbesartan

In a single-dose, crossover study in 18 healthy subjects, 10 mL of an antacid containing **aluminium/magnesium hydroxide** (*Unimaalox*) given with, or 2 hours before, a single 300-mg dose of irbesartan had little effect on irbesartan pharmacokinetics. The only difference was that the AUC of irbesartan was reduced by 10% when the antacid was given 2 hours before the irbesartan, when compared with irbesartan alone. However, this change is not considered to be clinically relevant.[1]

(b) Olmesartan

The steady-state AUC of olmesartan 20 mg daily was 12% lower when it was given 15 minutes after a daily dose of an **aluminium/magnesium hydroxide** antacid, when compared with olmesartan alone, but this was not considered to be clinically significant.[2]

2. Laeis P, Püchler K, Kirch W. The pharmacokinetic and metabolic profile of olmesartan medoxomil limits the risk of clinically relevant drug interaction. *J Hypertens* (2001) 19 (Suppl 1), S21–S32.

Angiotensin II receptor antagonists + Aspirin or NSAIDs

Indometacin may attenuate the antihypertensive effect of losartan, valsartan, or other angiotensin II receptor antagonists. However, low-dose aspirin does not appear to alter the antihypertensive effect of losartan. No clinically relevant *pharmacokinetic* interactions occur between telmisartan and ibuprofen, or between valsartan and indometacin. The combination of an NSAID and angiotensin II receptor antagonist can increase the risk of renal impairment and hyperkalaemia.

Clinical evidence

A. Effects on blood pressure

Various large epidemiological studies and meta-analyses of clinical studies have been conducted to assess the effect of NSAIDs on blood pressure in patients treated with antihypertensives, and the findings of these are summarised in 'Table 23.2', (p.1027). In these studies, NSAIDs were not always associated with an increase in blood pressure, and the maximum increase was 6.2 mmHg.

(a) Aspirin

A double-blind, placebo-controlled study in 10 patients with hypertension taking **losartan** (mean daily dose 47.5 mg) found that both aspirin 81 mg daily and aspirin 325 mg daily for 2 weeks did not have a significant effect on blood pressure.[1]

(b) Indometacin

In a study in 111 patients with hypertension, **losartan** 50 mg daily for 6 weeks reduced their blood pressure by a mean of 7.9/5.3 mmHg. Indometacin 75 mg daily was then added for one week and this caused a rise in blood pressure in the group as a whole of 3.8/2.2 mmHg (reduction of about 45% in the effect of **losartan**). A rise in ambulatory diastolic blood pressure was seen in 69% of the patients taking **losartan** during indometacin use.[2] In contrast, a much smaller study in 10 patients with essential hypertension taking **losartan** found that indometacin 50 mg twice daily for one week caused sodium and fluid retention, but did not significantly attenuate the antihypertensive effects of **losartan**.[3]

In a placebo-controlled, crossover study in 56 hypertensive patients whose blood pressure was adequately controlled by **valsartan** 80 to 160 mg daily, the addition of indometacin 50 mg twice daily for 2 weeks produced an increase in mean blood pressure of 2.1/1.9 mmHg.[4] A study in normotensive subjects given a fixed sodium intake and **valsartan** 80 mg daily, with or without indometacin 50 mg twice daily for one week, found that indometacin reduced the natriuretic response to angiotensin receptor blockade.[5]

B. Effects on renal function

In 2002, 28 of 129 reports to the Australian Adverse Drug Reactions Advisory Committee of acute renal failure were associated with the concurrent use of ACE inhibitors or angiotensin II receptor antagonists, diuretics, and NSAIDs (including coxibs), and these cases had a fatality rate of 10%. In patients taking this triple combination, renal failure appeared to be precipitated by mild stress such as diarrhoea or dehydration. In other patients, the addition of a third drug (usually an NSAID) to a stable combination of the other two, resulted in acute renal failure.[6] In a multivariate analysis,

the use of an ACE inhibitor or angiotensin II receptor antagonist, and NSAIDs or diuretics was associated with significant renal impairment when two or more drugs from these groups was taken.[7]

C. Pharmacokinetic studies

(a) Ibuprofen

In a crossover study in 12 healthy subjects, **telmisartan** 120 mg daily had no effect on the pharmacokinetics of ibuprofen 400 mg three times daily for 7 days. Similarly, the pharmacokinetics of **telmisartan** were unaffected by the concurrent use of ibuprofen, when compared with previous studies of telmisartan alone.[8]

(b) Indometacin

In 12 healthy subjects, the pharmacokinetics of single oral doses of **valsartan** 160 mg or indometacin 100 mg were not significantly changed when the drugs were given together, although the pharmacokinetics of valsartan showed wide variations between subjects.[9]

Mechanism

Some evidence suggests that prostaglandins may be partially involved in the hypotensive action of angiotensin II receptor antagonists, and that NSAIDs, by inhibiting prostaglandin synthesis, may antagonise their effects. However, a non-specific mechanism such as sodium retention may also be involved, as indometacin has been shown to reduce the hypotensive effect of other classes of antihypertensive drugs.[4,5] Both NSAIDs and angiotensin II receptor antagonists alone can cause renal impairment: in patients whose kidneys are under perfused, they may cause further deterioration in renal function if they are used together. Renal impairment increases the risk of hyperkalaemia.

Importance and management

As with other antihypertensives, the **blood pressure-lowering effect** of angiotensin II receptor antagonists may be attenuated by NSAIDs such as indometacin. Patients taking losartan or valsartan or other angiotensin II receptor antagonists, who require indometacin and probably other NSAIDs, should be monitored for alterations in blood pressure control. Low-dose aspirin is unlikely to alter the blood pressure-lowering effect of angiotensin II receptor antagonists. However, for a discussion of the controversy as to whether low-dose aspirin might attenuate the benefits of *ACE inhibitors* in patients with heart failure, see 'ACE inhibitors + Aspirin', p.15.

Poor renal perfusion may increase the risk of **renal failure** if angiotensin II receptor antagonists are given with NSAIDs and so regular hydration of the patient and monitoring of renal function is recommended.[10] The Australian Adverse Drug Reactions Advisory Committee consider that the triple combination of angiotensin II receptor antagonists or ACE inhibitors with diuretics and NSAIDs (including coxibs) should be avoided if possible.[6]

Angiotensin II receptor antagonists + Azoles

Fluconazole reduces the conversion of losartan to its active metabolite and decreases the metabolism of irbesartan. Fluconazole is unlikely to affect the pharmacokinetics of other angiotensin II receptor antagonists; one study found it does not appear to influence the pharmacokinetics of eprosartan. Itraconazole does not significantly affect the pharmacokinetics or antihypertensive effects of losartan, and ketoconazole does not affect the pharmacokinetics of eprosartan or losartan.

Clinical evidence, mechanism, importance and management

(a) Fluconazole

In a study, healthy subjects were given **losartan** 100 mg daily (16 subjects) and **eprosartan** 300 mg twice daily (16 subjects) for 20 days, with fluconazole 200 mg daily on days 11 to 20. Fluconazole increased the AUC and maximum plasma levels of **losartan** by 69% and 31%, respectively, and reduced those of E-3174, the active metabolite of **losartan**, by 41% and 54%, respectively. However, fluconazole had no significant effect on the pharmacokinetics of **eprosartan**.[1] In a randomised, crossover study, 11 healthy subjects were given a single 50-mg dose of **losartan** after taking fluconazole (400 mg on day one and 200 mg daily on days 2 to 4). The AUC of **losartan** was increased by 27% while its maximum plasma level was reduced by 23%. The AUC and the maximum plasma levels of E-3174 were reduced by 47% and 77%, respectively. However, no significant changes in the hypotensive effect of **losartan** were noted.[2]

A study in 15 healthy subjects given **irbesartan** 150 mg daily for 20 days found that fluconazole 200 mg daily on days 11 to 20 increased the steady-state AUC and maximum levels by about 55% and 18%, respectively.[3]

It is thought that fluconazole inhibits the conversion of **losartan** to its active metabolite mainly by inhibiting the cytochrome P450 isoenzyme CYP2C9,[1,2,4,5] although other isoenzymes may play a minor role. Similarly, **irbesartan** is primarily metabolised by CYP2C9,[6] and is therefore also affected by fluconazole.[3]

The lack of pharmacodynamic changes with **losartan** and fluconazole suggests that the pharmacokinetic interaction may not be clinically important, but the possibility of a decreased therapeutic effect should be kept in mind.[2]

The modest increases in **irbesartan** levels were considered unlikely to be clinically relevant and a dose reduction would not generally be required.[7]

Other angiotensin II receptor antagonists would not be expected to interact, see the 'introduction', (p.12), to this section.

(b) Itraconazole

In 11 healthy subjects the pharmacokinetics and hypotensive effects of a single 50-mg dose of **losartan** and its active metabolite, E-3174, were not significantly affected by itraconazole 200 mg daily for 4 days.[2] Inhibition of the cytochrome P450 isoenzyme CYP3A4 alone (caused by itraconazole) does not appear to prevent the conversion of **losartan** to E-3174. No special precautions would appear to be needed if these drugs are used concurrently.

(c) Ketoconazole

A placebo-controlled, crossover study in 11 healthy subjects given a single 30-mg intravenous dose of **losartan**, found that ketoconazole 400 mg daily for 4 days did not affect the conversion of **losartan** to its active metabolite, E-3174, or the plasma clearance of **losartan**.[8] Inhibition of the cytochrome P450 isoenzyme CYP3A4 alone (caused by ketoconazole) does not appear to prevent the conversion of **losartan** to E-3174.

The plasma clearance of a 20-mg intravenous dose of E-3174, the active metabolite of losartan, was also unaffected by pretreatment with ketoconazole.[8] Similarly, in a study involving 27 healthy subjects, ketoconazole 200 mg daily for 5 days was found to have no effect on the pharmacokinetics of **eprosartan** or **losartan** and its active metabolite.[9] No special precautions would appear to be needed if these drugs are used concurrently.

Angiotensin II receptor antagonists + Beta blockers

There appears to be no clinically significant pharmacokinetic interaction between atenolol and valsartan, and, as expected, concurrent use enhances the blood pressure-lowering effects. The combination of angiotensin II receptor antagonists and beta blockers is in established clinical use.

Clinical evidence, mechanism, importance and management

In a single-dose, crossover study in 12 healthy subjects, the pharmacokinetics of **valsartan** 160 mg and **atenolol** 100 mg were not significantly altered by concurrent use. The combination had some additive effects on resting blood pressure.[1]

Although pharmacokinetic information is apparently limited to this drug pair, no significant adverse pharmacokinetic interaction would be expected between angiotensin II receptor antagonists and beta blockers, and the combination is clinically useful in a number of cardiovascular disorders.

1. Czendlik CH, Sioufi A, Preiswerk G, Howald H. Pharmacokinetic and pharmacodynamic interaction of single doses of valsartan and atenolol. *Eur J Clin Pharmacol* (1997) 52, 451–9.

Angiotensin II receptor antagonists + Calcium-channel blockers

No significant pharmacokinetic interactions occur between nifedipine and candesartan or irbesartan, or between amlodipine and olmesartan, telmisartan or valsartan. Nisoldipine increases the exposure to telmisartan. Calcium-channel blockers have been given uneventfully with eprosartan, irbesartan, losartan, and telmisartan.

Clinical evidence, mechanism, importance and management

(a) Amlodipine

1. Losartan. A double-blind study in 198 patients with hypertension found that a fixed combination of amlodipine 5 mg with losartan 100 mg compared favourably in terms of blood pressure control and tolerability with either amlodipine 10 mg or losartan 100 mg given alone.[1]

2. Olmesartan. Analysis of data from four phase I studies in healthy subjects and one phase III study in patients with hypertension found that the clearance of olmesartan and amlodipine were not significantly affected on concurrent use. The effect of both drugs in combination was greater than either drug alone, but slightly less than the sum of the effects of each drug.[2]

3. Telmisartan. In a study in 12 healthy subjects, telmisartan 120 mg daily had no clinically relevant effect on the pharmacokinetics of amlodipine 10 mg daily for 9 days, and there was no evidence of any marked effect of amlodipine on the pharmacokinetics of telmisartan. Although there were no serious adverse effects, mild to moderate adverse events (most commonly headache) occurred slightly more frequently with the combination, compared with amlodipine alone (19 events versus 12 events).[3] A placebo-controlled study in patients with moderate or severe hypertension found that combinations of telmisartan 40 to 80 mg with amlodipine 5 to 10 mg were effective at lowering blood pressure and the number of patients with adverse effects was comparable between combination and monotherapy groups.[4]

4. Valsartan. In 12 healthy subjects the pharmacokinetics of single oral doses of valsartan 160 mg and amlodipine 5 mg were not significantly altered by concurrent use, although the pharmacokinetics of valsartan showed wide variations between subjects.[5]

(b) Nifedipine

In 12 healthy subjects nifedipine 30 mg daily did not significantly affect the pharmacokinetics of **candesartan** 16 mg daily.[6]

In vitro studies indicated that nifedipine inhibited the oxidation of **irbesartan**, which was mediated by the cytochrome P450 isoenzyme CYP2C9.[7] However, a randomised, crossover study in 11 healthy subjects given **irbesartan** 300 mg daily alone or with nifedipine 30 mg daily for 4 days, found that nifedipine did not alter the pharmacokinetics of **irbesartan**.[7] The manufacturer says that **irbesartan** has been safely given with antihypertensives such as long-acting calcium-channel blockers.[8] Similarly the manufacturer of **eprosartan** notes that it has been safely given with calcium-channel blockers (such as sustained-release nifedipine).[9]

(c) Nisoldipine

In a study, 37 patients with hypertension were given **telmisartan** 40 mg daily, nisoldipine 10 mg daily or both drugs together for 3 weeks. The doses were then increased to **telmisartan** 80 mg daily, nisoldipine 20 mg daily, or a combination of **telmisartan** 80 mg daily and nisoldipine 10 mg daily for a further 3 weeks. The AUC of **telmisartan** 80 mg was increased by 132% when it was given with nisoldipine 10 mg and its clearance was lower, compared with telmisartan alone. There was a non-significant trend towards higher maximum plasma levels and AUC of nisoldipine when it was given with **telmisartan**. **Telmisartan** alone or with nisoldipine significantly reduced blood pressure whereas, in this study, nisoldipine alone had only a minor effect on blood pressure. More study is required to confirm whether this pharmacokinetic interaction enhances antihypertensive efficacy with unchanged tolerability.[10]

Angiotensin II receptor antagonists + Diuretics; Loop, Thiazide and related

Symptomatic hypotension may occur when an angiotensin II receptor antagonist is started in patients taking high-dose diuretics. Potassium levels may be either increased, decreased or not affected. No clinically relevant pharmacokinetic interactions appear to occur between candesartan, eprosartan, irbesartan, losartan, olmesartan, telmisartan or valsartan and hydrochlorothiazide, although the bioavailability of hydrochlorothiazide may be modestly reduced. Similarly, there is no clinically significant pharmacokinetic interaction between valsartan and furosemide.

Clinical evidence, mechanism, importance and management

(a) Hypotension

Angiotensin II receptor antagonists and thiazide or related diuretics have useful additive effects in the control of hypertension and are generally well tolerated. For example, in one double-blind, placebo-controlled study in 604 patients with hypertension, **losartan** 50 mg given with **hydrochlorothiazide** 12.5 mg daily produced an additive reduction in trough sitting systolic and diastolic blood pressure, and the incidence of dizziness and headache was not significantly different from placebo.[1] However, symp-

tomatic hypotension, especially after the first dose, may occur when angiotensin II receptor antagonists are started in patients with heart failure or those with hypertension who also have sodium and/or volume depletion, such as those taking **high-dose diuretics**. It is recommended that any volume and/or sodium depletion should be corrected before the angiotensin II receptor antagonist is given. In some situations it may be appropriate to reduce the dose of the diuretic and/or use a lower starting dose of the angiotensin II receptor antagonist. A similar problem occurs with the ACE inhibitors, see 'ACE inhibitors + Diuretics; Loop, Thiazide and related', p.23.

(b) Pharmacokinetic studies

The changes in **furosemide** and **hydrochlorothiazide** pharmacokinetics appear to be of no practical importance, and the combination with an angiotensin II receptor antagonist can produce a significant and useful additional reduction in blood pressure. Details of these studies are given below.

1. Furosemide. In 12 healthy subjects, the relative bioavailability of furosemide 40 mg was reduced by about 26% when it was given with **valsartan** 160 mg. However, this pharmacokinetic interaction had no influence on the diuretic effect of furosemide. The simultaneous use of **valsartan** and furosemide did not modify the pharmacokinetics of **valsartan**.[2]

2. Hydrochlorothiazide. In 18 healthy subjects the concurrent use of hydrochlorothiazide 25 mg daily and **candesartan** 12 mg daily for 7 days increased the AUC and maximum serum levels of **candesartan** by 18% and 23%, respectively, and reduced the AUC of hydrochlorothiazide by 14%, but these changes were not considered to be clinically relevant.[3]
In 18 healthy subjects **eprosartan** 800 mg decreased the AUC of hydrochlorothiazide 25 mg by about 20%, but this was not considered to be clinically important. In addition, hydrochlorothiazide had no effect on **eprosartan** pharmacokinetics.[4]
In a study in 12 patients with mild or moderate hypertension given **losartan** 50 mg alone or with hydrochlorothiazide 12.5 mg daily for 7 days, the AUC of hydrochlorothiazide was decreased by 17% during concurrent use (not clinically significant) while the pharmacokinetics of **losartan** were unchanged.[5]
A single-dose study in 12 healthy subjects found that **valsartan** 160 mg reduced the systemic availability of hydrochlorothiazide 25 mg (AUC decreased by 31%), but the mean amount of hydrochlorothiazide excreted in the urine did not seem to change significantly. The pharmacokinetics of **valsartan** were not significantly affected by hydrochlorothiazide.[6]
In a randomised, crossover study in 13 healthy subjects, **telmisartan** 160 mg daily was given with hydrochlorothiazide 25 mg daily for 7 days. There was no difference in AUC and maximum plasma concentrations of either drug compared with when they were given alone.[7]
No clinically significant pharmacokinetic interactions have been found between **irbesartan**[8] or **olmesartan**[9] and hydrochlorothiazide.

(c) Serum potassium levels

Angiotensin receptor II antagonists are potassium sparing, whereas loop and thiazide diuretics are potassium depleting. Giving an angiotensin receptor II antagonist with a diuretic could result in an increase, a decrease, or no change to the potassium levels, although logically adding an angiotensin II receptor antagonist to established treatment with a diuretic would seem more likely to raise potassium, and vice versa. Serum potassium should be routinely monitored when angiotensin II antagonists are used in patients with heart failure, renal impairment, or in the elderly.

Angiotensin II receptor antagonists + Diuretics; Potassium-sparing

There is an increased risk of hyperkalaemia if angiotensin II receptor antagonists are given with potassium-sparing diuretics (such as amiloride and the aldosterone antagonists, eplerenone and spironolactone), particularly if other risk factors are also present.

Clinical evidence

In a study in 13 hypertensive patients aged 61 to 83 years with mild chronic heart failure, the concurrent use of **valsartan** 80 mg daily and spironolactone 100 mg daily was considered to be effective and safe. However in one patient, the serum potassium increased from 4.3 mmol/L to 5.8 mmol/L.[1]

An 84-year-old woman, taking several drugs including **losartan** 50 mg daily and spironolactone 25 mg daily, developed hyperkalaemia (potassium level 8.4 mmol/L), bradycardia, drowsiness and respiratory depression. She recovered after haemodialysis and ventilatory assistance.[2] There is also a report of life-threatening hyperkalaemia (9.4 mmol/L) in a patient with mild renal impairment given **candesartan** 8 mg daily and spironolactone 25 mg daily. Hyperkalaemia did not recur when she was given **candesartan** and a loop diuretic.[3]

Life-threatening hyperkalaemia occurred in 6 patients with congestive heart failure who were taking **spironolactone** and an angiotensin II receptor antagonist (**candesartan**, **losartan** or **telmisartan**). Analysis of these patients, together with another 38 similar patients who had received ACE inhibitors, identified certain conditions that may lead to the development of severe hyperkalaemia. These were advanced age, dose of **spironolactone** greater than 25 mg, reduced renal function and type 2 diabetes.[4]

A study in patients with chronic heart failure taking spironolactone 25 or 50 mg daily, furosemide and either enalapril, **candesartan** 8 mg daily, or **losartan** 50 mg daily, for 12 months, found that hyperkalaemia occurred in about 9% of patients In patients given furosemide 40 mg and **spironolactone** 25 mg daily, hypokalaemia occurred in 14.3% and 6.5% of patients taking **losartan** or **candesartan**, respectively, but did not occur when patients were given **spironolactone** 50 mg daily.[5]

Mechanism

Angiotensin II receptor antagonists reduce the levels of aldosterone, which results in the retention of potassium. This would be expected to be additive with the potassium-retaining effects of amiloride, triamterene, spironolactone and eplerenone, leading to hyperkalaemia, but usually only if other risk factors are present.

Importance and management

The concurrent use of potassium-sparing diuretics (namely **amiloride**, **triamterene** and the aldosterone antagonists **eplerenone** and spironolactone) may increase serum potassium. There is a greater risk of hyperkalaemia if renal impairment and/or heart failure or diabetes are present. Because angiotensin II receptor antagonists have potassium-sparing effects, amiloride and triamterene should not normally be given concurrently. Aldosterone antagonists such as spironolactone may be useful in heart failure, but the combined use of angiotensin II receptor antagonists requires increased monitoring of serum potassium. Note that the combination should be avoided in patients with a glomerular filtration rate of less than 30 mL/minute.[6]

A retrospective study in hospitalised patients who developed hyperkalaemia found that risk factors associated with a rapid rate of increase in serum potassium levels in decreasing order of importance were: the use of potassium supplements, severe renal impairment, the use of ACE inhibitors or angiotensin II receptor antagonists, the use of potassium-sparing diuretics, diabetes mellitus. Further, the presence of two or more of these risk factors is associated with an even faster development of hyperkalaemia. As the rate at which hyperkalaemia develops is also correlated with its severity, the authors recommend close monitoring in patients with two

or more risk factors, and that a rapid increase in serum potassium (greater than 0.5 mmol/L per day) should prompt the identification and possible removal of any risk factors for hyperkalaemia.[7] Hyperkalaemia associated with spironolactone is dose-related, but in the presence of an angiotensin II receptor antagonist, its occurrence may increase even if the dose of spironolactone is as low as 25 mg daily and so potassium levels should be closely monitored.[5] It has been recommended that the dose of spironolactone should not exceed 25 mg daily if an angiotensin II receptor antagonist is also given.[6]

The UK manufacturer of eplerenone says that caution is required when it is given with angiotensin II receptor antagonists, especially in renal impairment, and that potassium levels and renal function should be monitored.[8] This seems prudent.

Angiotensin II receptor antagonists + Food

Food slightly increases the AUC of eprosartan and losartan, slightly reduces the AUC of telmisartan, and modestly reduces the AUC of valsartan. Food has no effect on the AUC of candesartan, irbesartan or olmesartan.

Clinical evidence, mechanism, importance and management

(a) Candesartan

Food does not affect the bioavailability of candesartan,[1,2] and the manufacturer states that it may be given with or without food.

(b) Eprosartan

Food delays eprosartan absorption, and slightly increases its AUC and maximum plasma concentrations by up to 25%. The UK manufacturer recommends that eprosartan is given with food,[3] but the US manufacturer suggests that the change in absorption is not clinically significant, and that eprosartan may be taken with or without food.[4]

(c) Irbesartan

In a study in 16 healthy men, a high-fat breakfast had no clinically relevant effects on the bioavailability of a single 300-mg dose of irbesartan,[5] therefore it may be taken with or without food.

(d) Losartan

In a crossover study in healthy subjects, the AUC and maximum levels of a single 100-mg dose of losartan, given 30 minutes before a high-fat breakfast was increased by 17% and 35%, respectively, when compared with the fasted state. Food caused a less than 10% decrease in AUC and maximum level of the losartan metabolite, E-3174.[6] These minor changes are unlikely to be clinically significant, and the manufacturer says that losartan may be given with or without food.[7,8]

(e) Olmesartan

Food does not affect the bioavailability of olmesartan,[9,10] and the manufacturer states that it may be given with or without food.

(f) Telmisartan

Food slightly reduces the AUC of telmisartan by about 6 to 20% depending on dose,[11,12] but this would not be expected to cause a reduction in therapeutic efficacy, and telmisartan may be taken with or without food.[12]

(g) Valsartan

Food modestly decreased the AUC of valsartan by 40%,[13] but the manufacturer states that it may be taken with or without food.[13,14]

Angiotensin II receptor antagonists + H_2-receptor antagonists

Cimetidine may cause a small rise in valsartan levels, but did not significantly affect the pharmacokinetics and blood pressure-lowering effect of losartan in one study. Ranitidine does not appear to significantly alter the pharmacokinetics of eprosartan.

Clinical evidence, mechanism, importance and management

(a) Cimetidine

1. Losartan. In a randomised, crossover study in 8 healthy subjects, when losartan 100 mg was given after cimetidine 400 mg four times daily for 6 days, the pharmacokinetics and pharmacodynamics of losartan and its active metabolite, E-3174, were not changed to a clinically relevant extent, although there was a minor increase of 18% in the AUC of losartan.[1] No special precautions are needed if these drugs are used concurrently.

2. Valsartan. In a single-dose, crossover study, cimetidine 800 mg, given one hour before valsartan 160 mg, increased the initial rate of absorption of valsartan (attributed to a raised gastric pH) resulting in a roughly 50% increase in its maximum plasma concentration. However, the AUC was only slightly increased and there were large inter-subject variations in the pharmacokinetics of valsartan.[2] The changes in valsartan pharmacokinetics seen with cimetidine are unlikely to be clinically relevant.

(b) Ranitidine

A single 400-mg dose of **eprosartan** was given to 17 healthy subjects, both alone and after ranitidine 150 mg twice daily for 3 days. The ranitidine caused some slight changes in the pharmacokinetics of the **eprosartan** (maximum plasma concentration and AUC reduced by about 7% and 11%, respectively), but these were not statistically significant.[3]

Angiotensin II receptor antagonists + Mannitol

A report describes mannitol-induced acute renal failure in a diabetic patient taking losartan.

Clinical evidence, mechanism, importance and management

A man with diabetic nephropathy taking **losartan** 25 mg twice daily for hypertension developed acute renal failure after being given a total of 420 g of intravenous mannitol over 4 days for haemorrhagic glaucoma. The patient recovered after the mannitol and **losartan** were discontinued, and after receiving haemodialysis.[1] It is not fully understood why this combination caused acute renal failure, but it may result in a marked decrease in glomerular filtration rate. The general relevance of this isolated case in unclear, but the authors of the report recommend caution on concurrent use.[1]

1. Matsumura M. Mannitol-induced toxicity in a diabetic patient receiving losartan. *Am J Med* (2001) 110, 331.

Angiotensin II receptor antagonists + Potassium compounds

There may be a risk of hyperkalaemia if angiotensin II receptor antagonists are given with potassium supplements or potassium-containing salt substitutes, particularly in those patients where other risk factors are present.

Clinical evidence, mechanism, importance and management

Angiotensin II receptor antagonists are potassium-sparing, as a result of their effects on aldosterone, and their potential to cause clinically important hyperkalaemia is well established. The incidence of hyperkalaemia varies depending on the clinical indication and other disease conditions, being lowest in essential hypertension, and highest in heart failure, diabetes, and renal impairment. For example, the incidence of hyperkalaemia in clinical studies in patients with hypertension was 0.9% with **eprosartan**[1,2] and 1.5% with **losartan**;[3] in patients with type 2 diabetes with nephropathy, the incidence was 9.9% with **losartan**[3] and 18.6% with **irbesartan**;[4] and in those with heart failure the incidence was 6.3% with **candesartan**.[5]

A retrospective study in hospitalised patients who developed hyperkalaemia found that risk factors associated with a rapid rate of increase in serum potassium levels in decreasing order of importance were: the use of potassium supplements, severe renal impairment, the use of ACE inhibitors or angiotensin II receptor antagonists, the use of potassium-sparing diuretics, and then diabetes mellitus. Further, the presence of two or more of these risk factors is associated with an even faster rate of development of hyperkalaemia. As the rate of development of hyperkalaemia is also correlated with its severity, the authors recommend close monitoring in patients with two or more risk factors (which would include those taking potassium supplements with angiotensin II receptor antagonists), and that a rapid increase in serum potassium (greater than 0.5 mmol/L per day) should prompt the identification and possible removal of any risk factors for hyperkalaemia.[6]

Potassium supplements are generally unlikely to be needed in patients taking angiotensin II receptor antagonists, particularly if they have other risk factors for hyperkalaemia, and it may be prudent for such patients to be told to avoid using potassium-containing **salt substitutes**. If concurrent use is considered necessary, potassium levels should be closely monitored.

Angiotensin II receptor antagonists + Rifampicin (Rifampin)

Rifampicin increases the metabolism of losartan and its active metabolite, E-3174, which may result in reduced antihypertensive effects.

Clinical evidence, mechanism, importance and management

Ten healthy subjects were given **losartan** 50 mg daily for a week and then, after a 6-day washout period, **losartan** 50 mg daily with rifampicin 300 mg twice daily for a week. It was found that rifampicin reduced the AUC of **losartan** by 36%, reduced its half-life from 2 to 0.9 hours, and increased its clearance by 60%. The AUC of the active metabolite, E3174, was reduced by 41% and its half-life was reduced from 5.1 hours to 2.5 hours. Diastolic blood pressure was significantly reduced by **losartan** alone, but not by the combination.[1] The presumed reason for this interaction is that rifampicin (a recognised enzyme inducer) increases the metabolism of **losartan** to its active metabolite by the cytochrome P450 isoenzyme CYP2C9.

The clinical importance of this interaction still awaits assessment, but it would seem likely that the antihypertensive effects of **losartan** would be reduced by rifampicin. If both drugs are used, be alert for the need to increase the **losartan** dose. There seems to be no information regarding other angiotensin II receptor antagonists, but note that **irbesartan**, and to a limited extent **candesartan**, are also metabolised by CYP2C9 (see under 'ACE inhibitors and Angiotensin II receptor antagonists', (p.12)).

1. Williamson KM, Patterson JH, McQueen RH, Adams KF, Pieper JA. Effects of erythromycin or rifampin on losartan pharmacokinetics in healthy volunteers. *Clin Pharmacol Ther* (1998) 63, 316–23.

Angiotensin II receptor antagonists; Losartan + Amodiaquine

Amodiaquine inhibited the metabolism of losartan to its active metabolite, E-3174.

Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects found that amodiaquine 600 mg taken 2 to 3 hours before a single 25-mg dose of losartan, significantly increased the metabolic ratio of losartan to its metabolite by 72% compared with baseline values for losartan. This was due to decreases in the metabolism of losartan to its active metabolite, E-3174, by amodiaquine and/or its metabolite, *N*-desethylamodiaquine, which inhibit the cytochrome P450 isoenzyme CYP2C9.[1]

The clinical relevance of the findings of this study is unclear. The reduction in metabolism of losartan to its active metabolite might suggest that the therapeutic effects of losartan could be reduced. However, note that the effect of fluconazole (see 'Angiotensin II receptor antagonists + Azoles', p.39), which is a known potent inhibitor of CYP2C9, was probably not clinically relevant, which suggests the effect of amodiaquine is also unlikely to be clinically relevant.

1. Wennerholm A, Nordmark A, Pihlsgård M, Mahindi M, Bertilsson L, Gustafsson LL. Amodiaquine, its desethylated metabolite, or both, inhibit the metabolism of debrisoquine (CYP2D6) and losartan (CYP2C9) in vivo. *Eur J Clin Pharmacol* (2006) 62, 539–46.

Angiotensin II receptor antagonists; Losartan + AST-120

AST-120 does not appear to have an important effect on the pharmacokinetics of losartan.

Clinical evidence, mechanism, importance and management

When a single 100-mg dose of losartan was given 30 minutes before a high-fat breakfast, with AST-120 3 g three times daily for 48 hours started 30 minutes after the breakfast, the AUC of losartan was not significantly altered, although there was a minor 12% decrease in the maximum losartan level. Similarly, various other schedules (losartan with breakfast, then AST-120 started 30 minutes later, or AST-120 started 30 minutes after breakfast, then losartan given 30 minutes after that), did not significantly alter the AUC of losartan, when compared with losartan given 30 minutes before breakfast. However, there were minor to modest increases in the AUC of losartan (of up to 37%) when these schedules were compared with losartan given in the fasting state, which was attributed to the effect of food.[1]

AST-120 is a predominantly carbon-based oral absorbent, and might therefore interfere with absorption of other drugs. Data from this pharma-

cokinetic study indicate that AST-120 has minimal effects on the pharmacokinetics of losartan. The authors suggest that giving AST-120 one hour after losartan may be preferred.[1]

1. Marier JF, Guilbaud R, Kambhampati SR, Mathew P, Moberly J, Lee J, Salazar DE. The effect of AST-120 on the single-dose pharmacokinetics of losartan and losartan acid (E-3174) in healthy subjects. *J Clin Pharmacol* (2006) 46, 310–20.

Angiotensin II receptor antagonists; Losartan + Erythromycin

The pharmacokinetics and blood pressure-lowering effect of losartan do not seem to be affected by erythromycin.

Clinical evidence, mechanism, importance and management

When 10 healthy subjects were given losartan 50 mg daily for a week and then, after a 6-day washout period, losartan 50 mg daily with erythromycin 500 mg four times daily for a week, it was found that erythromycin had no significant effect on the pharmacokinetics of losartan or its active metabolite, E-3174. In addition, erythromycin did not alter the blood pressure-lowering effect of losartan.[1] Inhibition of the cytochrome P450 isoenzyme CYP3A4 alone does not appear to prevent the conversion of losartan to E-3174. There would therefore appear to be no reason to take any special precautions if both drugs are used concurrently.

1. Williamson KM, Patterson JH, McQueen RH, Adams KF, Pieper JA. Effects of erythromycin or rifampin on losartan pharmacokinetics in healthy volunteers. *Clin Pharmacol Ther* (1998) 63, 316–23.

Angiotensin II receptor antagonists; Losartan + Fluorouracil

Fluorouracil inhibits the metabolism of losartan to its active metabolite, E-3174, and the extent of inhibition appears to increase as the total cumulative dose of fluorouracil increases.

Clinical evidence, mechanism, importance and management

In a study, 17 patients with colorectal cancer, receiving fluorouracil 425 mg/m^2 and folinic acid as a one-hour infusion for at least 3 consecutive days for each cycle of treatment, were given a single 25-mg dose of losartan at least 2 days before the start of the first cycle of fluorouracil, and a further 25-mg dose on the last day of the cycle. Five of the patients also received losartan 25 mg at the end of the third cycle. The ratio of losartan to its active metabolite, E-3174, increased from an average of 0.5 to 0.64 (28%) after the first cycle of fluorouracil, but there was large interpatient variation (ranging between a 71% decrease and a 223% increase) with increases in 10 of the patients and no change in one patient. The metabolic ratio increased significantly after the third cycle of fluorouracil from 0.44 to 2.32 (a 5.3-fold increase) even though in 2 of the 5 patients the ratio had decreased after the first cycle of fluorouracil. Fluorouracil appears to inhibit the metabolism of losartan to E-3174 by cytochrome P450 isoenzyme CYP2C9 and the inhibition becomes more pronounced as the cumulative dose of fluorouracil is increased.[1]

The clinical relevance of the findings of this study is unclear. The reduction in metabolism of losartan to its active metabolite might suggest that the therapeutic effects of losartan could be reduced, but this remains to be established.

1. Gunes A, Coskun U, Boruban C, Gunel N, Babaoglu MO, Sencan O, Bozkurt A, Rane A, Hassan M, Zengil H, Yasar U. Inhibitory effect of 5-fluorouracil on cytochrome P450 2C9 activity in cancer patients. *Basic Clin Pharmacol Toxicol* (2006) 98, 197–200.

Angiotensin II receptor antagonists; Losartan + Grapefruit juice

Grapefruit juice has a minor effect on the pharmacokinetics of losartan and its active metabolite, E-3174.

Clinical evidence, mechanism, importance and management

In a study in 9 healthy subjects, grapefruit juice approximately doubled the time for a single 50-mg dose of losartan to be detected in the serum (from 40 minutes to 1.3 hours) and reduced the AUC of its active metabolite, E-3174, by 21%. Losartan is partly metabolised by the cytochrome P450 isoenzyme CYP3A4 and transported by P-glycoprotein, both of which can be affected by grapefruit juice. This may explain the minor changes seen.[1] However, this interaction is unlikely to be clinically relevant.

1. Zaidenstein R, Soback S, Gips M, Avni B, Dishi V, Weissgarten Y, Golik A, Scapa E. Effect of grapefruit juice on the pharmacokinetics of losartan and its active metabolite E3174 in healthy volunteers. *Ther Drug Monit* (2001) 23, 369–73.

Angiotensin II receptor antagonists; Losartan + Phenobarbital

Phenobarbital minimally alters the levels of losartan and its active metabolite.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study 15 healthy subjects were given phenobarbital 100 mg daily for 16 days with a single 100-mg dose of losartan. Phenobarbital slightly reduced the AUC of losartan and its active metabolite, E-3174, by about 20%, but this was not considered to be clinically significant.[1]

1. Goldberg MR, Lo MW, Deutsch PJ, Wilson SE, McWilliams EJ, McCrea JB. Phenobarbital minimally alters plasma concentrations of losartan and its active metabolite E-3174. *Clin Pharmacol Ther* (1996) 59, 268–74.

Angiotensin II receptor antagonists; Losartan + Phenytoin

Phenytoin inhibited the metabolism of losartan to its active metabolite, E-3174.

Clinical evidence, mechanism, importance and management

In this crossover study in 16 healthy subjects the concurrent use of phenytoin and losartan 50 mg daily for 10 days reduced the AUC of the active metabolite of losartan, E-3174, by 63%, but did not significantly alter the AUC of losartan. The pharmacokinetics of phenytoin were not affected by losartan. In this study phenytoin was given at a dose of 4 mg/kg rounded to the nearest 100 mg, not to exceed 400 mg daily, and the dose was adjusted on the fourth day, if necessary, based on serum phenytoin levels. Phenytoin did not alter the effect of losartan on blood pressure. The effect of phenytoin appeared to be CYP2C9 genotype-specific, with increases in losartan AUC seen in the 14 subjects who were CYP2C9 extensive metabolisers (that is, those with normal levels of this isoenzyme) and decreases in the 2 subjects who were poor metabolisers (that is those lacking this isoenzyme).[1]

Both phenytoin and losartan are substrates for the cytochrome P450 isoenzyme CYP2C9. It appears that phenytoin had an inhibitory effect on losartan metabolism. The conversion of losartan to E-3174 represents about 5 to 15% of the clearance of an oral losartan dose,[1] but E-3174 is much more active than losartan.

The clinical importance of this interaction still awaits assessment. Until more is known, if phenytoin is added to established treatment with losartan, it may be prudent to initially monitor blood pressure more closely. More study is needed.

1. Fischer TL, Pieper JA, Graff DW, Rodgers JE, Fischer JD, Parnell KJ, Goldstein JA, Greenwood R, Patterson JH. Evaluation of potential losartan-phenytoin drug interactions in healthy volunteers. *Clin Pharmacol Ther* (2002) 72, 238–46.

Angiotensin II receptor antagonists; Losartan + Tamoxifen

Tamoxifen may inhibit the metabolism of losartan to its active metabolite.

Clinical evidence

In a study, 13 patients were given a single 25-mg dose of losartan 2 days before and 2 weeks after starting to take tamoxifen 20 mg daily. The metabolism of losartan was reduced in 10 patients (as assessed by an increase in the losartan to E3174 metabolic ratio), but there was a wide inter-individual variation. The change in metabolic ratio in the 13 patients ranged from a decrease of 11% to an increase of 532%, with a median increase of 127%.[1]

Mechanism

Losartan is metabolised to its active metabolite E3174 by the cytochrome P450 isoenzyme CYP2C9, and this study indicates that tamoxifen inhibits this isoenzyme.

Importance and management

The clinical relevance of the findings of this study is unclear. The reduction in metabolism of losartan to its active metabolite might suggest that the therapeutic effects of losartan could be reduced. However, note that the effect of fluconazole (see 'Angiotensin II receptor antagonists + Azoles', p.39), which is a known potent inhibitor of CYP2C9, was probably not clinically relevant, which suggests the effect of tamoxifen is also unlikely to be clinically relevant.

Angiotensin II receptor antagonists; Telmisartan + Paracetamol (Acetaminophen)

No pharmacokinetic interaction occurs between telmisartan and paracetamol.

Clinical evidence, mechanism, importance and management

In a single-dose study in 12 healthy subjects telmisartan 120 mg had no effect on the pharmacokinetics of paracetamol 1 g. The pharmacokinetics of telmisartan were also unaffected by paracetamol, when compared with previous studies of telmisartan alone.[1]

Alcohol

For social and historical reasons alcohol is usually bought from a store or in a bar or restaurant, rather than from a pharmacy, because it is considered to be a drink and not a drug. However, pharmacologically it has much in common with medicinal drugs that depress the central nervous system. Objective tests show that as blood-alcohol levels rise, the ability to perform a number of skills gradually deteriorates as the brain becomes progressively disorganised. The myth that alcohol is a stimulant has arisen because at parties and social occasions it helps people to lose some of their inhibitions and it allows them to relax and unwind. Professor JH Gaddum put it amusingly and succinctly when, describing the early effects of moderate amounts of alcohol, he wrote that "logical thought is difficult but after dinner speeches easy." The expansiveness and loquaciousness that are socially acceptable can lead on, with increasing amounts of alcohol, to unrestrained behaviour in normally well-controlled individuals, through to drunkenness, unconsciousness, and finally death from respiratory failure. These effects are all a reflection of the progressive and deepening depression of the CNS.

'Table 3.1', (p.47) gives an indication in very broad terms of the reactions of men and women to different amounts and concentrations of alcohol.

On the whole women have a higher proportion of fat in which alcohol is not very soluble, their body fluids represent a smaller proportion of their total body mass, and their first-pass metabolism of alcohol is less than men because they have less alcohol dehydrogenase in their stomach walls. Consequently if a man and woman of the same weight matched each other, drink for drink, the woman would finish up with a blood alcohol level about 50% higher than the man. The values shown assume that the drinkers regularly drink, have had a meal and weigh between 9 and 11 stones (55 to 70 kg). Higher blood-alcohol levels would occur if alcohol was drunk on an empty stomach and lower values in much heavier individuals. The liver metabolises about one unit of alcohol per hour so the values will fall with time.

Since alcohol impairs the skills needed to drive safely, almost all national and state authorities have imposed maximum legal blood alcohol limits. In a number of countries this has been set at 80 mg/100 mL (35 micrograms per 100 mL in the breath) but impairment is clearly detectable at lower concentrations, for which reason some countries have imposed much lower legal limits, even down to 0 mg/100 mL in some cases. Even within countries the legal limit can vary, depending on the type of vehicle being driven and the age of the driver.

Alcohol can interact with many drugs both by pharmacokinetic and/or pharmacodynamic mechanisms. The quantity and frequency of alcohol consumption can affect the bioavailability of alcohol and other drugs. Several hepatic enzymes are important in the metabolism of alcohol; primarily alcohol dehydrogenases convert alcohol into acetaldehyde, but other enzymes, in particular the cytochrome P450 isoenzyme CYP2E1, are also involved, especially in moderate to heavy alcohol consumption. The cytochrome P450 isoenzymes CYP3A4 and CYP1A2 may also have a role in the metabolism of alcohol.

Alcohol can induce CYP2E1 (and possibly other isoenzymes) after prolonged heavy intake, and this can result in an increased metabolic rate and lower blood levels of drugs metabolised via this system. Conversely, short term binge drinking is likely to cause inhibition of this enzyme group by direct competition for binding sites and therefore decrease the metabolism of other drugs.

Probably the most common drug interaction of all occurs if alcohol is drunk by those taking other drugs that have CNS depressant activity, the result being even further CNS depression. Blood-alcohol levels well within the legal driving limit may, in the presence of other CNS depressants, be equivalent to blood-alcohol levels at or above the legal limit in terms of worsened driving and other skills. This can occur with some antihistamines, antidepressants, anxiolytics, hypnotics, opioid analgesics, and others. This section contains a number of monographs that describe the results of formal studies of alcohol combined with a number of recognised CNS depressants, but there are still many other drugs that await study of this kind, and which undoubtedly represent a real hazard.

A less common interaction that can occur between alcohol and some drugs, chemical agents, and fungi, is the flushing (*Antabuse*) reaction. This is exploited in the case of disulfiram (*Antabuse*) as a drink deterrent (see 'Alcohol + Disulfiram', p.66), but it can occur unexpectedly with some other drugs, such as some antifungals and cephalosporins, chlorpropamide and metronidazole, and can be both unpleasant and possibly frightening, but it is not usually dangerous.

Table 3.1 Reactions to different concentrations of alcohol in the blood

Amounts of alcohol drunk

Man 11 stones (70 kg)	**Woman 9 stones (55 kg)**	**Blood-alcohol levels mg% (mg per 100 mL)**	**Reactions to different % of alcohol in the blood**
2 units	1 unit	25 to 30	Sense of well-being enhanced. Reaction times reduced
4 units	2 units	50 to 60	Mild loss of inhibition, judgement impaired, increased risk of accidents at home, at work and on the road; no overt signs of drunkenness
5 units	3 units	75 to 80	Physical co-ordination reduced, more marked loss of inhibition; noticeably under the influence; at the maximum legal limit for driving in some countries
7 units	4 units	100 or more	Clumsiness, loss of physical control, tendency to extreme responses; definite intoxication
10 units	6 units	150	Slurred speech, possible loss of memory the following day, probably drunk and disorderly
24 units	14 units	360	Dead drunk, sleepiness, possible loss of consciousness
33 units	20 units	500	Coma and possibly death

1 unit	= half a pint (300 mL medium strength beer)	= glass of wine (100 mL)	= single sherry or martini (50 mL)	= single spirit (25 mL)
					alcohol 3 to 4%	alcohol 11%	alcohol 17 to 20%	alcohol 37 to 40%

Alcohol + Alpha blockers

The plasma levels of both indoramin and alcohol may be raised by concurrent use, and the combination has been reported to increase drowsiness, which may possibly increase the risks when driving or using machinery. Prazosin appears to enhance the hypotensive effects of alcohol.

Clinical evidence

(a) Indoramin

When 10 healthy subjects were given a single 50-mg oral dose of indoramin together with alcohol 0.5 g/kg in 600 mL of alcohol-free lager, the AUC of indoramin was increased by 25% and its peak plasma levels were raised by 58%.[1,2] When the subjects were given a single 175 microgram/kg intravenous dose of indoramin together with the same oral dose of alcohol, a 26% rise in blood-alcohol levels occurred during the first 1.25 hours after dosing, but no change in indoramin pharmacokinetics were seen. The combination of alcohol and indoramin caused more sedation than either drug alone.[2]

(b) Prazosin

A study in 10 Japanese hypertensive patients found that alcohol 1 mL/kg decreased blood pressure for several hours. Treatment with prazosin 1 mg three times daily caused a significant reduction in blood pressure and enhanced alcohol-induced hypotension.[3]

Mechanism

Uncertain. Increased absorption of indoramin from the gut or reduced liver metabolism may be responsible for the raised indoramin serum levels. The increase in sedation would appear to be due to the additive sedative effects of the two drugs. The effects may be restricted to Oriental/Asian patients because the alcohol flush syndrome, caused by accumulation of vasodilative acetaldehyde due to a genetic alteration in aldehyde dehydrogenase, is rare in whites and blacks.[3]

Importance and management

Information is limited but the interaction between indoramin and alcohol appears to be established. The clinical importance of the raised levels of both drugs is uncertain. However since indoramin sometimes causes drowsiness when it is first given, there is the possibility that alertness will be reduced, which could increase the risks of driving or handling machinery. Patients should be warned. The clinical significance of the drop in blood pressure with prazosin is uncertain, as the dose of prazosin was relatively small and the dose of alcohol was relatively large; therefore these findings may not apply to more moderate drinking or higher doses of prazosin. Note that chronic moderate to heavy drinking may decrease the effects of antihypertensives, see 'Alcohol + Antihypertensives', p.51.

Alcohol + Amfetamines and related drugs

Dexamfetamine can reduce the deleterious effects of alcohol to some extent, but some impairment still occurs making it unsafe to drive. Ecstasy may reduce subjective sedation associated with alcohol, without reversing the effects of alcohol on impulsivity or psychomotor skills. Another report suggests the combination of metamfetamine and alcohol produces an increase in perceived total intoxication, and may also increase cardiac adverse effects. Alcohol may enhance the transient immune dysfunction associated with ecstasy. Alcohol may slightly increase the plasma levels of ecstasy, while alcohol levels may be slightly reduced by ecstasy.

Clinical evidence

(a) Dexamfetamine

In 12 healthy subjects alcohol 0.85 g/kg (2 mL/kg of 100 proof vodka in orange juice) worsened the performance of a SEDI task (Simulator Evaluation of Drug Impairment).[1] This task is believed to parallel the skills needed to drive safely, and involves tests of attention, memory, recognition, decision making and reaction times. When the subjects were also given dexamfetamine 90 or 180 micrograms/kg, there was a dose-related improvement in the performance of the SEDI task, but the subjective assessment of intoxication was unchanged. Blood-alcohol levels reached a maximum of about 100 mg% at approximately one hour, and the bioavailability of alcohol was slightly increased.[1]

Earlier reports using different testing methods found that in some tests dexamfetamine modified the effects of alcohol,[2,3] but the total picture was complex. Other reports found no antagonism.[4,5] Another study found that in stress situations, where relief of fatigue or boredom alone will not produce improved performance, dexamfetamine failed to improve attentive motor performance impaired by alcohol.[6]

(b) Ecstasy (MDMA, Methylenedioxymethamphetamine)

1. Effect on behaviour or psychomotor skills. A study in 9 healthy subjects found that the combination of alcohol 0.8 g/kg and ecstasy 100 mg induced a longer lasting euphoria and sense of well-being than either ecstasy or alcohol alone. Ecstasy reversed the subjective feelings of sedation associated with alcohol, but did not reverse feelings of drunkenness, or the effects of alcohol on psychomotor performance.[7] Similarly, in a placebo-controlled, crossover study in 18 recreational users of ecstasy, alcohol-induced impairment in response inhibition tasks was not affected by single 75- or 100-mg doses of ecstasy. This indicated that the CNS-stimulating effects of ecstasy do not overcome alcohol-induced impairment of impulse-control or risk-taking behaviour.[8] In a placebo-controlled study, 18 healthy subjects were given a single 75- or 100-mg dose of ecstasy with sufficient alcohol to give a blood-alcohol level of 5 mg%. Alcohol alone impaired the performance of some psychomotor tests and driving performance. The addition of ecstasy improved the performance in some, but not all, of these tests. Subjects reported that the combined use of ecstasy and alcohol counteracted the feelings of sedation and lethargy caused by alcohol alone.[9] Another report also indicates that although ecstasy may reduce sedation in response to alcohol, it does not reduce the impairment psychomotor skills caused by alcohol.[10]

2. Effect on immune system. A study in 6 healthy subjects found that a single dose of ecstasy produced a time-dependent immune dysfunction. Ecstasy impaired CD4 T-cell function, which is responsible for cellular immunity. Alcohol alone may produce a decrease in T-helper cells and in B lymphocytes, which are responsible for humoral immunity. Concurrent ecstasy and alcohol increased the suppressive effect of ecstasy on CD4 T-cells and increased natural killer cells.[11]

3. Pharmacokinetic studies. A study in 9 healthy subjects found that alcohol 0.8 g/kg increased the maximum plasma levels of a single 100-mg dose of ecstasy by 13%, with no change in its AUC. The AUC and maximum plasma levels of alcohol were reduced by 9% and 15%, respectively, after ecstasy use.[7] Another single-dose study in 18 recreational users of ecstasy found a similar decrease in mean blood-alcohol levels and a small increase in ecstasy levels when the two drugs were given together, but the results were not statistically significant.[8]

(c) Metamfetamine

One study found that, while the combination of alcohol and metamfetamine diminished the subjective feelings of alcohol intoxication, there was actually an increase in feelings of total intoxication.[12] The combination of alcohol and metamfetamine may increase cardiac toxicity.[12]

Mechanism

Not understood. Although alcohol is a CNS depressant and the amfetamines are CNS stimulants, there is no simple antagonism between the two.[3]

Importance and management

Clear-cut conclusions cannot be drawn from the evidence presented in the reported studies. There is some evidence that the effects of alcohol are modified or reduced by amfetamines, but driving skills appear to remain impaired to some extent. The study using ecstasy suggests that this inter-

action may have implications for road safety, as subjects may consider they are driving better when actual performance is impaired by alcohol.[7] The increase in perceived total intoxication noted in one report has been suggested as a possible reason for the popularity of the illicit use of the combination.[12]

Information about an increase in cardiac toxicity with the combination of metamfetamine and alcohol is limited, and no general conclusions can be drawn.

The effects of ecstasy and alcohol on immune function require more study; however, it has been suggested that the transient defect in immunological homoeostasis could have clinical consequences such as increased susceptibility to infectious diseases.[11]

Alcohol + Aminosalicylic acid

Alcohol can abolish the lipid-lowering effects of aminosalicylic acid.

Clinical evidence, mechanism, importance and management

The effectiveness of PAS-C (purified aminosalicylic acid recrystallised in vitamin C) and diet on the treatment of hyperlipidaemia types IIa and IIb was studied in a group of 63 subjects. It was noted that when 3 of the subjects drank unstated amounts of alcohol (beer or cocktails), the effects of the PAS-C on lowering serum cholesterol, triglyceride and LDL-cholesterol levels were completely abolished.[1] The reasons are not understood.

There seems to be no evidence that alcohol affects the treatment of tuberculosis with aminosalicylic acid.

Alcohol + Amisulpride

No pharmacokinetic interaction appears to occur between amisulpride and alcohol.

Clinical evidence, mechanism, importance and management

No significant pharmacokinetic interactions were seen in 18 healthy subjects given single 50- and 200-mg doses of amisulpride with alcohol 0.8 g/kg, nor were the detrimental effects of alcohol on performance increased by amisulpride.[1] Nevertheless, the manufacturer advises that the central effects of alcohol may be enhanced by amisulpride, and so they do not recommend the combination.[2]

Alcohol + Antiepileptics

Moderate social drinking does not appear to cause a clinically significant alteration in the serum levels of carbamazepine, ethosuximide, gabapentin, phenobarbital, phenytoin, sodium valproate or tiagabine. However, the adverse effects of both alcohol and some antiepileptics, such as enhanced sedation, may be additive.

Clinical evidence, mechanism, importance and management

A study in 29 non-drinking epileptics found that when they drank 1 to 3 glasses of an alcoholic beverage (1 to 3 units) over a 2-hour period, twice a week for 16 weeks, the serum levels of **carbamazepine**, **ethosuximide** and **phenytoin** were unchanged, when compared with a control group of 23 epileptics given drinks without alcohol. There was a marginal change in **phenobarbital** levels, and some increase in serum **valproate** levels. However, this effect is hard to interpret as **valproate** levels are known to fluctuate and are hard to reproduce. Other antiepileptics used were **clonazepam**, **primidone** and **sultiame**, but too few patients used these drugs to allow valid statistical analysis. Maximum blood-alcohol levels ranged from 5 to 33 mg%. More important than any changes that occurred in serum antiepileptic levels, was the finding that social drinking had no effect on the frequency of tonic-clonic convulsions, partial complex seizures, or on the epileptic activity as measured by EEGs.[1]

In study of patients with head injuries the clearance of unbound **valproate** was found to be modestly increased (by up to 14%) in subjects who had measurable alcohol levels at the time of admission, when compared with those without detectable alcohol levels.[2] Another study in healthy subjects excluded any pharmacodynamic or pharmacokinetic interaction between **tiagabine** and alcohol. In this study, **tiagabine** 4 mg three times daily did not alter the effect of a single dose of alcohol, as assessed in a range of cognitive tests.[3] A study in 17 subjects who were considered to be heavy drinkers (average 34 drinks per week), found that **gabapentin** in doses of 1 g and 2 g did not affect the pharmacokinetics of alcohol, nor did it affect a number of subjective, physiological or performance measures, when compared with alcohol alone. However, the increase in heart rate seen with alcohol was increased to a *statistically* significant extent by gabapentin (exact figures not given).[4]

For the effect of chronic heavy drinking on the pharmacokinetics of carbamazepine or phenytoin, see 'Alcohol + Carbamazepine', p.61 and 'Alcohol + Phenytoin', p.82.

There are very few studies, but there seem to be no reasons for epileptic patients to avoid alcohol in moderate social amounts (1 or 2 drinks per occasion; no more than 3 to 6 drinks per week).[5] However, patients who drink moderate to heavy amounts of alcohol (3 to 4 drinks or more) should be warned that they are at increased risk of seizures, with the greatest risk occurring 7 to 48 hours after the last drink.[5] The British Epilepsy Association comments that most people with epilepsy find they can have one or two units of alcohol, perhaps more, without increasing the chances of having a seizure, whereas other people find that even a small amount of alcohol triggers their seizures.[6] Patients who drink heavily may also get alcohol withdrawal seizures, and binge drinking has been associated with seizures even in non-epileptic people. The British Epilepsy Association also say that anyone taking antiepileptics is likely to be more sensitive to the effects of alcohol and alcohol can exaggerate the adverse effects of the antiepileptics.[6] Some antiepileptics such as **carbamazepine**, **clonazepam**, '**phenobarbital**', (p.55), **primidone**, and **topiramate** have sedative effects, which may be additive with those of alcohol.

Individuals need to decide what level of alcohol intake is appropriate for them, and be aware that a change in medication, or an increase in dose of antiepileptic, may make them more susceptible to the effects of alcohol. Patients should also be made aware that drinking alcohol when taking antiepileptics may reduce their ability to perform certain skilled tasks, such as driving.

Alcohol + Antihistamines

Some antihistamines cause drowsiness, which can be increased by alcohol. The detrimental effects of alcohol on driving skills are considerably increased by the use of the older more sedative antihistamines and appear to be minimal or absent with the newer non-sedating antihistamines.

Clinical evidence

(a) Non-sedating antihistamines

A double-blind study found that **terfenadine** 60 to 240 mg alone did not affect psychomotor skills, nor did it alter the adverse effects of alcohol.[1] Another study had similar findings.[2] However, a later study found that **terfenadine** 240 mg slowed brake reaction times in the laboratory when given either alone or with alcohol.[3] **Acrivastine** 4 and 8 mg, given with and without alcohol, was found in a study to behave like **terfenadine** (which interacts minimally or not at all).[4] Other studies have shown that **astemizole** 10 to 30 mg daily,[5-7] **desloratadine**,[8] **ebastine** 20 mg,[9] **fexofenadine** 120 to 240 mg,[10,11] **levocabastine** 2 nasal puffs of 0.5 mg/mL,[12] **loratadine** 10 to 20 mg[2,13] and **mizolastine** 10 mg[14] do not interact with alcohol. **Cetirizine** 10 mg did not appear to interact with alcohol in two studies[14,15] but some slight additive effects were detected in other studies.[13,16] Similarly, a single oral dose of **rupatadine** 10 mg did not interact with alcohol, but a 20-mg dose given with alcohol produced more cognitive and psychomotor impairment than alcohol alone.[16]

(b) Sedating antihistamines

The effects of alcohol (blood levels about 50 mg%) and antihistamines, alone or together, on the performance of tests designed to assess mental and motor performance were examined in 16 subjects. **Clemizole** 40 mg alone or **tripelennamine** 50 mg alone did not significantly affect the performance under the stress of delayed auditory feedback, neither did they potentiate the effect of alcohol.[17] **Clemastine** in 3-mg doses had some additive detrimental effects with alcohol on co-ordination, whereas **clemastine** 1.5 mg and 1 mg did not.[18,19] A study in 5 subjects showed that the detrimental effects of 100 mL of whiskey on the performance of driving tests on a racing car simulator (blood-alcohol level estimated as less than 80 mg%) were not increased by **cyclizine** 50 mg.[20] However 3 of the subjects experienced drowsiness after **cyclizine**, and other studies have shown that **cyclizine** alone causes drowsiness in the majority of subjects.[21] Significant impairment of psychomotor performance was seen in healthy subjects given **chlorphenamine** 12 mg with alcohol 0.5 g/kg.[5] A further study similarly found significant impairment in driving skills when **chlorphenamine** was given with alcohol, see (*c*) below. In 13 healthy subjects alcohol 0.75 g/kg given with **dexchlorpheniramine** 4 mg/70 kg significantly impaired the performance of a number of tests (standing steadiness, reaction time, manual dexterity, perception, etc.).[22] A study in 17 subjects found that **mebhydrolin** 0.71 mg/kg enhanced the alcohol-induced deficits in the performance of a number of tests of perceptual, cognitive and motor functions.[23] No interaction was detected in one study of the combined effects of **pheniramine aminosalicylate** 50 mg or **cyproheptadine hydrochloride** 4 mg and alcohol 0.95 mL/kg.[24] **Triprolidine** 10 mg alone can significantly affect driving performance,[2] and marked deterioration in driving skills has been demonstrated with 10 mL of *Actifed Syrup* (**triprolidine** with pseudoephedrine) alone and with a double whiskey.[25]

(c) Significantly-sedating antihistamines

Diphenhydramine in doses of 25 or 50 mg was shown to increase the detrimental effects of alcohol on the performance of choice reaction and co-ordination tests in subjects who had taken 0.5 g/kg of alcohol.[18] The interaction between **diphenhydramine** in doses of 50, 75 or 100 mg and alcohol 0.5 to 0.75 g/kg has been confirmed in other reports.[1,17,26-28] **Emedastine**, in oral doses of 2 or 4 mg twice daily, was found to be sedating and impair driving ability in 19 healthy subjects. The addition of alcohol increased this impairment.[29] A marked interaction can also occur with **hydroxyzine**[11,16] or **promethazine**.[30] A very marked deterioration in driving skills was clearly demonstrated in a test of car drivers given 20 mL of *Beechams Night Nurse* (**promethazine** with dextromethorphan), 10 mL of *Benylin* (**diphenhydramine** with dextromethorphan), or 30 mL of *Lemsip Night time flu medicine* (**chlorphenamine** with dextromethorphan). Very poor scores were seen when they were also given a double Scotch whiskey about 1.5 hours later.[25]

Mechanism

When an interaction occurs it appears to be due to the combined or additive central nervous depressant effects of both the alcohol and the antihistamine. The highly-sedating antihistamines are highly lipophilic and readily cross the blood-brain barrier; consequently they have considerable sedative effects that may persist into the next day. The sedating antihistamines do not cross the blood-brain barrier so readily, and are therefore less sedating. Most of the non-sedating antihistamines, such as fexofenadine, do not appear to cross the blood-brain barrier,[11] and would therefore not be expected to cause much, if any, sedation. The authors of one study found that the sedating effects of cetirizine and emedastine were more marked in women than in men, and they noted that they had also previously seen this with acrivastine, clemastine and mizolastine.[29] The reason for this is not established although it has been suggested that a smaller volume of distribution in women may result in higher plasma antihistamine levels.

Importance and management

An adverse interaction between alcohol and the **highly-sedating antihistamines** (see 'Table 15.1', (p.663)) is well established and clinically important. Marked drowsiness can occur with these antihistamines taken alone, which makes driving or handling other potentially dangerous machinery much more hazardous. This can be further worsened by alcohol. Patients should be strongly warned. Remember that some of these antihistamines are present in non-prescription products licensed as antiemetics and sedatives, and as components of cough, cold, and influenza remedies (e.g. some preparations of *Benylin*, *Lemsip*, and *Night Nurse*). Emedastine may also cause marked sedation when used orally, but it is usually given as eye drops, and its use would therefore not be expected to result in a clinically relevant interaction with alcohol.

The situation with some of the **sedating antihistamines** is less clear cut, and tests with some of them failed to detect an interaction with normal doses and moderate amounts of alcohol; however, it has been clearly seen with *Actifed Syrup* (containing triprolidine). It would therefore be prudent to issue some cautionary warning, particularly if the patient is likely to drive.

The **non-sedating antihistamines** seem to cause little or no drowsiness in most patients and the risks if taken alone or with alcohol appear to be minimal or absent. However, the incidence of sedation varies with the non-sedating antihistamine (e.g. sedation appears to be lower with fexofenadine and loratadine than with acrivastine or cetirizine)[31] and with the individual (e.g. women may be more affected than men).[29] Therefore, patients should be advised to be alert to the possibility of drowsiness if they have not taken the drug before. Any drowsiness would be apparent after the first few doses. The manufacturer of cetirizine suggests avoiding excessive amounts of alcohol,[32] and, although they note that cetirizine has not been shown to potentiate the effects of alcohol, the manufacturers of **levocetirizine** advise caution with the concurrent use of alcohol.[33]

The possible interactions of alcohol with other antihistamines not cited here do not seem to have been formally studied, but increased drowsiness and increased driving risks would be expected with any that cause some sedation. Patients should be warned about drinking alcohol when taking sedative antihistamines. The risks with antihistamines given as eye drops or nasal spray (e.g. **azelastine**, **epinastine**) are probably minimal, but this needs confirmation.

Alcohol + Antihypertensives

Chronic moderate to heavy drinking raises blood pressure and reduces, to some extent, the effectiveness of antihypertensive drugs. A few patients may experience postural hypotension, dizziness and fainting shortly after having drunk alcohol. Alpha blockers may enhance the hypotensive effect of alcohol in subjects susceptible to the alcohol flush syndrome.

Clinical evidence, mechanism, importance and management

(a) Hypertensive reaction

A study in 40 men with essential hypertension (taking **beta blockers**, **captopril**, **diuretics**, **methyldopa**, **prazosin** or **verapamil**) who were moderate to heavy drinkers, found that when they reduced their drinking over a 6-week period from an average of 450 mL of alcohol weekly (about 6 drinks daily) to 64 mL of alcohol weekly, their average blood pressure fell by 5/3 mmHg.[1] The reasons for this effect are uncertain.

The Atherosclerosis Risk in Communities (ARIC) study involving 8334 subjects who were free from hypertension at baseline and were assessed after 6 years, found that higher levels of consumption of alcoholic beverages (210 g or more of alcohol per week; approximately 3 drinks or more per day) were associated with a higher risk of hypertension. Low to moderate consumption of alcohol (up to 3 drinks daily) was associated with an increase in blood pressure in black, but not in white men.[2] A study in Japanese men found that the effect of alcohol intake on the risk of developing hypertension was dose-dependent, starting at low-to-moderate levels of alcohol (less than 23 g daily).[3]

These findings are consistent with those of other studies in hypertensive[4] and normotensive[5] subjects. It seems likely that this effect will occur with any antihypertensive. Patients with hypertension who are moderate to heavy drinkers should be encouraged to reduce their intake of alcohol. It may then become possible to reduce the dosage of the antihypertensive. It should be noted that epidemiological studies show that regular light to moderate alcohol consumption is associated with a *lower* risk of cardiovascular disease.[6]

(b) Hypotensive reaction

A few patients taking some antihypertensives feel dizzy or begin to 'black out' or faint if they stand up quickly or after exercise. This orthostatic and exertional hypotension may be exaggerated in some patients shortly after drinking alcohol, possibly because it can lower the cardiac output (noted in patients with various types of heart disease[7,8]). For other reports of postural hypotension with alcohol, see 'alpha blockers', (p.48), and 'calcium-channel blockers', (p.60). Some manufacturers of antihypertensives e.g. **ACE inhibitors** (enalapril and captopril)[9,10] and **thiazide diuretics** (hydrochlorothiazide)[11] warn that acute alcohol intake may enhance the hypotensive effects, particularly at the start of treatment,[10] and this could apply to any antihypertensive. Patients just beginning antihypertensive treatment should be warned.

(c) CNS and other effects

Alcohol + Antimuscarinics

Propantheline appears not to affect blood-alcohol levels, whereas atropine may cause a modest reduction. Marked impairment of attention can occur if alcohol is taken in the presence of atropine or glycopyrronium (glycopyrrolate), probably making driving more hazardous. No adverse interaction usually appears to occur with hyoscine (scopolamine) and alcohol, although hyoscine hydrobromide presents more of a theoretical risk than hyoscine butylbromide.

Clinical evidence, mechanism, importance and management

(a) Atropine

In a study in 3 subjects, a single 3-mg oral dose of atropine, given 2 hours before alcohol reduced the AUC of alcohol by a modest 20%.[1] Another study in healthy subjects found that oral atropine 500 micrograms given with alcohol 0.5 g/kg either did not affect or improve reaction times and co-ordination; however, there was a marked impairment of attention, which was large enough to make driving more hazardous.[2] Patients should be warned.

(b) Glycopyrronium

A study in healthy subjects found that glycopyrronium 1 mg given with alcohol 0.5 g/kg either did not affect or improve reaction times and co-ordination; however, there was a marked impairment of attention, which was large enough to make driving more hazardous.[2] Patients should be warned.

(c) Hyoscine (Scopolamine)

A double-blind crossover study in 12 healthy subjects found that a transdermal hyoscine preparation (*Scopoderm-TTS*) did not alter the effects of alcohol on the performance of several psychometric tests (Critical Flicker Fusion Frequency, Choice Reaction Tasks), nor was the clearance of alcohol or hyoscine changed. Blood-alcohol levels of up to 80 mg%, and 130 mg%, were studied.[3] In a study investigating the metabolism of alcohol, 10 patients were given hyoscine butylbromide 20 mg with oral alcohol 0.225 g/kg. Peak serum alcohol levels were not significantly altered, but were delayed from about 23 minutes to 50 minutes by the hyoscine, when compared with alcohol alone. Gastric emptying time was also significantly increased, from about 44 minutes to 71 minutes.[4] Although the evidence would seem to suggest that a clinically significant pharmacokinetic interaction is unlikely, the manufacturer of *Scopoderm-TTS* suggests caution in patients receiving drugs that act on the CNS, and advises that patients should not drink alcohol.[5] This is presumably because drowsiness and other CNS adverse effects have occasionally been reported with transdermal hyoscine.[5,6] The manufacturers of travel tablets and injections containing hyoscine hydrobromide recommend avoiding alcohol.[7,8] However, unlike hyoscine and hyoscine hydrobromide, the quaternary derivatives, such as hyoscine butylbromide or hyoscine methobromide, do not readily pass the blood-brain barrier,[9] and would therefore be expected to be less likely to cause additive adverse effects with alcohol.

(d) Propantheline

In a study in 3 subjects oral propantheline (15 mg four times daily or 30 mg three times daily for 5 days, with 30 mg or 60 mg two hours before alcohol) did not affect blood-alcohol levels.[1]

Alcohol + Antimycobacterials

The hepatotoxicity of some antimycobacterials may possibly be increased by high alcohol consumption. Alcohol may increase the risk of epileptic episodes in patients taking cycloserine. A psychotoxic reaction in a patient taking ethionamide was attributed to concurrent heavy alcohol consumption. Isoniazid slightly increases the hazards of driving after drinking alcohol. Isoniazid-induced hepatitis may also possibly be increased by alcohol, and the effects of isoniazid are possibly reduced in some heavy drinkers. Acute alcohol intake does not appear to affect the pharmacokinetics of a single-dose of isoniazid.

Clinical evidence, mechanism, importance and management

(a) Combined antitubercular regimens

Hepatotoxicity can occur with several antimycobacterial drugs including **ethionamide, isoniazid, pyrazinamide** and **rifampicin** and high alcohol consumption/chronic alcoholism has been reported to increase the risk.[1,2] However, one study in patients with active tuberculosis taking **rifampicin** and **pyrazinamide**, found that of the 14 patients who developed hepatotoxicity, only 5 of these reported alcohol use (not quantified), and alcohol was not found to be associated with an increased risk of hepatotoxicity.[3] Similarly, another study found that alcohol consumption was not a risk factor for antimycobacterial-induced hepatotoxicity.[4]

(b) Cycloserine

A brief report describes an enhancement of the effects of alcohol in 2 patients taking cycloserine.[5] The clinical significance of this report is unclear. However, the manufacturer of cycloserine states that it is 'incompatible' with alcohol because of an increased risk of epileptic episodes, and contraindicate its use in alcohol abuse.[6]

(c) Ethionamide

A psychotoxic reaction seen in a patient taking ethionamide was attributed to the concurrent heavy consumption of alcohol.[7] It is unclear whether this represents a clinically meaningful interaction but it appears to be the only case on record. However, because of this reaction, the manufacturer advises that patients should avoid drinking excessive amounts of alcohol.[8]

(d) Isoniazid

The effects of isoniazid 750 mg with alcohol 0.5 g/kg were examined in 100 subjects given various psychomotor tests, and in a further 50 drivers using a driving simulator. No major interaction was seen in the psychomotor tests, but the number of drivers who drove off the road on the simulator was increased.[9,10] There would therefore appear to be some extra risks for patients taking isoniazid who drink and drive, but the effect does not appear to be large. Patients should nevertheless be warned.

The incidence of severe progressive liver damage due to isoniazid is said to be higher in those who drink alcohol regularly,[11-13] and the clinical effects of isoniazid are also said to be reduced by heavy drinking in some patients.[11] The manufacturer advises care in giving isoniazid to patients with chronic alcoholism.[14]

Acute alcohol intake in 16 healthy subjects did not have any effect on the pharmacokinetics of a single 200-mg dose of isoniazid.[15] Alcohol is metabolised to acetaldehyde in the liver and isoniazid has been found to interact with acetaldehyde *in vitro*. The clinical significance of this is unknown, but if this binding occurs *in vivo,* it could lead to decreased bioavailability of isoniazid and possibly the acetaldehyde-modified drug formed could mediate some adverse effects.[16]

Alcohol + Antipsychotics

The detrimental effects of alcohol on the skills related to driving are made worse by chlorpromazine, and, to a lesser extent, by flupentixol, sulpiride and thioridazine. Small or single-dose studies with haloperidol or tiapride suggest that any interaction would seem to be mild; nevertheless, all antipsychotic drugs that cause drowsiness have the potential to enhance the effects of alcohol. There is also some evidence to suggest that drinking can precipitate the emergence of extrapyramidal adverse effects in patients taking antipsychotics.

Clinical evidence

(a) Effect on driving and other skills

Twenty-one subjects showed a marked deterioration in the performance of a number of skills related to driving when they were given **chlorpromazine** 200 mg daily and alcohol (blood levels 42 mg%). Many complained of feeling sleepy, lethargic, dull, groggy, and poorly coordinated; and most considered themselves more unsafe to drive than with alcohol alone.[1] A later study confirmed these findings with **chlorpromazine** 1 mg/kg and blood-alcohol levels of 80 mg%.[2] Increased sedation was clearly seen in another study with alcohol and **chlorpromazine**,[3] and clear impairment of psychomotor skills related to driving have also been found.[4]

Single 500-microgram doses of **haloperidol** or **flupentixol** strongly impaired attention, but did not significantly interact with alcohol in one study.[5] However, a double-blind study in subjects given **flupentixol** 500 micrograms three times a day for 2 weeks found that, when combined with alcohol 0.5 g/kg, their performance of a number of tests (choice reaction, coordination, attention) was impaired to such an extent that driving or handling other potentially dangerous machinery could be hazardous.[6]

Sulpiride 50 mg three times daily for 2 weeks caused a mild decrease in psychomotor skills with alcohol in healthy subjects, but not as much as that seen with **chlorpromazine** and alcohol.[4,7] **Thioridazine** 25 mg caused some additive effects with alcohol, with a moderately deleterious effect on attention.[5] Another study found that **thioridazine** and alcohol affected skills related to driving, but not as much as the effects seen with **chlorpromazine**.[2] A further study found no difference between the effects of **thioridazine** and a placebo with alcohol.[4,8]

A study in 9 alcoholics given **tiapride** 400 to 600 mg daily found that wakefulness was not impaired when alcohol 0.5 g/kg was given, and in fact appeared to be improved, but the effect on driving skills was not studied.[9]

(b) Precipitation of extrapyramidal adverse effects

A report describes 7 patients who developed acute extrapyramidal adverse effects (akathisia, dystonia) while taking **trifluoperazine**, **fluphenazine**, **perphenazine**, or **chlorpromazine** and drinking alcohol.[10] The author stated that these were examples of numerous such alcohol-induced toxicity reactions observed by him over an 18-year period involving phenothiazines and butyrophenones. Elsewhere he describes the emergence of drug-induced parkinsonism in a woman taking **perphenazine** and amitriptyline when she began to drink alcohol.[11] Eighteen cases of **haloperidol**-induced extrapyramidal reactions among young drug abusers, in most instances associated with the ingestion of alcohol, have also been described.[12] Similarly, a study involving 41 patients with schizophrenia found that those with a substance use disorder (alcohol or cannabis with or without cocaine) displayed more extrapyramidal symptoms compared with non-abusing patients.[13]

(c) Toxicity

A study involving 332 fatal poisonings in Finland found that alcohol was present in 65% of cases involving **promazine**, and when alcohol was present, relatively small overdoses of **promazine** could result in fatal poisoning.[14] It appears that **promazine** and possibly **levomepromazine** may be more toxic when combined with alcohol.[15]

(d) Pharmacokinetic studies

A study in 12 patients taking **chlorpromazine** 600 mg to 1.2 g daily long-term, found that **chlorpromazine** had no apparent effect on alcohol metabolism. However, about half of the patients had a statistically significant decrease (up to 33%) in urinary excretion of **chlorpromazine** and its metabolites during the 24-hour period following the consumption of 50 to 75 mL of alcohol.[16]

A study in 7 schizophrenics found that when they were given 40 g of alcohol to drink at about the same time as their regular injection of **fluphenazine decanoate** (25 to 125 mg every 2 weeks), their serum **fluphenazine** levels were reduced by 30% at 2 hours and by 16% at 12 hours.[17]

Mechanism

Uncertain. Additive CNS depressant effects are one explanation of this interaction. One suggestion to account for the emergence of the drug adverse effects is that alcohol lowers the threshold of resistance to the neurotoxicity of these drugs. Also alcohol may possibly impair the activity of tyrosine hydroxylase so that the dopamine/acetylcholine balance within the corpus striatum is upset.[11] In addition, chlorpromazine has been found to inhibit alcohol dehydrogenase, which may facilitate the formation of biogenic amines that have been implicated in extrapyramidal adverse effects.[18]

Pharmacokinetic interactions between acute and chronic alcohol ingestion, and single or multiple doses of antipsychotic drug are complex; acute alcohol intake can decrease metabolic clearance, whereas chronic intake can increase clearance.[19] Alcohol may also affect the peripheral circulation and membrane permeability, which might affect absorption from an injection site.[17]

Importance and management

The documentation is limited. The manufacturers of flupentixol[20] and haloperidol[21] warn that, in common with other antipsychotic drugs, the effects of alcohol maybe enhanced. Warn patients that if they drink alcohol while taking chlorpromazine, and to a lesser extent flupenthixol, sulpiride or thioridazine (probably other related drugs as well), they may become very drowsy, and should not drive or handle other potentially dangerous machinery. Some risk is possible with any antipsychotic that causes drowsiness, including those used as antiemetics, such as **prochlorperazine**.

The authors of the reports describing the emergence of serious adverse effects to antipsychotics in those who drink alcohol, consider that patients should routinely be advised to abstain from alcohol during antipsychotic treatment.

It has been suggested that a less dangerous alternative to promazine, and possibly levomepromazine, should be chosen when indications of alcohol abuse or suicide risk are present.[15]

The clinical importance of the pharmacokinetic studies is uncertain, but the changes observed were mostly slight.

Alcohol + Antiretrovirals

Heavy alcohol intake may affect the virological response to HAART. Theoretically, alcohol consumption may induce liver enzymes, which interfere with the metabolism of some antivirals such as the protease inhibitors. Alcohol reduces the metabolism of abacavir but this does not appear to be clinically significant.

Clinical evidence, mechanism, importance and management

(a) Alcohol and HAART regimens

A study of 94 HIV-positive patients receiving HAART, which included 2 **nucleoside analogues** plus either **indinavir**, **ritonavir**, **saquinavir**, **nelfinavir**, or **ritonavir**/**saquinavir**, found that the amount of alcohol consumed did not affect the antiviral response. However, the proportion of complete responders was slightly lower (57%) in heavy drinkers (more than 60 g of alcohol per day) compared with 68% in both non-drinkers and moderate drinkers (less than 60 g of alcohol per day), although this was not a significant finding. There was also a high prevalence of infection with hepatitis C virus, and liver decompensation occurred in 2 patients (both heavy drinkers).[1] Alcohol may affect thymus-induced immune repletion in HIV-positive patients and it has been reported that heavy alcohol users taking antiretrovirals are twice as likely not to achieve a positive virological response, compared with those who do not use alcohol.[2]

Alcohol consumption can induce the cytochrome P450 isoenzyme CYP3A4 and there is concern that HAART may not be as effective in some individuals who consume alcohol.[3] CYP3A4 is involved in the metabolism of the protease inhibitors **amprenavir**, **fosamprenavir**, **indinavir**, **lopinavir**, **nelfinavir**, **ritonavir**, and **saquinavir** and the NNRTIs **delavirdine**, **efavirenz**, and **nevirapine**, and therefore CYP3A4 induction may result in enhanced drug metabolism and reduced therapeutic levels.[4] Avoidance of alcohol has been suggested for HIV-positive patients receiving protease inhibitor therapy,[3,4] but at present there does not seem to be any clinical data to support this. Nevertheless, a reduction in alcohol consumption would seem sensible. More studies are needed. Note that some preparations of **ritonavir** contain alcohol, see 'Alcohol + Disulfiram', p.66.

(b) Effect of alcohol on abacavir

A study in 24 HIV-positive patients found that alcohol 0.7 g/kg increased the AUC of a single 600-mg dose of abacavir by 41%. The half-life of abacavir was increased by 26%, from 1.42 to 1.79 hours. The pharmacokinetics of alcohol were not affected by abacavir.[5] Alcohol may inhibit the formation of abacavir carboxylate resulting in a trend towards increased abacavir glucuronide formation and reduced abacavir metabolism. The increase in exposure to abacavir was not considered to be clinically significant, since it is within levels seen in other studies using higher doses, which demonstrated no additional safety concerns at doses of up to three times the recommended daily dose of abacavir.[5] No special precautions therefore appear to be necessary.

Alcohol + Apomorphine

Apomorphine may increase the effects of alcohol and the hypotensive adverse effects of apomorphine may possibly be increased by alcohol.

Clinical evidence, mechanism, importance and management

In a study, 12 healthy subjects were given alcohol-containing drinks to give a blood-alcohol level of about 100 mg%, followed by a single 5-mg dose of apomorphine. Subjective and objective measures of drunkenness were significantly increased by apomorphine, but the peak blood-alcohol levels were not altered.[1]

The manufacturer of a preparation of apomorphine used for erectile dysfunction advised that interaction studies in subjects given apomorphine found that alcohol increased the incidence and extent of hypotension (one of the adverse effects of apomorphine). They also pointed out that alcohol can diminish sexual performance.[2] The US manufacturer advises the avoidance of alcohol.[3]

Alcohol + Aspirin or other Salicylates

A small increase in the gastrointestinal blood loss caused by aspirin occurs in patients if they also drink alcohol, but any increased damage to the lining of the stomach is small and appears usually to be of minimal importance in most healthy individuals. However, heavy drinkers who regularly take aspirin should be warned of the increased risk of gastric bleeding. Some limited information suggests that aspirin can raise or lower blood-alcohol levels, and alcohol may cause slight changes in salicylate levels.

Clinical evidence

(a) Gastrointestinal effects

The mean daily blood loss from the gut of 13 healthy men was 0.4 mL while taking no medication, 3.2 mL while taking 2.1 g of soluble unbuffered aspirin (*Disprin*) and 5.3 mL while taking aspirin with 180 mL of Australian whiskey (alcohol 31.8%). In this study, alcohol alone did not cause gastrointestinal bleeding.[1] Similar results were reported in another study in healthy subjects.[2]

An epidemiological study of patients admitted to hospital with gastrointestinal haemorrhage showed a statistical association between bleeding and the ingestion of aspirin alone, and the combination with alcohol produced a significant synergistic effect.[3] A large case-controlled study found similar results: the overall relative risk of bleeding with regular use of aspirin, at doses greater than 325 mg, was 7 among drinkers and 5.1 among people who never drank alcohol. For those who drank less than 1 to 20 drinks a week there was no evidence of a trend of increasing or decreasing relative risk as levels of alcohol consumption increased, but among those who consumed 21 or more drinks a week there was a large association with upper gastrointestinal bleeding (crude estimated risk 27). For regular aspirin use at doses of 325 mg or less, the overall relative risk among all current drinkers and among people who never drank alcohol was 2.8 and 2.2, respectively.[4] Another case-control study suggested that the odds ratio for gastrointestinal complications in those regularly consuming more than 5 drinks during a drinking session was increased from 2.8 to 8.1 when aspirin was also taken. This was also increased when compared with the use of aspirin alone (odds ratio 3).[5]

Endoscopic examination revealed that aspirin and alcohol have additive damaging effects on the gastric mucosa (not on the duodenum), but the extent is small.[6] However, a further case-control study found that large amounts of red wine (roughly over 500 mL of wine daily) increased the risk of upper gastrointestinal bleeding associated with low-dose aspirin, and small amounts of red wine (roughly less than 200 mL of wine daily) reduced this risk.[7] Another study, using gastric mucosal potential difference as a measure of mucosal damage, found that aspirin with alcohol caused additive damage to the mucosa.[8] In a review of the evidence, it was considered that while more study was needed, data available are highly suggestive that the gastrointestinal toxicity of alcohol and aspirin are combined in individuals who are heavy daily drinkers and heavy aspirin users.[9]

No increased gastrointestinal bleeding occurred in 22 healthy subjects given three double gins or whiskies (equivalent to 142 mL of alcohol 40%) and 728 mg of buffered sodium acetylsalicylate (*Alka-Seltzer*).[10]

(b) Effect on blood-alcohol levels

Five healthy subjects were given a standard breakfast with and without aspirin 1 g followed one hour later by alcohol 0.3 g/kg. The aspirin increased the peak blood-alcohol levels by 39% and the AUC by 26%.[11] Similarly, in another study, 28 healthy subjects were given a midday meal (two sandwiches and a cup of tea or coffee), followed 90 minutes later by 600 mg of aspirin or a placebo, and then 30 minutes later by two standard drinks (35.5 mL of vodka 37.5% (21.6 g of alcohol) plus 60 mL of orange juice), which were drunk within a 15-minute period. The blood-alcohol levels of the men were raised by 31% after one hour (from about 24 to 32 mg%) and by 18% (from about 21 to 25 mg%) after 2 hours. The blood-alcohol levels of the women were raised by 32% (from about 37 to 49 mg%) after one hour and by 21% (from about 38 to 46 mg%) after 2 hours.[12]

However, a later study (effectively a repeat of a study[11] above) in

12 healthy subjects found that aspirin did not appear to affect blood-alcohol levels.[5] A crossover study in 10 healthy male subjects found that after taking aspirin 75 mg daily for one week, their mean blood alcohol AUC following a 0.3 g/kg-dose was not significantly altered. However, individual *maximum* blood levels varied; one subject showed a rise, two were unchanged, and five were lowered: overall the reduction was 23%.[13]

(c) Effect on salicylate levels

One study (effectively a repeat of a study[11] above) in 12 healthy subjects found that alcohol reduced peak aspirin levels by 25%.[5] In a study in 5 healthy subjects the AUC and maximum levels of a single 500-mg dose of aspirin were found to be increased by a modest 11% by 50 mL of 40% alcohol, but decreased by 13% and 17%, respectively, when taken with 200 mL of beer.[14]

Mechanism

(a) Gastrointestinal effects

Aspirin and alcohol can damage the mucosal lining of the stomach, one measure of the injury being a fall in the gastric potential difference. Once the protective mucosal barrier is breached, desquamation of the cells occurs and damage to the capillaries follows. Aspirin causes a marked prolongation in bleeding times, and this can be increased by alcohol.[15] The total picture is complex.

(b) Effect on blood-alcohol levels

The increased blood-alcohol levels in the presence of food and aspirin may possibly occur because the aspirin reduces the enzymic oxidation of the alcohol by alcohol dehydrogenase in the gastric mucosa, so that more remains available for absorption.[11] Any decreases with low-dose aspirin may possibly be due to delayed gastric emptying.[13]

(c) Effect on salicylate levels

It is possible that several mechanisms are involved in the alteration of aspirin bioavailability by alcohol, including increased dissolution and altered gastric emptying.[14]

Importance and management

The combined effect of aspirin and alcohol on the stomach wall is established. Aspirin 3 g daily for a period of 3 to 5 days induces an average blood loss of about 5 mL or so. Some increased loss undoubtedly occurs with alcohol, but it seems to be quite small and unlikely to be of much importance in most healthy individuals using moderate salicylate doses drinking moderate amounts of alcohol. In one study it was found that alcohol was a mild damaging agent or a mild potentiating agent for other drugs that damaged the gastrointestinal mucosa.[6] However, it should be remembered that chronic and/or gross overuse of salicylates and alcohol may result in gastric ulceration. People who consume at least 3 or more alcoholic drinks daily and who regularly take more than 325 mg of aspirin have been shown to have a high risk of bleeding.[16] The FDA in the US has ruled that non-prescription pain relievers and fever reducers, containing aspirin or salicylates, must carry a warning label advising people who consume moderate amounts of alcohol to consult their doctor before using these drugs, and that stomach bleeding may occur with these drugs.[17] However, the Australian Medicines Evaluation Committee has decided against such action as, for most people with mild to moderate alcohol intake, there is little risk especially if the aspirin is taken only as needed.[16]

Information about the increase in blood-alcohol levels caused by aspirin after food is very limited and contradictory, and of uncertain practical importance. However, no practically relevant interaction has been seen with other drugs (such as the 'H_2-receptor antagonists', (p.70)), which have been extensively studied, and which appear to interact by the same mechanism. The pattern for these drugs is that the increases in blood-alcohol levels are appreciable with small doses of alcohol, but usually they become proportionately too small to matter with larger doses of alcohol (i.e. those that give blood and breath levels at or around the legal driving limit in the UK).

The change in salicylate levels with alcohol is almost certainly too small to be of clinical relevance.

Alcohol + Barbiturates

Alcohol and the barbiturates are CNS depressants, which together can have additive and possibly even synergistic effects. Activities requiring alertness and good co-ordination, such as driving a car or handling other potentially dangerous machinery, can be made more difficult and more hazardous. Alcohol may also continue to interact the next day if the barbiturate has hangover effects.

Clinical evidence

A study in healthy subjects of the effects of a single 0.5-g/kg dose of alcohol, taken in the morning after a dose of **amobarbital** 100 mg every night for 2 weeks, found that the performance of co-ordination skills was much more impaired than with either drug alone.[1]

This increased CNS depression due to the combined use of alcohol and barbiturates has been described in other clinical studies with **phenobarbital**.[2,3] However, a study in healthy subjects found that although **phenobarbital** 45 mg daily for one week and alcohol (35 to 45 mg%) affected some perceptual-motor tests when given separately, these effects were not always found when they were given together.[4] Nevertheless, high doses of **phenobarbital** can affect driving skills[5] and increased CNS depression has featured very many times in coroners' reports of fatal accidents and suicides involving barbiturates and alcohol.[6] A study of the fatalities due to this interaction indicated that with some barbiturates the CNS depressant effects are more than additive.[7] There is also some evidence that blood-alcohol levels may be reduced in the presence of a barbiturate.[8,9]

For the interaction between thiopental and alcohol, see 'Anaesthetics, general + Alcohol', p.102.

Mechanism

Both alcohol and the barbiturates are CNS depressants, and simple additive CNS depression provides part of the explanation. Acute alcohol ingestion may inhibit the liver enzymes concerned with the metabolism of barbiturates such as phenobarbital and **pentobarbital**, but chronic exposure to alcohol increases hepatic microsomal enzyme activity and may reduce sedation from barbiturates in patients without liver impairment.[10,11] Similarly, chronic exposure to a barbiturate such as phenobarbital may increase alcohol metabolism due to enzyme induction and consequently reduce blood-alcohol levels.[7]

Importance and management

Few formal studies in normal clinical situations have been made of the interactions between alcohol and the barbiturates, and most of these studies are old and involved barbiturates used as hypnotics. However, the effects

(particularly those that result in fatalities) are very well established, serious, and of clinical importance. The most obvious hazards are increased drowsiness, lack of alertness, and impaired co-ordination, which make the handling of potentially dangerous machinery (e.g. car driving), and even the performance of everyday tasks (e.g. walking downstairs) more difficult and dangerous. Only amobarbital and phenobarbital appear to have been specifically studied, but this interaction would be expected with all of the barbiturates. Some barbiturate hangover effects may be present the next morning and may therefore continue to interact significantly with alcohol. Patients should be warned.

For comments on the use of alcohol in epileptic patients taking drugs including phenobarbital, see 'Alcohol + Antiepileptics', p.49.

Alcohol + Benzodiazepines and related drugs

Benzodiazepine and related hypno-sedatives increase the CNS depressant effects of alcohol to some extent. The risks of car driving and handling other potentially dangerous machinery are increased. The risk is heightened because the patient may be unaware of being affected. Some benzodiazepines used at night for sedation are still present in appreciable amounts the next day and therefore may continue to interact. Alcohol may also increase the plasma levels of brotizolam, clobazam, diazepam, and possibly triazolam, whereas alprazolam may increase blood-alcohol levels. Alcohol has been reported to increase aggression or amnesia and/or reduce the anxiolytic effects of some benzodiazepines.

Clinical evidence

(a) Additive CNS depressant effects

It is very difficult to assess and compare the results of the very many studies of this interaction because of the differences between the tests, their duration, the dosages of the benzodiazepines and alcohol used, whether the drugs were given chronically or acutely, and a number of other variables. However, the overall picture seems to be that benzodiazepines and related drugs including **diazepam**,[1-12] **alprazolam**,[13-15] **bromazepam**,[16] **brotizolam**,[17] **chlordiazepoxide**,[12,18-22] **clobazam**,[23] **dipotassium clorazepate**,[24] **flunitrazepam**,[25,26] **flurazepam**,[27-31] **loprazolam**,[28,32] **lorazepam**,[10,33-36] **lormetazepam**,[37] **medazepam**,[38] **midazolam**,[39] **nitrazepam**,[3,40,41] **oxazepam**,[6] **temazepam**,[41-43] **triazolam**,[29,42,44-46] and **zopiclone**[46] enhance the effects of alcohol i.e. cause increased drowsiness, impaired performance and driving skills.

Patients taking benzodiazepines including **lorazepam**[34] or **triazolam**[44] may be unaware of the extent of the impairment that occurs. Furthermore, changes in CNS functioning may possibly occur in heavy social drinkers; a placebo-controlled study in 20-year-olds suggested that **lorazepam** 2 mg had more impairment on delayed auditory verbal memory performance in those who were heavy social drinkers (more than 20 drinks; 200 g of alcohol per week) than light social drinkers (20 g or less of alcohol per week).[47]

Some of the benzodiazepines and related drugs that are used primarily to aid sleep, such as **flunitrazepam**,[25,26] **flurazepam**,[27,28,30,31,48] **nitrazepam**,[3,40] and **temazepam**,[48,49] when taken the night before alcohol or in the evening with alcohol, can still interact with alcohol the next morning. However, **midazolam**,[39] **loprazolam**,[28] **lormetazepam**,[37] **triazolam**,[31,46] **zolpidem**,[50] and **zopiclone**[25,30,46] have been reported not to do so. The sedative effects of **midazolam** alone, and **midazolam** with fentanyl have been shown to have dissipated within 4 hours, and to not be affected by alcohol after this time.[51,52] However, some patients may metabolise **midazolam** more slowly and so an interaction could still be possible,[53] especially in older patients or those receiving additional drugs.[54]

Some contrasting effects have also been reported. One study suggested that alcohol might mitigate the effects of **loprazolam** on psychological performance.[32] Similarly, some antagonism has been reported between **chlordiazepoxide** and alcohol, but this is unlikely to be of practical importance.[18,19] The development of tolerance between benzodiazepines and alcohol with chronic use has also been suggested.[55,56]

(b) Increased aggression, anxiety, or amnesia

The anxiolytic effects of **lorazepam**[35] and possibly **chlordiazepoxide**[20] may be opposed by alcohol. **Alprazolam** and alcohol together may possibly increase behavioural aggression.[57] Similarly, **flunitrazepam** abuse can cause violent behaviour, impulsive decision-making and anterograde amnesia: a report looking at violent crimes committed by abusers of **flunitrazepam** found that alcohol was almost always also present.[58] Alcoholic drinks also enhance the effects of **flunitrazepam** when it is used as a 'date rape' drug.[59]

(c) Pharmacokinetic effects

Several studies have reported that alcohol increases the plasma levels of **diazepam**[13,60] and that alcohol accelerates the absorption of **diazepam**,[5] but others have suggested that alcohol has no significant effect on diazepam pharmacokinetics.[9,11,61] Plasma levels of **brotizolam**[17] and **clobazam**[23] may be increased by alcohol. One study reported that the plasma levels of **triazolam** were increased by alcohol,[44] but other studies have found only a minimal pharmacokinetic interaction.[45,46] However, two *in vitro* studies have demonstrated that alcohol weakly inhibits the metabolism of **triazolam**;[62,63] one study showed that this was due to inhibition of the cytochrome P450 subfamily CYP3A.[62] Another *in vitro* study reported that the formation of **flunitrazepam** metabolites was weakly inhibited by alcohol,[64] but a pharmacokinetic study suggested that there was no interaction.[26] Alcohol appears to have minimal effects on the pharmacokinetics of **alprazolam**,[13] and **zopiclone**.[46,65]

The pharmacokinetics of alcohol do not appear to be affected to a clinically significant extent by **diazepam**,[11] **flunitrazepam**,[26] **zolpidem**,[50] or **zopiclone**,[46] but **alprazolam**[13] may increase blood-alcohol levels.

Mechanism

The CNS depressant actions of the benzodiazepines and alcohol are mainly additive and it appears that different aspects of CNS processing may be involved.[41,66]

A pharmacokinetic interaction can sometimes occur, but the mechanisms seem to be quite complex. Acute alcohol intake increases the absorption and raises the serum levels of some benzodiazepines[23,60] and there may be direct competitive *inhibition* of metabolism.[67] It has been suggested that clearance of benzodiazepines via phase I metabolism, by *N*-demethylation and/or hydroxylation, tends to be more affected by alcohol intake than that of drugs such as lorazepam, oxazepam or lormetazepam that only undergo phase II conjugation. In addition, phase I metabolism is inhibited or decreases with increasing age and liver disease.[67] However, phase I metabolism is *increased* by chronic administration of substances that induce the cytochrome P450 isoenzyme system, such as alcohol,[67] and moderate alcohol consumption may cause intestinal CYP3A induction resulting in reduced bioavailability of some benzodiazepines, such as midazolam.[68]

Importance and management

Extensively studied, well established and clinically important interactions. The overall picture is that these drugs worsen the detrimental effects of alcohol.[69] Up to a 20 to 30% increase in the impairment of psychomotor function has been suggested.[44] The deterioration in skills will depend on the particular drug in question, its dosage and the amounts of alcohol taken. With modest amounts of alcohol the effects may be quite small in most patients (although a few may be more markedly affected[11]), but anyone taking any of these drugs should be warned that their usual response to alcohol may be greater than expected, and their ability to drive a car, or carry out any other tasks requiring alertness, may be impaired. They may be

quite unaware of the deterioration or that the effects may still be present the following day. Benzodiazepines and alcohol are frequently found in the blood of car drivers involved in traffic accidents, which suggests that the risks are real.[56,69-72] Furthermore, alcohol may contribute to fatal poisonings and other deaths involving benzodiazepines, particularly diazepam[73-76] and temazepam.[77] Alcohol may contribute to drug-related accidents and deaths due to a disregard for safety;[72,78] and there is also an association between alcohol and benzodiazepines and violence-related accidents.[72]

Alcohol + Beta blockers

The haemodynamic and pharmacokinetic effects of atenolol and metoprolol in healthy subjects do not appear to be changed by alcohol. There is some evidence that alcohol modestly reduces the haemodynamic effects of propranolol, and some of the effects of sotalol may also be changed by alcohol. Some evidence suggests that the effects of alcohol and atenolol with chlortalidone or propranolol are additive on the performance of some psychomotor tests, but the importance of this is uncertain.

Clinical evidence, mechanism, importance and management

(a) CNS effects

In 12 healthy subjects the performance of a number of psychomotor tests was found to be impaired by alcohol 0.6 g/kg and by one tablet of *Tenoretic* (**atenolol** 100 mg with chlortalidone 25 mg). When alcohol and *Tenoretic* were taken together there was some evidence of additive effects but the practical importance of this is not clear.[1]

In 12 healthy subjects **propranolol** 40 mg every 6 hours had no effect on the impairment of performance of a number of psychomotor tests caused by 50 mL/70 kg of alcohol, except that **propranolol** antagonised the effect of alcohol in one test (pursuit meter).[2] However, in another study, **propranolol** enhanced the effects of alcohol on some tests (inebriation and divided attention).[3]

The manufacturer of **oxprenolol** warns that the effects of alcohol and beta blockers on the CNS have been observed to be additive.[4] Similarly, one manufacturer of **bisoprolol** notes that, although bisoprolol did not impair driving performance in one study, some patients may be affected, and this should be considered, particularly when alcohol is also given.[5]

(b) Haemodynamic and pharmacokinetic effects

In 8 healthy subjects the pharmacokinetics of single 100-mg doses of **atenolol** or **metoprolol** were unaffected 6 hours after they had drunk the equivalent of 200 mL of absolute alcohol. No clinically significant changes in blood pressure or pulse rate were seen.[6] A similar study in 23 healthy subjects found that **atenolol** 100 mg did not affect the pharmacokinetics of alcohol 1 g/kg. However, alcohol increased the reduction in heart rate and blood pressure in response to **atenolol** (from 60 bpm to 56 bpm and from 124/82 mmHg to about 109/76 mmHg at 2 and 3 hours after ingestion).[7]

A study in 6 healthy subjects found that alcohol (sufficient to maintain blood-alcohol levels of 80 mg%) raised the mean AUC of a single 80-mg oral dose of **propranolol** by about 17% in 5 subjects and decreased it by 37% in the other subject, but this was considered unlikely to be clinically important. No changes in heart rate or blood pressure were seen.[8] In contrast, a double-blind study in 14 healthy subjects found that alcohol (equivalent to 32 to 72 mL of absolute alcohol) increased the clearance of a single 80-mg dose of **propranolol** and diminished its ability to lower blood pressure. **Propranolol** was not able to abolish the alcohol-induced rise in heart rate.[9] Similarly, another study found that alcohol decreased the rate of absorption and increased the rate of elimination of **propranolol**, but the clinical significance of this small alteration was not assessed.[10] Other studies have found that **propranolol** enhances the decrease in blood pressure seen with alcohol,[11,12] but attenuates[11] or does not alter[12] its effects on heart rate. Furthermore, alcohol may increase peak propranolol levels by 2- to 3.5-fold.[12]

A study in 6 healthy subjects found that although the blood pressure lowering effects of **sotalol** 160 mg were increased by alcohol, **sotalol** did not cancel out the alcohol-induced rise in heart rate.[9]

It would seem prudent to be alert for changes in response to beta blockers that may be due to alcohol. See also, 'Alcohol + Antihypertensives', p.51.

Alcohol + Bicalutamide, Flutamide or Nilutamide

Alcohol intolerance (facial flushing, malaise, hypotension) has been reported in patients taking nilutamide, but not in those taking bicalutamide or flutamide.

Clinical evidence, mechanism, importance and management

Several studies have described alcohol intolerance (facial flushes, malaise, hypotension) in patients taking nilutamide.[1-4] The incidence has been reported to be between 3% and 19%.[1-3,5] It is recommended that patients who experience this reaction should avoid drinking alcohol.[5]

Flutamide and bicalutamide have not been reported to produce these effects when patients drink alcohol,[3] and so in some cases they may be considered as an alternative option to nilutamide.

Alcohol + Bromocriptine

There is some very limited evidence to suggest that the adverse effects of bromocriptine may possibly be increased by alcohol.

Clinical evidence, mechanism, importance and management

Intolerance to alcohol, which improved on continued treatment, has been briefly mentioned in a report about patients taking bromocriptine for acromegaly.[1] In another report two patients with high prolactin levels were said to have developed bromocriptine adverse effects, even in low doses, while continuing to drink. When they abstained, the frequency and the severity of the adverse effects fell, even with higher doses of bromocriptine.[2] This, it is suggested, may be due to some alcohol-induced increase in the sensitivity of dopamine receptors.[2] There would seem to be little reason, on the basis of this extremely sparse evidence, to tell all patients taking bromocriptine not to drink alcohol, but if adverse effects develop, it would be reasonable to warn them to try avoiding alcohol.

Alcohol + Bupropion

The concurrent use of bupropion and alcohol does not appear to affect the pharmacokinetics of either drug; however, some adverse CNS effects may occur on concurrent use.

Clinical evidence, mechanism, importance and management

Single-dose studies in healthy subjects found that the pharmacokinetics of bupropion 100 mg were not affected by the concurrent use of alcohol, and bupropion did not affect blood-alcohol levels.[1,2] However, rare cases of adverse neuropsychiatric events and reduced alcohol tolerance have been reported in patients who drink alcohol while taking bupropion.[3,4] Because of this, the manufacturers recommend that the consumption of alcohol should be minimised or avoided.[3,4] Moreover, because abrupt withdrawal from alcohol is a risk factors for seizures, and there is a small dose-related risk of seizures with bupropion, the manufacturers contraindicate the use of bupropion in patients undergoing abrupt withdrawal from alcohol, and caution its use in alcohol abuse.[3,4]

Alcohol + Buspirone

The use of buspirone with alcohol may cause drowsiness and weakness, although it does not appear to impair the performance of a number of psychomotor tests.

Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects found that, in contrast to lorazepam, buspirone 10 or 20 mg did not appear to interact with alcohol (i.e. worsen the performance of certain psychomotor tests), but it did make the subjects feel drowsy and weak.[1,2] Similarly, another study in 13 healthy subjects found that giving buspirone (15 and 30 mg/70 kg) with alcohol caused sedation, but very little impairment of performance. In this study, the sedative effects were broadly similar to those seen with alprazolam plus alcohol, but alprazolam plus alcohol clearly impaired performance.[3] Similar findings were reported in another earlier comparison with diazepam.[4] A further study reported that single 5 to 15-mg doses of buspirone had a minimal effect on performance in both light and moderate female social drinkers.[5]

The UK manufacturer notes that there is no information on higher therapeutic doses of buspirone given with alcohol, and they suggest that it would be prudent to avoid alcohol while taking buspirone.[6] They also caution patients of the potential hazards of driving or handling other potentially dangerous machinery until they are certain that buspirone does not adversely affect them.[6] The evidence would appear to support this suggestion.

Alcohol + Butyraldoxime

A disulfiram-like reaction can occur in those exposed to *N*-butyraldoxime if they drink alcohol.

Clinical evidence, mechanism, importance and management

Workers in a printing company complained of flushing of the face, neck and upper trunk, shortness of breath, tachycardia and drowsiness very shortly after drinking alcohol (about 45 mL of whiskey), and were found to have increased levels of acetaldehyde in their blood. The reason appeared to be that the printing ink they were using contained *N*-butyraldoxime, an antioxidant which, like 'disulfiram', (p.66), can inhibit the metabolism of alcohol causing acetaldehyde to accumulate.[1] It is possible that it is a metabolite of *N*-butyraldoxime that causes this effect, rather than *N*-butyraldoxime itself.[2] This reaction would seem to be more unpleasant and socially disagreeable than serious. No treatment normally seems necessary.

Alcohol + Caffeine

Objective tests show that caffeine may counteract some of the effects of alcohol. However, it does not completely sober up those who have drunk too much, and may even make them more accident-prone.

Clinical evidence

(a) Effect on skills related to driving

A study in a large number of healthy subjects given a cup of **coffee** containing caffeine 300 mg/70 kg, either alone or immediately after drinking alcohol 0.75 g/kg, found that caffeine did not antagonise the deleterious effect of alcohol on the performance of psychomotor skill tests. Only reaction times were reversed.[1] Two other studies also found that caffeine did not antagonise the effects of alcohol in a variety of tests.[2,3] A further study in 8 subjects found that, contrary to expectations, caffeine increased the frequency of errors in the performance of a serial reaction time task,[4] although a later study did not find this effect.[5] Caffeine has also been reported to *increase* the detrimental effects of alcohol.[6]

In contrast, more recent studies (usually using caffeine in capsule form) have found that some of the performance-impairing effects of alcohol such as increased reaction time,[7-9] increased errors with four choice reaction time,[10] impaired performance of divided attention tasks,[5] sedation,[11] and slowing of psychomotor speed[10] can be antagonised by caffeine given with the alcohol. However, caffeine does not appear to restore most subjective effects e.g. feelings of drunkenness.[7,11,12] One study found that the alcohol-caffeine combination typically altered the effects of caffeine alone rather than altering the effects of alcohol alone. For example the addition of alcohol reduced the jitteriness and alertness produced by caffeine, and although caffeine modestly antagonised alcohol impairment of driving, there was still a 9% increase in brake-response time, when compared with placebo.[12]

(b) Pharmacokinetic effects

In a placebo-controlled, crossover study in 8 healthy subjects, the AUC of a 400-mg caffeine capsule was 30% greater when it was taken with alcohol 0.8 g/kg than when taken alone. Blood-alcohol levels were not affected by caffeine use.[7] Similarly, other studies reported that alcohol increases serum-caffeine levels[2] and that blood-alcohol levels were not modified by caffeine.[1,2,8] However, one study in 8 healthy subjects reported that caffeine 3.3 mg/kg reduced blood-alcohol levels, measured 30 minutes after a single 0.7-g/kg dose of ethanol, from 38 mg% to 26 mg%.[9]

Mechanism

Not fully understood. Caffeine is a CNS stimulant, which seems to oppose some of the CNS depressant effects of alcohol. It appears that only those objective tests able to detect an enhancement due to a CNS stimulant show the clearest antagonistic effects.[7]

Alcohol appears to modestly inhibit the hepatic metabolism of caffeine.[2]

Importance and management

It is not known why some studies report that caffeine antagonises some of the detrimental effects of alcohol and others report no interaction. However, the type of psychomotor tests, the amount of alcohol and caffeine consumed, and the timing and administration of the caffeine may affect the results.

Caffeine does appear to improve some of the detrimental effects of alcohol in some psychomotor tests, which is probably why there is a long-standing and time-hallowed belief in the value of strong black coffee to sober up those who have drunk too much. In addition, it is just possible that the time taken to drink the coffee gives the liver just a little more time to metabolise some of the alcohol. However, it seems that it is not effective

in all aspects of alcohol impairment, particularly subjective effects. In addition, caffeine does not reduce blood-alcohol levels. **Coffee** and other sources of caffeine do not make it safe to drive or handle dangerous machinery, and it may even make drivers more accident-prone.

Alcohol + Calcium carbimide

Alcohol causes a disulfiram-like reaction in patients taking calcium carbimide. Calcium carbimide has been used as an alcohol deterrent.

Clinical evidence, mechanism, importance and management

Calcium carbimide interacts with alcohol in a similar way to disulfiram and by a similar mechanism[1] (see 'Alcohol + Disulfiram', p.66). Both of these drugs bind to aldehyde dehydrogenase, but calcium carbimide is said to have fewer adverse effects because it does not bind to dopamine beta hydroxylase.[2] However, marked cardiovascular effects and fatalities have occurred in those who drank alcohol while taking calcium carbimide.[3,4] Like disulfiram it is used to deter alcoholics from continuing to drink.[1,2]

Alcohol + Calcium-channel blockers

Blood-alcohol levels can be raised and may remain elevated for a much longer period of time in patients taking verapamil. Alcohol may also increase the bioavailability of felodipine, nifedipine and possibly prolonged-release diltiazem, but amlodipine appears not to interact. An increased incidence of postural hypotension has been reported in patients who took felodipine with alcohol.

Clinical evidence

(a) Amlodipine

A study in 30 healthy subjects found that single and multiple doses of amlodipine 10 mg for 15 days (with or without lisinopril and simvastatin) had no effect on the pharmacokinetics of alcohol 0.8 g/kg, and subjective psychological performance was unaffected. Alcohol did not alter the pharmacokinetics of amlodipine.[1]

(b) Felodipine

A study in 8 healthy subjects given enough alcohol to maintain their blood levels at 80 to 120 mg% found that their felodipine levels (following a single 10-mg oral dose) were approximately doubled (AUC increased by 77%, maximum blood levels increased by 98%). Diuresis was approximately doubled and heart rates were increased.[2]

In a study, 8 non-smoking, healthy subjects were given a single 10-mg dose of an extended-release preparation of felodipine, with 250 mL red wine, on an empty stomach and 4 hours before a meal. Red wine reduced felodipine levels for the first 4 hours of the study, when compared with 250 mL water, but felodipine levels rose rapidly 5 hours after dosing, resulting in a peak level that was higher with red wine than with water.[3]

Another study suggested that alcohol increased the haemodynamic effects of felodipine (lower total peripheral resistance, lower blood pressure, higher heart rate) and increased the rate of adverse effects (e.g. postural lightheadedness).[4] However, the alcohol was given in grapefruit juice, which is known to increase felodipine levels; indeed, felodipine levels were reported as being higher than expected in this study, so it is possible these effects were, at least in part, due to an interaction with 'grapefruit juice', (p.1034).

(c) Isradipine

In a placebo-controlled study, 9 healthy subjects were given isradipine 5 or 10 mg followed by alcohol 0.5 or 1 g/kg. The performance impairment in response to alcohol was not affected by isradipine. However, increases in heart rate, and decreases in blood pressure appeared to be enhanced when both drugs were taken together. Furthermore, isradipine 10 mg caused a small decrease in breath-alcohol levels.[5]

(d) Nifedipine

Alcohol (75 mL of alcohol 94% with 75 mL of orange juice) given to 10 healthy subjects increased the AUC of a single 20-mg dose of nifedipine by 54%, but no significant changes in heart rate or blood pressure were seen.[6] Another study, involving 226 patients taking sustained-release nifedipine, found that reported alcohol use was associated with reduced nifedipine clearance (8.6 mL/minute per kg compared with 10.8 mL/minute per kg for alcohol use and no alcohol, respectively).[7] In another study no evidence was found that nifedipine 10 or 20 mg antagonised the effects of alcohol.[8]

(e) Nimodipine

In a randomised study in 6 healthy subjects, a single 30 or 60-mg dose of nimodipine had no significant effect on the subjective or psychomotor response to a single oral 0.7-g/kg dose of alcohol, and there were no clinically significant changes in blood pressure or heart rate. Nimodipine 60 mg reduced the peak breath-alcohol level by 20 mg%, but this was considered slight.[9]

(f) Verapamil

In one study, 10 healthy subjects were given verapamil 80 mg three times daily for 6 days with alcohol 0.8 g/kg on day 6. Peak blood-alcohol levels were found to be raised by almost 17% (from about 106 to 124 mg%) and the $AUC_{0\text{-}12}$ was raised by almost 30%. The time that blood-alcohol levels exceeded 100 mg% was prolonged from 0.2 to 1.3 hours and the subjects said they felt more intoxicated.[10] In another study no evidence was found that verapamil 80 or 160 mg antagonised the effects of alcohol.[8] A further randomised study in 6 healthy subjects found that a single 80-mg dose of verapamil had no significant effect on the subjective or psychomotor response to a single oral 0.7-g/kg dose of alcohol, and no clinically significant changes were noted in blood pressure or heart rate. The pharmacokinetics of alcohol were not affected by verapamil.[9]

Mechanism

Not understood. It seems possible that verapamil inhibits the metabolism of alcohol by the liver, thereby reducing its loss from the body. Alcohol also appears to inhibit the metabolism of nifedipine, and to increase the bioavailability of felodipine. Red wine may have caused "dose dumping" of felodipine from the extended-release preparation, which altered its pharmacokinetic profile, but the reason why the felodipine levels remained low until after a meal is unclear.[3] An *in vitro* study demonstrated that alcohol inhibited the oxidative metabolism of nifedipine by the cytochrome P450 subfamily CYP3A.[11]

Importance and management

Information seems to be limited to these reports and they need confirmation. Information regarding **verapamil** is conflicting, with one study finding no pharmacokinetic interaction and another finding an almost 17% increase in blood-alcohol levels. This increase could be enough to raise legal blood levels to illegal levels if driving. Moreover the intoxicant effects of alcohol persisted for a much longer period of time (five times longer) in

this study. Therefore, despite the conflicting findings, it may be prudent to bear the possibility of an interaction in mind. The decreases in breath-alcohol levels with **felodipine** and **nimodipine** were modest, and unlikely to be of clinical significance because performance indicators were not altered. However, the bioavailability of **felodipine** and **nifedipine** appear to be increased by alcohol. The manufacturers of some calcium-channel blockers warn that inter-individual variations in the response to these drugs can occur and some patients ability to drive or operate machinery may be impaired, particularly at the start of treatment and in conjunction with alcohol.[12,13] Patients should therefore be advised about these effects. The manufacturers of a prolonged-release **diltiazem** preparation (*Adizem*) similarly warn that alcohol may increase the rate of diltiazem release, and therefore suggest that alcohol should not be taken at the same time as this preparation.[14]

Note that long-term moderate to heavy drinking can impair the efficacy of antihypertensives, see 'Alcohol + Antihypertensives', p.51.

Alcohol + Cannabis

The detrimental effects of drinking alcohol and smoking cannabis may be additive on some aspects of driving performance. However, there is some evidence that regular cannabis use *per se* does not potentiate the effects of alcohol. Smoking cannabis may alter the bioavailability of alcohol.

Clinical evidence and mechanism

(a) CNS effects

Simultaneous use of alcohol and oral Δ^9-tetrahydrocannabinol (THC, the major active ingredient of cannabis) reduced the performance of psychomotor tests, suggesting that those who use both drugs together should expect the deleterious effects to be additive.[1] In a further placebo-controlled study, subjects smoked cannabis containing 100 or 200 micrograms/kg of Δ^9-tetrahydrocannabinol and drank alcohol (to achieve an initial blood level of 70 mg%, with further drinks taken to maintain levels at 40 mg%) 30 minutes before driving. They found that cannabis, even in low to moderate doses, negatively affected driving performance in real traffic situations. Further, the effect of combining moderate doses of both alcohol and cannabis resulted in dramatic performance impairment as great as that observed with blood-alcohol levels of 140 mg% alone.[2,3] Similar results (including a suggestion of a synergistic impairment of performance[4]) have been found in a number of other studies,[4,5] including different doses of cannabis and regular cannabis users.[5]

A study in 22 healthy subjects, who occasionally used cannabis cigarettes and drank moderate amounts of alcohol, found that the number of euphoric events in response to a cannabis cigarette was greater after alcohol ingestion, and the duration of euphoric events was longer. The speed of onset of the effects of cannabis was also faster when it was smoked after the ingestion of alcohol.[6]

One study in 14 regular cannabis users (long-term daily use) and 14 infrequent cannabis users found that regular use reduced the disruptive effects of alcohol on some psychomotor skills relevant to driving, whereas infrequent use did not have this effect. In this study, neither group had smoked any cannabis in the 12 hours before the alcohol test.[7] Another study found that moderate doses of alcohol and cannabis, consumed either alone or in combination, did not produce significant behavioural or subjective impairment the following day.[8]

A study in 12 healthy subjects who regularly used both cannabis and alcohol found that alcohol 0.5 g/kg significantly increased break latency without affecting body sway, whereas cannabis given as a cigarette containing tetrahydrocannabinol 3.33%, increased body sway but did not affect brake latency. There were no significant additive effects on brake latency, body sway, or mood when the two drugs were used together.[9] A population-based study of 2,777 drivers involved in fatal road crashes, who drank alcohol and/or used cannabis, found that although both cannabis and alcohol increased the risk of being responsible for a fatal crash, no statistically significant interaction was observed between the two drugs.[10]

(b) Pharmacokinetic studies

Fifteen healthy subjects given alcohol 0.7 g/kg developed peak plasma alcohol levels of about 78 mg% at 50 minutes, but if they smoked a cannabis cigarette 30 minutes after the drink, their peak plasma alcohol levels were only 55 mg% and they occurred 55 minutes later. In addition, their subjective experience of the drugs decreased when used together.[11] However, another study found that smoking cannabis 10 minutes before alcohol consumption did not affect blood-alcohol levels.[8] A further study found that blood-alcohol levels were not affected by Δ^9-tetrahydrocannabinol given orally one hour before alcohol.[1] A study in 22 healthy subjects, who occasionally used cannabis cigarettes and drank moderate amounts of alcohol, found that plasma Δ^9-tetrahydrocannabinol levels were higher when alcohol was consumed before smoking a cannabis cigarette.[6]

Importance and management

Several studies have found that cannabis and alcohol produce additive detrimental effects on driving performance, but other studies have not found any potentiation. This is probably due to the variety of simulated driving tests used and possibly the time lag between the administration of alcohol and cannabis; behavioural impairment after cannabis has been reported to peak within 30 minutes of smoking.[8] Nevertheless, both drugs have been shown to affect some aspects of driving performance and increase the risk of fatal car accidents. Concurrent use of cannabis and alcohol before driving should therefore be avoided.

Alcohol + Carbamazepine

Moderate social drinking does not affect the serum levels of carbamazepine. Heavy drinking may possibly increase the metabolism of carbamazepine, and this may be further increased in alcoholics who abstain from drinking alcohol.

Clinical evidence, mechanism, importance and management

(a) Heavy drinking and alcohol withdrawal

A study in 7 alcoholics who consumed a mean dose of 750 mL of spirits (240 g of alcohol) daily found that the early (0 to 4 hours) bioavailability of a single 400-mg dose of carbamazepine was not affected by 9 days of controlled alcohol withdrawal. However, over the 4 to 12-hour period, carbamazepine levels were higher, and those of its epoxy metabolite lower, in alcoholics following alcohol exposure, when compared with abstinence. This effect was thought to be due to the acute inhibition of carbamazepine metabolism by alcohol and/or accelerated carbamazepine metabolism in the abstinence phase. The absorption rate of carbamazepine in alcoholics appeared to be slower, when compared with 8 healthy subjects, probably due to alcoholism-induced chronic gastrointestinal changes; however, this did not significantly affect the maximum serum levels of alcohol. However, adverse effects occurred in all of the healthy subjects but in none of the alcoholics, possibly indicating that long-term alcohol exposure may make the patient less sensitive to acute carbamazepine exposure.[1]

The long-term use of alcohol can cause induction of hepatic enzyme systems possibly resulting in increased metabolism and reduced plasma levels of carbamazepine. The risk of seizures may also increase on tapering or stopping alcohol because of an increase in metabolism and elimination caused by the relative lack of a competing substrate.[2]

(b) Moderate social drinking

Alcohol 25 g did not affect the bioavailability of carbamazepine in 8 healthy subjects.[1] A study in non-drinking epileptics (21 in the experimental alcohol group, 18 in the control group) found that the serum levels of carbamazepine were unchanged by moderate drinking (1 to 3 glasses of an alcoholic beverage, containing 9.85 g of alcohol, twice weekly), and there was no influence on tonic-clonic convulsions or partial complex seizures.[3]

For comment on moderate social drinking in epileptics and also the possible increased sedative effect of carbamazepine with alcohol, see 'Alcohol + Antiepileptics', p.49.

Alcohol + Carmofur

A disulfiram-like reaction occurred in a patient taking carmofur when he was given a coeliac plexus blockade with alcohol.

Clinical evidence, mechanism, importance and management

A man with pancreatic carcinoma taking carmofur 500 mg daily for 25 days experienced a disulfiram-like reaction (facial flushing, diaphoresis, hypotension with BP 60/30 mmHg, and tachycardia of 128 bpm) within 30 minutes of being given a coeliac plexus alcohol blockade for pain relief. Blood acetaldehyde levels were found to have risen sharply, supporting the belief that the underlying mechanism is similar to the disulfiram-alcohol interaction (see 'Alcohol + Disulfiram', p.66, for further explanation). It is suggested that alcohol blockade should be avoided for 7 days after treatment with carmofur.[1]

Alcohol + Cephalosporins

Disulfiram-like reactions can occur in those who take cefamandole, cefmenoxime, cefoperazone, cefotetan, latamoxef (moxalactam) and possibly cefonicid, and drink alcohol. This is not a general reaction of the cephalosporins, but is confined to those with particular chemical structures.

Clinical evidence

A young man with cystic fibrosis was given **latamoxef** 2 g intravenously every 8 hours for pneumonia. After 3 days of treatment he drank, as was his custom, a can of beer with lunch. He rapidly became flushed with a florid macular eruption over his face and chest. This faded over the next 30 minutes but he complained of severe nausea and headache. Similarly, a patient taking **latamoxef** became flushed, diaphoretic and nauseated after drinking a cocktail of vodka and tomato juice.[1] This reaction has also been described in two subjects who drank alcohol while receiving **latamoxef**,[2] two of 10 subjects given **latamoxef** and alcohol,[3] and a patient taking **latamoxef** given theophylline elixir containing alcohol 20%.[4] It has also been seen in a patient taking **latamoxef** following the injection of alcohol into the para-aortic space for coeliac plexus block.[5] The symptoms experienced by these patients have included flushing of the face, arms and neck, shortness of breath, headache, tachycardia, dizziness, hyper- and hypotension, and nausea and vomiting.

Similar reactions have been described in patients or subjects receiving **cefamandole**,[6,7] **cefoperazone**,[8-15] **cefmenoxime**,[16] **cefonicid**[17] and **cefotetan**,[18] after drinking wine, beer, or other alcoholic drinks, or after the ingestion of an 8.5% alcoholic elixir.[16]

This disulfiram-like reaction is not a general reaction of all the cephalosporins. One study found no interaction in those taking **cefpirome** and alcohol,[19] and in another, **ceftizoxime** was reported not to interact with alcohol.[20] No interaction was seen with **cefonicid** and alcohol in one placebo-controlled study;[21] however, a case report describes a disulfiram-reaction in one patient taking the combination.[17]

Mechanism

These reactions appear to have the same pharmacological basis as the disulfiram/alcohol reaction (see 'Alcohol + Disulfiram', p.66). Three of these cephalosporins (latamoxef, cefamandole and cefoperazone) can raise blood acetaldehyde levels in *rats* when alcohol is given, but to a lesser extent than disulfiram.[2,11,22] It appears that any reaction normally only occurs with cephalosporins that possess a methyltetrazolethiol group in the 3-position on the cephalosporin molecule,[11,23] but it has also been seen with cefonicid, which possesses a methyl sulphonthiotetrazolic group instead.[17] Some amine-containing cephalosporins (**cefalexin**, **cefadroxil** and **cefradine**) have also been reported to interact with acetaldehyde *in vitro*, but the clinical significance of this is unknown.[24]

Importance and management

Established but unpredictable interactions of varying incidence. In studies, two out of 10 subjects taking latamoxef and alcohol reacted,[3] five out of 8 taking cefotetan reacted,[18] and 8 out of 9 taking cefoperazone reacted.[14,15] The reaction appears normally to be more embarrassing or unpleasant and frightening than serious, with the symptoms subsiding spontaneously after a few hours. There is evidence that the severity varies; in one study cefoperazone was said to be worse than latamoxef, which in turn was said to be worse than **cefmetazole**.[25] Treatment is not usually needed but there are two reports[4,6] of two elderly patients who needed treatment for hypotension, which was life-threatening in one case;[4] plasma expanders and dopamine have been used as treatment.[4,6]

Because the reaction is unpredictable, warn all patients taking these potentially interacting cephalosporins (cefamandole, cefmenoxime, cefmetazole, cefonicid, cefoperazone, cefotetan, latamoxef) that it can occur during and up to 3 days after the course of treatment is over. Advise them to avoid alcohol. Those with renal or hepatic impairment in whom the drug clearance is prolonged should wait a week. It should not be forgotten that some foods and pharmaceuticals contain substantial amounts of alcohol, and a reaction with some topically applied alcohol-containing products cannot be excluded (see 'Alcohol + Disulfiram', p.66).

A number of other cephalosporins are possible candidates for this reaction because they possess the methyltetrazolethiol group in the 3-position. These include, **ceforanide**, **cefotiam**, and **cefpiramide**,[11,23] but there do not appear to be any reports of an interaction between alcohol and these drugs.

Alcohol + Ciprofloxacin

Ciprofloxacin does not significantly affect the pharmacokinetics of alcohol or its effects on psychomotor performance. There is an isolated report of a cutaneous reaction to ciprofloxacin, which may have been precipitated by alcohol consumption.

Clinical evidence, mechanism, importance and management

In a study in 12 healthy subjects, ciprofloxacin 500 mg twice daily for 3 days had no significant effect on the pharmacokinetics of a single 30-g oral dose of alcohol (75 mL of vodka), and the performance of a number of psychomotor tests was unaffected.[1] A study in 8 healthy male subjects found that ciprofloxacin 750 mg twice daily for 7 days decreased the elimination rate of alcohol 0.63 g/kg by about 10% and increased its AUC by 11%, which would not be expected to be clinically significant. It was suggested that ciprofloxacin reduced the number of aerobic bacteria in the gut, which reduced alcohol dehydrogenase activity and therefore reduced ethanol metabolism.[2]

There is an isolated report of red blotches developing on the face and body of a tetraplegic patient taking ciprofloxacin 250 mg twice daily, which developed within 10 minutes of drinking 2 cans of beer containing alcohol 4.7%. He did not feel unwell or drowsy, and the blotches faded over a period of 30 minutes. Previous courses of ciprofloxacin had not produced any adverse effects and the same brand of alcohol caused no problems in the absence of ciprofloxacin.[3] The general clinical importance of this report is unknown, but it seems likely to be small.

Alcohol + Clomethiazole

Clomethiazole has been successfully used to treat alcohol withdrawal, but the long-term use of alcohol with clomethiazole can cause serious CNS depression, due to additive CNS depressant effects. This is potentially fatal, even with short-term use in alcoholics with cirrhosis. The concurrent use of clomethiazole and alcohol may affect driving skills, and the bioavailability of clomethiazole may be increased by alcohol.

Clinical evidence, mechanism, importance and management

(a) Enhanced adverse effects and bioavailability

The following is taken from an editorial in the British Medical Journal, which was entitled 'Chlormethiazole and alcohol: a lethal cocktail'.[1]

Clomethiazole is commonly used to treat withdrawal from alcohol because of its hypnotic, anxiolytic and anticonvulsant effects. It is very effective if a rapidly reducing dosage regimen is followed over six days, but if it is used long-term and drinking continues it carries several serious risks.

Alcoholics readily transfer dependency to clomethiazole and may visit several practitioners and hospitals to get their supplies. Tolerance develops so that very large amounts may need to be taken (up to 25 g daily). Often alcohol abuse continues and the combination of large amounts of alcohol and clomethiazole can result in coma and even fatal respiratory depression, due mainly to simple additive CNS depression.[1]

Other factors contributing to the increase in CNS depression seen include increases in the bioavailability of clomethiazole, probably caused by alcohol impairing first pass metabolism,[2] and, in the case of those with alcoholic cirrhosis, the systemic bioavailability of clomethiazole may be increased tenfold because of venous shunting.[3] A randomised study in 8 healthy subjects found that alcohol 0.8 g/kg increased the AUC of a single 192-mg dose of clomethiazole by 82%.[2] However, one study in 6 healthy subjects reported that intravenous alcohol 0.8 mL/kg given acutely had no effect on the disposition or elimination of clomethiazole. It was proposed that alcohol given orally might affect the absorption or rate of uptake of clomethiazole.[4]

Clomethiazole should not be given long-term for alcohol withdrawal states[1] or to those who continue to drink alcohol.[5] Use for more than 9 days is not recommended.[5,6] It has been said that if prescribers choose to manage detoxification at home, it should be done under very close supervision, issuing prescriptions for only one day's supply to ensure daily contact and to minimise the risk of abuse. Further, if the patient shows evidence of tolerance or clomethiazole dependency or of continuing to drink alcohol, the only safe policy is rapid admission for inpatient care.[1] The manufacturer warns that alcohol combined with clomethiazole particularly in alcoholics with cirrhosis can lead to fatal respiratory depression, even with short-term use.[5]

(b) Effects on driving and related skills

There do not appear to be any studies on the combined effects of clomethiazole and alcohol on driving and related skills, but concurrent use would be expected to increase the risks.

There is a report of a man who had a blood-alcohol level of 23 mg% who was driving dangerously and caused a traffic accident. The clinical signs of impairment were far greater than expected and further analysis of the blood sample identified a high level of clomethiazole (5 mg/L). In 13 other impaired driving cases where clomethiazole was detected in blood samples, the concentrations ranged from 0.3 to 3.3 mg/L.[7] The manufacturer warns that clomethiazole may potentiate or be potentiated by CNS depressant drugs, including alcohol.[5]

Alcohol + Cloral hydrate

Both alcohol and cloral hydrate are CNS depressants, and their effects may be additive, or possibly even synergistic. Some patients may experience a disulfiram-like flushing reaction if they drink alcohol after taking cloral hydrate for several days.

Clinical evidence

Studies in 5 healthy subjects given cloral hydrate 15 mg/kg and alcohol 0.5 g/kg found that both drugs given alone impaired their ability to carry out complex motor tasks. When taken together, the effects were additive, and possibly even more than additive. After taking cloral hydrate for 7 days, one of the subjects experienced a disulfiram-like reaction (bright red-purple flushing of the face, tachycardia, hypotension, anxiety and persistent headache) after drinking alcohol.[1,2]

The disulfiram-like reaction has been described in other reports.[3] Note that the earliest report was published more than a century ago in 1872 and described two patients taking cloral hydrate who experienced this reaction after drinking half a bottle of beer.[2]

Mechanism

Alcohol, cloral and trichloroethanol (to which cloral hydrate is metabolised) are all CNS depressants. During concurrent use, the metabolic pathways used for their elimination are mutually inhibited: blood-alcohol levels rise because the trichloroethanol competitively depresses the oxidation of alcohol to acetaldehyde, while trichloroethanol levels also rise because its production from cloral hydrate is increased and its further conversion and clearance as the glucuronide is inhibited. As a result the rises in the blood levels of alcohol and trichloroethanol are exaggerated, and their effects are accordingly greater.[1,2,4,5] In one subject, blood levels of acetaldehyde during the use of cloral hydrate with alcohol were only 50% of those after alcohol alone, so that the flushing reaction, despite its resemblance to the disulfiram reaction, may possibly have a partially different basis.[2]

Importance and management

A well-documented and established interaction, which has been comprehensively reviewed.[1,2] Only a few references are given here. Patients given cloral hydrate should be warned about the extensive CNS depression that can occur if they drink, and of the disulfiram-like reaction that may occur if they drink after taking cloral hydrate for a period of time. Its incidence is uncertain. The legendary Mickey Finn, which is concocted of cloral hydrate and alcohol, is reputed to be so potent that deep sleep can be induced in an unsuspecting victim within minutes of ingestion, but the evidence seems to be largely anecdotal. Very large doses of both drugs would be likely to cause serious and potentially life-threatening CNS depression.

It seems likely that **cloral betaine**, **triclofos** and other compounds closely related to cloral hydrate will interact with alcohol in a similar manner, but this requires confirmation.

Alcohol + Cocaine

Alcohol increases the levels of cocaine and its active metabolite cocaethylene. Subjective effects such as euphoria are enhanced and some of the CNS-depressant effects of alcohol, such as sedation, are attenuated by cocaine. The combination may be potentially more toxic, with increased cardiovascular effects particularly heart rate.

Clinical evidence

A study in 8 cocaine users found that intranasal cocaine 100 mg and alcohol 0.8 g/kg produced a greater euphoria and feeling of well-being than cocaine alone, and reduced alcohol sedation without altering the feeling of drunkenness. Compared with placebo, the peak heart-rate was increased by 17 bpm, 23 bpm, and 41 bpm, with alcohol, cocaine, or the combination, respectively. In addition, the combination resulted in higher plasma levels of cocaine and the appearance of cocaethylene, an active and potentially toxic metabolite produced by the interaction of the two drugs.[1] Other similar studies have reported comparable findings.[2,3] A further study found that intranasal cocaine 96 mg/70 kg improved behavioural performance, measured by the digit symbol substitution test (DSST), whereas alcohol 1 g/kg decreased DSST performance. The combination of alcohol 1 g/kg with intranasal cocaine 48 or 96 mg/70 kg reduced the DSST below that found with cocaine alone. The combination also additively increased heart rate and diastolic blood pressure. Blood-alcohol levels were not significantly affected by the concurrent use of intranasal cocaine.[4] A study in 6 male subjects found that alcohol 0.85 g/kg, taken 30 minutes after snorting cocaine, did not alter the effect of cocaine on heart rate, did not alter cocaine or blood-alcohol levels, and did not affect subjective ratings of drunkenness.[5]

In contrast, a study in 11 healthy male subjects found that when alcohol 0.85 g/kg was given 15 minutes before snorting cocaine (either 1.25 mg/kg or 1.9 mg/kg), the bioavailability of cocaine was increased, and there were significant increases in heart rate, cardiac output, and blood pressure.[6]

Mechanism

In the presence of alcohol, cocaine is metabolised in the liver to cocaethylene, which appears to have the same stimulant effects as cocaine, but a longer half-life (2 hours compared with about 38 minutes for cocaine). *Animal* studies suggest that this metabolite is more toxic than cocaine.[7] In addition, chronic alcohol exposure may facilitate the metabolism of cocaine, promoting the formation of intermediate metabolites that may cause liver damage, potentiating the hepatotoxic properties of alcohol.[8] It has been suggested that the ingestion of alcohol before snorting cocaine results in greater absorption of cocaine through the nasal vasculature due to increased dilatation by ethanol.[5]

Importance and management

It has been suggested that the enhanced psychological effects associated with alcohol and cocaine may lead to the use of larger amounts of the combination with an increased risk for toxic effects,[2] such as cardiotoxicity.[1] It has been reported that users of alcohol and cocaine who also have coronary artery disease have 21.5 times the risk for sudden death than users of cocaine alone.[7] The longer half-life of the metabolite cocaethylene explains why many people who experience cocaine-related heart attacks and strokes do so when the cocaine levels in their blood are low, as cocaethylene can remain active in the body for 7 hours after cocaine has disappeared.[7] Patients with coronary artery disease or alcoholics may be particularly vulnerable to the combined toxic effects of alcohol and cocaine.

Alcohol + Codergocrine mesilate (Ergoloid mesylates)

Codergocrine mesilate causes a very small reduction in blood-alcohol levels.

Clinical evidence, mechanism, importance and management

Thirteen subjects were given 0.5 g/kg of alcohol 25% in orange juice after breakfast, before and after taking 4.5 mg of codergocrine mesilate (ergoloid mesylates, *Hydergine*) every 8 hours for nine doses. The codergocrine caused a small reduction in blood-alcohol levels (maximum serum levels reduced from 59 mg% to 55.7 mg%), and the clearance was reduced by a

modest 11%.[1] The reason is not understood. This interaction is almost certainly not of clinical importance.

1. Savage IT, James IM. The effect of Hydergine on ethanol pharmacokinetics in man. *J Pharm Pharmacol* (1993) 45 (Suppl 2), 1119.

Alcohol + Co-trimoxazole

A disulfiram-like reaction has been reported when two patients taking co-trimoxazole drank beer.

Clinical evidence, mechanism, importance and management

A 31-year-old man who had been taking prophylactic double-strength co-trimoxazole twice daily for 3 days experienced flushing, palpitations, dyspnoea, headache and nausea 10 to 20 minutes after drinking about 780 mL of beer. Symptoms resolved gradually over 2 to 3 hours, but occurred again the next day when he drank about 170 mL of beer. A similar experience occurred in another man taking double-strength co-trimoxazole after drinking of one litre of beer. However, on the previous day, he drank 4 to 5 beers (approximately 1.4 L) without a problem, even though he had taken co-trimoxazole.[1] The clinical and practical significance of these case reports is unknown as there do not appear to be any other reports of this interaction. Note that some formulations of co-trimoxazole contain ethanol.

Alcohol + Cyproterone acetate

Excessive alcohol consumption may reduce the antiandrogenic effect of cyproterone acetate in the treatment of hypersexuality, but the relevance of this effect in prostatic carcinoma is not known; there seems to be no evidence that normal social amounts of alcohol interact.

Clinical evidence, mechanism, importance and management

The UK manufacturer of cyproterone acetate (*Androcur*) says that alcohol appears to reduce its effects, and so it is of no value in chronic alcoholics.[1] This appears to be based solely on a simple and unelaborated statement in an abstract of studies[2] in 84 men whose hyper- or abnormal sexuality was treated with cyproterone acetate, which stated that "antiandrogens do not inhibit male sexual behaviour during alcohol excess."

The suggested reasons for this reaction are unknown, but it may possibly be due to several factors. These include enzyme induction by the alcohol, which could possibly increase the metabolism and clearance of cyproterone; increased sexual drive caused by alcohol, which might oppose the effects of cyproterone; and reduced compliance by alcoholic patients, who forget to take their tablets while drinking to excess.[3]

It seems therefore that cyproterone may not be effective in alcoholic patients, but there is nothing to suggest that the effects of cyproterone are opposed by normal moderate social amounts of alcohol. The relevance of this in prostatic carcinoma is not known; nevertheless, it has been suggested that the use of alcohol during treatment with cyproterone acetate is not advisable.[4] It would seem prudent to limit alcohol intake in patients taking cyproterone.

Alcohol + Dimethylformamide

A disulfiram-like reaction can occur in workers exposed to dimethylformamide vapour if they drink alcohol; incidences of 20% and 70% have been reported. Alcohol may possibly enhance the toxic effects of dimethylformamide on liver function.

Clinical evidence

A 3-year study in a chemical plant where dimethylformamide (DMF) was used found that about 20% (19 out of 102 men) exposed to DMF vapour experienced flushing of the face, and often of the neck, arms, hands, and chest, after drinking alcohol. Sometimes dizziness, nausea, and tightness of the chest also occurred. A single glass of beer was enough to induce a flush lasting 2 hours. The majority of the men experienced the reaction within 24 hours of exposure to DMF, but it could occur even after 4 days.[1] Three further cases of this interaction are described in other reports.[2,3]

Another study, in 126 factory workers exposed to DMF and 54 workers who had no contact with DMF, indicated that DMF adversely affected liver function, and that concurrent alcohol had a synergistic effect (both drugs are hepatotoxic), although individual differences in tolerance to the interaction were observed. Flush symptoms after alcohol consumption were reported by 86 out of 126 (approximately 70%) of workers exposed to DMF, compared with 2 out of 54 (4%) of controls.[4]

Mechanism

Subjects exposed to DMF vapour develop substantial amounts of DMF and its metabolite (*N*-methylformamide) in their blood and urine.[1] This latter compound in particular has been shown in *rats* given alcohol to raise their blood acetaldehyde levels by a factor of five, so it would seem probable that the *N*-methylformamide is similarly responsible for this disulfiram-like reaction in man.[5] For more details of this mechanism, see under 'Alcohol + Disulfiram', p.66.

Importance and management

An established interaction, with the incidence reported to be between about 20% and 70%.[1] Those who come into contact with DMF, even in very low concentrations, should be warned of this possible interaction with alcohol. It would appear to be more unpleasant than serious in most instances, and normally requires no treatment, however the hepatotoxic effects are clearly more of a concern.

Alcohol + Dimethyl sulfoxide (DMSO)

Dimethyl sulfoxide appears to increase the psychomotor impairment that occurs in response to alcohol.

Clinical evidence, mechanism, importance and management

A case report describes a man who had applied 'relatively large' amounts of dimethyl sulfoxide to his hands in the course of his work, for 2 days before, and while drinking 6 or 7 bottles of beer over 6 hours. Seven hours after he had drunk the last bottle of beer he was noted to be driving erratically, and a positive alcohol breath test was recorded (details not given). The amount of alcohol ingested and the timescale was not expected to result in a positive breath test, and interaction with DMSO was suspected.[1] Anecdotal reports imply that this is not the only case of increased psychomotor impairment that has been attributed to this interaction.[1,2]

A study in 30 healthy subjects found that the absorption of oral alcohol 0.75 g/kg was not affected by DMSO applied topically, either 1 hour before or with the alcohol. However, even though DMSO appeared to increase the clearance of alcohol, the subjects developed twice the psychomotor impairment, when compared with alcohol alone.[2]

Although the effect of DMSO on blood-alcohol levels is unclear (the study only measured clearance, which was increased, and the case only reported breath alcohol levels, which were increased), it seems clear that the concurrent use of both drugs increases psychomotor impairment. Those applying DMSO should be reminded that gloves should be worn; those be-

ing treated with DMSO should be warned of the potential consequences of consuming alcohol.

Alcohol + Disopyramide

In healthy subjects, the renal clearance of disopyramide may be slightly increased by alcohol-induced diuresis.

Clinical evidence, mechanism, importance and management

A crossover study in 6 healthy subjects found that the half-life and total body clearance of disopyramide were not affected by alcohol, but the amount of the metabolite mono-*N*-dealkylated disopyramide excreted in the urine was reduced. Alcohol increased diuresis in 5 of the 6 subjects, and the renal clearance of disopyramide was increased by 19% in these subjects.[1] The overall clinical effect is likely to be minimal.

Alcohol + Disulfiram

Drinking alcohol while taking disulfiram will result in flushing and fullness of the face and neck, tachycardia, breathlessness, giddiness, hypotension, and nausea and vomiting. This is called the disulfiram or *Antabuse* reaction. It is used to deter alcoholic patients from drinking. A mild flushing reaction of the skin may possibly occur in particularly sensitive individuals if alcohol is applied to the skin or if alcohol vapour is inhaled.

Clinical evidence

(a) Alcoholic drinks

One of the earliest descriptions of a disulfiram-like interaction with alcohol was made in 1937 by Dr EE Williams[1] who noted it amongst workers in the rubber industry who were handling **tetramethylthiuram disulphide**:

"Even beer will cause a flushing of the face and hands, with rapid pulse, and some of the men describe palpitations and a terrible fullness of the face, eyes and head. After a glass of beer the blood pressure falls about 10 points, the pulse is slightly accelerated and the skin becomes flushed in the face and wrists. In 15 minutes the blood pressure falls another 10 points, the heart is more rapid, and the patient complains of fullness in the head."

The later observation of the same reaction with the ethyl congener of **tetramethylthiuram disulphide**, disulfiram, led to its introduction as an alcoholic drink deterrent.[2] Patients experience throbbing in head and neck, giddiness, sweating, nausea, vomiting, thirst, chest pain, difficulty in breathing, and headache. The severity of the reaction can depend upon the amount of alcohol ingested, but some individuals are extremely sensitive. Respiratory depression, cardiovascular collapse, cardiac arrhythmias, unconsciousness, and convulsions may occur. There have been fatalities.[3]

An unusually severe reaction has been described in the case report of a patient who developed hypotension (blood pressure 63/15 mmHg), tachycardia of 140 bpm, and ST depression after drinking a can of beer 2 weeks after starting to take disulfiram; he needed noradrenaline (norepinephrine) to maintain an adequate blood pressure.[4] Another unusual and isolated report describes painful, intermittent and transient myoclonic jerking of the arms and legs as the predominant manifestation of the disulfiram reaction in one patient.[5] A further unusual case has been reported in which a woman with a history of bipolar disorder and alcoholism, who was taking disulfiram, was admitted to hospital with a 3- to 4-day history of changes in her mental state, including difficulties with orientation, concentration and visual hallucinations. The confusional state was attributed to alcohol consumption while taking disulfiram, and the probability of this was supported by an earlier similar, though shorter, episode experienced by the patient.[6] Some alcoholics find that disulfiram potentiates the euphoric effects of low doses of alcohol, which alone would be relatively ineffective.[7]

(b) Products containing alcohol

A mild disulfiram reaction is said to occur in some patients who apply alcohol to the skin, but it is probably largely due to inhalation of the vapour.[8] It has been reported after using **after-shave lotion** (50% alcohol),[8] **tar gel** (33% alcohol)[9] and a **beer-containing shampoo** (3% alcohol).[10] A **contact lens wetting solution** (containing **polyvinyl alcohol**) used to irrigate the eye has also been implicated in a reaction,[11,12] although the probability of an interaction with this secondary alcohol has been disputed.[13] It has also been described in a patient who inhaled vapour from paint in a poorly ventilated area and from the inhalation of '**mineral spirits**'.[14] A 36-year-old man with no known cardiac disorders, taking disulfiram 500 mg daily, had a myocardial infarction, which was attributed to **fermented vinegar** in a salad dressing and the use of an **after-shave lotion**.[15]

Furthermore, an unusual case describes a woman taking disulfiram who reported vaginal stinging and soreness during sexual intercourse, and similar discomfort to her husband's penis, which seemed to be related to the disulfiram dosage and how intoxicated her husband was.[16]

The UK manufacturer of the oral solution of **ritonavir** (*Norvir*) says that since it contains alcohol 43% v/v (which they say is about equivalent to 27 mL of wine per dose) the preparation should not be taken with disulfiram or other drugs such as **metronidazole** because a disulfiram-like reaction is possible.[17] However, in practice the risk is probably fairly small because the recommended dose of **ritonavir** in this form is only 7.5 mL. **Ritonavir** (*Norvir*) soft capsules also contain alcohol 12% w/w.[18] The oral concentrate of sertraline (*Zoloft oral concentrate*) is contraindicated with disulfiram due to the alcohol content (12%).[19]

Mechanism

Partially understood. Alcohol is normally rapidly metabolised within the liver, firstly by alcohol dehydrogenase to acetaldehyde, then by acetaldehyde dehydrogenase, and then by a series of biochemical steps to water and carbon dioxide. Disulfiram inhibits the enzyme acetaldehyde dehydrogenase so that the acetaldehyde accumulates.[3] The authors of the report of a case of myocardial infarction suggest that an increased acetaldehyde level in the blood may have caused cause coronary vasospasm and myocardial infarction.[15]

Although the symptoms of the disulfiram-alcohol reaction are due partly to the high levels of acetaldehyde, not all of the symptoms can be reproduced by injecting acetaldehyde, so that some other biochemical mechanism(s) must also be involved. The conversion of dopamine to noradrenaline is also inhibited and the depletion of noradrenaline in the heart and blood vessels allows acetaldehyde to act directly on these tissues to cause flushing, tachycardia and hypotension.[20] Prostaglandin release may also be involved.[21] It has been suggested that the mild skin flush that can occur if alcohol is applied to the skin is not a true disulfiram reaction.[22]

However, some individuals appear to be more sensitive than others, which might be partially due to liver function and variations in the metabolism of disulfiram to its active metabolite by the cytochrome P450 isoenzymes.[23,24]

Importance and management

An extremely well-documented and important interaction exploited therapeutically to deter alcoholics from drinking alcohol. Initial treatment should be closely supervised because an extremely intense and potentially serious reaction occurs in a few individuals, even with quite small doses of alcohol. Apart from the usual warnings about drinking alcohol, patients should also be warned about the unwitting ingestion of alcohol in some pharmaceutical preparations.[25] The risk of a reaction is real. It has been seen following a single-dose of an alcohol-containing **cough mixture**,[26] whereas the ingestion of small amounts of **communion wine** and the absorption of alcohol from a **bronchial nebuliser spray** or **ear drops** did not result in any reaction in 3 individuals.[27] The severity of the reaction is reported to be proportional to the dosage of both disulfiram and alcohol.[28] Patients should also be warned about the exposure to alcohol from some foods, cosmetics, solvents etc. The manufacturers advise that certain foods (sauces and vinegars), liquid medicines, remedies (cough mixtures, tonics, back rubs), and toiletries (aftershave, perfumes and aerosol sprays) may contain sufficient alcohol to elicit a reaction.[20,28] Caution should also be exercised with low-alcohol and "non-alcohol" or "alcohol-free" beers and wines, which may provoke a reaction when consumed in sufficient quantities.[20] Disulfiram is eliminated slowly from the body and therefore drinking alcohol may produce unpleasant symptoms up to 14 days after taking the last dose of disulfiram.[28]

Treatment

The disulfiram reaction can be treated, if necessary, with ascorbic acid. A dose of 1 g given orally is reported to be effective in mild cases (heart rate less than 100 bpm and general condition good). It works within 30 to 45 minutes. Moderately severe cases (heart rate 100 to 150 bpm, blood pressure 150/100 mmHg) can be treated with 1 g of intravenous ascorbic acid and this is effective within 2 to 5 minutes. Critically ill patients may need other standard supportive emergency measures.[29]

Alcohol + Edible fungi

A disulfiram-like reaction can occur if alcohol is taken after eating the smooth ink(y) cap fungus (*Coprinus atramentarius*) or certain other edible fungi.

Clinical evidence

A man who drank 3 pints of beer 2 hours after eating a meal of freshly picked and fried **ink(y) caps** (***Coprinus atramentarius***) developed facial flushing and a blotchy red rash over the upper half of his body. His face and hands swelled, and he became breathless, sweated profusely, and vomited during the 3 hours when the reaction was most severe. On admission to hospital he was tachycardic and 12 hours later he was in atrial fibrillation, which lasted for 60 hours. The man's wife, who ate the same meal but without an alcoholic drink, did not show the reaction.[1]

This reaction has been described on many occasions in medical and pharmacological reports[2-7] and in books devoted to descriptions of edible and poisonous fungi. Only a few are listed here. Mild hypotension and "….alarming orthostatic features…." are said to be common symptoms[8] but the arrhythmia seen in the case cited here[1] appears to be rare. Recovery is usually spontaneous and uncomplicated. A similar reaction has been described after eating ***Boletus luridus***,[6,9] and other fungi including ***Coprinus micaceus***, ***Clitocybe claviceps*** and certain **morels**.[9,10] An African relative of ***Coprinus atramentarius***, ***Coprinus africanus***, which also causes this reaction, is called the **Ajeimutin** fungus by the Nigerian Yoruba people. The literal translation of this name is the 'eat-without-drinking-alcohol' mushroom.[11]

Mechanism

An early and attractive idea was that the reaction with *Coprinus atramentarius* was due to the presence of disulfiram (one group of workers actually claimed to have isolated it from the fungus[12]), but this was not confirmed by later work,[13,14] and it now appears that the active ingredient is coprine (*N*-5-(1-hydroxycyclopropyl)-glutamine).[15,16] This is metabolised in the body to 1-aminocyclopropanol, which appears, like disulfiram, to inhibit aldehyde dehydrogenase (see 'Alcohol + Disulfiram', p.66). The active ingredients in the other fungi are unknown.

Importance and management

An established and well-documented interaction. It is said to occur up to 24 hours after eating the fungus. The intensity depends upon the quantity of fungus and alcohol consumed, and the time interval between them.[1,4,17] Despite the widespread consumption of edible fungi and alcohol, reports of this reaction in the medical literature are few and far between, suggesting that even though it can be very unpleasant and frightening, the outcome is usually uncomplicated. Treatment appears normally not to be necessary.

The related fungus ***Coprinus comatus*** (the '**shaggy ink cap**' or '**Lawyers wig**') is said not to interact with alcohol,[8,18] nor is there anything to suggest that it ever occurs with the **common field mushroom** (***Agaricus campestris***) or the cultivated variety (***Agaricus bisporis***).[18]

Alcohol + Erythromycin

Alcohol can cause a moderate reduction in the absorption of erythromycin ethylsuccinate. There is some evidence that intravenous erythromycin can raise blood-alcohol levels but the extent and the practical importance of this is unknown.

Clinical evidence, mechanism, importance and management

(a) Effects on alcohol

A study in 10 healthy subjects found that erythromycin base 500 mg three times daily did not alter the pharmacokinetics of oral alcohol 0.8 g/kg, and the subjects' perception of intoxication was unaltered.[1] In contrast, another study in 8 healthy subjects, primarily investigating the effects of intravenous erythromycin lactobionate 3 mg/kg on gastric emptying, found that when they were given a liquid meal of orange juice, alcohol 0.5 g/kg and lactulose 10 g immediately after a solid meal, the mean peak blood-alcohol levels were raised by about 40% and the AUC over the first hour was increased by 33%. After that the curve was virtually the same as that

seen with a saline placebo. The authors suggest that the increased blood-alcohol levels are a result of erythromycin causing more rapid gastric emptying, so that the alcohol is exposed to metabolism by the gastric mucosa for a shorter time.[2]

What this means in terms of an increase in the effects of alcohol (e.g. on driving) is not known.

(b) Effects on erythromycin

When a single 500-mg dose of erythromycin ethylsuccinate was taken by 9 healthy subjects with two 150-mL alcoholic drinks (one immediately and the other 2.5 hours later) the erythromycin AUC was decreased by about 27% and its absorption was delayed. One subject had a 185% *increase* in absorption. The alcoholic drink was pisco sour, which contains lemon juice, sugar and pisco (a brandy-like liqueur). Blood-alcohol levels achieved were about 50 mg%.[3]

The reason for the reduced absorption of erythromycin is not understood but it is suggested that the slight delay occurs because alcohol delays gastric emptying, so erythromycin reaches its absorption site in the duodenum a little later.[3] The extent to which this reduced absorption might alter the antibacterial effects of erythromycin is uncertain but it seems likely to be small.

Alcohol + Fluvastatin

Alcohol does not significantly interact with fluvastatin.

Clinical evidence, mechanism, importance and management

Ten healthy subjects took a single 40-mg dose of fluvastatin and 70 g of alcohol diluted in lemonade. This acute ingestion of alcohol had no effect on the peak serum levels of fluvastatin or its AUC, but the half-life was reduced by almost one-third.[1] In a second related study, 20 patients with hypercholesterolaemia were given 40 mg of fluvastatin and 20 g of alcohol daily for 6 weeks. The AUC of fluvastatin was slightly increased and the half-life was increased by almost one-third, but the lipid profile with fluvastatin plus alcohol was little different from fluvastatin alone.[1,2] The conclusion was reached that although long-term moderate drinking has some small effect on the pharmacokinetics of fluvastatin, its safety and efficacy are unaltered.[1] There would seem to be no reason for patients taking fluvastatin to avoid alcohol.

Alcohol + Food

Food and milk decrease the absorption of alcohol and meals increase the metabolism of alcohol. Foods rich in serotonin (e.g. bananas) taken with alcohol may produce adverse effects such as diarrhoea and headache. Previous alcohol consumption and the glycaemic load of a meal appear to interact to influence both mood and memory.

Clinical evidence, mechanism, importance and management

(a) Alcohol absorption and metabolism

In one study 10 subjects were given 25 mL of alcohol (equivalent to a double whiskey) after drinking about 850 mL of water or **milk** during the previous 90 minutes. Blood-alcohol levels at 90 minutes were reduced by about 40%, and at 120 minutes by about 25% by the presence of the **milk**. The intoxicant effects of the alcohol were also clearly reduced.[1] In a randomised, crossover study, 24 healthy subjects were given alcohol 0.3 g/kg either one hour before or after an **evening meal**. It was found that the maximum alcohol levels were increased by 87% from 21.3 to 39.9 mg%, and the AUC was increased by 63% when alcohol was given in the fasting rather than the fed state. However there was large inter and intra-individual variability in alcohol bioavailability.[2] Other studies have shown similar effects,[3-5] and have found that this is not limited to specific components of food,[4,5] as well as demonstrating that food reduces the feeling of intoxication and reduces the time required to eliminate alcohol from the body.[3]

After food, the rate of gastric emptying is slower, and hepatic blood flow and the activities of alcohol-metabolising enzymes are increased, which allows greater first-pass metabolism of alcohol. Thus, the effects of alcohol are greatest when taken on an empty stomach.

(b) Dietary serotonin

Serotonin (5-hydroxytryptamine, 5-HT) is excreted in the urine as 5-hydroxyindole-3-acetic acid (5-HIAA) and 5-hydroxytryptophol (5-HTOL). The ratio of 5-HTOL to 5-HIAA is normally very low (less than 0.01). A study in 10 healthy subjects found that 4 hours after the ingestion of alcohol 0.5 g/kg the ratio was increased by about 70-fold. When the same amount of alcohol was given with 3 **bananas**, a food rich in serotonin, the ratio was increased about 100-fold at 4 hours and was still significantly raised at 24 hours. Within 4 hours, 7 of the 10 subjects experienced adverse effects including diarrhoea, headache and fatigue. The symptoms were attributed to high levels of 5-HTOL, which is usually a minor metabolite of serotonin. Other foods rich in serotonin such as **pineapple**, **kiwi fruit** or **walnuts** may produce similar effects if taken with even moderate amounts of alcohol.[6]

(c) Glycaemic load

Breakfasts that release glucose at different speeds were found to interact with alcohol drunk the previous evening to influence cognition and mood. When less than 4.5 g of alcohol had been drunk, a breakfast high in rapidly available glucose was associated with better memory later in the morning. In contrast, when more than 4.5 g of alcohol had been drunk, a breakfast high in slowly available glucose resulted in better memory. After a high glycaemic-load lunch, the rapidly available glucose breakfast resulted in a more confused feeling than the slowly available glucose breakfast or fasting, in those who had drunk more than 4.5 g of alcohol the previous evening.[7]

Alcohol + Furazolidone

A disulfiram-like reaction may occur in patients taking furazolidone if they drink alcohol.

Clinical evidence

A patient taking furazolidone 200 mg four times daily complained of facial flushing, lachrymation, conjunctivitis, weakness, and light-headedness within 10 minutes of drinking beer. These effects occurred on several occasions and lasted 30 to 45 minutes.[1] A man prescribed furazolidone 100 mg four times daily and who had taken only three doses, developed intense facial flushing, wheezing and dyspnoea (lasting one hour), within one hour of drinking about 60 mL of brandy. The same thing happened again the next day after drinking a *Martini* cocktail. No treatment was given.[2] A report originating from the manufacturers of furazolidone stated that by 1976, 43 cases of a disulfiram-like reaction had been reported, of which 14 were produced experimentally using above-normal doses of furazolidone.[3] A later study in 1986 described 9 out of 47 patients (19%) who complained of a disulfiram-like reaction after drinking alcohol while taking furazolidone 100 mg four times daily for 5 days.[4]

Mechanism

Uncertain. It seems possible that furazolidone acts like disulfiram by inhibiting the activity of acetaldehyde dehydrogenase (see *Mechanism*, under 'Alcohol + Disulfiram', p.66).

Importance and management

An established and clinically important interaction of uncertain incidence. One report suggests that possibly about 1 in 5 may be affected.[4] Reactions of this kind appear to be more unpleasant and possibly frightening than serious, and normally need no treatment; however, patients should be warned about what may happen if they drink alcohol.

Alcohol + Ginseng

***Panax ginseng* (Asian ginseng) increases the clearance of alcohol and lowers blood-alcohol levels.**

Clinical evidence

Fourteen healthy subjects, each acting as their own control, were given alcohol (72 g/65 kg as a 25% solution) with and without a *Panax ginseng* (Asian ginseng) extract (3 g/65 kg) mixed in with it. They drank the alcohol or the alcohol/ginseng mixture over a 45-minute period in 7 portions, the first four at 5-minute intervals and the next three at 10-minute intervals. Measurements taken 40 minutes later showed that the presence of the ginseng lowered blood-alcohol levels by an average of about 39%. The alcohol levels of 10 subjects were lowered by 32 to 51% by the ginseng, 3 showed reductions of 14 to 18%, and one showed no changes at all.[1]

Mechanism

The reasons for this interaction are uncertain, but it is suggested that *Panax ginseng* possibly increases the activity of the enzymes (alcohol and aldehyde dehydrogenase)[2] that are concerned with the metabolism of the alcohol, thereby increasing the clearance of the alcohol.

Importance and management

What this reduction in blood-alcohol levels means in practical terms is not clear but the authors of the report suggest the possibility of using ginseng to treat alcoholic patients and those with acute alcohol intoxication;[1] however, this needs confirmation in further clinical studies. The available data suggests that the concurrent use of alcohol and *Panax ginseng* is unlikely to be detrimental.

Alcohol + Glutethimide

The combination of glutethimide and alcohol results in greater impairment in some psychomotor tests, but improvement in others. Alcohol does not interact with glutethimide taken the previous night.

Clinical evidence, mechanism, importance and management

In a series of studies, blood-alcohol levels were raised by a mean of 11% by glutethimide, while plasma and urinary glutethimide levels were reduced.[1] Neither glutethimide nor alcohol alone significantly impaired reaction times, but the combination did. However, in two other tests (tracking efficacy and finger tapping) impairment was greatest after glutethimide alone and reduced by the presence of alcohol.[1] In contrast, a later study found that glutethimide did not subjectively or objectively impair the performance of a number of psychomotor skill tests related to driving, and did not interact with alcohol given the morning after the glutethimide dose.[2] Both drugs are CNS depressants and their effects would be expected to be additive.

The information is limited and somewhat contradictory, nevertheless patients should be warned about the probable results of taking glutethimide and alcohol together. Driving, handling dangerous machinery, or undertaking any task needing alertness and full co-ordination, is likely to be made more difficult and hazardous. There is no evidence of a hangover effect, which could result in an interaction with alcohol the next day.[2]

Alcohol + Glyceryl trinitrate (Nitroglycerin)

Patients who take glyceryl trinitrate while drinking may feel faint and dizzy.

Clinical evidence, mechanism, importance and management

The results of studies[1,2] on the combined haemodynamic effects of alcohol and glyceryl trinitrate give support to earlier claims that their concurrent use increases the risk of exaggerated hypotension and fainting.[3,4] Their vasodilatory effects would appear to be additive.[5] The greatest effect was seen when the glyceryl trinitrate was taken one hour or more after starting to drink alcohol.[1] It is suggested that this increased susceptibility to postural hypotension should not be allowed to stop patients from using glyceryl trinitrate if they have been drinking alcohol, but they should be warned about the possible effects and told what to do if they feel faint and dizzy (i.e. sit or lie down).[1]

Alcohol + Griseofulvin

An isolated case report describes a very severe disulfiram-like reaction when a man taking griseofulvin drank a can of beer. Other isolated reports describe flushing and tachycardia, or increased alcohol effects, when patients taking griseofulvin consumed alcohol.

Clinical evidence

A man took griseofulvin 500 mg daily for about 2 weeks without problems. Subsequently he drank a can of beer, took his usual dose of griseofulvin about one hour later, and within 30 to 60 minutes developed a severe disulfiram-like reaction (flushing, severe nausea, vomiting, diarrhoea, hypotension, and paraesthesias of all extremities). He was successfully treated with intravenous sodium chloride 0.9%, potassium, dopamine, and intramuscular promethazine.[1]

Another isolated case of flushing and tachycardia has been attributed to the concurrent use of alcohol and griseofulvin; rechallenge produced the same effects.[2]

It has been suggested that griseofulvin can increase the effects of alcohol, but the descriptions of this response are very brief. One of them describes a man who had a decreased tolerance to alcohol and emotional instability manifested by crying and nervousness, which was said to be so severe that the drug was stopped.[3] Another states that this effect has been noted in a very small number of patients, but gives no further information.[4]

Mechanism

Not understood. The reaction described above might possibly have the same pharmacological basis as the disulfiram/alcohol reaction, see 'Alcohol + Disulfiram', p.66.

Importance and management

The documentation is extremely sparse, which would seem to suggest that adverse interactions between alcohol and griseofulvin are uncommon; however, the disulfiram-like reaction described was unusually severe in one patient.

Concurrent use need not be avoided but it may be prudent to warn patients about the possible effects (e.g. flushing and tachycardia).

Alcohol + H_2-receptor antagonists

Although some studies have found that blood-alcohol levels can be raised to some extent in those taking an H_2-receptor antagonist and possibly remain elevated for longer than usual, others report that no significant interaction occurs. Drinking may worsen the gastrointestinal disease for which these H_2-receptor antagonists are being given. Hypoglycaemia associated with alcohol may be enhanced by H_2-receptor antagonists.

Clinical evidence

(a) Cimetidine

A double-blind study in 6 healthy subjects found that cimetidine 300 mg four times daily for 7 days, increased the peak plasma levels of alcohol 0.8 g/kg by about 12% (from 146 to 163 mg%) and increased the AUC by about 7%. The subjects assessed themselves as being more intoxicated while taking cimetidine and alcohol than with alcohol alone.[1]

An essentially similar study[2,3] found that blood-alcohol levels were raised by 17% (from 73 to 86 mg%) by cimetidine. However, another study found that cimetidine almost doubled peak blood-alcohol levels.[4] A study in 6 healthy subjects also found that cimetidine 400 mg twice daily for one week approximately doubled the AUC of a single 0.15-g/kg oral dose of alcohol and raised peak alcohol levels by about 33%. No changes were seen when the alcohol was given intravenously.[5] A further study in healthy subjects given cimetidine for only 2 days found that peak plasma alcohol levels were raised by 17%, and the time that blood levels remained above the 80 mg% mark (the legal driving limit in some countries) was prolonged by about one-third.[6]

A study in 6 subjects given 0.75 g/kg of alcohol found that a single 800 mg dose of cimetidine, raised blood alcohol levels at 45 minutes by 32% (from about 76 mg% to 100 mg%), and the AUC at 120 minutes was increased by 25%. Each of the subjects said they felt more inebriated after taking cimetidine.[7]

In subjects with substantial first-pass metabolism of alcohol, cimetidine increased the blood levels of repeated small drinks of alcohol to a greater degree than that which occurred after an equivalent single dose. The levels reached were associated with psychomotor impairment.[8]

In contrast, another study found that a combination of chlorphenamine (which blocks H_1-receptors) and cimetidine reduced the rate of absorption and peak blood-alcohol levels, and suppressed alcohol-induced flushing.[9]

A study in 10 healthy subjects given alcohol 0.5 g/kg before and after cimetidine 400 mg twice daily for 7 days, found that hypoglycaemia following alcohol ingestion was enhanced.[10]

In contrast to these findings a number of studies, using a variety of doses of cimetidine, and a variety of types of alcohol, have found that no interaction occurs.[11-21]

(b) Famotidine

Two studies that found an interaction between other H_2-receptor antagonists and alcohol found that famotidine had no significant effect on blood-alcohol levels.[4,7] Similarly a number of other studies, using a variety of doses of famotidine, and a variety of types of alcohol, have found no interaction occurs.[14-16,18,19,21] However, a study in 10 healthy subjects given alcohol 0.5 g/kg before and after famotidine 40 mg once daily for 7 days, found that marked hypoglycaemia occurred following alcohol ingestion.[10]

(c) Nizatidine

A study in subjects given 0.75 g/kg of alcohol found that a single 300-mg dose of nizatidine raised blood-alcohol levels at 45 minutes by 20% (from about 76 mg% to 90 mg%), and the AUC at 120 minutes was increased by 20%.[7]

Another report briefly mentions that nizatidine has similar effects on alcohol absorption to cimetidine,[22] whereas two other studies found no interaction between nizatidine and alcohol.[21,23]

(d) Ranitidine

A placebo-controlled study in 8 healthy subjects found that ranitidine 300 mg daily for 7 days did not affect the peak plasma levels of alcohol 0.8 g/kg.[2,3] However, another study found that ranitidine 150 mg twice daily for 8 days increased the peak levels of a 0.3 g/kg oral dose of alcohol by 34%.[4] A further study in healthy subjects given ranitidine for only 2 days found that peak plasma alcohol levels were raised by 28%, and the time that blood levels remained above the 80 mg% mark (the legal driving limit in some countries) was prolonged by about one-third.[6]

A study in subjects given 0.75 g/kg of alcohol found that a single 300-mg dose of ranitidine raised blood-alcohol levels at 45 minutes by 6% (from about 75 mg% to 81 mg%), and the AUC at 120 minutes was increased by 10%.[7]

Ranitidine 150 mg twice daily for 7 days considerably increased blood-alcohol levels and the high levels persisted for longer in social drinkers (with substantial first-pass metabolism) receiving 4 drinks of 0.15 g/kg of alcohol at 45-minute intervals.[24] Another report briefly mentions that ranitidine has similar effects on alcohol absorption to cimetidine.[22]

A study in 10 healthy subjects given alcohol 0.5 g/kg before and after ranitidine 150 mg twice daily for 7 days, found that hypoglycaemia following alcohol ingestion was enhanced.[10]

In contrast to these findings a number of studies, using a variety of doses of ranitidine, and a variety of types of alcohol, have found no interaction occurs.[12,14,16-21,25-27]

Mechanism

It would appear that the interacting H_2-receptor antagonists inhibit the activity of alcohol dehydrogenase (ADH) in the gastric mucosa so that more alcohol passes unmetabolised into the circulation, thereby raising the levels.[28-32] Most of the studies assessing the interaction of H_2-receptor antagonists with larger quantities of alcohol have not found an interaction. The decrease in first pass metabolism with increasing amounts of alcohol could explain this, as it implies that a significant interaction with H_2-receptor antagonists would be more likely with smaller quantities of alcohol.[8,33] Other factors that affect the first pass metabolism of alcohol, such as fasting, chronic alcoholism and female gender may also affect the outcome. The increase in blood-alcohol levels with cimetidine or ranitidine and a low alcohol dose may also be explained by the effect of H_2-receptor antagonists or alcohol on gastric emptying times.[27,33] In one study the decrease in first-pass metabolism correlated with a ranitidine-induced increase in the rate of gastric emptying and an increase in blood-alcohol levels.[34] However, with small quantities of alcohol the magnitude of the effect on peak levels may be too small to increase effects on psychomotor performance,[33,35] although two studies suggested that an effect might occur.[8]

The hypoglycaemic effect is not considered to be due to effects on alcohol absorption but may be an effect of H_2-receptor antagonists on glucose metabolism.[10]

Importance and management

The contrasting and apparently contradictory results cited here clearly show that this interaction is by no means established. Extensive reviews of the data concluded that the interaction is not, in general, clinically significant.[32,33,36-38] Under conditions mimicking social drinking there is some evidence that H_2-receptor antagonists may[10,24] or may not[20] increase blood-alcohol levels to those associated with impairment of psychomotor skills. However, as yet, there are insufficient grounds to justify any general warning regarding alcohol and H_2-receptor antagonists. However, note that many of the conditions for which H_2-receptor antagonists are used may be made worse by alcohol, so restriction of alcohol intake may be prudent. Other factors that may affect this interaction are discussed under *Mechanism*, above.

Alcohol + Hormonal contraceptives or HRT

Estradiol does not affect blood-alcohol levels, but alcohol clearance may be reduced in women taking combined hormonal contraceptives; nevertheless the detrimental effects of alcohol may be reduced to some extent. Small amounts of alcohol may possibly improve some aspects of cognitive function in patients using HRT. Alcohol does not affect the pharmacokinetics of ethinylestradiol; however, acute ingestion of alcohol markedly increases the levels of circulating estradiol in women using oral HRT; a smaller increase is seen with transdermal HRT. In addition, alcohol intake appears to increase the risk of breast cancer in women receiving HRT.

Clinical evidence

(a) Effect of oestrogens on alcohol

A controlled study in 54 women found that those taking an oral combined hormonal contraceptive (30, 35, or 50 micrograms of oestrogen) unexpectedly tolerated the effects of alcohol better than those not taking oral contraceptives (as measured by a reaction-time test and a bead-threading test), but their blood-alcohol levels and its rate of alcohol clearance were unchanged.[1] Similarly, a study in 12 healthy postmenopausal women found that HRT (**estradiol** 1 mg daily and **medroxyprogesterone acetate** 10 mg daily for 10 out of each 25 days) did not affect blood-alcohol levels.[2] A study of 214 postmenopausal women suggested that small amounts of alcohol may enhance visuospatial processes (improved cognitive function measured by block design performance). HRT also appeared to be linked with better visuospatial performance, but only when the task was difficult. There was a trend (not statistically significant) towards improved performance with alcohol consumption (up to approximately half a standard drink per day) and oestrogen replacement therapy.[3]

(b) Effect of alcohol on oestrogens

Alcohol ingestion did not have any significant effect on **ethinylestradiol** pharmacokinetics in 9 healthy women taking a combined oral contraceptive (ethinylestradiol/gestodene 30/75 micrograms). In this study, alcohol was given as a single dose of 0.4 g/kg (2 to 3 standard drinks) on day 14 then 0.4 g/kg twice daily for 7 days. In contrast, 12 healthy postmenopausal women receiving HRT (**estradiol** 1 mg daily and **medroxyprogesterone acetate** 10 mg daily for 10 out of each 25 days) were given an alcoholic drink (0.7 g/kg, a dose shown to achieve mean peak alcohol serum levels of about 97 mg% after about 1 hour) during the oestrogen-only phase of the HRT cycle. It was found that their peak **estradiol** levels rose threefold and were significantly above the baseline for 5 hours. No significant increases in the levels of circulating estrone (an oestrogen secreted by the ovaries) were seen.[2] A similar, smaller 1.2-fold increase in peak **estradiol** levels was seen in another study when women using **transdermal estradiol** were given alcohol.[4]

(c) Risk of breast cancer

Since both alcohol and HRT are linked with a small increase in breast cancer risk, it has been postulated that the combination of HRT and alcohol could have additive risks.[5] A prospective study of 51 847 postmenopausal women confirmed an association with alcohol intake and breast cancer risk (for oestrogen receptor-positive (ER+) tumours, but not oestrogen receptor-negative (ER–) tumours). Furthermore, among women who consumed alcohol, postmenopausal hormone use was associated with an increased risk for the development of ER+ tumours. For women with the highest alcohol intake (10 g (approximately 1 drink) or more daily) the relative risk of developing oestrogen receptor-positive/progesterone receptor-positive (ER+PR+) breast cancer was 1.2 and 1.8 for non-users and users of HRT, respectively, compared with non-drinkers who had never used postmenopausal hormones; the relative risk of developing ER+PR– tumours was even greater, being approximately 2.5 and 3.5, respectively.[6] Another study also reported a similar increased risk of developing ER+PR+ tumours with alcohol and oestrogen replacement therapy, but only a slight risk for ER+PR– tumours; the risk for ER–PR– breast cancer was, however, greatest.[7] The Women's Health Study found that an alcohol intake of greater than 10 g of alcohol per day and postmenopausal hormone use was associated with a relative risk of developing breast cancer of 1.84, compared with those who did not consume alcohol or take postmenopausal hormones.[8]

Mechanism

The reasons for the changes in estradiol levels are not understood. Alcohol can increase *endogenous* estradiol levels in postmenopausal women, although the findings are variable. Another possible explanation is altered clearance of estradiol in women who drink alcohol.[9] The effects on ethinylestradiol are in contrast. This may be because the ethinyl group in ethinylestradiol confers protection from the effects of alcohol.[10]

Importance and management

The authors say that they do not recommend women taking oral contraceptives should attempt to drink more than usual, since even if alcohol is tolerated better, blood-alcohol levels are not reduced.[1] However, two other studies suggest that peak blood-alcohol levels may be reduced in those taking oral contraceptives, but alcohol clearance is also reduced and so alcohol may be present for longer in women who are taking oral contraceptives.[11,12]

Regular consumption of alcohol as low as 1 to 2 drinks per day may possibly contribute to a modest increased risk of some types of breast cancer,[9] and it has been suggested that women taking HRT should limit their alcohol intake;[5] about one drink or less per day has been proposed.[9] More study is needed to confirm the amount and frequency of alcohol consumption needed to have a deleterious effect in women who use HRT.

Alcohol + Inotropes and Vasopressors

Alcohol does not affect the cardiovascular response to isoprenaline. Alcohol increases the plasma levels of noradrenaline, but reduces its effects on diastolic blood pressure. Similarly alcohol reduces the increase in blood pressure in response to methoxamine.

Clinical evidence, mechanism, importance and management

(a) Isoprenaline (Isoproterenol)

A study in 21 healthy subjects found that a 1-mL/kg oral dose of 20% alcohol did not alter the effects of isoprenaline, given in doses of up to 1.78 micrograms, on blood pressure and heart rate.[1]

(b) Methoxamine

In a placebo-controlled study, 8 subjects were given 1 mL/kg of 20% alcohol, followed after 90 to 150 minutes by an infusion of methoxamine 200, 400, 800, 1600, and 2000 micrograms/minute, each for one minute. The increase in blood pressure was reduced after a cumulative 5 mg dose of methoxamine (from about 33/31 mmHg to 19/11 mmHg), but heart rate was not significantly affected.[2] This study suggests that patients who have drunk alcohol may require higher doses of methoxamine.

(c) Noradrenaline (Norepinephrine)

In a placebo-controlled study, 8 subjects were given 1 mL/kg of 20% alcohol, followed after 45 minutes by an infusion of noradrenaline 24, 48 and 90 nanograms/kg per minute, each for 20 minutes. There was a significant increase in plasma noradrenaline levels after the ingestion of alcohol at the lower two doses of noradrenaline. Systolic blood pressure was not significantly affected, but there was a significant (approximately twofold) decrease in diastolic blood pressure at each dosing level. Heart rate was not significantly affected.[2] This study suggests that patients who have drunk alcohol may require higher doses of noradrenaline; however, as noradrenaline is titrated to effect, this interaction seems unlikely to be clinically relevant.

Alcohol + Interferons

Studies have found a reduced response to interferon in patients who drink alcohol. Those who drink the most seem to exhibit the lowest response to interferon.

Clinical evidence, mechanism, importance and management

In a study involving 245 patients, alcohol intake, and its effect on treatment, were retrospectively evaluated, between 1 and 3 years after diagnosis of hepatitis C virus-related chronic liver disease. Less than 50% of the patients who drank alcohol stopped after being diagnosed with liver disease, despite being advised to abstain from alcohol. Alcohol intake affected fibrosis, especially in women, and response to interferon therapy. Seventeen out of 65 patients (26.1%) who were treated with **interferon alfa** had a sustained response to therapy. However, the number of responders decreased as alcohol intake increased; there were more drinkers (63.1%) than abstainers (10.7%) among the 73.8% of patients who did not respond.[1] A study in non-drinkers, light drinkers (less than 70 g ethanol per day) and heavy drinkers (more than 70 g ethanol per day), with hepatitis C, assessed the response to interferon (alpha and beta). It was found that drinking reduced the response to interferon; with 47%, 57%, and 100% of subjects not responding in the non-drinking group, moderate drinking group, and heavy drinking group, respectively.[2] Other studies have found similar results,[3,4] with one study finding that heavy drinkers, who abstained from drinking for at least 6 months before receiving interferon, had similar outcomes to infrequent drinkers.[3]

One manufacturer notes that hepatotoxicity has been reported with **interferon beta-1a**. They say the potential additive toxicity with hepatotoxic drugs such as alcohol has not been determined, and caution is warranted.[5]

There appears to be insufficient information to suggest that patients receiving interferons should avoid alcohol completely; however, alcohol intake, particularly heavy drinking, may increase the risk of hepatotoxicity and reduce the response to treatment with interferon.

Alcohol + Ivermectin

Alcohol may increase the bioavailability of ivermectin.

Clinical evidence, mechanism, importance and management

Anecdotal reports from Nigeria suggest that ivermectin is more potent when taken with palm wine, a local alcoholic drink, and a few cases of ataxia and postural hypotension occurring with ivermectin were considered to be due to an interaction with alcohol.[1] Ivermectin formulated as an alcoholic solution has been found to have about twice the systemic availability of tablets and capsules.[2] In one study, 20 healthy subjects were given ivermectin 150 micrograms/kg with either 750 mL of beer (alcohol 4.5%) or 750 mL of water. Beer increased the plasma levels of ivermectin at 1 to 4 hours by about 51% to 66%, respectively, when compared with water. No adverse effects were reported in either group.[1] The evidence suggests that concurrent use may be of benefit, if adverse effects such as

postural hypotension are not troublesome; this may be more of a problem in those with pre-existing heart disease.

Alcohol + Kava

There is some evidence that kava may worsen the CNS depressant effects of alcohol.

Clinical evidence, mechanism, importance and management

Forty healthy subjects underwent a number of cognitive tests and visuomotor tests after taking alcohol alone, kava alone, or both together. The subjects took 0.75 g/kg of alcohol (enough to give blood-alcohol levels above 50 mg%) and the kava dose was 1 g/kg. The kava drink was made by mixing middle grade Fijian kava (Kava-Kava; the pepper plant *Piper methysticum*) with water and straining it to produce about 350 mL of kava liquid. It was found that kava alone had no effect on the tests, but when the kava was given with alcohol it potentiated both the perceived and measured impairment that occurred with alcohol alone.[1] However, another study found that a kava extract (WS 1490) did not enhance the negative effects of alcohol on performance tests.[2]

No very strong conclusions can be drawn from the results of the studies, but it is possible that car driving and handling other machinery may be more hazardous if kava and alcohol are taken together. However, note that the use of kava-kava is restricted in the UK because of reports of idiosyncratic hepatotoxicity.[3]

Alcohol + Ketoconazole

A few cases of disulfiram-like reactions have been reported in patients who drank alcohol while taking ketoconazole.

Clinical evidence, mechanism, importance and management

One patient (an alcoholic), out of group of 12 patients with Candida infections taking ketoconazole 200 mg daily, experienced a disulfiram-like reaction (nausea, vomiting, facial flushing) after drinking alcohol.[1] No further details are given, and the report does not say whether any of the others drank alcohol. A woman taking ketoconazole 200 mg daily developed a disulfiram-like reaction when she drank alcohol.[2] Another report describes a transient 'sunburn-like' rash or flush on the face, upper chest and back of a patient taking ketoconazole 200 mg daily when she drank modest quantities of wine or beer.[3] The reasons for the reactions are not known but it seems possible that ketoconazole may act like disulfiram and inhibit the activity of acetaldehyde dehydrogenase (see *Mechanism*, under 'Alcohol + Disulfiram', p.66). The incidence of this reaction appears to be very low (these appear to be the only reports) and its importance is probably small. Reactions of this kind are usually more unpleasant than serious; the manufacturers note that symptoms resolve within a few hours.[4] Nevertheless, to avoid these effects, the manufacturer advises avoidance of alcohol while taking ketoconazole.[5]

Alcohol + Levamisole

The manufacturer of levamisole notes that a disulfiram-like reaction has been reported when levamisole was given with alcohol.[1] Reactions of this kind are usually more unpleasant than serious; and symptoms often resolve within a few hours. It would seem prudent to warn patients of the possibility.

Alcohol + Levosimendan

Levosimendan appears not to interact adversely with alcohol.

Clinical evidence, mechanism, importance and management

A double-blind, randomised, crossover study in 12 healthy subjects given oral alcohol 0.8 g/kg with intravenous levosimendan 1 mg found no clinically significant pharmacokinetic or pharmacodynamic interactions.[1] There therefore seems no reason to avoid the use of levosimendan in patients that have recently consumed alcohol.

Alcohol + Lithium

Some limited evidence suggests that the use of lithium carbonate with alcohol may make driving more hazardous.

Clinical evidence, mechanism, importance and management

In 9 out of 10 healthy subjects alcohol 0.5 g/kg raised the serum levels of a single 600-mg dose of lithium carbonate by 16%. Four subjects had at least a 25% increase in lithium levels. However these rises were not considered to be clinically important.[1] Two studies suggest that lithium does not affect blood-alcohol levels.[2,3]

In a study, 20 healthy subjects were given lithium carbonate (to achieve lithium serum levels of 0.75 mmol/L) and alcohol 0.5 g/kg, and undertook various psychomotor tests to assess any impairment of skills related to driving. Lithium carbonate alone prolonged reaction times and increased the inaccuracy of responses, whereas alcohol alone increased the number of mistakes in tests of co-ordination and attention; both drugs together were therefore considered to present extra risks than either drug alone.[2] In a placebo-controlled study, 35 alcoholic patients were given about 1.25 g/kg of alcohol after taking lithium for 14 days (mean serum lithium level of 0.89 mmol/L). Patients considered themselves to be less intoxicated when taking lithium with alcohol (compared with placebo) and there was an improvement in performance in 3 of the 6 cognitive tests used, but not in the tests of skills related to driving.[3]

Information is very limited but patients should be warned about the possible increased risk of driving or other potentially hazardous activities when taking both drugs.

Alcohol + Liv 52

***Liv 52,* an Ayurvedic herbal remedy, appears to reduce hangover symptoms after drinking, reducing blood-alcohol and acetaldehyde levels at 12 hours. However *Liv 52* also raises the**

blood-alcohol levels of moderate drinkers for the first few hours after drinking.

Clinical evidence

Nine healthy subjects who normally drank socially (alcohol 40 to 100 g weekly) took *Liv 52* two hours before drinking alcohol (four 60 mL doses of whiskey, equivalent to 90 g of alcohol). After taking 6 tablets of *Liv 52* their 1-hour blood-alcohol levels were increased by 15% (from 75 mg% to 86.2 mg%), and after taking 3 tablets of *Liv 52* daily for 2 weeks, their 1-hour blood-alcohol levels were raised by 27% (from 75 to 95.3 mg%).[1] Acetaldehyde levels in the blood and urine were markedly lowered at 12 hours, and hangover symptoms seemed to be reduced.[1] In a similar study, the blood-alcohol levels of 9 moderate drinkers were raised over the first 2 hours by about 28 to 44% after taking three tablets of *Liv 52* twice daily for two weeks, and by 17 to 19% over the following 2 hours.[2] Only a minor increase in blood-alcohol levels occurred in 8 occasional drinkers.[2]

Mechanism

Not understood. The *Liv 52* preparation in this study was said to contain the active principles from *Capparis spinosa*, *Cichorium intybus*, *Solanum nigrum*, *Cassia occidentalis*, *Terminalia arjuna*, *Achillea millefolium*, *Tamarix gallica* and *Phyllanthus amarus*.[1] These appear to increase the absorption of alcohol, or reduce its metabolism by the liver, thereby raising the blood-alcohol levels. It is suggested that the reduced hangover effects may possibly occur because it prevents the binding of acetaldehyde to cell proteins allowing a more rapid elimination.[1]

Importance and management

Direct pharmacokinetic evidence seems to be limited to these two studies.[1,2] *Liv 52* appears to reduce the hangover effects after drinking, but at the same time it can significantly increase the blood-alcohol levels of moderate drinkers for the first few hours after drinking. Increases of up to 30% may be enough to raise blood-alcohol levels from legal to illegal, when driving. Moderate drinkers should be warned. Occasional drinkers appear to develop higher blood-alcohol levels than moderate drinkers but *Liv 52* does not seem to increase them significantly.[2]

Alcohol + Mecamylamine

Mecamylamine appears to reduce some of the effects of alcohol, without affecting alcohol levels.

Clinical evidence, mechanism, importance and management

In a crossover study in 22 healthy subjects, a single 7.5- to 12.5-mg dose of mecamylamine reduced the levels of alcohol (0.7 or 0.8 g/kg) by about 14% (estimated from graph), and reduced the pleasurable and stimulant effects of alcohol.[1] A placebo-controlled study in 27 healthy subjects given a single 7.5- or 15-mg dose of mecamylamine with alcohol 0.8 g/kg found that none of the physiological effects of mecamylamine or alcohol, or blood-alcohol levels, were affected by concurrent use. Mecamylamine reduced the stimulant effects of alcohol and reduced the desire for more alcohol; this effect appeared greater in men.[2]

These studies suggest that mecamylamine may safely be given with alcohol; however, the manufacturer of mecamylamine warns that alcohol may enhance its hypotensive effect,[3] an effect common to many antihypertensive drugs, see 'Alcohol + Antihypertensives', p.51.

Alcohol + Mefloquine

Mefloquine does not normally appear to interact with alcohol, although excessive alcohol intake may possibly contribute to its adverse effects on the liver. An isolated report describes two incidents of severe psychosis and depression when a man taking mefloquine drank large quantities of alcohol.

Clinical evidence, mechanism, importance and management

Mefloquine 250 mg or placebo was given to two groups of 20 healthy subjects on three occasions, each time the day before they drank enough alcohol to achieve blood levels of about 35 mg%. Mefloquine did not affect blood-alcohol levels, nor did it increase the effects of alcohol on two real-highway driving tests, or on psychomotor tests done in the laboratory. In fact, the mefloquine group actually drove better than the placebo group.[1]

A 40-year-old man with no previous psychiatric history, taking mefloquine 250 mg weekly for malaria prophylaxis, had no problems with the first 2 doses. However, on two separate occasions when taking the third and fourth doses he also drank about half a litre of whisky, whereupon he developed severe paranoid delusions, hallucinations and became suicidal. When he stopped drinking he had no further problems while taking subsequent doses of mefloquine. He was used to drinking large amounts of alcohol and had experienced no problems while previously taking proguanil and chloroquine.[2]

The broad picture is that mefloquine appears not to worsen the psychomotor effects of moderate amounts of alcohol. Just why an unusual toxic reaction developed in one individual is not known, although mefloquine alone can increase the risk of psychiatric events.[3,4] It has been suggested that many of the adverse effects of mefloquine are associated with liver damage, and concurrent insults to the liver, such as from alcohol and dehydration, may be related to the development of severe or prolonged adverse reactions to mefloquine. In a review of 516 published case reports of mefloquine adverse effects, 11 cited alcohol as a possible contributing factor.[4] It was suggested that travellers taking mefloquine should avoid alcohol, particularly within 24 hours of their weekly mefloquine dose.[4] However, the manufacturers have not issued such a warning.[5,6] More study is needed.

Alcohol + Meprobamate

The intoxicant effects of alcohol can be considerably increased by the presence of meprobamate. Driving or handling other potentially dangerous machinery is made much more hazardous.

Clinical evidence

A study in 22 subjects, given meprobamate 400 mg four times daily for one week, found that with blood-alcohol levels of 50 mg% the performance of a number of coordination and judgement tests was much more impaired than with either drug alone.[1] Four of the subjects were quite obviously drunk while taking both meprobamate and alcohol, and showed marked incoordination and social disinhibition. Two could not walk without assistance. The authors say this effect was much greater than anything seen with alcohol alone.

Other studies confirm this interaction, although the effects appeared to be less pronounced.[2-6]

Mechanism

Both meprobamate and alcohol are CNS depressants, which appear to have additive effects. There is also some evidence that alcohol may inhibit or increase meprobamate metabolism, depending on whether it is taken acutely or chronically, but the contribution of this to the enhanced CNS depression is uncertain.[7,8] Meprobamate does not appear to increase blood-alcohol levels.[5]

Importance and management

A well-documented and potentially serious interaction. Normal daily dosages of meprobamate in association with relatively moderate blood-alcohol levels, well within the UK legal limit for driving, can result in obviously hazardous intoxication. Patients should be warned; the patient information leaflet for meprobamate says that alcohol should be avoided.[9]

Alcohol + Methaqualone

The CNS depressant effects of alcohol and its detrimental effects on the skills relating to driving or handling other potentially dangerous machinery are increased by the concurrent use of methaqualone with or without diphenhydramine.

Clinical evidence

(a) Methaqualone

A retrospective study of drivers arrested for driving under the influence of drugs and/or alcohol found that, generally speaking, those with blood methaqualone levels of 1 mg/L or less had no symptoms of sedation, whereas those with levels above 2 mg/L demonstrated staggering gait, drowsiness, incoherence and slurred speech. These effects were increased if the drivers had also been drinking alcohol. The authors state that the levels of methaqualone needed for driving skills to become impaired are considerably lowered by alcohol, but no precise measure of this is presented in the paper.[1]

(b) Methaqualone with diphenhydramine

A double-blind study in 12 healthy subjects given two *Mandrax* tablets (methaqualone 250 mg with diphenhydramine 25 mg) showed that the resulting sedation and reduction in cognitive skills were enhanced by alcohol 0.5 g/kg. Residual amounts of a single dose of *Mandrax* continued to interact for as long as 72 hours. Methaqualone blood levels are also raised by regular moderate amounts of alcohol.[2] Similar effects on sedation were seen in another study.[3]

Mechanism

Alcohol, methaqualone and 'diphenhydramine', (p.50), are all CNS depressants, the effects of which are additive. A hangover can occur because the elimination half-life of methaqualone is long (10 to 40 hours).

Importance and management

An established interaction of importance. Those taking either methaqualone or methaqualone with diphenhydramine should be warned that handling machinery, driving a car, or any other task requiring alertness and full coordination, will be made more difficult and hazardous if they drink alcohol. Levels of alcohol below the legal driving limit with normal amounts of methaqualone may cause considerable sedation. Patients should also be told that a significant interaction may possibly occur the following day, because methaqualone has a long half-life.

Note that methaqualone has been withdrawn from the market in many countries because of problems of abuse.

Alcohol + Methotrexate

There is some inconclusive evidence that the consumption of alcohol may increase the risk of methotrexate-induced hepatic cirrhosis and fibrosis.

Clinical evidence, mechanism, importance and management

It has been claimed that alcohol can increase the hepatotoxic effects of methotrexate.[1] Two reports of patients treated for psoriasis indicate that this may be so. In one, 3 out of 5 patients with methotrexate-induced cirrhosis were reported to have taken alcohol concurrently (2 patients greater than 85 g of alcohol per week, one patient 25 to 85 g of alcohol per week):[2] in the other, the subject was known to drink excessively.[3] The evidence is by no means conclusive and no direct causal relationship has been established. However, one manufacturer of methotrexate advises the avoidance of drugs, including alcohol, which have hepatotoxic potential,[4] and another contraindicates the use of methotrexate in patients with alcoholism or alcoholic liver disease.[5]

Alcohol + Methylphenidate

Alcohol may increase methylphenidate levels and exacerbate some of its CNS effects.

Clinical evidence, mechanism, importance and management

In 17 subjects who had taken methylphenidate orally or intranasally with alcohol on at least 10 separate occasions, the primary reason for concurrent use was given as an alteration in psychotropic effects with increased euphoria and energy and a diminished sense of drunkenness. In addition, a minority of subjects also reported occasionally experiencing unpleasant adverse effects such as increased nausea (3 subjects), insomnia (2), and jaw clenching (1).[1] In a study in 20 subjects, alcohol 0.6 g/kg was given either 30 minutes before or 30 minutes after a single 0.3-mg/kg dose of methylphenidate. Alcohol significantly increased the AUC and maximum serum levels of methylphenidate, regardless of the timing of administration, by about 25% and 40%, respectively.[2]

Methylphenidate has a short half-life mainly due to conversion to the inactive metabolite ritalinic acid, but the concurrent use of alcohol and methylphenidate has been reported to result in production of a minor metabolite, ethylphenidate, which has CNS activity.[3,4] However, a more recent study found that the ethylphenidate formed is predominantly of the inactive enantiomer, so is unlikely to contribute to the additive CNS effects of alcohol and methylphenidate.[2]

The UK manufacturer of methylphenidate advises that alcohol may exacerbate the CNS effects of methylphenidate and therefore recommends that alcohol should be avoided during treatment.[5] In addition, methylphenidate should be given cautiously to patients with a history of drug dependence or alcoholism because of its potential for abuse.[1,5,6]

Alcohol + Metoclopramide

There is some evidence that metoclopramide can increase the rate of alcohol absorption, raise maximum blood-alcohol levels, and possibly increase alcohol-related sedation.

Clinical evidence, mechanism, importance and management

A study in 7 subjects found that 20 mg of intravenous metoclopramide increased the rate of alcohol absorption, and the peak blood-alcohol levels were raised from 55 mg% to 86 mg%.[1] Increases in blood-alcohol levels were also seen in 2 healthy subjects[1] and in a small study[2] in which metoclopramide was given orally.[1] Another study in 7 healthy subjects found that 10 mg of intravenous metoclopramide accelerated the rate of absorption of alcohol 70 mg/kg given orally, and increased its peak levels, but not to a statistically significant extent. Blood-alcohol levels remained below 12 mg%. More importantly the sedative effects of the alcohol were increased.[3] The reasons for this effect are not fully understood, but it appears to be related to an increase in gastric emptying. These studies were done to find out more about intestinal absorption mechanisms rather than to identify daily practicalities, so the importance of their findings is uncertain. However, it seems possible that the effects of alcohol will be increased by metoclopramide. Note that metoclopramide alone can sometimes cause drowsiness, and if affected, patients should not drive or operate machinery.

Alcohol + Metronidazole and related drugs

A number of patients taking oral metronidazole have developed a disulfiram-like reaction after drinking alcohol. There is one report of its occurrence when metronidazole was applied as a vaginal insert, and another when metronidazole was given intravenously. Some clinical studies have not confirmed the interaction, and its existence is disputed in some reports. The interaction is alleged to occur with all other 5-nitroimidazoles (e.g. tinidazole).

Clinical evidence

A man who had been in a drunken stupor for 3 days was given two metronidazole tablets (a total of 500 mg) one hour apart by his wife in the belief that they might sober him up. Twenty minutes after the first tablet he was awake and complaining that he had been given disulfiram (which he had taken some months before). Immediately after the second tablet, he took another drink and developed a classic disulfiram-like reaction with flushing of the face and neck, nausea and epigastric discomfort.[1] Other individual cases have been reported,[2] including a reaction with a metronidazole vaginal insert.[3]

In a test of the value of metronidazole 250 mg twice daily as a possible drink-deterrent, all 10 alcoholic patients studied experienced some disulfiram-like reactions of varying intensity (facial flushing, headaches, sensation of heat, fall in blood pressure, vomiting) when given alcohol.[4] In another study in 60 alcoholic patients, given metronidazole 250 to 750 mg daily, most developed mild to moderate disulfiram-like reactions during an alcohol tolerance test.[5] A lower incidence of this reaction, between 2 and 24%, has also been reported.[6-8]

Pharmaceutical preparations containing alcohol have also been implicated. A 2-year-old child became flushed and dyspnoeic when metronidazole was given with both *Stopayne* syrup (an analgesic/sedative combination) and a phenobarbital syrup, both of which contained alcohol.[9] Another reaction has been seen in a patient receiving intravenous metronidazole and a co-trimoxazole preparation containing alcohol 10%.[10] A further patient who had just finished a 7-day course of metronidazole developed severe, prolonged nausea and vomiting postpartum: she had received a single 800-mg dose of prophylactic clindamycin intravenously before the birth and it was thought that the benzyl alcohol present in the clindamycin preparation could have caused the reaction. However, other factors such as intrathecal anaesthesia may have also contributed to the adverse effects.[11] For mention of other preparations containing alcohol, see 'Alcohol + Disulfiram', p.66.

An interaction has also been reported in association with metabolic acidosis in an intoxicated man 4 hours after he was given intravenous metronidazole as prophylaxis following injury.[12] A fatality occurred in a frail 31-year old woman, which was attributed to cardiac arrhythmias caused by acetaldehyde toxicity resulting from the interaction between alcohol and metronidazole, linked to autonomic distress caused by a physical assault.[13] Alcohol is also said to taste unpleasant[1,4] or to be less pleasurable[8] while taking metronidazole. Some drug abusers apparently exploit the reaction for 'kicks'.[14]

In contrast, a study in 207 patients with inflammatory bowel disease, assessed using a phone survey, the presence of adverse reactions to alcohol in patients taking chronic metronidazole and/or mercaptopurine or neither drug; all of the patients consumed less than 4 alcoholic beverages per day. There was a trend towards more adverse effects in both the metronidazole and mercaptopurine study groups, but no statistically significant interaction between alcohol and metronidazole was found.[15] There are other reports, including two well-controlled studies, showing that metronidazole has no disulfiram-like effects.[16-18]

Mechanism

Not understood. In the disulfiram reaction, the accumulation of acetaldehyde appears to be responsible for most of the symptoms, see *Mechanism*, under 'Alcohol + Disulfiram', p.66. Some workers have reported an increase in acetaldehyde levels due to the interaction between metronidazole and alcohol,[13] but others have reported no effect[18] or a reduction in plasma acetaldehyde levels.[19] Furthermore, some studies with metronidazole indicate a lack of a disulfiram-like reaction,[16,17] and it has been suggested that if such a reaction does occur it may be by a mechanism other than the inhibition of hepatic acetaldehyde dehydrogenase.[18] It appears that metronidazole, like disulfiram, can inhibit other enzymes related to alcohol metabolism including xanthine oxidase and alcohol dehydrogenase.[20,21] Inhibition of xanthine oxidase may cause noradrenaline excess, and inhibition of alcohol dehydrogenase can lead to activation of microsomal enzyme oxidative pathways that generate ketones and lactate, which could produce acidosis.[12]

Importance and management

A reasonably well studied interaction, but it remains a controversial issue. The incidence is variously reported as between 0 and 100%, with more recent reports disputing its existence.[18,19] Nevertheless because of the uncertainty, all patients given metronidazole should be warned about what may happen if they drink alcohol. The manufacturers recommend avoiding alcohol when metronidazole is taken, and for at least 48 hours after it has been stopped (UK) or 24 hours after it has been stopped (US).[22,23] In the US, for the capsules, and extended-release preparation, 72 hours is recommended.[24,25] However, the authors of one report suggest a cautious trial of alcohol in patients that are starting and will be taking metronidazole on a chronic basis.[15]

The reaction, when it occurs, normally seems to be more unpleasant and possibly frightening than serious, and usually requires no treatment, although one report describes a serious reaction when intravenous metronidazole was given to an intoxicated man,[12] and one possible fatality has been reported.[13] The risk of a reaction with metronidazole used intravaginally seems to be small because the absorption is low (about 20% compared with about 100% orally), but evidently it can happen, even if only rarely.[3] Patients should be warned. It has been alleged that the disulfiram-like reaction with alcohol occurs with all of the related 5-nitroimidazoles,[26,27] but there do not appear to be any published reports of it occurring with **nimorazole**, **ornidazole**, **secnidazole** or **tinidazole**. The

manufacturer of **tinidazole** notes that, as with related compounds, there is a possibility of a disulfiram-like reaction with alcoholic beverages, and recommends that alcohol should be avoided until 72 hours after discontinuing tinidazole.[28]

Alcohol + Mirtazapine

The sedative effects of mirtazapine may be increased by alcohol.

Clinical evidence, mechanism, importance and management

In 6 healthy subjects alcohol (equivalent to 60 g) had a minimal effect on plasma levels of mirtazapine 15 mg.[1] However the sedation and CNS impairment seen with mirtazapine is additive with that produced by alcohol, and the manufacturers recommend avoiding concurrent use.[1,2] Mirtazapine does not affect the absorption of alcohol.[3]

Alcohol + Muscle relaxants

Three reported cases of modest overdosage with methocarbamol and alcohol resulted in death due to combined CNS depression. Concurrent use of small or moderate amounts of alcohol with muscle relaxants may increase drowsiness and reduce alertness.

Clinical evidence, mechanism, importance and management

(a) Baclofen

The manufacturer of baclofen warns that it may enhance the sedative effect of alcohol.[1] However, tolerance to the sedative effect of baclofen has been reported in alcohol-addicted patients after a period of abstinence, as well as after a relapse.[2]

(b) Dantrolene

The manufacturer of dantrolene advises caution if it is given with alcohol[3] and the patient information leaflet suggests that alcohol should be avoided because it may increase drowsiness.[4]

(c) Methocarbamol

Fatal cerebral anoxia produced by CNS respiratory depression occurred in a 31-year-old man after he took significant amounts of methocarbamol and alcohol. Two other lethal overdoses have been reported with these 2 drugs. In all 3 cases the methocarbamol doses exceeded the recommended daily dosages, but were estimated to be less than the reported maximum tolerated single dose of 12 g. Acute alcohol intoxication combined with methocarbamol usage can lead to combined CNS depression, which may be sufficient to cause death.[5] The manufacturers of methocarbamol warn that it may potentiate the effects of alcohol[6,7] and the patient information leaflet suggests that patients taking methocarbamol should avoid alcohol.[8]

(d) Other muscle relaxants

For enhanced CNS effects with alcohol with other muscle relaxants, see 'benzodiazepines', (p.56), 'meprobamate', (p.74), and 'tizanidine', (p.1573).

Alcohol + Nefazodone

In one study nefazodone 400 mg was found not to increase the sedative-hypnotic effects of alcohol.[1]

1. Frewer LJ, Lader M. The effects of nefazodone, imipramine and placebo, alone and combined with alcohol, in normal subjects. *Int Clin Psychopharmacol* (1993) 8, 13–20.

Alcohol + Niclosamide

Alcohol may possibly increase the adverse effects of niclosamide.

Clinical evidence, mechanism, importance and management

The manufacturer of niclosamide advises avoiding alcohol while taking niclosamide. The reasoning behind this is that while niclosamide is virtually insoluble in water, it is slightly soluble in alcohol. Therefore taking niclosamide with alcohol might possibly increase its absorption by the gut, resulting in an increase in its adverse effects. There are no formal reports of this but the manufacturer says that they have some anecdotal information that is consistent with this suggestion.[1]

1. Bayer. Personal communication, July 1992.

Alcohol + Nicotine

Nicotine (as a patch) may possibly enhance the effect of alcohol on heart rate and reduce the time to peak alcohol levels. The concurrent use of alcohol and a nicotine nasal spray did not affect the pharmacokinetics of either drug.

Clinical evidence, mechanism, importance and management

A placebo-controlled study in 12 otherwise healthy tobacco smokers found that alcohol-induced increases in heart rate were enhanced by pre-

treatment with a 21-mg nicotine transdermal patch. The time to peak alcohol levels with a 0.4 g/kg dose of ethanol was faster with nicotine pretreatment (43 minutes) compared with 52 minutes in the absence of nicotine; however, this effect was not seen with a 0.7 g/kg dose of alcohol.[1] Another study in 12 otherwise healthy tobacco smokers found that although alcohol 0.4 or 0.8 g/kg (equivalent to approximately 2 or 4 drinks, respectively) influenced selected subjective responses and heart rate, pretreatment with alcohol did not affect the subjects responses to low-dose nicotine 3 to 20 micrograms/kg given as a nasal spray (20 microgram/kg dose is equivalent to about one-half of a cigarette). The concurrent use of nicotine and alcohol did not influence the blood levels of either drug.[2]

Alcohol + Nicotinic acid (Niacin)

An isolated report describes delirium and metabolic acidosis when a patient taking nicotinic acid for hypercholesterolaemia drank about one litre of wine. The manufacturers warn that the concurrent use of nicotinic acid and alcohol may result in an increase in adverse effects such as flushing and pruritus, and possibly liver toxicity.

Clinical evidence, mechanism, importance and management

An isolated report describes delirium and metabolic acidosis after a patient taking nicotinic acid 3 g daily for hypercholesterolaemia drank about one litre of wine. Delirium had occurred on a previous similar occasion after he drank a large quantity of beer while taking nicotinic acid. It is suggested that the nicotinic acid may have caused liver impairment, which was exacerbated by the large amount of alcohol. The patient did have some elevations in liver enzymes.[1] Acidosis has been associated with alcohol intoxication[2] (although the frequency of this association has been disputed[3]) and there has been a report of lactic acidosis associated with the use of high-dose (3 g daily) nicotinic acid,[4] and therefore a combined effect would seem possible. However, no general conclusions can be drawn from this single case.

Hepatic toxicity can occur with nicotinic acid and the manufacturers advise caution in patients who consume substantial quantities of alcohol. They also suggest the avoidance of alcohol around the same time as nicotinic acid is taken, as the adverse effects of flushing and pruritus may be increased.[5,6]

Alcohol + Nitrofurantoin

There appears to be no good clinical evidence for an alleged interaction between alcohol and nitrofurantoin.

Clinical evidence, mechanism, importance and management

Despite claims in some books and reviews, an extensive literature search failed to find any experimental or clinical evidence for an alleged disulfiram-like reaction between alcohol and nitrofurantoin.[1] A study in healthy subjects failed to demonstrate any such interaction[2] and a survey of the reports in the manufacturer's database also failed to find good evidence for alcohol intolerance.[3] It is concluded that this 'interaction' is erroneous.[1]

Alcohol + Nitrous oxide

In a double-blind study in 11 healthy subjects there were several instances when alcohol 0.25 to 5 g/kg (equivalent to 1 to 3 drinks) enhanced the effects of nitrous oxide 30% in oxygen, inhaled for 35 minutes. Some effects were seen with the drug combination, which were not seen with either drug alone; these included subjective effects and delayed free recall.[1] For mention of the effect of alcohol following anaesthesia, see 'Anaesthetics, general + Alcohol', p.102.

1. Zacny JP, Camarillo VM, Sadeghi P, Black M. Effects of ethanol and nitrous oxide, alone and in combination, on mood, psychomotor performance and pain reports in healthy volunteers. *Drug Alcohol Depend* (1998) 52, 115–23.

Alcohol + NSAIDs

Alcohol may increase the risk of gastrointestinal haemorrhage associated with NSAIDs. The skills related to driving are impaired by indometacin and phenylbutazone and this is made worse if patients drink alcohol while taking phenylbutazone, but this does not appear to occur with indometacin. A few isolated reports attribute acute renal failure to the concurrent use of NSAIDs and acute excessive alcohol consumption.

Clinical evidence, mechanism, importance and management

(a) Gastrointestinal complications

In healthy subjects the concurrent use of alcohol with **ibuprofen** 2.4 g over 24 hours increased the damaging effect of **ibuprofen** on the stomach wall, although this did not reach statistical significance.[1] A case-control study, involving 1224 patients admitted to hospital with upper gastrointestinal bleeding and 2945 controls, found that alcohol consumption was associated with a threefold increase in the incidence of acute upper gastrointestinal haemorrhage from light drinking (less than one alcoholic drink per week) to heavy drinking (21 alcoholic drinks or more per week). There was some evidence to suggest that the risk of upper gastrointestinal bleeding was increased by the concurrent use of **ibuprofen**.[2] Another case-control study suggested that the odds ratio for gastrointestinal complications in those regularly consuming more than 5 drinks during a drinking session was increased from 2.8 to 6 when an NSAID was also taken. This was also increased when compared with the use of an NSAID alone (odds ratio 3.8).[3] A third case-control study found that the use of prescription NSAIDs or non-prescription **naproxen** or **ibuprofen** in those with a history of alcohol abuse produced a risk ratio of adverse gastrointestinal effects that was greater than the expected additive risk. Both NSAID use and excessive alcohol consumption carry the risk of gastrointestinal adverse effects. This information suggests that NSAIDs should be used with caution in heavy drinkers.[4] The FDA in the US has ruled that non-prescription pain relievers and fever reducers containing **ibuprofen**, **ketoprofen**, or **naproxen** must carry a warning label advising people who consume moderate amounts of alcohol to consult their doctor before using these drugs, and that stomach bleeding may occur with these drugs.[5]

(b) Psychomotor skills and alcohol levels

A study in a large number of healthy subjects found that the performance of various psychomotor skills related to driving (choice reaction, coordination, divided attention tests) were impaired by single doses of **indometacin** 50 mg or **phenylbutazone** 200 mg. Alcohol 0.5 g/kg made things worse in those taking **phenylbutazone**, but the performance of those taking **indometacin** was improved to some extent.[6] The reasons are not understood. The study showed that the subjects were subjectively unaware of the adverse effects of **phenylbutazone**. Information is very limited, but patients should be warned if they intend to drive. In two studies, **ibuprofen** 800 mg had no significant effect on blood-alcohol levels of healthy subjects.[7,8]

The pharmacokinetics of alcohol 1 g/kg and the results of performance tests were found to be similar in subjects given **dipyrone** 1 g or a placebo.[9] No special precautions seem to be necessary.

(c) Renal complications

A normal healthy young woman with no history of renal disease developed acute renal failure after taking **ibuprofen** 400 mg the evening before, 400 mg the following morning, and then 375 mL of **rum** later in the day, followed by two further 400-mg tablets of **ibuprofen**.[10] Another similar case was reported in a 22-year-old woman who had taken **ibuprofen** 1.2 g the morning after binge drinking.[11] Both recovered.[10,11] A further case describes renal impairment in a young woman, which was associated with the use of **ketoprofen** 600 mg and binge drinking.[12] It is suggested that volume depletion caused by the alcohol (and compounded by vomiting) predisposed these patients to NSAID-induced renal toxicity.[11,12] The general importance of these isolated cases remains to be determined.

Alcohol + Olanzapine

Postural hypotension and possibly drowsiness may be increased when alcohol is given with olanzapine.

Clinical evidence, mechanism, importance and management

The manufacturer says that patients taking olanzapine have shown an increased heart rate and accentuated postural hypotension when given a single-dose of alcohol.[1] In a study, 9 of 11 subjects experienced orthostatic hypotension when they drank alcohol one hour after taking olanzapine 10 mg.[2] No pharmacokinetic interaction has been seen.[1-3] In practical terms this means that patients should be warned of the risk of faintness and dizziness if they stand up quickly, and advised to sit or lie down if this occurs. The manufacturers also say that drowsiness is a common adverse effect of olanzapine, and they advise caution in patients taking other products that can cause CNS depression, including alcohol.[3,4]

Alcohol + Ondansetron

Ondansetron does not appear to affect the pharmacokinetics of alcohol, but may increase its subjective effects.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study, 12 healthy subjects were given ondansetron 8 mg with an oral dose of alcohol (0.65 and 0.75 [g/kg] for women and men, respectively). It was found that ondansetron did not significantly alter the pharmacokinetics of alcohol or increase the objective measures of sedation that occurred in response to alcohol. However, *subjective* measures of impairment and intoxication caused by alcohol were increased by ondansetron.

It therefore seems unlikely that a particularly detrimental effect occurs if patients receiving ondansetron drink alcohol, but they may well feel more intoxicated.[1]

Alcohol + Opioids

In general the opioid analgesics can enhance the CNS depressant effects of alcohol, which has been fatal in some cases: this appears to be a particular problem with dextropropoxyphene. This may be related to that fact that the bioavailability of dextropropoxyphene is increased by alcohol. Alcohol has been associated with rapid release of hydromorphone and morphine from extended-release preparations, which could result in potentially fatal doses. The acute use of alcohol and methadone appears to result in lower blood-alcohol levels.

Clinical evidence

(a) Buprenorphine

A study in 12 patients taking buprenorphine found that alcohol 14.7 g/70 kg produced a lower blood-alcohol level, when compared with a group of patients not taking buprenorphine (56 mg% compared with 40 mg%), but this was not statistically significant.[1] See also, *Methadone*, below.

(b) Codeine

Double-blind studies in a large number of professional army drivers found that 50 mg of codeine and alcohol 0.5 g/kg, both alone and together, impaired their ability to drive safely on a static driving simulator. The number of collisions, neglected instructions and the times they drove off the road were increased.[2,3] Alcohol does not appear to affect the pharmacokinetics of codeine.[4] See also, *Controlled-release opioids*, below.

(c) Dextropropoxyphene

In a study in 8 healthy subjects, alcohol alone (blood levels of 50 mg%) impaired the performance of various psychomotor tests (motor co-ordination, mental performance and stability of stance) more than dextropropoxyphene 65 mg alone. When given together there was some evidence that the effects were greater than with either drug alone, but in some instances the impairment was no greater than with alcohol alone. The effect of alcohol clearly predominated.[5] In contrast, other studies have found that dextropropoxyphene does not enhance the psychomotor impairment seen with alcohol,[6,7] but the bioavailability of the dextropropoxyphene has been reported to be raised by 25 to 31% by alcohol.[7,8] A retrospective study involving 332 fatal poisonings in Finland found that alcohol was present in 73% of cases involving dextropropoxyphene and, when alcohol was present, relatively small overdoses of dextropropoxyphene could result in fatal poisoning.[9] Further reports describe alcohol reducing the lethal dose of dextropropoxyphene.[10-12]

(d) Hydromorphone

A young man died from the combined cardiovascular and respiratory depressant effects of hydromorphone and alcohol.[13] He fell asleep, the serious nature of which was not recognised by those around him. Post-mortem analysis revealed alcohol and hydromorphone concentrations of 90 mg% and 100 nanograms/mL, respectively, neither of which is particularly excessive. A study in 9 healthy subjects found that pre-treatment with hydromorphone 1 or 2 mg did not significantly affect the subject-rated effects of alcohol 0.5 or 1 g/kg. However, hydromorphone enhanced the sedative scores of alcohol on the adjective rating scale.[14] See also, *Controlled-release opioids*, below.

(e) Methadone

A study in 21 opioid-dependent subjects who had been receiving methadone or **buprenorphine** for 3 months, and 21 matched non-drug-using controls, found that although alcohol (target blood-alcohol level around 50 mg%) resulted in decreased driving performance, there appeared to be no difference in simulated driving tests in the opioid-treated patients, when compared with controls. It was suggested that restrictions on opioids and driving are not necessary in stabilised patients receiving maintenance

buprenorphine or methadone treatment, but little is known about the effects in the initial treatment period. This study also found that blood-alcohol levels were lower in the opioid-treated patients, when compared with the controls, despite both groups receiving the same amount of alcohol.[15] A study in 14 patients taking methadone also found that alcohol 14.7 g/70 kg produced a lower blood-alcohol level, when compared with a group of patients not taking methadone (56 mg% compared with 40 mg%).[1]

However, clinical anecdotal reports have indicated that taking methadone with alcohol produces an additive and/or synergistic response,[16] which may result in serious respiratory depression and hypotension.[17]

(f) Controlled-release opioids

Pharmacokinetic data in healthy subjects has shown that consuming alcohol with a particular 24-hour extended-release formulation of **hydromorphone** *(Palladone XL Capsules; Purdue Pharma, USA)* could lead to rapid release (dose dumping) and absorption of a potentially fatal dose of hydromorphone.[18,19] Although no reports of serious problems had been received, the FDA in the US asked for the product to be withdrawn from the market.[20] Health Canada warned that this interaction might occur with other slow-release opioid analgesics.[21] However, the Canadian distributor of hydromorphone has commented that the controlled-release technology employed in *Palladone XL* is not the same as that of many other controlled-release opioid formulations. Dose-dumping with alcohol is said not to occur with:

- **morphine** sustained-release tablets: *MS Contin*,[22,23] *MST continus* suspension and tablets, *MXL* capsules,[23]
- **codeine** controlled-release tablets: *Codeine Contin*,[22,23]
- **dihydrocodeine** controlled-release tablets: *DHC Continus* tablets,[23]
- **hydromorphone** controlled-release capsules: *Hydromorph Contin*,[22] *Palladone SR*,[23]
- **oxycodone** controlled-release tablets: *OxyContin*,[22,23]
- **tramadol** (once daily and twice daily formulations).[23]

In contrast, in laboratory studies, an extended-release capsule preparation of **morphine** (*Avinza; King Pharmaceuticals, USA*) was found to release morphine earlier than expected when exposed to alcohol, and this effect increased dramatically with increasing alcohol concentration.[24,25] The product literature for *Avinza* now carries a warning to avoid alcohol, including medications containing alcohol, while taking this preparation.[25] Although most opioid preparations do not appear to interact with alcohol in this way, the concurrent use of alcohol and opioid analgesics is never advisable because of the potential for an interaction between CNS depressant drugs, see above.

Mechanism

Both opioids and alcohol are CNS depressants, and there may be enhanced suppression of the medullary respiratory control centre.[10-12] Acute administration of alcohol appears to increase methadone effects due to inhibition of hepatic microsomal enzymes, but chronic alcoholism reduces the AUC and half-life of methadone because cytochrome P450 isoenzymes are induced.[16]

Importance and management

The reports describing increased sedation and even fatalities emphasise the importance of warning patients about the potentially hazardous consequences of drinking while taking potent CNS depressants like the opioids. This seems to be a particular risk with dextropropoxyphene overdosage, and it has been suggested that a less dangerous alternative could be chosen when indications of alcohol abuse or suicide risk are present.[26] The US manufacturers recommend caution when prescribing dextropropoxyphene in patients who use alcohol in excess.[27] There is less information about therapeutic doses of dextropropoxyphene with moderate social drinking. In general it is suggested that alcohol intake should be avoided where possible, or limited in those taking opioids, but some manufacturers actually contraindicate alcohol. The objective evidence is that the interaction with moderate doses of alcohol and opioids is quite small (with the exception of the dose dumping effect). It would seem prudent to warn patients that opioids can cause drowsiness and this may be exaggerated to some extent by alcohol. They should be warned that driving or handling potentially hazardous machinery may be more risky, but total abstinence from alcohol does not seem to be necessary. Smaller doses, such as those available without a prescription, would be expected to have a smaller effect, but this does not appear to have been studied. One of the manufacturers of methadone contraindicates its use with all CNS depressants, including alcohol,[17] but this seems to pose almost unworkable restrictions on its use.

Alcohol + Orlistat

A study in healthy subjects found that orlistat 120 mg three times daily for 6 days had no significant effect on the pharmacokinetics of alcohol.[1] There is nothing to suggest that alcohol should be avoided while taking orlistat.

1. Melia AT, Zhi J, Zelasko R, Hartmann D, Güzelhan C, Guerciolini R, Odink J. The interaction of the lipase inhibitor orlistat with ethanol in healthy volunteers. *Eur J Clin Pharmacol* (1998) 54, 773–7.

Alcohol + Paracetamol (Acetaminophen)

Many case reports describe severe liver damage, sometimes fatal, in some alcoholics and persistent heavy drinkers who take only moderate doses of paracetamol. However, other controlled studies have found no association between alcohol intake and paracetamol-induced hepatotoxicity. There is controversy about the use of paracetamol in alcoholics. Some consider standard therapeutic doses can be used, whereas others recommend the dose of paracetamol should be reduced, or paracetamol avoided. Occasional and light to moderate drinkers do not seem to be at any extra risk.

Clinical evidence

(a) Increased hepatotoxicity

Three chronic alcoholic patients developed severe liver damage after taking paracetamol. They had AST levels of about 7 000 to 10 000 units. Two of them had taken 10 g of paracetamol over 24 or 48 hours before admission (normal dosage is up to 4 g daily), and the third patient had taken about 50 g of paracetamol over 72 hours. One of them developed hepatic encephalopathy and died, and subsequent post-mortem revealed typical paracetamol toxicity. Two of them also developed renal failure.[1] A case of severe liver impairment has also been reported in a moderate social drinker who regularly drank 3 glasses of wine with dinner, but had stopped drinking alcohol whilst taking paracetamol for a viral infection.[2]

There are numerous other case reports of liver toxicity in alcoholics or chronic heavy alcohol users attributed to the concurrent use of alcohol and paracetamol. In the reports cited here, which include a total of about 30 patients, about one-third had been taking daily paracetamol doses of up to 4 g daily, and one-third had taken doses within the range 4 to 8 g daily.[3-19] Fasting possibly makes things worse.[20] A later survey reviewed a total of 94 cases from the literature, and described a further 67 patients who were regular users of alcohol, 64% of whom were alcoholics, who developed liver toxicity after taking paracetamol. In 60% of cases the paracetamol dose did not exceed 6 g daily and in 40% of cases the dose did not exceed 4 g daily. More than 90% of the patients developed AST levels ranging from 3 000 to 48 000 units.[21]

(b) No effect on hepatotoxicity

In a retrospective review of 553 cases of paracetamol-induced severe hepatotoxicity treated at a liver failure unit over a 7-year period, there was no association between the level of alcohol consumption and the severity of the hepatotoxicity (mean INR and serum creatinine levels in the first 7 days after overdose). Alcohol consumption was categorised into 4 groups ranging from non-drinkers to heavy drinkers (greater than 60 g of alcohol daily in men and 40 g daily in women).[22]

In a randomised, placebo-controlled study, there was no difference in measures of hepatotoxicity (mean AST levels, mean INR) between 102 alcoholic patients who received paracetamol 1 g four times daily for 2 days, and 99 alcoholic patients who received placebo. In this study, patients had entered an alcohol detoxification centre, and were given paracetamol immediately after stopping alcohol use[23] (the assumed time of greatest susceptibility, see *Mechanism*, below). A systematic review by the same research group concluded that the use of therapeutic doses of paracetamol in alcoholic patients is not associated with hepatic injury.[24]

(c) Effect on alcohol levels

Paracetamol 1 g was found to have no effect on the single-dose pharmacokinetics of alcohol in 12 healthy subjects.[25] Another study found that blood-alcohol levels were raised by 1 g of paracetamol but this was not statistically significant.[26]

Mechanism

Uncertain. The interaction between paracetamol and alcohol is complex, because acute and chronic alcohol consumption can have opposite effects.[27,28] Paracetamol is usually predominantly metabolised by the liver to non-toxic sulfate and glucuronide conjugates. Persistent heavy drinking appears to stimulate a normally minor biochemical pathway involving the cytochrome P450 isoenzyme CYP2E1, and possibly the CYP3A subfamily, which allows the production of unusually large amounts of highly hepatotoxic metabolites via oxidation.[20,28,29] Unless sufficient glutathione is present to detoxify these metabolites (alcoholics often have an inadequate intake of protein), they become covalently bound to liver macromolecules and damage results. Fasting may also make things worse by reducing the availability of glucose, and thus shifting paracetamol metabolism from glucuronidation towards microsomal oxidation.[20] However, most studies have failed to demonstrate an increase in hepatotoxic metabolites in alcoholics.[27,30] In fact alcoholics may possibly be most susceptible to toxicity during alcohol withdrawal because, while drinking, alcohol may possibly compete with the paracetamol for metabolism, and even inhibit it. Acute ingestion of alcohol by non-alcoholics may possibly protect them against damage because the damaging biochemical pathway is inhibited rather than stimulated. The relative timing of alcohol and paracetamol intake is therefore critical;[27] for example, a study in 10 healthy subjects found that ingestion of 500 mg of paracetamol 8 hours after an intravenous infusion of alcohol (roughly equivalent to a bottle of wine) resulted in an increased production of the toxic metabolite of paracetamol, *N*-acetyl-*p*-benzoquinoneimine (NABQI), when compared with dextrose 5%.[31]

Importance and management

The incidence of unexpected paracetamol toxicity in chronic alcoholics is uncertain, but possibly fairly small, bearing in mind the very wide-spread use of paracetamol and alcohol. Note that most of the evidence for an interaction comes from anecdotal case reports and case series, albeit in large numbers. However, the damage, when it occurs, can be serious and therefore some have advised that alcoholics and those who persistently drink heavily should avoid paracetamol or limit their intake considerably.[21] The normal daily recommended 'safe' maximum of 4 g is said to be too high in some alcoholics.[21] Because of this, the FDA in the US have required that all paracetamol-containing non-prescription products bear the warning that those consuming 3 or more alcoholic drinks every day should ask their doctor whether they should take paracetamol.[32] However, others consider that the evidence does not prove that there is an increase in paracetamol hepatotoxicity in alcoholics,[24,27] and is insufficient to support any change in paracetamol use or dose in alcoholics.[24,33] They note that the alternatives, aspirin and NSAIDs, are associated with a greater risk of gastrointestinal adverse effects in alcoholics,[24] see 'Alcohol + Aspirin or other Salicylates', p.54 and 'Alcohol + NSAIDs', p.78'. Further study is needed. The risk for non-alcoholics, moderate drinkers and those who very occasionally drink a lot appears to be low, although some chronic moderate social drinkers may be at risk, especially if alcohol intake is abruptly stopped.[34]

Note that chronic alcohol intake increases the risk of hepatotoxicity after paracetamol *overdose*.

Alcohol + Paraldehyde

Both alcohol and paraldehyde have CNS depressant effects, which can be additive. The use of paraldehyde in the treatment of acute alcohol intoxication has caused fatalities.

Clinical evidence, mechanism, importance and management

A report describes 9 patients who died suddenly and unexpectedly after treatment for acute alcohol intoxication with 30 to 90 mL of paraldehyde (the authors quote a normal dose range of 8 to 30 mL; fatal dose 120 mL or more, usually preceded by coma). None of the patients had hepatic impairment, although one did have some fatty changes.[1] Both drugs are CNS depressants and may therefore be expected to have additive effects at any dosage, although an *animal* study suggested that the effect might be less than additive,[2] and cross-tolerance may occur as paraldehyde is pharmacologically similar to alcohol.[3] Nevertheless, it would seem prudent to avoid giving paraldehyde to intoxicated patients wherever possible.

Alcohol + Penicillins

No adverse interaction normally occurs between alcohol and phenoxymethylpenicillin or amoxicillin.

Clinical evidence, mechanism, importance and management

A long-standing and very common belief among members of the general public (presumably derived from advice given by doctors and pharmacists) is that alcohol should be strictly avoided while taking any antibacterial. It has been claimed that alcohol increases the degradation of penicillin in the gut and reduces the amount available for absorption.[1] However, one study showed that the pharmacokinetics of **phenoxymethylpenicillin** (**penicillin V**) were unaffected by alcoholic drinks,[2] and another study found that alcohol delayed the absorption of **amoxicillin** but did not affect the total amount absorbed.[3] An *in vitro* study did report that acetaldehyde, at concentrations occurring *in vivo* during alcohol metabolism, reacted with amine containing penicillins (**amoxicillin**, **ampicillin**, and **ciclacillin**), which theoretically could lead to decreased drug bioavailability and possibly adverse effects.[4] However, there seems to be no clinical evidence to support claims of an adverse interaction.

Alcohol + Phenytoin

Acute alcohol intake may possibly increase serum phenytoin levels, but moderate social drinking appears to have little clinical effect. However, chronic heavy drinking reduces serum phenytoin levels so that above-average doses of phenytoin may be needed to maintain adequate levels.

Clinical evidence

(a) Acute alcohol ingestion

In a study designed to test the effects of acute alcohol intoxication in epileptics, 25 patients were given about 340 mL of alcohol 25%. Blood-alcohol levels ranged from 39 to 284 mg%. All patients had signs of alcohol intoxication without any effect on seizure frequency.[1] The metabolism of a single dose of phenytoin was not affected in one study in healthy subjects by the acute ingestion of alcohol.[2]

(b) Heavy drinking

In a group of 15 drinkers (consuming a minimum of 200 g of ethanol daily for at least 3 months) phenytoin levels measured 24 hours after the last dose of phenytoin were approximately half of those in 76 non-drinkers. The phenytoin half-life was reduced by 30%.[3]

Another study confirmed that alcoholics without liver disease have lower than expected plasma levels of phenytoin while drinking.[4] Two reports describe a chronic alcoholic who was resistant to large doses of phenytoin;[5] and seizures, which developed in a man when an increase in his alcohol consumption appeared to cause a reduction in his serum phenytoin levels.[6]

(c) Moderate social drinking

A study in non-drinking epileptics (17 in the experimental group, 14 in the control group) found that the serum levels of phenytoin were unchanged by moderate drinking, and there was no influence on tonic-clonic convulsions or partial complex seizures. The experimental group drank 1 to 3 glasses of an alcoholic beverage (equivalent to a glass of beer containing 9.85 g of ethanol) over a 2-hour period, twice a week, for 16 weeks, and their maximum blood-alcohol levels ranged from 5 to 33 mg%.[7]

Mechanism

Supported by *animal* data,[8] the evidence suggests that repeated exposure to large amounts of alcohol induces liver microsomal enzymes so that the rate of metabolism and clearance of phenytoin is increased. Conversely, acute alcohol intake may decrease hepatic metabolism.[9]

Importance and management

An established and clinically important interaction, although the documentation is limited. Heavy drinkers may need above-average doses of phenytoin to maintain adequate serum levels. However, be aware that patients with liver impairment usually need lower doses of phenytoin, so the picture may be more complicated. Note that, the manufacturers of phenytoin suggest that acute alcohol intake may increase phenytoin levels,[10,11] but a single-dose study suggests that no significant interaction occurs. Moderate drinking appears to be safe in those taking phenytoin.[1,7] Consider also 'Alcohol + Antiepileptics', p.49.

Alcohol + Phosphodiesterase type-5 inhibitors

Sildenafil, tadalafil and vardenafil do not usually alter the effects of alcohol on blood pressure, although postural hypotension has been seen in some subjects given tadalafil and alcohol, and headache and flushing has been reported in one patient taking sildenafil and alcohol. Alcohol does not affect the pharmacokinetics of tadalafil or vardenafil.

Clinical evidence, mechanism, importance and management

(a) Sildenafil

Sildenafil 50 mg did not potentiate the hypotensive effect of alcohol (mean maximum blood-alcohol levels of 80 mg%) in healthy subjects.[1,2] A study in 8 healthy subjects also found that sildenafil 100 mg did not affect the haemodynamic effects of red wine (e.g. heart rate, mean arterial pressure).[3] However, a case report describes potentiation of the adverse effects of sildenafil when alcohol was consumed within one hour of taking the drug: a 36-year-old hypertensive patient receiving regular treatment with amlodipine was given sildenafil 25 mg, which he took 3 times a week without any adverse effects. However, after having 2 drinks of whiskey (55.2 g of alcohol) he experienced severe headache and flushing about 15 minutes after taking sildenafil. The next day he took sildenafil 25 mg without any alcohol and no symptoms developed, but one week later, a challenge dose of sildenafil was given after a single 30-mL drink of whiskey and similar symptoms of severe headache and flushing occurred.[4] The UK patient information leaflet says that drinking alcohol can temporarily impair the ability to get an erection and advises patients not to drink large amounts of alcohol before taking sildenafil.[5]

(b) Tadalafil

A study in 48 healthy subjects given a single 20-mg dose of tadalafil followed by alcohol 0.6 mg/kg found that standing and supine blood pressure, and heart rate were not significantly altered, when compared with placebo and alcohol.[6] Similar or the same work is quoted by the manufacturers. In addition they note that some subjects given both alcohol and tadalafil experienced dizziness and postural hypotension, and the effects of alcohol on cognitive function were unchanged by tadalafil 10 mg.[7] The pharmacokinetics of tadalafil 10 or 20 mg and alcohol were also unaffected by concurrent use.[7,8] However, the manufacturers say that because both alcohol and tadalafil can cause peripheral vasodilation, additive blood pressure lowering effects are possible,[8,9] especially with substantial amounts of alcohol (5 units) and the US manufacturer states that this may result in postural hypotension, increased heart rate, dizziness and headache.[8] Alcohol may also affect the ability to have an erection.[9]

(c) Vardenafil

A placebo-controlled study in 12 healthy subjects found that when alcohol 0.5 g/kg was given with vardenafil 20 mg the pharmacokinetics of both drugs were not significantly altered, and there were no clinically relevant changes in systolic or diastolic blood pressure. Both alcohol and vardenafil alone increased heart rate, the use of both drugs further increased heart rate, but this was only significant when compared with vardenafil alone.[10] The manufacturers note that alcohol (mean blood level of 73 mg%) did not affect the pharmacokinetics of vardenafil 20 mg.[11] There would therefore seem to be no need to avoid the combination. However, alcoholic drink can worsen erection difficulties.[12]

Alcohol + Procainamide

Alcohol may modestly increase the clearance of procainamide.

Clinical evidence, mechanism, importance and management

In a study in 11 healthy subjects, alcohol 0.73 g/kg followed by alcohol 0.11 g/kg every hour, increased the clearance and decreased the elimination half-life of a single 10-mg/kg oral dose of procainamide by 34% and 25%, respectively. This was due to increased acetylation of procainamide to its active metabolite *N*-acetylprocainamide.[1] The clinical relevance of these modest changes is probably small.

1. Olsen H, Mørland J. Ethanol-induced increase in procainamide acetylation in man. *Br J Clin Pharmacol* (1982) 13, 203–8.

Alcohol + Procarbazine

A flushing reaction has been seen when patients taking procarbazine drank alcohol.

Clinical evidence

One report describes 5 patients taking procarbazine whose faces became very red and hot for a short time after drinking wine.[1] Another says that flushing occurred in 3 patients taking procarbazine after they drank beer.[2] Two out of 40 patients taking procarbazine in a third study complained of facial flushing after taking a small alcoholic drink, and one patient thought that the effects of alcohol were markedly increased.[3] Yet another study describes a 'flush syndrome' in 3 out of 50 patients who drank alcohol while taking procarbazine.[4]

Mechanism

Unknown, but it seems possible that in man, as in *rats*,[5] the procarbazine inhibits acetaldehyde dehydrogenase in the liver causing a disulfiram-like reaction (see 'Alcohol + Disulfiram', p.66).

Importance and management

An established interaction but of uncertain incidence. It seems to be more embarrassing, possibly frightening, than serious, and if it occurs it is unlikely to require treatment; however, patients should be warned. The manufacturers say it is best to avoid alcohol.[6] Note also that some alcoholic beverages contain significant amounts of tyramine (see 'Table 32.2', (p.1394)), so there is a slight possibility that the tyramine reaction might occur if a patient taking procarbazine consumes significant quantities of these, as procarbazine is a weak inhibitor of MAO, see 'Procarbazine + Sympathomimetics', p.763.

Alcohol + Proton pump inhibitors

Lansoprazole, omeprazole and pantoprazole do not interact with alcohol: other proton pump inhibitors therefore seem unlikely to interact.

Clinical evidence

(a) Lansoprazole

A study in 30 healthy subjects given 0.6 g/kg of alcohol before and after taking lansoprazole 30 mg daily for 3 days found that the pharmacokinetics of alcohol were not significantly changed, and blood-alcohol levels were not raised, by lansoprazole.[1]

(b) Omeprazole

A number of studies have shown that omeprazole does not affect blood-alcohol levels.[2-6]

(c) Pantoprazole

In a placebo-controlled study 16 healthy subjects were given pantoprazole 40 mg daily for 7 days, with alcohol 0.5 g/kg in 200 mL of orange juice 2 hours after a standard breakfast on day 7. The maximum serum levels and the AUC of alcohol were not significantly changed by pantoprazole.[7]

Mechanism

The proton pump inhibitors do not affect alcohol dehydrogenase activity[3,8] (compare with the 'H_2-receptor antagonists', (p.70)), and would not be expected to alter the first-pass metabolism of alcohol.

Importance and management

The proton pump inhibitors do not appear to interact with alcohol, and no special precautions are necessary with concurrent use; although note that some of the conditions for which these drugs are used may be made worse by alcohol, so restricting alcohol intake may be prudent.

Alcohol + Quetiapine

Postural hypotension and possibly drowsiness may be increased when alcohol is given with quetiapine. Quetiapine does not appear to affect the pharmacokinetics of alcohol.

Clinical evidence, mechanism, importance and management

A randomised, crossover study in 8 men with psychotic disorders found that quetiapine 250 mg three times daily did not affect the mean breath-alcohol concentration after they took 0.8 g/kg of alcohol in orange juice. Some statistically significant changes in the performance of psychomotor tests were seen, but these were considered to have little clinical relevance.[1] However, the US manufacturers of quetiapine say that, in clinical studies, the motor and cognitive effects of alcohol were potentiated by quetiapine. Therefore the US manufacturer of quetiapine[2] advises avoiding alcohol, and the UK manufacturer[3] advises caution with the concurrent use of alcohol. Note that drowsiness is the most common adverse effect of quetiapine, occurring in over 10% of patients (over 30% in some studies).[2,3] Quetiapine may occasionally induce postural hypotension,[2,3] which could be exacerbated by alcohol. In practical terms this means that patients should be warned of the risk of faintness and dizziness if they stand up quickly, and advised to sit or lie down if this occurs.

Alcohol + Reboxetine

A study in 10 healthy subjects found that reboxetine does not affect cognitive or psychomotor function, and there is no interaction with alcohol.[1]

1. Kerr JS, Powell J, Hindmarch I. The effects of reboxetine and amitriptyline, with and without alcohol on cognitive function and psychomotor performance. *Br J Clin Pharmacol* (1996) 42, 239–41.

Alcohol + Retinoids

The consumption of alcohol may increase the serum levels of etretinate in patients taking acitretin. A single case report describes a marked reduction in the effects of isotretinoin following the acute intake of alcohol.

Clinical evidence, mechanism, importance and management

(a) Acitretin

A study, in 10 patients with psoriasis taking acitretin, found that the concurrent use of alcohol seemed to be associated with an increase in the formation of etretinate, a metabolite that has a much longer half-life than acitretin.[1] A later study by some of the same authors, in 86 patients taking acitretin, similarly found that alcohol increases the levels of etretinate, and the magnitude of the increase appeared to be related to the amount of alcohol that they drank.[2] The implications of these studies are not known, but it is suggested that it may have some bearing on the length of the period after acitretin therapy during which women are advised not to conceive.[1,2]

(b) Isotretinoin

A former alcoholic, who no longer drank alcohol, was treated for acne conglobata, with some success, with isotretinoin 60 mg daily for 3 months. When for 2 weeks he briefly started to drink alcohol again as part of his job (he was a sherry taster) his skin lesions reappeared and the isotretinoin adverse effects (mucocutaneous dryness) vanished. When he stopped drinking alcohol his skin lesions became controlled again and the drug adverse effects re-emerged. The following year, while receiving another course of isotretinoin, the same thing happened when he started and stopped drinking alcohol. The reasons are not known, but one suggestion is that the alcohol briefly induced the liver microsomal enzymes responsible for the metabolism of isotretinoin, thereby reducing both its therapeutic and adverse effects.[3] The general importance of this apparent interaction is not known.

3. Soria C, Allegue F, Galiana J, Ledo A. Decreased isotretinoin efficacy during acute alcohol intake. *Dermatologica* (1991) 182, 203.

Alcohol + Salbutamol (Albuterol)

A patient with high blood-alcohol levels developed lactic acidosis after being exposed to fire smoke and receiving salbutamol.

Clinical evidence, mechanism, importance and management

An isolated report describes a 49-year-old male alcoholic who developed severe lactic acidosis after exposure to fire smoke and treatment of bronchospasm with salbutamol. The correction of lactic acidosis followed salbutamol withdrawal and a transitory increase in lactate after salbutamol re-introduction suggested hypersensitivity to salbutamol. However, the patient also had a very high plasma-alcohol level (240 mg%), and the metabolism of the alcohol was thought to have competed with the conversion of lactate to pyruvate resulting in reduced lactate clearance, thus potentiating the acidosis caused by the salbutamol.[1] The clinical significance of this report is unclear as beta agonist-induced exacerbation of lactic acidosis has been reported in asthmatics, both adults and children. The authors of the above report suggest close monitoring of lactate levels in alcoholic patients receiving beta-agonists.[1]

1. Taboulet P, Clemessy J-L, Fréminet A, Baud FJ. A case of life-threatening lactic acidosis after smoke inhalation – interference between ß-adrenergic agents and ethanol? *Intensive Care Med* (1995) 21, 1039–42.

Alcohol + Sibutramine

There does not seem to be a clinically relevant interaction between sibutramine and alcohol.

Clinical evidence, mechanism, importance and management

In a randomised study, 20 healthy subjects were given sibutramine 20 mg, with 0.5 g/kg of alcohol diluted in ginger beer or placebo. Sibutramine did not potentiate the cognitive or psychomotor effects of alcohol, and in one

test sibutramine slightly reduced the impairment caused by alcohol.[1] However, the manufacturer notes that the consumption of alcohol is generally not compatible with the dietary modifications that are recommended in those given sibutramine.[2]

1. Wesnes KA, Garratt C, Wickens M, Gudgeon A, Oliver S. Effects of sibutramine alone and with alcohol on cognitive function in healthy volunteers. *Br J Clin Pharmacol* (2000) 49, 110–17.

Alcohol + SNRIs

No important psychomotor interaction normally appears to occur between duloxetine or venlafaxine and alcohol. However, the manufacturer warns that use of duloxetine with heavy alcohol intake may be associated with severe liver injury.

Clinical evidence, mechanism, importance and management

(a) Duloxetine

In a single-dose study in healthy subjects, duloxetine 60 mg and alcohol, given in a dose sufficient to produce blood levels of about 100 mg%, did not worsen the psychomotor impairment observed with alcohol alone.[1] Nevertheless, the UK manufacturer advises caution,[2] and the US manufacturer warns that duloxetine should ordinarily not be prescribed for patients with substantial alcohol use as severe liver injury may result.[3]

(b) Venlafaxine

In a study in 15 healthy subjects, venlafaxine 50 mg every 8 hours was found to have some effect on psychomotor tests (digit symbol substitution, divided attention reaction times, profile of mood scales), but these changes were small and not considered to be clinically significant. No pharmacodynamic or pharmacokinetic interactions occurred when alcohol 0.5 g/kg was also given.[4]

In therapeutic doses venlafaxine does not appear to interact significantly with alcohol; however, the manufacturers state that, as with all centrally-active drugs, patients should be advised to avoid alcohol whilst taking venlafaxine.[5,6] This is presumably because both drugs act on the CNS and also because alcohol is more likely to be abused by depressed patients.

Alcohol + Sodium cromoglicate (Cromolyn sodium)

No adverse interaction occurs between sodium cromoglicate and alcohol.

Clinical evidence, mechanism, importance and management

A double-blind, crossover study in 17 healthy subjects found that the inhalation of 40 mg of sodium cromoglicate had little or no effect on the performance of a number of tests on human perceptual, cognitive, and motor skills, whether taken alone or with alcohol 0.75 g/kg. Nor did it affect blood-alcohol levels.[1] This is in line with the common experience of patients, and no special precautions seem to be necessary if patients taking sodium cromoglicate want to drink alcohol.

1. Crawford WA, Franks HM, Hensley VR, Hensley WJ, Starmer GA, Teo RKC. The effect of disodium cromoglycate on human performance, alone and in combination with ethanol. *Med J Aust* (1976) 1, 997–9.

Alcohol + Sodium oxybate

The concurrent use of sodium oxybate and alcohol appears to increase respiratory depression, lead to an increase in adverse effects, and is expected to increase sedation.

Clinical evidence, mechanism, importance and management

In a randomised placebo-controlled study, 16 healthy subjects were given alcohol 0.3 g/kg with sodium oxybate 50 mg/kg. The study found that the pharmacokinetics of both drugs were not significantly changed when taken together and sodium oxybate did not alter the effects of alcohol on blood pressure and heart rate, although there were two episodes of postural hypotension (systolic BP 71 to 73 mmHg). Vomiting occurred more frequently compared with alcohol or gamma-hydroxybutyric acid alone, and oxygen saturations were decreased by just over 2% by the combination (modest effect), which was greater than the effect of alcohol alone, which suggests that the combination increases respiratory depression.[1]

Sodium oxybate is the sodium salt of **gamma hydroxybutyrate** (GHB) a CNS depressant substance with well known abuse potential. When used clinically it is predicted to have additive effects with alcohol and other CNS depressants and the manufacturers specifically say it should not be used with these.[2,3] Patients should be warned not to drink alcoholic beverages while taking sodium oxybate.[2,3] In light of the findings in the study the manufacturers recommendations appear cautious, but prudent.

Alcohol + SSRIs

Citalopram, escitalopram, fluoxetine, paroxetine and sertraline have no significant pharmacokinetic interaction with alcohol, but some modest increase in sedation may possibly occur with fluvoxamine and paroxetine.

Clinical evidence and mechanism

(a) Citalopram

The manufacturers of citalopram say that no pharmacodynamic interactions have been noted in clinical studies in which citalopram was given with alcohol.[1,2]

(b) Escitalopram

The manufacturers of escitalopram say that no pharmacokinetic interactions are expected to occur if alcohol is given with escitalopram, and no pharmacodynamic interaction has been seen.[3]

(c) Fluoxetine

In a study in healthy subjects the concurrent use of fluoxetine 30 to 60 mg and alcohol (about 120 mL of whiskey) did not affect the pharmacokinetics of either drugs, and fluoxetine did not alter the effect of alcohol on psychomotor activity (stability of stance, motor performance, manual coordination).[4] Similarly, in 12 healthy subjects, blood-alcohol levels of 80 mg% impaired the performance of a number of psychomotor tests but the addition of fluoxetine 40 mg daily taken for 6 days before the alcohol had little further effect.[5] Another study also found no change in the performance of a number of psychophysiological tests when fluoxetine was given with alcohol.[6] No problems were found in a study of 20 alcohol-dependent patients taking fluoxetine 60 mg daily when they drank alcohol, or in approximately 31 patients taking fluoxetine 20 mg daily who drank unspecified small quantities of alcohol.[7]

(d) Fluvoxamine

One study found that fluvoxamine 150 mg daily with alcohol impaired alertness and attention more than alcohol alone.[8] However, another study in subjects given 40 g of alcohol (blood-alcohol levels up to 70 mg%) found no evidence to suggest that the addition of fluvoxamine 50 mg twice daily worsened the performance of the psychomotor tests, and it even appeared to reverse some of the effects.[9] The pharmacokinetics of alcohol were hardly affected by fluvoxamine, but the steady state maximum plas-

ma levels of the fluvoxamine were increased by 20%, although the fluvoxamine AUC was unchanged.[9] It was suggested that alcohol may have promoted the dissolution of fluvoxamine and increased the absorption rate without affecting bioavailability.[9] Another study also found that fluvoxamine does not appear to enhance the detrimental effects of alcohol on the performance of psychomotor tests.[10]

(e) Paroxetine

Studies have found that paroxetine alone caused little impairment of a series of psychomotor tests related to car driving, and with alcohol the effects were unchanged, except for a significant decrease in attentiveness and an increase in reaction time.[11,12] Another study suggested that the alcohol-induced sedation was antagonised by paroxetine.[13]

(f) Sertraline

Sertraline (in doses of up to 200 mg for 9 days) was found not to impair cognitive or psychomotor performance, and it also appeared not to increase the effects of alcohol.[14]

Importance and management

The results of the few studies reported above suggest that no pharmacokinetic or pharmacodynamic interactions occur between most SSRIs and alcohol, although modest effects were seen with fluvoxamine and possibly paroxetine. However, most manufacturers of SSRIs suggest that concurrent use with alcohol is not advisable. This is presumably because both drugs act on the CNS and also because of the risk of alcohol abuse in depressed patients.[15]

Alcohol + Sulfiram

Disulfiram-like reactions have been seen in at least three patients who drank alcohol after using a solution of sulfiram on the skin for the treatment of scabies.

Clinical evidence

A man who used undiluted *Tetmosol* (a solution of sulfiram) for 3 days on the skin all over his body developed a disulfiram-like reaction (flushing, sweating, skin swelling, severe tachycardia and nausea) on the third day, after drinking 3 double whiskies. The same thing happened on two subsequent evenings again after he drank 3 double whiskies.[1] Similar reactions have been described in 2 other patients who drank alcohol while using *Tetmosol* or *Ascabiol* (also containing sulfiram).[2,3]

Mechanism

Sulfiram (tetraethylthiuram *monosulphide*) is closely related to disulfiram (tetraethylthiuram *disulphide*) and can apparently undergo photochemical conversion to disulfiram when exposed to light. The longer it is stored, the higher the concentration.[4,5] The reaction with alcohol appears therefore to be largely due to the presence of disulfiram,[6] see 'Alcohol + Disulfiram', p.66.

Importance and management

An established interaction. It has been suggested that alcohol should be avoided before, and for at least 48 hours after the application of sulfiram, but this may not always be necessary. The writer of a letter,[7] commenting on one of the cases cited,[1] wrote that he had never encountered this reaction when using a diluted solution of *Tetmosol* on patients at the Dreadnought Seamen's Hospital in London who he described as "not necessarily abstemious". This would suggest that the reaction is normally uncommon and unlikely to occur if the solution is correctly diluted (usually with 2 to 3 parts of water), thereby reducing the amount absorbed through the skin. However, one unusually sensitive patient is said to have had a reaction (flushing, sweating, tachycardia) after using diluted *Tetmosol*, but without drinking alcohol. It was suggested that she reacted to the alcohol base of the formulation passing through her skin.[8]

Alcohol + Tacrolimus or Pimecrolimus

Alcohol may cause facial flushing or skin erythema in patients receiving tacrolimus ointment; this reaction appears to be fairly common. Alcohol intolerance has been reported rarely with pimecrolimus cream.

Clinical evidence

Six patients reported facial flushing with small quantities of beer or wine during facial treatment with tacrolimus ointment. Re-exposure to tacrolimus 0.1% ointment, applied to the face twice daily for 4 days, followed by 100 mL of white wine on the fifth day, resulted in a facial flush reaction in all the patients, which occurred within 5 to 15 minutes of alcohol ingestion. The intensity of the erythema varied among the patients and was not confined to the treated areas, but started to fade after 30 minutes; a slight headache occurred in one patient. Forearm skin was also exposed to an epicutaneous patch containing 70 mg of tacrolimus 0.1% ointment, but these sites remained unchanged following alcohol exposure. After a tacrolimus washout period of at least 4 weeks, controlled exposure to alcohol in 2 patients was tolerated normally.[1] Another report describes one patient using tacrolimus ointment for mild eyelid eczema who experienced eyelid erythema, limited to the area the tacrolimus ointment was applied, after drinking wine. Two other patients experienced an erythematous rash after drinking alcohol when using topical tacrolimus; areas affected included the elbows, ears, eyes and face. The response to alcohol disappeared within 2 weeks of discontinuing tacrolimus ointment.[2]

Three patients experienced application site erythema following the consumption of alcohol after using topical tacrolimus or pimecrolimus for the treatment of facial dermatoses. Two of the patients then participated in a double-blind, controlled evaluation of the reaction. Both patients consumed alcohol (240 mL of red or white wine) without experiencing flushing, but following tacrolimus or pimecrolimus application, they experienced moderate or severe facial flushing (limited to the area of application) 5 to 10 minutes after alcohol consumption. The intensity of the erythema was sharply reduced after taking aspirin 325 mg twice daily for 3 days before alcohol consumption, but cetirizine 10 mg daily with cimetidine 400 mg twice daily for 3 days appeared to have little effect.[3]

There are other reports of this interaction between tacrolimus and alcohol,[3-8] including 3 cases in children aged 6 months to 3.5 years who were

given oral medicines containing alcohol while receiving tacrolimus ointment.[8] The reaction is usually confined to the face[4,8] and the intensity may be related to the amount of alcohol ingested.[4] In an open study of 316 patients, alcohol intolerance (facial flushing) was observed in 19% of the patients using tacrolimus 0.1% ointment[6] and in a controlled study, 6.9% of patients experienced the reaction with tacrolimus 0.1% ointment, and 3.4% of patients experienced the reaction with tacrolimus 0.03% ointment.[5]

Mechanism

The mechanism of this interaction is not understood. It has been proposed that tacrolimus may act on the same biochemical pathway as alcohol, potentiating a capsaicin-mediated release of neuropeptides, which increase vasodilatory effects. Alternatively, cutaneous aldehyde dehydrogenase inhibition in areas where tacrolimus has been applied may increase cutaneous aldehyde levels that, through prostaglandins as mediators, could lead to vasodilation following alcohol consumption.[1,4]

Importance and management

The interaction between topical tacrolimus and alcohol is established and appears to occur in about 6 to 7% of patients treated with tacrolimus 0.1% ointment. Patients should be warned of the possibility of a flushing reaction with alcohol and that consumption of alcohol may need to be avoided if this occurs. Clinicians should be aware of the interaction and obtain a careful history, including alcohol use (including alcohol intake from medicinal products), in patients who present with new acute symptoms while using tacrolimus. It has been suggested that aspirin may possibly reduce the symptoms of this reaction,[3] but this needs further study. Alcohol intolerance with pimecrolimus has been reported,[3,9] but appears to be rare.[10]

Alcohol + Tetracyclic antidepressants

Mianserin and maprotiline can cause drowsiness and impair the ability to drive or handle other dangerous machinery, particularly during the first few days of treatment. This impairment may be increased by alcohol. Pirlindole does not appear to interact with alcohol.

Clinical evidence

(a) Maprotiline

A double-blind, crossover study in 12 healthy subjects found that a single 75-mg oral dose of maprotiline subjectively caused drowsiness, which was increased by 1 g/kg of alcohol. The performance of a number of psychomotor tests was also worsened after the addition of alcohol.[1] However, in a later study, the same group found that maprotiline 50 mg twice daily for 15 days did not increase the detrimental effects of alcohol.[2] A case report attributes two epileptic seizures in a 21-year old woman taking maprotiline 125 mg daily to an increase in her alcohol intake during the preceding week (3 to 4 beers or 3 to 4 glasses of champagne each night). She was also taking alprazolam 500 micrograms four times daily.[3]

(b) Mianserin

A double-blind, crossover study in 13 healthy subjects given 10 to 30 mg of mianserin twice daily for 8 days, with and without alcohol 1 g/kg, found that their performance in a number of psychomotor tests (choice reaction, coordination, critical flicker frequency) were impaired both by mianserin alone and by the concurrent use of alcohol. The subjects were aware of feeling drowsy, muzzy, and less able to carry out the tests.[4] These results confirm the findings of other studies.[5,6]

(c) Pirlindole

A study in healthy subjects given pirlindole 75 to 150 mg daily for 4 days indicated that it did not affect the performance of a number of psychomotor tests, both with and without 0.4 g/kg of alcohol.[7]

Mechanism

The CNS depressant effects of mianserin, and possibly maprotiline, appear to be additive with those of alcohol. In the case report it was suggested that the seizures occurred due to high levels of maprotiline caused by the alcohol intake.[3]

Importance and management

Drowsiness is a frequently reported adverse effect of mianserin, particularly during the first few days of treatment. Patients should be warned that driving or handling dangerous machinery will be made more hazardous if they drink. It would also be prudent to warn patients taking maprotiline of the possible increased risk if they drink.[2] Pirlindole appears not to interact.

The general relevance of the case of seizures with maprotiline and alcohol is unclear.

Alcohol + Tetracyclines

Doxycycline serum levels may fall below minimum therapeutic levels in alcoholic patients, but tetracycline is not affected. There is nothing to suggest that moderate amounts of alcohol have a clinically relevant effect on the serum levels of any tetracycline in non-alcoholic subjects.

Clinical evidence

(a) Alcoholic patients

A study into the effects of alcohol on **doxycycline** and **tetracycline** pharmacokinetics found that the half-life of **doxycycline** was 10.5 hours in 6 alcoholics (with normal liver function) compared with 14.7 hours in 6 healthy subjects. The serum **doxycycline** levels of 3 of the alcoholic patients fell below the generally accepted minimum inhibitory concentration at 24 hours. The half-life of **tetracycline** was the same in both groups. All of the subjects were given **doxycycline** 100 mg daily after a 200-mg loading dose, and **tetracycline** 500 mg twice daily after an initial 750-mg loading dose.[1]

(b) Non-alcoholic patients

Single 500-mg doses of **tetracycline** were given to 9 healthy subjects with water or alcohol 2.7 g/kg. The alcohol caused a 33% rise in the maximum serum levels of **tetracycline** from 9.3 to 12.4 micrograms/mL, and a 50% rise in the AUC of **tetracycline**.[2] The clinical relevance of this rise is unknown.

Another study in healthy subjects found that cheap red wine, but not whisky (both 1 g/kg) delayed the absorption of **doxycycline**, probably because of the presence of acetic acid, which slows gastric emptying. However, the total absorption was not affected. The authors concluded that acute intake of alcoholic beverages has no clinically relevant effects on the pharmacokinetics of **doxycycline**.[3]

Mechanism

Heavy drinkers can metabolise some drugs much more quickly than non-drinkers due to the enzyme-inducing effects of alcohol.[4] The interaction with doxycycline would seem to be due to this effect, possibly allied with some reduction in absorption from the gut.

Importance and management

Information is limited, but the interaction between doxycycline and alcohol appears to be established and of clinical significance in alcoholics but not in non-alcoholic individuals. One possible solution to the problem of enzyme induction is to give alcoholic subjects double the dose of doxycycline,[5] or in some cases tetracycline may be a suitable non-interacting alternative. There is nothing to suggest that moderate or even occasional heavy drinking has a clinically relevant effect on any of the tetracyclines in non-alcoholic subjects.

Alcohol + Thiopurines

Alcohol has been tolerated in patients receiving mercaptopurine. A single case report describes liver toxicity in a patient taking azathioprine, which was attributed to his alcohol intake.

Clinical evidence, mechanism, importance and management

A study in 207 patients with inflammatory bowel disease assessed (using a phone survey) the presence of adverse reactions to alcohol in patients taking **mercaptopurine** and/or metronidazole long-term, or neither drug. All of the patients consumed less than 4 alcoholic beverages per day. The proportion of patients experiencing any clinically significant adverse effects was: metronidazole group 16.3%, **mercaptopurine** group 14.5%, control group (not taking either drug) 8.97%. Although there was a trend towards more adverse effects in the drug study groups, this was not statistically significant. The authors suggest a cautious trial of alcohol is advisable in patients that are starting and will be taking either of the medications on a chronic basis.[1]

A case report describes a man taking **azathioprine** for Crohn's disease, who developed peliosis hepatis (liver toxicity) several months after three episodes of excessive alcohol consumption. The patient's liver function returned to normal after stopping **azathioprine**. **Azathioprine** alone is rarely associated with peliosis hepatis, which has been suggested to occur as a result of glutathione depletion. The authors considered that the excessive alcohol intake in this patient led to glutathione depletion, which increased **azathioprine** toxicity, resulting in the liver damage seen.[2] This appears to be an isolated case, but it reinforces the need for cautious alcohol use in patients taking thiopurines.

Alcohol + Tianeptine

In one study alcohol reduced the absorption of tianeptine and lowered its plasma levels by about 30%.

Clinical evidence, mechanism, importance and management

In 12 healthy subjects the absorption and peak plasma levels of a single 12.5-mg dose of tianeptine were reduced by about 30% by alcohol. The subjects were given vodka diluted in orange juice to give blood-alcohol levels between 64 and 77 mg%. The plasma levels of the major metabolite of tianeptine were unchanged.[1] No behavioural studies were done so that the clinical significance of these studies is uncertain.

1. Salvadori C, Ward C, Defrance R, Hopkins R. The pharmacokinetics of the antidepressant tianeptine and its main metabolite in healthy humans — influence of alcohol co-administration. *Fundam Clin Pharmacol* (1990) 4, 115–25.

Alcohol + Tolazoline

A disulfiram-like reaction may occur in patients taking tolazoline if they drink alcohol.

Clinical evidence, mechanism, importance and management

Seven healthy subjects were given tolazoline 25 mg daily for 4 days. Within 15 to 90 minutes of drinking 90 mL of port wine (alcohol 18.2%), 2 hours after the last dose of tolazoline, 6 experienced tingling over the head, and 4 developed warmth and fullness of the head.[1] The reasons are not understood, but this reaction is not unlike a mild disulfiram reaction, and may possibly have a similar mechanism (see *Mechanism*, under 'Alcohol + Disulfiram', p.66). Patients given tolazoline should be warned about this reaction if they drink alcohol, and advised to limit their consumption. Reactions of this kind with drugs other than disulfiram are usually more unpleasant or frightening than serious, and treatment is rarely needed. In infants given tolazoline, it would seem sensible to avoid preparations containing alcohol, where possible.

1. Boyd EM. A search for drugs with disulfiram-like activity. *Q J Stud Alcohol* (1960) 21, 23–5.

Alcohol + Trazodone

Trazodone can make driving or handling other dangerous machinery more hazardous, particularly during the first few days of treatment, and further impairment may occur with alcohol.

Clinical evidence, mechanism, importance and management

A study in 6 healthy subjects comparing the effects of single-doses of amitriptyline 50 mg and trazodone 100 mg found that both drugs impaired the performance of a number of psychomotor tests, causing drowsiness and reducing 'clearheadedness' to approximately the same extent. Only manual dexterity was further impaired when the subjects taking trazodone were given sufficient alcohol to give blood levels of about 40 mg%.[1]

Another study similarly found that the impairment of psychomotor performance by trazodone was increased by alcohol.[2] This appears to be due to simple additive depression of the CNS. This is an established interaction, and of practical importance. Patients should be warned that their ability to drive, handle dangerous machinery or to do other tasks needing complex psychomotor skills might be impaired by trazodone, and further worsened by alcohol.

Alcohol + Trichloroethylene

A flushing skin reaction similar to a mild disulfiram reaction can occur in those who drink alcohol following exposure to trichloroethylene. Alcohol may also increase the risk of liver toxicity due to trichloroethylene exposure.

Clinical evidence

An engineer from a factory where trichloroethylene was being used as a degreasing agent, developed facial flushing, a sensation of increased pressure in the head, lachrymation, tachypnoea and blurred vision within 12 minutes of drinking 85 mL of bourbon whiskey. The reaction did not develop when he was no longer exposed to the trichloroethylene. Other workers in the same plant reported the same experience.[1] Vivid red blotches, in a symmetrical pattern on the face, neck, shoulders and back, were seen in other workers when they drank about 2 pints of beer[2] after having been exposed for a few hours each day for 3 weeks to increasing concen-

trations of trichloroethylene vapour (up to 200 ppm). Note that this was twice the maximum permissible level for trichloroethylene in air at that time.[3] This reaction has been described as the "degreasers' flush".[2]

A later study involving 188 workers occupationally exposed to trichloroethylene found a statistically significant synergistic toxic interaction between trichloroethylene and alcohol. There were 30 cases (15.9%) of degreasers' flush and 10 cases (5.3%) of clinical liver impairment.[4]

There is also some evidence that short-term exposure to the combination may possibly reduce mental capacity, although in this study the concentration of trichloroethylene was quite high (200 ppm).[5]

Another study investigated the metabolism of trichloroethylene in 5 healthy subjects who inhaled trichloroethylene 50 ppm for 6 hours per day for 5 days and then again 2 weeks later in the presence of alcohol. Inhalation of trichloroethylene with blood-alcohol levels of 60 mg% resulted in increased blood and expired air concentrations of trichloroethylene 2 to 3 times greater than without alcohol.[6] A simulation study suggested that drinking moderate amounts of alcohol (0.23 to 0.92 g/kg) before the start of work or at lunchtime, but not at the end of work, could cause pronounced increases in blood-trichloroethylene levels and decreases in the urinary excretion rates of trichloroethylene metabolites. However, when alcohol was consumed the previous evening there was a negligible effect on the metabolism of trichloroethylene (exposure below 100 ppm).[7]

Mechanism

Uncertain. One suggested mechanism is a disulfiram-like inhibition of acetaldehyde metabolism by trichloroethylene (see *Mechanism*, under 'Alcohol + Disulfiram', p.66). Another suggested mechanism is inhibition of trichloroethylene metabolism in the presence of alcohol, resulting in increased plasma levels and possibly an accumulation of trichloroethylene in the CNS.[6]

Importance and management

The flushing reaction is an established interaction that has been reported to occur in about 16% of workers who are exposed to trichloroethylene and then drink alcohol. It would seem to be more unpleasant and socially disagreeable than serious, and normally requires no treatment. However, the hepatotoxicity of trichloroethylene and other organic solvents may be increased by alcohol; increased body fat has been reported to increase the risk of solvent toxicity and heavy alcohol consumption may further increase the risk of liver toxicity.[8]

Alcohol + Tricyclic antidepressants

The ability to drive, to handle dangerous machinery or to do other tasks requiring complex psychomotor skills may be impaired by amitriptyline, and to a lesser extent by doxepin or imipramine, particularly during the first few days of treatment. This impairment can be increased by alcohol. Amoxapine, clomipramine, desipramine, and nortriptyline appear to interact with alcohol only minimally. Information about other tricyclics appears to be lacking, although most manufacturers of tricyclics warn that the effects of alcohol may be enhanced. There is also evidence that alcoholics (without liver disease) may need larger doses of desipramine and imipramine to control depression. However, the toxicity of some tricyclics may be increased by alcohol, and in alcoholics with liver disease.

Clinical evidence

(a) Amitriptyline

A single-dose, crossover study in 5 healthy subjects found that the plasma levels of amitriptyline 25 mg over an 8-hour period were markedly increased by alcohol (blood-alcohol level maintained at approximately 80 mg%). Compared with amitriptyline alone, the $AUC_{0\text{-}8}$ increased by a mean of 44% following alcohol consumption, and was associated with decreased standing steadiness, recent memory and alertness.[1] Amitriptyline 800 micrograms/kg impaired the performance of three motor skills tests related to driving in 21 healthy subjects. When alcohol to produce blood levels of about 80 mg% was also given the performance was even further impaired.[2] Similar results have been very clearly demonstrated in considerable numbers of subjects using a variety of psychomotor skill tests,[1-6] the interaction being most marked during the first few days of treatment, but tending to wane as treatment continues.[5] Unexplained blackouts lasting a few hours have been described in 3 women after they drank only modest amounts of alcohol;[7] they had been taking amitriptyline or imipramine for a month. There is some limited evidence from *animal* studies that amitriptyline may possibly enhance the fatty changes induced in the liver by alcohol,[8] but this still needs confirmation from human studies.

A study involving 332 fatal poisonings in Finland found that alcohol was present in 67% of cases involving amitriptyline, and when alcohol was present, relatively small overdoses of amitriptyline could result in fatal poisoning.[9] It appears that amitriptyline may be more toxic when given with alcohol, and it has been suggested that a less dangerous alternative could be chosen when indications of alcohol abuse or suicide risk are present.[10]

(b) Amoxapine

The interaction between amoxapine and alcohol is said to be slight,[11] but two patients who experienced reversible extrapyramidal symptoms (parkinsonism, akathisia) while taking amoxapine, which was apparently caused by drinking alcohol.[12]

(c) Clomipramine

Studies in subjects with blood-alcohol levels of 40 to 60 mg% found that clomipramine had only slight or no effect on various choice reaction, coordination, memory and learning tests.[4,13,14] A case describes a fatal poisoning in a chronic alcoholic patient taking clomipramine for depression. The ultimate toxic effect was thought to be due to alcohol-induced decreased biotransformation of clomipramine, as post-mortem examination revealed toxic liver damage, and low levels of the metabolite were found in blood and hair samples.[15]

(d) Desipramine

Plasma desipramine levels were transiently, but non-significantly increased after healthy subjects drank alcohol, and breath-alcohol concentrations were not affected by the antidepressant. Further, skilled performance tests in subjects given desipramine 100 mg indicated that no significant interaction occurred with alcohol.[16] The half-life of oral desipramine was about 30% lower in recently detoxified alcoholics (without liver disease), when compared with healthy subjects, and the intrinsic clearance was 60% greater.[17]

(e) Doxepin

A placebo-controlled, crossover study in 20 healthy subjects given various combinations of alcohol and doxepin found that with blood-alcohol levels of 40 to 50 mg% their choice reaction test times were prolonged and the number of mistakes increased. Coordination was obviously impaired after 7 days of treatment with doxepin, but not after 14 days.[4] In an earlier study doxepin appeared to cancel out the deleterious effects of alcohol on the performance of a simulated driving test.[18] It appears that doxepin may be more toxic when given with alcohol, and it has been suggested that a less dangerous alternative could be chosen when indications of alcohol abuse or suicide risk are present.[10]

(f) Imipramine

Imipramine 150 mg daily has been reported to enhance some of the hypno-sedative effects of alcohol,[19] and unexplained blackouts lasting a few hours have been described in 3 women after they drank only modest amounts of alcohol;[7] they had been taking amitriptyline or imipramine for only a month. The half-life of oral imipramine was about 45% lower in recently detoxified alcoholics (without liver disease) compared with healthy subjects, and the intrinsic clearance was 200% greater.[17]

(g) Nortriptyline

Studies in subjects with blood-alcohol levels of 40 to 60 mg% found that nortriptyline had only slight or no effects on various choice reaction, coordination, memory and learning tests,[4,13,20] although the acute use of alcohol with nortriptyline impaired learning in one study.[13]

Mechanism

Part of the explanation for the increased CNS depression is that both alcohol and some of the tricyclics, particularly amitriptyline, cause drowsiness and other CNS depressant effects, which can be additive with the effects of alcohol.[6] The sedative effects have been reported to be greatest with amitriptyline, then doxepin and imipramine, followed by nortriptyline, and least with amoxapine, clomipramine, desipramine, and **protriptyline**.[21-24] In addition acute alcohol intake causes marked increases (100 to 200%) in the plasma levels of amitriptyline, probably by inhibiting its first pass metabolism.[1,25] Alcohol-induced liver damage could also result in impaired amitriptyline metabolism.[23] The lower serum levels of imipramine and desipramine seen in abstinent alcoholics are attributable to induction of the cytochrome P450 isoenzymes by alcohol.[17]

Importance and management

The increased CNS depression resulting from the interaction between amitriptyline and alcohol is well documented and clinically important. The interaction between alcohol and doxepin or imipramine is less well documented and the information is conflicting. Amoxapine, clomipramine, desipramine, and nortriptyline appear to interact only minimally with alcohol. Direct information about other tricyclics seems to be lacking, but there appear to be no particular reasons for avoiding concurrent use, although tricyclics with greater sedation such as **trimipramine** are more likely to interact. During the first 1 to 2 weeks of treatment many tricyclics (without alcohol) may temporarily impair the skills related to driving.[11] Therefore it would seem prudent to warn any patient given a tricyclic that driving or handling dangerous machinery may be made more hazardous if they drink alcohol, particularly during the first few days of treatment, but the effects of the interaction diminish during continued treatment. Most manufacturers of tricyclic antidepressants warn that the effects of alcohol may be enhanced by tricyclics and several suggest avoiding the concurrent use of alcohol.

Also be aware that alcoholic patients (without liver disease) may need higher doses of imipramine (possibly doubled) and desipramine to control depression, and if long-term abstinence is achieved the dosages may then eventually need to be reduced.

Alcohol + Trinitrotoluene

Men exposed to trinitrotoluene (TNT) in a munitions factory were found to have a greater risk of TNT-induced liver damage if they had a long history of heavy alcohol drinking than if they were non-drinkers.[1]

1. Li J, Jiang Q-G, Zhong W-D. Persistent ethanol drinking increases liver injury induced by trinitrotoluene exposure: an in-plant case-control study. *Hum Exp Toxicol* (1991) 10, 405–9.

Alcohol + Triptans

Alcohol does not appear to alter the pharmacokinetics of frovatriptan, naratriptan or sumatriptan.

Clinical evidence, mechanism, importance and management

In a retrospective analysis of data from 178 healthy subjects involved in phase I studies, alcohol consumption did not affect the pharmacokinetics **frovatriptan**.[1]

In a study in 16 healthy subjects the pharmacokinetics of a single 5-mg dose of **naratriptan** were not altered when it was given 30 minutes after alcohol (amount not specified).[2]

A single 0.8-g/kg dose of alcohol was given to 16 healthy subjects, followed 30 minutes later by 200 mg of sumatriptan. No statistically significant changes were seen in the pharmacokinetics of **sumatriptan**.[3]

There is nothing to suggest that alcohol should be avoided while taking **frovatriptan**, **naratriptan** or **sumatriptan**.

Alcohol + Vitamin A (Retinol)

Heavy consumption of alcohol may increase betacarotene levels and affect vitamin A metabolism; there have been reports of possible increased toxicity.

Clinical evidence, mechanism, importance and management

A study involving 30 abstinent male alcoholics found that 5 of 15 given high-dose vitamin A (10 000 units daily by mouth) for 4 months developed liver abnormalities during treatment, compared with 1 of 15 patients given placebo. Two of the 6 patients admitted intermittent alcohol consumption. Five of these patients continued with vitamin A and the abnormal liver function tests resolved in 4 of these patients.[1]

The interaction between alcohol and vitamin A is complex. They have overlapping metabolic pathways; a similar 2-step process is involved in the metabolism of both alcohol and vitamin A, with alcohol dehydrogenases and acetaldehyde dehydrogenases being implicated in the conversion of vitamin A to retinoic acid.[2,3] Alcohol appears to act as a competitive inhibitor of vitamin A oxidation.[2,4] In addition, chronic alcohol intake can induce cytochrome P450 isoenzymes that appear to increase the breakdown of vitamin A (retinol and retinoic acid) into more polar metabolites in the liver, which can cause hepatocyte death. So chronic alcohol

consumption may enhance the intrinsic hepatotoxicity of high-dose vitamin A. Alcohol has also been shown to alter retinoid homoeostasis by increasing vitamin A mobilisation from the liver to extrahepatic tissues, which could result in depletion of hepatic stores of vitamin A.[2,3]

It appears that consumption of substantial amounts of alcohol is associated with vitamin A deficiency partially due to poor nutrition and also the direct effects of alcohol on the metabolism of vitamin A. Vitamin A supplementation may therefore be indicated in heavy drinkers, but is complicated by the hepatotoxicity of large amounts of vitamin A, which may be potentiated by alcohol.[3] It would therefore seem reasonable to try to control alcohol consumption when vitamin A supplementation is required. Patients who consume alcohol, particularly heavy drinkers or alcoholics, should be questioned about their use of vitamin supplements as some non-prescription vitamin A and D supplements contain substantial amounts of vitamin A.

Alcohol + Xylene

Some individuals exposed to xylene vapour, who subsequently drink alcohol, may experience dizziness and nausea. A flushing skin reaction has also been seen.

Clinical evidence, mechanism, importance and management

Studies in subjects exposed to *m*-xylene vapour at concentrations of approximately 145 or 280 ppm for 4 hours who were then given 0.4 or 0.8 g/kg of alcohol found that about 10 to 20% experienced dizziness and nausea.[1,2] One subject exposed to 300 ppm of *m*-xylene vapour developed a conspicuous dermal flush on his face, neck, chest and back. He also developed some erythema with alcohol alone.[3] A study using a population-based pharmacokinetic and pharmacodynamic model predicted that the probability of experiencing CNS effects following exposure to xylene at the current UK occupational exposure standard (100 ppm time-weighted average over 8 hours) increased markedly with alcohol dose; the effects were non-linear.[4]

The reasons for these reactions are not fully understood, but it is possible that xylene plasma levels are increased because alcohol impairs its metabolic clearance by the cytochrome P450 isoenzyme CYP2E1.[4] After alcohol intake, blood-xylene levels have been reported to rise about 1.5- to 2-fold;[2] acetaldehyde levels may also be transiently increased.[2]

Alcoholic beverages are quite often consumed during lunchtime or after work, and since the excretion of xylene is delayed by its high solubility and storage in lipid-rich tissues, the simultaneous presence of xylene and alcohol in the body is probably not uncommon and could result in enhancement of the toxicity of xylene.[5]

Alpha blockers

The selective and non-selective alpha blockers are categorised and listed in 'Table 4.1', (see below). The principal interactions of the alpha blockers are those relating to enhanced hypotensive effects. Early after the introduction of the selective alpha blockers it was discovered that, in some individuals, they can cause a rapid reduction in blood pressure on starting treatment (also called the 'first-dose effect' or 'first-dose hypotension'). The risk of this may be higher in patients already taking other antihypertensive drugs. A similar hypotensive effect can occur when the dose of the alpha blocker is increased, or if treatment is interrupted for a few days and then re-introduced.

The first-dose effect has been minimised by starting with a very low dose of the alpha blocker, and then escalating the dose slowly over a couple of weeks. Some manufacturers recommend giving the first dose on retiring to bed, or if not, avoiding tasks that are potentially hazardous if syncope occurs (such as driving) for the first 12 hours. If symptoms such as dizziness, fatigue or sweating develop, patients should be warned to lie down, and to remain lying flat until they abate completely.

It is unclear whether there are any real differences between the alpha blockers in their propensity to cause this first-dose effect. However, tamsulosin is reported to have some selectivity for the alpha receptor 1A subtype, which are found mostly in the prostate and so have less effect on blood pressure: an initial titration of the dose is therefore not considered to be necessary. Nevertheless, it would be prudent to exercise caution with all the drugs in this class.

Other alpha blockers are also used to increase urinary flow-rate and improve obstructive symptoms in benign prostatic hyperplasia. In this setting, their effects on blood pressure are more of an adverse effect, and their additive hypotensive effect with other antihypertensives may not be beneficial.

Some alpha blockers (e.g. alfuzosin, doxazosin, tamsulosin) are metabolised via the cytochrome isoenzyme system, particularly by CYP3A4, and so potent CYP3A4 inhibitors may possibly increase their plasma levels, see 'Alpha blockers + CYP3A4 or CYP2D6 inhibitors', p.96.

Table 4.1 Alpha blockers

Drug	*Principal indications*
Selective alpha$_1$ blockers (Alpha blockers)	
Alfuzosin	BPH
Bunazosin	Hypertension
Doxazosin	BPH; Hypertension
Indoramin	BPH; Hypertension; Migraine
Prazosin	BPH; Heart failure; Hypertension; Raynaud's syndrome
Tamsulosin	BPH
Terazosin	BPH; Hypertension
Other drugs with alpha-blocking actions	
Moxisylate	Peripheral vascular disease; Erectile dysfunction
Phenoxybenzamine	Hypertensive episodes in phaeochromocytoma
Tolazoline	Peripheral vascular disease; Pulmonary hypertension
Phentolamine	Erectile dysfunction; Hypertensive episodes in phaeochromocytoma
Urapidil	Hypertension

Alpha blockers + ACE inhibitors or Angiotensin II receptor antagonists

Severe first-dose hypotension and synergistic hypotensive effects, that occurred when a patient taking enalapril was given bunazosin, have been replicated in healthy subjects. The first-dose effect seen with alpha blockers (particularly alfuzosin, prazosin and terazosin) is likely to be potentiated by ACE inhibitors and probably angiotensin II receptor antagonists. In one small study tamsulosin did not have any clinically relevant effects on blood pressure that was already well controlled by enalapril.

Clinical evidence

(a) Alfuzosin

The manufacturer of alfuzosin[1] warns that patients receiving antihypertensive drugs are at particular risk of developing postural hypotension after the first dose of the alpha blocker.

(b) Bunazosin

A patient taking **enalapril** developed severe first-dose hypotension after being given bunazosin, resulting in this interaction being further studied in 6 healthy subjects. When **enalapril** 10 mg or bunazosin 2 mg was given, their mean blood pressure over 6 hours was reduced by 9.5/6.7 mmHg. When bunazosin was given one hour after **enalapril** the blood pressure fell by 27/28 mmHg. Blood pressure still fell by 19/22 mmHg, even when the dose of **enalapril** was reduced to 2.5 mg.[2]

(c) Doxazosin

For comment that doxazosin appeared to have less effect on blood pressure in patients with BPH receiving ACE inhibitors than in those taking beta blockers or diuretics, see 'Alpha blockers + Beta blockers', p.94.

(d) Prazosin

The manufacturer of prazosin[3] warns that patients receiving antihypertensive drugs (they specifically name ACE inhibitors) are at particular risk of developing postural hypotension after the first dose of alpha blocker.

(e) Tamsulosin

In a placebo-controlled study in 6 hypertensive men with blood pressure well controlled by **enalapril**, the addition of tamsulosin 400 micrograms daily for 7 days then 800 micrograms daily for a further 7 days had no clinically relevant effects on blood pressure (assessed after 6 and 14 days of tamsulosin). In addition, no first-dose hypotensive effect was seen on the day tamsulosin was started, or on the day the tamsulosin dose was increased.[4]

(f) Terazosin

Retrospective analysis of a large multinational study in patients with BPH given terazosin 5 or 10 mg daily found that terazosin only affected the blood pressure of patients taking ACE inhibitors (**enalapril**, **lisinopril** or **perindopril**) if the blood pressure was uncontrolled. No change in blood pressure was seen in those with normal blood pressure (i.e. those without hypertension and those with hypertension controlled by ACE inhibitors). The most common adverse effect in the 10-week terazosin phase was dizziness, and the incidence of this appeared to be lower in those taking antihypertensives (13 to 16%) than in those not taking antihypertensives (21 to 25%).[5] However, the manufacturer of terazosin notes that the incidence of dizziness in patients taking terazosin was higher when they were also receiving an ACE inhibitor.[6]

Mechanism

The first-dose effect of alpha blockers (see 'Alpha blockers', (p.92)) may be potentiated by ACE inhibitors. Tamsulosin possibly has less effect on blood pressure since it has some selectivity for alpha receptors in the prostate.

Importance and management

Direct information is limited. Acute hypotension (dizziness, fainting) sometimes occurs unpredictably with the first dose of some alpha blockers (particularly, alfuzosin, prazosin and terazosin; but there is insufficient evidence to suggest that the alpha blockers differ significantly in their propensity to cause this effect). Note that the acute hypotensive reaction appears to be short-lived.

When starting an alpha blocker it is often recommended that those already taking an antihypertensive should have their dose reduced to a maintenance level, while initiating the alpha blocker at a low dose, with the first dose taken just before going to bed. Patients should also be warned about the possibility of postural hypotension and how to manage it (i.e. lay down, raise the legs and, when recovered, get up slowly). Similarly, when adding an antihypertensive to an alpha blocker, it may be prudent to decrease the dose of the alpha blocker and re-titrate as necessary.

There is limited evidence that tamsulosin and possibly terazosin may not cause an additional hypotensive effect when given in the longer term in patients with BPH who have hypertension already well controlled with ACE inhibitors. Nevertheless, caution should be exercised in this situation, and a dose reduction of the ACE inhibitor may be required.

Angiotensin II receptor antagonists would be expected to interact in the same way as ACE inhibitors. Some manufacturers of angiotensin II receptor antagonists warn that enhanced hypotensive effects can occur with other antihypertensive drugs, but they do not specifically mention alpha blockers.

Alpha blockers + Aspirin or NSAIDs

Indometacin reduces the blood pressure lowering effects of prazosin in some individuals. However, indometacin and other alpha blockers do not appear to interact adversely. Diclofenac may possibly increase the elimination rate of tamsulosin.

Clinical evidence

(a) Doxazosin

The manufacturers comment that doxazosin has been given without any evidence of adverse interaction to patients receiving NSAIDs,[1] including ibuprofen and indometacin.[2] *In vitro* data in human plasma indicated that although doxazosin is highly bound to plasma proteins, it does not affect the protein binding of **indometacin**.[1,2]

(b) Prazosin

A study in 9 healthy subjects found that **indometacin** 50 mg twice daily for 3 days had no statistically significant effect on the hypotensive effect of a single 5-mg dose of prazosin. However, in 4 of the subjects it was noted that the maximum fall in the mean standing blood pressure due to the prazosin was 20 mmHg less when they were taking **indometacin**. Three of these 4 felt faint when given prazosin alone, but not while they were also taking the **indometacin**.[3] The manufacturer says that prazosin has been given with **indometacin** (and also **aspirin** and **phenylbutazone**) without any adverse interaction in clinical experience to date.[4]

(c) Tamsulosin

Other *in vitro* studies showed that **diclofenac** did not change the free fraction of tamsulosin in human plasma,[5,6] nor was the protein binding of **diclofenac** affected by tamsulosin.[6] The US manufacturer reported that incubation of tamsulosin and **diclofenac** with human liver microsomes showed ambiguous *in vitro* evidence of a metabolic interaction.[6] However, based on *in vitro* data some UK manufacturers suggest that **diclofenac** may increase the elimination rate of tamsulosin.[5,7,8]

(d) Terazosin

The manufacturers of terazosin also note that no adverse interactions have been seen between terazosin and analgesics/anti-inflammatories.[9]

Mechanism

Not established. It seems probable that indometacin inhibits the production of hypotensive prostaglandins by the kidney.

Importance and management

Information about the interactions between alpha blockers and NSAIDs or aspirin appears to be limited, but the general picture suggests that no interaction of significance occurs. A possible exception is the use of indometacin with prazosin, which is consistent with the way indometacin reduces the effects of many other different antihypertensives (e.g. see 'ACE inhibitors + NSAIDs', p.32, and 'Beta blockers + Aspirin or NSAIDs', p.997). It apparently does not affect every patient. If indometacin is added to established treatment with prazosin, be alert for a reduced antihypertensive response. It is not known exactly what happens in patients taking both drugs long-term, but note that with other interactions between antihypertensives and NSAIDs the effects seem to be modest.

Alpha blockers + Beta blockers

The risk of first-dose hypotension with prazosin is higher if the patient is already taking a beta blocker. This is also likely to be true of other alpha blockers, particularly alfuzosin and terazosin. In a small study tamsulosin did not have any clinically relevant effects on blood pressure that was already well controlled by atenolol. Alpha blockers and beta blockers may be combined for additional lowering of blood pressure in patients with hypertension.

Clinical evidence

(a) Alfuzosin

In a single-dose study in 8 healthy subjects no pharmacokinetic interaction occurred when alfuzosin 2.5 mg was given with **atenolol** 100 mg.[1] However, the manufacturer reports that, in a similar study, **atenolol** increased the maximum plasma level and AUC of alfuzosin by 28% and 21%, respectively, and alfuzosin increased atenolol levels by 26% and 14%, respectively. There were also significant reductions in mean blood pressure and heart rate.[2] One manufacturer notes that postural hypotension may occur in patients receiving antihypertensives when they start alfuzosin.[3]

(b) Doxazosin

A study involving 2363 patients, with hypertension controlled with a single antihypertensive drug, investigated the effects of adding doxazosin for BPH. The dose of doxazosin was increased gradually to 4 mg daily and then the patients were monitored for 14 weeks. The addition of doxazosin was found to be well tolerated, and adverse effects mainly occurred early after onset of treatment or in patients with lower systolic and diastolic blood pressure. However, the antihypertensive effect was more marked in patients taking beta blockers or diuretics than in patients taking ACE inhibitors or calcium-channel blockers.[4] The manufacturers of doxazosin state that no adverse drug interaction has been observed between doxazosin and beta blockers,[5,6] although they do note that the most common adverse reactions associated with doxazosin are of a postural hypotension type.[5] They specifically note that doxazosin has been given with **atenolol** and **propranolol** without evidence of an adverse interaction.[6]

(c) Indoramin

One manufacturer of indoramin states that concurrent use with beta blockers may enhance hypotensive effects, and that titration of the dose of the beta blocker may be needed when initiating the indoramin.[7]

(d) Prazosin

A marked hypotensive reaction (dizziness, pallor, sweating) occurred in 3 out of 6 hypertensive patients taking **alprenolol** 400 mg twice daily when they were given the first 500-microgram dose of prazosin. In all 6 patients the reduction in blood pressure was greater after the first prazosin dose than after 2 weeks of treatment with prazosin 500 micrograms three times daily with no beta blocker (mean reduction 22/11 mmHg compared with 4/4 mmHg). A further 3 patients already taking prazosin 500 micrograms three times daily had no unusual fall in blood pressure when they were given a 200-mg dose of **alprenolol**.[8] The severity and the duration of the first-dose effect of prazosin were also found to be increased in healthy subjects given a single dose of **propranolol**.[9]

Two studies have shown that the pharmacokinetics of prazosin are not affected by either **alprenolol**[8] or **propranolol**.[10]

(e) Tamsulosin

In a placebo-controlled study in 8 hypertensive men with blood pressure well controlled by **atenolol**, the addition of tamsulosin 400 micrograms daily for 7 days, then 800 micrograms daily for a further 7 days, had no clinically relevant effect on blood pressure (assessed after 6 and 14 days of tamsulosin). No hypotension was seen with the first dose of tamsulosin or when the dose of tamsulosin was increased.[11] *In vitro* evidence suggested that **propranolol** and tamsulosin did not change the free fraction of either drug in human plasma.[12]

(f) Terazosin

Retrospective analysis of a large multinational study, in patients with BPH given terazosin 5 or 10 mg daily, found that terazosin only affected the blood pressure of patients taking beta blockers (**atenolol**, **labetalol**, **metoprolol**, **sotalol**, and **timolol**) if the blood pressure was uncontrolled. No change in blood pressure was seen in those with normal blood pressure (i.e. those without hypertension and those with hypertension controlled by beta blockers). The most common adverse effect in the 10-week terazosin phase was dizziness, and the incidence of this appeared to be lower in those taking antihypertensives (13 to 16%) than in those not taking antihypertensives (21 to 25%).[13]

Mechanism

The normal cardiovascular response (a compensatory increased cardiac output and heart rate) that should follow the first-dose hypotensive reaction to alpha blockers is apparently compromised by the presence of a beta blocker. The problem is usually only short lasting because some physiological compensation occurs within hours or days, and this allows the blood pressure to be lowered without falling precipitously. Tamsulosin possibly has less effect on blood pressure since it has some selectivity for alpha receptors in the prostate.

Importance and management

An established interaction. Some patients experience acute postural hypotension, tachycardia and palpitations when they begin to take prazosin or other alpha blockers. A few patients even collapse in a sudden faint within 30 to 90 minutes, and this can be exacerbated if they are already taking a beta blocker. The evidence seems to suggest that this is greater with alfuzosin and terazosin, but it is unclear whether there are any real differences between the alpha blockers in their propensity to cause these effects.

When starting an alpha blocker it is recommended that those already taking a beta blocker should have their dose of beta blocker reduced to a maintenance dose and begin with a low dose of the alpha blocker, with the first dose taken just before going to bed. They should also be warned about the possibility of postural hypotension and how to manage it (i.e. lay down, raise the legs and, when recovered, get up slowly). Similarly, when adding a beta blocker to an alpha blocker, it may be prudent to decrease the dose of the alpha blocker and re-titrate as necessary. There is limited evidence that tamsulosin and possibly terazosin may not cause an additional hypotensive effect when taken long term by patients with BPH who have hypertension already well controlled with beta blockers. Nevertheless, caution should be exercised in this situation, and a dose reduction of the beta blocker may still be required.

Alpha blockers + Calcium-channel blockers

Alpha blockers and calcium-channel blockers may be combined for additional blood pressure lowering in patients with hypertension. Blood pressure may fall sharply when calcium-channel blockers are first given to patients already taking alpha blockers (particularly prazosin and terazosin), and *vice versa*. In a small study, tamsulosin did not have any clinically relevant effects on blood pressure well controlled by nifedipine. Verapamil may increase the AUC of prazosin and terazosin, and may also increase the adverse effects related to tamsulosin. The concurrent use of diltiazem and alfuzosin can raise the levels of both drugs.

Clinical evidence

(a) Alfuzosin

The US manufacturer notes that when **diltiazem** 240 mg daily was given with alfuzosin 2.5 mg three times daily the maximum serum levels and AUC of alfuzosin were raised by 50% and 30%, respectively, and the maximum serum levels and AUC of **diltiazem** were raised by 40%. However, no changes in blood pressure were seen.[1]

(b) Doxazosin

In a study, 6 normotensive subjects were given **nifedipine** 20 mg twice daily for 20 days with doxazosin 2 mg once daily for the last 10 days. Although there was a tendency for first-dose hypotension, no serious adverse events or postural symptoms were seen. The same results were noted in 6 other normotensive subjects given the drugs in the opposite order, and no pharmacokinetic interactions were found.[2] The US manufacturer notes a study in which slight (less than 20%) alterations were found in the pharmacokinetics of **nifedipine** and doxazosin when they were given concurrently; however, these pharmacokinetic effects would not be expected to be clinically significant. As would be expected, blood pressures were lower when both drugs were given.[3]

For comment that doxazosin appeared to have less effect on blood pressure in patients with BPH receiving calcium-channel blockers than in those taking beta blockers or diuretics, see 'Alpha blockers + Beta blockers', p.94.

(c) Prazosin

1. Nifedipine. In a placebo-controlled, crossover study 12 hypertensive subjects were given nifedipine 20 mg and prazosin 2 mg, separated by one hour. The combination of the two drugs reduced blood pressure more than either drug alone, although the effects of prazosin were delayed when it was given after nifedipine.[4] Another study similarly showed that prazosin, given 2 hours before nifedipine, caused an enhanced hypotensive effect.[5]

Two patients with severe hypertension given prazosin 4 or 5 mg experienced a sharp fall in blood pressure shortly after being given nifedipine *sublingually*. One of them complained of dizziness and had a reduction in standing blood pressure from 232/124 to 88/48 mmHg about 20 minutes after taking nifedipine 10 mg. However, in a further 8 patients with hypertension taking prazosin, the reduction in blood pressure 20 minutes after the addition of *sublingual* nifedipine was smaller (mean reduction of 25/12 mmHg when lying and 24/17 mmHg when standing).[6] It is not clear what contribution prazosin had to the effect seen with *sublingual* nifedipine, since the experiment was not repeated using a prazosin placebo, but blood pressure in these patients had earlier remained unchanged 1 hour after taking prazosin alone. It should also be noted that *sublingual* nifedipine alone may cause a dangerous drop in blood pressure.

2. Verapamil. A study in 8 normotensive subjects given a single 1-mg dose of prazosin found that the peak serum prazosin levels were raised by 85% (from 5.2 to 9.6 nanograms/mL) and the prazosin AUC was increased by 62% when it was given with a single 160-mg dose of verapamil. The standing blood pressure 4 hours after dosing was unchanged after verapamil alone, but fell from 114/82 to 99/73 mmHg with prazosin alone, and was further reduced to 89/68 mmHg when both drugs were given together.[7] A similar pharmacokinetic interaction was noted in another study in hypertensive patients.[8] In this study, the first 1-mg dose of prazosin alone caused a 23 mmHg fall in standing systolic blood pressure, and half the patients (3 of 6) experienced symptomatic postural hypotension. A similar fall in blood pressure occurred when the first 1-mg dose of prazosin was given to 6 patients who had been taking verapamil for 5 days: 2 patients experienced symptomatic postural hypotension.[8]

(d) Tamsulosin

1. Nifedipine. In a placebo-controlled study in 8 hypertensive men with blood pressure well controlled by nifedipine, the addition of tamsulosin 400 micrograms daily for 7 days then 800 micrograms daily for a further 7 days had no clinically relevant effect on blood pressure (assessed after 6 and 14 days of tamsulosin). In addition, no first-dose hypotension was seen on the first day of tamsulosin, or when the tamsulosin dose was increased.[9]

2. Verapamil. A study into the safety of tamsulosin, with particular regard to the use of other medications, found that the concurrent use of verapamil increased the risk of adverse events related to tamsulosin by threefold. The use of other calcium-channel blockers (not specified) did not appear to increase adverse effects, although there was a trend towards an increase.[10]

(e) Terazosin

1. Dihydropyridine calcium-channel blockers. Retrospective analysis of a large multinational study, in patients with BPH given terazosin 5 or 10 mg daily, found that terazosin only affected the blood pressure of patients taking calcium-channel blockers (**amlodipine**, **felodipine**, **flunarizine**, **isradipine** and **nifedipine**) if the blood pressure was uncontrolled. No change in blood pressure was seen in those with normal blood pressure (i.e. those without hypertension and those with hypertension controlled by calcium-channel blockers). The most common adverse effect in the 10-week terazosin phase was dizziness, and the incidence of this appeared to be lower in those taking antihypertensives (13 to 16%) than in those not taking antihypertensives (21 to 25%).[11]

2. Verapamil. When verapamil 120 mg twice daily was given to 12 hypertensive patients taking terazosin 5 mg daily, the peak plasma levels and the AUC of terazosin were increased by about 25%. In contrast, in another 12 patients taking verapamil 120 mg twice daily, the addition of terazosin (1 mg increased to 5 mg daily) did not affect verapamil pharmacokinetics.[12] Both groups of patients had significant falls in standing blood pressure when they first started taking both drugs. Symptomatic orthostatic hypotension (which lessened within about 3 weeks) occurred in 4 patients when verapamil was first added to terazosin, and in 2 patients when terazosin was first added to verapamil.[12]

Mechanism

Not fully understood. It would seem that the vasodilatory effects of the alpha blockers and the calcium-channel blockers can be additive or synergistic, particularly after the first dose.[2,5,13] Tamsulosin possibly has less effect on blood pressure since it has some selectivity for alpha receptors in the prostate. It has been suggested that the interaction between tamsulosin and verapamil occurs because verapamil has alpha antagonist effects,[10] but as tamsulosin is, in part, metabolised by the cytochrome P450 isoenzyme CYP3A4,[14] which verapamil modestly inhibits, there may be a pharmacokinetic component to the interaction.

The fall in blood pressure seen with prazosin or terazosin and verapamil may, in part, result from a pharmacokinetic interaction, involving reduced hepatic metabolism, although the exact mechanism is not certain.[7,12,13] The pharmacokinetic interaction between alfuzosin and diltiazem appears to occur because diltiazem is a moderate inhibitor of CYP3A4, which is the principal enzyme involved in the hepatic metabolism of alfuzosin.[1]

Importance and management

The interaction between calcium-channel blockers and alpha blockers would appear to be established and of clinical importance, although the documentation is limited. Marked additive hypotensive effects can occur when concurrent use is first started, and the effects may be increased if a pharmacokinetic interaction also occurs (for example with alfuzosin and diltiazem, and prazosin or terazosin with verapamil). When starting an alpha blocker it is recommended that patients already taking a calcium-channel blocker should have their dose of calcium-channel blocker reduced and begin with a low-dose of alpha blocker, with the first dose taken just before going to bed. Caution should also be taken when calcium-channel blockers are added to established treatment with an alpha blocker. Patients should be warned about the possibilities of exaggerated hypotension, and told what to do if they feel faint and dizzy (i.e. lay down, raise the legs, and, when recovered, get up slowly). There is limited evidence that tamsulosin and possibly terazosin may not cause an additional hypotensive effect when taken longer term in patients with BPH who have hypertension already well controlled with calcium-channel blockers. Nevertheless, caution should be exercised in this situation, and a dose reduction of the calcium-channel blocker may be required. It seems likely that any pharmacokinetic interaction will be accounted for by this dose titration.

Alpha blockers + Cimetidine

No important interaction occurs between cimetidine and either alfuzosin or doxazosin in healthy subjects. Tamsulosin does not appear to have a clinically significant interaction with cimetidine, but caution is recommended with high tamsulosin doses.
For mention of an interaction between tolazoline and cimetidine or ranitidine, see 'Tolazoline + H_2-receptor antagonists', p.1076.

Clinical evidence, mechanism, importance and management

(a) Alfuzosin

In 10 healthy subjects cimetidine 1 g daily in divided doses for 20 days was found to have minimal effects on the pharmacokinetics of a single 5-mg dose of alfuzosin. The maximum serum levels and AUC of alfuzosin were increased by up to 24%, (not statistically significant) and the half-life was shortened by 14%. Cimetidine did not appear to increase the incidence of postural hypotension seen with alfuzosin.[1] These changes were not thought to be clinically relevant, and there would seem to be no reason for avoiding concurrent use. However, caution has been recommended for elderly patients, where the bioavailability of alfuzosin is generally increased and, consequently, even a small increase in plasma levels might be clinically relevant.[1] Other H_2-receptor antagonists would not be expected to interact, but there does not seem to be any evidence to support this suggestion.

(b) Doxazosin

The manufacturers of doxazosin note that, in a placebo-controlled study in healthy subjects, cimetidine 400 mg twice daily increased the AUC of a single 1-mg dose of doxazosin given on day 4 by 10%.[2,3] This seems unlikely to be of clinical significance, especially as this is within the expected intersubject variation of the doxazosin AUC.[3]

(c) Tamsulosin

A study in 10 healthy subjects found that giving cimetidine 400 mg four times daily with a single 400-microgram dose of tamsulosin resulted in a 44% increase in the AUC of tamsulosin and a 26% reduction in tamsulosin clearance. Adverse events were not increased by concurrent use.[4] The UK manufacturer of tamsulosin considers that no dosage adjustment is necessary.[5] However, the US manufacturer advises caution, particularly with doses greater than 400 micrograms.[6] In practice this probably means being aware that an increase in the adverse effects of tamsulosin might occur as a result of this interaction. Other H_2-receptor antagonists would not be expected to interact, but there does not seem to be any evidence to support this suggestion.

Alpha blockers + CYP3A4 or CYP2D6 inhibitors

Potent CYP3A4 inhibitors may increase the levels of alfuzosin, and inhibitors of CYP3A4 and CYP2D6 may increase the levels of tamsulosin. *In vitro* studies suggest that doxazosin may also be affected by potent CYP3A4 inhibitors.

Clinical evidence, mechanism, importance and management

(a) Alfuzosin

The US manufacturer of alfuzosin XL briefly cites a study in which **ketoconazole** 400 mg increased the AUC and maximum levels of a 10-mg dose of alfuzosin by 3.2-fold and 2.3-fold, respectively. They therefore contraindicate the concurrent use of potent CYP3A4 inhibitors (they name **itraconazole**, **ketoconazole** and **ritonavir**).[1] Based on the information available the contraindication with alfuzosin seems somewhat cautious, although **ritonavir** may be expected to have a greater effect than **ketoconazole**. If any of the potent CYP3A4 inhibitors named is given with alfuzosin it would seem prudent to use the minimum dose of the alpha blocker and titrate the dose as necessary, monitoring for adverse effects, particularly first-dose hypotension when the dose is increased. Be aware that risks are likely to be greater in patients also taking other antihypertensives.

(b) Doxazosin

Doxazosin is extensively metabolised in the liver, and *in vitro* studies suggest that CYP3A4 is the primary enzyme involved, although CYP2D6 and CYP2C19 metabolic pathways also contribute.[2] The US manufacturer advises caution when a potent CYP3A4 inhibitor, such as **atazanavir**, **clarithromycin**, **indinavir**, **itraconazole**, **ketoconazole**, **nefazodone**, **nelfinavir**, **ritonavir**, **saquinavir**, **telithromycin** or **voriconazole** is given with doxazosin.[2] The clinical relevance of these predictions is unclear, but until more is known some caution seems prudent. If concurrent use is undertaken be aware that the effects of doxazosin may be increased.

(c) Tamsulosin

The US manufacturer states that tamsulosin is extensively metabolised (mainly by CYP2D6 and CYP3A4). They therefore state that tamsulosin 400 micrograms should not be given with strong inhibitors of CYP3A4 (e.g. **ketoconazole**). In addition, they suggest that tamsulosin should be used with caution in combination with moderate or strong inhibitors of CYP2D6 (e.g. **fluoxetine**) and moderate inhibitors of CYP3A4 (e.g. **erythromycin**), in patients that are CYP2D6 poor metabolisers (that is, those with low levels or those deficient in this isoenzyme), particularly at doses higher than 400 micrograms.[3] The clinical relevance of these pre-

dictions is unclear, and the metaboliser status of a patient is rarely known. Until more is known some caution seems prudent. If concurrent use is undertaken be aware that the effects of tamsulosin may be increased.

Alpha blockers + Diuretics

As would be expected, the use of an alpha blocker with a diuretic may result in an additive hypotensive effect, but aside from first-dose hypotension, this usually seems to be a beneficial interaction in patients with hypertension. The effects in patients with congestive heart failure may be more severe.

Clinical evidence

(a) Alfuzosin

In a single-dose study in 8 healthy subjects no pharmacokinetic interaction occurred when alfuzosin 5 mg was given with **hydrochlorothiazide** 25 mg.[1] The manufacturer notes that postural hypotension may occur when patients receiving antihypertensives start alfuzosin.[2]

(b) Doxazosin

A study, involving 2363 patients with hypertension controlled with a single antihypertensive drug, investigated the effects of adding doxazosin for BPH. The dose of doxazosin was increased gradually to 4 mg daily and then the patients were monitored for a further 14 weeks of treatment. The addition of doxazosin was found to be well tolerated, and adverse effects mainly occurred early after onset of treatment or in patients with lower systolic and diastolic blood pressure. However, the antihypertensive effect was more marked in patients taking diuretics or beta blockers than in patients taking ACE inhibitors or calcium-channel blockers.[3] The manufacturer of doxazosin notes that no adverse drug interaction has been seen between doxazosin and **thiazides** (including **hydrochlorothiazide**)[4,5] or **furosemide**.[4] However, they point out that doxazosin doses of greater then 4 mg daily increase the likelihood of adverse effects such as postural hypotension and syncope.[5]

(c) Indoramin

The manufacturers of indoramin state that concurrent use with diuretics (especially **thiazides**) may enhance the hypotensive action.[6,7]

(d) Tamsulosin

The US manufacturer of tamsulosin[8] notes that when 10 healthy subjects taking tamsulosin 800 micrograms daily were given a single 20-mg intravenous dose of **furosemide** the AUC of tamsulosin was reduced by about 12%. Both the UK and US manufacturers note that as levels remained within the normal range no change in dosage is necessary.[8,9] *In vitro* evidence suggested that tamsulosin and **trichlormethiazide** did not change the free fraction of either drug in human plasma.[10]

(e) Terazosin

A study in 296 hypertensive patients found that terazosin 5 mg daily lowered the supine and standing blood pressure by 4.8/8.1 mmHg and 2.6/6.1 mmHg, respectively, when compared with placebo. When **methyclothiazide** 5 mg daily was also given, the blood pressure was reduced by 20.6/14.4 mmHg and 23.3/14.6 mmHg, respectively, when compared with placebo. A similar reduction in blood pressure (17.3/12.4 mmHg and 16/11.2 mmHg, respectively) occurred when the dose of **methyclothiazide** was halved. The combination, starting with terazosin and then adding a thiazide diuretic, was considered to be effective and well tolerated.[11]

Retrospective analysis of a large multinational study in patients with BPH given terazosin 5 or 10 mg daily found that terazosin only affected the blood pressure of patients taking diuretics (**amiloride**, **bendroflumethiazide**, **chlortalidone**, **hydrochlorothiazide** and **spironolactone**) if the blood pressure was uncontrolled. No change in blood pressure was seen in those with normal blood pressure (i.e. those without hypertension and those with hypertension controlled by diuretics). The most common adverse effect in the 10-week terazosin phase was dizziness, and the incidence of this appeared to be lower in those taking antihypertensives (13 to 16%) than in those not taking antihypertensives (21 to 25%).[12] However, the UK manufacturer of terazosin notes that the incidence of dizziness in patients taking terazosin was higher when they were also taking a diuretic.[13] Similarly, in clinical studies in patients with hypertension, a higher proportion experienced dizziness when they took terazosin with a diuretic, than when they took a placebo with a diuretic (20% versus 13%).[14]

Mechanism, importance and management

The acute first-dose hypotension that can occur with alpha blockers can be exacerbated by 'beta blockers', (p.94) and 'calcium-channel blockers', (p.95), but there seems to be no direct evidence that diuretics normally do the same. However, the manufacturer of **prazosin** suggests that it is particularly important that patients with congestive heart failure who have undergone vigorous diuretic treatment should be started on the lowest dose of prazosin (500 micrograms two to four times daily), with the initial dose given at bedtime. The reason is that left ventricular filling pressure may decrease in these patients with a resultant fall in cardiac output and systemic blood pressure.[15] There seems to be no reason for avoiding concurrent use if these precautions are taken. The only other direct evidence of a possible problem is with terazosin, and the manufacturer of terazosin states that when it is added to a diuretic, dose reduction and re-titration may be necessary.[13]

No guidance is given with the other alpha blockers, but as most manufacturers note that postural hypotension is a possibility, it may be prudent to warn patients about the possibilities of exaggerated hypotension, and tell them what to do if they feel faint and dizzy (i.e. lay down, raise the legs, and, when recovered, get up slowly).

Alpha blockers + Dutasteride or Finasteride

No clinically important interaction has been found to occur between finasteride and doxazosin. In one study terazosin did not interact with finasteride, but in another there was a suggestion of modestly increased finasteride levels. No clinically significant interaction appears to occur between dutasteride and tamsulosin or terazosin.

Clinical evidence, mechanism, importance and management

(a) Dutasteride

A study in 24 subjects given dutasteride 500 micrograms daily for 14 days found that when they were also given **tamsulosin** 400 micrograms daily or **terazosin** (titrated to 10 mg daily) for 14 days, the pharmacokinetics of the alpha blockers remained unchanged.[1] Furthermore, a clinical study in 327 men demonstrated that the combination of **tamsulosin** and dutasteride was well tolerated over a period of 6 months.[2]

(b) Finasteride

In a parallel study, 48 healthy subjects were divided into three groups. One group took **terazosin** 10 mg daily for 18 days, another took finasteride 5 mg daily for 18 days, and the third group took both drugs. The pharmacokinetics and pharmacodynamics of both drugs remained unchanged, and the serum levels of testosterone and dihydrotestosterone were also unaltered by concurrent use.[3] However, another study, comparing groups of healthy subjects taking finasteride and alpha blockers, found that after 10 days of combined use, the maximum finasteride level was 16% higher and the AUC 31% higher. The levels of the group taking finasteride and **doxazosin** were not significantly different. The clinical significance of the possible modest increased finasteride levels with **terazosin** is not clear,[4] but is likely to be small.

Incubation of **tamsulosin** and finasteride with human liver microsomes showed no *in vitro* evidence of clinically significant metabolic interactions.[5]

Alpha blockers + Food

Food appears to have no clinical effect on the pharmacokinetics of alfuzosin, doxazosin, or terazosin; however, food may affect the absorption from some extended-release preparations of these alpha blockers. The bioavailability of tamsulosin is reduced by food.

Clinical evidence, mechanism, importance and management

The manufacturer of **alfuzosin** says that its pharmacokinetics are not affected by food,[1] but the extent of absorption of the extended-release preparation is 50% lower under fasting conditions[2] and therefore extended-release preparations should be taken immediately after a meal.[2,3]

In a crossover study in 12 hypertensive subjects, the mean maximum plasma concentration and AUC of **doxazosin** were not significantly affected by food. However, when compared with the fasting state, food increased the maximum levels and AUC of extended-release doxazosin (*Cardura XL*) by 32% and 18%, respectively.[4] The US manufacturer says that, in order to provide the most consistent exposure, *Cardura XL* should be given with breakfast,[4] but the UK manufacturer says that the modified-release tablet may be taken with or without food.[5]

The manufacturer of **tamsulosin** states that under fasted conditions, there is a 30% increase in bioavailability and a 40% to 70% increase in the maximum levels, when compared with fed conditions.[6] However, some manufacturers recommend that, for uniformity of absorption, **tamsulosin** should be taken after the same meal each day.[6-8] With other formulations (e.g. the prolonged-release tablet *Flomaxtra XL*) the rate and extent of absorption of **tamsulosin** is not affected by food and the manufacturer says *Flomaxtra XL* may be taken with or without food.[9]

The manufacturer of **terazosin** states that food has little or no effect on its bioavailability.[10]

Alpha blockers + Miscellaneous

The manufacturers of several of the alpha blockers provide lists of drugs that are not expected to interact. These are shown in 'Table 4.2', (p.99). In some cases these predictions are based on *in vitro* studies or from observation of clinical usage. Although this type of data can provide a guide, remember that it gives only the broadest indication of whether or not a drug interacts.

Alpha blockers + Nitrates

There may be an enhanced hypotensive effect if alpha blockers are given with nitrates.

The UK manufacturer of **alfuzosin** warns that it might interact with nitrates.[1] Although this interaction is not specifically mentioned for other alpha blockers, most manufacturers warn of enhanced hypotensive effects with other drugs that can lower blood pressure. Consider also 'Antihypertensives + Other drugs that affect blood pressure', p.1051.

In addition, the manufacturer of **prazosin** warns that when prazosin is initially given to patients with congestive heart failure who have undergone vigorous diuretic or other vasodilator treatment, the resultant decrease in left ventricular filling pressure may be associated with a significant fall in cardiac output and systemic blood pressure. Observance of the recommended starting dose of **prazosin** followed by gradual dosage increase is particularly important in such patients.[2]

Alpha blockers; Bunazosin + Rifampicin (Rifampin)

Rifampicin markedly reduces bunazosin serum levels.

Clinical evidence, mechanism, importance and management

In 15 healthy subjects a 7-day course of rifampicin 600 mg daily reduced the mean maximum serum levels of bunazosin 6 mg daily by 82% (from 11.6 to 2.1 nanograms/mL). The bunazosin AUC was reduced by more than sevenfold. The duration of the blood pressure lowering effect of bunazosin was shortened, the heart rate increase was less pronounced, and some adverse effects of bunazosin (fatigue, headache) disappeared.[1,2] The probable reason is that the rifampicin (a recognised, potent enzyme inducer) increases the metabolism of bunazosin by the liver so that its levels are reduced, and its effects therefore diminished.

The evidence seems to be limited to this study, but anticipate the need to raise the bunazosin dosage if rifampicin is added. Information about other alpha blockers does not seem to be available.

Alpha blockers; Indoramin + MAOIs

Based on early theoretical considerations, the manufacturers of indoramin contraindicate its use with MAOIs.

Clinical evidence, mechanism, importance and management

The concurrent use of MAOIs is contraindicated by the manufacturers of indoramin.[1,2] This was included in the datasheet at the time indoramin was first licensed, and was based on a theoretical suggestion that the effects of

Table 4.2 Drugs that are not expected to interact with alpha blockers as listed by the manufacturers

noradrenaline (norepinephrine) may be potentiated by indoramin,[3] leading to vasoconstriction, with a possible increase in blood pressure. However, the pharmacology of these drugs suggests just the opposite, namely that hypotension is the more likely outcome. (Note that the hypertensive effects of noradrenaline (norepinephrine) may be treated with a non-selective alpha blocker such as phentolamine.) The manufacturers are not aware of any reported interactions between indoramin and MAOIs.[3] Note that the MAOIs are not contraindicated with any of the other alpha blockers.

Anaesthetics and Neuromuscular blockers

Many patients undergoing anaesthesia may be taking long-term medication, which may affect their haemodynamic status during anaesthesia. This section is limited to drug interactions and therefore does not cover the many precautions relating to patients taking long-term medication and undergoing anaesthesia.

(a) General anaesthetics

In general anaesthesia a balanced approach is often used to meet the main goals of the anaesthetic procedure. These goals are unconsciousness/amnesia, analgesia, muscle relaxation, and maintenance of homoeostasis. Therefore general anaesthesia often involves the use of several drugs, including benzodiazepines, opioids, and anticholinesterases, as well as general anaesthetics (sometimes more than one) and neuromuscular blockers. The use of several different types of drugs in anaesthesia means that there is considerable potential for drug interactions to occur in the peri-operative period, but this section concentrates on the effects of drugs on general anaesthetics and neuromuscular blockers. The interactions of other drugs used peri-operatively are mainly covered under 'anticholinesterases', (p.396), 'benzodiazepines', (p.831), and 'opioids', (p.149).

There may be difficulty in establishing which of the drugs being used in a complex regimen are involved in a suspected interaction. It should also be borne in mind that disease processes and the procedure for which anaesthesia is used may also be factors to be taken into account when evaluating a possible interaction.

Some established interactions are advantageous and are employed clinically. For example, the hypnotic and anaesthetic effects of 'propofol and midazolam', (p.106), are found to be greater than the expected additive effects and this synergy allows for lower dosage regimens in practice. Similarly nitrous oxide reduces the required dose of inhalational general anaesthetics (see 'Anaesthetics, general + Anaesthetics, general', p.103).

The general anaesthetics mentioned in this section are listed in 'Table 5.1', (p.101). Barbiturates used as anaesthetics (e.g. thiopental) are largely covered here, whereas barbiturates used predominantly for their antiepileptic or sedative properties (e.g. phenobarbital or secobarbital) are dealt with in the appropriate sections.

Many anaesthetics have been associated with arrhythmias, due to their sensitising effects on the myocardium. A suggested listing of inhalational anaesthetics in order of decreasing sensitising effect on the myocardium is as follows: cyclopropane, halothane, enflurane/methoxyflurane, desflurane/isoflurane/sevoflurane.

(b) Local anaesthetics

The interactions discussed in this section mainly involve the interaction of drugs with local anaesthetics used for epidural or spinal anaesthesia. The interactions of lidocaine used as an antiarrhythmic is dealt with in 'Antiarrhythmics', (p.273). The local anaesthetics mentioned in this section are listed in 'Table 5.1', (p.101).

(c) Neuromuscular blockers

The competitive (non-depolarising) neuromuscular blockers and depolarising neuromuscular blockers mentioned in this section are listed in 'Table 5.2', (p.101). The modes of action of the two types of neuromuscular blocker are discussed in the monograph 'Neuromuscular blockers + Neuromuscular blockers', p.142. It should be noted that mivacurium (a competitive blocker) and suxamethonium (a depolarising blocker) are hydrolysed by cholinesterase, so share some interactions in common that are not relevant to other competitive neuromuscular blockers.

Table 5.1 Anaesthetics

General anaesthetics			
Halogenated inhalational anaesthetics	**Miscellaneous inhalational anaesthetics**	**Barbiturate parenteral anaesthetics**	**Miscellaneous parenteral anaesthetics**
Chloroform	Anaesthetic ether	Methohexital	Etomidate
Desflurane	Cyclopropane	Thiamylal	Ketamine
Enflurane	Nitrous oxide	Thiopental	Propofol
Halothane	Xenon		
Isoflurane			
Methoxyflurane			
Sevoflurane			
Trichloroethylene			
Local anaesthetics			
Amide-type	**Ester-type (ester of benzoic acid)**	**Ester-type (ester of para-aminobenzoic acid)**

	Tubocurarine (d-Tubocurarine)	

Anaesthetics, general + ACE inhibitors or Angiotensin II receptor antagonists

The concurrent use of general anaesthetics and antihypertensives generally need not be avoided but it should be recognised that the normal homoeostatic responses of the cardiovascular system will be impaired. For example, marked hypotension has been seen in patients taking ACE inhibitors or angiotensin-II receptor antagonists during anaesthetic induction.

Clinical evidence, mechanism, importance and management

(a) ACE inhibitors

Marked hypotension (systolic BP 75 mmHg), which did not respond to surgical stimulation, occurred in a 42-year-old man taking **enalapril** when he was anaesthetised with **propofol**. He responded slowly to the infusion of one litre of Hartmann's solution.[1] Severe and unexpected hypotension has been seen during anaesthetic induction in patients taking **captopril**.[2] In a randomised clinical study, the incidence of hypotension during anaesthetic induction was higher in patients who had taken **captopril** or **enalapril** on the day of surgery than in those who had stopped these drugs 12 or 24 hours before surgery.[3] In 18 patients induction of anaesthesia for coronary artery bypass surgery resulted in a significant reduction in blood pressure and heart rate, irrespective of whether or not they were taking ACE inhibitors. The patients taking ACE inhibitors showed a marked decrease in cardiac index but no changes in systemic vascular resistance compared with the patients not taking ACE inhibitors.[4] In another study in patients undergoing coronary artery bypass surgery, short-lasting hypotensive episodes (less than 60 seconds) occurred in 9 of 16 patients receiving **captopril**, **enalapril**, **perindopril** or **lisinopril**, compared with 2 of 16 patients who were not taking ACE inhibitors. The patients experiencing hypotension required additional intravenous fluids and vasoconstrictors to maintain haemodynamic stability.[5] Similar findings are reported in another study, which included patients taking **captopril**, **enalapril**, **ramipril**, or **lisinopril**.[6] Another experimental study found that a single dose of **captopril** at induction of anaesthesia caused a small reduction in cerebral blood flow, when compared with control patients or patients given metoprolol.[7]

Particular care would seem to be needed with patients taking ACE inhibitors, but there is insufficient evidence to generally recommend discontinuing ACE inhibitors before surgery. Whether ACE inhibitors are discontinued or continued, haemodynamic instability may occur after induction of anaesthesia.[8] One report in patients undergoing cardiac surgery found that intravenous **enalaprilat** effectively reduced blood pressure and also exerted a beneficial effect on the endocrine regulators of macro- and microcirculation by blunting the increase in vasoconstrictors.[9]

One recommendation is that intravenous fluids should be given to all patients taking ACE inhibitors who are anaesthetised.[1] If hypotension occurs, blood pressure can be restored in most patients by giving sympathomimetics such as phenylephrine.[8] However, sympathomimetics may not be fully effective in treating hypotension due to ACE inhibitors and anaesthesia because ACE inhibitor administration may result in a decrease in the adrenergic vasoconstrictive response.[5,10] Terlipressin (a vasopressin analogue that has some effects as a vasopressin agonist) is reported to be an effective treatment for refractory hypotension during anaesthesia in patients taking ACE inhibitors.[8,11,12] One study found that severe hypotension during anaesthetic induction in patients chronically taking ACE inhibitors could be controlled with an intravenous injection of angiotensin II (*Hypertensine*).[13]

(b) Angiotensin II receptor antagonists

A study in 12 hypertensive patients taking angiotensin II receptor antagonists found that hypotension occurred in all patients after induction of anaesthesia. This was more frequent than that found in matched groups of hypertensive patients receiving either beta blockers and/or calcium-channel blockers (27 out of 45) or ACE inhibitors (18 of 27). The magnitude of hypotension was also significantly greater in those treated with angiotensin II receptor antagonists and it was less responsive to ephedrine and phenylephrine.[11] Terlipressin has been found to be effective in patients with refractory hypotension taking angiotensin II receptor antagonists.[11,12]

Anaesthetics, general + Alcohol

Those who regularly drink alcohol may need more thiopental or propofol than those who do not. In theory, alcohol may increase the risk of renal damage with sevoflurane. It is also probably unwise to drink for several hours following anaesthesia because of the combined central nervous depressant effects.

Clinical evidence, mechanism, importance and management

A study in 532 healthy patients, aged from 20 to over 80 years, found that those who normally drank alcohol (more than 40 g weekly, roughly 400 mL of wine) needed more **thiopental** to achieve anaesthesia than non-drinkers. After adjusting for differences in age and weight distribution, men and women who were heavy drinkers (more than 40 g alcohol daily) needed 33% and 44% more **thiopental**, respectively, for induction than non-drinkers.[1] Chronic alcohol intake is known to increase barbiturate metabolism by cytochrome P450 enzymes,[2] see 'Alcohol + Barbiturates', p.55.

Another study found that 26 chronic alcoholics (drinkers of about 40 g of alcohol daily, with no evidence of liver impairment) needed about one-third more **propofol** to induce anaesthesia than another 20 patients who only drank socially. However, there was great interindividual variation in the amount of **propofol** needed in the alcoholic group.[3]

When 12 healthy subjects were given 0.7 g/kg of alcohol 4 hours after receiving 5 mg/kg of **thiopental** 2.5%, body sway and lightheadedness were accentuated.[4] This suggests that an interaction may occur if an ambulatory patient drinks alcohol within 4 hours of receiving an induction dose of **thiopental**. Patients should be cautioned not to drink alcohol following anaesthesia and surgery.

The manufacturer of **sevoflurane** notes that its metabolism may be increased by known inducers of the cytochrome P450 isoenzyme CYP2E1 including alcohol.[5,6] This may increase the risk of renal damage because

Table 5.3 Effects of the concurrent use of anaesthetics

Anaesthetic	*Effect*	*Refs*
Ketamine		
Barbiturate anaesthetics	Effects of ketamine prolonged. Recovery may be delayed.	1,2
Nitrous oxide		
Inhalational anaesthetics	Nitrous oxide usually reduces the MAC of inhalational anaesthetics in a simple additive manner; an inspired concentration of 60 to 70% nitrous oxide is commonly used with volatile anaesthetics.	3
Barbiturate anaesthetics	Reduces the required dose of intravenous barbiturate anaesthetics.	4
Propofol	Concurrent use produces a deeper sedation than that produced by propofol alone. Reduced propofol dose may be required.	5,6
Sevoflurane	Reduces the required dose of sevoflurane.	7
Propofol		
Inhalational anaesthetics	Generally expected to increase the effects of propofol. Reduced propofol dose may be required.	5
Halothane	Propofol levels raised by about 20% during maintenance of general anaesthesia. Propofol effects expected to be increased.	5,8
Isoflurane	Serum propofol concentrations by about 20% during the maintenance of general anaesthesia. Propofol effects expected to be increased.	5,8
Intravenous anaesthetics	Generally expected to increase the effects of propofol. Reduced propofol dose may be required.	5
Etomidate	Synergistic effect: patients given induction doses of either etomidate or propofol alone required about a 15% higher dose than those given half etomidate and half propofol in sequence.	9
Sevoflurane		
Intravenous anaesthetics	Lower concentrations may be required following the use of an intravenous anaesthetic.	10
Propofol	In a study in surgical patients concurrent use was additive (loss of consciousness and movement to skin incision assessed). Lower sevoflurane concentrations may be required following the use of propofol. Concurrent use in ECT results in a longer recovery time, probably due to deeper anaesthesia, but results in smaller increases in heart rate and blood pressure than with sevoflurane alone and a shorter seizure duration than with propofol alone. (Note that the UK manufacturers of propofol do not recommend its use in ECT.)	10-13

Anaesthetics, general + Anaesthetics, general

In general, the effects of the combined use of general anaesthetics are at least additive. See 'Table 5.3', (above), for specific comments about pairs of anaesthetics.

Anaesthetics, general + Anaesthetics, local

An isolated report describes convulsions associated with the use of propofol with topical cocaine Arrhythmias have been reported in patients given propofol and topical cocaine. Cocaine abuse may increase the risk of cardiovascular complications during inhalational anaesthesia. Abstinence from cocaine or the avoidance of anaesthetics with sympathomimetic properties has been suggested. The dosage of propofol may need to be reduced after the use of bupivacaine, ropivacaine, or lidocaine (e.g. during regional anaes-

thetic techniques). Similarly, epidural lidocaine reduces sevoflurane requirements, and is likely to have the same effect on other inhalational anaesthetics.

Clinical evidence, mechanism, importance and management

Note that drugs such as adrenaline (epinephrine), which are used with local anaesthetics, may interact with inhalational anaesthetics such as halothane to increase the risk of arrhythmias, see 'Anaesthetics, general + Inotropes and Vasopressors', p.111.

(a) Bupivacaine

In a placebo-controlled study of patients undergoing minor gynaecological surgery, giving intramuscular bupivacaine 0.5% 30 minutes before induction of anaesthesia significantly enhanced the hypnotic effect of intravenous **propofol** in a dose-dependent manner. Only the lowest dose of bupivacaine tested (250 micrograms/kg) lacked a significant effect on the hypnotic dose of **propofol**. The highest dose of bupivacaine (1 mg/kg) reduced the hypnotic requirements for **propofol** by about 40%. The dose of **propofol** should therefore be modified after the intramuscular use of bupivacaine.[1] The UK manufacturer of **propofol** also notes that required doses may be lower when general anaesthesia is used in association with regional anaesthetic techniques.[2]

(b) Cocaine

A patient with no history of epilepsy, undergoing septorhinoplasty for cosmetic reasons, was premedicated with papaveretum and hyoscine, and intubated after **propofol** and suxamethonium (succinylcholine) were given. Anaesthesia was maintained with **nitrous oxide**/oxygen and **isoflurane** 2%. During anaesthesia a paste containing cocaine 10% was applied to the nasal mucosa. During recovery the patient experienced a dystonic reaction, which developed into a generalised convulsion. The authors of the report suggest that a possible interaction between the **propofol** and cocaine might have been responsible, although they also suggest that the convulsions may have been an adverse effect of the propofol.[3]

In one study, **thiopental** with either 5 mL of lidocaine 4% or 3 mL of cocaine 5%, was found to be an effective anaesthetic when performing a laryngoscopy and biopsy. However, the procedure for applying cocaine topically in these circumstances prolongs the procedure and hence increases **thiopental** requirements. Also serious cardiac arrhythmias (bigeminal rhythms and ectopic ventricular contractions) occurred in 7 of 20 patients given cocaine (which resolved, either without treatment or with intravenous propranolol). Arrhythmias did not occur in those given lidocaine.[4] In another study, **thiopental** and suxamethonium were used to induce anaesthesia in 45 patients and anaesthesia was maintained with **nitrous oxide**/oxygen and **halothane**. When a stable level of anaesthesia had been obtained, topical cocaine 20, 35, or 50 mg in 2 mL of water was sprayed into both nostrils to shrink the nasal mucosa before nasal surgery. Two patients who received cocaine 35 mg developed atrial and ventricular extrasystoles. Two other cases of AV nodal rhythm and two cases of bradycardia, which responded to atropine, were also observed.[5] However, in another study in 20 patients, topical application of cocaine (1 mL of 25% paste or 4 mL of 4% solution) with or without adrenaline (epinephrine) 0.1%, after induction of anaesthesia with **thiopental**, did not cause any cardiac toxicity.[6]

Reviews of the anaesthetic implications of illicit drug use have stated that anaesthetists should be aware of the medical complications of cocaine abuse, such as myocardial ischaemia, hypertension and tachycardia due to sympathetic nervous system stimulation.[7,8] It was suggested that the concurrent use of cocaine and inhalational anaesthetics, such as **halothane**, that are known to significantly sensitise the myocardium to circulating catecholamines, should be avoided, and that other halogenated anaesthetics should be used with caution.[7,8] Theoretically, **isoflurane** would be a better choice of inhalational anaesthetic since it has less cardiovascular effects.[7] **Ketamine** should also be avoided because of its sympathomimetic effects. **Nitrous oxide**, **thiopental** and fentanyl were considered to be useful for general anaesthesia in patients who regularly abuse cocaine.[7,8] Although it has been suggested that anaesthesia is safe for patients with chronic cocaine abuse after abstinence for 24 hours, the occurrence of ventricular fibrillation in one such patient during anaesthesia with **thiopental** and **isoflurane**, led the authors of the case report to conclude that there should be a cocaine-free interval of at least one week before elective surgical procedures. They also suggest that if an emergency operation is required during acute cocaine intoxication, all sympathomimetic anaesthetic drugs should be avoided.[9]

(c) Lidocaine

A double-blind, randomised study of 17 patients requiring ventilatory support demonstrated that hourly laryngotracheal instillation of 5 mL of 1% lidocaine significantly reduced the dose of **propofol** required to maintain adequate sedation (overall reduction of 50%) when compared with pre-study values.[10]

In a placebo-controlled study of patients undergoing minor gynaecological surgery, giving intramuscular lidocaine 4% 10 minutes before induction of anaesthesia significantly enhanced the hypnotic effect of intravenous **propofol** in a dose-dependent manner. Only the lowest dose of lidocaine tested (500 micrograms/kg) lacked a significant effect on the hypnotic dose of **propofol**. The highest dose of lidocaine (3 mg/kg) reduced the hypnotic requirements for **propofol** by about 34%. The dose of **propofol** should therefore be modified after the intramuscular use of lidocaine or bupivacaine.[1] The UK manufacturer of **propofol** also notes that required doses may be lower when general anaesthesia is used in association with regional anaesthetic techniques.[2]

An *in vitro* study using liver microsomes found that **propofol** inhibited the metabolism of lidocaine by cytochrome P450 isoenzymes.[11] However, a further study by the same authors in 31 patients undergoing anaesthesia with either **propofol** or **sevoflurane**, and receiving epidural lidocaine, found that, compared with **sevoflurane** (which does not inhibit lidocaine metabolism), **propofol** did not affect the metabolism of epidural lidocaine. The lack of interaction in the latter study could be due to the lower doses of **propofol** involved and because other isoenzymes or extrahepatic metabolism of lidocaine might possibly be involved.[12] A study in patients undergoing surgery found that a single 2-mg/kg dose of **propofol** did not affect serum lidocaine levels in subjects who smoked and consumed alcohol chronically. Enzyme inhibition by **propofol** may be countered by enzyme induction associated with cigarette smoking and alcohol, but it is probable in this study, that the single dose of **propofol** was insufficient to produce enzyme inhibition.[13]

A randomised, double-blind, placebo-controlled study involving 44 patients found that lidocaine epidural anaesthesia (15 mL of 2% plain lidocaine) reduced the MAC of **sevoflurane** required for general anaesthesia by approximately 50% (from 1.18 to 0.52%). This implies that a lower dose of **inhalational anaesthetic** provides adequate anaesthesia during combined epidural-general anaesthesia than for general anaesthesia alone.[14]

(d) Ropivacaine

In an *in vitro* study using liver microsomes, **propofol** inhibited the cytochrome P450 isoenzyme CYP3A4-mediated metabolism of ropivacaine.[15]

Anaesthetics, general + Anthracyclines

Pretreatment with anthracyclines may result in prolongation of the QT interval during isoflurane anaesthesia.

Clinical evidence, mechanism, importance and management

A study in women with breast cancer found that the QTc interval was prolonged (to more than 440 milliseconds) during anaesthesia with **isoflurane** (end-tidal concentration 0.5 vol%) in more than half of the 20 patients who had received chemotherapy, compared with only 1 of 20 patients who had not previously received chemotherapy. However, QTc intervals of 600 milliseconds and above, which may be associated with serious arrhythmias, were not observed. The chemotherapy, which was given about 1 month before surgery, consisted of fluorouracil and cyclophosphamide and either **doxorubicin** or **epirubicin**. Anthracyclines (such as **doxorubicin** and **epirubicin**) and **isoflurane** can prolong the QT interval. The patients had also received midazolam, which is reported to reduce QTc prolongation induced by other anaesthetics. It was noted that the use of higher **isoflurane** concentrations in patients given anthracyclines could result in greater QTc interval prolongation.[1] Several drugs used in anaesthesia may affect the QT interval. For example **thiopental** and **sufentanil** are also reported to prolong the QT interval, while **propofol** and **halothane** are said to shorten it.[1] This should be borne in mind if patients treated with anthracyclines or other drugs that prolong the QT interval undergo anaesthesia.

1. Owczuk R, Wujtewicz MA, Sawicka W, Wujtewicz M, Swierblewski M. Is prolongation of the QTc interval during isoflurane anaesthesia more prominent in women pretreated with anthracyclines for breast cancer? *Br J Anaesth* (2004) 92, 658–61.

Anaesthetics, general + Anticholinesterases

Inhalation anaesthetics may impair the efficacy of anticholinesterases in reversing neuromuscular blockade, although propofol does not affect the reversal of rocuronium block by neostigmine. Physostigmine pre-treatment increased propofol requirements by 20% in one study.

Clinical evidence, mechanism, importance and management

(a) Neostigmine

Inhalational anaesthetics can impair neostigmine reversal of neuromuscular blockade. In one study, neostigmine took longer to reverse pancuronium blockade after anaesthesia with **enflurane**, when compared with fentanyl or **halothane**.[1] Another study found that the reversal of vecuronium block with neostigmine 40 micrograms/kg was more dependent on the concentration of **sevoflurane** than the degree of block present. At the lowest concentration of **sevoflurane** (0.2 MAC), adequate reversal was obtained in all patients within 15 minutes, but with increasing concentrations (up to 1.2 MAC) satisfactory restoration of neuromuscular function was not achieved within 15 minutes, probably because of a greater contribution of **sevoflurane** to the degree of block.[2] In another randomised study, 120 patients were given **sevoflurane**, **isoflurane** (adjusted to 1.5 MAC), or intravenous **propofol** 6 to 12 mg/kg per hour for maintenance of anaesthesia. Neuromuscular block was induced with rocuronium and monitored using train-of-four stimulation (TOF) of the ulnar nerve. Neostigmine was given when the first response in TOF had recovered to 20 to 25%. At this point **isoflurane** or **sevoflurane** was stopped, or the **propofol** dose reduced, in half of the patients in each of the three groups. The times to recovery of the TOF ratio to 0.8 were 12 minutes and 6.8 minutes in the **sevoflurane** continued and stopped groups, respectively, 9 minutes and 5.5 minutes in the **isoflurane** continued and stopped groups, respectively, and 5.2 minutes and 4.7 minutes in the **propofol** continued and reduced groups, respectively. Only 9/20 and 15/20 patients in the **sevoflurane** and **isoflurane** continued groups, respectively, achieved a TOF ratio of 0.8 within 15 minutes. This showed that the reversal of rocuronium block by neostigmine is slowed by **sevoflurane** and to a lesser extent by **isoflurane**, but not significantly affected by **propofol**.[3] The manufacturers of neostigmine injection[4] and tablets[5] state that neostigmine should not be given during **cyclopropane** or **halothane** anaesthesia, but may be given after the withdrawal of these anaesthetics.

Note that inhalation anaesthetics potentiate neuromuscular blockers, see 'Anaesthetics, general + Neuromuscular blockers', p.113.

(b) Physostigmine

A study of 40 patients found that physostigmine pre-treatment (2 mg intravenously 5 minutes before induction of anaesthesia) increased **propofol** requirements by 20%.[6]

Anaesthetics, general + Antiemetics

Metoclopramide pre-treatment reduces the dosage requirements of propofol and thiopental. Droperidol, but not ondansetron, reduces the dose requirements of thiopental.

Clinical evidence

(a) Metoclopramide or Droperidol

A randomised, placebo-controlled study of 60 surgical patients, half of whom were given metoclopramide 150 micrograms/kg 5 minutes before induction, found that the induction dose of **propofol** was reduced by 24% in the group given metoclopramide.[1] Similar results were seen in another study of 21 patients, in which metoclopramide 10 or 15 mg reduced the dose requirements of **propofol** by about 25% and 41%, respectively.[2] In a randomised, placebo-controlled study in 96 female patients, both metoclopramide and droperidol reduced the amount of **thiopental** needed to induce anaesthesia by about 45%.[3]

(b) Ondansetron

In a randomised, placebo-controlled study of 168 female patients ondansetron 100 or 200 micrograms/kg given intravenously 5 minutes before **thiopental** induction did not influence the hypnotic requirements of **thiopental**.[4]

Mechanism

The exact mechanism by which metoclopramide reduces propofol or thiopental dose requirements is unclear, but it appears to involve the blockade of dopamine (D_2) receptors. Droperidol probably interacts with thiopental by a similar mechanism.

Importance and management

Although the evidence is limited these interactions between metoclopramide and thiopental or propofol, and between droperidol and thiopental would appear to be established. Droperidol has not been studied with propofol, but, on the basis of other interactions it would be expected to behave like metoclopramide. When patients are pretreated with either metoclopramide or droperidol, be alert for the need to use less propofol and thiopental to induce anaesthesia. If the mechanism is correct, it seems likely that other dopamine antagonists used as antiemetics, such as **haloperidol**, will interact similarly, although this does not appear to have been studied. Ondansetron appears not to interact.

Anaesthetics, general + Antipsychotics

An isolated report describes a grand mal seizure in a man taking chlorpromazine and flupentixol when he was anaesthetised with enflurane. Another report describes delayed recovery from anaesthesia in a patient taking clozapine, but the use of alprazolam may have been a contributory factor. The sedative properties of antipsychotics may be enhanced by thiopental. Lower etomidate doses are recommended in patients taking antipsychotics.

Clinical evidence, mechanism, importance and management

An isolated report[1] describes an unexpected grand mal seizure in a schizophrenic patient without a history of epilepsy when he was given **enflurane** anaesthesia. He was taking **chlorpromazine** 50 mg three times daily (irregularly) and **flupentixol** 40 mg intramuscularly every 2 weeks. The suggested reason is that the **enflurane** had a synergistic effect with the two antipsychotics, all of which are known to lower the seizure threshold. The general importance of this interaction is not known. Another isolated report[2] describes delayed recovery in a patient taking **clozapine** after short duration (1 hour) anaesthesia induced by **thiopental**, sufentanil and atracurium and maintained with **desflurane** and nitrous oxide/oxygen. However, the patient was also taking alprazolam which may also have contributed to the delayed recovery, see 'Anaesthetics, general + Benzodiazepines', below.

The manufacturer of thiopental notes that, as would be expected, the sedative properties of antipsychotics may be potentiated by **thiopental**.[3] The manufacturer of **etomidate** recommends that the dose of **etomidate** should be reduced in patients taking antipsychotics.[4] **Droperidol** and other drugs with dopamine antagonist properties, such as many of the antipsychotics, may reduce the dose requirements of **thiopental**, see 'Anaesthetics, general + Antiemetics', p.105.

In general, drugs with sedative properties, including many antipsychotics, have the potential to enhance the sedative effects of general anaesthetics, which may result in delayed recovery. However, there appear to be no reports of a problem in practice, and so it would seem reasonable to conclude that, in most patients, any effect is modest.

Anaesthetics, general + Aspirin

The anaesthetic dosage of thiopental is reduced by pretreatment with aspirin.

Clinical evidence

In a study in patients undergoing surgery, intravenous lysine aspirin increased mean free **thiopental** levels in the plasma by 39%, and 3 of 7 patients fell asleep again during recovery from **thiopental** anaesthesia.[1] Another study[2] in patients about to undergo surgery found that pretreatment with aspirin 1 g (given as intravenous lysine aspirin) one minute before induction reduced the dosage of **thiopental** by 34%, from 5.3 to 3.5 mg/kg.

Mechanism

Not understood. It has been suggested that aspirin increases the amount of free (and active) thiopental in the plasma since it competes for the binding sites on the plasma albumins.[1,2]

Importance and management

Information is limited but what is known shows that the effects of thiopental are increased by aspirin. Be alert for the need to reduce the dosage. However, note also that regular aspirin use may increase the risk of bleeding during surgery, and it is often recommended that aspirin should not be taken in the week before surgery.[3]

Anaesthetics, general + Baclofen

A patient taking baclofen had severe seizures during induction of anaesthesia with propofol.

Clinical evidence, mechanism, importance and management

A 48-year-old man with a cyst in his spinal cord taking baclofen for flexor spasms underwent surgery for the relief of obstructive hydrocephalus. His last dose of baclofen was 6 hours before induction of anaesthesia with pethidine (meperidine) 40 mg followed by **propofol**. After he had received about 60 mg of **propofol** he developed severe myoclonic seizures, which lasted about 3 minutes. The patient was given additional **propofol** 40 mg because he appeared to be awakening, and severe generalised seizures lasting 2 minutes occurred. He was then given vecuronium, and anaesthesia was maintained with isoflurane and nitrous oxide/oxygen without further problem.[1]

Seizures have been reported in patients with and without epilepsy receiving **propofol**. They mainly occur at induction or emergence or are delayed after anaesthesia, suggesting changes in cerebral levels of **propofol** may be causal.[2] Baclofen can cause acute desensitisation of $GABA_B$ receptors producing persistent epileptiform discharges.[1] It was suggested that in this patient the seizures were mediated by both baclofen and **propofol**.[1] Opioid analgesics may induce seizures and opisthotonos has been reported in patients given opioids and **propofol** (see 'Anaesthetics, general + Opioids', p.115). However, generalised seizures attributed to pethidine are probably due to a metabolite. The time course therefore makes pethidine an unlikely cause of the seizure in this patient.[1]

Anaesthetics, general + Benzodiazepines

Midazolam markedly potentiates the anaesthetic action of halothane. Similarly, the effects of propofol or thiopental are greater than would be expected by simple addition when midazolam is given concurrently, although the extent varies between the endpoints measured (analgesic, motor, hypnotic). Quazepam reduces induction time for propofol anaesthesia and premedication with diazepam reduces the dose of ketamine required.

Clinical evidence

(a) Halothane

In a study in 50 women undergoing surgery, **midazolam** markedly potentiated the anaesthetic action of halothane: a mean **midazolam** dose of 278 micrograms/kg reduced the halothane MAC by about 51%.[1]

(b) Ketamine

A study in patients undergoing major abdominal surgery found that in 10 patients premedicated with rectal **diazepam** one hour before induction, the haemodynamic effects of ketamine (increases in heart rate and blood pressure) were significantly reduced, when compared with 31 controls. Also, a lower rate of ketamine infusion was required during the initial 30 minutes of anaesthesia, the half-life of ketamine was significantly increased, and the plasma levels of the hydroxylated metabolites of keta-

mine were reduced. These findings suggest that both pharmacodynamic and pharmacokinetic interactions exist between **diazepam** and ketamine. In the same study, 3 patients were given 20 mg of intravenous **clorazepate** about one hour before induction of anaesthesia, but this did not affect either the dose of ketamine required or its pharmacokinetics.[2]

(c) Propofol

Two studies found that if propofol and **midazolam** were given together, the hypnotic and anaesthetic effects were greater than would be expected by the simple additive effects of both drugs.[3,4] In one of these studies, the ED_{50} (the dose required for 50% of the patients to respond) for hypnosis was 44% less than that expected with the individual drugs and the addition of **midazolam** 130 micrograms/kg caused a 52% reduction in the ED_{50} of propofol required for anaesthesia.[3] A pharmacokinetic study found a very modest 20% increase in the levels of free **midazolam** in the plasma when it was given with propofol, but this was considered too small to explain the considerable synergism.[5] In a further placebo-controlled study in 24 patients, premedication with intravenous **midazolam**, 50 micrograms/kg given 20 minutes before induction of anaesthesia, reduced the propofol dose requirements for multiple anaesthetic end-points, including hypnotic, motor, EEG and analgesia. However, the potentiating effect and the mechanism of the interaction appeared to vary with the anaesthetic end-point and the dose of propofol. Notably, the interaction was most marked for analgesia.[6] Another placebo-controlled study in 60 children aged 1 to 3 years found that oral **midazolam** 500 micrograms/kg approximately 30 minutes before the induction of anaesthesia delayed early recovery from anaesthesia, which was induced with propofol and maintained with **sevoflurane** and **nitrous oxide**/**oxygen**. However, the time to hospital discharge was not prolonged.[7]

A further placebo-controlled study in 24 patients found that propofol decreased the clearance of **midazolam** by 37% and increased its elimination half-life by 61%.[8]

A study in 33 patients found that **quazepam** 15 or 30 mg given the night before induction of anaesthesia with propofol and fentanyl reduced the induction time when compared with a third group of patients not given a hypnotic. **Quazepam** did not affect blood pressure or heart rate, but the 30 mg dose of **quazepam** did increase anterograde amnesia.[9]

(d) Thiopental

Thiopental has been shown to act synergistically with **midazolam** at induction of anaesthesia in two studies.[10,11] In one of these studies, **midazolam** reduced the dose of thiopental required to produce anaesthesia by 50%.[11] In a further placebo-controlled study in 23 patients, premedication with intravenous **midazolam** 50 micrograms/kg, given 20 minutes before the induction of anaesthesia, reduced the thiopental dose requirements for multiple anaesthetic end-points, including hypnotic, motor, EEG and analgesia. Potentiation was greatest for the motor end-point (about 40%) and smallest for analgesia (18%).[12]

Mechanism

Propofol, barbiturates and halothane appear to interact with benzodiazepines through their effects on the GABA receptor.

Diazepam appears to undergo similar oxidative processes as ketamine and therefore competitively inhibits ketamine metabolism.[2] Clorazepate is only slowly decarboxylated and is therefore not affected.[2]

An *in vitro* study suggests that propofol may reduce the clearance of midazolam by inhibition of the cytochrome P450 isoenzyme CYP3A4.[8]

Importance and management

The interactions between propofol or thiopental and midazolam are well established. This synergy has been utilised for the induction of anaesthesia.[13] Midazolam also reduces the dose requirements of halothane. Other benzodiazepines may also potentiate the effects of general anaesthetics. In general this may reduce the dose of anaesthetic required and/or slow recovery from the anaesthetic. In many cases this interaction is exploited clinically.

Anaesthetics, general + Beta-agonist bronchodilators

Arrhythmias developed in two patients anaesthetised with halothane when terbutaline was given.

Clinical evidence, mechanism, importance and management

Two patients developed ventricular arrhythmias while anaesthetised with **halothane** and nitrous oxide/oxygen when given **terbutaline** 250 to 350 micrograms subcutaneously for wheezing. Both developed unifocal premature ventricular contractions followed by bigeminy, which responded to lidocaine.[1] **Halothane** was replaced by **enflurane** in one case, which allowed the surgery to be completed without further incident.[1]

Halothane is known to cause arrhythmias and it has been suggested that it may increase susceptibility to the adverse cardiac effects of beta-agonist bronchodilators,[2] which can cause arrhythmias. A number of inhalational anaesthetics have been associated with arrhythmias. For a list, in order of arrhythmogenic potential, see 'Anaesthetics and Neuromuscular blockers', (p.100). This interaction is therefore, in theory, possible with any of these anaesthetics and a $beta_2$-agonist bronchodilator, although the case above appears to be the only one reported.

Anaesthetics, general + Beta blockers

Anaesthesia in the presence of beta blockers normally appears to be safer than withdrawal of the beta blocker before anaesthesia, provided certain inhalational anaesthetics are avoided (methoxyflurane, cyclopropane, trichloroethylene) and atropine is used to prevent bradycardia. Bradycardia and marked hypotension occurred in a man using timolol eye drops when he was anaesthetised.

Acute peri-operative administration of beta blockers may reduce the dose of anaesthetic required for induction and may result in deeper anaesthesia.

Clinical evidence and mechanism

A. Cardiac depressant effects

It used to be thought that beta blockers should be withdrawn from patients before surgery because of the risk that their cardiac depressant effects would be additive with those of inhalational anaesthetics, resulting in a reduction in cardiac output and blood pressure, but it seems that any effect depends on the anaesthetic used.[1] It has been suggested that the ranking order of compatibility (from the least to the most compatible with beta blockers) is as follows: **methoxyflurane**, **cyclopropane**, **trichloroethylene**, **enflurane**, **halothane**, **isoflurane**.[1] This review pre-dated the advent of newer anaesthetics, such as sevoflurane.

(a) Cyclopropane, Methoxyflurane, and Trichloroethylene

A risk of cardiac depression certainly seems to exist with cyclopropane because its depressant effects on the heart are normally counteracted by the release of catecholamines, which would be blocked by the presence of a beta blocker. There is also some evidence (clinical and/or *animal*) that unacceptable cardiac depression may occur with methoxyflurane and trichloroethylene when a beta blocker is present. This has been the subject of two reviews.[2,3] For these three inhalational anaesthetics it has been stated that an absolute indication for their use should exist before giving them in combination with a beta blocker.[1]

(b) Enflurane, Halothane, and Isoflurane

Although a marked reduction in cardiac performance has been described in a study in *dogs* given **propranolol** and enflurane (discussed in two reviews[2,3]) these drugs have been widely used without apparent difficulties.[1] Normally beta blockers and halothane or isoflurane appear to be safe.

(c) Methohexital and Propofol

A study on the effects of adding a beta blocker to anaesthesia was undertaken in 80 patients who were given oxycodone and atropine as pre-medication and then anaesthetised with either methohexital or propofol, either alone or with **esmolol**. The QTc intervals were recorded before any drugs were given and after the administration of propofol or methohexital alone or with esmolol. The addition of **esmolol** to either methohexital or propofol significantly shortened the QTc interval. The heart rate tended to decrease in the propofol plus **esmolol** group. Blood pressure decreased significantly in all four groups but diastolic pressure was significantly lower in the propofol plus **esmolol** group, when compared with the other groups. It was concluded that haemodynamic responses were controlled with methohexital plus **esmolol** or propofol alone, but that propofol plus **esmolol** tended to cause haemodynamic depression.[4]

(d) Unnamed general anaesthetic

A 75-year-old man being treated with **timolol** eye drops for glaucoma developed bradycardia and severe hypotension when anaesthetised and responded poorly to intravenous atropine, dextrose-saline infusion and elevation of his feet.[5] It would seem that there was sufficient systemic absorption of the **timolol** for its effects to be additive with the anaesthetic and cause marked cardiodepression.

B. Reduction of anaesthetic requirements

(a) Atenolol

Intra-operative intravenous atenolol given in 5 mg stepwise doses (median dose 20 mg; range 10 to 80 mg) was found to reduce the **isoflurane** requirement by about 40% without affecting the bispectral index (a predictor of the depth of anaesthesia). Patients also received on average 21% less fentanyl compared with control patients who were not given atenolol.[6]

(b) Esmolol

Several studies have found that the use of esmolol reduces the required dose of **isoflurane** or **propofol**, or results in a deeper anaesthesia (as measured by BIS), but only in the presence of an opioid.[7-11] As there appears to be no pharmacokinetic interaction between esmolol and **propofol**[7,9] it has been suggested that esmolol could be interacting with the opioid.[7,11]

However, in one study 60 patients were given one of three treatments before induction of anaesthesia with **propofol**: esmolol 1 mg/kg followed by an infusion of 250 micrograms/kg per minute; midazolam; or placebo (sodium chloride 0.9%). No opioids were given. Esmolol and midazolam reduced the required induction doses of **propofol** by 25% and 45%, respectively. Esmolol reduced the mean heart rate by 7.6 bpm in the pre-induction period, when compared with placebo, and the only adverse effect noted was a transient episode of bradycardia (44 bpm) in one patient receiving esmolol.

Esmolol reduces cardiac output by reduction of heart rate and stroke volume and this possibly reduces the required induction dose of **propofol** by changing its distribution.[12]

Another study found that a single 80-mg dose of esmolol after induction of anaesthesia with **propofol** and either fentanyl or placebo did not affect the depth of anaesthesia (measured by bispectral index; a predictor of the depth of anaesthesia) in either group of patients, even though cardiovascular effects were seen (reduction in systolic arterial pressure and heart rate).[13]

Importance and management

The consensus of opinion is that beta blockers should not be withdrawn before anaesthesia and surgery[14,15] because of the advantages of maintaining beta-blockade, and because the risks accompanying withdrawal are considerable. But, if inhalational anaesthetics are used, it is important to select the safest anaesthetics (isoflurane, halothane), and avoid those that appear to be most risky (methoxyflurane, cyclopropane, trichloroethylene: most of which are no longer regularly used), as well as ensuring that the patient is protected against bradycardia by atropine. The manufacturers of bisoprolol, labetalol, nadolol and sotalol recommend avoiding anaesthetics such as cyclopropane and trichloroethylene,[16-19] as they cause myocardial depression,[16,17] and note that labetalol may increase the hypotensive effects of halothane.[16]

Although most manufacturers do not contraindicate the continuation of beta blockers during anaesthesia, many do recommend a specific withdrawal period if a clinical decision is made to discontinue beta blockade:

- **Acebutolol**,[20] **atenolol**,[21] **labetalol**,[16] **nebivolol**,[22] **propranolol**,[23] and **timolol**[24] should be discontinued for at least 24 hours before the procedure.
- The dose of **bisoprolol**[17,25] and **metoprolol**[26,27] should be gradual reduced and stopped at least 24 to 48 hours before anaesthesia.
- The dose of **celiprolol**[28] and **oxprenolol**[29] should be gradually reduced and stopped at least 48 hours before anaesthesia.
- One manufacturer of **sotalol**[18] advises that it may be stopped 4 days before surgery.
- **Nadolol**[19] and **pindolol**[30] should be gradually withdrawn several days before surgery.

The manufacturers of nadolol state that in no circumstances should beta blockers be discontinued before surgery in patients with phaeochromocytoma or thyrotoxicosis.[19]

The authors of the report[5] concerning topically applied beta blockers suggest that if such patients are to be anaesthetised, low concentrations of timolol should be used (possibly withhold the drops pre-operatively), and that "induction agents should be used judiciously and beta-blocking antagonists kept readily available." It is easy to overlook the fact that systemic absorption from eye drops can be high enough to cause adverse interactions.

There appear to be considerable benefits to be gained from the continued use of beta blockers during anaesthesia. Their sudden withdrawal from patients treated for angina or hypertension can result in the development of acute and life-threatening cardiovascular complications whether the patient is undergoing surgery or not. In the peri-operative period patients benefit from beta blockade because it can minimise the effects of sympathetic overactivity of the cardiovascular system during anaesthesia and surgery (for example during endotracheal intubation, laryngoscopy, bronchoscopy and various surgical manoeuvres), which can cause cardiac arrhythmias and hypertension.

Although several studies suggest that beta blockers, such as atenolol and esmolol, given before induction reduce the anaesthetic dose requirement and may potentiate hypnosis there are concerns that reducing the dose of anaesthetic may increase the risk of intra-operative awareness, and it has been suggested that the use of BIS to predict the depth of anaesthesia in the presence of beta blockers may not be valid.[31] There is a possibility that acute as well as chronic administration of beta blockers may prevent peri-operative cardiac complications,[13,15] but more study is needed on this.[15,31]

Anaesthetics, general + Calcium-channel blockers

Impaired myocardial conduction has been seen in two patients taking diltiazem after they were anaesthetised with enflurane, and prolonged anaesthesia has been seen when patients taking verapamil were anaesthetised with etomidate, but it has been suggested that chronic administration of oral calcium-channel blockers up to the day of surgery is usually beneficial. Intravenous dihydropyridines have been used to control peri-operative hypertension, but the use of intravenous verapamil is not recommended in patients anaesthetised with either halothane or enflurane.

Clinical evidence, mechanism, importance and management

(a) Dihydropyridines

Enhanced hypotension was seen in a study in which patients were given intravenous **nimodipine** during general anaesthesia involving **halothane** or **isoflurane**.[1]

The presence of low concentrations of **isoflurane** (0.6%) or **sevoflurane** (0.9%) are reported not to have a marked effect on the pharmacological action of **nicardipine**.[2] In one study intravenous **nicardipine** 17 micrograms/kg was given to 30 neurosurgical patients anaesthetised with either **enflurane**, **isoflurane** or **sevoflurane**. Peak reductions in blood pressure occurred 3 minutes after **nicardipine** was given, and were greatest in the group receiving **sevoflurane**. However, with **isoflurane** peak reductions in blood pressure persisted for longer (30 minutes), as did increases in heart rate, even though the clearance of **nicardipine** was most rapid in patients given **isoflurane**.[3]

Some caution is clearly appropriate, especially with intravenous calcium-channel blockers given during surgery, but general experience suggests that long-term treatment with *oral* dihydropyridine calcium-channel blockers need not be avoided in most patients undergoing anaesthesia, and may be continued until the day of surgery. Further, *intravenous* dihydropyridines have been reported to be safe and effective for the control of peri-operative hypertension.[4]

(b) Diltiazem or Verapamil

The author of a review about calcium-channel blockers and anaesthetics concludes that their concurrent use in patients with reasonable ventricular function is normally beneficial, except where there are other complicating factors. Thus he warns about possible decreases in ventricular function in patients undergoing open chest surgery given *intravenous* verapamil or diltiazem.[5] A report describes a patient taking diltiazem and atenolol who had impaired AV and sinus node function before anaesthesia, which worsened following the use of **enflurane**.[6] Another patient taking diltiazem (and atenolol) had to be paced due to bradycardia of 35 bpm at induction, but despite this he developed severe sinus bradycardia, which progressed to asystole when **enflurane** was given.[6] The authors of this latter report suggest that **enflurane** and diltiazem can have additive depressant effects on myocardial conduction. The presence of low concentrations of **isoflurane** (0.6%) or **sevoflurane** (0.9%) are reported not to have a marked effect on the pharmacological action of diltiazem.[2] Two cases of prolonged anaesthesia and Cheyne-Stokes respiration have been reported in patients who were undergoing cardioversion. Both received verapamil and were induced with **etomidate**.[7] One manufacturer states that concurrent use of verapamil and inhalational anaesthetics is not recommended.[8]

The authors of a review concluded that *intravenous* verapamil or diltiazem are not recommended in patients anaesthetised with either **halothane** or **enflurane**, especially if the patients have cardiac failure or conduction disturbances.[9]

Anaesthetics, general + Clonidine

Clonidine significantly attenuates the responses to hypercapnia in patients anaesthetised with propofol, but not with isoflurane. Clonidine reduces the dose of thiamylal required for induction of anaesthesia.

Clinical evidence, mechanism, importance and management

Note that additive hypotensive effects are theoretically possible in patients taking clonidine who are given general anaesthetics.

(a) Propofol or Isoflurane

In a study, 60 patients were premedicated with famotidine or famotidine with clonidine 5 micrograms/kg, and anaesthesia was induced with propofol and vecuronium, and maintained with either isoflurane or propofol. The cardiovascular responses (mean arterial pressure, heart rate and cardiac index) to hypercapnia were significantly attenuated in the patients given clonidine and propofol, when compared with those given propofol without clonidine or isoflurane with or without clonidine.[1]

(b) Thiamylal

In a double-blind study 60 children were given either oral clonidine 2 micrograms/kg, 4 micrograms/kg or placebo, 105 minutes before induction of anaesthesia with thiamylal 1% at a rate of 1 mg/kg every 15 seconds until completion of induction (assessed by loss of eyelash reflex). The thiamylal dose required for induction was 5.4 mg/kg, 4.5 mg/kg, and 3.4 mg/kg in the placebo, clonidine 2 micrograms/kg and clonidine 4 micrograms/kg groups respectively, indicating a dose-dependent clonidine reduction in thiamylal requirements. Systolic blood pressure decreased by 6.8%, 5.6%, and 6.6% and heart rate increased by 5.7%, 4.8%, and 4.1% with placebo, clonidine 2 micrograms/kg and 4 micrograms/kg, respectively. The authors note that smaller doses of

thiamylal may be needed if given as a bolus dose rather than by incremental administration.[2] In an earlier report, there was a greater decrease in blood pressure in children given a bolus dose of thiamylal 5 mg/kg with clonidine 4 micrograms/kg than those given thiamylal with diazepam.[3]

Anaesthetics, general + Dexmedetomidine

Dexmedetomidine may reduce the dose requirements of thiopental, isoflurane, propofol and probably other anaesthetics. In an *animal* study, the analgesic effects of nitrous oxide were increased by dexmedetomidine.

Clinical evidence, mechanism, importance and management

Dexmedetomidine reduced the **thiopental** dose requirement for EEG burst suppression by 30% in 7 patients, when compared with 7 control patients given placebo. In this study, dexmedetomidine was given for 35 minutes before anaesthesia and during anaesthesia at a dose of 100 nanograms/kg per minute for the first 10 minutes, 30 nanograms/kg per minute for the following 15 minutes, and 6 nanograms/kg per minute thereafter. There was no pharmacodynamic synergism, and pharmacokinetic analysis showed that dexmedetomidine significantly reduced the **thiopental** distribution, probably due to reduced cardiac output and decreased regional blood flow.[1]

A placebo-controlled study in women undergoing abdominal hysterectomy found that a dexmedetomidine infusion started 15 minutes before induction of anaesthesia caused a dose-dependent reduction in the **isoflurane** MAC (by 35% and 47%, with dexmedetomidine plasma levels maintained at 0.37 nanograms/mL and 0.69 nanograms/mL, respectively).[2] In another study, in 9 healthy subjects, dexmedetomidine reduced the ED_{50} dose requirement of **isoflurane** for anaesthesia (motor response). Dexmedetomidine plasma levels of 0.35 nanograms/mL and 0.75 nanograms/mL reduced the requirements for **isoflurane** by about 30% and 50%, respectively. Subjects who had received dexmedetomidine took longer to wake up.[3]

In a study, 9 healthy subjects were given stepwise increases in **propofol** concentrations (1 to 13.8 micrograms/mL) 45 minutes after the start of either dexmedetomidine or placebo infusions.[4] Dexmedetomidine did not significantly affect the pharmacokinetics of **propofol**; however, the concurrent use of dexmedetomidine reduced the **propofol** concentration required for sedation by 65 to 80% and reduced the **propofol** concentration required for suppression of motor responses by 40%. It was suggested that the **propofol** dose for sedation and induction may have to be reduced in the presence of dexmedotomidine.[4] Another study in 40 patients given a mean dose of intravenous dexmedetomidine of 63 nanograms/kg found that concurrent use reduced the concentration and dose of **propofol** required to produce loss of consciousness.[5]

An *animal* study found that the analgesic effects of **nitrous oxide** were enhanced by dexmedetomidine.[6]

Dexmedetomidine has sedative, analgesic and anxiolytic effects[7] and therefore, like other sedatives, may reduce the dose requirements of anaesthetics. However, it may also affect the distribution of **thiopental** and possibly other **intravenous anaesthetics**.

Anaesthetics, general + Enzyme inducers

A child developed phenytoin toxicity following halothane anaesthesia, a near fatal hepatic reaction occurred in a woman given rifampicin (rifampin) after halothane anaesthesia, and hepatitis occurred in a patient taking phenobarbital who was given halothane anaesthesia.

Clinical evidence

A 10-year-old girl receiving long-term treatment with phenytoin 300 mg daily was found to have **phenytoin** plasma levels of 25 micrograms/mL before surgery. Three days after anaesthesia with **halothane** her plasma **phenytoin** levels had risen to 41 micrograms/mL and she had marked signs of **phenytoin** toxicity.[1]

A woman taking promethazine and **phenobarbital** 60 mg three times daily died from **halothane**-associated hepatitis within 6 days of being given **halothane** for the first time.[2]

A nearly fatal, shock-producing hepatic reaction occurred in a woman 4 days after she was given **halothane** anaesthesia immediately followed by a course of **rifampicin** 600 mg daily and isoniazid 300 mg daily.[3]

Mechanism

It seems possible that the general adverse hepatotoxic effects of halothane can slow the normal rate of phenytoin metabolism. One suggested explanation for the increased adverse effects on the liver is that, just as in *animals*, pre-treatment with phenobarbital and phenytoin increases the rate of drug metabolism and therefore increases the levels of the hepatotoxic metabolites of halothane and other halogenated hydrocarbons.[4,5] As well as increased metabolism, the halothane-rifampicin interaction might also involve additive hepatotoxicity.

Importance and management

No firm conclusions can be drawn from these isolated cases, but they serve to emphasise the potential hepatotoxicity when halogenated anaesthetics are given to patients taking these drugs. It has been suggested that patients taking enzyme-inducing drugs (such as phenobarbital and phenytoin) may constitute a high-risk group for liver damage after halogenated anaesthetics.[6] Consider also 'Anaesthetics, general + Isoniazid', p.112, and 'Anaesthetics, general; Methoxyflurane + Miscellaneous', p.120.

Anaesthetics, general + Herbal medicines

There are two isolated reports, of profound hypotension during anaesthesia, and of prolonged anaesthesia, following the long-term use of St John's wort. A report describes increased bleeding, which was tentatively attributed to the concurrent use of sevoflurane and aloe vera. The American Society of Anesthesiologists recommends that all herbal medicines should be stopped two weeks before elective surgery.

Clinical evidence and mechanism

(a) Aloe vera

A case report describes a 35-year-old woman undergoing surgery for a haemangioma of the left thigh, who had twice the expected intra-operative blood loss. The patient had been taking 4 tablets of aloe vera for 2 weeks before surgery, and so the blood loss was attributed to an interaction between the herbal medicine and **sevoflurane**, which was used to maintain anaesthesia.[1] **Sevoflurane** can inhibit platelet aggregation by inhibiting

thromboxane A_2, and aloe vera affects prostaglandin synthesis, which may also impair platelet aggregation. However, it should be noted that the patient's aPTT and INR were not assessed pre-operatively and the authors do state that the vascularity and size of the haemangioma were the most important factors in the blood loss,[1] so an interaction is by no means proven.

(b) Kava

There is one case report of kava potentiating the effect of benzodiazepines (see 'Benzodiazepines + Kava', p.852), and it has been suggested that it could potentiate other CNS depressants including **barbiturates**[2,3] (e.g. **thiopental**), and may prolong or potentiate the effects of anaesthetics.[4-6] Kava may act via GABA receptors, and kavalactones (one group of active constituents) also have skeletal muscle relaxant and local anaesthetic properties.[2,3] Toxic doses can produce muscle weakness and paralysis.[2,3]

(c) St John's wort (Hypericum perforatum)

It has been suggested that St John's wort may prolong anaesthesia.[4-7] The prediction appears to have been based on the possibility that St John's wort acts as an MAOI,[5,7,8] (although this has been disputed[9]) and the limited evidence that MAOIs may cause hepatic enzyme inhibition and potentiate the effects of barbiturates (see 'MAOIs + Barbiturates', p.1372). However, there is now increasing evidence that St John's wort induces hepatic enzymes, and might therefore increase the metabolism of barbiturates (see 'Antiepileptics + St John's wort (*Hypericum perforatum*)', p.598). This suggests that it could in fact increase requirements for **thiopental** anaesthesia. However, prolonged anaesthesia has been reported in a 21-year-old woman who had been taking St John's wort 1 g three times daily for 3 months before general anaesthetics were given for the surgical removal of an abscess. Anaesthesia was induced by intravenous **fentanyl citrate** 1 microgram/kg and **propofol** 3 mg/kg, and maintained throughout the procedure by **sevoflurane** and **nitrous oxide** using a face mask.[10]

The possible MAOI activity of St John's wort has led to the recommendation that the same considerations apply as for other MAOIs and general anaesthetics,[7,8] see 'Anaesthetics, general + MAOIs and related drugs', p.112.

Another case report describes a healthy 23-year-old woman who had been taking St John's wort on a daily basis for 6 months, who developed severe hypotension (BP 60/20 mmHg) during general anaesthesia, which responded poorly to ephedrine and phenylephrine (BP increased to 70/40 mmHg). It was suggested that the St John's wort might have caused adrenergic desensitisation with decreased responsiveness to the vasopressors.[11]

Importance and management

Not established. The evidence presented suggests that some caution may be warranted in patients using kava, or St John's wort if they are given general anaesthetics. The situation with aloe vera is less clear. Many other herbs have the potential to cause problems in the care of patients undergoing surgery (other than via drug interactions with anaesthetics) and these have been reviewed.[5-7] Because of the limited information, the American Society of Anesthesiologists have recommended discontinuation of all herbal medicines 2 weeks before an elective anaesthetic[4,6] and if there is any doubt about the safety of a product, this may be a prudent precaution.[5]

Anaesthetics, general + Inotropes and Vasopressors

Patients anaesthetised with inhalational anaesthetics (particularly cyclopropane and halothane, and to a lesser extent desflurane, enflurane, isoflurane, methoxyflurane, and sevoflurane) can develop cardiac arrhythmias if they are given adrenaline (epinephrine) or noradrenaline (norepinephrine), unless the dosages are very low. Children appear to be less susceptible to this interaction. The addition of adrenaline to intrathecal tetracaine enhances the sedative effects of propofol.

Clinical evidence, mechanism, importance and management

As early as 1895, it was noted that an adrenal extract could cause ventricular fibrillation in a *dog* anaesthetised with **chloroform**,[1] and it is now very well recognised that similar cardiac arrhythmias can be caused by **adrenaline** (**epinephrine**) and **noradrenaline** (**norepinephrine**) in humans anaesthetised with **inhalational anaesthetics**. The mechanism appears to be a sensitisation of the myocardium to β-adrenergic stimulation, caused by the **inhalational anaesthetic**. The likelihood of arrhythmias is increased by hypoxia and marked hypercapnia. It has been reported that the highest incidence of complications has been in patients anaesthetised with **cyclopropane**, but that the incidence is also high with **trichloroethylene** and **halothane**.[2] A suggested listing of inhalational anaesthetics in order of decreasing sensitising effect on the myocardium is as follows:[3] **cyclopropane**, **halothane**, **enflurane**/**methoxyflurane**, **isoflurane**. **Sevoflurane**[4] and **desflurane**[5] appear to behave like **isoflurane**. Similarly, others consider that if **adrenaline** is used for haemostasis during surgery, **isoflurane** or **sevoflurane** carry less risk of cardiac arrhythmias than **halothane**.[6]

It has been recommended that if **adrenaline** is used to reduce surgical bleeding in patients anaesthetised with **halothane**/**nitrous oxide**/**oxygen**, the dosage of **adrenaline** should not exceed 10 mL of 1:100 000 in any given 10 minute period, or 30 mL per hour (i.e. about a 100 microgram bolus or 1.5 micrograms/kg per 10 minutes for a 70 kg person), and adequate alveolar ventilation must be assured.[7] This dosage guide should also be safe for use with other inhalational anaesthetics since **halothane** is more arrhythmogenic than the others,[3] with the exception of **cyclopropane**, which is no longer widely used. However, some have suggested that the concurrent use of **halothane** and **adrenaline** may have been a contributing factor in 3 deaths in patients undergoing tooth implant surgery.[8] Solutions containing **lidocaine** 0.5% with **adrenaline** 1:200 000 also appear to be safe because lidocaine may help to control the potential dysrhythmic effects. For example, a study in 19 adult patients anaesthetised with **halothane** found that the dose of **adrenaline** needed to cause three premature ventricular contractions in half the group was 2.11 micrograms/kg when it was given in sodium chloride 0.9% but 3.69 micrograms/kg when it was given in **lidocaine** 0.5%. Note that both these values were less than that in 16 patients anaesthetised with **isoflurane** (6.72 micrograms/kg), demonstrating that **isoflurane** was still safer.[9] It should be borne in mind that the arrhythmogenic effects of **adrenaline** are increased if sympathetic activity is increased, and in hyperthyroidism and hypercapnia.[3]

Children appear to be much less susceptible to these effects than adults. A retrospective study of 28 children found no evidence of arrhythmia during **halothane** anaesthesia, with **adrenaline** doses of up to 8.8 micrograms/kg, and a subsequent study in 83 children (aged 3 months to 17 years) found that 10 micrograms/kg doses of **adrenaline** were safe.[10]

A study in 20 patients undergoing spinal anaesthesia with tetracaine found that **propofol** sedation (as measured by bispectral index monitoring (BIS)) was enhanced when **adrenaline** was added to the intrathecal tetracaine.[11] A study in *sheep* found that **adrenaline**, **noradrenaline** and **dopamine** decreased **propofol** concentrations during a continuous propofol infusion, with the result that **propofol** anaesthesia was reversed. This was thought to be due to increased first pass clearance of **propofol** secondary to increased cardiac output. It was concluded that this could be of clinical importance if **propofol** is used in hyperdynamic circulatory conditions induced by catecholamine infusions or disease states such as sepsis.[12]

Anaesthetics, general + Isoniazid

Isoniazid may increase the metabolism of enflurane, isoflurane or sevoflurane and thereby increase plasma-fluoride concentrations.

Clinical evidence, mechanism, importance and management

A 46-year-old woman underwent anaesthesia for renal transplantation 6 days after starting to take isoniazid 300 mg daily. Anaesthesia was induced with intravenous thiopental and maintained for 4 hours with 60% nitrous oxide, fentanyl and **isoflurane**. Serum fluoride ions increased, from 4.3 micromol preoperatively, to approximately 30 micromol between 2 and 8 hours after starting **isoflurane**. However, no impairment of renal function occurred. A second patient who was given 5 times the first patient's exposure to **isoflurane** and who had received isoniazid for 13 years had no increase in serum fluoride concentrations over preoperative values, but did show an increase in tri*fluoro*acetic acid levels.[1]

When **enflurane** was given to 20 patients who had been taking isoniazid 300 mg daily for between one week and one year, 9 had an increase in peak fluoride ion levels. These 9 patients had a fourfold higher fluoride level than both 36 control subjects not taking isoniazid and 11 other subjects taking isoniazid only. By 48 hours after anaesthesia, there was no difference in fluoride levels. Despite the increase in fluoride levels, there was no change in renal function.[2]

Isoniazid may increase the metabolism of **enflurane**, **isoflurane** or **sevoflurane**[3,4] in some patients (probably related to isoniazid acetylator phenotype[2]) and so increase the release of fluoride ions that may cause nephrotoxicity. However, there do not appear to be any reports of this resulting in a significant clinical effect on renal function.

Anaesthetics, general + Levothyroxine

Two patients taking levothyroxine developed marked hypertension and tachycardia when they were given ketamine.

Clinical evidence, mechanism, importance and management

Two patients taking levothyroxine developed severe hypertension (240/140 mmHg and 210/130 mmHg, respectively) and tachycardia (190 bpm and 150 bpm) when they were given **ketamine**. Both were effectively treated with 1 mg of intravenous propranolol.[1] It was not clear whether this was an interaction or simply a particularly exaggerated response to **ketamine**, but care is clearly needed if **ketamine** is given to patients receiving thyroid replacement therapy.

1. Kaplan JA, Cooperman LH. Alarming reactions to ketamine in patients taking thyroid medication — treatment with propranolol. *Anesthesiology* (1971) 35, 229–30.

Anaesthetics, general + MAOIs and related drugs

It is generally recommended that MAOIs should be withdrawn at least 2 weeks before anaesthesia. Individual cases of both hypo- and hypertension have been seen and MAOIs can interact dangerously with other drugs sometimes used during surgery (particularly pethidine (meperidine) and ephedrine).

Clinical evidence

The absence of problems during emergency general anaesthesia in 2 patients taking MAOIs prompted further study in 6 others receiving long-term treatment with unnamed MAOIs. All 6 were premedicated with 10 to 15 mg of diazepam 2 hours before surgery, induced with **thiopental**, given suxamethonium (succinylcholine) before intubation, and maintained with **nitrous oxide**/**oxygen** with either **halothane** or **isoflurane**. Pancuronium was used for muscle relaxation, and morphine was given postoperatively. One patient experienced hypotension that responded to repeated 100-microgram intravenous doses of phenylephrine without hypertensive reactions. No other untoward events occurred either during or after the anaesthesia.[1]

A retrospective review of 32 patients taking **isocarboxazid** 10 mg daily who underwent elective surgery (involving **thiopental** or **ketamine** for induction of anaesthesia and maintenance with an inhalation anaesthetic with or without a muscle relaxant or analgesic) found that 5 patients experienced intra-operative hypotension, another patient developed hypertension, and bradycardia occurred in 4 patients. No postoperative complications were attributed to the interaction between the MAOI and the drugs given peri-operatively.[2]

Unexplained hypertension has been described in a patient taking **tranylcypromine** when **etomidate** and atracurium were given.[3] Severe and prolonged cardiovascular collapse occurred in one patient in whom long-term **tranylcypromine** 10 mg four times daily was discontinued 20 days before surgery. During surgery **etomidate** and suxamethonium were given for induction, and **isoflurane** and **nitrous oxide**/**oxygen** for maintenance, as well as epidural anaesthesia with bupivacaine, but without an opioid.[4]

Further reports describe a lack of adverse reactions in:

- 27 patients taking MAOIs (**tranylcypromine**, **phenelzine**, **isocarboxazid**, **pargyline**) when they were anaesthetised,[5]
- 2 patients taking **phenelzine** and anaesthetised with **propofol**,[6,7]
- 3 patients taking **tranylcypromine** or **phenelzine** and anaesthetised with **propofol** (and alfentanil),[8,9]
- one patient taking **tranylcypromine** when **ketamine** was given,[10]
- one patient taking **phenelzine** when anaesthetised with **sevoflurane**, then **isoflurane**, and an infusion of remifentanil.[11]

Further case reports describe the uneventful use of selective MAOIs in patients undergoing general anaesthesia: one patient taking **selegiline** was uneventfully anaesthetised with fentanyl, **isoflurane** and midazolam,[12] and **moclobemide** was stopped on the morning of surgery in a patient who was anaesthetised with **propofol** and later **isoflurane** in **nitrous oxide** and oxygen. Atracurium, morphine and droperidol were also used.[13]

Mechanism, importance and management

There seems to be little documentary evidence that the withdrawal of MAOIs before giving an anaesthetic is normally necessary. Scrutiny of reports[14] alleging an adverse reaction usually shows that what happened could be attributed to an interaction between the MAOI and other drugs used during the surgery (e.g. either 'directly-acting sympathomimetics', (p.1388), 'indirectly-acting sympathomimetics', (p.1388), 'pethidine (meperidine)', (p.1381), or 'fentanyl', (p.1380)) rather than with the anaesthetics.

The authors of two of the reports cited here offer the opinion that 'general and regional anaesthesia may be provided safely without discontinuation of MAOI therapy, provided proper monitoring, adequate preparation, and prompt treatment of anticipated reactions are utilised'.[1,5] This implies that the possible interactions between the MAOI and other drugs are fully recognised, but be alert for the rare unpredictable response. The conclusion of another report was that patients on low-dose MAOIs could be safely anaesthetised.[2]

The BNF[15] states that 'in view of their hazardous interactions MAOIs should normally be stopped 2 weeks before surgery.' It has also been sug-

gested that a longer period of time (more than 20 days) between discontinuing MAOIs and surgery may be required, not so much to recover MAO enzyme activity but to recover depressed adrenergic receptor function.[4] These warnings are probably more to avoid interactions with the anaesthetic adjuncts mentioned above, rather than the MAOIs themselves. Therefore in an emergency situation it would seem possible to anaesthetise a patient, but it must be remembered that the choice of anaesthetic adjuncts is likely to be restricted.

Anaesthetics, general + Melatonin

Melatonin slightly reduces the dose of propofol needed for the induction of anaesthesia.

Clinical evidence

A study in 45 adult patients found that the induction dose of intravenous **propofol**, as measured by bispectral index and loss of eyelash reflex, was 15% lower in patients who had received a single 3- or 5-mg oral dose of melatonin 100 minutes preoperatively, compared with patients who had received placebo. The time to recover from the anaesthetic was not affected by premedication with melatonin. **Propofol** was given in an incremental dose fashion in this study so that any difference could be assessed, but is usually given as a bolus dose.[1]

Mechanism

Melatonin appears to have anxiolytic and sedative effects, which might reduce the required induction dose of propofol.

Importance and management

This study was conducted to assess the clinical value of using melatonin premedication, which is not an established use. The reduction in required dose of propofol was small, and on the basis of these data, it is unlikely that any untoward effects would be seen in the situation where a patient who had recently taken a melatonin supplement was anaesthetised with propofol.

Anaesthetics, general + Methylphenidate

A single report described difficulty in sedating a child taking methylphenidate, and a possible delayed interaction between ketamine and methylphenidate, which resulted in nausea, vomiting and dehydration. The use of methylphenidate after ketamine anaesthesia increased the incidence of vomiting, excessive talking, and limb movements in one study. Methylphenidate should probably be withheld before anaesthesia with inhalational anaesthetics, because of the potential risk of hypertension and/or arrhythmias.

Clinical evidence, mechanism, importance and management

A 6-year-old boy weighing 22 kg, who was taking methylphenidate 5 mg twice daily for attention deficit disorder, was found to be difficult to sedate for an echocardiogram. Sedation was attempted with oral cloral hydrate 75 mg/kg without success. One week later he received midazolam 20 mg orally, but was only mildly sedated 20 minutes later and would not lie still. Despite an additional oral dose of midazolam 10 mg mixed with oral **ketamine** 60 mg the child was still alert and uncooperative 20 minutes later. He was finally given intravenous glycopyrronium (glycopyrrolate) 100 micrograms followed by intravenous midazolam 5 mg given over 5 minutes and was successfully sedated. He recovered from sedation uneventfully, but developed nausea, vomiting and lethargy after discharge from hospital, which responded to rehydration treatment.[1] In a double-blind study, methylphenidate was given as a single 20-mg intravenous dose to try to speed recovery at the end of **ketamine** anaesthesia for short urological procedures. However, methylphenidate did not improve recovery, and increased the incidence of vomiting, excessive talking, and limb movements.[2]

In the first case, the stimulant effect of methylphenidate was thought to have antagonised the sedative effect of the midazolam and **ketamine**. It has been suggested that methylphenidate may also have delayed the absorption of the oral drugs, and inhibited liver microsomal enzymes delaying the elimination of both **ketamine** and midazolam. These effects may have resulted in hazardous plasma concentrations;[1] however, the study did not find evidence of these effects.

These appear to be the only reports, so any effect is not established. Be aware that methylphenidate may possibly antagonise the effect of sedative drugs, and may also be associated with an increased incidence of vomiting. Note that methylphenidate is an indirectly-acting sympathomimetic, and as such might be expected to increase the risk of hypertension and arrhythmias if used with **inhalational anaesthetics** (consider 'Anaesthetics, general + Inotropes and Vasopressors', p.111). Because of this, the manufacturer of one brand of methylphenidate recommends that, if surgery with halogenated anaesthetics is planned, methylphenidate treatment should not be given on the day of surgery.[3] Taken together, these reports suggest this advice may be a prudent precaution for any form of sedation and/or general anaesthesia.

Anaesthetics, general + Neuromuscular blockers

Many inhalational anaesthetics increase the effects of the neuromuscular blockers, and in some cases this allows for a dosage reduction of the neuromuscular blocker. Nitrous oxide appears not to interact significantly and halothane seems less likely to interact. Propofol and xenon are reported not to interact with mivacurium or rocuronium.
Bradycardia has been reported with combinations of anaesthetics (propofol, etomidate or thiopental) and neuromuscular blockers (atracurium, suxamethonium or vecuronium), particularly in the presence of an opioid.

Clinical evidence, mechanism, importance and management

The effects of neuromuscular blockers are increased by inhalational anaesthetics, the greater the dosage of the anaesthetic the greater the increase in blockade. In broad terms **desflurane**, **ether**, **enflurane**, **isoflurane**, **methoxyflurane** and **sevoflurane** have a greater effect than **halothane**, which is more potent than **cyclopropane**, whereas **nitrous oxide** appears not to interact significantly with competitive blockers.[1-7]

The mechanism is not fully understood but seems to be multifactorial. It has been suggested that the anaesthetic may:

- have an effect via the CNS (including depression of spinal motor neurones);
- have an effect on the neuromuscular junction (including a decrease in the release of acetylcholine and in the sensitivity of the motor end-plate to acetylcholine);
- affect the muscle tissue itself.[6,8]

The duration of exposure to the anaesthetic and the duration of effect of the various neuromuscular blockers also appear to affect the degree of potentiation that occurs.[8,9]

Reports pertaining to interactions between specific neuromuscular blockers and anaesthetics are discussed in the subsections below.

(a) Atracurium

In a study in which the muscle relaxant was given about 5 minutes after the start of inhalational anaesthesia, **enflurane** prolonged the action of atracurium. It was suggested that more prolonged exposure to the anaesthetic, allowing equilibration of the anaesthetic to the tissues, might result in more significant potentiation of the neuromuscular blockers.[9] Similarly, in another study, **ketamine** prolonged the duration of neuromuscular blockade induced by atracurium.[10] In contrast, **halothane** did not significantly prolong the clinical duration of atracurium.[9]

The dosage of atracurium can be reduced by 25 to 30% if, instead of balanced anaesthesia (with **thiopental**, fentanyl and **nitrous oxide**/oxygen),[11] **enflurane** is used, and by up to 50% if **isoflurane** or **desflurane** are used.[4,12,13] Another study recommended reduced doses of neuromuscular blockers such as atracurium and **tubocurarine** in children undergoing anaesthesia with **enflurane** or **isoflurane**.[14]

Bradycardia and asystole have been reported in a patient given **propofol**, fentanyl and atracurium.[15]

(b) Cisatracurium

A myasthenic patient developed marked potentiation of neuromuscular block following the combination of **sevoflurane** and a small dose of cisatracurium 25 micrograms/kg.[16]

(c) Mivacurium

It has been suggested that higher plasma levels of mivacurium, especially of the potent *trans-trans* isomer, occur in the presence of **isoflurane**, and these could contribute to the enhanced neuromuscular blockade observed in patients given this combination. Lower infusion rates of mivacurium were required in those given **isoflurane** rather than **propofol** (which does not appear to interact).[17]

Xenon is reported not to affect the onset time, duration and recovery from mivacurium.[18]

(d) Pancuronium

In a study in which the muscle relaxant was given about 5 minutes after the start of inhalational anaesthesia, **enflurane** prolonged the action of pancuronium. It was suggested that more prolonged exposure to the anaesthetic, allowing equilibration of the anaesthetic to the tissues, might result in more significant potentiation of the neuromuscular blocker.[9] In this study, **halothane** did not significantly prolong the clinical duration of pancuronium;[9] however, in an early study, **halothane** was found to *shorten* the recovery from pancuronium.[19,20]

(e) Pipecuronium

In a study in which the muscle relaxant was given about 5 minutes after the start of inhalational anaesthesia, **enflurane** prolonged the action of pipecuronium. It was suggested that more prolonged exposure to the anaesthetic, allowing equilibration of the anaesthetic to the tissues, might result in more significant potentiation of the neuromuscular blockers.[9] In this study, **halothane** did not significantly prolong the clinical duration of pipecuronium.[9]

(f) Rapacuronium

One study demonstrated considerable prolongation of neuromuscular blockade with rapacuronium in the presence of **sevoflurane**; the recovery times were approximately doubled compared with those given in the published literature using **thiopental**/opioid-**nitrous oxide** anaesthesia. This led to the study being prematurely terminated as spontaneous recovery of neuromuscular function was required after short surgical procedures.[21]

(g) Rocuronium

The rate of infusion of rocuronium (0.39 mg/kg per hour) was significantly less in 10 patients anaesthetised with **isoflurane** and **nitrous oxide** when compared with the rate (0.61 to 0.67 mg/kg per hour) in 50 other patients anaesthetised with **etomidate**, fentanyl, midazolam, **propofol**, or **thiopental** and **nitrous oxide**.[22]

In one study when the volatile anaesthetics were given about 10 minutes before the neuromuscular blocker, **sevoflurane** was reported to increase and prolong the blockade of rocuronium more than **isoflurane** or **propofol**.[23] However, another study found that after a 40-minute equilibration period of the inhalation anaesthetic (steady-state conditions), there was no significant difference between **desflurane**, **isoflurane** and **sevoflurane** in relation to potency, infusion requirements or recovery characteristics of rocuronium; the potency of rocuronium was increased by 25 to 40% under inhalational anaesthesia, when compared with **propofol**.[24]

It is reported that the neuromuscular blocking effects of rocuronium are not prolonged by **xenon**.[25]

In *animals*, **ketamine** and **thiopental** potentiated the neuromuscular blocking effects of rocuronium, whereas **propofol** had no effect.[26]

(h) Suxamethonium (Succinylcholine)

Although it is generally assumed that **nitrous oxide** does not affect the potency of neuromuscular blockers, one study found that **nitrous oxide** did increase suxamethonium neuromuscular blockade.[27]

In children receiving suxamethonium, those anaesthetised with **halothane** had much higher levels of serum myoglobulin than those undergoing intravenous induction with **thiopental** followed by **halothane**. This suggests that prior use of **halothane** may have potentiated suxamethonium-induced muscle damage.[28]

In one study, **ketamine** did not influence suxamethonium-induced neuromuscular blockade.[29] However, the UK manufacturers of suxamethonium still warn of a possible interaction because they say that **ketamine** may reduce normal plasma cholinesterase activity.[30]

Serious sinus bradycardia (heart rates of 30 to 40 bpm) developed rapidly in two young women when they were anaesthetised with a slow intravenous injection of **propofol** 2.5 mg/kg, followed by suxamethonium 1.5 mg/kg. This was controlled with 600 micrograms of intravenous atropine. Four other patients premedicated with 600 micrograms of intramuscular atropine given 45 minutes before induction of anaesthesia did not develop bradycardia.[31] It would appear that **propofol** lacks central vagolytic activity and can exaggerate the muscarinic effects of suxamethonium.[31] Another report describes a woman who became asystolic when given an anaesthetic induction sequence of fentanyl, **propofol** and suxamethonium.[32] The authors of this report suggest that atropine or glycopyrronium (glycopyrrolate) pretreatment should attenuate or prevent such reactions.[32] Bradycardia and asystole has also been seen following the sequential use of **propofol** and fentanyl in 2 patients.[33,34] All of these three drugs (fentanyl, **propofol**, suxamethonium) alone have been associated with bradycardia and their effects can apparently be additive.

(i) Vecuronium

In a study in which the muscle relaxant was given about 5 minutes after the start of inhalational anaesthesia, **enflurane** did not significantly affect vecuronium. It was suggested that the duration of effect of the vecuronium may have been too short for interaction with a volatile anaesthetic that had not had time to equilibrate with the tissues.[9] In this study, **halothane** did not significantly prolong the clinical duration of vecuronium.[9] One study in children found that the potentiation of vecuronium was greater with **isoflurane** than with **enflurane**, and **halothane** had a lesser effect.[35] In another study, **enflurane** and **isoflurane** reduced the vecuronium infusion rate requirements by as much as 70%, when compared with fentanyl anaesthesia.[36] Another study found that although **halothane** and **isoflurane** could both increase the neuromuscular potency of vecuronium, only **isoflurane** prolonged the recovery from neuromuscular blockade.[37]

The duration of exposure to **sevoflurane** also influences the dose-response of vecuronium, but it has been suggested that **sevoflurane**-induced potentiation of neuromuscular blockers might be more rapid than with other inhalational anaesthetics.[8]

Xenon is reported to have less effect on recovery from vecuronium-induced neuromuscular block than **sevoflurane**.[38]

The original formulation of **propofol** in *Cremophor* was found to increase the blockade due to vecuronium,[39] but the more recent formulation in soybean oil and egg phosphatide has been found in an extensive study not to interact with vecuronium.[40]

Bradycardia occurring during anaesthetic induction with vecuronium

and **etomidate**, or to a lesser extent **thiopental**, has also been reported, particularly in patients also receiving fentanyl.[41] Consider also 'Neuromuscular blockers + Opioids', p.144.

Anaesthetics, general + Opioids

The effects of inhalational anaesthetics may be enhanced by opioid analgesics, and the dose requirements of desflurane, etomidate, propofol and thiopental may be lower after opioid use. The respiratory depressant effects of ketamine and morphine may be additive. Opisthotonos or grand mal seizures have rarely been associated with the use of propofol with alfentanil and/or fentanyl.

Clinical evidence, mechanism, importance and management

(a) Inhalational anaesthetics

Opioid analgesics have been reported to reduce the MAC values of inhalational anaesthetics. For example, **fentanyl** has been shown to lower the MAC value of **desflurane**, probably in a dose-dependent manner, and this has been the subject of a review.[1] The manufacturer notes that lower doses of **desflurane** are required in patients receiving opioids.[2] **Remifentanil** at a target-controlled plasma level of 1 nanogram/mL was found to decrease the MAC of **sevoflurane** with **nitrous oxide** by 60%, and **remifentanil** 3 nanograms/mL produced a further 30% decrease in the MAC of **sevoflurane**.[3] Another study found that **remifentanil** dose-dependently decreased the level of **sevoflurane** required to maintain anaesthesia.[4] However, 100 microgram/kg doses of **morphine** given during anaesthesia did not alter the awakening concentration of **sevoflurane**.[5]

(b) Etomidate

The manufacturer of etomidate recommends that the dose of etomidate should be reduced in patients who have already received opioids.[6]

(c) Ketamine

A study in 11 healthy subjects found that the combination of ketamine and **morphine** almost abolished windup-like pain (progressive increase in pain intensity on repeated stimulation) in a skin burn injury. This effect was not found with either drug alone. Further, although ketamine alone reduced the area of secondary hyperalgesia of the local burn and increased the pain threshold, the combination did not appear to enhance this effect. The reduction of wind-up pain may be due to ketamine-induced prevention of acute tolerance to **morphine**.[7] Ketamine is a respiratory depressant like **morphine**, but less potent. Nevertheless its effects can be additive with morphine.[8]

Another study in healthy subjects using various experimental pain models found that ketamine *antagonised* the respiratory depressant effect of **remifentanil**. **Remifentanil** alone produced analgesic effects with all pain tests, but ketamine only enhanced the effect of **remifentanil** on intramuscular electrical stimulation. Acute **remifentanil**-induced hyperalgesia and tolerance were detected only by the pressure pain test and were not suppressed by ketamine. The combined effects of **remifentanil** and ketamine probably depend on the type of pain.[9]

The manufacturer notes that a prolonged recovery time may occur if opioids are used with ketamine.[10]

(d) Propofol

A 71-year-old man undergoing a minor orthopaedic operation was given a 500-microgram intravenous injection of **alfentanil** followed by a slow injection of propofol 2.5 mg/kg. Approximately 15 seconds after the propofol, the patient developed strong bilateral fits and grimaces, which lasted for 10 seconds. Anaesthesia was maintained with nitrous oxide/oxygen and halothane and there were no other intra- or postoperative complications. The patient had no history of convulsions.[11] There is a further report of opisthotonos during recovery from anaesthesia with **alfentanil**, propofol and nitrous oxide.[12] Propofol has been associated with opisthotonos (a spasm where the head and heels bend backwards and the body arches forwards) in two patients given **fentanyl** with or without **alfentanil**,[13] and seizures have been reported in patients with and without epilepsy receiving propofol. They mainly occur during induction and emergence or are delayed after anaesthesia, suggesting that they may be caused by changes in cerebral levels of propofol,[14] and post-anaesthetic opisthotonos may be due to a propofol-induced tolerance to inhibitory transmitters (glycine and

GABA).[12] Any association with the opioid remains unknown, although it has been suggested that opioids may aggravate propofol-induced opisthotonos by antagonising the actions of glycine.[12]

Alfentanil has been found to reduce the amount of propofol needed for loss of eyelash reflex and loss of consciousness, as well as enhancing the reduction in blood pressure produced by propofol.[15] Propofol inhibits both **alfentanil** and **sufentanil** metabolism causing an increase in plasma concentrations of these opioids, while **alfentanil** also increases propofol concentrations (which has been the subject of a review[16] and also described in more recent reports[17-20]). Pretreatment with **fentanyl** may also decrease the propofol requirements for induction of anaesthesia,[16] and increase blood concentrations of propofol.[21] However, another study was unable to confirm that **fentanyl** had an effect on blood propofol concentrations.[22]

A study in 2 groups of 20 patients undergoing similar types of surgery with similar propofol consumption, the duration of clinical anaesthesia with **remifentanil** and propofol was longer than with **fentanyl** and propofol.[23] **Remifentanil** has been reported to reduce the dose of propofol needed for anaesthesia and also to reduce the recovery time.[24,25] Further, propofol and **remifentanil** caused dose-dependent respiratory-depression, which, during combined use, was synergistic.[26] One study using EEG-controlled dosing of propofol and **remifentanil** for anaesthesia found their pharmacodynamic effects were no more than additive.[27] Although **remifentanil** alone appears to be ineffective at countering the response to stimuli, a study in healthy subjects has found that **remifentanil** can significantly reduce the levels of propofol required to remove a response to shouting, shaking or laryngoscopy (synergistic effect), but the effects on EEG measures were additive.[28] In another study in healthy subjects given **remifentanil** and propofol, the synergy that occurred for both analgesic and hypnotic endpoints was found to be greatest at lower levels of the drugs, which for each drug alone would not be producing maximal effects.[29] Another study found changes in BIS (bispectral index) that suggested that **remifentanil** may have some hypnotic properties or that it can potentiate the hypnotic effect of propofol.[30] It has been suggested that the increased hypnotic effects may be due to a dose-dependent decrease in cardiac output by **remifentanil**, resulting in an increase in arterial and brain propofol with increased anaesthetic effect.[31] One pharmacokinetic study found that the levels of **remifentanil** may be increased during concurrent propofol infusion,[32] while another study found that concurrent propofol reduced volume of distribution and distribution clearance of **remifentanil** by 41%. It was concluded that although propofol affects **remifentanil** bolus dose pharmacokinetics, maintenance infusion rates and recovery times would not be significantly affected.[33]

The manufacturer notes that the required induction dose of propofol may be reduced in patients who have received opioids, and that these drugs may increase the anaesthetic and sedative effects of propofol, and also cause greater reductions in blood pressure and cardiac output. They also state that propofol requirements for maintenance of anaesthesia may be reduced in the presence of opioids.[34]

Two reviews have discussed the use of opioids and propofol in anaesthesia, their pharmacokinetic and pharmacodynamic interactions, and administration and monitoring techniques.[35,36]

(e) Thiopental

Opioid analgesics would be expected to potentiate the respiratory depressant effects of barbiturate anaesthetics. A study has found that the dose of thiopental required to induce anaesthesia was reduced by pretreatment with **fentanyl**.[37] The manufacturer recommends reduced doses of thiopental in patients premedicated with opioids.[38]

Anaesthetics, general + Parecoxib

Limited evidence suggests parecoxib does not affect the pharmacokinetics or clinical effects of propofol. Parecoxib does not appear to interact with nitrous oxide and isoflurane.

Clinical evidence, mechanism, importance and management

A randomised, placebo-controlled, crossover study in 12 healthy subjects found that pretreatment with 40 mg of intravenous parecoxib, given one hour before a 2 mg/kg intravenous bolus of **propofol**, did not significantly affect the pharmacokinetics of **propofol**. Moreover, parecoxib did not alter the clinical effects of **propofol** (e.g. the time to loss of consciousness or the speed of awakening).[1] These limited data suggest that no special precautions should be required during concurrent use.

The UK manufacturer of parecoxib says that no formal interaction studies have been done with inhalational anaesthetics, but in surgical studies, where parecoxib was given preoperatively, there was no evidence of phar-

macodynamic interactions in patients who had been given **nitrous oxide** and **isoflurane**.[2]

Anaesthetics, general + Phenylephrine, topical

Phenylephrine eye drops given to patients undergoing general anaesthesia caused marked cyanosis and bradycardia in a baby, and hypertension in a woman.

Clinical evidence, mechanism, importance and management

A 3-week-old baby anaesthetised with **halothane** and **nitrous oxide**/**oxygen** became cyanosed shortly after 2 drops of phenylephrine 10% solution were put into one eye. The heart rate decreased from 160 to 60 bpm, ST-segment and T-wave changes were seen, and blood pressure measurements were unobtainable. The baby recovered uneventfully when anaesthesia was stopped and oxygen given. It was suggested that the phenylephrine caused severe peripheral vasoconstriction, cardiac failure and reflex bradycardia.[1] A 54-year-old woman anaesthetised with **isoflurane** developed hypertension (a rise from 125/70 to 200/90 mmHg) shortly after having two drops of phenylephrine 10% solution put into one eye. The hypertension responded to nasal glyceryl trinitrate (nitroglycerin) and increasing concentrations of isoflurane.[1] The authors of this report consider that general anaesthesia may have contributed to the systemic absorption of the phenylephrine. They suggest that phenylephrine should be given 30 to 60 minutes before anaesthesia, and not during anaesthesia; however, if it is necessary to give phenylephrine, use the lowest concentration (2.5%). They also point out that the following are effective mydriatics: single drop combinations of cyclopentolate 0.5% and phenylephrine 2.5%, or tropicamide 0.5% and phenylephrine 2.5%.

Phenylephrine is a sympathomimetic, and as such may carry some risk of potentiating arrhythmias if it is used with inhalational anaesthetics such as halothane – see 'Anaesthetics, general + Inotropes and Vasopressors', p.111. However, it is considered that it is much less likely than adrenaline (epinephrine) to have this effect, since it has primarily alpha-agonist activity.[2]

Anaesthetics, general + Probenecid

The anaesthetic dosage of thiopental is reduced, and its effects prolonged by pretreatment with probenecid.

Clinical evidence

A study[1] in patients about to undergo surgery found that probenecid 1 g given one hour before anaesthesia reduced the thiopental dosage by 23%, from 5.3 to 4.1 mg/kg.

A further double-blind study[2] in 86 women found that probenecid given 3 hours before surgery prolonged the duration of anaesthesia with thiopental:

- In patients premedicated with atropine 7.5 micrograms/kg, pethidine (meperidine) 1 mg/kg, and 500 mg of probenecid, the duration of anaesthesia with thiopental 7 mg/kg was prolonged by 65%,
- In patients premedicated with atropine 7.5 micrograms/kg, pethidine 1 mg/kg, and *1 g of probenecid*, the duration of anaesthesia with thiopental 7 mg/kg was prolonged by 46%,
- In patients premedicated with atropine 7.5 micrograms/kg (*no pethidine*) and 500 mg of probenecid, the duration of anaesthesia with thiopental 7 mg/kg was prolonged by 26%,
- In patients premedicated with atropine 7.5 micrograms/kg (*no pethidine*) and 500 mg of probenecid, and *no surgical stimulus* the duration of anaesthesia with *thiopental 4 mg/kg* was prolonged by 109%.

Mechanism

Not understood. It has been suggested that probenecid increases the amount of free (and active) thiopental in the plasma since it competes for the binding sites on the plasma albumins.[1]

Importance and management

Information is limited but what is known shows that the effects of thiopental are increased by probenecid. As the change in propofol requirements is modest, and because the dose would be expected to be titrated to effect, this interaction seems likely to be of minimal clinical relevance.

Anaesthetics, general + Sparteine sulfate

Patients given thiamylal sodium had a marked increase in cardiac arrhythmias when they were given intravenous sparteine sulfate, but those given thiopental or etomidate did not.

Clinical evidence, mechanism, importance and management

A group of 109 women undergoing dilatation and curettage were premedicated with atropine and fentanyl, and given either **thiamylal sodium** 2% (5 mg/kg), **etomidate** 0.2% (0.3 mg/kg) or **thiopental** 2.5% (4 mg/kg) to induce anaesthesia, which was maintained with **nitrous oxide**/**oxygen**. During the surgical procedure they were given a slow intravenous injection of sparteine sulfate 100 mg. Fourteen out of 45 patients given **thiamylal sodium** developed cardiac arrhythmias; 10 had bigeminy and 4 had frequent ventricular premature contractions. Only two patients given **etomidate** or **thiopental** developed any cardiac arrhythmias. It is not understood why sparteine should interact with **thiamylal sodium** in this way. Although the arrhythmias were effectively treated with lidocaine, the authors of this report suggest that the concurrent use of sparteine and **thiamylal sodium** should be avoided.[1]

Anaesthetics, general + SSRIs

One patient had a seizure when she was given methohexital while taking paroxetine. Spontaneous movements have been seen in two patients taking fluoxetine when they were anaesthetised with propofol.

Clinical evidence, mechanism, importance and management

(a) Methohexital

A generalised tonic-clonic seizure occurred in a 42-year-old woman immediately after she was anaesthetised with 120 mg of intravenous methohexital for the last in a series of six electroconvulsive therapies. She had been receiving **paroxetine** 40 mg daily throughout the series.[1] The authors suggest that paroxetine should be given with caution to patients receiving ECT or methohexital anaesthesia.[1] Note that this appears to be an isolated report.

(b) Propofol

Two women in their mid-twenties, who had been taking **fluoxetine** 20 mg daily for 4 to 6 months, had pronounced involuntary upper limb movements lasting 20 to 30 seconds immediately after anaesthetic induction with 180 mg of propofol (2 to 2.5 mg/kg). The movements ceased spontaneously and the rest of the anaesthesia and surgery were uneventful. Neither had any history of epilepsy or movement disorders. It is not clear whether this was an interaction between propofol and **fluoxetine** or just a rare (but previously reported) reaction to propofol.[2]

Anaesthetics, general + Sulfonamides

The anaesthetic effects of thiopental are increased, but shortened, by sulfafurazole. Phenobarbital appears not to affect the pharmacokinetics of sulfafurazole or sulfisomidine.

Clinical evidence

A study in 48 patients found that intravenous **sulfafurazole** 40 mg/kg reduced the required anaesthetic dosage of **thiopental** by 36%, but the duration of action was shortened.[1] This interaction has also been observed in *animal* experiments.[2] A study in children found that **phenobarbital** did not affect the pharmacokinetics of **sulfafurazole** or **sulfisomidine**.[3]

Mechanism

It has been suggested that sulfafurazole successfully competes with thiopental for plasma protein binding sites,[4] the result being that more free and active barbiturate molecules remain in circulation to exert their anaesthetic effects and therefore smaller doses are required.

Importance and management

The evidence for an interaction between sulfafurazole and thiopental is limited, but it appears to be strong. Less thiopental than usual may be required to achieve adequate anaesthesia, but since the awakening time is shortened repeated doses may be needed.

Phenobarbital does not appear to affect the pharmacokinetics of the sulfonamides.

Anaesthetics, general + Theophylline

Cardiac arrhythmias can develop during the concurrent use of halothane and aminophylline. One report attributes seizures to an interaction between ketamine and aminophylline. Theophylline would be expected to interact similarly.

Clinical evidence, mechanism, importance and management

(a) Development of arrhythmias

A number of reports describe arrhythmias apparently due to an interaction between **halothane** and theophylline or aminophylline. One describes intraoperative arrhythmias in three out of 45 adult asthmatics who had received preoperative theophylline or aminophylline followed by **halothane** anaesthesia.[1] Nine other patients developed heart rates exceeding 140 bpm when given aminophylline and **halothane**, whereas tachycardia did not occur in 22 other patients given only **halothane**.[1] There are other reports of individual adult and child patients who developed ventricular tachycardias attributed to this interaction.[2-5] One child had a cardiac arrest.[5] The same interaction has been reported in *animals*.[6,7] One suggested reason for the interaction with **halothane** is that theophylline causes the release of endogenous catecholamines (adrenaline (epinephrine), noradrenaline (norepinephrine)), which are known to sensitise the myocardium, see 'Anaesthetics, general + Inotropes and Vasopressors', p.111. For a report describing supraventricular tachycardia, in a patient taking aminophylline who was anaesthetised with thiopental and fentanyl and then given pancuronium, see 'Neuromuscular blockers + Theophylline', p.146.

The authors of one of the reports advise avoiding concurrent use, and suggest waiting approximately 13 hours after the last dose of aminophylline before using **halothane**[2] but another[8] says that: "my own experience with the liberal use of these drugs has convinced me of the efficacy and wide margin of safety associated with their use in combination." For a list of inhalational anaesthetics, in order of arrhythmogenic potential, see 'Anaesthetics and Neuromuscular blockers', (p.100).

(b) Development of seizures

Over a period of 9 years, tachycardia and extensor-type seizures were observed in 4 patients taking theophylline or aminophylline, who were initially anaesthetised with **ketamine**, and then given **halothane** or **enflurane**.[9] Based on a subsequent study in *mice*, the authors attributed the seizures to an interaction between **ketamine** and theophylline or aminophylline, and they suggest that the combination should perhaps be avoided in some, or antiepileptic premedication be given to patients at risk. However, these cases come from one isolated report. Note that, in *mice*, **ketamine** had no effect on aminophylline-induced seizures.[10]

Anaesthetics, general + Tizanidine

Premedication with oral tizanidine appears to reduce the MAC of sevoflurane.

Clinical evidence, mechanism, importance and management

In a study, 52 patients were given either oral tizanidine 4 mg or placebo 70 minutes before induction of anaesthesia with **sevoflurane** 5%. The MAC of **sevoflurane** was 2.2% and 1.8% in the control and tizanidine-treated groups, respectively. The sedation score in the tizanidine group was higher than in the placebo group, and the time to loss of consciousness in the tizanidine and control groups was about 60 seconds and 74 seconds, respectively. Tizanidine therefore exerted a hypnotic effect and reduced the MAC of **sevoflurane** by 18%. No tizanidine-related adverse effects, such as hypotension, were reported.[1] The general relevance is not yet established, but the changes seen were minimal and therefore would not be expected to clinically significant.

1. Wajima Z, Yoshikawa T, Ogura A, Imanaga K, Shiga T, Inoue T, Ogawa R. Oral tizanidine, an α_2-adrenoceptor agonist, reduces the minimum alveolar concentration of sevoflurane in human adults. *Anesth Analg* (2002) 95, 393–6.

Anaesthetics, general + Topiramate

Topiramate and may reduce the anaesthetic properties of amobarbital. One study suggests that topiramate may attenuate the effects of ketamine, whereas another did not find an interaction.

Clinical evidence, mechanism, importance and management

(a) Amobarbital

In a retrospective study, it was found that 11 of 56 epileptic patients who had undergone the intracarotid amobarbital procedure (IAP) recovered very rapidly from the anaesthetic (within 60 seconds) or had anaesthetic failure. Seven of the 11 were taking topiramate and one had recently discontinued topiramate at the time of the procedure. The other 3 patients had been taking **zonisamide** (2), or furosemide (1). A further 2 patients taking topiramate or hydrochlorothiazide had a rapid recovery (within 90 seconds).

It was suggested that the anaesthetic effect of amobarbital may be affected by the carbonic anhydrase-inhibiting activity of these drugs. No anaesthetic failures were reported in patients taking combinations of antiepileptics such as carbamazepine, phenytoin and valproate but without drugs with carbonic anhydrase-inhibiting effects.[1] The mechanism is not understood but may be due to interference with the activity of amobarbital

on $GABA_A$ receptors by effects on electrochemical gradients across cell membranes or via metabolic acidosis.

The authors recommend that topiramate, **zonisamide** or other carbonic anhydrase inhibitors should be discontinued at least 8 weeks before the IAP.[1] Similar findings are reported in a review of 40 other patients.[2]

(b) Ketamine

A study in 36 healthy subjects found that a single 50-mg dose of topiramate slightly decreased the effect of sub-anaesthetic doses of ketamine (slow intravenous injection of 120 micrograms/kg followed by 500 micrograms/kg over one hour) on a cognitive performance test (anti-saccade test). Pharmacokinetic analysis also found that ketamine levels were increased by about 25% in the subjects given topiramate.[3] A follow-up, placebo-controlled study by the same authors in 36 healthy subjects found that pretreatment with a single 50-mg dose of topiramate did not significantly affect the reaction time to ketamine (same dose as the previous study).[4] The general significance of these results in patients taking topiramate and undergoing sedation or anaesthesia with ketamine is unclear. Further study is needed.

Anaesthetics, general + Trichloroethane

Two patients had evidence of chronic cardiac toxicity after repeated exposure to trichloroethane. There was circumstantial evidence in both cases of a deterioration in cardiac function following halothane anaesthesia.

Clinical evidence, mechanism, importance and management

Two patients, who had been repeatedly exposed to trichloroethane; one during solvent abuse including *Tipp-Ex* typewriter correcting fluid thinner and the other due to industrial exposure including *Genklene* for degreasing steel, showed evidence of chronic cardiac toxicity. In both cases there was circumstantial evidence of cardiac deterioration after routine anaesthesia with **halothane**. Some **solvents** have a close chemical similarity to **inhalational anaesthetic** drugs, particularly the halogenated hydrocarbons, and these related compounds might have a toxic interaction.[1]

1. McLeod AA, Marjot R, Monaghan MJ, Hugh-Jones P, Jackson G. Chronic cardiac toxicity after inhalation of 1,1,1-trichloroethane. *BMJ* (1987) 294, 727–9.

Anaesthetics, general and/or Neuromuscular blockers + Tricyclic and related antidepressants

Tricyclic antidepressants may increase the risk of arrhythmias and hypotension during anaesthesia. Tachyarrhythmias have been seen in patients taking imipramine who were given halothane and pancuronium. Some very limited evidence suggests that amitriptyline may increase the likelihood of enflurane-induced seizure activity. A man taking maprotiline and lithium developed a tonic-clonic seizure when given propofol. Tricyclics may cause an increase in the duration of barbiturate anaesthesia.

Clinical evidence, mechanism, importance and management

(a) Development of arrhythmias

Two patients who were taking **nortriptyline** (one also taking fluphenazine) developed prolonged cardiac arrhythmias during general anaesthesia with **halothane**.[1] Two further patients taking **imipramine** developed marked tachyarrhythmias when anaesthetised with **halothane** and given **pancuronium**.[2] This adverse interaction was subsequently clearly demonstrated in *dogs*.[2] The authors concluded on the basis of their studies that:

- **pancuronium** should be given with caution to patients taking any **tricyclic antidepressant** if **halothane** is used;
- **gallamine** probably should be avoided but **tubocurarine** may be an acceptable alternative to **pancuronium**;
- **pancuronium** is probably safe in the presence of a tricyclic if **enflurane** is used.

However, this last conclusion does not agree with that reached by the authors of another report[3], who found that the combination of **pancuronium** and **enflurane** increased the risk of seizures.

One manufacturer[4] has recommended stopping tricyclics several days before elective surgery where possible. However, the BNF advises that tricyclic antidepressants need not be stopped, but there may be an increased risk of arrhythmias and hypotension (and dangerous interactions with vasopressor drugs, see 'Tricyclic and related antidepressants + Inotropes and Vasopressors', p.1507). Therefore, the anaesthetist should be informed if they are not stopped.[5]

(b) Development of seizures

1. Enflurane + Tricyclics. Two patients taking **amitriptyline** developed clonic movements of the leg, arm and hand during surgery while anaesthetised with enflurane and **nitrous oxide**. The movements stopped when the enflurane was replaced by **halothane**.[3] A possible reason is that **amitriptyline** can lower the threshold at which enflurane-induced seizure activity occurs. It is suggested that it may be advisable to avoid enflurane in patients needing tricyclic antidepressants, particularly in those who have a history of seizures, or when hyperventilation or high concentrations of enflurane are likely to be used.[3]

2. Propofol + Maprotiline. A man with a bipolar disorder taking maprotiline 200 mg four times daily and lithium carbonate 300 mg daily, underwent anaesthesia during which he received fentanyl, **tubocurarine** and propofol 200 mg. Shortly after the injection of the propofol the patient complained of a burning sensation in his face. He then became rigid, his back and neck extended and his eyes turned upwards. After 15 seconds, rhythmic twitching developed in his eyes, arms and hands. This apparent seizure lasted for about one minute until suxamethonium (succinylcholine) was given. The patient regained consciousness after several minutes and the surgery was cancelled.[6] It is not known whether the reaction was due to an interaction between propofol and the antidepressants, or due to just one of the drugs, because both propofol[7,8] and maprotiline[9] have been associated with seizures. However, the authors of this report suggest that it would now be prudent to avoid using propofol in patients taking drugs that significantly lower the convulsive threshold, and this would be expected to include tricyclic antidepressants. More study of this possible interaction is needed.

(c) Increased duration of anaesthesia

A study in *dogs* found that **imipramine** caused about a 50% increase in the duration of **thiopental**-induced sleep.[10] In an early review of electroconvulsive therapy and anaesthesia, it was noted that tricyclics interact with **barbiturates** resulting in an increased sleep time and duration of anaesthesia, and therefore it was suggested that lower doses of barbiturate anaesthetics such as **thiopental** should be given to patients taking tricyclics.[11] However, in a later review, it was noted that no complications have been attributed to the use of ECT (which has often been undertaken using **methohexital** or possibly **propofol**) in patients taking tricyclic antidepressants.[12] Apart from the study in *animals,*[10] there seems little published information to suggest that tricyclics interact significantly with barbiturate anaesthetics, but even if there is an interaction, as the dose of barbiturate should be carefully adjusted according to the patient's response any interaction will probably be accounted for by standard anaesthetic procedures. Consider also 'Tricyclic and related antidepressants + Barbiturates or Phenytoin', p.1499.

Anaesthetics, general; Methoxyflurane + Miscellaneous

The nephrotoxic effects of methoxyflurane appear to be increased by the use of tetracyclines, and possibly some aminoglycoside antibacterials and barbiturates.

Clinical evidence, mechanism, importance and management

Methoxyflurane has been withdrawn in many countries because it is nephrotoxic. This damage can be exacerbated by the concurrent use of other nephrotoxic drugs or possibly by the chronic use of hepatic enzyme-inducing drugs. Five out of 7 patients anaesthetised with methoxyflurane who had been given **tetracycline** before or after surgery had rises in blood urea nitrogen, and three died. Post-mortem examination found pathological changes (oxalosis) in the kidneys.[1] Another study identified renal tubular necrosis associated with calcium oxalate crystals in 6 patients who had been anaesthetised with methoxyflurane and given **tetracycline** (4 patients) and **penicillin** with **streptomycin** (2 patients).[2] Other reports support the finding of increased nephrotoxicity with **tetracycline** and methoxyflurane.[3-5] Another study suggested that **penicillin**, **streptomycin** and **chloramphenicol** appear not to increase the renal toxicity of methoxyflurane,[1] but **gentamicin** and **kanamycin** possibly do so.[6] There is also some evidence that **barbiturates** can exacerbate the renal toxicity because they enhance the metabolism of the methoxyflurane and increase the production of nephrotoxic metabolites.[7,8]

The risk of nephrotoxicity with methoxyflurane would therefore appear to be increased by some of these drugs and the concurrent use of **tetracycline** or **nephrotoxic antibiotics** should be avoided. Similarly, methoxyflurane should only be used with great caution, if at all, following the chronic use of hepatic enzyme-inducing drugs.

Anaesthetics, local + Acetazolamide

In a study in 6 healthy subjects, the mean procaine half-life was increased by 66% (from 1.46 to 2.43 minutes) 2 hours after they were given acetazolamide 250 mg orally. This appears to be because the hydrolysis of the procaine is inhibited by the acetazolamide.[1] As the evidence for this interaction is limited to one report, its general significance is unclear.

Anaesthetics, local + Alcohol and/or Antirheumatics

Limited evidence suggests that the failure rate of spinal anaesthesia with bupivacaine may be markedly increased in patients who are receiving antirheumatic drugs and/or who drink alcohol.

Clinical evidence, mechanism, importance and management

The observation that regional anaesthetic failures seemed to be particularly high among patients undergoing orthopaedic surgery who were suffering from rheumatic joint diseases, prompted further study of a possible interaction. It was found that the failure rate of low-dose spinal anaesthesia with **bupivacaine** 0.5% (average volume of 2 mL) increased from 5% in the control group (no alcohol or long-term treatment) to 32% to 42% in those who had been taking antirheumatic drugs (**indometacin** or unspecified) for at least 6 months or who drank at least 80 g of ethanol daily, or both. The percentage of those patients who had a reduced response (i.e. an extended latency period and/or a reduced duration of action) also increased from 3% up to 39 to 42%.[1] The reasons are not understood. This appears to be the only report of such an effect.

1. Sprotte G, Weis KH. Drug interaction with local anaesthetics. *Br J Anaesth* (1982) 54, 242P–243P.

Anaesthetics, local + Anaesthetics, local

Mixtures of local anaesthetics are sometimes used to exploit the most useful characteristics of each drug. This normally seems to be safe although it is sometimes claimed that it increases the risk of toxicity. There is a case report of a man who developed toxicity when bupivacaine and mepivacaine were mixed together. Spinal bupivacaine followed by epidural ropivacaine may also interact to produce profound motor blockade. However, the effectiveness of bupivacaine in epidural anaesthesia may be reduced if it is preceded by chloroprocaine.

Clinical evidence and mechanism

(a) Evidence of no interaction

A study designed to assess the possibility of adverse interactions retrospectively studied the records of 10 538 patients over the period 1952 to 1970 who had been given **tetracaine** combined with **chloroprocaine**, **lidocaine**, **mepivacaine**, **prilocaine** or **propoxycaine** for caudal, epidural, or peripheral nerve block. The incidence of systemic toxic reactions was found to be no greater than when used singly and the conclusion was reached that combined use was advantageous and safe.[1] An *animal* study using combinations of **bupivacaine**, **lidocaine** and **chloroprocaine** also found no evidence that the toxicity was greater than if the anaesthetics were used singly.[2]

A study investigating the use of **chloroprocaine** 3%, **bupivacaine** 0.5% or a mixture of **chloroprocaine** 1.5% with **bupivacaine** 0.375% in obstetric epidural anaesthesia found that the time to onset of analgesia, the time to maximum analgesia, and the effectiveness of analgesia were similar irrespective of the treatment regimen. **Bupivacaine** 0.5% alone had a longer duration of action than **chloroprocaine** or the mixture of anaesthetics.[3] Another study found that **lidocaine** did not affect the pharmacokinetics of **bupivacaine**.[4]

(b) Evidence of reduced analgesia

A study designed to examine the clinical impression that **bupivacaine** given epidurally did not relieve labour pain effectively if preceded by **chloroprocaine** confirmed that this was so. Using an initial 10-mL dose of **chloroprocaine** 2% followed by an 8-mL dose of **bupivacaine** 0.5%, given when pain recurred, the pain relief was less and the block took longer to occur, had a shorter duration of action and had to be augmented more frequently than if only **bupivacaine** was used.[5] This interaction could not be corrected by adjusting the pH of the local anaesthetics.[6]

(c) Evidence of enhanced effect/toxic interaction

An isolated case report describes a patient given **bupivacaine** 0.75% and **mepivacaine** 2% who demonstrated lethargy, dysarthria and mild muscle tremor. The authors of the report suggested that this correlated with a

marked increase in the percentage of unbound (active) **mepivacaine**, which was attributed to its displacement from protein binding sites by **bupivacaine**.[7] **Bupivacaine** has also been shown *in vitro* to displace **lidocaine** from α_1-acid glycoprotein.[8] Two cases of prolonged, profound motor blockade, have occurred in patients receiving patient-controlled epidural analgesia with **ropivacaine** 0.1% following spinal **bupivacaine** for caesarean section. Including these 2 patients, a total of 11 out of 23 patients given regional anaesthesia with **bupivacaine** had clinical evidence of motor weakness 8 hours after subsequently starting **ropivacaine**.[9]

Importance and management

Well studied interactions. The overall picture is that combined use does not normally result in increased toxicity, although there may be some exceptions. For example, until more is known, caution should be exercised when giving epidural ropivacaine postoperatively to patients who have had bupivacaine spinal anaesthesia, as unexpected motor block may occur.[9] Reduced effectiveness might be seen if bupivacaine is preceded by chloroprocaine.

Anaesthetics, local + Antihypertensives

Severe hypotension and bradycardia have been seen in patients taking captopril or verapamil when they were given epidural anaesthesia with bupivacaine. Verapamil does not appear to interact with epidural lidocaine. Acute hypotension occurred in a man taking prazosin when he was given epidural anaesthesia with bupivacaine.

Clinical evidence

(a) ACE inhibitors

An 86-year-old man who had been receiving **captopril** 25 mg twice daily and bendroflumethiazide 25 mg daily [sic] for hypertension, underwent a transurethral resection of his prostate under spinal anaesthesia using 3 to 3.5 mL of heavy **bupivacaine** 0.5%. At the end of surgery, he was returned to the supine position and he suddenly developed severe sinus bradycardia (35 bpm), his arterial blood pressure fell to 65/35 mmHg and he became unrousable. Treatment with head-down tilt, oxygen and atropine 1.2 mg produced rapid improvement in cardiovascular and cerebral function. A further hypotensive episode (without bradycardia) occurred approximately one hour later, which responded rapidly to methoxamine 4 mg.[1]

(b) Alpha blockers

A man taking **prazosin** 5 mg three times daily for hypertension developed marked hypotension (BP 60/40 mmHg) within 3 to 5 minutes of receiving **bupivacaine** 100 mg through an L3–4 lumbar epidural catheter.[2] He was unresponsive to intravenous phenylephrine (five 100-microgram boluses) but his blood pressure rose within 3 to 5 minutes of starting a 0.05-micrograms/kg per minute infusion of adrenaline (epinephrine).

(c) Beta blockers

See 'Anaesthetics, local + Beta blockers', p.122, for reports of cardiotoxicity in patients given beta blockers with local anaesthetics.

(d) Calcium-channel blockers

Four patients taking long-term **verapamil** developed severe hypotension (systolic pressure as low as 60 mmHg) and bradycardia (48 bpm) 30 to 60 minutes after an epidural block with **bupivacaine** 0.5% and adrenaline (epinephrine). This was totally resistant to atropine and ephedrine, and responded only to calcium gluconate or calcium chloride. No such interaction was seen in a similar group of patients when epidural **lidocaine** was used.[3]

(e) Clonidine

See 'Anaesthetics, local + Clonidine', p.123.

Mechanism

Spinal anaesthesia can produce bradycardia and a fall in cardiac output resulting in arterial hypotension, which may be magnified by the action of the antihypertensive drug, and by hypovolaemia. Other factors probably contributed to the development of this interaction in these particular patients.

Importance and management

Direct information seems to be limited to the reports cited. Their general relevance is uncertain, but they serve to emphasise the importance of recognising that all antihypertensive drugs interfere in some way with the normal homoeostatic mechanisms that control blood pressure, so that the normal physiological response to hypotension during epidural anaesthesia may be impaired. Intravenous calcium effectively controls the hypotension and bradycardia produced by verapamil toxicity by reversing its calcium-channel blocking effects.[3,4]

Accidental intravenous administration of local anaesthetics during spinal anaesthesia may cause cardiovascular collapse and, on theoretical grounds, the serious cardiac depressant effects could be enhanced in patients taking antihypertensives, and it has been suggested that this may be a particular risk in elderly patients with impaired cardiovascular function.[5] Particular care would seem to be important with any patient given epidural anaesthesia while taking antihypertensives.

Anaesthetics, local + Benzodiazepines

Diazepam may increase the maximum plasma concentrations of bupivacaine, but the rate of bupivacaine elimination may also be increased. Midazolam has been reported to cause a modest decrease in lidocaine, but not mepivacaine, levels. Spinal anaesthesia with bupivacaine, lidocaine, or tetracaine may increase the sedative effects of midazolam. A case of possible lidocaine toxicity has been described when a woman taking sertraline was given flurazepam and then intraoperative lidocaine.

Clinical evidence

(a) Diazepam

Twenty-one children aged 2 to 10 years were given a single 1-mL/kg caudal injection of a mixture of **lidocaine** 0.5% and **bupivacaine** 0.125% for regional anaesthesia. Pretreatment with diazepam 10 mg rectally half-an-hour before the surgery had no significant effect on the plasma levels of **lidocaine**, but the AUC and maximum plasma **bupivacaine** levels were increased by 70 to 75%.[1] In another study in adult patients giving intravenous diazepam slightly, but not significantly, increased the mean maximum plasma levels of subsequent epidural **bupivacaine** or **etidocaine**. However, the elimination half-lives of both anaesthetics were significantly decreased, by about a half.[2]

(b) Flurazepam

A single report describes possible **lidocaine** toxicity following tumescent liposuction in a patient given perioperative sedation with flurazepam

30 mg orally. Ten hours after the completion of the procedure, in which a total of 58 mg/kg of lidocaine was used, the patient developed nausea and vomiting, an unsteady gait, mild confusion, and speech impairment. Her lidocaine level was 6.3 mg/L (levels greater than 6 mg/L were considered to be associated with an increased risk of toxicity). The patient was also taking sertraline.[3]

(c) Midazolam

In a study, 20 children aged 2 to 7 years were given a caudal block with 1 mL/kg of a solution containing **lidocaine** 0.5% and **bupivacaine** 0.125%, with midazolam 400 micrograms/kg given rectally half-an-hour before surgery. Midazolam caused a slight but non-significant reduction in the AUC and plasma levels of **bupivacaine**, whereas the AUC of **lidocaine** was reduced by 24%,[4] which would not be expected to be clinically significant. In another study, midazolam 400 micrograms/kg given rectally as a premedication was found to have no significant effect on plasma **mepivacaine** levels.[5] In a further study in which patients were given intravenous midazolam following an intramuscular injection of either **bupivacaine**, **lidocaine** or sodium chloride 0.9%, it was found that both anaesthetics enhanced the effect of midazolam. This effect was dose-dependent and it was concluded that the use of **lidocaine** or **bupivacaine** for regional blocks or local infiltration could alter the effect of midazolam from sedative to hypnotic.[6]

Twenty patients undergoing surgery were given repeated 1-mg intravenous doses of midazolam as induction anaesthesia every 30 seconds until they failed to respond to three repeated commands to squeeze the anaesthetist's hand. This was considered as the induction end-point 'titrated' dose. It was found that the 10 patients who had previously been given spinal anaesthesia with **tetracaine** 12 mg needed only half the dose of midazolam (7.6 mg) than the 10 other patients who had not received **tetracaine** (14.7 mg). The reasons are not known.[7]

Mechanism

The reasons for the pharmacokinetic interaction between diazepam and bupivacaine are not understood. The authors of the case report[3] describing lidocaine toxicity with flurazepam suggested that the flurazepam and sertraline inhibited lidocaine metabolism by the cytochrome P450 isoenzyme CYP3A4. However, note that flurazepam and sertraline are not usually considered to have inhibitory effects on this isoenzyme.

Both benzodiazepines and local anaesthetics are CNS depressants and therefore their concurrent use may result in additive CNS depression.

Importance and management

The clinical importance of these interactions is uncertain, but be aware that increased bupivacaine plasma levels have been seen with diazepam. One Canadian manufacturer of bupivacaine[8] suggests that reduced doses should be given if bupivacaine is given with sedatives. Note that, as with the use of any two CNS depressant drugs, consideration should be given to the potential for increased sedation.

Anaesthetics, local + Beta blockers

Propranolol reduces the clearance of bupivacaine and so theoretically the toxicity of bupivacaine may be increased. There has been a single report of enhanced bupivacaine cardiotoxicity in a patient also receiving metoprolol and digoxin. The coronary vasoconstriction caused by cocaine is increased by propranolol. Nadolol appears to increase the duration of anaesthesia seen with lidocaine combined with adrenaline but not with lidocaine alone. Transient hypertension has been reported in a patient taking propranolol and given mepivacaine with corbadrine.

Clinical evidence, mechanism, importance and management

(a) Bupivacaine

1. Metoprolol. A case report describes enhanced bupivacaine cardiotoxicity in a patient taking enalapril 5 mg daily, metoprolol 25 mg twice daily and **digoxin** 250 micrograms four times daily (serum digoxin level 1.1 nanograms/mL). Cardiac arrest occurred 15 minutes after the injection of bupivacaine 0.5% with adrenaline (epinephrine) for intercostal nerve block (total bupivacaine dose 100 mg). The cardiodepressant effects of metoprolol, **digoxin** and bupivacaine were thought to have combined to produce toxicity at a dose of bupivacaine not usually considered toxic. The authors suggest that patients taking **digoxin** with a beta blocker and/or calcium-channel blocker should be considered at higher risk for bupivacaine cardiotoxicity.[1] See also 'Anaesthetics, local + Antihypertensives', p.121, for further discussion of the use of local anaesthetics in patients receiving antihypertensives.

2. Propranolol. In a study in 6 healthy subjects, the clearance of bupivacaine was modestly reduced by about 35% when they were given bupivacaine 30 to 50 mg intravenously over 10 to 15 minutes after taking propranolol 40 mg every 6 hours for one day. It was suggested that propranolol inhibited the activity of the liver microsomal enzymes by changing hepatic blood flow, thereby reducing the metabolism of the bupivacaine. Changes in blood flow to the liver are unlikely to affect bupivacaine metabolism substantially because it is relatively poorly extracted from the blood. The clinical importance of this interaction is uncertain, but it is suggested that an increase in local anaesthetic toxicity might occur and caution should be exercised if multiple doses of bupivacaine are given.[2] See also 'Anaesthetics, local + Antihypertensives', p.121, for further discussion of the use of local anaesthetics in patients receiving antihypertensives.

(b) Cocaine

A study in 30 patients being evaluated for chest pain found that 2 mg/kg of an intranasal solution of cocaine 10% reduced coronary sinus flow by about 14% and coronary artery diameter by 6 to 9%. The coronary vascular resistance increased by 22%. The addition of **propranolol** 400 micrograms/minute by intracoronary infusion (to a total of 2 mg) reduced coronary sinus flow by a further 15% and increased the coronary vascular resistance by 17%. These effects were thought to occur because cocaine stimulates the alpha receptors of the coronary blood vessels causing vasoconstriction. When the beta receptors are blocked by **propranolol**, the resultant unopposed alpha-adrenergic stimulation may lead to enhanced coronary vasoconstriction (see also 'Beta blockers + Inotropes and Vasopressors', p.1011). The clinical importance of these findings is uncertain but the authors of the report suggest that beta blockers should be avoided in patients with myocardial ischaemia or infarction associated with the use of cocaine.[3]

(c) Local anaesthetics with vasoconstrictors

In a randomised, placebo-controlled, crossover study in 10 healthy subjects, the upper lateral incisor teeth were anaesthetised using **lidocaine** with or without **adrenaline** (epinephrine). The mean duration of anaesthesia using 1 mL of lidocaine 2% containing 1:100 000 adrenaline was increased by 58% (17 minutes) for pulpal anaesthesia and 19% (16.5 minutes) for soft-tissue anaesthesia in subjects pretreated with **nadolol** 80 mg orally. Pretreatment with the beta blocker did not affect the duration of anaesthesia when lidocaine without adrenaline was used.[4] It seems likely that the combined effects of **adrenaline** (epinephrine) and **nadolol** caused increased local vasoconstriction, which resulted in the lidocaine persisting for longer. Therefore when a small amount of local anaesthetic with adrenaline is injected for dental procedures an increased duration of analgesia may result. Also note that a case report describes a transient hypertensive reaction in a patient taking **propranolol** when injections of **mepivacaine** 2% with **corbadrine** 1:20 000 were given for dental anaesthesia.[5] Larger doses of adrenaline have resulted in serious hypertension and bradycardia because of the interaction between non-selective beta blockers and adrenaline (see 'Beta blockers + Inotropes and Vasopressors', p.1011). It has been suggested that, for dental procedures, the minimum amount of local anaesthetic containing the lowest concentration of adrenaline should be used. Alternatively, if excessive bleeding is unlikely, a local anaesthetic without adrenaline is preferred.[4]

Propranolol and some other beta blockers are known to reduce the metabolism of intravenous and possibly oral lidocaine, see 'Lidocaine + Beta blockers', p.297. Note that this interaction is not expected to be important when lidocaine is given as a throat spray.[6]

Anaesthetics, local + Clonidine

Studies suggest that the plasma levels of lidocaine (after epidural use) may be reduced in patients given clonidine. The addition of clonidine to bupivacaine spinal block shortens the onset time and increases the duration of sensory and motor block.

Clinical evidence

A study in 35 children undergoing ureteroneocystostomy found that the addition of clonidine 1 microgram/kg increased the duration of caudal block with **bupivacaine** 0.125% (with adrenaline (epinephrine) 1:400 000) and reduced the postoperative morphine requirements.[1] In a study in patients undergoing transurethral resection of prostate or bladder tumours patients were given spinal anaesthesia with hyperbaric **bupivacaine** 12 mg (**bupivacaine** 0.75% and glucose 82.5 mg) alone or with clonidine 30 micrograms. Onset time of motor block was shorter in the patients given **bupivacaine** with clonidine, when compared with those given **bupivacaine** alone (time to reach Bromage 3 motor block 11.7 minutes and 20.7 minutes, respectively). The duration of the sensory and motor block was longer in those given clonidine. No differences in the heart rate or mean arterial pressures were found between the groups.[2]

Another study, in children, found that oral premedication with clonidine 4 micrograms/kg reduced the plasma levels of epidural **lidocaine** by 25 to 50%.[3] Similar findings are reported in another study in which clonidine was given with epidural **lidocaine**.[4]

Mechanism

Not fully understood. An *in vitro* study using liver microsomes found that clonidine, at clinical levels, is unlikely to affect the metabolism of lidocaine.[5] However, the haemodynamic effects of clonidine may lead to decreased hepatic blood flow and reduced metabolism.[5]

Importance and management

Evidence of an interaction between bupivacaine and clonidine appears to be limited to two studies, which suggest that clonidine may increase the response to bupivacaine without causing adverse cardiac effects. This interaction may be beneficial.

Evidence for an interaction between lidocaine and clonidine is also limited, but what is known suggests that clonidine may reduce the levels of lidocaine appearing in the plasma, following epidural administration. This interaction may also be beneficial.

Note that clonidine used as an antihypertensive could, theoretically, cause severe hypotension if given with local anaesthetics. See also 'Anaesthetics, local + Antihypertensives', p.121.

Anaesthetics, local + CYP3A4 inhibitors

Itraconazole may reduce the clearance of bupivacaine. Itraconazole, ketoconazole or clarithromycin may slightly decrease ropivacaine clearance.

Clinical evidence, mechanism, importance and management

(a) Bupivacaine

In a placebo-controlled, crossover study in 7 healthy subjects pretreatment with **itraconazole** 200 mg daily for 4 days reduced the clearance of bupivacaine (300 micrograms/kg given intravenously over 60 minutes) by 20 to 25%.[1] It seems unlikely that a decrease of this magnitude in the clearance of bupivacaine will be clinically relevant.

(b) Ropivacaine

In a study in 8 healthy subjects, pretreatment with **itraconazole** 200 mg daily or **clarithromycin** 250 mg twice daily for 4 days did not significantly affect the pharmacokinetics of intravenous ropivacaine 600 microgram/kg. However, there was considerable interindividual variation in the findings. A small but statistically insignificant 20% increase in the AUC of ropivacaine occurred, and the peak plasma concentrations of the metabolite 2′,6′-pipecoloxylidide were decreased by **clarithromycin** and **itraconazole**, by 44% and 74%, respectively. Both **itraconazole** and **clarithromycin** inhibit the formation of this metabolite by the cytochrome P450 isoenzyme CYP3A4.[2] Similar results were found with **ketoconazole** and ropivacaine.[3] Potent inhibitors of CYP3A4 appear to cause only a minor decrease in clearance of ropivacaine, which is unlikely to be of clinical relevance.[3] For a report of erythromycin, an inhibitor of CYP3A4, enhancing the effect of fluvoxamine, an inhibitor of CYP1A2, on the clearance of ropivacaine, see 'Anaesthetics, local; Ropivacaine + Fluvoxamine', p.126.

Anaesthetics, local + H_2-receptor antagonists

Some studies suggest that both cimetidine and ranitidine can modestly raise the plasma levels of bupivacaine, whereas other evidence suggests that no significant interaction occurs. Some studies found that cimetidine does not affect lidocaine when used as an anaesthetic, whereas others found that cimetidine increased plasma lidocaine levels. Ranitidine and probably famotidine do not appear to significantly affect the pharmacokinetics of lidocaine.

Clinical evidence

(a) Bupivacaine

1. Cimetidine. In a study in 16 women undergoing caesarean section, pretreatment with cimetidine 300 mg intramuscularly 1 to 4 hours before epidural anaesthesia with bupivacaine 0.5% had no effect on the pharmacokinetics of bupivacaine in either the women or the neonates, when compared with 20 control women, although the maternal unbound bupivacaine plasma levels rose by 22%.[1] These findings were confirmed in two similar studies in which women receiving bupivacaine were pretreated with cimetidine before caesarean section,[2,3] and a further study in 7 healthy subjects (6 women and one man) given two oral doses of cimetidine 400 mg before intramuscular bupivacaine.[4] However, in a further study in 4 healthy male subjects, the AUC of bupivacaine was increased by 40% (when compared to placebo) by cimetidine. In this study cimetidine 400 mg was given at 10 pm and 8 am the following day, with a 50-mg infusion of bupivacaine given at 11 am.[5]

2. Ranitidine. In a study in 10 subjects given extradural anaesthesia for caesarean section, pretreatment with oral ranitidine 150 mg 1.5 to 2 hours before bupivacaine increased the maximum plasma levels of bupivacaine by about 36%, when compared with 10 patients given no pretreatment.[3] A further study in 9 patients also found that pretreatment with ranitidine

150 mg increased plasma bupivacaine levels.[6] Another study found that two oral doses of ranitidine 150 mg caused a 25% increase in the mean AUC of bupivacaine, but this was not statistically significant.[5] No increased bupivacaine toxicity was described in any of these reports. However, two other studies in 36 and 28 women undergoing caesarean section found no measurable effect on the bupivacaine disposition when ranitidine 150 mg was given the night before and on the morning of anaesthesia,[2] or when ranitidine 50 mg was given intramuscularly 2 hours before anaesthesia, respectively.[7]

(b) Lidocaine

1. Cimetidine. In 5 women given epidural anaesthesia for caesarean section, the pharmacokinetics of 400 mg of lidocaine 2% (with adrenaline (epinephrine) 1:200 000) were unchanged by a single 400-mg oral dose of cimetidine given about 2 hours preoperatively.[8] Another very similar study in 9 women found no statistically significant rises in whole blood lidocaine levels (although they tended to be higher), in the presence of cimetidine 300 mg, given intramuscularly, at least one hour preoperatively.[9] However, in patients pretreated with cimetidine (200 mg orally on the night before surgery and 400 mg one hour before induction) peak plasma levels of epidural lidocaine 2% (with adrenaline 1:200 000) were 3.2 micrograms/mL. Lidocaine levels in patients who did not receive pretreatment with H_2-receptor antagonists were 2.3 micrograms/mL.[10]

2. Famotidine. In patients pretreated with famotidine (20 mg orally on the night before surgery plus 20 mg intramuscularly one hour before induction), peak plasma levels of epidural lidocaine 2% (with adrenaline 1:200 000) were 2.4 micrograms/mL. Lidocaine levels in patients who did not receive pretreatment with H_2-receptor antagonists were 2.3 micrograms/mL.[10] In another study, the effects of famotidine on lidocaine were found to be less than those of cimetidine, but greater than in patients not given an H_2-receptor antagonist.[11]

3. Ranitidine. In 7 women given epidural anaesthesia for caesarean section the pharmacokinetics of 400 mg of lidocaine 2%, (with adrenaline (epinephrine) 1:200 000) were unchanged after a single 150-mg oral dose of ranitidine given about 2 hours preoperatively.[8] A similar study in 8 women also found no statistically significant rises in whole blood lidocaine levels in the presence of ranitidine 150 mg given orally at least 2 hours preoperatively.[9]

Mechanism

Not understood. It has been suggested that cimetidine reduces the hepatic metabolism of bupivacaine and lidocaine. Protein binding displacement has also been suggested.

Importance and management

A confusing situation. No clinically important interaction has been established, but be alert for any evidence of increased bupivacaine toxicity resulting from raised total plasma levels and rises in unbound bupivacaine levels during the concurrent use of cimetidine. Ranitidine may modestly increase the levels of bupivacaine but this does not appear to be clinically significant.

Cimetidine (but not ranitidine) has been shown to raise plasma lidocaine levels when lidocaine is used as an antiarrhythmic (see 'Lidocaine + H_2-receptor antagonists', p.299), but some of the studies cited above found cimetidine did not affect lidocaine levels when lidocaine is used as a local anaesthetic. However, in the studies comparing the effects of cimetidine and famotidine, cimetidine was found to increase lidocaine levels and it was suggested that famotidine may be preferable to cimetidine as pretreatment before epidural lidocaine.[10,11]

Anaesthetics, local + Rifampicin (Rifampin)

Rifampicin increases the metabolism of ropivacaine.

Clinical evidence, mechanism, importance and management

A study in 10 healthy non-smokers and 8 otherwise healthy smokers given ropivacaine 600 micrograms/kg by intravenous infusion over 30 minutes found that pretreatment with rifampicin 600 mg daily for 5 days increased the clearance of the metabolite 3-hydroxyropivacaine and decreased the urinary excretion of 2′,6′-pipecoloxylidide by 93% and 46%, respectively, decreased the AUC by 52% and 38%, respectively, and decreased the half-life of ropivacaine in both non-smokers and smokers.[1] Ropivacaine undergoes oxidative hepatic metabolism mainly by the cytochrome P450 isoenzymes CYP1A2 and CYP3A4. The elimination of ropivacaine may be considerably accelerated by rifampicin, which is a potent cytochrome P450 enzyme inducer. However, in clinical use the local anaesthetic is given near the nerves to be desensitised and induction of these isoenzymes is not likely to affect the local anaesthetic before it enters the systemic blood circulation.[1] This interaction is therefore of little clinical relevance.

Rifampicin may also increase the metabolism of lidocaine to a minor extent, see 'Lidocaine + Rifampicin (Rifampin)', p.302.

1. Jokinen MJ, Olkkola KT, Ahonen J, Neuvonen PJ. Effect of rifampin and tobacco smoking on the pharmacokinetics of ropivacaine. *Clin Pharmacol Ther* (2001) 70, 344–50.

Anaesthetics, local + Tobacco

Smoking appears to have only a minor effect on ropivacaine pharmacokinetics. Tobacco smoking may enhance cocaine-associated myocardial ischaemia.

Clinical evidence, mechanism, importance and management

(a) Cocaine

In a study in 42 smokers (36 with proven coronary artery disease), the mean product of the heart rate and systolic arterial pressure increased by 11% after intranasal cocaine 2 mg/kg, by 12% after one cigarette and by 45% after both cocaine use and one cigarette. Compared with baseline measurements, the diameters of non-diseased coronary arterial segments decreased on average by 7% after cocaine use, 7% after smoking and 6% after cocaine and smoking. However, the diameters of diseased segments decreased by 9%, 5% and 19%, respectively.[1] Cigarette smoking increases myocardial oxygen demand and induces coronary-artery vasoconstriction through an alpha-adrenergic mechanism similar to cocaine and therefore tobacco smoking may enhance cocaine-associated myocardial ischaemia.[1,2]

(b) Ropivacaine

A study in 10 healthy non-smokers and 8 otherwise healthy smokers given ropivacaine 600 micrograms/kg by intravenous infusion over 30 minutes found that smoking increased the urinary excretion of the metabolite 3-hydroxyropivacaine and decreased the urinary excretion of the metabolite 2′,6′-pipecoloxylidide by 62%, but did not significantly affect the ropivacaine AUC.[3]

Ropivacaine undergoes oxidative hepatic metabolism mainly by the cytochrome P450 isoenzymes CYP1A2 and CYP3A4. Cigarette smoking is known to induce CYP1A2 and may therefore increase the metabolism of ropivacaine. However, in clinical use the local anaesthetic is given near the nerves to be desensitised and induction of isoenzymes is not likely to affect the local anaesthetic before it enters the systemic blood circulation.[3] This interaction is therefore of little clinical relevance.

Note that smoking may reduce the bioavailability of *oral* lidocaine, see 'Lidocaine + Tobacco', p.302.

Anaesthetics, local; Bupivacaine + Antipsychotics

Exaggerated hypotension occurred in a patient taking risperidone when she was given spinal anaesthesia with bupivacaine.

Clinical evidence, mechanism, importance and management

A patient with bipolar disorder, taking lithium 600 mg twice daily and **risperidone** 2 mg at bedtime, was given spinal anaesthesia with hyperbaric bupivacaine 0.75% (12 mg), fentanyl 10 micrograms and morphine 200 micrograms for an elective caesarean section. Within a few minutes, her blood pressure decreased from 120/50 mmHg to 70/30 mmHg, for which she was given ephedrine 50 mg and Ringer's lactate solution. Her heart rate increased from about 80 bpm to 130 bpm, with little improvement in the hypotension until phenylephrine 600 micrograms was given, after which her vital signs gradually improved over 10 minutes. A previous caesarean section in the same patient, while taking lithium but not **risperidone** and using the same epidural anaesthesia, had been accompanied by hypotension to about 80/50 mmHg which had rapidly normalised with ephedrine 20 mg and phenylephrine 40 micrograms.

Hypotension is a common adverse effect of bupivacaine and lithium may cause hypotension in toxicity. However, the patient's lithium level was subtherapeutic on the morning of the caesarean section. **Risperidone** is an antagonist of alpha-adrenergic receptors, which the authors believe contributed to the difficulty in treating the peri-operative hypotension seen in the case report above. Further, it was suggested that the tachycardia without improvement in the hypotension after ephedrine was given may have been due to the beta-adrenergic effects of ephedrine combined with the alpha-adrenergic antagonism of risperidone.[1]

The general importance of this isolated case is unclear; however, it serves as a reminder that the adverse hypotensive effects that are common to many antipsychotics, could be additive with the hypotensive effects of bupivacaine.

1. Williams JH, Hepner DL. Risperidone and exaggerated hypotension during a spinal anesthetic. *Anesth Analg* (2004) 98, 240–1.

Anaesthetics, local; Bupivacaine + Dexmedetomidine

The addition of dexmedetomidine to bupivacaine spinal block shortens the onset time and increases the duration of sensory and motor block.

Clinical evidence, mechanism, importance and management

In a study in patients undergoing transurethral resection of prostate or bladder tumours patients were given spinal anaesthesia with hyperbaric bupivacaine 12 mg (bupivacaine 0.75% and glucose 82.5 mg) alone or with dexmedetomidine 3 micrograms. Onset time of motor block was shorter in the patients given bupivacaine with dexmedetomidine, when compared with those given bupivacaine alone (time to reach Bromage 3 motor block, 13.2 minutes and 20.7 minutes, respectively). The duration of the sensory and motor block was significantly longer in those given the combination. No differences in the heart rate or mean arterial pressures were found between the groups.[1]

Evidence appears to be limited to this study, but it demonstrates that concurrent use may be beneficial.

1. Kanazi GE, Aouad MT, Jabbour-Khoury SI, Al Jazzar MD, Alameddine MM, Al-Yaman R, Bulbul M, Baraka AS. Effect of low dose dexmedetomidine or clonidine on the characteristics of bupivacaine spinal block. *Acta Anaesthesiol Scand* (2006) 50, 222–7.

Anaesthetics, local; Cocaine + Adrenaline (Epinephrine)

Arrhythmias occurred in three patients given a concentrated nasal paste containing cocaine and adrenaline (epinephrine).

Clinical evidence, mechanism, importance and management

Two children and one adult patient undergoing general anaesthesia[1] developed arrhythmias shortly after nasal application of a paste containing cocaine 25% and adrenaline (epinephrine) 0.18%. All 3 patients received doses of cocaine that exceeded the maximum dose (1.5 mg/kg) recommended in the BNF[2] for healthy adults.

Cocaine has sympathomimetic actions (tachycardia, peripheral vasoconstriction, and hypertension). Combined use with sympathomimetics such as adrenaline increases these effects, and the risk of life-threatening arrhythmias. This risk may be further increased if halothane anaesthesia is used (two of the above patients received halothane[1]). See also 'Anaesthetics, general + Anaesthetics, local', p.103, and 'Anaesthetics, general + Inotropes and Vasopressors', p.111.

The use of adrenaline with topical cocaine is controversial. Some consider that the addition of adrenaline is of doubtful value and that the combination should not be used, especially in the form of a concentrated paste.[1] However, others consider the combination to be safe and useful.[3] Note also that the use of local anaesthetics containing adrenaline should be avoided in patients who abuse cocaine, unless it is certain that they have not used cocaine for at least 24 hours.[4]

Anaesthetics, local; Cocaine + Disulfiram

Disulfiram increases plasma levels of inhaled and intravenous cocaine. Disulfiram increases the cardiovascular effects associated with inhaled, but not intravenous cocaine, whereas it does not significantly affect the behavioural responses to inhaled cocaine but decreases the behavioural responses to intravenous cocaine.

Clinical evidence

A preliminary study in 6 subjects taking cocaine by inhalation found that disulfiram 250 mg daily significantly increased plasma levels of cocaine 1 mg/kg by threefold and increased the plasma levels of cocaine 2 mg/kg by greater than fourfold, respectively. Concurrent treatment also increased the heart rate and blood pressure but did not affect 'high' and 'nervous' ratings.[1]

In a further study by the same authors, 7 subjects from the initial study were given disulfiram 250 mg, disulfiram 500 mg or placebo daily for 5 days. Intranasal cocaine 1 or 2 mg/kg or placebo was started after the third disulfiram dose. Following treatment with disulfiram 250 or 500 mg, the AUC of cocaine was increased three- to sixfold and plasma cocaine levels were increased two- to threefold. Increases in heart rate with disulfiram alone just reached significance, but disulfiram treatment significantly increased the heart rate responses to inhaled cocaine. Disulfiram alone had no significant effect on blood pressure. However, systolic and diastolic blood pressure increased after disulfiram 500 mg daily with cocaine 2 mg/kg, and tended to increase after the disulfiram 250 mg dose. Disulfiram had no significant effects on the behavioural responses to cocaine.[2]

In a further study, cocaine-dependent subjects were given disulfiram 62.5 mg, disulfiram 250 mg or placebo daily for 6 days, with intravenous cocaine 250 micrograms/kg (9 subjects), 500 micrograms/kg (3 subjects) or placebo, taken 2 hours after the disulfiram dose, on days 4 to 6. Disulfiram 62.5 mg and 250 mg increased the AUC of cocaine 250 micrograms/kg by 67 to 84%. Larger increases were seen with the cocaine 500 microgram/kg dose, although these did not reach statistical significance. The clearance of cocaine was also reduced. Disulfiram did not

affect the cardiovascular responses to either dose of intravenous cocaine. The behavioural responses to cocaine 250 micrograms/kg ('highs', 'rush') were significantly decreased by disulfiram; similar effects were seen with the larger dose but this did not reach statistical significance due to the small sample size.[3]

The studies above differed in the routes of administration of cocaine (intranasal versus intravenous) and the latter study noted that the dose of intravenous cocaine used produced lower overall levels of cocaine than the intranasal dose studied.[3]

Of interest, a report of a cost-effectiveness study looking at the benefits of using disulfiram to treat cocaine use in methadone-maintained opioid addicts, found that disulfiram use was associated with a reduction in the amount of cocaine used.[4]

Mechanism

Disulfiram has been reported to inhibit carboxylesterases and plasma cholinesterase, which are enzymes involved in the metabolism of cocaine.[3]

Importance and management

It would appear that disulfiram may significantly increase the plasma levels and reduce the clearance of both intranasal and intravenous cocaine. There is conflicting data as to whether this enhances the cardiovascular and behavioural effects of cocaine use. Overall, it would be prudent to exercise caution when giving disulfiram to patients using cocaine as the increase in cocaine levels may result in cocaine toxicity.

Anaesthetics, local; Cocaine + Progesterone

There is some evidence to suggest that progesterone may attenuate some of the cardiovascular and subjective effects of smoked or intravenous cocaine, but not the effects of intranasal cocaine.

Clinical evidence, mechanism, importance and management

A preliminary, placebo-controlled study in 5 female cocaine-dependent subjects found that a single 200-mg dose of progesterone, given during days 3 to 9 of the menstrual cycle, attenuated the subjective effects of smoked cocaine.[1] In a further placebo-controlled study by the same authors, 6 male and 4 female cocaine-dependent subjects were given two doses of progesterone 200 mg at 10 pm the day before, and at 8 am on the morning of, intravenous cocaine administration. The initial dose of cocaine 300 micrograms/kg was given 2 hours after the second progesterone dose. Subjects then started a self-administration period in which 5 optional doses of cocaine were available in a 2.5-hour period. Progesterone attenuated cocaine-induced increases in diastolic blood pressure but did not affect systolic blood pressure or heart rate increases. Progesterone also attenuated subjective ratings of 'high' and 'feel the effect of the last dose' in response to cocaine, but did not affect self-administration behaviour.[2]

In a pilot study, male methadone-stabilised cocaine users were given either placebo (15 subjects) or progesterone (dose gradually increased from 100 mg to 300 mg twice daily over 4 weeks; 30 subjects) for 10 weeks. Cocaine positive urine tests showed a slight decrease in cocaine use in the progesterone group and a slight increase in use in the placebo group. However, at weeks 9 and 10, the placebo group showed a significantly lower use of cocaine (as measured by the cocaine positive urine test), when compared with the group given progesterone, suggesting a lack of efficacy of progesterone as a treatment for cocaine dependence in male users.[3]

These findings are probably more relevant to the potential use of progesterone in cocaine dependence, but they do demonstrate that the concurrent use of progesterone in patients taking cocaine is unlikely to result in an adverse outcome.

Anaesthetics, local; Lidocaine + Ondansetron

Ondansetron may reduce the efficacy of the sensory block induced by lidocaine.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study oral ondansetron 4 mg was given to patients the evening before surgery, followed by intravenous ondansetron 4 mg given over 15 minutes before subarachnoid anaesthesia with lidocaine 5% in dextrose 8%. Ondansetron significantly reduced the sensory block measured at 30 minutes. Motor block was unaffected. In this study 54 patients were enrolled, but not all patients were assessed for both motor and sensory block.[1]

Evidence appears to be limited to this one study, but, until more is known, it may be prudent to monitor closely for a reduction in the efficacy of the sensory block with lidocaine if ondansetron is also given.

Anaesthetics, local; Ropivacaine + Fluvoxamine

Fluvoxamine inhibits the clearance of ropivacaine.

Clinical evidence, mechanism, importance and management

In a randomised, crossover study in 12 healthy subjects fluvoxamine decreased the mean total plasma clearance of ropivacaine by 68%, and almost doubled the half-life of ropivacaine. Fluvoxamine was given at a dose of 25 mg twice daily for 2 days, and a single 40-mg intravenous dose of ropivacaine was given over 20 minutes one hour after the morning dose of fluvoxamine on the second day.[1]

Fluvoxamine is a potent inhibitor of the cytochrome P450 isoenzyme CYP1A2 and so reduces the metabolism of ropivacaine to its major metabolite 3-hydroxyropivacaine. In one study in healthy subjects the combination of fluvoxamine with **erythromycin**, an inhibitor of CYP3A4, which on its own has little effect on the pharmacokinetics of ropivacaine, was found to decrease the clearance of ropivacaine more than fluvoxamine alone.[2]

The UK manufacturer recommends that the prolonged use of ropivacaine should be avoided in patients given potent CYP1A2 inhibitors, such as fluvoxamine.[3] Be aware that CYP3A4 inhibitors, such as erythromycin, in combination with CYP1A2 inhibitors may further reduce ropivacaine clearance.[2]

3. Naropin (Ropivacaine hydrochloride monohydrate). AstraZeneca UK Ltd. UK Summary of product characteristics, August 2008.

Anaesthetics, local; Ropivacaine + Quinolones

Ciprofloxacin may decrease the clearance of ropivacaine. It is also likely that enoxacin will inhibit the metabolism of ropivacaine.

Clinical evidence, mechanism, importance and management

A study in 9 healthy subjects found that **ciprofloxacin** 500 mg twice daily decreased the mean clearance of a single 600-microgram/kg intravenous dose of ropivacaine by 31%, but there was considerable inter-individual variation in the effects of **ciprofloxacin**. The reduction in clearance probably occurs because **ciprofloxacin** inhibits the cytochrome P450 isoenzyme CYP1A2, which metabolises ropivacaine to its major metabolite 3-hydroxyropivacaine. For some patients concurrent use may cause toxi-

city.[1] Bear the potential for an interaction in mind if ropivacaine is given to a patient taking **ciprofloxacin**.

On the basis of data with 'fluvoxamine', (p.126), the UK manufacturer of ropivacaine has recommended that the prolonged use of ropivacaine should be avoided in patients taking potent CYP1A2 inhibitors such as **enoxacin**.[2]

Neuromuscular blockers + Aminoglycosides

The aminoglycoside antibacterials possess neuromuscular blocking activity. Appropriate measures should be taken to accommodate the increased neuromuscular blockade and the prolonged and potentially fatal respiratory depression that can occur if these antibacterials are used with conventional neuromuscular blocking drugs.

Clinical evidence

Two examples from many:

A 38-year-old patient anaesthetised with cyclopropane experienced severe respiratory depression after being given intraperitoneal **neomycin** 500 mg. She had also received **suxamethonium** (**succinylcholine**) and **tubocurarine**. This antibacterial-induced neuromuscular blockade was resistant to treatment with edrophonium.[1]

A 71-year-old woman received a standard bowel preparation consisting of oral erythromycin and **neomycin** (a total of 3 g). Surgery was postponed for one day and she received a second similar bowel preparation pre-operatively. Anaesthesia was induced with sufentanil and etomidate and maintained with isoflurane and sufentanil. **Rocuronium** (total dose of 60 mg over 2 hours) was used to facilitate tracheal intubation and maintain muscle relaxation. Despite clinical appearance of a reversal of the neuromuscular blockade by neostigmine 3.5 mg and glycopyrronium (glycopyrrolate) 400 micrograms, the patient complained of dyspnoea and required reintubation twice. The effects of additional doses of neostigmine were inconsistent and the use edrophonium 50 mg or calcium chloride 500 mg intravenously did not result in an improvement.[2]

Many other reports confirm that some degree of respiratory depression or paralysis can occur if aminoglycosides are given to anaesthetised patients. When a conventional neuromuscular blocker is also used, the blockade is deepened and recovery prolonged. If the antibacterial is given towards the end of surgery the result can be that a patient who is recovering normally from neuromuscular blockade suddenly develops serious apnoea, which can lead to prolonged and in some cases fatal respiratory depression.

A review of the literature[3] lists more than 100 cases over the period 1956 to 1970 involving:

- **tubocurarine** with **neomycin** or **streptomycin,**
- **gallamine** with **neomycin**, **kanamycin** or **streptomycin**,
- **suxamethonium** with **neomycin**, **kanamycin** or **streptomycin**.

The routes of antibacterial administration were oral, intraperitoneal, oesophageal, intraluminal, retroperitoneal, intramuscular, intrapleural, cystic, beneath skin flaps, extradural and intravenous.

Later reports involve:

- **pancuronium**; with **amikacin**,[4] **gentamicin**,[5] **neomycin**,[6] or **streptomycin**,[7,8]
- **pipecuronium** with **netilmicin**,[9]
- **suxamethonium** with **dibekacin**,[10]
- **tubocurarine**; with **amikacin**,[11] **dibekacin**,[10,12] **framycetin** (eye irrigation),[13] **ribostamycin**,[10,12] or **tobramycin**,[14]
- **vecuronium**; with **amikacin/polymyxin**,[15] **gentamicin**,[16-18] **gentamicin/clindamycin**,[19] **neomycin/clindamycin**,[20] or **tobramycin**.[17,21]

Aminoglycosides and neuromuscular blockers that have been reported not to interact are:

- **alcuronium** with **tobramycin**,[22]
- **atracurium** with **gentamicin** or **tobramycin**,[17]
- **suxamethonium** with **tobramycin** or **ribostamycin**.[10]

Mechanism

The aminoglycosides appear to reduce or prevent the release of acetylcholine at neuromuscular junctions (related to an impairment of calcium influx) and they may also lower the sensitivity of the post-synaptic membrane, thereby reducing transmission. These effects would be additive with those of conventional neuromuscular blockers, which act at the post-synaptic membrane.

Importance and management

Extremely well documented, very long established, clinically important and potentially serious interactions. Ten out of the 111 cases in one review[3] were fatal, related directly or indirectly to aminoglycoside-induced respiratory depression. Concurrent use need not be avoided, but be alert for increased and prolonged neuromuscular blockade with every aminoglycoside and neuromuscular blocker, although the potencies of the aminoglycosides differ to some extent. In *animal* studies, at concentrations representing the maximum therapeutic levels, the neuromuscular blocking potency of various aminoglycosides was rated (from highest to lowest): neomycin, streptomycin, gentamicin, kanamycin.[23] The postoperative recovery period should also be closely monitored because of the risk of recurarisation if the aminoglycoside is given during surgery. High-risk patients appear to be those with renal disease and hypocalcaemia, who may have elevated serum antibacterial levels, and those with pre-existing muscular weakness. Treatment of the increased blockade with anticholinesterases and calcium has met with variable success because the response seems to be inconsistent.

Neuromuscular blockers + Anaesthetics, local

The neuromuscular blockade due to suxamethonium (succinylcholine) can be increased and prolonged by procaine. Increased toxicity occurred when mivacurium and prilocaine were given together for regional anaesthesia. Local anaesthetics have some

neuromuscular blocking activity and may theoretically also enhance the block produced by competitive neuromuscular blockers.

Clinical evidence

A study found that **procaine** prolonged the apnoea following the use of **suxamethonium** 700 micrograms/kg. A dose-relationship was established. The duration of apnoea was approximately doubled by 2.2 mg/kg of procaine intravenously, and tripled by 11.2 mg/kg, although the effects of procaine at higher doses were more marked.[1]

In a study in 10 healthy subjects, prolonged muscle weakness and symptoms of local anaesthetic toxicity were experienced after deflation of the tourniquet when 40 mL of **prilocaine** 0.5% and **mivacurium** 600 micrograms were used together for intravenous regional anaesthesia of the forearm. Giving **prilocaine** or **mivacurium** alone did not produce these effects. The slow recovery suggested that **mivacurium** was not broken down in the ischaemic limb,[2] but inhibition of plasma cholinesterase by **prilocaine** would not fully explain the prolonged weakness once the cuff was deflated.[3]

Mechanism

Uncertain. Some local anaesthetics (ester-type[4]) such as procaine appear to inhibit plasma cholinesterase,[5] which might prolong the activity of suxamethonium. There may additionally be competition between suxamethonium and procaine for hydrolysis by plasma cholinesterase, which metabolises them both.[1,6] These effects are particularly important in patients with abnormal plasma cholinesterase.[7] This may also partially explain the interaction with mivacurium.

All local anaesthetics have some neuromuscular blocking activity and may enhance the block produced by competitive neuromuscular blockers if given in sufficient doses.[7,8]

Importance and management

Information is limited but the interaction between suxamethonium and procaine appears to be established and of clinical importance. Be alert for signs of increased blockade and/or recurarisation with apnoea during the recovery period from suxamethonium, although note that in the study cited, procaine was given intravenously, and local administration would be expected to produce less dramatic effects.

In general, local anaesthetics (e.g. **lidocaine**, procaine) have some neuromuscular blocking activity and may also enhance the block produced by competitive neuromuscular blockers if given in sufficient doses. However, again, there seems to be an absence of reports of this, probably because the amount of local anaesthetic absorbed into the circulation following a local block is usually modest.[8]

Some local anaesthetics (e.g. lidocaine) are also used as antiarrhythmics. For the use of lidocaine and other antiarrhythmics with neuromuscular blockers, see 'Neuromuscular blockers + Antiarrhythmics', below.

Neuromuscular blockers + Antiarrhythmics

The neuromuscular blockade due to suxamethonium (succinylcholine) can be increased and prolonged by lidocaine and possibly procainamide. These drugs have some neuromuscular blocking activity and may theoretically also enhance the block produced by competitive neuromuscular blockers.

Clinical evidence

A patient anaesthetised with fluroxene and nitrous oxide demonstrated 100% blockade with **suxamethonium** (**succinylcholine**) and **tubocurarine**. About 50 minutes later, when twitch height had fully returned and tidal volume was 400 mL, she was given **lidocaine** 50 mg intravenously for premature ventricular contractions. She immediately stopped breathing and the twitch disappeared. About 45 minutes later the tidal volume was 450 mL. Later it was found that the patient had a dibucaine number (a measure of cholinesterase activity) of 23%.[1]

A study has confirmed that **lidocaine** prolongs the apnoea following the use of **suxamethonium** 700 micrograms/kg. A dose-relationship was established, with the duration of apnoea approximately doubled by intravenous lidocaine 5 mg/kg, and tripled by lidocaine 16.6 mg/kg.[2]

Procainamide has been reported to increase the effects of **suxamethonium** in *animals*,[3] increase muscle weakness in a myasthenic patient,[4] and reduce plasma cholinesterase activity in *in vitro* plasma samples from healthy subjects.[5]

Mechanism

Uncertain. Therapeutic procainamide plasma concentrations of 5 to 10 micrograms/mL have been found to inhibit cholinesterase activity by 19 to 32%. Procainamide also has acetylcholine receptor channel blocking activity.[6]

Importance and management

Information is limited but the interaction between suxamethonium (succinylcholine) and lidocaine appears to be established and of clinical importance. Be alert for signs of increased blockade and/or recurarisation with apnoea during the recovery period from suxamethonium in patients given intravenous lidocaine.

Despite the potential for an interaction between suxamethonium and procainamide, no marked interaction has yet been reported. Nevertheless be aware that some increase in the neuromuscular blocking effects is possible.

Lidocaine and procainamide both have some neuromuscular blocking activity and may also enhance the block produced by competitive neuromuscular blockers. However, again, there seems to be an absence of reports of this effect in practice.

Neuromuscular blockers + Anticholinesterases

Anticholinesterases oppose the actions of competitive neuromuscular blockers (e.g. tubocurarine) and can therefore be used as an antidote to restore muscular activity following their use. Conversely, anticholinesterases increase and prolong the actions of the depolarising neuromuscular blockers (e.g. suxamethonium (succinylcholine)). Anticholinesterases used to treat Alzheimer's disease may also interact with neuromuscular blockers.

Clinical evidence, mechanism, importance and management

There are two main types of neuromuscular blockers: competitive (non-depolarising) and depolarising (i.e. suxamethonium (succinylcholine)), see 'Table 5.2', (p.101).

(a) Competitive (non-depolarising) neuromuscular blockers

Competitive (non-depolarising) neuromuscular blockers (e.g. **tubocurarine**) compete with acetylcholine for receptors on the motor endplate. Anticholinesterases (e.g. **ambenonium**, **edrophonium**, **neostigmine**, **physostigmine**, **pyridostigmine**, etc.) can be used as an antidote to this kind of neuromuscular blockade, because they inhibit the enzymes that de-

stroy acetylcholine so that the concentration of acetylcholine at the neuromuscular junction builds up. In this way the competition between the molecules of the blocker and the acetylcholine for occupancy of the receptors swings in favour of the acetylcholine so that transmission is restored. These drugs are used routinely following surgery to reactivate paralysed muscles. However, note that the **aminoglycosides** can act as neuromuscular blockers (see 'Neuromuscular blockers + Aminoglycosides', p.127) and therefore the use of an aminoglycoside may unintentionally antagonise the effects of the anticholinesterases.

Some inhalational anaesthetics can impair the effect of anticholinesterases on neuromuscular blockers (see 'Anaesthetics, general + Anticholinesterases', p.105).

(b) Suxamethonium (Succinylcholine)

The depolarising neuromuscular blockers (such as suxamethonium) act like acetylcholine to depolarise the motor endplate, but unlike acetylcholine, they are not immediately removed by cholinesterase. The anticholinesterase drugs increase the concentration of acetylcholine at the neuromuscular junction, which enhances and prolongs this type of blockade, and therefore anticholinesterases cannot be used as an antidote for this kind of blocker. Care should be taken if an anticholinesterase has been given to antagonise a competitive neuromuscular block before the use of suxamethonium, as the duration of the suxamethonium block may be prolonged.[1]

(c) Tacrine and other centrally-acting anticholinesterases

1. Competitive (non-depolarising) neuromuscular blockers. Tacrine, like other anticholinesterases, has been used *intravenously* in anaesthetic practice to reverse the effects of competitive (non-depolarising) blockers such as **tubocurarine**.[2] However, tacrine is now more commonly used *orally* for its central effects in the treatment of Alzheimer's disease. Therefore be alert for a reduction in the effects of any competitive neuromuscular blocker in patients taking tacrine. Other centrally acting anticholinesterases (including **galantamine**, **rivastigmine** and possibly **donepezil**) would be expected to behave like tacrine.

The clinical relevance of this warning is supported by a case report, which describes prolonged **suxamethonium**-induced relaxation in a 75-year-old man who had been taking **donepezil** for 14 months. In this patient the effect of **atracurium** was found to be inadequate even at higher than usual doses, based on the patient's weight.[3]

2. Suxamethonium (Succinylcholine). Tacrine, like other anticholinesterases, has been used *intravenously* in anaesthetic practice to prolong the effects of depolarising blockers such as suxamethonium.[2,4-7] For example, one study found that only one-third of the normal dosage of suxamethonium was needed in the presence of 15 mg of intravenous tacrine.[8] However, tacrine is now more commonly used *orally* for its central effects in the treatment of Alzheimer's disease. Therefore be alert for an increase in the effects of suxamethonium in patients taking tacrine. Other centrally acting anticholinesterases (including **galantamine**, **rivastigmine** and possibly **donepezil**) would be expected to behave like tacrine.

There is a report of such an interaction in a 72-year-old woman taking **donepezil** who had prolonged paralysis after induction of anaesthesia with propofol and suxamethonium. It is possible that levels of **donepezil** in this patient were high due to the concurrent use of 'fluoxetine', (p.402), and this may have contributed to the prolonged action of suxamethonium.[9] Another report describes an 85-year-old woman taking **donepezil**, who developed prolonged neuromuscular blockade after she was given neostigmine to reverse the effects of pancuronium (she had also received suxamethonium). This patient probably had atypical pseudocholinesterase activity, and the authors suggest the interaction may not be clinically relevant in patients with normal enzyme activity.[10]

(d) Organophosphorus compounds

Organophosphorus compounds are potent anticholinesterases, see 'Neuromuscular blockers + Organophosphorus compounds', p.144.

Neuromuscular blockers + Antineoplastics

The effects of suxamethonium (succinylcholine) can be increased and prolonged in patients receiving cyclophosphamide because their plasma cholinesterase levels are depressed. Respiratory insufficiency and prolonged apnoea have been reported. Irinotecan may prolong the neuromuscular blocking effects of suxamethonium and antagonise that of non-depolarising drugs. *Animal* data suggests that thiotepa may also enhance the effects of suxamethonium. An isolated report describes a marked increase in the neuromuscular blocking effects of pancuronium in a myasthenic patient who was given thiotepa, but normally it appears not to interact with competitive neuromuscular blockers.

Clinical evidence

(a) Cyclophosphamide

Respiratory insufficiency and prolonged apnoea occurred in a patient taking cyclophosphamide on two occasions, both during anaesthesia during which **suxamethonium** (**succinylcholine**) and **tubocurarine** were given. Plasma cholinesterase levels were found to be low. Anaesthesia without the **suxamethonium** was uneventful. Seven out of 8 patients subsequently examined also showed depressed plasma cholinesterase levels while taking cyclophosphamide.[1]

Respiratory depression and low plasma cholinesterase levels have been described in other reports in patients taking cyclophosphamide.[2-5] Similarly, in the discussion of an *in vitro* study, the authors report preliminary results from a study in patients, showing a 35 to 70% reduction in cholinesterase activity, which lasted for several days after cyclophosphamide use.[2] See also *Mechanism*, below.

(b) Irinotecan

The manufacturer of irinotecan warns that it could possibly prolong the neuromuscular blocking effects of suxamethonium (succinylcholine) and antagonise the neuromuscular blockade of competitive (non-depolarising) drugs.[6] This is based on the fact that irinotecan has anticholinesterase activity.[6,7] See 'Neuromuscular blockers + Anticholinesterases', p.128, for an explanation of this mechanism.

(c) Thiotepa

A myasthenic patient developed very prolonged respiratory depression very shortly after being given thiotepa intraperitoneally, following the use of **pancuronium**.[8] Thiotepa has also been shown to increase the duration of **suxamethonium** (**succinylcholine**) neuromuscular blockade in *dogs*.[9] However, an *in vitro* study showed that thiotepa was a poor inhibitor of plasma cholinesterase.[2] See also *Mechanism*, below.

Mechanism

Cyclophosphamide inhibits the activity of plasma cholinesterase,[4] and as a result the metabolism of the suxamethonium is reduced and its actions are enhanced and prolonged. Other alkylating agents are also reported to reduce plasma cholinesterase activity.[10] An *in vitro* study found that human motor endplate or red blood cell acetylcholinesterase was inhibited by alkylating antineoplastics, with chlormethine exerting the greatest effect, followed by dacarbazine, nimustine, cyclophosphamide and ifosfamide. Chlormethine and cyclophosphamide inhibited plasma pseudocholinesterase most strongly, followed by thiotepa, nimustine, dacarbazine, ifosfamide, and carmustine.[10]

Importance and management

The interaction between suxamethonium (succinylcholine) and cyclophosphamide is well documented and established. It is of clinical importance, but whether all patients are affected to the same extent is uncertain. The depression of the plasma cholinesterase levels may last several days,

possibly weeks, so that ideally plasma cholinesterase levels should be checked before using suxamethonium. In patients taking cyclophosphamide, suxamethonium should certainly be used with caution, and the dosage should be reduced.[2] Some have suggested that concurrent use should be avoided.[1] Irinotecan may possibly enhance the effects of suxamethonium and antagonise the effects of non-depolarising drugs. *Animal* data suggest thiotepa may enhance the effects of suxamethonium, while *in vitro* data and a case report in a patient with myasthenia,[11] suggest some other antineoplastics may also have an effect. The general silence in the literature would seem to indicate that no special precautions are generally necessary. However, patients with malignant tumours often have a reduced plasma cholinesterase activity, so care is warranted in these patients.[12]

Neuromuscular blockers + Antipsychotics

An isolated report describes prolonged apnoea in a patient given promazine while recovering from neuromuscular blockade with suxamethonium (succinylcholine). The use of intravenous chlorpromazine before suxamethonium was found not to affect the activity of suxamethonium. Recovery from the neuromuscular blocking effects of suxamethonium is prolonged by fentanyl with droperidol.

Clinical evidence

(a) Chlorpromazine

In a study in 50 patients undergoing elective ophthalmic surgery, intravenous chlorpromazine 100 micrograms/kg given 3 minutes before **suxamethonium** (**succinylcholine**) 500 micrograms/kg did not significantly affect time to maximum neuromuscular block or reappearance and complete recovery of the twitch response, when compared with patients who had not been given chlorpromazine.[1]

(b) Fentanyl with Droperidol

The observation that patients who had received *Innovar* (fentanyl with droperidol) before anaesthesia appeared to have prolonged **suxamethonium** (**succinylcholine**) effects, seen as apnoea, prompted further study of this possible interaction.[2] An average delay in recovery from neuromuscular blockade of 36% to 80% was seen in two studies.[2,3] Another study[4] showed that the droperidol component of *Innovar* was probably responsible for this interaction.

(c) Promazine

A woman recovering from surgery during which she had received **suxamethonium** (**succinylcholine**), was given promazine 25 mg intravenously for sedation. Within 3 minutes she had become cyanotic and apnoeic, and required assisted respiration for 4 hours.[5]

Mechanism

Not understood. It has been suggested that promazine[5] and droperidol[4] depress plasma cholinesterase levels, which would reduce the metabolism of the suxamethonium and thereby prolong recovery. It has also been suggested that droperidol might act as a membrane stabiliser at neuromuscular junctions.[4]

Importance and management

Some caution would seem appropriate if promazine is given to any patient who has been given suxamethonium (succinylcholine). The use of intravenous chlorpromazine just before suxamethonium appears not to affect suxamethonium activity. There seems to be no information about other phenothiazines and other neuromuscular blockers.

Delayed recovery should be anticipated in patients given suxamethonium if droperidol is used. This is an established interaction.

Neuromuscular blockers + Aprotinin

Apnoea developed in a number of patients after they were given aprotinin while recovering from neuromuscular blockade with suxamethonium (succinylcholine), either alone or with tubocurarine.

Clinical evidence

Three patients undergoing surgery who had received **suxamethonium** (**succinylcholine**), either alone or with **tubocurarine**, were given aprotinin intravenously in doses of 2500 to 12 000 KIU (kallikrein inactivator units) at the end of, or shortly after, the operation when spontaneous breathing had resumed. In each case respiration rapidly became inadequate and apnoea lasting periods of 7, 30 and 90 minutes occurred.[1] Seven other cases have been reported elsewhere.[2]

Mechanism

Not fully understood. Aprotinin is only a very weak inhibitor of serum cholinesterase (100 000 KIU caused a maximal 16% inhibition)[3] and on its own would have little effect on the metabolism of suxamethonium. However, it might tip the balance in those whose cholinesterase was already very depressed.

Importance and management

The incidence of this interaction is uncertain but probably low. Only a few cases have been reported. It seems probable that it only affects those whose plasma cholinesterase levels are already very low for other reasons. No difficulties should arise in those whose plasma cholinesterase levels are normal.

Neuromuscular blockers + Benzodiazepines

A few studies report that diazepam and other benzodiazepines increase the effects of neuromuscular blockers, but many others have not found an interaction. If an interaction does occur, the response is likely to be little different from the individual variations in response of patients to neuromuscular blockers.

Clinical evidence

(a) Increased blockade

A comparative study of 10 patients given **gallamine** and 4 others given **gallamine** with intravenous **diazepam** 150 to 200 micrograms/kg found that **diazepam** prolonged the duration of activity of **gallamine** by a factor of three, and doubled the depression of the twitch response.[1] Persistent muscle weakness and respiratory depression was seen in two other patients given **tubocurarine** after premedication with **diazepam**.[2] A small

reduction (approximately 10%) in neuromuscular blocker requirement has been described when **diazepam** was given with **tubocurarine**[3] or **suxamethonium** (**succinylcholine**), but see also (b) below.[4] In a study in 10 patients, giving **diazepam** 200 micrograms/kg 3 minutes before **vecuronium** 100 micrograms/kg during anaesthetic induction shortened the time to onset of **vecuronium** and prolonged its duration of action, when compared with the activity of **vecuronium** in a similar group of patients not given **diazepam**.[5]

Another study found that recovery to 25% and 75% of the twitch height after **vecuronium** was prolonged by about 25% by 15 mg of intravenous **midazolam**, when compared with control patients.[6] The same study found that **midazolam** prolonged the recovery from the effects of **atracurium** by about 20%. However, the increased recovery time due to **midazolam** was not statistically significant when compared with control patients, but was significantly longer when compared with patients receiving 20 mg of intravenous **diazepam**.[6] See also (b) below.

(b) Reduced blockade or no interaction

The duration of paralysis due to **suxamethonium** was reduced in one study by 20% when **diazepam** (150 micrograms/kg) was also given, and the recovery time was shortened.[1] **Diazepam** also slightly reduced the time to 25% and 75% recovery of twitch height in patients given **vecuronium** by about 15% (not statistically significant).[6] In *animals*, **diazepam** increased the mean dose of **rocuronium** required by 13%, but this was not statistically significant.[7]

In other studies **diazepam** was found to have no significant effect on the neuromuscular blockade due to **alcuronium**,[8] **atracurium**,[6] **gallamine**,[9] **pancuronium**,[8,10] **suxamethonium**[8,11] or **tubocurarine**.[8,9,11,12] **Lorazepam** and **lormetazepam** have been reported to have little or no effects on **atracurium** or **vecuronium**,[6] and **midazolam** has been reported to have no effect on **suxamethonium**, **pancuronium**,[13] **rocuronium**[14] or **vecuronium**.[15,16]

Mechanism

Not understood. One suggestion is that where some alteration in response is seen it may be a reflection of a central depressant action rather than a direct effect on the myoneural junction.[9] Another study suggests that a direct action on the muscle may be responsible.[17]

Importance and management

What is known shows that the benzodiazepines may sometimes unpredictably alter the depth and prolong the recovery period from neuromuscular blockade, but the extent may not be very great and may possibly be little different from the individual variations in the response of patients to neuromuscular blockers.

Given that benzodiazepines are commonly given as premedication it seems likely that any significant interaction would have come to light by now.

Neuromuscular blockers + Beta-agonist bronchodilators

Bambuterol can prolong the recovery time from neuromuscular blockade with suxamethonium (succinylcholine) or mivacurium. A case report describes modestly enhanced neuromuscular blockade when pancuronium or vecuronium were given after intravenous salbutamol.

Clinical evidence

(a) Bambuterol

A double-blind study in 25 patients found that the recovery time from neuromuscular blockade with **suxamethonium** (**succinylcholine**) was prolonged by about 30% in those who had been given 10 mg of bambuterol 10 to 16 hours before surgery, and by about 50% in those who had been given 20 mg of bambuterol.[1]

This confirms two previous studies,[2,3] one of which found that 30 mg of bambuterol given about 10 hours before surgery approximately doubled the duration of **suxamethonium** blockade.[2] Furthermore, in 7 patients who had abnormal plasma cholinesterase levels, 20 mg of bambuterol taken 2 hours before surgery prolonged **suxamethonium** blockade two- to threefold, and in 4 patients a phase II block occurred.[4]

Similar results have been found in a study involving 27 patients given **mivacurium**. A marked decrease in plasma cholinesterase activity, leading to reduced clearance and prolonged elimination half-life of **mivacurium,** occurred when oral bambuterol 20 mg was given 2 hours before induction of anaesthesia. The duration of action of **mivacurium** was prolonged three- to fourfold, when compared with placebo.[5]

(b) Salbutamol

A case report describes a 28-year-old man undergoing elective surgery who was given three intravenous doses of salbutamol 125 micrograms over 3.5 hours for the treatment and prophylaxis of bronchospasm. Muscle relaxation was maintained with **pancuronium** and then **vecuronium**. The neuromuscular blockade (measured by the force of contraction of the adductor pollicis in response to ulnar nerve stimulation) increased after the salbutamol injection, from 45% to 66% during **pancuronium** blockade and from 66% to 86% following **vecuronium**. In addition, recovery of neuromuscular function with neostigmine appeared to be slower than expected.[6]

Mechanism

Bambuterol is an inactive prodrug, which is slowly converted enzymatically in the body to its active form, terbutaline. The carbamate groups that are split off can selectively inhibit the plasma cholinesterase that is necessary for the metabolism of suxamethonium and mivacurium. As a result, the metabolism of these neuromuscular blockers is reduced and their effects are thereby prolonged. The effect appears to be related to the dose of the bambuterol and the time lag after administration; maximal depression of plasma cholinesterase activity appears to occur about 2 to 6 hours following oral administration, but is still markedly depressed after 10 hours.[2]

The effect of intravenous salbutamol was probably a direct effect at the neuromuscular junction.[6]

Importance and management

The interaction with bambuterol is an established interaction. It may be more important where other factors reduce plasma cholinesterase activity or affect the extent of blockade in other ways (e.g. subjects with abnormal plasma cholinesterase levels). This interaction only applies to beta agonists that are metabolised to carbamic acid (bambuterol appears to be the only one available).

The interaction between intravenous salbutamol and pancuronium or vecuronium appears to be limited to the one report cited, and is probably of only minor clinical importance.

Neuromuscular blockers + Beta blockers

Increases or decreases (often only modest) in the extent of neuromuscular blockade have been seen in patients taking beta blockers. The bradycardia and hypotension sometimes caused by anaesthetics and beta blockers is not counteracted by atracurium.

Clinical evidence

(a) Alcuronium

Bradycardia and hypotension were seen in a patient given alcuronium while using **timolol** eye drops for glaucoma.[1]

(b) Atracurium

Eight out of 42 patients taking unnamed beta blockers given atracurium developed bradycardia (less than 50 bpm) and hypotension (systolic pressure less than 80 mmHg). Most of them had been premedicated with diazepam, induced with methohexital, and maintained with droperidol, fentanyl and nitrous oxide/oxygen. A further 24 developed bradycardia, associated with hypotension on 9 occasions. All responded promptly to 300 to 600 micrograms of intravenous atropine.[2]

A patient using **timolol** 0.5% eye drops for glaucoma developed bradycardia and hypotension when atracurium was given.[3] Bradycardia and hypotension have also been seen in a patient, who was given atracurium while taking **atenolol** for hypertension.[1]

(c) Rocuronium

A study of 16 patients who had been taking various beta blockers (**propranolol** 5, **atenolol** 5, **metoprolol** 2, **bisoprolol** 2, **oxprenolol** 1, **celiprolol** 1) for longer than one month found no difference in the onset and duration of action of rocuronium, when compared with a control group not taking beta blockers.[4]

(d) Suxamethonium (Succinylcholine)

In a study in 8 patients, the effects of suxamethonium were slightly, but not significantly, reduced by a 1-mg/15 kg intravenous dose of **propranolol**, given 15 minutes pre-operatively.

In 8 patients, intravenous **esmolol** 300 to 500 micrograms/kg per minute reduced the increase in heart rate during intubation, and slightly but significantly prolonged the recovery from blockade with suxamethonium by approximately 3 minutes, when compared with 8 patients given placebo.[5] In another study, intra-operative **esmolol** did not affect the onset and recovery time from suxamethonium blockade in patients with normal plasma cholinesterase (pseudocholinesterase) activity.[6]

(e) Tubocurarine

In a study in 8 patients, **propranolol**, given intravenously 20 to 40 minutes after the onset of action of tubocurarine, shortened the recovery from tubocurarine.[7] Another study described a shortened recovery period from tubocurarine due to **oxprenolol** or **propranolol**, but **pindolol** only slightly affected recovery in a few subjects.[8] Two patients with thyrotoxicosis showed prolonged neuromuscular blockade with tubocurarine after they had taken **propranolol** 120 mg daily for 14 days before surgery.[9]

(f) Vecuronium

For reports of bradycardia associated with vecuronium and opioids in patients also receiving beta blockers, see 'Neuromuscular blockers + Opioids', p.144.

Mechanism

The changes in the degree of blockade are not understood but the interaction appears to occur at the neuromuscular junction. It has been seen in *animal* studies.[10,11] The bradycardia and hypotension were probably due to the combined depressant effects on the heart of the anaesthetics and the beta blocker not being offset by atracurium, which has little or no effect on the vagus nerve at doses within the recommended range. Note that neuromuscular blockers with vagolytic activity can cause tachycardia and hypotension.

Importance and management

Information is fairly sparse, but these interactions appear normally to be of relatively minor importance. Be aware that changes in neuromuscular blockade (increases or decreases) can occur if beta blockers are used, but they seem to be unpredictable, and then often only modest in extent. The possible combined cardiac depressant effects of beta blockade and anaesthesia are well known (see 'Anaesthetics, general + Beta blockers', p.107). These effects may not be prevented when a neuromuscular blocker is used that has little or no effect on the vagus (such as atracurium or vecuronium).

Neuromuscular blockers + Calcium-channel blockers

Limited evidence indicates that intra-operative intravenous diltiazem, nicardipine, nifedipine and verapamil can decrease the requirements for vecuronium and other competitive neuromuscular blockers. Intravenous nimodipine did not alter vecuronium effects in one study.
An isolated case report describes potentiation of tubocurarine and pancuronium by oral verapamil. However, long-term oral nifedipine did not alter vecuronium or atracurium effects, and long-term therapy with various calcium-channel blockers did not interact with rocuronium. Calcium-channel blockers do not ncrease the plasma potassium rise due to suxamethonium (succinylcholine).

Clinical evidence

(a) Intravenous calcium-channel blockers

A study in 24 surgical patients[1] anaesthetised with nitrous oxide and isoflurane found that **diltiazem** 5 or 10 microgram/kg per minute decreased the **vecuronium** requirements by up to 50%. Another study in 24 surgical patients found that **diltiazem** (5 mg bolus followed by a 4-microgram/kg per minute infusion) decreased **vecuronium** requirements by 45%, when compared with a control group (no **diltiazem**), or those receiving **diltiazem** at half the infusion dose.[2] Reductions in the requirements for **vecuronium** were also noted in other surgical patients receiving intravenous **diltiazem** or **nicardipine**.[3] A study in patients given **vecuronium** 100 micrograms/kg for tracheal intubation found that **nicardipine** 10 micrograms/kg shortened the onset of blockade, making it the same as in other patients given **vecuronium** 150 micrograms/kg alone. Recovery times were unaffected by the **nicardipine**.[4] Yet another study showed that **nicardipine** reduced the requirements for **vecuronium** in a dose-dependent manner: nicardipine 1, 2 and 3 micrograms/kg per minute reduced the vecuronium dose requirement to 79%, 60% and 53% of the control, respectively.[5] A study in 44 patients anaesthetised with isoflurane in nitrous oxide/oxygen found that 1 mg of intravenous **nifedipine** prolonged the neuromuscular blockade due to **atracurium** from 29 minutes to 40 minutes, and increased the neuromuscular blockade of **atracurium** or **vecuronium** from 75% to 90%.[6] In contrast, a study in 20 patients found

that an intravenous infusion of **nimodipine** had no significant effect on the time course of action of **vecuronium**.[7]

A 66-year-old woman with renal impairment, receiving 5 mg of intravenous **verapamil** three times daily for supraventricular tachycardia, underwent abdominal surgery during which she was initially anaesthetised with thiopental and then maintained on nitrous oxide/oxygen with fentanyl. **Vecuronium** was used as the muscle relaxant. The effects of the **vecuronium** were increased and prolonged, and at the end of surgery reversal of the blockade using neostigmine was difficult and extended.[8] Intravenous **verapamil** alone has caused respiratory failure in a patient with poor neuromuscular transmission (Duchenne's dystrophy).[9] Note that *in vitro* and *animal* studies have confirmed that the neuromuscular blocking effects of **tubocurarine**, **pancuronium**, **vecuronium**, **atracurium** and **suxamethonium** (**succinylcholine**) are increased by **diltiazem**, **verapamil** and **nifedipine**.[9-11]

(b) Oral calcium-channel blockers

A report describes increased neuromuscular blockade in a patient taking long-term **verapamil** 40 mg three times daily who was given **pancuronium** 2 mg and **tubocurarine** 5 mg. The neuromuscular blockade was difficult to reverse with neostigmine, but responded well to edrophonium.[12] However, the authors of this report say that many patients taking long-term **verapamil** do not show a clinically significant increase in sensitivity to muscle relaxants.[12] This case also contrasts with another study in which 30 predominantly elderly patients taking long-term **nifedipine** (mean daily dose 33 mg) showed no changes in the time to onset of maximum block nor the duration of clinical relaxation in response to **atracurium** or **vecuronium**, when compared with 30 control patients not taking nifedipine.[13] Similarly, a study in 17 patients taking calcium-channel blockers (**nifedipine** 12, **diltiazem** 2, **nicardipine** 2, **amlodipine** 1) found no changes in the neuromuscular blocking effects of **rocuronium**.[14]

A comparative study in 21 patients taking calcium-channel blockers long term (**diltiazem**, **nifedipine**, **verapamil**) and 15 other patients not taking calcium-channel blockers found that, although **suxamethonium** (**succinylcholine**) caused a modest average peak rise of 0.5 mmol/L in plasma potassium levels, there were no differences between the two groups.[15]

Mechanism

Not fully understood. One suggested explanation is that nerve impulses arriving at nerve endings release calcium ions, which in turn causes the release of acetylcholine. Calcium-channel blockers can reduce the concentration of calcium ions within the nerve so that less acetylcholine is released. This would be additive with the effects of a neuromuscular blocker.[11,12]

Importance and management

Direct information so far seems to be limited. Increased neuromuscular blockade seems possible in any patient given an intravenous calcium-channel blocker (except possibly nimodipine) during surgery, but it seems likely that any effect will be managed by routine dose titration of the neuromuscular blocker and standard pre- and post-operative monitoring. From the limited evidence available it appears that increased blockade is not likely in patients taking long-term oral calcium-channel blockers, although one case has been reported with verapamil.

It would also seem that patients taking chronic calcium-channel blocker treatment are at no greater risk of hyperkalaemia with suxamethonium than other patients.

Neuromuscular blockers + Carbamazepine

The effects of many competitive neuromuscular blockers are reduced and shortened if carbamazepine is given for longer than one week, but they may be increased if carbamazepine is given acutely (e.g. during surgery). Carbamazepine does not appear not to interact with mivacurium.

Clinical evidence

(a) Carbamazepine given long-term

1. Atracurium or Cisatracurium. One study found that the recovery time from intravenous atracurium 500 micrograms/kg was shorter in 14 patients taking long-term carbamazepine (5.93 minutes) than in 21 non-epileptic patients (8.02 minutes). This was assessed using the recovery index (time between 25% and 75% recovery of baseline electromyogram values).[1] However, carbamazepine has also been reported to have no effect on atracurium.[2,3]

A study found that the recovery time from intravenous cisatracurium was shorter in patients taking carbamazepine or phenytoin than in patients not receiving carbamazepine or 'phenytoin', (p.145); the recovery index (times between 25% and 75% recovery) was 16.2 minutes and 21.2 minutes, respectively. Clearance of cisatracurium was increased by about 25% in patients taking carbamazepine or phenytoin, and the steady-state plasma level of cisatracurium required to maintain 95% block was increased by 20%, indicating increased resistance to the action of cisatracurium.[4]

2. Doxacurium. In a study, 9 patients taking carbamazepine for at least one week and undergoing surgery were given doxacurium. These patients took 66 minutes to reach 50% recovery compared with 161 minutes in a control group not taking carbamazepine.[5] Similar findings were obtained in another study.[6]

3. Mivacurium. In contrast to other neuromuscular blockers, the long-term (greater than 4 weeks) use of carbamazepine does not appear to affect mivacurium-induced neuromuscular blockade.[7] Similarly, a study in 32 patients who had been taking carbamazepine alone or with phenytoin or **valproic acid** for greater than 2 weeks found no resistance to mivacurium,[8] although an earlier preliminary study by the same research group found a trend towards a shorter recovery from mivacurium in 13 patients taking unspecified antiepileptics (not statistically significant).[9]

4. Pancuronium. In 18 patients undergoing craniotomy for tumours, seizure foci or cerebrovascular surgery, the recovery from neuromuscular blockade with pancuronium was on average 65% shorter in those patients taking carbamazepine.[10]

5. Pipecuronium. The effects of pipecuronium are reduced by carbamazepine.[11,12] In one study it was found that the *onset* time for pipecuronium blockade was lengthened (although this was not statistically significant) in patients with therapeutic plasma concentrations of carbamazepine, but not in those with subtherapeutic levels. However, a shorter duration of action was seen regardless of antiepileptic levels.[12]

6. Rapacuronium. A reduced duration of action has been reported with rapacuronium in a patient taking carbamazepine.[13]

7. Rocuronium. Several reports and studies have found that rocuronium has a shorter duration of action following long-term carbamazepine use,[14-17] although preliminary investigations found no effect.[18,19]

8. Suxamethonium (Succinylcholine). Eight patients who had been taking phenytoin and/or carbamazepine for at least one month took longer to recover from suxamethonium blockade, than 9 control patients; the time for return to baseline twitch height was 14.3 minutes and 10 minutes, respectively.[20]

9. Vecuronium. Several studies have found that carbamazepine shortens the recovery time from vecuronium blockade in adults[2] and in children.[21]

(b) Carbamazepine given short-term

An *in vitro* study found that the acute neuromuscular effects of **carbamazepine** reduced the concentrations required for 50% paralysis with both a depolarising neuromuscular blocker (**suxamethonium** (**succinylcholine**)) and a competitive neuromuscular blocker (**atracurium**) by about 30%.[22]

Mechanism

Not fully understood, but it appears to be multifactorial. The acute use of carbamazepine may result in neuromuscular block and potentiation of the action of competitive (non-depolarising) blockers.[22]

The long-term use of carbamazepine may produce subclinical neuromuscular blockade thought to be due to modest blockade of acetylcholine effects and a decrease in acetylcholine release; this antagonism may induce changes at the neuromuscular junction including an increased number of acetylcholine receptors on the muscle membrane (up-regulation), with decreased sensitivity.[20,21] Other suggestions to account for the reduced response with the long-term use of carbamazepine include induction of liver enzyme activity (carbamazepine is a potent inducer of cytochrome P450 isoenzymes), which would increase the metabolism and clearance of the neuromuscular blocker; and changes in plasma protein binding.[20,21] It has been shown that carbamazepine doubles the clearance of vecuronium.[21,23]

Importance and management

Established and clinically important interactions. Anticipate the need to use a larger dose of the neuromuscular blocker in patients who have taken carbamazepine for more than one week, and expect an accelerated recovery. The neuromuscular blockers appear to interact to differing extents, with mivacurium apparently unaffected.

Although evidence is limited, if carbamazepine is given acutely, it may be prudent to anticipate the need to use a smaller neuromuscular blocker dosage, or prepare for a longer recovery time.

Neuromuscular blockers + Chloroquine, Hydroxychloroquine or Quinine

A report describes respiratory insufficiency during the recovery period following surgery, which was attributed to the use of chloroquine diorotate. Hydroxychloroquine would be expected to interact similarly. An isolated report describes recurarisation and dyspnoea in a patient given intravenous quinine after recovering from neuromuscular blockade with suxamethonium (succinylcholine) and pancuronium.

Clinical evidence, mechanism, importance and management

(a) Chloroquine

Studies were carried out on the possible neuromuscular blocking actions of chloroquine diorotate in *animals,* because it was noticed that when it was used in the peritoneal cavity to prevent adhesions following abdominal surgery in man, it caused respiratory insufficiency during the recovery period. These studies found that it had a non-depolarising blocking action at the neuromuscular junction, which was opposed by neostigmine.[1] It would seem therefore that during the recovery period the effects of the chloroquine can be additive with the residual effects of the conventional neuromuscular blocker used during the surgery.

Although this appears to be the only report of this interaction, it is consistent with the way chloroquine can unmask or aggravate myasthenia gravis, or oppose the effects of drugs used in its treatment. Be alert for this reaction if chloroquine is used. Note that **hydroxychloroquine** would be expected to interact similarly.

(b) Quinine

A 47-year-old man with acute pancreatitis, taking quinine 600 mg three times daily, was given penicillin and gentamicin intravenously before undergoing surgery, during which **pancuronium** and **suxamethonium** (**succinylcholine**) were used uneventfully. After surgery the neuromuscular blockade was reversed with neostigmine and atropine, and the patient awoke and was breathing well. A 6-hour intravenous infusion of quinine 500 mg was started 90 minutes postoperatively. Within 10 minutes (after receiving about 15 mg of quinine) he became dyspnoeic, his breathing became totally ineffective and he needed re-intubation. Muscle flaccidity persisted for 3 hours.[2] The reason for this reaction is not fully understood. A possible explanation is that it may have been the additive neuromuscular blocking effects of the gentamicin (well recognised as having neuromuscular blocking activity; see 'Neuromuscular blockers + Aminoglycosides', p.127) and the quinine (an optical isomer of quinidine; see 'Neuromuscular blockers + Quinidine', p.146) and the residual effects of the **pancuronium** and **suxamethonium**.

There seem to be no other reports of problems in patients receiving neuromuscular blockers with quinine, but this isolated case serves to emphasise the importance of being alert for any signs of recurarisation in patients given drugs possessing some neuromuscular blocking activity, particularly during the postoperative recovery period.

Neuromuscular blockers + Corticosteroids

Two reports describe antagonism of the neuromuscular blocking effects of pancuronium by high-dose prednisone, or prednisolone and hydrocortisone. A third report in a patient with adrenocortical insufficiency describes reversal of the pancuronium block by hydrocortisone. Some evidence suggests the dosage of vecuronium may need to be almost doubled in those receiving intramuscular betamethasone. However, prolonged coadministration of high-dose corticosteroids and neuromuscular blockers may

increase the risk of myopathy, resulting in prolonged paralysis following the discontinuation of the neuromuscular blocker.

Clinical evidence

(a) Neuromuscular blocking effects

A man undergoing surgery who was taking oral **prednisone** 250 mg daily, had good muscular relaxation in response to intravenous **pancuronium** 8 mg (100 micrograms/kg) early in the operation, but one hour later he began to show signs of inadequate relaxation, and continued to do so for the next 75 minutes despite being given four additional 2-mg doses of **pancuronium**.[1] Another patient taking large doses of **hydrocortisone**, **prednisolone** and aminophylline proved to be resistant to the effects of **pancuronium**.[2] A hypophysectomised man taking **cortisone** developed profound paralysis when given **pancuronium**, which was rapidly reversed with 100 mg of **hydrocortisone sodium succinate**.[3]

Inadequate neuromuscular blockade with **vecuronium** (presenting as unexpected movements) occurred in 2 patients during neurosurgery. They had both been given a preoperative course of **betamethasone** 4 mg four times daily to reduce raised intracranial pressure.[4] This prompted a retrospective search of the records of 50 other patients, which revealed that those given intramuscular **betamethasone** preoperatively had needed almost double the dose of **vecuronium** (134 micrograms/kg per hour compared with 76 micrograms/kg per hour).[4]

These reports contrast with another, in which 25 patients who had no adrenocortical dysfunction or histories of corticosteroid use were given **pancuronium**, **metocurine**, **tubocurarine** or **vecuronium**. Neuromuscular blockade was not altered when a single intravenous dose of **dexamethasone** 400 micrograms/kg or **hydrocortisone** 10 mg/kg was given.[5]

(b) Increased risk of myopathy

A report describes 3 patients in status asthmaticus who developed acute reversible myopathy after treatment with high-dose intravenous **methylprednisolone** 320 to 750 mg daily and steroidal neuromuscular blockers (**vecuronium** or **pancuronium**), used concurrently for at least 8 days.[6] A review of the literature from 1977 to 1995 found over 75 cases of prolonged weakness associated with combined use of neuromuscular blockers and **corticosteroids**.[7] This condition has been referred to as 'blocking agent–corticosteroid myopathy' (BACM). Before 1994, virtually all cases involved either **pancuronium** or **vecuronium**, leading some authors to suggest that **atracurium** might be safer as it does not have the steroidal structure of these neuromuscular blockers.[6] However, there have since been reports of prolonged paralysis associated with extended treatment with high-dose **corticosteroids** and **atracurium**[8,9] or **cisatracurium**.[10]

Mechanism

Not understood. For the partial reversal of neuromuscular blockade, one idea, based on *animal* studies, is that adrenocortical insufficiency causes a defect in neuromuscular transmission, which is reversed by the corticosteroids.[3] Another idea is that the effects seen are connected in some way with the steroid nucleus of the pancuronium and vecuronium, and are mediated presynaptically.[4,11]

The increased myopathy may be due to an additive effect, as both neuromuscular blockers and corticosteroids can cause myopathy. Results of an *in vitro* study suggested that the combination of vecuronium and methylprednisolone might augment pharmacologic denervation, which may lead to myopathy and contribute to the prolonged weakness observed in some critically ill patients.[12]

Importance and management

The evidence for antagonism of neuromuscular-blocking effects seems to be limited to the reports cited, and involve only pancuronium and vecuronium. Careful monitoring is clearly needed if either is used in patients who have been treated with corticosteroids, being alert for the need to increase the dosage of the neuromuscular blocker. Note that *animal* studies suggest that atracurium may also possibly be affected by betamethasone to the same extent as vecuronium.[11] However, also be aware that prolonged coadministration of competitive neuromuscular blockers and corticosteroids, particularly in patients in intensive care, may result in a marked prolongation of muscle weakness (several months of rehabilitation have been needed in some cases[6]). The complex state of the critically ill patient means that the effects of neuromuscular blockers may be unpredictable.

Neuromuscular blockers + Dantrolene

In one patient dantrolene increased the effects of vecuronium, whereas two other patients were unaffected.

Clinical evidence, mechanism, importance and management

A 60-year-old woman, given a total of 350 mg of dantrolene orally during the 28 hours before surgery to prevent malignant hyperthermia, developed increased neuromuscular blockade and a slow recovery rate when **vecuronium** was subsequently given.[1] This report contrasts with another describing two patients taking long-term dantrolene 20 to 50 mg daily who had no changes in **vecuronium**-induced neuromuscular blockade during or after surgery.[2] Dantrolene is a muscle relaxant that acts directly on the muscle by lowering intracellular calcium concentrations in skeletal muscle; it reduces the release of calcium from the sarcoplasmic reticulum. It may also possibly inhibit calcium-dependent presynaptic neurotransmitter release.[3]

Evidence of an interaction appears to be limited to this one case but, given the potential mechanism, it may be prudent to be alert for any increased effects if dantrolene is given with vecuronium, and possibly other neuromuscular blockers. These case reports indicate that the effects could be dose-related, and so patients receiving higher doses of dantrolene may be at greater risk, although more study is needed to confirm this.

Neuromuscular blockers + Dexmedetomidine

Dexmedetomidine caused a minor increase in plasma rocuronium levels in one study.

Clinical evidence, mechanism, importance and management

A study in 10 healthy subjects under general anaesthesia with alfentanil, propofol and nitrous oxide/oxygen, found that an intravenous infusion of dexmedetomidine (950 to 990 nanograms/kg) increased plasma **rocuronium** levels by 7.6%, which was not clinically significant, and decreased the twitch tension from 51% to 44% after 45 minutes. Dexmedetomidine also decreased finger blood flow and increased systemic blood pressure. It was suggested these pharmacokinetic changes occurred due to peripheral

vasoconstriction,[1] and therefore seem possible with other neuromuscular blockers. However, the effects are unlikely to be of clinical significance.

Neuromuscular blockers + Disopyramide

An isolated case report suggests that disopyramide may oppose the effects of neostigmine used to reverse neuromuscular blockade with vecuronium.

Clinical evidence, mechanism, importance and management

A case report[1] suggests that the normal antagonism of **vecuronium** neuromuscular blockade by neostigmine may be opposed by therapeutic serum levels of disopyramide (5 micrograms/mL). Disopyramide has also been shown to decrease neostigmine-induced antagonism of the neuromuscular blockade of **tubocurarine** on the *rat* phrenic nerve-diaphragm preparation.[2] The general clinical importance of these observations is not known.

Neuromuscular blockers + Diuretics

The effects of some neuromuscular blockers (e.g. pancuronium, tubocurarine) have been both increased and decreased by furosemide.

Clinical evidence

(a) Increased neuromuscular blockade

Three patients receiving kidney transplants[1] developed increased neuromuscular blockade with **tubocurarine** (seen as a pronounced decrease in twitch tension) when given furosemide 40 or 80 mg and mannitol 12.5 g intravenously. One of them had the same reaction when later given only 40 mg of furosemide but no mannitol. The residual blockade was easily antagonised with pyridostigmine 14 mg or neostigmine 3 mg with atropine 1.2 mg.

(b) Decreased neuromuscular blockade

Ten neurosurgical patients given furosemide 1 mg/kg 10 minutes before induction of anaesthesia, took 14.7 minutes to recover from 95 to 50% blockade with **pancuronium** (as measured by a twitch response) compared with 21.8 minutes in 10 similar patients who had not received furosemide.[2]

Mechanism

Uncertain. *Animal* studies indicate that what happens probably depends on the dosage of furosemide: 0.1 to 10 micrograms/kg increased the blocking effects of tubocurarine and **suxamethonium** (succinylcholine) whereas 1 to 4 mg/kg opposed the blockade.[3] One suggestion is that low doses of furosemide may inhibit protein kinase causing a reduction in neuromuscular transmission, whereas higher doses cause inhibition of phosphodiesterase resulting in increased cyclic AMP activity and causing antagonism of neuromuscular blockade. It has also been suggested that large doses of loop diuretics may affect the renal excretion of neuromuscular blockers that are cleared by this route, resulting in more rapid recovery from the blockade.[3]

Importance and management

The documentation is very limited. Be aware of changes in the response to any neuromuscular blocker if furosemide is used, although it seems likely that any effect will be detected as part of routine monitoring. Note that the manufacturers of *Moduretic* (amiloride/**hydrochlorothiazide**) suggest that these diuretics may interact similarly, and enhance the effects of the non-depolarising (competitive) neuromuscular blockers.[4] This prediction appears to be based on some old experimental data using thiazides in *animals*.

Neuromuscular blockers + Ecothiopate iodide

The neuromuscular blocking effects of suxamethonium (succinylcholine) are markedly increased and prolonged in patients receiving ecothiopate iodide.

Clinical evidence

In 1965 a study showed that ecothiopate iodide eye drops could markedly lower pseudocholinesterase levels.[1] It was noted that "within a few days of commencing therapy, levels are reached at which protracted apnoea could occur, should these patients require general anaesthesia in which muscle relaxation is obtained with **succinylcholine**". Cases of apnoea due to this interaction were reported the following year,[2,3] and other cases have been subsequently reported.[4,5] In one case, a woman given **suxamethonium** (**succinylcholine**) 200 mg had apnoea for 5.5 hours.[2] Other studies have confirmed that ecothiopate given orally[6] or as eye drops[7] markedly reduced the levels of plasma cholinesterase, and can prolong recovery after **suxamethonium**.[6]

One report describes the successful and uneventful use of **atracurium** in a patient receiving ecothiopate.[5]

Mechanism

Suxamethonium is metabolised in the body by plasma cholinesterase. Ecothiopate iodide depresses the levels of this enzyme so that the metabolism of the suxamethonium is reduced and its effects are thereby enhanced and prolonged.[3,6] One study in 71 patients found that two drops of ecothiopate iodide 0.06% three times a week in each eye caused a twofold reduction in plasma cholinesterase (pseudocholinesterase) activity in about one-third of the patients, and a fourfold reduction in 1 in 7 patients.[8] It has been reported that, on discontinuing ecothiopate, it takes between several weeks and 2 months for enzyme activity to return to normal.[7]

Importance and management

An established, adequately documented and clinically important interaction. The dosage of suxamethonium should be reduced appropriately because of the reduced plasma cholinesterase levels caused by ecothiopate. The study cited above[8] suggests that prolonged apnoea is likely in about 1 in 7 patients. One report describes the successful use of approximately one-fifth of the normal dosage of suxamethonium in a patient receiving ecothiopate 0.125% iodide solution, one drop twice a day in both eyes, and with a plasma cholinesterase activity 62% below normal. Recovery from the neuromuscular blockade was rapid and uneventful.[9] **Mivacurium** is also metabolised by plasma cholinesterase, and would be expected to interact with ecothiopate in the same way as suxamethonium.[10]

Neuromuscular blockers + Ephedrine

Ephedrine may reduce the onset time of rocuronium and suxamethonium (succinylcholine), Some, but not all studies suggest ephedrine has a similar effect on cisatracurium and vecuronium, but possibly not on atracurium.

Clinical evidence

(a) Atracurium

A study in 40 patients found that premedication with ephedrine 10 mg did not significantly alter the onset time of atracurium.[1]

(b) Cisatracurium

In a study in 30 patients, ephedrine 70 micrograms/kg or sodium chloride 0.9%, was given 5 seconds before the patients were anaesthetised with sufentanil and propofol, and followed by cisatracurium 150 micrograms/kg after loss of consciousness. The onset time of cisatracurium was found to be shorter after ephedrine was given with cisatracurium, than when sodium chloride 0.9% was given with cisatracurium (167 seconds compared with 235 seconds, respectively). Neuromuscular block at intubation was also greater in the patients given ephedrine, and the frequency of excellent intubating conditions was higher after ephedrine (87%) than after sodium chloride 0.9% (40%). No significant differences in haemodynamic parameters were noted between the two groups, although a trend towards a slightly higher heart rate and blood pressure was seen in the ephedrine group.[2] In contrast, another study in 60 patients found that the addition of ephedrine 0.5 mg/mL or 1 mg/mL to anaesthesia with remifentanil, propofol and cisatracurium 150 micrograms/kg had no significant effects on the onset time of cisatracurium.[3] Slight increases in the heart rate, blood pressure and overall mean arterial pressure were seen; however, no adverse cardiac events occurred.[3]

(c) Rocuronium

The effects of pretreatment with ephedrine 75, 100, or 150 micrograms/kg or sodium chloride 0.9% on intubation conditions and haemodynamics were studied in 100 patients given propofol and rocuronium 600 micrograms/kg. A significant increase in heart rate and mean arterial pressure occurred in patients pretreated with ephedrine 75 or 150 micrograms/kg. However, the overall hypotensive effect of the anaesthesia was not completely abolished. Intubation conditions were also significantly better in those pretreated with ephedrine 75 or 100 micrograms/kg but less so in the group who received ephedrine 150 micrograms/kg.[4] Similarly, ephedrine pretreatment was found to improve intubating conditions in another study in patients given propofol and rocuronium. A significant increase in the mean arterial pressure and heart rate was seen in those patients given both ephedrine and propofol in this study although no clinically significant adverse cardiac events, such as arrhythmias, occurred in this group.[5] A study in 60 patients found that ephedrine 70 micrograms/kg given with thiopental anaesthesia reduced the onset time of rocuronium 600 micrograms/kg, with no adverse cardiac effects,[6] and another study, in 40 patients, found that premedication with ephedrine 10 mg reduced the onset time of rocuronium by roughly 30%.[1]

One study in 60 patients found that the onset of rocuronium was 22% shorter after ephedrine 500 micrograms/kg was given (but 26% longer after esmolol, which decreases cardiac output).[7]

(d) Suxamethonium (Succinylcholine)

A study in patients given either ephedrine 70 micrograms/kg or sodium chloride 0.9% three minutes before the induction of anaesthesia with propofol and remifentanil, found that the onset time of suxamethonium was shorter in the ephedrine group than the sodium chloride group (26 seconds compared with 43 seconds, respectively). The heart rate and mean arterial pressure were increased in the ephedrine group at one minute; however, there were no other significant differences at all other measurement times and no adverse cardiac effects were reported.[8]

(e) Vecuronium

In a study, 119 patients were pretreated with ephedrine 30, 70 or 110 micrograms/kg or sodium chloride 0.9%, anaesthetised with fentanyl and propofol and tracheal intubation was performed 2 minutes after vecuronium 100 micrograms/kg was given. The onset time of vecuronium was shorter, intubating conditions were improved and neuromuscular blockade was greater in the patients who received ephedrine but the higher dose was associated with adverse haemodynamic effects (tachycardia and an increase in the mean arterial pressure of more than 30%). No arrhythmias occurred in the ephedrine-treated patients. It was suggested that ephedrine 70 micrograms/kg was a suitable dose to improve tracheal intubation conditions at 2 minutes after vecuronium, by increasing cardiac output but without adverse haemodynamic effects.[9] In contrast, in another study in 53 patients maintained under anaesthesia with propofol, the onset time of neuromuscular block with vecuronium 100 micrograms/kg was not affected by pretreatment with ephedrine 210 micrograms/kg when compared with sodium chloride, despite an increase in systolic blood pressure and the cardiac index (around 17%). However, the authors suggest that because vecuronium was given 10 minutes after the start of the propofol infusion this may have affected the result,[10] whereas ephedrine was given immediately before or just after propofol induction in the studies that found a beneficial effect on the onset of neuromuscular block.[2,4,5,9]

Mechanism

The onset time of neuromuscular blockers is partly dependent on circulatory factors such as muscle blood flow and cardiac output. Ephedrine is thought to decrease the onset times of neuromuscular blockers by increasing cardiac output and improving circulation time of the neuromuscular blocker to the muscle.[9,11] However, other studies that found a reduced onset time of neuromuscular blockade with ephedrine found no difference in haemodynamic parameters.[2,6] It has also been suggested that neuromuscular blockers with a fast onset of action are more likely to be affected by changes in cardiac output and blood flow than those with an intermediate onset of action such as atracurium.[11]

Importance and management

Some studies[1,2,7,9] suggest that small doses of ephedrine reduce the onset time of some neuromuscular blockers and improve intubating conditions. However, other studies[1,3,10] found that ephedrine did not significantly decrease the onset time of neuromuscular blockers. Its use may also be associated with increases in blood pressure and heart rate[3-5,10] and may lead to adverse haemodynamic affects, such as tachycardia, particularly at higher doses.[9] It should be noted that, in the studies above, no patients developed significant arrhythmias, although in most cases patients with pre-existing cardiac disease were excluded. These haemodynamic changes may be of more clinical significance in at-risk patients such as those with ischaemic heart disease.

Neuromuscular blockers + H_2-receptor antagonists

Isolated reports suggest that the effects of suxamethonium (succinylcholine) and vecuronium are prolonged by cimetidine. *Animal* studies suggest that the effects of tubocurarine and pancuronium may also be increased by cimetidine. Other reports suggest that no interaction generally occurs between neuromuscular blockers and other H_2-receptor antagonists, but not all combinations have been studied.

Clinical evidence

(a) Cimetidine

A study in 10 patients given cimetidine 300 mg orally at bedtime and another 300 mg 2 hours before anaesthesia, found that while the onset of action of **suxamethonium** (**succinylcholine**) 1.5 mg/kg intravenously was unchanged, when compared with 10 control patients, the time to recover 50% of the twitch height was prolonged 2- to 2.5-fold (from 8.6 to 20.3 minutes). One patient took 57 minutes to recover. His plasma cholinesterase levels were found to be normal.[1] It was later reported that some patients were also taking metoclopramide, which is known to interact in this way.[2] See also 'Neuromuscular blockers + Metoclopramide', p.141.

A study in 10 patients given 400 mg of cimetidine orally at bedtime and again 90 minutes before anaesthesia found no evidence of an effect on the neuromuscular blockade caused by **suxamethonium**, nor on its duration or recovery period, when compared with 10 control patients.[3] Another controlled study in patients given cimetidine 300 mg the night before and 1 to 2 hours before surgery, found no evidence that the duration of action of **suxamethonium** or the activity of plasma cholinesterase were altered.[2] Other studies similarly suggest that cimetidine does not alter the neuromuscular blocking effects of **suxamethonium**.[4,5]

Another study[6] in 16 patients found that cimetidine 400 mg significantly prolonged the recovery (T1–25 period) from **vecuronium**, but few patients had any response to cimetidine 200 mg. This slight prolongation of action of **vecuronium** due to cimetidine 400 mg was confirmed in another placebo-controlled study (mean time to return of T1 was 30 versus 22.5 minutes).[7] A study using a *rat* phrenic nerve hemi-diaphragm preparation found that, at clinically relevant concentrations, cimetidine produces neuromuscular paralysis and may potentiate the response to **vecuronium**.[8] A similar study using a *rat* phrenic nerve diaphragm preparation found that cimetidine increased the neuromuscular blocking effects of **tubocurarine** and **pancuronium**, but there seem to be no reports confirming this in man.[9]

Cimetidine appears not to alter the effects of **atracurium** or **rocuronium**.[10]

(b) Other H_2-receptor antagonists

A study in 8 patients found that the response to vecuronium was generally unchanged by **ranitidine** 100 mg, although some patients did show a slight prolongation in recovery.[6] A study using a *rat* phrenic nerve hemidiaphragm preparation found that, at clinically relevant concentrations, **ranitidine** produced neuromuscular paralysis and may potentiate the response to **vecuronium**, but low concentrations of **ranitidine** may antagonise the effects of **vecuronium**.[8] Another controlled study in patients given **ranitidine** 150 mg the night before and 1 to 2 hours before surgery, found no evidence that the duration of action of **suxamethonium** (**succinylcholine**) or the activity of plasma cholinesterase were altered.[2] Other studies suggest that **ranitidine** and **famotidine** do not alter the neuromuscular blocking effects of suxamethonium.[4,5]

Ranitidine does not appear to alter the effects of **atracurium**[10] or **vecuronium**.[7] Another study found that premedication with **ranitidine** did not affect **vecuronium** blockade in postpartum patients, but that the neuromuscular blockade was prolonged in these patients, when compared with non-pregnant controls.[11] A study using a *rat* phrenic nerve hemidiaphragm preparation found that **famotidine** lacked significant neuromuscular effects and did not alter the response to **vecuronium**.[8]

Mechanism

Not understood. Studies with human plasma failed to find any evidence that cimetidine in therapeutic concentrations inhibits the metabolism of suxamethonium.[2,12] However, metoclopramide may do and therefore is possibly the drug responsible for any interaction seen. *In vitro* studies with very high cimetidine concentrations found inhibition of plasma cholinesterase (pseudocholinesterase) activity.[13] The interaction between cimetidine and vecuronium is not understood, but it has been suggested that cimetidine may reduce the hepatic metabolism of vecuronium.[7]

Importance and management

Information seems to be limited to the reports cited. The most likely explanation for the discord between the results from studies with suxamethonium (succinylcholine) is that in the one study reporting increased suxamethonium effects[1] some of the patients were also given metoclopramide, which can inhibit plasma cholinesterase and prolong the effects of suxamethonium[2,5] (see also 'Neuromuscular blockers + Metoclopramide', p.141). In four other studies, cimetidine and other H_2-receptor antagonists did not alter suxamethonium effects. Therefore, it seems unlikely that an interaction exists. There is some evidence that cimetidine may slightly prolong the effects of vecuronium, but ranitidine appears not to interact. Atracurium and rocuronium appear not to be affected. Overall these possible interactions seem to be of little clinical significance.

Neuromuscular blockers + Immunosuppressants

There is limited evidence to suggest that the neuromuscular blocking effects of atracurium, pancuronium and vecuronium may be increased in some patients taking ciclosporin. There is also some evidence of reduced neuromuscular blockade with azathioprine and antilymphocyte immunoglobulins, but other evidence suggests that there is no clinically relevant interaction with azathioprine.

Clinical evidence

(a) Azathioprine or Antilymphocyte immunoglobulins

A retrospective study found that patients taking azathioprine or antilymphocyte immunoglobulins following organ transplantation needed an increased dosage of unspecified **muscle relaxants** to achieve satisfactory muscle relaxation.[1] A control group of 74 patients not receiving immunosuppression needed 0 to 10 mg of a **competitive** (**non-depolarising**) **muscle relaxant**; 13 patients taking azathioprine needed 12.5 to 25 mg; 11 patients receiving antilymphocyte immunoglobulins (antilymphocyte globulin) needed 10 to 20 mg and two patients taking azathioprine and guanethidine needed 55 and 90 mg.[1] However, a controlled study of 28 patients undergoing renal transplantation, who were receiving **atracurium**, **pancuronium** or **vecuronium** at a constant infusion rate, found that an injection of azathioprine 3 mg/kg given over 3 minutes caused a rapid, but only small and transient decrease of neuromuscular blockade. Ten minutes after the end of the azathioprine injection, a residual interaction was only detectable in those patients who had been given **pancuronium**.[2]

(b) Ciclosporin

A retrospective study found that 4 of 36 patients receiving **atracurium** and 4 of 29 patients receiving **vecuronium** experienced prolonged neuromuscular blockade after anaesthesia for renal transplantation. Respiratory failure occurred more often in patients who were given intravenous ciclosporin during surgery.[3] Extended recovery times after **atracurium** and **vecuronium** are described in another report in renal transplant patients who had been taking oral ciclosporin.[4] Similarly, a prolonged duration of action of **vecuronium** was noted in 7 renal transplant recipients, when compared with patients with normal renal function, and ciclosporin was considered to be a factor in this.[5] Two case reports describe prolonged

neuromuscular blockade, which was attributed to intravenous ciclosporin. In the first report,[6] a woman with a 2-year renal transplant underwent surgery during which **pancuronium** 5.5 mg was used as the neuromuscular blocker. She was also given intravenous ciclosporin before and after surgery. The surgery lasted for 4 hours and no additional doses of **pancuronium** were given. Residual paralysis was inadequately reversed with neostigmine and atropine, and so edrophonium was given before extubation. However, she had to be re-intubated 20 minutes later because of increased respiratory distress. In the second report,[7] a 15-year-old girl receiving intravenous ciclosporin with serum levels of 138 micrograms/L was anaesthetised using fentanyl, thiopental and **vecuronium** 100 micrograms/kg. Anaesthesia was maintained with nitrous oxide, oxygen and isoflurane. Attempts were later made to reverse the blockade with edrophonium, atropine and neostigmine but full neuromuscular function was not restored until 3 hours and 20 minutes after the **vecuronium** was given. Another report describes a prolongation of the effects of **vecuronium** in a renal-transplant recipient taking oral ciclosporin, azathioprine, and prednisolone.[8]

Mechanism

The reasons for the reduction in neuromuscular blockade with azathioprine and antilymphocyte immunoglobulins are not understood. It has been suggested that azathioprine may inhibit phosphodiesterase at the motor nerve terminal resulting in increased release of acetylcholine.[9]

The ciclosporin interaction may be partly due to the vehicle used in intravenous preparations. One idea is that *Cremophor*, a surfactant which has been used as a solvent for ciclosporin, may increase the effective concentration of pancuronium at the neuromuscular junction.[6] In *animal* studies both compounds have been observed to increase vecuronium blockade,[10] and *Cremophor* has also been seen to decrease the onset time of pancuronium blockade in patients given *Cremophor*-containing anaesthetics.[11] However, this is not the entire answer because the interaction has also been seen with oral ciclosporin, which does not contain *Cremophor*.[8]

Importance and management

Direct information seems to be limited to the reports cited, and the interactions are not established. Although retrospective data suggest that azathioprine and antilymphocyte immunoglobulins can cause a reduction in the effects of neuromuscular blockers, and in some cases the dosage may need to be increased two- to fourfold,[1] the only prospective study found that the interaction with azathioprine was not clinically significant.[2] The general importance of the ciclosporin interaction is also uncertain, but be aware that the effects of atracurium, pancuronium or vecuronium may be increased in any patient receiving ciclosporin. Not all patients appear to develop this interaction.[3] Any effects seem likely to be managed by routine dose titration of the neuromuscular blocker and standard post-operative monitoring.

Neuromuscular blockers + Lithium

The concurrent use of neuromuscular blockers and lithium is normally safe and uneventful, but four patients taking lithium experienced prolonged blockade and respiratory difficulties after receiving standard doses of pancuronium and/or suxamethonium (succinylcholine).

Clinical evidence

A manic depressive woman taking lithium carbonate, with a lithium level of 1.2 mmol/L, underwent surgery and was given thiopental, **suxamethonium** (**succinylcholine**) 310 mg over a period of 2 hours, and **pancuronium** 500 micrograms. Prolonged neuromuscular blockade with apnoea occurred.[1]

Three other patients taking lithium experienced enhanced neuromuscular blockade when given **pancuronium**,[2] or **pancuronium** with **suxamethonium**.[3,4] The authors of one of these reports[4] also suggest that they have seen several other cases where of the neuromuscular blockade produced by **suxamethonium** was potentiated in patients taking lithium carbonate, but give no further details. In contrast, a retrospective analysis of data from 17 patients taking lithium carbonate who received **suxamethonium** during a total of 78 ECT treatments, did not reveal any instances of unusually prolonged recovery.[5] Interactions between lithium and pancuronium[1] or suxamethonium[6,7] have been demonstrated in *dogs,* and an interaction between lithium and **tubocurarine** has been demonstrated in *cats*,[8] but no clear interaction has been demonstrated with any other neuromuscular blocker.[7,9] A case of lithium toxicity has been described in a woman taking lithium who was given **suxamethonium**, but it is doubtful if it arose because of an interaction.[10]

Mechanism

Uncertain. One suggestion is that, when an interaction occurs, it may be due to changes in the electrolyte balance caused by the lithium, which results in changes in the release of acetylcholine at the neuromuscular junction.[8,11]

Importance and management

Information is limited. There are only four definite reports of this interaction in man, and good evidence that no adverse interaction normally occurs. The concurrent use of lithium and neuromuscular blockers need not be avoided, and, on the rare occurrence an interaction occurs, it seems likely that it will be managed by routine intra-operative and post-operative monitoring.

Neuromuscular blockers + Magnesium compounds

The effects of cisatracurium, mivacurium, pancuronium, rocuronium, tubocurarine, vecuronium, and probably other competitive neuromuscular blockers can be increased and prolonged by magnesium sulfate given parenterally. There is some evidence that magnesium may interact similarly with suxamethonium (succinylcholine), but also evidence from well-controlled studies to suggest that it does not.

Clinical evidence

(a) Competitive (non-depolarising) neuromuscular blockers

A pregnant 40-year-old with severe pre-eclampsia and receiving magnesium sulfate by infusion, underwent emergency caesarean section during which she was initially anaesthetised with thiopental, maintained with nitrous oxide/oxygen and enflurane, and given firstly suxamethonium (succinylcholine) and later **vecuronium** as muscle relaxants. At the end of

surgery she rapidly recovered from the anaesthesia but the neuromuscular blockade was very prolonged (an eightfold increase in duration).[1] In a series of randomised studies involving 125 patients, pretreatment with intravenous magnesium sulfate 40 mg/kg reduced the dose requirement of **vecuronium** by 25%, approximately halved the time to the onset of action, and prolonged the duration of action from about 25 minutes to 43 minutes.[2] Another study found that pretreatment with magnesium sulfate 40 mg/kg decreased the onset and prolonged the recovery time from **vecuronium** blockade, but magnesium sulfate 20 mg/kg had no effect.[3] Evidence of enhanced **vecuronium** neuromuscular blockade by magnesium sulfate is described in one other study,[4] and case report.[5] A further study in 20 patients found that recurarisation (sufficient to compromise respiration) occurred when magnesium sulfate 60 mg/kg was given in the postoperative period, shortly after recovery from neuromuscular block with **vecuronium**.[6] In a randomised study, neostigmine-induced recovery from **vecuronium** block was attenuated by about 30% in patients pretreated with magnesium sulfate. The authors demonstrated this was due to slower spontaneous recovery and not decreased response to neostigmine.[7]

In two patients who underwent cardiac surgery, neuromuscular block with either **pancuronium**, or **pancuronium** and **rocuronium** was prolonged by more than 10 hours. This was attributed to the effects of high doses of neuromuscular blockers potentiated by magnesium sulfate 2.5 g. Moderate renal impairment may also have been a factor.[8] A fourfold increase in the duration of neuromuscular blockade of **rocuronium** 0.9 mg/kg was reported in a pregnant woman given magnesium sulfate.[9] A further randomised, placebo-controlled study confirmed that pretreatment with magnesium sulfate 60 mg/kg increased the duration of neuromuscular block produced by **rocuronium** (time to initial recovery increased from about 25 minutes to 42 minutes), but the onset time was not affected.[10]

A patient given **cisatracurium** 14 mg during induction of anaesthesia was then given intravenous magnesium sulfate 2 g over 5 minutes for atrial fibrillation, which had developed about 15 minutes after the end of surgery. Within a few minutes of receiving magnesium, recurarisation occurred (despite, the patient having been given 2 doses of neostigmine and glycopyrrolate postoperatively), and the patient required re-intubation and artificial ventilation for about 20 minutes.[11] A study in 20 patients undergoing elective cardiac surgery found that magnesium sulfate 70 mg/kg given before induction, followed by 30 mg/kg per hour prolonged the neuromuscular blockade induced with the first maintenance dose of **cisatracurium** by just over 30 minutes.[12]

The infusion rate of **mivacurium** required to obtain relaxation in women undergoing a caesarean section was about threefold lower in 12 women who had received magnesium sulfate for pre-eclampsia than in 12 women who had not.[13] In another study in 10 hypertensive patients undergoing caesarean section and given magnesium sulfate 30 or 60 mg/kg at induction, the action of **mivacurium** was prolonged when compared with normotensive controls or hypertensive controls not given magnesium.[14]

Prolonged neuromuscular block with **rapacuronium** has also been reported in a patient undergoing emergency caesarean section who received magnesium sulfate and clindamycin,[15] although the clindamycin was thought to be mainly responsible (see also 'Neuromuscular blockers + Miscellaneous anti-infectives', p.141).

Prolonged neuromuscular blockade has been described in three women with pre-eclampsia who were given magnesium sulfate and either **tubocurarine** alone or with suxamethonium (succinylcholine).[16,17] Increased blockade by magnesium has been demonstrated with **tubocurarine** in *animals*.[16,18]

(b) Suxamethonium (Succinylcholine)

An early study in 59 women undergoing caesarean section found that those given magnesium sulfate for eclampsia and pre-eclampsia needed less suxamethonium than control patients (4.73 compared with 7.39 mg/kg per hour).[19] Prolonged neuromuscular blockade has been described in three women with pre-eclampsia who were given magnesium sulfate and either tubocurarine alone or with suxamethonium.[16,17] A 71-year-old woman given magnesium sulfate and lidocaine for ventricular tachycardia underwent emergency cardioversion and had a delayed onset and prolonged neuromuscular blockade when she was given suxamethonium.[20] Increased blockade by magnesium has been seen with suxamethonium in *animals*.[16,18]

However, a randomised study involving 20 patients found that pretreatment with a single 60-mg/kg bolus dose of magnesium sulfate did not significantly affect the onset of neuromuscular blockade, or prolong the block produced by suxamethonium.[21] Similar results were found in a non-randomised study[4] and in a double-blind, randomised study.[22] In randomised studies, the use of magnesium sulfate has also been reported to reduce suxamethonium-associated fasciculations[22] and reduce the increase in serum potassium levels produced by suxamethonium.[21]

Mechanism

Magnesium sulfate has direct neuromuscular blocking activity by inhibiting the normal release of acetylcholine from nerve endings, reducing the sensitivity of the postsynaptic membrane and depressing the excitability of the muscle membranes. These effects are seen when serum magnesium levels rise above the normal range (hypermagnesaemia) and are possibly simply additive (or perhaps more than additive) with the effects of competitive neuromuscular blockers.

Importance and management

The interaction between competitive (non-depolarising) neuromuscular blockers and parenteral magnesium is established. Magnesium may decrease the time to onset of neuromuscular blockade, prolong the duration of action, and reduce the dose requirement of competitive neuromuscular blockers. Be alert for an increase in the effects of any competitive neuromuscular blocker if intravenous magnesium sulfate has been used, and anticipate the need to reduce the dose. Some have suggested that the decreased time to onset with vecuronium may be of use clinically to improve the intubating conditions for rapid sequence induction if suxamethonium is not suitable.[2] Intravenous calcium gluconate was used to assist recovery in one case of prolonged block.[16] Also be aware that recurarisation may occur when intravenous magnesium compounds are used in the postoperative period.[6,11] The authors of one report suggest that magnesium sulfate should be avoided for at least 30 minutes after reversal of residual neuromuscular block, to minimise the risk of recurarisation.[11] Hypermagnesaemia can occur in patients receiving magnesium in antacids, enemas or parenteral nutrition, especially if there is impaired renal function, but an interaction would not normally be expected, as oral magnesium compounds generally result in lower systemic levels than intravenous magnesium due to poor absorption.[23]

The interaction between magnesium and suxamethonium is not established. Although some *animal* and clinical evidence suggests potentiation of suxamethonium can occur, well-controlled studies have not confirmed this. Therefore some authors consider that magnesium sulfate does not significantly affect the clinical response to suxamethonium.[4,24]

Neuromuscular blockers + MAOIs

The effects of suxamethonium (succinylcholine) were enhanced in three patients taking phenelzine.

Clinical evidence, mechanism, importance and management

Two patients, one taking **phenelzine** and the other who had ceased to do so 6 days previously, developed apnoea following ECT during which **suxamethonium** (**succinylcholine**) was used. Both responded to injections of nikethamide and positive pressure ventilation with oxygen.[1] A later study observed the same response in another patient taking **phenelzine**.[2] This would appear to be explained by the finding that **phenelzine** caused a reduction in the levels of plasma cholinesterase (pseudocholinesterase) in 4 out of 10 patients studied. Since the metabolism of **suxamethonium** depends on this enzyme, reduced levels of the enzyme would result in a reduced rate of **suxamethonium** metabolism and in a prolongation of its effects. None of 12 other patients taking **tranylcypromine**, **isocarboxazid** or **mebanazine** had reduced plasma cholinesterase levels.[2]

It would clearly be prudent to be on the alert for this interaction in patients taking **phenelzine**. **Phenelzine** may be anticipated to react similarly with **mivacurium** as it is also metabolised by plasma cholinesterase.[3]

Neuromuscular blockers + Metoclopramide

The neuromuscular blocking effects of suxamethonium (succinylcholine) and mivacurium can be increased and prolonged in patients taking metoclopramide.

Clinical evidence

Metoclopramide 10 mg given intravenously 1 to 2 hours before induction of anaesthesia prolonged the time to 25% recovery after **suxamethonium** (**succinylcholine**) by 1.83 minutes (23%) in 19 patients, when compared with 21 control patients.[1,2] A larger 20-mg dose of metoclopramide prolonged the time to recovery by 56% in a further 10 patients.[1] In another study by the same research group, the recovery from neuromuscular blockade (time from 95% to 25% suppression of the activity of the adductor pollicis muscle) due to **suxamethonium** was prolonged by 67% in 11 patients who were given metoclopramide 10 mg intravenously during surgery, one minute before the **suxamethonium**.[3]

A randomised, placebo-controlled study in 30 patients found that intravenous metoclopramide 150 micrograms/kg given about 10 minutes before anaesthetic induction with **mivacurium** 150 micrograms/kg prolonged the duration of action of **mivacurium** by about 30%.[4] Another report found that infusion rates of **mivacurium** were reduced by up to about 80% in patients given metoclopramide 10 or 20 mg intravenously, 5 minutes before induction, and metoclopramide delayed complete recovery from neuromuscular block after **mivacurium** by 36% (10 mg dose) and 50% (20 mg dose).[5] Metoclopramide 20 mg delayed the recovery from **mivacurium** block by 78% in another study.[6]

Mechanism

It has been suggested that metoclopramide may reduce the activity of plasma cholinesterase, which is responsible for the metabolism of suxamethonium and mivacurium. One *in vitro* study found that a metoclopramide level of 800 nanograms/mL inhibited plasma cholinesterase activity by 50%. However, a 10-mg dose of metoclopramide in adult patients weighing 50 to 70 kg produces peak plasma levels five times less than this (140 nanograms/mL).[7] Further, in an *in vivo* study, metoclopramide had only minimal inhibitory effects on plasma cholinesterase, and there was no difference in plasma cholinesterase levels in patients who had received metoclopramide and those who had not.[4]

Importance and management

The interaction between metoclopramide and suxamethonium is an established but not extensively documented interaction of only moderate or minor clinical importance. However, some enhancement of blockade can occur. The authors of the suxamethonium reports also point out that plasma cholinesterase activity is reduced in pregnancy and so suxamethonium sensitivity is more likely in obstetric patients.

The interaction between metoclopramide and mivacurium has only more recently been demonstrated. Metoclopramide appears to allow a reduction in the infusion rate of mivacurium and it causes a significant delay in recovery from neuromuscular block. Care is recommended during combined use.[5]

Ester-type local anaesthetics also depend on plasma cholinesterase activity for metabolism[1,7] and their effects would therefore be expected to be additive with the effects of metoclopramide, see 'Neuromuscular blockers + Anaesthetics, local', p.127.

Neuromuscular blockers + Miscellaneous anti-infectives

Colistin, colistimethate sodium, polymyxin B, clindamycin, lincomycin, some penicillins (apalcillin, azlocillin, mezlocillin, piperacillin) and vancomycin possess some neuromuscular blocking activity. Increased and prolonged neuromuscular blockade is possible if these antibacterials are used with neuromuscular blocking drugs. In theory amphotericin B might also interact. No clinically significant interaction has been seen with cefoxitin, cefuroxime, or metronidazole.

Clinical evidence

(a) Amphotericin B

Amphotericin B can induce hypokalaemia resulting in muscle weakness,[1] which might be expected to enhance the effects of neuromuscular blockers, but there appear to be no reports in the literature confirming that a clinically significant interaction actually occurs.

(b) Cephalosporins

In a controlled study, intravenous **cefuroxime**, given shortly before **pipecuronium**[2] or **rocuronium**[3] did not alter the neuromuscular-blocking effects of these drugs. Similarly, intravenous **cefoxitin** given before, during and after surgery was not associated with a clinically important prolongation of **vecuronium** blockade.[4]

(c) Clindamycin and Lincomycin

Enhanced blockade has been seen in patients given **pancuronium** and lincomycin, which was reversed by neostigmine.[5] Respiratory paralysis was seen 10 minutes after lincomycin 600 mg was given intramuscularly to a man recovering from neuromuscular blockade with **tubocurarine**[6] and this interaction was confirmed in another report.[7] Other case reports[8-10] and clinical studies[11] describe minor to marked increases in neuromuscular blockade in patients receiving **pancuronium**,[9] **pipecuronium**,[11] **rapacuronium**[10] or **suxamethonium** (**succinylcholine**)[8] when they were given clindamycin. One patient developed very prolonged blockade after being unintentionally given clindamycin 2.4 g instead of 600 mg shortly after recovery from **suxamethonium** and **tubocurarine**.[12] Prolongation

of the neuromuscular blocking effects of **vecuronium** has also been reported in a patient who received both clindamycin and gentamicin.[13]

(d) Metronidazole

An increase in the neuromuscular blocking effects of **vecuronium** with metronidazole has been reported in *cats*;[14] however, a later study in patients found no evidence of an interaction,[15] and another study with **rocuronium** also found no evidence of an interaction with metronidazole.[3] Similarly, no interaction was seen with **rocuronium** and metronidazole/cefuroxime,[3] and another study found no significant interaction between **pipecuronium** and metronidazole.[2]

(e) Penicillins

A study in patients found that the neuromuscular blocking effects of **vecuronium** were prolonged by a number of penicillins: **apalcillin** 26%, **azlocillin** 55%, **mezlocillin** 38%, and **piperacillin** 46%.[16] Reinstitution of neuromuscular blockade and respiratory failure occurred in a postoperative patient given **piperacillin** 3 g by intravenous infusion following the reversal of **vecuronium** blockade.[17] However, a randomised, study in 30 patients found that **piperacillin** or cefoxitin, given by intravenous infusion, pre- and intraoperatively, were not associated with clinically important prolongation of the neuromuscular block induced by **vecuronium**. Of 27 patients who could be evaluated, 22 showed a modest overall decrease in recovery time and 2 patients given **piperacillin** exhibited a slight prolongation in recovery time, but these patients all responded readily to neostigmine or other anticholinesterases and subsequent recurarisation did not occur.[4]

(f) Polymyxins

A literature review of interactions between antibacterials and neuromuscular blockers identified 17 cases over the period 1956 to 1970 in which **colistin** (**polymyxin E**) or **colistimethate sodium**, with or without conventional neuromuscular blockers, were responsible for the development of increased blockade and respiratory muscle paralysis. Some of the patients had renal disease.[18] A later report describes prolonged respiratory depression in a patient receiving **pancuronium** and **colistin**. Calcium gluconate was found to reverse the blockade.[19] A placebo-controlled study found that one million units of **colistin** considerably prolonged the recovery time from **pipecuronium** blockade.[11] Six cases of enhanced neuromuscular blockade involving **polymyxin B** have also been reported.[18] An increase in the blockade due to **pancuronium** by **polymyxin B** and bacitracin wound irrigation is described in another report; pyridostigmine, neostigmine and edrophonium were ineffective antagonists of this block and only partial improvement occurred after calcium chloride was given.[20] Prolonged and fatal apnoea occurred in another patient given **suxamethonium** when his peritoneal cavity was instilled with a solution containing 100 mg of **polymyxin B** and 100 000 units of bacitracin.[21]

(g) Vancomycin

A man recovering from neuromuscular blockade with **suxamethonium** (with some evidence of residual Phase II block) developed almost total muscle paralysis and apnoea when given an intravenous infusion of vancomycin. He recovered spontaneously when the vancomycin was stopped, but it took several hours.[22] The neuromuscular blockade due to **vecuronium** was increased in a patient who was given an infusion of vancomycin (1 g in 250 mL of sodium chloride 0.9% over 35 minutes).[23] Transient apnoea and apparent cardiac arrest have also been described in a patient following a 1-g intravenous injection of vancomycin given over 2 minutes.[24] However, in both of these cases[23,24] the vancomycin was given more rapidly than the current recommendations. It is now known that rapid infusion of vancomycin can provoke histamine release, which can result in apnoea, hypotension, anaphylaxis and muscular spasm, effects similar to those seen in these two patients.

Mechanism

Not fully understood but several sites of action at the neuromuscular junction (pre and/or post, effects on ion-channels or receptors) have been suggested.

The neuromuscular blocking properties of the polymyxins (polymyxin B, colistin, colistimethate sodium) involve a number of mechanisms, which may explain the difficulty in reversing the blockade.[25]

Importance and management

The interactions involving polymyxin B, colistin, colistimethate sodium, lincomycin, and clindamycin are established and clinically important. The incidence is uncertain. Concurrent use need not be avoided, but be alert for increased and prolonged neuromuscular blockade. The recovery period should be well monitored because of the risk of recurarisation. There seem to be no reports of an interaction with amphotericin B, but it may be prudent to be aware of a potential for interaction during the recovery period.

No interaction would be expected with cefuroxime, cefoxitin, or metronidazole, but some caution would seem appropriate with azlocillin, mezlocillin and piperacillin.

The situation with vancomycin is less clear. The evidence does suggest a link between vancomycin and increased neuromuscular blockade following the use of suxamethonium, and possibly vecuronium. However, vancomycin is given routinely as antibacterial prophylaxis before surgical procedures. The sparsity of reports therefore suggests that, in practice, vancomycin rarely causes a clinically significant interaction with neuromuscular blockers.

Neuromuscular blockers + Neuromuscular blockers

Combinations of competitive neuromuscular blockers may have additive or synergistic effects. However, the sequence of administration may also affect the interaction. The previous use of a small dose of a competitive neuromuscular blocker (e.g. vecuronium) generally reduces the effects of suxamethonium (succinylcholine), but if suxamethonium is given during recovery from a competitive neuromuscular blocker, antagonism, enhancement or a combination of the two may occur. The effects of a competitive blocker may be increased if it is given after suxamethonium.

Clinical evidence, mechanism, importance and management

Neuromuscular blockers are of two types: competitive (non-depolarising) and depolarising. The competitive or non-depolarising blockers (**atracurium** and others listed in 'Table 5.2', (p.101)) compete with acetylcholine for the receptors on the endplate of the neuromuscular junction. Thus the receptors fail to be stimulated and muscular paralysis results. **Suxamethonium** (**succinylcholine**), a depolarising neuromuscular blocker, also occupies the receptors on the endplate but it acts like acetylcholine to cause depolarisation. However, unlike acetylcholine, it is not immediately removed by cholinesterase so that the depolarisation persists and the muscle remains paralysed.

(a) Combinations of competitive (non-depolarising) neuromuscular blockers

Combinations of competitive (non-depolarising) neuromuscular blockers may have additive or synergistic effects. Structural differences between the interacting neuromuscular blockers may have an effect; it has been suggested that structurally similar neuromuscular blockers tend to produce an additive response, whereas structurally different blockers may be synergistic.[1,2] For a list of competitive neuromuscular blockers by structural type, see 'Table 5.2', (p.101).

Additive effects have been found with the following structurally similar combinations:

- **atracurium** and **cisatracurium**[3] or **mivacurium**,[4]
- **pancuronium** and **vecuronium**,[5]
- **pipecuronium** and **vecuronium**,[6]
- **tubocurarine** and **metocurine**.[1]

Synergism has been reported with the following structurally similar combinations:

- **cisatracurium** and **mivacurium**,[3]
- **tubocurarine** and **atracurium**.[7]

Potentiation of neuromuscular blockade or synergy has been reported with the following structurally different combinations:

- **atracurium** and **vecuronium**,[8]
- **cisatracurium** and **rocuronium**,[3,9,10] or **vecuronium**,[3]
- **metocurine** and **pancuronium**,[1]
- **mivacurium** and **pancuronium**[2,11] or **rocuronium**,[12]
- **tubocurarine** and **pancuronium**[1] or **vecuronium**.[7]

In addition to affecting response, the initial blocker may modify the duration of action of the supplemental blocker.[13,14] The blocking action of **pancuronium** was shortened when it was given during **vecuronium**-induced partial neuromuscular blockade.[14] Conversely, the duration of action of **mivacurium**[2,15] or **vecuronium**[14] was lengthened when they were given after **pancuronium**-induced neuromuscular block. Therefore, care should be taken if a small dose of a short-acting blocker is given near the end of an operation in which a longer-acting blocker has already been given.

(b) Competitive neuromuscular blocker given first

The combination of a competitive neuromuscular blocker and **suxamethonium** (**succinylcholine**) has an intrinsic antagonistic effect. This interaction has been used clinically to reduce muscle fasciculations caused by **suxamethonium**. A small dose of competitive neuromuscular blocker given shortly before **suxamethonium** generally reduces its effects and duration of action.[16] **Suxamethonium** would be expected to antagonise competitive neuromuscular blockers due to their opposite mechanisms of action (**suxamethonium** exerts a receptor agonist-type activity whereas competitive blockers exhibit receptor antagonism). However, **suxamethonium** may also reverse a competitive block by enhancing the effect of acetylcholine postsynaptically.[17,18]

The neuromuscular blockade will also be affected by the competitive neuromuscular blocker used and whether or not an anticholinesterase has been given.[19,20] See also, 'Neuromuscular blockers + Anticholinesterases', p.128.

1. Atracurium. If suxamethonium is given during the recovery from a paralysing dose of atracurium, the resultant neuromuscular block is influenced by the depth of residual block and the dose of suxamethonium used.[19,20] In a study in 38 patients recovering from atracurium 400 micrograms/kg, lower intravenous doses of suxamethonium 0.25 to 1 mg/kg mainly antagonised the partial block, whereas higher doses (1.5 to 3 mg/kg) usually enhanced the blockade.[19] However, the degree of recovery from the underlying block also influences the effects of suxamethonium: early on when the residual block is still considerable, suxamethonium may appear to have no effect or produce a partial antagonism of the block, but later, a biphasic response may be seen (antagonism of the competitive block initially before superimposing a depolarising block); a combination of antagonism and enhancement may also occur in different muscle groups.[20]

2. Pancuronium. Following pancuronium pretreatment, the duration of suxamethonium blockade appears to be prolonged,[16] and this is probably due to the inhibition of cholinesterase by pancuronium.[21]

(c) Suxamethonium (Succinylcholine) given first

In general, when a competitive blocker is given following suxamethonium, the onset time may be reduced and the potency or duration of the block may be increased, although not always significantly. In a study in 350 patients, the previous use of suxamethonium 1 mg/kg significantly accelerated the onset of neuromuscular blockade with **atracurium**, **pancuronium**, **pipecuronium** and **vecuronium**, when these were given after full recovery from the suxamethonium block. However, the duration of blockade was only significantly prolonged with **vecuronium**.[22]

It has been suggested that suxamethonium may have a presynaptic action resulting in reduced acetylcholine output.[17] Although not always clinically significant, be aware that a reduction in the dose of competitive blocker may be necessary following the use of a depolarising neuromuscular blocker.

1. Atracurium. A study showed that the effect of the previous use of suxamethonium on atracurium neuromuscular block appears to depend on the level of recovery from suxamethonium. As with previous studies, the onset of atracurium blockade was shortened when given after full recovery from the suxamethonium. However, this effect was less apparent when the atracurium was given before full suxamethonium recovery.[23]

2. Cisatracurium. Pretreatment with suxamethonium reduced the time to onset of cisatracurium block, but did not potentiate it or prolong recovery.[24]

3. Pancuronium or Vecuronium. One study found potentiation of vecuronium when it was given up to 30 minutes after full recovery from a single 1-mg/kg intravenous dose of suxamethonium.[25] Another study found that the effects of vecuronium or pancuronium were potentiated for at least 2 hours after full recovery from an intubating dose of suxamethonium.[26]

4. Rocuronium. Pretreatment with suxamethonium decreased the onset time and increased the duration of action or rocuronium.[27]

Neuromuscular blockers + Ondansetron

Ondansetron does not affect atracurium-induced neuromuscular blockade.

Clinical evidence, mechanism, importance and management

A double-blind, placebo-controlled study in 30 patients undergoing elective surgery found that intravenous ondansetron 8 or 16 mg given over 5 minutes had no effect on subsequent neuromuscular blockade with **atracurium**.[1] No special precautions would therefore seem necessary. The authors suggest that no interaction is likely with other non-depolarising neuromuscular blockers, but this needs confirmation.

Neuromuscular blockers + Opioids

A woman experienced hypertension and tachycardia when she was given pancuronium after induction of anaesthesia with morphine and nitrous oxide/oxygen. Bradycardia has been reported when vecuronium was given with alfentanil, fentanyl, or sufentanil, sometimes in patients taking beta blockers and/or calcium-channel blockers.

Clinical evidence, mechanism, importance and management

(a) Pancuronium

A woman about to receive a coronary by-pass graft was premedicated with **morphine** 10 mg and hyoscine 400 micrograms, intramuscularly, one hour before the induction of anaesthesia. **Morphine** 1 mg/kg was then slowly infused while the patient was ventilated with 50% nitrous oxide/oxygen. With the onset of neuromuscular relaxation with pancuronium 150 micrograms/kg, her blood pressure rose sharply from 120/60 mmHg to 200/110 mmHg and her pulse rate increased from 54 bpm to 96 bpm, persisting for several minutes but restabilising when halothane 1% was added.[1] The suggested reason for this reaction is that pancuronium can antagonise the vagal tone (heart slowing) induced by the **morphine**, thus allowing the blood pressure and heart rate to rise. The authors of the report point out the undesirability of this in those with coronary heart disease.

(b) Vecuronium

Two patients, one aged 72 years and the other aged 84 years, undergoing elective carotid endarterectomy developed extreme bradycardia following induction with **alfentanil** and vecuronium; both were premedicated with **morphine**. The first was taking **propranolol** 20 mg every 8 hours and, as the drugs were injected, his heart rate fell from 50 bpm to 35 bpm and his blood pressure fell from 160/70 mmHg to 75/35 mmHg. He responded to atropine, ephedrine and phenylephrine. The other patient was taking nifedipine and quinidine. His heart rate fell from 89 bpm to 43 bpm, and his blood pressure dropped from 210/80 mmHg to 120/45 mmHg. Both heart rate and blood pressures recovered following skin incision.[2]

Bradycardia in the presence of vecuronium has been seen during anaesthetic induction with other drugs including **fentanyl**,[3,4] and **sufentanil** (in 3 patients taking beta blockers with or without diltiazem).[5] The lack of vagolytic effects associated with vecuronium may mean that opioid-induced bradycardia is unopposed.[4,5] The beta blockers and diltiazem may also have played a part in the bradycardia seen in some of these patients[5] (see also 'Neuromuscular blockers + Beta blockers', p.132, and 'Neuromuscular blockers + Calcium-channel blockers', p.132). Be alert for this effect if vecuronium is given with any of these drugs. Atropine 500 micrograms given intravenously at the time of induction may prevent the bradycardia.[4]

For reports of bradycardia occurring with atracurium or suxamethonium used with propofol and fentanyl, see 'Anaesthetics, general + Neuromuscular blockers', p.113.

Neuromuscular blockers + Organophosphorus compounds

Exposure to organophosphorus insecticides such as malathion and dimpylate (diazinon) can markedly prolong the neuromuscular blocking effects of suxamethonium (succinylcholine).

Clinical evidence

A man admitted to hospital for an appendectomy became apnoeic during the early part of the operation when given **suxamethonium** (**succinylcholine**) 100 mg to facilitate tracheal intubation. He remained apnoeic throughout the 40 minutes of surgery. Restoration of neuromuscular activity occurred about 180 minutes after he had received the **suxamethonium**. Later studies showed that he had an extremely low plasma cholinesterase activity (3 to 10%), even though he had a normal phenotype for this enzyme. It subsequently turned out that he had been working with **malathion** for 11 weeks without any protection.[1]

Another report describes a man whose recovery from neuromuscular blockade with **suxamethonium** was very prolonged. He had attempted suicide approximately 2 weeks earlier with **dimpylate** (**diazinon**), a household insecticide. His pseudocholinesterase was found to be 2.5 units/L (normal values 7 to 19 units/L) and his dibucaine number (a measurement of cholinesterase activity) was too low to be measured.[2]

Other cases of prolonged **suxamethonium**-induced paralysis associated with organophosphate poisoning have been reported.[3-7] These cases have involved accidental ingestion of **chlorpyrifos**[3] or **dichlorvos**[7] in children, and one case resulted from subclinical exposure to **chlorpyrifos** and **propetamphos** following the treatment of carpets for pests.[4] Also, prolonged **suxamethonium**-induced paralysis has occurred following suicide attempts in adults with **chlorpyrifos**[6] or *Diazinon* [**dimpylate**].[5] In one report a patient was given ECT 2 weeks after attempted suicide with **chlorpyrifos** and, despite low plasma cholinesterase levels, paralysis with **suxamethonium** was carried out successfully using one-fifth of the normal dose.[6]

Mechanism

Malathion, dimpylate, and other organophosphorus insecticides inhibit the activity of plasma cholinesterase, thereby reducing the metabolism of the suxamethonium and prolonging its effects.

Importance and management

An established and well understood interaction. The organophosphorus pesticides are potent anticholinesterases used in agriculture and horticulture to control insects on crops, and in veterinary practice to control various ectoparasites. They are applied as sprays and dips. Anyone who is exposed to these toxic pesticides may therefore show changes in their responses to neuromuscular blockers. Widely used organophosphorus pesticides are said to include **azamethiphos**, **bromophos**, **chlorpyrifos**, **clofenvinfos**, **coumafos**, **cythioate**, **dichlorvos**, **dimethoate**, **dimpylate**, **dioxation**, **ethion**, **famphur**, **fenitrothion**, **fenthion**, **heptenophos**, **iodofenphos**, **malathion**, **naled**, **parathion**, **phosmet**, **phoxim**, **pirimiphos-methyl**, **propetamphos**, **pyraclofos**, **temefos**.[8] A number of the

nerve gases (such as **sarin**, **soman**, **tabun** and **VX**) are also potent anticholinesterases.

Neuromuscular blockers + Phenytoin

The effects of many competitive neuromuscular blockers are reduced and shortened if phenytoin is given for longer than one week, but they appear to be increased if phenytoin is given acutely (e.g. during surgery). Phenytoin appears not to interact with mivacurium.

Clinical evidence

(a) Phenytoin given long-term

1. Atracurium. A reduced recovery time from atracurium-induced neuromuscular blockade was found in one study in patients taking long-term antiepileptics including phenytoin.[1] In contrast, other studies suggest that atracurium is normally minimally affected by phenytoin.[2-4]

2. Cisatracurium. A study found that the recovery time from intravenous cisatracurium was shorter in patients taking 'carbamazepine', (p.133), or phenytoin than in patients not receiving carbamazepine or phenytoin; the recovery index (times between 25% and 75% recovery) was 16.2 minutes and 21.2 minutes, respectively. Clearance of cisatracurium was increased by about 25% in patients taking carbamazepine or phenytoin. Furthermore, the steady-state plasma level of cisatracurium required to maintain 95% block was increased by 20%, indicating increased resistance to the action of cisatracurium.[5]

3. Mivacurium. A study in 32 patients who had been taking carbamazepine alone or with phenytoin or valproic acid for greater than 2 weeks found no resistance to mivacurium,[6] although an earlier preliminary study by the same research group found a trend towards a shorter recovery from mivacurium in 13 patients taking unspecified antiepileptics (not statistically significant).[7]

4. Pancuronium. In the preliminary report of a study, the reduction in the time to recover from 25 to 75% of the response to ulnar nerve stimulation, in patients who had received phenytoin for longer than one week was 40% for pancuronium.[4] In another study about 80% more pancuronium was needed in 9 patients taking long-term phenytoin (58 micrograms/kg per hour) than in 18 others not receiving phenytoin (32 micrograms/kg per hour).[8] Resistance to pancuronium and a shortening of the recovery period due to long-term phenytoin[9,10] or unspecified antiepileptics[11] has also been described in other reports.

5. Pipecuronium. Some reports suggest that the recovery period from pipecuronium is reduced by phenytoin.[12,13] In one study it was found that the *onset* time for pipecuronium blockade was lengthened (although this was not statistically significant) for patients with therapeutic plasma concentrations of phenytoin or carbamazepine, but not in those with subtherapeutic levels. However, a shorter duration of action occurred regardless of the level of the antiepileptic drug.[13]

6. Suxamethonium (Succinylcholine). Eight patients who had been taking phenytoin and/or carbamazepine for at least one month took longer to recover from suxamethonium blockade, compared with 9 control patients; the time for return to baseline twitch height was 14.3 minutes and 10 minutes, respectively.[14]

7. Miscellaneous neuromuscular blockers. In the preliminary report of a study, the reduction in the time to recover from 25 to 75% of the response to ulnar nerve stimulation, in patients who had received phenytoin for longer than one week was 58% for **metocurine**. Some reduction in response was seen with **tubocurarine** but this was not statistically significant.[4] The **metocurine** results are published in full elsewhere.[15] The recovery period from **doxacurium**,[9,16] **rapacuronium** (case report),[17] **rocuronium**[18,19] and **vecuronium**[2,20-23] is also reduced by phenytoin.

(b) Phenytoin given short-term

A retrospective review of 8 patients taking long-term phenytoin (greater than 2 weeks) and 3 others given phenytoin within 8 hours of surgery found that the average doses of **vecuronium** used from induction to extubation were 155 micrograms/kg per hour (long-term use) and 61.5 micrograms/kg per hour (acute use).[24] Others have reported similar results.[21] Short-term phenytoin use may have been a contributing factor in the prolonged clearance of **vecuronium** in another patient.[25,26] Another study found that the sensitivity of patients to **vecuronium** was increased by phenytoin given intravenously during surgery,[27] and this has also been seen in *animal* studies using **tubocurarine** and phenytoin.[28] Similarly, a study of 20 patients undergoing craniotomy found that phenytoin (10 mg/kg over about 30 minutes) given during the operation augmented the neuromuscular block produced by **rocuronium**.[29]

Mechanism

Not fully understood, but it appears to be multifactorial. The acute use of phenytoin may result in neuromuscular block and potentiation of the action of competitive (non-depolarising) blockers.

The long-term use of phenytoin may produce subclinical neuromuscular blockade thought to be due to modest blockade of acetylcholine effects and a decrease in acetylcholine release; this antagonism may induce changes at the neuromuscular junction including increased number of acetylcholine receptors on the muscle membrane (up-regulation), with decreased sensitivity.[14,20,30] Other suggestions to account for the reduced response with chronic antiepileptics include: induction of liver enzyme activity (phenytoin is a potent inducer of cytochrome P450 isoenzymes), which would increase the metabolism and clearance of the neuromuscular blocker; and changes in plasma protein binding.[14,20,30] It has been shown that phenytoin possibly increases the plasma clearance of pancuronium[10] and rocuronium.[18]

Importance and management

Established and clinically important interactions. Anticipate the need to use more (possibly up to twice as much) doxacurium, metocurine, pancuronium, pipecuronium, rocuronium and vecuronium in patients who have taken phenytoin for more than a week,[21] and expect an accelerated recovery. The effects on tubocurarine and atracurium appear only to be small or moderate, whereas mivacurium appears not to interact.

In patients are given phenytoin acutely, anticipate the need to use a smaller neuromuscular blocker dosage, or prepare for a longer recovery time.

Neuromuscular blockers + Quinidine

The effects of both depolarising neuromuscular blockers (e.g. suxamethonium (succinylcholine)) and competitive neuromuscular blockers (e.g. tubocurarine) can be increased by quinidine. Recurarisation and apnoea have been seen in patients when quinidine was given during the recovery period from neuromuscular blockade.

Clinical evidence

A patient given **metocurine** during surgery regained her motor functions and was able to talk coherently during the recovery period. However, within 15 minutes of being given quinidine sulfate 200 mg by injection she developed muscular weakness and respiratory depression. She needed intubation and assisted respiration for a period of two and a half hours. Edrophonium and neostigmine were used to aid recovery.[1]

This interaction has also been described in case reports involving **tubocurarine**[2] and **suxamethonium** (**succinylcholine**),[3,4] and has been confirmed in *animal* studies.[5-7]

Mechanism

Not fully understood, but it has been shown that quinidine can inhibit the enzyme (choline acetyltransferase), which is concerned with the synthesis of acetylcholine at nerve endings.[8] Neuromuscular transmission would be expected to be reduced if the synthesis of acetylcholine is reduced. Quinidine also inhibits the activity of plasma cholinesterase, which is concerned with the metabolism of suxamethonium.[4]

Importance and management

The interaction between quinidine and neuromuscular blockers is an established interaction of clinical importance, but the documentation is limited. The incidence is uncertain, but it was seen in one report cited to a greater or lesser extent in 5 of the 6 patients studied.[3] It has only been reported clinically with metocurine, tubocurarine and suxamethonium, but it occurs in *animals* with **gallamine**, and it seems possible that it could occur clinically with any depolarising or non-depolarising neuromuscular blocker. Be alert for increased neuromuscular blocking effects, particularly after surgery.

Neuromuscular blockers + Testosterone

An isolated report describes marked resistance to the effects of suxamethonium (succinylcholine) and vecuronium, apparently due to the long-term use of testosterone. Another case reports resistance to vecuronium in a patient with elevated plasma testosterone levels.

Clinical evidence, mechanism, importance and management

A transsexual who had been receiving testosterone enantate 200 mg intramuscularly twice monthly for 10 years was resistant to intravenous **suxamethonium** (**succinylcholine**) 100 mg and needed intravenous **vecuronium** 100 micrograms/kg for effective tracheal intubation before surgery. During the surgery it was found necessary to use a total of 22 mg of **vecuronium** over a 50-minute period to achieve acceptable relaxation of the abdominal muscles for a hysterectomy and salpingo-oophorectomy to be carried out.[1] Considerably higher than usual doses of **vecuronium** were required in a patient with testicular feminisation and elevated plasma testosterone levels.[2]

The reasons are not understood. However, it has been suggested that the close structural similarity between testosterone and **vecuronium**, with respect to their common steroidal core, might mean that they share similar metabolic pathways (see also 'Neuromuscular blockers + Corticosteroids', p.134). Chronic elevation of circulating testosterone may up-regulate the hepatic metabolism of steroidal molecules in general, and so enhance the hepatic elimination of **vecuronium**.[2]

Neuromuscular blockers + Theophylline

Supraventricular tachycardia occurred in a patient taking aminophylline when pancuronium was given. Isolated cases suggest that the effects of pancuronium, but not vecuronium, can be opposed by aminophylline. Theophylline would be expected to interact similarly.

Clinical evidence, mechanism, importance and management

A report describes supraventricular tachycardia in a patient taking aminophylline who was anaesthetised with thiopental and fentanyl, and then given **pancuronium**. Three minutes later his heart rate rose to 180 bpm and an ECG revealed supraventricular tachycardia.[1] The authors of this report attributed this reaction to an interaction between the **pancuronium** and the aminophylline, because previous surgery with these drugs in the absence of aminophylline had been without incident.[1] Marked resistance to the effects of **pancuronium** (but not **vecuronium**) was seen in one patient receiving an aminophylline infusion.[2] Two other patients are reported to have shown a similar resistance to **pancuronium** but they had also been given hydrocortisone, which could have had a similar effect[3,4] (see also 'Neuromuscular blockers + Corticosteroids', p.134). These appear to be the only clinical reports of such an interaction and their general relevance

is unclear. Note that, any interaction would also be expected to apply to theophylline, although this needs confirmation.

Neuromuscular blockers + Tobacco

There is some evidence that smokers may need more vecuronium and possibly more rocuronium, but less atracurium to achieve the same effects as non-smokers. However, results are variable and another study found that rocuronium appeared to be unaffected by smoking. Passive-smoking children appear to require less rocuronium than those not exposed to environmental tobacco smoke.

Clinical evidence, mechanism, importance and management

Variable results have been reported on the effect of smoking on neuromuscular blockers. The amount of **atracurium** required was about 25% lower in smokers, when compared with non-smokers.[1] However, in another study, smokers required more **vecuronium** than non-smokers (96.8 micrograms/kg per hour compared with 72.11 micrograms/kg per hour, respectively; a 34% increase).[2] Similarly another study in patients undergoing minor surgery found that the 20 smokers required about 20% more **rocuronium** than the 20 non-smokers.[3] However, this study has been criticised for having too few patients, which meant that it was unable to properly detect a statistically significant difference between the smokers and non-smokers.[4] In yet another study, the onset and recovery times from the neuromuscular blocking effects of **rocuronium** 600 micrograms/kg were reported to be not significantly affected by smoking more than 10 cigarettes daily.[5] In another study in children aged 4 to 10 years, those with a history of passive smoking required less **rocuronium** during similar anaesthesia than those without a familial smoking history.[6]

Tobacco smoke contains many different compounds and has enzyme-inducing properties, which may affect the dose requirements of neuromuscular blockers. In addition, the time interval in refraining from smoking will affect plasma **nicotine** concentrations; small doses of nicotine may stimulate the neuromuscular junction, but larger doses may block transmission.[2]

Although an interaction is established it seems unlikely to be generally important, as the dose of neuromuscular blocker is individualised and titrated to effect.

Neuromuscular blockers + Trimetaphan

Trimetaphan can increase the effects of suxamethonium (succinylcholine), which may result in prolonged apnoea. This may possibly occur with other neuromuscular blocking drugs, such as alcuronium.

Clinical evidence

A man undergoing neurosurgery was given **tubocurarine** and **suxamethonium** (**succinylcholine**). Neuromuscular blockade was prolonged postoperatively, lasting about 2.5 hours, and this was attributed to the concurrent use of trimetaphan 4.5 g, given over a 90-minute period. Later, when he underwent further surgery using essentially the same anaesthetic techniques and drugs, but with a very much smaller dose of trimetaphan (35 mg over a 10-minute period), the recovery was normal.[1]

Nine out of 10 patients receiving ECT and given **suxamethonium** had an almost 90% prolongation in apnoea (from 142 seconds to 265 seconds) when trimetaphan 10 to 20 mg was used instead of 1.2 mg of atropine.[2] Prolonged apnoea has been seen in another patient given **suxamethonium** and trimetaphan.[3] On the basis of an *in vitro* study it was calculated that a typical dose of trimetaphan would double the duration of paralysis due to **suxamethonium**.[4] Prolonged neuromuscular blockade was also seen in a man given **alcuronium** and trimetaphan.[5]

Mechanism

Not fully understood. Trimetaphan can inhibit plasma cholinesterase to some extent,[2,5] which would reduce the metabolism of suxamethonium and thereby prolong its activity. Studies in *rats*[6,7] and case reports[8] also indicate that trimetaphan has direct neuromuscular blocking activity. Its effects are at least additive with the neuromuscular blocking effects of the **aminoglycosides**.[7]

Importance and management

Information is limited but the interaction appears to be established. If trimetaphan and suxamethonium (succinylcholine) are used concurrently, be alert for enhanced and prolonged neuromuscular blockade. This has also been seen with alcuronium, and trimetaphan may interact with other competitive neuromuscular blockers.[5] Respiratory arrest has been seen when large doses of trimetaphan were given in the absence of a neuromuscular blocker, so that caution is certainly needed.[8] *Animal* studies suggested that the blockade might not be reversed by neostigmine or calcium chloride,[7] but neostigmine and calcium gluconate were successfully used to reverse the effects of alcuronium and trimetaphan in one case.[5]

Neuromuscular blockers + Ulinastatin

Ulinastatin delays the onset and hastens the recovery from vecuronium neuromuscular block.

Clinical evidence, mechanism, importance and management

A randomised, placebo-controlled study in 60 patients found that a 5000 unit/kg intravenous bolus dose of ulinastatin given before induction of anaesthesia, and again 2 minutes before intravenous **vecuronium** 100 micrograms/kg, delayed the onset of neuromuscular blockade, when compared with placebo (250 seconds compared with 214 seconds). The recovery from neuromuscular block (measured as return of post-tetanic count) was significantly shorter after ulinastatin than placebo (11 minutes compared with 17.7 minutes). The effects of ulinastatin were thought to be due to an increase in the release of acetylcholine at the neuromuscular junction and enhanced **vecuronium** elimination due to increases in liver blood flow and urine volume.[1]

If the mechanism of interaction is correct, it seems possible that other neuromuscular blockers could interact similarly. However, the clinical rel-

evance of this interaction seems likely to be small, as any effect is likely to be detected by routine monitoring.

Neuromuscular blockers; Atracurium + Danazol or Tamoxifen

Two isolated case reports describe prolonged atracurium effects, which were attributed to the use of tamoxifen or danazol.

Clinical evidence, mechanism, importance and management

A case report describes a 67-year-old mastectomy patient taking methyldopa, hydrochlorothiazide, triamterene and long-term tamoxifen 10 mg twice daily who developed prolonged neuromuscular blockade after a single 500-microgram/kg dose of atracurium, which the authors suggest might be due to an interaction between atracurium and tamoxifen.[1] There is an earlier report[2] of prolonged atracurium blockade where the patient was taking danazol, another antioestrogenic drug. These interactions are probably not of general importance.

2. Bizzarri-Schmid MD, Desai SP. Prolonged neuromuscular blockade with atracurium. *Can Anaesth Soc J* (1986) 33, 209–12.

Neuromuscular blockers; Botulinum toxin + Miscellaneous

Theoretically, the neuromuscular blocking effects of botulinum toxin can be increased by other drugs with neuromuscular blocking effects, such as the aminoglycosides and muscle relaxants, but no such interactions appear to have been reported.

Clinical evidence, mechanism, importance and management

A case report describes a 5-month-old baby boy who was admitted to hospital because of lethargy, poor feeding, constipation and muscle weakness (later identified as being due to a *Clostridium botulinum* infection). One hour after starting intravenous treatment with ampicillin and **gentamicin** 7.5 mg/kg daily (in divided doses every 8 hours) for presumed sepsis, he stopped breathing and died. The reason appeared to be the additive neuromuscular blocking effects of the systemic botulinum toxin produced by the *Clostridium botulinum* infection and the **gentamicin**.[1] *Animal* studies confirm that **gentamicin** and **tobramycin** potentiate the neuromuscular blocking effects of systemic botulinum toxin (used to mimic botulism),[1] and there is every reason to believe that any of the other drugs known to cause neuromuscular blockade (**aminoglycosides**, conventional **neuromuscular blockers**, etc.) will behave similarly. However, note that clinically, botulinum A toxin is injected for its local effect in specific muscles, and is not used systemically; and so the situation is not analogous to that described in the case of the child with systemic botulism. Nevertheless, several manufacturers prudently advise caution if drugs that affect neuromuscular transmission are given concurrently.[2-4] **Aminoglycosides**, **spectinomycin**, and **neuromuscular blockers** are specifically named.

Neuromuscular blockers; Suxamethonium (Succinylcholine) + Dexpanthenol

An isolated report describes an increase in the neuromuscular blocking effects of suxamethonium, which was attributed to the concurrent use of dexpanthenol, but a further study using pantothenic acid (the main metabolite of dexpanthenol) failed to confirm this interaction.

Clinical evidence, mechanism, importance and management

A study in 6 patients under general anaesthesia found that their response to suxamethonium was unaffected by the infusion of 500 mg of **pantothenic acid**.[1] This study was conducted in response to an earlier case report, which reported respiratory depression requiring re-intubation following the use of intramuscular dexpanthenol (which is converted to pantothenic acid in the body) shortly after stopping a suxamethonium infusion.[1]

Apart from the single unconfirmed report there seems to be little other reason for avoiding concurrent use or for taking particular precautions. However, the US manufacturer of dexpanthenol recommends that it should not be given within one hour of suxamethonium.[2]

2. Dexpanthenol Injection. American Regent, Inc. US Prescribing information, January 2003.

Neuromuscular blockers; Vecuronium + Clonidine

There is limited evidence to suggest that clonidine modestly increases the duration of action of vecuronium.

Clinical evidence, mechanism, importance and management

In a study in 16 surgical patients, 8 patients took oral clonidine 4 micrograms/kg to 5.5 micrograms/kg 90 minutes before their operation. Anaesthesia was induced by thiamylal, and maintained with nitrous oxide/oxygen and isoflurane supplemented by fentanyl. Clonidine increased the duration of neuromuscular blockade following the use of vecuronium by 26%, when compared with the patients not taking clonidine.[1]

The reasons for this modest increase in neuromuscular blockade are not understood. The clinical importance of this interaction would appear to be small.

1. Nakahara T, Akazawa T, Kinoshita Y, Nozaki J. The effect of clonidine on the duration of vecuronium-induced neuromuscular blockade in humans. *Jpn J Anesthesiol* (1995) 44, 1458–63.

Neuromuscular blockers; Vecuronium + Lansoprazole

There is some evidence to suggest that lansoprazole increases the duration of action of vecuronium.

Clinical evidence, mechanism, importance and management

In a study of 50 adult surgical patients, half of whom received lansoprazole 30 mg the night before their operation, it was found that there was no significant difference between the time to onset of neuromuscular blockade by **vecuronium** in the two groups, but lansoprazole increased the duration of neuromuscular blockade by about 34%.[1] This interaction needs confirmation and the clinical relevance requires assessment.

Analgesics and NSAIDs

The drugs dealt with in this section include aspirin and other salicylates, NSAIDs, opioid analgesics, and the miscellaneous analgesics, such as nefopam and paracetamol. 'Table 6.1', (p.150) contains a listing, with a further classification of the NSAIDs.

Interactions

(a) Aspirin and NSAIDs

Aspirin and the NSAIDs generally undergo few clinically significant pharmacokinetic interactions. The majority are highly protein bound, and have the potential to interact with other drugs via this mechanism. However, with a few exceptions, most of these interactions are not clinically important (see 'Protein-binding interactions', (p.3)).

Of the newer NSAIDs, celecoxib is metabolised by the cytochrome P450 isoenzyme CYP2C9, and inhibits CYP2D6. Rofecoxib, now withdrawn, inhibits CYP1A2, see 'Tizanidine + CYP1A2 inhibitors', p.1572. Nevertheless, most of the important interactions with NSAIDs and aspirin are pharmacodynamic. Aspirin and all non-selective NSAIDs inhibit platelet aggregation, and so can increase the risk of bleeding and interact with other drugs that have this effect. NSAIDs that are highly selective for cyclooxygenase-2 (COX-2) do not inhibit platelet aggregation.

Aspirin and all NSAIDs (including COX-2 selective NSAIDs) affect the synthesis of renal prostaglandins, and so can cause salt and water retention. This can increase blood pressure and affect antihypertensive therapy.

Aspirin and non-selective NSAIDs inhibit the mechanisms that protect the gastrointestinal mucosa and so cause gastrointestinal toxicity. COX-2 selective NSAIDs (coxibs) are less likely to have this effect, but they can still cause gastrointestinal toxicity.

(b) Opioids

Morphine is metabolised by glucuronidation by UDP-glucuronyltransferases, mainly to one active and one inactive metabolite. The glucuronidation of morphine can be induced or inhibited by various drugs. Morphine is not significantly affected by cytochrome P450 isoenzymes. The semi-synthetic morphine analogues, hydromorphone and oxymorphone, are metabolised similarly.

Codeine, dihydrocodeine, and hydrocodone are thought to be prodrugs, and require metabolic activation, possibly by CYP2D6 or glucuronyltransferases. Inhibitors of these enzymes may therefore reduce their efficacy. Oxycodone is also metabolised by CYP2D6 and CYP3A4.

Pethidine (meperidine) is metabolised by several cytochrome P450 isoenzymes. If the metabolism of pethidine is increased it can lead to increased production of the toxic metabolite, norpethidine, and increased CNS adverse effects.

Methadone is metabolised by several cytochrome P450 isoenzymes including CYP3A4, CYP2B6, and CYP2D6, although CYP2C8, CYP2C9 and CYP2C19 may also play a role.

Buprenorphine is metabolised by CYP3A4, and alfentanil is extensively metabolised by CYP3A4, and has been used as a probe drug for assessing CYP3A4 activity. Fentanyl and sufentanil are also metabolised by CYP3A4, but because they are high hepatic-extraction drugs (see 'Changes in first-pass metabolism', (p.4)) they are less affected by inhibitors or inducers of CYP3A4, although in some instances this may still lead to clinically significant effects.

(c) Paracetamol

Paracetamol is not absorbed from the stomach, and the rate of absorption is well correlated with the gastric emptying rate. Paracetamol has therefore been used as a marker drug in studies of gastric emptying. Paracetamol is primarily metabolised by the liver to a variety of metabolites, principally the glucuronide and sulfate conjugates. Hepatotoxicity of paracetamol is thought to be due to a minor metabolite, *N*-acetyl-p-benzoquinone imine (NAPQI), which is inactivated with glutathione and excreted as mercapturate and cysteine conjugates. When the liver stores of glutathione are depleted, and the rate of production of NAPQI exceeds the rate of production of glutathione, excess NAPQI attaches to liver proteins and causes liver damage. CYP2E1 may be involved in the formation of this hepatotoxic metabolite.

Table 6.1 Analgesics and NSAIDs

Group	*Drugs*
Aspirin and oral salicylates	Aloxiprin, Aspirin, Benorilate, Choline salicylate, Diflunisal, Ethenzamide, Lysine aspirin, Magnesium salicylate, Salsalate, Sodium salicylate
NSAIDs	
Fenamates	Floctafenine, Flufenamic acid, Meclofenamic acid, Mefenamic acid, Tolfenamic acid
Indole- and indene-acetic acids	Acemetacin, Etodolac, Indometacin, Sulindac
Oxicams	Lornoxicam, Meloxicam, Piroxicam, Tenoxicam
Phenylacetic acid derivatives	Aceclofenac, Alclofenac, Diclofenac
Propionic acid derivatives	Dexibuprofen, Dexketoprofen, Fenbufen, Fenoprofen, Flurbiprofen, Ibuprofen, Ketoprofen, Naproxen, Oxaprozin, Tiaprofenic acid
Pyrazolone derivatives	Azapropazone, Feprazone, Kebuzone, Metamizole sodium (Dipyrone), Oxyphenbutazone, Phenylbutazone
Selective inhibitors of cyclo-oxygenase-2 (Coxibs)	Celecoxib, Etoricoxib, Lumiracoxib, Meloxicam (see under *Oxicams*), Parecoxib, Rofecoxib, Valdecoxib
Other	Benzydamine hydrochloride, Felbinac, Ketorolac, Nabumetone, Nimesulide, Phenazone (Antipyrine), Tolmetin
Opioid and related analgesics	
Anaesthetic adjuncts	Alfentanil, Fentanyl, Remifentanil, Sufentanil
Mild to moderate pain	Codeine, Dextropropoxyphene (Propoxyphene), Dihydrocodeine
Moderate to severe pain:	
Partial agonists and agonists/antagonists	Buprenorphine (also used for opioid dependence), Butorphanol, Meptazinol, Nalbuphine, Pentazocine
Pure agonists	Dextromoramide, Diamorphine (Heroin), Dipipanone, Hydrocodone, Hydromorphone, Methadone (also used for opioid dependence), Morphine, Oxycodone, Oxymorphone, Papaveretum, Pethidine (Meperidine), Tramadol
Miscellaneous	Nefopam, Paracetamol (Acetaminophen)

Aspirin or other Salicylates + Antacids

The serum salicylate levels of patients taking large, anti-inflammatory doses of aspirin or other salicylates can be reduced to subtherapeutic levels by some antacids. The maximum plasma levels of single doses of aspirin may be increased by giving an antacid, although the extent of absorption is unaltered.

Clinical evidence

A study in 10 healthy subjects found that the mean maximum plasma level of a single 650-mg dose of aspirin was about 70% higher when it was given 10 minutes after an antacid (**aluminium/magnesium hydroxide**), when compared with aspirin alone. However, there was no change in the time to reach the peak level or the AUC. There were also no significant changes in the pharmacokinetics of the metabolites, salicylic acid and salicyluric acid.[1]

A child with rheumatic fever taking aspirin 600 mg five times daily had a serum salicylate level of between 82 and 118 mg/L while taking 30 mL of *Maalox* (**aluminium/magnesium hydroxide** suspension). When the *Maalox* was withdrawn, the urinary pH fell from a range of 7 to 8 down to a range of 5 to 6.4, whereupon the serum salicylate level rose three- to fourfold to about 380 mg/L, which required a dose reduction.[2] An associated study in 13 healthy subjects taking aspirin 4 g daily for a week found that **sodium bicarbonate** 4 g daily reduced serum salicylate levels by 44%, from 270 mg/L to 150 mg/L. This reflected a rise in the urinary pH from a range of 5.6 to 6.1 up to around 6.2 to 6.9.[2,3]

Similar changes have been reported in other studies with:

- aspirin or **choline salicylate** and **aluminium/magnesium hydroxide**;
- aspirin and **magnesium trisilicate/aluminium hydroxide**;
- aspirin or **sodium salicylate** and **sodium bicarbonate**.[4-8]

There is some evidence to suggest that this effect does not occur at low serum salicylate levels,[5,6] or if the pH of the urine is unchanged by the antacid.[6]

Mechanism

Aspirin and other salicylates are acidic compounds that are excreted by the kidney tubules and are ionised in solution. In alkaline solution, much of the drug exists in the ionised form, which is not readily reabsorbed, and therefore is lost in the urine. If the urine is made more acidic (e.g. with ammonium chloride), much more of the drug exists in the un-ionised form, which is readily reabsorbed, so that less is lost in the urine and the drug is retained in the body.[7,8]

In vitro data show that magnesium oxide and aluminium hydroxide strongly adsorb aspirin and sodium salicylate.[9] However, in three of the studies above aluminium hydroxide-containing antacids had no effect on the extent of absorption of salicylate,[1,4,6] although the rate of absorption may be increased as a result of an increase in the solubility of salicylate in a less acidic gastric environment.[1]

Importance and management

A well established and clinically important interaction for those receiving long-term treatment with large doses of salicylates, because the serum salicylate level may become subtherapeutic. This interaction can occur with both 'systemic' antacids (e.g. sodium bicarbonate) as well as some 'non-systemic' antacids (e.g. aluminium/magnesium hydroxide), but only appears to occur if there is an increase in the urinary pH. Care should be taken to monitor serum salicylate levels if any antacid is started or stopped in patients where the control of salicylate levels is critical.

No important adverse interaction would be expected in those taking occasional doses of aspirin for analgesia. Some aspirin formulations actually include antacids as buffering agents to increase absorption rates and raise peak serum levels,[10] which gives more rapid analgesia, and/or in an attempt to decrease gastric irritation. Note that antacids may also increase the rate of absorption of aspirin given as enteric-coated tablets.[11]

Aspirin + Bile-acid binding resins

Colestyramine and colestipol do not appear to have any clinically important effects on the absorption of aspirin.

Clinical evidence, mechanism, importance and management

(a) Colestipol

In 12 healthy subjects the extent of absorption of a single 650-mg dose of aspirin was unaffected by colestipol 10 g. However, the rate of aspirin absorption was increased by colestipol: at 60 minutes after the dose the plasma level was increased by about 40%.[1] No particular precautions seem to be necessary during concurrent use.

(b) Colestyramine

A study in 3 healthy subjects and 3 patients, and a later study in 7 healthy subjects, found that colestyramine 4 g delayed the absorption of a single 500-mg dose of aspirin (time to peak levels extended from 30 to 60 minutes) but the total amount absorbed was only reduced by 5 to 6%. Some of the subjects had slightly higher serum aspirin levels while taking colestyramine.[2] Similar results were reported in another study (a 31% lower plasma aspirin level at 60 minutes, but no difference in total absorption).[1] There would seem to be little reason for avoiding concurrent use unless rapid analgesia is needed.

Aspirin or other Salicylates + Carbonic anhydrase inhibitors

A severe and even life-threatening toxic reaction can occur in patients taking high-dose salicylates if they are given carbonic anhydrase inhibitors, such as acetazolamide or diclofenamide.

Clinical evidence

An 8-year-old boy with chronic juvenile arthritis, taking prednisolone, indometacin and **aloxiprin**, was admitted to hospital with drowsiness, vomiting and hyperventilation (diagnosed as metabolic acidosis) within a month of the **aloxiprin** dose being increased from 3 to 3.6 g daily and starting to take **diclofenamide** 25 mg three times daily for glaucoma.[1]

Other cases of toxicity (metabolic acidosis) have included a 22-year-old woman taking **salsalate** with **acetazolamide** 250 mg four times daily,[1] and two elderly women taking large doses of aspirin with **acetazolamide** or **diclofenamide**.[2] A 50-year-old woman taking **acetazolamide** for glaucoma was admitted to hospital with confusion and cerebellar ataxia, associated with hyperchloraemic acidosis, 14 days after starting to take aspirin for acute pericarditis.[3] A man taking **diclofenamide** developed salicylate poisoning within 10 days of starting to take aspirin 3.9 g daily.[4] Coma developed in an 85-year-old woman taking aspirin 3.9 g daily when her dosage of **acetazolamide** was increased from 500 mg to 1 g daily,[5,6] and toxicity was seen in a very elderly man given both drugs: levels of unbound **acetazolamide** were found to be unusually high.[6] An elderly man became confused, lethargic, incontinent and anorexic while taking **acetazolamide** and **salsalate**. He needed intravenous hydration.[7]

Mechanism

Not fully established. One idea is that these carbonic anhydrase inhibitors (acetazolamide, diclofenamide) affect the plasma pH, so that more of the salicylate exists in the un-ionised (lipid-soluble) form, which can enter the CNS and other tissues more easily, leading to salicylate toxicity.[2] However, carbonic anhydrase inhibitors also make the urine more alkaline, which increases the loss of salicylate[8] (see also 'Aspirin or other Salicylates + Antacids', p.151). *Animal* studies confirm that carbonic anhydrase inhibitors increase the lethal toxicity of aspirin.[4] An alternative suggestion is that because salicylate inhibits the plasma protein binding of acetazolamide and its excretion by the kidney, acetazolamide toxicity, which mimics salicylate toxicity, may occur.[6]

Importance and management

Although there are few clinical reports on record, the interaction between carbonic anhydrase inhibitors and salicylates is established, well confirmed by *animal* studies, and potentially serious. One study recommended that carbonic anhydrase inhibitors should probably be avoided in those receiving high-dose salicylate treatment.[6] If they are used, the patient should be well monitored for any evidence of toxicity (confusion, lethargy, hyperventilation, tinnitus) because the interaction may develop slowly and insidiously.[2] In this context NSAIDs may be a safer alternative. Naproxen proved to be a satisfactory substitute in one case.[1] The authors of one study suggest that **methazolamide** may possibly be a safer alternative to acetazolamide because it is minimally bound to plasma proteins. They also suggest paracetamol (acetaminophen) as an alternative to salicylate in patients taking acetazolamide.[6] The reports cited here concern carbonic anhydrase inhibitors given orally, not as eye drops. It is not known whether the latter interact similarly, but there appear to be no reports.

Aspirin or other Salicylates + Corticosteroids or Corticotropin

Serum salicylate levels are reduced by the corticosteroids. This appears to be of most consequence if the corticosteroid is withdrawn. Concurrent use increases the risk of gastrointestinal bleeding and ulceration.

Clinical evidence

A 5-year-old boy taking long-term **prednisone** in doses of at least 20 mg daily, was given **choline salicylate** 3.6 g daily, and the **prednisone** was gradually tapered off to 3 mg daily over a 3-month period. Severe salicylate toxicity developed, and in a retrospective investigation of the cause, using frozen serum samples drawn for other purposes, it was found that the serum salicylate levels had risen from less than 100 mg/L up to 880 mg/L during the withdrawal of the **prednisone**.[1] Later studies in 3 other patients taking **choline salicylate** or aspirin and either **prednisone** or another unnamed corticosteroid, found about a threefold rise in salicylate levels during corticosteroid withdrawal.[1] **Hydrocortisone** was also found to increase the clearance of **sodium salicylate** in 4 other patients.[1] A serum salicylate rise has been described in a patient taking **aloxiprin** when **prednisolone** was withdrawn.[2] Other studies in both adults and children show that **prednisone**, **methylprednisolone**, **betamethasone** and **corticotropin** reduce serum salicylate levels.[3-5] Two studies also found that intra-articular **dexamethasone**, **methylprednisolone**, and **triamcinolone** transiently reduced serum salicylate levels in patients given enteric-coated aspirin.[6,7] However one study in patients found that **prednisone** 12 to 60 mg daily had no effect on the clearance of single doses of **sodium salicylate**.[8]

Mechanism

Uncertain. One idea is that the presence of the corticosteroid increases the glomerular filtration rate, which increases salicylate clearance. When the corticosteroid is withdrawn, the clearance returns to normal and the salicylate accumulates. Another suggestion is that the corticosteroids increase the metabolism of the salicylate.[3]

Importance and management

Well established interactions. Patients should be monitored to ensure that salicylate levels remain adequate when corticosteroids are added[4] and do not become excessive if they are withdrawn. It should also be remembered that concurrent use may increase the incidence of gastrointestinal bleeding and ulceration. See also 'Corticosteroids + NSAIDs', p.1266.

Aspirin + Dapsone

Dapsone does not significantly affect the pharmacokinetics of aspirin.

Clinical evidence, mechanism, importance and management

A comparison of the pharmacokinetics of aspirin in 8 healthy subjects and 8 patients with uncomplicated lepromatous leprosy found that the pharmacokinetics of a single 600-mg dose of aspirin was not affected by either leprosy, or by treatment with dapsone 100 mg daily for 8 days.[1] No aspirin dose adjustments would seem likely to be needed on concurrent use.

Aspirin + Food

Food delays the absorption of aspirin.

Clinical evidence, mechanism, importance and management

A study in 25 subjects given aspirin 650 mg in five different preparations found that food roughly halved their serum salicylate levels (measured 10 and 20 minutes later), compared with those seen when the same dose of aspirin was given while fasting.[1] Similar results were found in subjects given calcium aspirin 1.5 g.[2] In another study in 8 healthy subjects who were given effervescent aspirin 900 mg, serum salicylate levels at 15 minutes were roughly halved by food, but were more or less unchanged at one hour.[3]

A further study in 16 healthy subjects found that the extent of absorption of a single 900-mg dose of soluble aspirin was not significantly affected by a high-fat meal. The rate of absorption was reduced by food and the maximum plasma level was reduced by 18%, which was not considered to

be clinically significant. Furthermore, there was no statistically significant change in the time to maximum plasma levels (20 minutes fasted; 30 minutes fed).[4]

A possible reason for the reduced rate of absorption is that food delays gastric emptying. Thus, if rapid analgesia is needed, aspirin should be taken without food, but if aspirin is needed long-term, giving it with food is thought to help to protect the gastric mucosa.

Aspirin + Griseofulvin

An isolated report describes a marked fall in the serum salicylate levels of a child given aspirin and griseofulvin.

Clinical evidence, mechanism, importance and management

An 8-year-old boy with rheumatic fever taking aspirin 110 mg/kg daily and furosemide, digoxin, captopril, potassium, aluminium/magnesium hydroxide and iron, had a very marked fall in his serum salicylate levels (from a range of 18.3 to 30.6 mg/dL to less than 0.2 mg/dL) within 2 days of starting griseofulvin 10 mg/kg daily. Two days after the griseofulvin was stopped, the salicylate levels were back to their former levels. The reasons for this effect are not known, but it was suggested that the salicylate absorption was impaired in some way.[1] This appears to be the first and only report of this interaction so that its general importance is uncertain.

1. Phillips KR, Wideman SD, Cochran EB, Becker JA. Griseofulvin significantly decreases serum salicylate concentrations. *Pediatr Infect Dis J* (1993) 12, 350–2.

Aspirin + Kaolin-pectin

Kaolin-pectin causes a small reduction in the absorption of aspirin.

Clinical evidence, mechanism, importance and management

In 10 healthy subjects the absorption of aspirin 975 mg was reduced by 5 to 10% by 30 or 60 mL of kaolin-pectin.[1] A likely explanation is that the aspirin becomes adsorbed by the kaolin so that the amount available for absorption through the gut wall is reduced. However, this small reduction in absorption is unlikely to be of clinical importance.

1. Juhl RP. Comparison of kaolin-pectin and activated charcoal for inhibition of aspirin absorption. *Am J Hosp Pharm* (1979) 36, 1097–8.

Aspirin + Laxatives

Sodium sulfate and castor oil used as laxatives can cause a modest reduction in aspirin absorption.

Clinical evidence, mechanism, importance and management

In an experimental study of the possible effects of laxatives on drug absorption, healthy subjects were given 10 to 20 g of oral **sodium sulfate** and 20 g of **castor oil** (doses sufficient to provoke diarrhoea). Absorption, measured by the amount of drug excreted in the urine, was decreased at 4 hours. The reduction was 21% for **castor oil** and aspirin, and 27% for **sodium sulfate** and aspirin. However, serum levels of aspirin were relatively unchanged. The overall picture was that while these laxatives can alter the pattern of absorption, they do not seriously impair the total amount of drug absorbed.[1]

1. Mattila MJ, Takki S, Jussila J. Effect of sodium sulphate and castor oil on drug absorption from the human intestine. *Ann Clin Res* (1974) 6, 19–24.

Aspirin + Levamisole

The salicylate levels of a patient taking aspirin rose when levamisole was given, but this effect was not confirmed in a subsequent controlled study.

Clinical evidence, mechanism, importance and management

A preliminary report of a patient who had an increase in salicylate levels (magnitude not stated) when levamisole was given with aspirin 5.4 g daily[1] prompted a study in 9 healthy subjects of this possible interaction. Sustained-release aspirin 3.9 g daily in two divided doses was given over a period of 3 weeks, with levamisole 50 mg three times daily for a week, each subject acting as his own control. No significant changes in plasma salicylate levels were found.[2] The reasons for the increase in salicylate levels in the case report are unclear. No interaction would generally be expected.

2. Rumble RH, Brooks PM, Roberts MS. Interaction between levamisole and aspirin in man. *Br J Clin Pharmacol* (1979) 7, 631–3.

Aspirin + Pentazocine

A man regularly taking large doses of aspirin developed renal papillary necrosis when he was given pentazocine.

Clinical evidence, mechanism, importance and management

An isolated report describes a man, regularly taking aspirin 1.8 to 2.4 g daily, who developed renal papillary necrosis within 6 months of also starting to take pentazocine 800 to 850 mg daily. He developed abdominal pain, nausea and vomiting, and passed tissue via his urethra. Before starting the pentazocine and after it was stopped, no necrosis was apparent. The postulated reason for this reaction is that a pentazocine-induced reduction in blood flow through the kidney potentiated the adverse effects of chronic aspirin use.[1] The general importance of this isolated case is uncertain and no general recommendations can be made.

1. Muhalwas KK, Shah GM, Winer RL. Renal papillary necrosis caused by long-term ingestion of pentazocine and aspirin. *JAMA* (1981) 246, 867–8.

Aspirin + Phenylbutazone

Phenylbutazone reduces the uricosuric effects of high-dose aspirin. Concurrent use is likely to be associated with an increased risk of gastrointestinal damage.

Clinical evidence

The observation that several patients given aspirin and phenylbutazone developed elevated serum urate levels, prompted a study in 4 patients without gout. The study found that aspirin 2 g daily had little effect on the excretion of uric acid in the urine, but marked uricosuria occurred with aspirin 5 g daily. When phenylbutazone 200, 400 and then 600 mg daily (over 3 days) was also given the uricosuria was abolished. Serum uric acid levels rose from an average of about 40 mg/L to 60 mg/L. The interaction was confirmed in a patient with tophaceous gout. The retention of uric acid also occurs if the phenylbutazone is given first.[1]

Mechanism

Not understood. Phenylbutazone is structurally related to sulfinpyrazone, which interacts similarly, see 'Uricosuric drugs + Aspirin or other Salicylates', p.1575.

Importance and management

An established but sparsely documented interaction. The potential problems arising from this interaction should be recognised in any patient given aspirin and phenylbutazone. The concurrent use of aspirin and NSAIDs increases the risk of gastrointestinal damage and is not recommended. Although there does not appear to be any specific evidence for phenylbuta-

zone, it would be expected to interact in the same way as other NSAIDs, see 'NSAIDs + Aspirin', p.158.

Nefopam + Miscellaneous

The manufacturer states that nefopam is contraindicated in patients taking MAOIs. Caution should be used in those taking tricyclic antidepressants, antimuscarinics and sympathomimetics. The intensity and incidence of adverse effects are somewhat increased when nefopam is given with codeine, pentazocine or dextropropoxyphene (propoxyphene), and the CNS depressant effect of dihydrocodeine may have contributed to a fatal overdose with nefopam.

Clinical evidence, mechanism, importance and management

(a) Antidepressants

The manufacturer advises caution if nefopam is given with a **tricyclic antidepressant**,[1] presumably as nefopam alone may cause convulsions and the tricyclics can also lower the convulsive threshold. In addition, the antimuscarinic adverse effects of nefopam may be additive with those of tricyclics and other drugs with antimuscarinic effects[1] (see 'Antimuscarinics + Antimuscarinics', p.786). For example, the CSM in the UK has a number of reports of urinary retention caused by nefopam,[2] which would be expected to be worsened by the concurrent use of drugs with antimuscarinic activity, such as the tricyclics.

Nefopam appears to have sympathomimetic activity, therefore caution should be used when prescribing other drugs with sympathomimetic effects. The manufacturer contraindicates its use with the **MAOIs**[1] (see 'MAOIs or RIMAs + Sympathomimetics; Indirectly-acting', p.1388).

(b) Analgesics

The incidence of sedation with nefopam has been reported as 20 to 30% which, depending on the circumstances, may increase the risk of sedation if it is given with other **sedative drugs**.[3] A report describes a fatal overdose with nefopam, which was complicated by the CNS depressant effect of **dihydrocodeine**.[4]

In a study in *animals*, nefopam enhanced the analgesic potency of **morphine**,[5] and in a study in patients undergoing orthopaedic surgery intravenous nefopam had a **morphine**-sparing effect (up to 35% dose reduction).[6] However, a further study found that the effects were less than additive.[7] A study in 72 surgical patients found that the use of nefopam with **ketoprofen** had a synergistic analgesic effect.[8] See also *Other drugs*, below, for brief comment on the use of other analgesics with nefopam.

(c) Other drugs

A study was conducted in 45 healthy subjects divided into nine groups of five, each given oral nefopam 60 mg three times daily for 3 days with **aspirin** 650 mg, **codeine** 60 mg, **diazepam** 5 mg, **dextropropoxyphene (propoxyphene)** 65 mg, **hydroxyzine** 50 mg, **indometacin** 25 mg, **pentazocine** 50 mg, **phenobarbital** 60 mg, or placebo (all three times daily). The only changes were a possible additive increase in the intensity and incidence of adverse effects with nefopam and **codeine**, **pentazocine** or **dextropropoxyphene**. There was no evidence that the bioavailability of nefopam was changed by the other drugs.[9]

NSAIDs + Allopurinol

Allopurinol does not affect indometacin clearance or phenylbutazone levels.

Clinical evidence, mechanism, importance and management

In a study in 8 patients, allopurinol 300 mg each morning was given with **indometacin** 50 mg every 8 hours for 5 days. The allopurinol had no significant effect on the AUC of **indometacin** and the amounts of **indometacin** excreted in the urine were not significantly altered.[1]

Allopurinol 100 mg three times daily for a month had no effect on the elimination of **phenylbutazone** 200 mg daily in 6 healthy subjects, and no effect on the steady-state plasma levels of **phenylbutazone** 200 or 300 mg daily in 3 patients.[2] In another study in 8 patients with acute gouty arthritis it was found that allopurinol 100 mg every 8 hours produced a small but clinically unimportant effect on the half-life of **phenylbutazone** 6 mg/kg.[3]

There seems to be no pharmacokinetic reason for avoiding the concurrent use of these NSAIDs and allopurinol.

NSAIDs + Amoxicillin

A study in healthy subjects found that diclofenac increased the clearance of amoxicillin. An isolated report describes acute interstitial nephritis with nephrotic syndrome associated with the use of naproxen and amoxicillin.

Clinical evidence, mechanism, importance and management

(a) Diclofenac

In a study in 20 healthy subjects, diclofenac 100 mg caused a slight reduction in the AUC and a slight increase in the mean renal clearance of a single 2-g dose of amoxicillin.[1] It should be noted that there was considerable individual variation and overlapping between the two groups, and the clinical significance of this finding is unclear.

(b) Naproxen

A man without any previous renal problems developed acute interstitial nephritis with nephrotic syndrome after taking naproxen for 4 days (total 4 g) and amoxicillin for 10 days (total 24 g). He appeared to recover when the drugs were stopped, but 3 months later he developed renal failure and needed haemodialysis.[2] Acute interstitial nephritis is not only a rare syndrome (reported to be only 55 cases in the world literature in 1988)[2] but this is the first case involving both of these drugs. No special precautions would normally seem to be necessary.

NSAIDs + Anabolic steroids

Serum oxyphenbutazone levels are raised by methandienone (methandrostenolone). Phenylbutazone appears to be unaffected.

Clinical evidence

The serum levels of **oxyphenbutazone** 300 to 400 mg daily for 2 to 5 weeks were raised by 43% (range 5 to 100%) in 6 subjects given **methandienone (methandrostenolone)**.[1] Two other studies confirm this interaction with **oxyphenbutazone**.[2,3] One of them found no interaction with **phenylbutazone**.[2]

Mechanism

Uncertain. One idea is that the anabolic steroids alter the distribution of oxyphenbutazone between the tissues and plasma so that more remains in circulation. There may also possibly be some changes in metabolism.

Importance and management

The interaction is established but its importance is uncertain. There seem to be no reports of toxicity arising from concurrent use but the possibility should be borne in mind.

NSAIDs; Azapropazone + Antacids or Laxatives

A study in 15 patients taking azapropazone 300 mg three times daily found that antacids (dihydroxyaluminium sodium carbonate, aluminium magnesium silicate), bisacodyl or anthraquinone laxatives only caused a minor (5 to 7%) reduction in azapropazone plasma levels.[1] No special precautions would seem to be needed if any of these drugs are given together with azapropazone.

1. Faust-Tinnefeldt G, Geissler HE, Mutschler E. Azapropazon-Plasmaspiegel unter Begleitmedikation mit einem Antacidum oder Laxans. *Arzneimittelforschung* (1977) 27, 2411–14.

NSAIDs; Coxibs + Antacids

Aluminium/magnesium-containing antacids had no clinically significant effect on the bioavailability of celecoxib,[1,2] or lumiracoxib.[3] Aluminium/magnesium hydroxides or calcium carbonate had no clinically significant effect on the pharmacokinetics of etoricoxib.[4]

Antacids do not appear to affect meloxicam pharmacokinetics, see 'NSAIDs; Oxicam derivatives + Antacids', p.157.

NSAIDs; Diclofenac + Antacids

The absorption of diclofenac is not affected by aluminium hydroxide and/or magnesium hydroxide.

Clinical evidence, mechanism, importance and management

In a study in 7 healthy subjects, about 10 mL of a 5.8% suspension of **aluminium hydroxide** had no effect on the bioavailability of a single 50-mg dose of diclofenac.[1] In another study, in 6 healthy, fasted subjects, 10 mL of **magnesium hydroxide** suspension (850 mg) was found to have no significant effect on the rate or extent of absorption of a single 50-mg dose of diclofenac.[2] However, there was a tendency to an increased rate of absorption. *Aluco Gel* (**aluminium**/**magnesium hydroxide**) had no effect on the extent of absorption of enteric-coated diclofenac, but it may have reduced the rate of absorption.[3] No particular precautions would seem to be needed if these antacids are given with diclofenac.

NSAIDs; Diflunisal + Antacids

Antacids containing aluminium with or without magnesium can reduce the absorption of diflunisal by up to 40%, but no important interaction occurs if food is taken at the same time. Magnesium hydroxide can increase the rate of diflunisal absorption.

Clinical evidence

A study in 4 healthy, fasted subjects found that when a single 500-mg oral dose of diflunisal was given 2 hours before, together with, and 2 hours after three 15-mL doses of *Aludrox* (**aluminium hydroxide**), the diflunisal AUC was reduced by about 40%.[1] Another study found that the AUC of a single 500-mg dose of diflunisal was reduced by 13% when it was given with a single 30-mL dose of *Maalox* (**aluminium**/**magnesium hydroxide**), by 21% when it was given 1 hour after the antacid, and by 32% when the antacid was given four times daily.[2] However, in another study, **aluminium**/**magnesium hydroxide** had no effect on the AUC diflunisal when the diflunisal was given 30 minutes after food.[3] This study also found that the AUC of diflunisal was reduced by 26% by 15 mL of **aluminium hydroxide** gel in fasted subjects, but was not affected in fed subjects.[3] **Magnesium hydroxide** suspension markedly increased the rate of diflunisal absorption in fasted subjects. The plasma diflunisal level was increased by 130% at 30 minutes, and by 64% at one hour but the AUC was only increased by a modest 10%.[3]

Mechanism

It is unclear how aluminium antacids reduce the absorption of diflunisal, but adsorption or the formation of insoluble salts has been suggested. Food appears to diminish the effect of antacids on diflunisal absorption.[3] By raising the pH, magnesium hydroxide may promote the dissolution of diflunisal, so increasing its absorption.[3]

Importance and management

Aluminium-containing antacids appear to reduce the absorption of diflunisal in the fasted state, but not if the diflunisal is taken with food. NSAIDs should be taken with or after food to minimise gastrointestinal adverse effects, and so it would appear that this interaction has little clinical relevance.

Magnesium hydroxide increases the absorption of diflunisal in the fasted state, which may improve the onset of analgesia. However, note that magnesium hydroxide increased the endoscopically-detected gastric toxicity of ibuprofen in one study, see 'NSAIDs; Ibuprofen and related drugs + Antacids', p.156.

NSAIDs; Fenamates + Antacids

Magnesium hydroxide increases the rate of absorption of mefenamic acid and tolfenamic acid in fasted subjects. The rate of tolfenamic acid absorption is reduced by aluminium hydroxide alone or combined with magnesium hydroxide/magnesium carbonate, but is not affected by sodium bicarbonate.

Clinical evidence

Studies in 6 healthy, fasted subjects given a single dose of **mefenamic acid** 500 mg or **tolfenamic acid** 400 mg found that **magnesium hydroxide** increased the rate of the absorption of both drugs (the **mefenamic acid** AUC after 1 hour was increased threefold and the **tolfenamic acid** AUC

was increased sevenfold) but the total bioavailability was only slightly increased. In contrast, **aluminium hydroxide**, alone and in combination with **magnesium hydroxide**/**magnesium carbonate** (*Medisan Forte*), markedly *reduced* the rate of absorption of **tolfenamic acid**, but similarly, the total amount absorbed was not markedly changed. In this study **sodium bicarbonate** 1 g did not significantly alter the absorption of **tolfenamic acid**.[1]

Mechanism

Uncertain. It is suggested that magnesium hydroxide increases the solubility of acidic drugs such as the fenamates, possibly by forming a soluble salt and therefore enhancing their dissolution. In contrast, aluminium antacids may form insoluble salts of the drug. Note that food may reduce these effects, see 'NSAIDs; Diflunisal + Antacids', p.155.

Importance and management

Information is limited but it would appear that if rapid analgesia is needed with either mefenamic acid or tolfenamic acid, magnesium hydroxide can be given concurrently but aluminium hydroxide should be avoided. However, note that this applies to the fasted state, whereas NSAIDs are usually taken with or after food. Also note that magnesium hydroxide increased the endoscopically-detected gastric toxicity of ibuprofen in one study, see 'NSAIDs; Ibuprofen and related drugs + Antacids', below. Sodium bicarbonate does not interact.

1. Neuvonen PJ, Kivistö KT. Effect of magnesium hydroxide on the absorption of tolfenamic and mefenamic acids. *Eur J Clin Pharmacol* (1988) 35, 495–501.

NSAIDs; Ibuprofen and related drugs + Antacids

Magnesium hydroxide increased the initial absorption of ibuprofen and flurbiprofen, but had no effect on ketoprofen absorption. Unexpectedly, a pharmacodynamic study found increased gastric erosions when ibuprofen was formulated with magnesium hydroxide.
The absorption of dexketoprofen, fenoprofen, flurbiprofen and ibuprofen were not significantly affected by aluminium/magnesium hydroxide. Aluminium phosphate had no effect on ketoprofen absorption. Aluminium hydroxide caused a small reduction in ketoprofen absorption but had no effect on the bioavailability of tiaprofenic acid.
The rate of naproxen absorption is increased by sodium bicarbonate and aluminium/magnesium hydroxide, but decreased by aluminium hydroxide and magnesium oxide.
Simeticone did not affect ketoprofen bioavailability.

Clinical evidence

(a) Dexketoprofen

In 24 healthy subjects an **aluminium**/**magnesium hydroxide** antacid (*Maalox*) had no effect on the rate or extent of absorption of a single 25-mg dose of dexketoprofen, although the maximum level was slightly (13%) lower.[1]

(b) Fenoprofen

In a study in 6 subjects plasma levels of a single 600-mg dose of fenoprofen were not affected by a single 30-mL dose of *Maalox* (**aluminium**/**magnesium hydroxide**).[2]

(c) Flurbiprofen

In a group of young and old fasting healthy subjects, *Maalox* (**aluminium**/**magnesium hydroxide**) 30 mL, taken 30 minutes before a single 100-mg dose of flurbiprofen, was found to affect neither the rate nor extent of flurbiprofen absorption. Similarly, *Maalox* had no effect on steady-state pharmacokinetics of flurbiprofen when both drugs were given 90 minutes before food.[3] Another study, in fasted subjects, found that **magnesium hydroxide** increased the AUC_{0-2} of flurbiprofen by 61%, but the AUC_{0-8} was not changed, which indicated an increased rate of flurbiprofen absorption.[4]

(d) Ibuprofen

In 8 healthy, fasted subjects an antacid containing **aluminium**/**magnesium hydroxide**, given before, with, and after a single 400-mg dose of ibuprofen, did not alter the pharmacokinetics of ibuprofen.[5] In another study, the absorption of ibuprofen formulated with **aluminium** was delayed and reduced, when compared to that of ibuprofen without **aluminium**.[6]

A study in 6 healthy fasted subjects found that **magnesium hydroxide** 850 mg increased the AUC_{0-1} and the peak levels of a single 400-mg dose of ibuprofen by 65% and 31%, respectively. The time to the peak was shortened by about 30 minutes but the total bioavailability was unchanged.[7] In a pharmacodynamic study in healthy subjects, a 400-mg ibuprofen tablet buffered with 200 mg of **magnesium hydroxide**, given at a dose of two tablets three times daily for 5 days resulted in about a threefold increase in number of endoscopically-detected gastric erosions, when compared with the same dose of conventional ibuprofen tablets.[8]

A **sodium**/**potassium salt** (kanwa), often taken as an antacid in some West African countries, appeared to reduce the absorption of ibuprofen. The bioavailability of ibuprofen 400 mg given to 6 healthy subjects with a millet meal containing the salt extract (pH of 8.9) was reduced by about 80%, when compared with either the millet meal alone (pH 5.3) or following overnight fasting.[9]

(e) Ketoprofen

Five healthy, fasted subjects had a 22% reduction in the absorption of a 50-mg dose of ketoprofen (as measured by the amount excreted in the urine) when they were given a 1-g dose of **aluminium hydroxide**.[10] In 10 patients, **aluminium phosphate** 11 g (as a single then a daily dose) had no effect on the pharmacokinetics of ketoprofen 100 mg.[11]

A study in 12 healthy, fasted subjects showed that [activated] dimeticone (**simeticone**) did not significantly affect the bioavailability of a single 100-mg dose of ketoprofen.[12]

In one study, 10 mL of **magnesium hydroxide** suspension (equivalent to 850 mg) was found to have no significant effect on the rate or extent of absorption of ketoprofen 50 mg in fasted subjects, although the rate of ketoprofen absorption was already noted to be fast.[7]

(f) Naproxen

In a study in 14 healthy, fasted subjects, **sodium bicarbonate** 700 mg or 1.4 g increased the rate of absorption of a single 300-mg dose of naproxen, whereas **magnesium oxide** or **aluminium hydroxide** 700 mg reduced the rate of absorption. **Magnesium carbonate** had little effect.[13] On the other hand when 15 or 60 mL of **aluminium**/**magnesium hydroxide** (*Maalox*) was given, the rate and extent of absorption of naproxen were slightly increased.[13]

(g) Tiaprofenic acid

In a study in 7 healthy subjects, **aluminium hydroxide** did not affect the pharmacokinetics of **tiaprofenic acid**.[14]

Mechanism

Magnesium hydroxide appears to improve the rate of absorption of some acidic NSAIDs (which become more soluble as the pH rises) such as ibuprofen and flurbiprofen. An *in vitro* study found that magnesium hydroxide increased ibuprofen solubility, and increased the dissolution rate of 3 ibuprofen tablet formulations, with the greatest increase occurring with the slowest dissolving product.[15] Why this increased the gastric toxicity of ibuprofen in the one pharmacodynamic study is unclear.[8] Sodium bicarbonate appears to have a similar effect on rate of absorption. An *in vitro* study found that an insoluble ibuprofen salt was formed in the presence of aluminium ions[15] and this may explain why the rate/extent of absorption of some NSAIDs is reduced.

Importance and management

It would appear that the initial absorption of both ibuprofen and flurbiprofen is increased by magnesium hydroxide, but not if aluminium hydroxide is present as well. Thus if rapid analgesia is needed, consider using an antacid containing magnesium hydroxide but without aluminium hydroxide. However, the unexpected finding that magnesium hydroxide increased the endoscopically-detected gastric toxicity of ibuprofen[8] suggests that caution may be warranted, particularly on long-term use. Further study is needed.

The rate of naproxen absorption appears to be increased by sodium bicarbonate and decreased by aluminium hydroxide. However, note that these effects were seen in the fasted state, and may not apply when the NSAID is taken with or after food (as is recommended), as is the case with 'diflunisal', (p.155).

No particular precautions would seem to be needed if simeticone, alu-

minium phosphate or magnesium hydroxide are given with ketoprofen, and it seems doubtful if the effects of ketoprofen will be reduced to any great extent by aluminium hydroxide.

NSAIDs; Indometacin or Sulindac + Antacids

A variety of different antacids have been found to slightly alter the absorption of indometacin. Aluminium/magnesium hydroxide does not affect sulindac absorption.

Clinical evidence

In 12 healthy, fasted subjects the AUC of a single 50-mg dose of indometacin was reduced by 35% when formulated with 80% *Mergel* and by 18% when taken with 90% *Mergel*. *Mergel* contains **aluminium**/**magnesium hydroxide** and **magnesium carbonate**.[1]

In another single-dose study, in 6 healthy, fasted subjects, **aluminium hydroxide** suspension 700 mg reduced the rate of indometacin absorption, and reduced the peak indometacin plasma levels. Conversely, **sodium bicarbonate** 1.4 g appeared to increase the rate of absorption, but this did not reach significance because of wide inter-individual variation.[2] In a further study 30 mL of **aluminium**/**magnesium hydroxide** caused only slight changes in the absorption of a 50-mg dose of indometacin in fasted subjects.[3]

The manufacturer of sulindac notes that an antacid (**aluminium**/**magnesium hydroxide** suspension) had no effect on the extent of the absorption of sulindac.[4]

Mechanism

Not known. Aluminium compounds might form insoluble salts with indometacin.[2] Food might reduce this effect, see 'NSAIDs; Diflunisal + Antacids', p.155.

Importance and management

Adequately but not extensively documented interactions. Some reduction in indometacin levels is possible with some aluminium-containing antacids, but given the magnitude of this effect this interaction is unlikely to be clinically relevant. Sulindac absorption is not affected.

NSAIDs; Miscellaneous + Antacids

The rate and extent of absorption of ketorolac, dipyrone and tolmetin were not significantly affected by aluminium/magnesium hydroxide. Nabumetone absorption was not affected by aluminium hydroxide, and an unspecified antacid did not affect etodolac absorption.

Clinical evidence

(a) Dipyrone (Metamizole sodium)

The concurrent use of 20 mL of *Maaloxan* (**aluminium**/**magnesium hydroxide** gel) was reported to have had no effect on the pharmacokinetics of the metabolites of dipyrone.[1]

(b) Etodolac

A study in 18 healthy, fasted subjects found that when they were given a single 400-mg dose of etodolac with 30 mL of an unnamed antacid both the rate and the extent of etodolac absorption were unchanged.[2]

(c) Ketorolac

In 12 healthy, fasted subjects the AUC of oral ketorolac 10 mg was found to be reduced by 11% (not statistically significant) when it was taken with an unstated amount of **aluminium**/**magnesium hydroxide** suspension (*Maalox*). The rate of absorption was not affected.[3]

(d) Nabumetone

In 15 healthy, fasted subjects, the absorption of a single 1-g dose of nabumetone (as assessed by AUC and maximum plasma level) was not significantly altered by 160 mL of **aluminium hydroxide** suspension (*Aludrox*).[4]

(e) Tolmetin

A pharmacokinetic study in 24 healthy, fasted subjects found that **aluminium**/**magnesium hydroxide** suspension (*Maalox*), given as a single 20-mL dose four times daily for 3 days, had no significant effect on the absorption of a single 400-mg dose of **tolmetin**.[5]

Mechanism

None.

Importance and management

Although information is limited, no particular precautions would seem to be needed if aluminium or aluminium/magnesium antacids are given with any of these antacids. Note that antacids have been frequently given with NSAIDs to reduce their gastric irritant effects.

5. Ayres JW, Weidler DJ, MacKichan J, Sakmar E, Hallmark MR, Lemanowicz EF, Wagner JG. Pharmacokinetics of tolmetin with and without concomitant administration of antacid in man. *Eur J Clin Pharmacol* (1977) 12, 421–8.

NSAIDs; Oxicam derivatives + Antacids

The pharmacokinetics of lornoxicam, meloxicam, piroxicam and tenoxicam are not affected by aluminium/magnesium hydroxide antacids. Lornoxicam pharmacokinetics were also not altered by tripotassium dicitratobismuthate or aluminium hydroxide with calcium carbonate.

Clinical evidence, mechanism, importance and management

(a) Lornoxicam

In a study in 18 healthy, fasted subjects, either 10 mL of *Maalox* (**aluminium/magnesium hydroxide**) or 10 g of *Solugastril* (**aluminium hydroxide** with **calcium carbonate**) had no effect on the pharmacokinetics of a 4-mg lornoxicam film-coated tablet.[1] A later study similarly found no changes in the absorption or pharmacokinetics of a lornoxicam film-coated tablet given with **tripotassium dicitratobismuthate** 120 mg twice daily.[2] There would seem to be no reason for avoiding concurrent use.

(b) Meloxicam

In a randomised, crossover study 9 healthy, fasted subjects were given meloxicam 30 mg alone or with *Maalox* suspension (**aluminium/magnesium hydroxide** 900/600 mg) four times daily for 4 days. *Maalox* had no significant effect on the pharmacokinetics of meloxicam.[3] Therefore no adjustments of the dose of meloxicam are needed if given with this type of antacid.

(c) Piroxicam

A multiple-dose study in 20 healthy subjects found that *Mylanta* (**aluminium/magnesium hydroxide**) and *Amphojel* (**aluminium hydroxide**) did not significantly affect the bioavailability of piroxicam 20 mg daily taken after food.[4] Concurrent use need not be avoided.

(d) Tenoxicam

The bioavailability of tenoxicam 20 mg was found to be unaffected in 12 healthy subjects by **aluminium hydroxide** (*Amphojel*) or **aluminium/magnesium hydroxide** (*Mylanta*) whether taken before, with, or after the tenoxicam, and in the fasted state or with food.[5] No special precautions seem necessary.

NSAIDs + Aspirin

There is some evidence that non-selective NSAIDs such as ibuprofen antagonise the antiplatelet effects of low-dose aspirin, but that COX-2-selective NSAIDs (coxibs) do not. Some, but not other, epidemiological studies have shown that non-selective NSAIDs reduce the cardioprotective effects of low-dose aspirin. Furthermore, some NSAIDs (particularly coxibs) are associated with increased thrombotic risk and possibly increased risk of death if used in patients with a history of myocardial infarction. The combined use of NSAIDs and low-dose aspirin increases the risk of gastrointestinal bleeds. This seems to apply equally to coxibs.
The combined use of analgesic-dose aspirin and NSAIDs increases the risk of gastrointestinal damage. There are numerous early pharmacokinetic studies of aspirin and NSAIDs, many of which found that aspirin reduced the levels of NSAIDs.

Clinical evidence

A. Cardioprotective effects

A number of pharmacodynamic studies have investigated whether or not NSAIDs affect the antiplatelet effects of low-dose aspirin. **Celecoxib** 200 mg twice daily,[1-3] **diclofenac** 75 mg twice daily,[4] **etoricoxib** 120 mg daily,[5] **lumiracoxib** 400 mg daily,[6] **meloxicam** 15 mg daily,[7] **parecoxib** 40 mg twice daily,[8] **rofecoxib** 25 mg daily,[4] and **sulindac** 200 mg twice daily[3] have all been shown not to alter the antiplatelet effects of aspirin in doses of 75 to 325 mg daily. **Naproxen**,[3,9] **indometacin**,[3] and **tiaprofenic acid**[3] may antagonise the antiplatelet effects of aspirin. The effects of **ibuprofen** are less clear, and may be related to the order of drug administration.[4]

As a consequence of the evidence from a number of pharmacodynamic studies, various cohort/case-control studies or sub-group analyses have been conducted to see if **ibuprofen** and/or other NSAIDs reduce the cardioprotective effect of low-dose aspirin in patients, see 'Table 6.2', (p.159). Because these studies are neither prospective nor randomised, their findings are only suggestive, nevertheless they provide some useful insight. In addition to these studies, there are a number of controlled studies that specifically investigated the effects of using aspirin and ibuprofen.

(a) Ibuprofen

A placebo-controlled, randomised study in patients taking aspirin 100 mg daily long-term for its cardioprotective effects found that ibuprofen 600 mg three times daily for 7 days reduced the antiplatelet effects of aspirin.[2] Further, another placebo-controlled study in healthy subjects found that ibuprofen 400 mg every 12 hours for 3 doses antagonised the antiplatelet effects of a 300-mg dose of soluble aspirin.[3] In a prospective, randomised study, 47 healthy subjects were given aspirin 81 mg daily for 8 days, and then either ibuprofen 400 mg or placebo three times daily (1, 7 and 13 hours after the aspirin dose) for 10 days. No clinically meaningful loss of the cardioprotective effects of low-dose aspirin (as measured by thromboxane B_2 inhibition) occurred with this ibuprofen regimen. However, the authors noted that the continued use of ibuprofen for longer than 10 days might possibly have resulted in a clinically relevant interaction.[10]

B. Gastrointestinal effects

(a) Low-dose aspirin

Low-dose aspirin alone (300 mg or less daily) was associated with an increased risk of hospitalisation for bleeding peptic ulcer in a case-control study. The odds ratios were 2.3 for aspirin 75 mg daily, 3.2 for aspirin 150 mg daily, and 3.9 for aspirin 300 mg daily. Use of NSAIDs combined with low-dose aspirin was associated with a greater risk of bleeding (odds ratio 7.7) than use of either NSAIDs alone (5.4) or low-dose aspirin alone (3.3).[11] Similar findings were reported in a cohort study (rate ratio for gastrointestinal bleed for low-dose aspirin 2.6, and for combined use with NSAIDs 5.6).[12]

A case-control study found that coxib use alone was associated with a lower risk of upper gastrointestinal bleeding than that found with non-selective NSAIDs. However, when coxibs were given with low-dose aspirin, the gastrointestinal advantage tended to disappear.[13] Patients taking low-dose aspirin (325 mg or less daily) with **celecoxib** had a higher frequency of gastrointestinal complications than those taking **celecoxib** alone. Moreover, there was no difference in the frequency of gastrointestinal complications between those taking low-dose aspirin with **celecoxib** and those taking low-dose aspirin with **ibuprofen** or **diclofenac**. This was despite **celecoxib** alone being associated with a lower frequency of gastrointestinal adverse effects than **ibuprofen** or **diclofenac** alone.[14] Similar results were found with **rofecoxib** 25 mg daily, which increased the incidence of ulcers in patients taking enteric-coated aspirin 81 mg daily.[15]

(b) Analgesic-dose aspirin

In a case-control study of data from 1993 to 1998 in the UK General Practice Research Database the risk of upper gastrointestinal bleeding or perforation was increased by slightly more than an additive effect in patients taking both aspirin and NSAIDs (8.2-fold), when compared with aspirin alone (2.4-fold), or NSAIDs alone (3.6-fold). The specific NSAIDs were not mentioned.[16] Another study provided similar findings,[17] as have studies specifically looking at low-dose aspirin (325 mg or less daily), see above. Analysis of Yellow Card reports to the CSM in the UK of gastrointestinal perforation/obstruction, ulceration or bleeding with **diclofenac**, **naproxen**, and **ibuprofen** revealed that 28% of the patients were receiving concurrent aspirin (dose not stated).[18]

The one pharmacodynamic study (see below), that also measured gastrointestinal blood loss, found increased bleeding when anti-inflammatory doses of aspirin were given with **sodium meclofenamate**.[6]

A case report described acute ulcerative colitis in a woman taking **rofecoxib** 25 mg daily who also took aspirin.[19]

C. Pharmacokinetic and Pharmacodynamic studies

Early studies evaluating non-aspirin NSAIDs in rheumatoid arthritis commonly permitted the concurrent use of aspirin, which was then in wide use for this condition. The unexpected finding that **indometacin** was no more effective than placebo in patients taking aspirin in one study led to a number of pharmacokinetic studies with this combination (see *Indometacin*, below), and subsequently other NSAID/aspirin combinations. These studies generally have little clinical relevance to current clinical practice where anti-inflammatory doses of aspirin should not be used in combination with NSAIDs because of the increased risk of gastrointestinal bleed-

Table 6.2 Summary of studies on the effect of NSAIDs on the cardioprotective effect of antiplatelet-dose aspirin

Study type	*Criteria*	*Outcome*	*Drugs (Number of patients)*	*Comments*	*Refs*
Studies showing a decrease in the cardioprotection of aspirin with NSAIDs					
Retrospective cohort	Discharge after CVD	Mortality	Aspirin alone (6285) Aspirin with Ibuprofen (187) Aspirin with Diclofenac (206) Aspirin with other NSAID (429)	Increased all-cause mortality and cardiovascular mortality in those taking aspirin with ibuprofen compared with the other groups.	1
Subgroup analysis of an RCT	Male physicians randomised to aspirin 325 mg on alternate days or placebo	First MI	Aspirin alone (5273) Aspirin with intermittent NSAID (5147) Aspirin with regular NSAID (598)	Use of NSAIDs for 60 days or more per year was associated with an increased risk of MI in those taking aspirin.	2
Case-control		First non-fatal MI	Aspirin alone (694) Aspirin with NSAIDs (170) NSAIDs alone (128)	Both aspirin alone, and NSAIDs alone were associated with a reduced risk of MI, but combined use was not.	3
Studies showing no effect of NSAIDs on the cardioprotection of aspirin					
Retrospective cohort	Discharge after MI	Death in first year	Aspirin alone (36211) NSAID alone (736) Aspirin with NSAID (2096) Neither (9541)	Risk of death reduced to a similar extent by aspirin, NSAIDs, and the combination.	4
Retrospective cohort	Discharge after MI and on aspirin	Death in first year	Aspirin alone (66739) Aspirin with Ibuprofen (844) Aspirin with other NSAID (2733)	Risk of death comparable between the 3 groups.	5
Retrospective cohort	General Practice Research Database	Acute MI or death from coronary heart disease	NSAID alone (417) NSAID with Aspirin (163) Aspirin alone (1119) Non-NSAID users (1878)	Incidence of acute MI unaffected by NSAID alone. NSAID with aspirin similar to aspirin alone.	6
Studies showing an increase in the cardioprotection of aspirin with NSAIDs					
Retrospective cohort	Two consecutive prescriptions for aspirin or ibuprofen	Biochemical evidence of MI	Aspirin alone (10239) Aspirin with Ibuprofen (3859)	The aspirin alone group experienced 0.0044 MIs per patient month, compared with 0.0026 in the aspirin with ibuprofen group.	7

ing (see above) and lack of proven additional benefit. However, the pharmacokinetic studies are briefly summarised below.

(a) Diclofenac

Aspirin 900 mg reduced the AUC of diclofenac 50 mg by about one-third in a single-dose study.[20] In a clinical study, there was no significant difference in efficacy between diclofenac 50 mg three times daily alone or with aspirin 900 mg three times daily.[21]

(b) Fenamates

A study in 20 healthy subjects given aspirin 600 mg and **sodium meclofenamate** 100 mg both three times daily for 14 days found no significant reductions in plasma salicylate levels, but plasma **meclofenamate** levels were reduced to some extent. However, gastrointestinal blood loss was approximately doubled compared with either drug alone.[22]

(c) Ibuprofen and related drugs

Aspirin 1.3 to 3.6 g daily more than halved the serum levels of ibuprofen 800 mg to 2.4 g daily,[23,24] without affecting salicylate levels.[24] There was little additional clinical benefit from the combination.[24] Similarly, aspirin reduced the AUC of **flurbiprofen** by about two-thirds,[25] but without any clear changes in clinical effectiveness.[26] The pharmacokinetics of the aspirin were unchanged by **flurbiprofen**.[25] Aspirin 3.9 g daily also virtually halved the AUC of **fenoprofen** 2.4 g daily,[27] and reduced the AUC of **ketoprofen** 200 mg daily[28] by about one-third. The AUC of **naproxen** was only minimally reduced (by 10 to 15%).[29,30] **Choline magnesium trisalicylate** increased the clearance of **naproxen** by 56% and decreased its serum levels by 26% in one study.[31]

(d) Indometacin

The overall picture with aspirin and indometacin is confusing and contradictory. One early study found that indometacin had no additional benefit in patients already taking aspirin.[32] Consequently, a number of studies were conducted to see if there was a drug interaction. Some studies reported that aspirin reduced serum indometacin levels[27,33-35] or its efficacy,[36] or that the combination was no more effective than either drug alone.[37] Others report that no change in indometacin levels occurred.[38-40] Further studies using buffered aspirin claimed that it increased the rate of absorption of indometacin and was associated with an increase in adverse effects (tiredness, lack of coordination).[41,42] One study found that indometacin 50 mg given as suppositories at night was found to have a significant additive effect when given with slow-release aspirin 2 or 4.5 g daily, estimated by articular index and subjective ratings of pain and morning stiffness. However, the dose of aspirin (most often the 4.5 g dose) had to be reduced in 7 of the 24 treatment periods due to adverse effects.[43]

(e) Oxicams

Aspirin 3 g daily increased the maximum plasma levels of **meloxicam** 30 mg daily by 25% and its AUC by 10%.[44] Plasma levels of **piroxicam** 40 mg then 20 mg daily were not significantly affected by aspirin 3.9 g daily, and salicylate levels were unaffected by **piroxicam**.[45] Aspirin 2.6 to 3.9 g daily more than halved the serum levels of **tenoxicam** 20 mg daily.[46]

(f) Miscellaneous NSAIDs

Aspirin 600 mg four times daily caused a 15% reduction in the plasma levels of **diflunisal** 250 mg twice daily for 3 days.[47] Single-dose studies have shown that the absorption of **nabumetone** 1 g is not significantly altered by aspirin 1.5 g.[48] The plasma levels of **tolmetin** 1.2 g daily were slightly reduced by aspirin 3.9 g daily.[49]

Mechanism

Aspirin irreversibly blocks the production of thromboxane A2 by binding to cyclo-oxygenase (COX-1) in platelets, and so inhibits platelet aggregation. The beneficial cardiovascular effects are attributed to this effect. Other NSAIDs that are COX-1 inhibitors also have this effect, but it is more short-lived since they bind reversibly. These NSAIDs can therefore competitively inhibit the binding of aspirin to platelets (a fact that was shown *in vitro* as early as the 1980s[50]). When these NSAIDs are present in sufficient quantities when a daily low-dose of aspirin is given, they therefore reduce its antiplatelet effect. *In vitro* study confirms that COX-2 selective NSAIDs have less effect.[51]

The damaging effects of aspirin and NSAIDs on the gut appear to be additive. This occurs even at the low doses of aspirin used for antiplatelet effects (doses as low as 75 mg daily).[11] The mechanisms behind the pharmacokinetic changes have not been resolved. Changes in the rates of absorption and renal clearance and competition for plasma protein binding have been proposed.

Importance and management

A. Cardioprotective effects

The evidence currently available on the antagonism of the antiplatelet effects of aspirin by ibuprofen is conflicting. However, the FDA in the US warn that ibuprofen may interfere with the antiplatelet effects of low-dose aspirin and reduce its cardioprotective benefits. Until definitive clinical information is available, they recommend that patients taking immediate-release, low-dose aspirin (81 mg daily) should take the aspirin 30 minutes before or 8 hours after taking ibuprofen to prevent any possible interaction. The recommendation applies to patients taking ibuprofen chronically but does not apply to those taking enteric-coated aspirin formulations.[52] Others have concluded that ibuprofen is more likely to interact with aspirin than not, and that the interaction is more likely to occur in those who take ibuprofen long-term and more importantly in those at high cardiovascular risk.[53] It has also been suggested that non-selective NSAIDs should be avoided in patients taking low-dose aspirin, or that it may be advisable to replace aspirin with an alternative antiplatelet drug.[54] Some have concluded that when patients taking low-dose aspirin for cardioprotection require long-term NSAIDs for inflammatory conditions, the use of diclofenac would seem preferable to ibuprofen.[55] A coxib was also suggested as an alternative,[55] but the subsequent findings of an increased risk of serious cardiovascular effects with the coxibs (as a class[56]) probably precludes this. In 2006 the CHM in the UK advised that there may be a small increased risk of thrombotic events with the non-selective NSAIDs, particularly when used at high doses and for long-term treatment.[57] In addition, the European Society of Cardiology guidelines recommend that patients resistant to antiplatelet treatment should not be given either coxibs or non-selective NSAIDs with either aspirin or clopidogrel.[58]

Further, a retrospective analysis of 58 432 patients discharged from hospital after a first myocardial infarction found that the subsequent use of coxibs in all doses and non-selective NSAIDs in high doses resulted in increased mortality.[59] On the basis of this and other studies, the European Society of Cardiology guidelines recommend that coxibs and NSAIDs should not be used in the post myocardial infarction period.[58]

B. Gastrointestinal effects

The additive risk of gastrointestinal damage from combining aspirin and NSAIDs is established. Because of this, and because of the lack of clear benefit from the combination, the use of anti-inflammatory/analgesic doses of aspirin with NSAIDs should be avoided. With antiplatelet-dose aspirin, from a gastrointestinal perspective, the lowest dose of aspirin should be used (75 mg).[11] However, when combined with low-dose aspirin, the available evidence indicates that there is no gastrointestinal benefit to be obtained from using a coxib instead of diclofenac or ibuprofen.[14] Note that the CSM in the UK advised that the combination of a non-aspirin NSAID and low-dose aspirin should be used only if absolutely necessary.[18,60] They stated that patients taking long-term aspirin should be reminded to avoid NSAIDs, including those bought without prescription.[60] If concurrent use is necessary, where appropriate, the use of a proton pump inhibitor may be considered for prophylaxis of NSAID-induced gastrointestinal damage. Note also that the European Society of Cardiology advises against the use of anti-inflammatory drugs post-myocardial infarction (see A above).

NSAIDs + Azoles

Fluconazole markedly raises celecoxib levels, whereas ketoconazole has no effect on celecoxib levels. Fluconazole and ketoconazole moderately increase the levels of valdecoxib (the main metabolite of parecoxib). Ketoconazole moderately raises etoricoxib plasma levels. Fluconazole has no clinically relevant effect on lumiracoxib pharmacokinetics. Voriconazole markedly raises diclofenac and ibuprofen levels and fluconazole raises flurbiprofen and ibuprofen levels.

Clinical evidence

(a) Coxibs

1. Celecoxib. The manufacturer notes that **fluconazole** 200 mg daily increased the AUC of a single 200-mg dose of celecoxib by 130% and increased the maximum level by 60%. Conversely, **ketoconazole** had no effect on the pharmacokinetics of celecoxib.[1]

2. Etoricoxib. A single 60-mg dose of etoricoxib was given to healthy subjects on day 7 of an 11-day course of **ketoconazole** 400 mg daily. The AUC of etoricoxib was increased by 43% and its maximum plasma level was increased by 29%.[2]

3. Lumiracoxib. A placebo-controlled, crossover study in 13 healthy subjects[3] found that **fluconazole** 400 mg on day 1 and 200 mg on days 2 to 4 had no clinically relevant effect on the pharmacokinetics of a single 400-mg dose of lumiracoxib given on day 4.

4. Parecoxib. The manufacturer of parecoxib reports a study in which **fluconazole** increased the plasma levels of valdecoxib (the main metabolite of parecoxib) by 19% and raised its AUC by 62%.[4] **Ketoconazole** had a similar, but more moderate effect on the levels of valdecoxib (maximum plasma levels increased by 24%, AUC increased by 38%).[4]

(b) Diclofenac

In a randomised, crossover study, 10 healthy subjects were given either diclofenac 50 mg alone or one hour after the last dose of **voriconazole** (400 mg twice daily on the first day, 200 mg twice daily on the second day). The AUC of diclofenac was increased by 78% in the presence of **voriconazole**, its peak plasma level was approximately doubled and its renal clearance was decreased by 47%.[5]

(c) Ibuprofen and related drugs

1. Flurbiprofen. In a study, 14 healthy subjects were given a single 100-mg dose of flurbiprofen either alone or 30 minutes after two doses of **fluconazole** 200 mg. **Fluconazole** increased the peak plasma level and AUC of flurbiprofen by 23% and 81%, respectively, reduced its clearance by about 45% and prolonged its half-life from 3.3 hours to 5.3 hours. The AUC of the metabolite 4-hydroxyflurbiprofen was significantly reduced.[6]

2. Ibuprofen. In a study, 12 healthy subjects were given ibuprofen 400 mg, alone or one hour after the last dose of **voriconazole** (400 mg twice daily on the first day, 200 mg twice daily on the second day) or **fluconazole** (400 mg on the first day and 200 mg on the second day). **Voriconazole** increased the peak plasma level of *S*-ibuprofen by 22%, doubled its AUC, and increased its elimination half-life by 43%. **Fluconazole** increased the peak plasma level and AUC of *S*-ibuprofen by 16% and 83%, respectively, and increased its elimination half-life by 34%. **Voriconazole** and **fluconazole** had only weak effects on the pharmacokinetics of *R*-ibuprofen.[7]

Mechanism

Fluconazole is an inhibitor of the cytochrome P450 isoenzyme CYP2C9 and ketoconazole inhibits CYP3A4. Celecoxib is extensively metabolised by CYP2C9, and therefore shows marked rises in plasma levels when given with fluconazole but not ketoconazole. Etoricoxib is partially metabolised by CYP3A4, and therefore shows moderate rises in plasma levels with ketoconazole. Valdecoxib is metabolised by both CYP2C9 and CYP3A4, and therefore it is modestly affected by both fluconazole and ketoconazole. Parecoxib is a valdecoxib prodrug, and interacts similarly. From the study with lumiracoxib it appears that its pharmacokinetics are unlikely to be affected by inhibitors of CYP2C9, because, even though lumiracoxib is largely metabolised by CYP2C9, other pathways are also important (e.g. glucuronidation).[3] Voriconazole probably increased the levels of diclofenac by inhibiting its metabolism by CYP2C9 and possibly by CYP3A4,[5] and the metabolism of flurbiprofen and the *S*-enantiomer of ibuprofen by CYP2C9 is inhibited by fluconazole and voriconazole.[6,7]

Importance and management

The pharmacokinetic interactions between the coxibs and azoles are established, although their effect in clinical practice has not been assessed. The marked rise in celecoxib levels with fluconazole could be important, and the UK manufacturer recommends that the dose of celecoxib should be halved in patients receiving fluconazole,[1] whereas the US manufacturer suggests starting with the lowest recommended dose.[8] The rise in valdecoxib levels with fluconazole is less marked; nevertheless, the manufacturer recommends that for parecoxib the dose should be reduced (but they do not suggest by how much).[4] No dose adjustments are thought to be necessary if etoricoxib or parecoxib are given with ketoconazole, and if lumiracoxib is given with fluconazole.

The clinical importance of the interaction between voriconazole and diclofenac is not known, but lower doses of diclofenac may be adequate for patients also taking voriconazole.[5] Similarly, lower doses of ibuprofen,[7] or

possibly flurbiprofen, may be adequate if they are given with either fluconazole or voriconazole, especially if the initial NSAID dose is high.[7]

NSAIDs + Bile-acid binding resins

The simultaneous use of colestyramine markedly reduced the absorption of diclofenac and sulindac, modestly reduced the absorption of ibuprofen, but only delayed and did not reduce the extent of naproxen absorption. Giving colestyramine three or more hours after oral sulindac, piroxicam, or tenoxicam still markedly reduced their plasma levels. Markedly reduced NSAID levels have also been found when colestyramine is given after intravenous meloxicam or tenoxicam.
The simultaneous use of colestipol modestly reduced the oral absorption of diclofenac, but had no effect on ibuprofen absorption.

Clinical evidence

(a) Diclofenac

A single-dose, crossover study in 6 healthy, fasting subjects found that the simultaneous use of **colestyramine** 8 g markedly reduced the AUC of a single 100-mg oral dose of enteric-coated diclofenac by 62% and reduced its maximum plasma levels by 75%. **Colestipol** 10 g reduced the AUC of diclofenac by 33% and reduced its maximum plasma levels by 58%.[1]

(b) Ibuprofen

A single-dose, crossover study in 6 healthy fasting subjects found that the simultaneous use of **colestyramine** 8 g modestly reduced the AUC of a single 400-mg oral dose of ibuprofen by 26% and reduced its maximum plasma levels by 34%. The rate of absorption was also reduced. Conversely, **colestipol** 10 g had no significant effect on the pharmacokinetics of ibuprofen.[2]

(c) Meloxicam

A study in 12 healthy subjects found that **colestyramine** 4 g taken 2 hours before a 30-mg *intravenous* dose of meloxicam increased its clearance by 49% and reduced its mean residence time in the body by 39%.[3]

(d) Naproxen

In a study in 8 healthy fasting subjects the absorption of a single 250-mg dose of naproxen was delayed but not reduced by the simultaneous use of **colestyramine** 4 g in 100 mL of orange juice. The amount of naproxen absorbed after 2 hours was reduced from 96% to 51%, but was complete after 5 hours.[4]

(e) Piroxicam or Tenoxicam

A study in 8 healthy subjects found that **colestyramine** increased the clearance of a single 20-mg oral dose of piroxicam and a single 20-mg *intravenous* dose of tenoxicam by 52% and 105%, respectively, and reduced their half-lives by 40% and 52%, respectively. In this study, **colestyramine** 4 g three times daily was started 2 hours before the intravenous tenoxicam and 3.5 hours after the oral piroxicam.[5] In another multiple-dose study **colestyramine**, given 4 hours after oral piroxicam or oral tenoxicam, gave similar results,[6] as did a study starting **colestyramine** 24 hours after the last dose of a 14-day course of **piroxicam** 20 mg daily [which has a long half-life].[7] The elimination half-life of both analgesics was roughly doubled by **colestyramine** 24 g daily.[6]

(f) Sulindac

In 6 healthy subjects **colestyramine** 4 g twice daily with meals was found to reduce the AUC of a single 400-mg dose of sulindac (given simultaneously) by 78%, and reduced the AUC of the sulfide metabolite of sulindac by 84%. Even when sulindac was given 3 hours before **colestyramine**, the AUCs of the sulindac and its sulphide metabolite were reduced by 44% and 55%, respectively.[8]

Mechanism

The studies of simultaneous oral use suggest that the anion-exchange resin colestyramine, and to a lesser extent colestipol, bind anionic NSAIDs (e.g. diclofenac) in the gut, so reducing their absorption. The studies that found reduced plasma levels when colestyramine was given after intravenous oxicams or separated by at least 3 hours from some oral NSAIDs, suggest that colestyramine can reduce the enterohepatic recirculation of these drugs.

Importance and management

Established interactions. Colestyramine markedly reduces the initial absorption of some NSAIDs (seen with diclofenac), and if these NSAIDs also undergo enterohepatic recirculation, their clearance will also be increased (seen with meloxicam, piroxicam, sulindac, and tenoxicam). This latter interaction cannot be avoided by separating the doses, and it may be best not to use colestyramine with these NSAIDs. Colestyramine can be used to speed the removal of piroxicam and tenoxicam following overdosage.[4] Diclofenac has been formulated with colestyramine in an attempt to reduce gastric mucosal damage by reducing direct mucosal contact: 140 mg of diclofenac-colestyramine is considered equivalent to 70 mg of diclofenac.[9]

Any interaction between colestyramine and naproxen or ibuprofen is probably not clinically important, although colestyramine delayed the absorption of both drugs, which may be relevant if they are being taken for the management of acute pain. Information on many other NSAIDs appears to be lacking. *Animal* studies suggest that **mefenamic acid**, **flufenamic acid** and **phenylbutazone** will also be affected by colestyramine.[10,11] Note that it is usually recommended that other drugs are given 1 hour before or 4 to 6 hours after colestyramine.

The reduction in diclofenac absorption with colestipol may be clinically relevant; if the combination is required, monitor well. Note that it is usually recommended that other drugs are given 1 hour before or 4 hours after colestipol.

NSAIDs or Aspirin + Caffeine

Caffeine modestly increases the bioavailability, rate of absorption and plasma levels of aspirin. Adding caffeine to diclofenac may improve its efficacy in the treatment of migraine.

Clinical evidence, mechanism, importance and management

In a study in healthy subjects, caffeine citrate 120 mg given with a single 650-mg dose of aspirin increased the AUC of aspirin 36%, increased its maximum plasma levels by 15%, and increased its rate of absorption by 30%.[1] This confirms the results of previous studies.[2,3] These studies suggest that caffeine may modestly potentiate the efficacy of aspirin by a pharmacokinetic mechanism. However, a meta-analysis of randomised, controlled studies concluded that there was no therapeutic advantage to adding caffeine to analgesic doses of aspirin in patients experiencing postoperative pain.[4]

In a placebo-controlled study in patients with migraine, there was a non-significant trend towards improved analgesic effect in patients receiving **diclofenac** softgel capsules 100 mg and caffeine 100 mg, when compared with diclofenac alone, although the sample size was too small to provide meaningful results.[5]

NSAIDs + Febuxostat

Febuxostat does not affect the pharmacokinetics of indometacin and naproxen. Naproxen, but not indometacin, increases the plasma levels of febuxostat.

Clinical evidence, mechanism, importance and management

A crossover study in 26 healthy subjects found that the concurrent use of febuxostat 80 mg daily and **indometacin** 50 mg twice daily did not affect the pharmacokinetics of either drug.[1] In a further study, 25 healthy subjects were given febuxostat 80 mg daily, **naproxen** 500 mg twice daily, or both drugs together. **Naproxen** increased the peak plasma level and AUC of febuxostat by about 28% and 40%, respectively, but this was not expected to be clinically significant. Febuxostat did not affect the pharmacokinetics of **naproxen** (24 subjects evaluated). It was concluded that febuxostat may be given with either **indometacin** or **naproxen** without dose adjustments.[1]

NSAIDs + Fluvastatin

Fluvastatin may modestly reduce the clearance of diclofenac, but no clinically significant interactions between fluvastatin and NSAIDs appear to have been reported.

Clinical evidence, mechanism, importance and management

A study in 14 healthy subjects given fluvastatin 40 mg daily for 8 days and a single 25-mg dose of **diclofenac** found that fluvastatin increased the peak plasma level and AUC of diclofenac by 60% and 25%, respectively, although there was considerable inter-individual variation in these results. Clearance of **diclofenac** was decreased by about 15%. This was possibly due to inhibition of the cytochrome P450 CYP2C9-mediated metabolism of **diclofenac** by fluvastatin and the authors suggest that an interaction may occur in some patients.[1] However, the manufacturer of fluvastatin states that fluvastatin does not influence the metabolism of **phenazone** (**antipyrine**) so that interactions with drugs metabolised by hepatic enzyme systems are not expected.[2] They also state that in clinical studies in which fluvastatin was used with NSAIDs, no clinically significant adverse interactions occurred.[2]

NSAIDs + Food

In general, food has no clinically significant effect on the absorption of the NSAIDs; however, the delay in absorption that occurs may be important if NSAIDs are given in acute pain management.

Clinical evidence

(a) Celecoxib

A study in 50 children found that high-fat food, increased the maximum plasma concentration of a single 250-mg/m^2 dose of celecoxib by 82% and increased its AUC by 60%. When steady-state levels were achieved with celecoxib 250 mg/m^2 twice daily, food increased its maximum plasma concentration by 99% and increased its AUC by 75%.[1] The manufacturers of celecoxib note that a high-fat meal delayed celecoxib absorption by about one to 2 hours[2,3] and the total absorption was increased by 10% to 20%.[3]

(b) Dexketoprofen

The absorption of a single 25-mg dose of dexketoprofen was delayed by food (maximum level reduced by 45% and time to maximum level delayed by about 1 hour), but the AUC was not affected.[4]

(c) Diclofenac

In a study, 13 healthy subjects were given a single 105-mg dose of diclofenac potassium suspension (*Flogan*) while fasting and after food. The pharmacokinetics of diclofenac were not changed to a clinically relevant extent by food, except that absorption was delayed (time to maximum level increased by about 30 minutes).[5] Similar findings (an increase in time to maximum level of 1.5 to 3 hours) were reported for single doses of enteric-coated diclofenac tablets.[6] However, there was no difference in the steady-state levels of diclofenac 50 mg twice daily when given before or after food.[6]

(d) Etodolac

When 18 healthy subjects were given etodolac 400 mg after a high-fat meal, peak serum levels were roughly halved, and delayed, from 1.4 hours to 3.8 hours, but the total amount absorbed was not markedly changed, when compared to the fasting state.[7]

(e) Etoricoxib

A high-fat meal reduced the maximum level of etoricoxib by 36% and delayed it by 2 hours, without affecting the extent of absorption.[8]

(f) Flurbiprofen

Food slightly increased the maximum plasma level and AUC of sustained-release flurbiprofen (*Froben SR*) by 15% and 25%, respectively, but delayed the time to achieve the maximum level by about 5 hours.[9]

(g) Ibuprofen

Food had no effect on the pharmacokinetics of the *S*- and *R*-enantiomers of ibuprofen in one study.[10] However, in another study, food delayed the absorption of both enantiomers of ibuprofen, and slightly increased the ratio of the *S*- to *R*-enantiomer.[11] A study considering the effect of food on ibuprofen pharmacokinetics found that the maximum level of a single 400-mg dose of a standard release ibuprofen tablet and two readily soluble preparations (ibuprofen lysinate and ibuprofen extrudate), was consistently lower and appeared later when the dose was given after a standardised breakfast; the extent of ibuprofen absorption was also reduced by food for all three formulations.[12] However, in a further study, food increased the maximum plasma level of sustained-release ibuprofen (*Brufen Retard)* by 42% without affecting the time to achieve the maximum level or the bioavailability.[9]

(h) Indometacin

Studies in patients and healthy subjects, given single or multiple oral doses of indometacin have found that food delays and reduces peak serum indometacin levels, but the fluctuations in levels are somewhat reduced.[13]

(i) Ketoprofen

Food significantly decreased the rate and extent of absorption of ketoprofen in both single and multiple dose studies in healthy subjects. The AUC was decreased by about 40% and the time to maximum levels decreased by about 5 hours.[14] A further study found that the rate of absorption and the peak plasma levels of ketoprofen were reduced by food, although the AUC was unaltered.[15] In another study, the absorption of ketoprofen

(200 mg daily, as a gastric-juice resistant, sustained-release formulation, given 4 hours before the first meal of the day) was about 15 to 24% greater when 16 healthy subjects were given a low-calorie/low-fat diet rather than a high-calorie/high-fat diet.[16] In a further study in 4 healthy subjects, which measured the urinary excretion of ketoprofen after a single 50-mg dose given with water, whole skimmed milk, or a traditional Egyptian breakfast, it was concluded that the rate and extent of absorption of ketoprofen had been reduced by the presence of food, and the extent of absorption was also reduced by milk.[17]

(j) Meloxicam

In one study, the rate (time to peak serum levels) and extent of absorption (AUC) of meloxicam 30 mg was not altered by food intake.[18]

(k) Nabumetone

The absorption of a single 1-g dose of nabumetone was increased by food and milk, as shown by an increase of about 50% in the maximum levels and a 40% increase in the AUC_{0-24}. However, the AUC_{0-72} was not significantly increased.[19]

(l) Naproxen

Food did not have any clinically relevant effect on the pharmacokinetics of sustained-release naproxen in two studies.[20,21] Taking a single 550-mg dose of naproxen sodium with a meal had no effect on its analgesic efficacy in postoperative pain, when compared with the fasted state.[22] However, the rate of absorption of a single 550-mg dose of *S*-naproxen betainate sodium salt monohydrate was found to be reduced by a high-fat meal, when compared with the fasting state.[23]

(m) Piroxicam

Food caused some delay in the time to reach maximum levels of piroxicam in a single-dose study, but had no effect on total absorption.[24] In another study, the steady-state plasma levels of piroxicam 20 mg daily were unaffected by food.[25]

(n) Tenoxicam

In a study in 12 healthy subjects, the bioavailability of tenoxicam 20 mg was unaffected by food, although the time taken to reach peak serum levels was delayed by about 4 hours.[26]

Mechanism

Food delays gastric emptying, therefore frequently affects the rate, but not the extent, of absorption of the NSAIDs.

Importance and management

Food reduces the rate of absorption but has little or no effect on the extent of absorption of most of the NSAIDs studied. The effect of food was seen to vary with different formulations of NSAIDs; however, these changes in absorption will have little clinical relevance when these drugs are being used regularly to treat chronic pain and inflammation. If these drugs are being used for the treatment of acute pain, giving them on an empty stomach would be preferable in terms of onset of effect, and is suggested by the manufacturers of dexketoprofen[27] and etoricoxib.[8] However, it is usually recommended that NSAIDs are given with or after food in an attempt to minimise their gastrointestinal adverse effects.

Although food delayed the absorption of celecoxib, the UK manufacturer says that it can be taken with or without food.[2] However, high-fat food may increase the total absorption of celecoxib and the US manufacturer suggests that higher doses (400 mg twice daily) should be given with food to improve absorption.[3]

NSAIDs + Ginkgo (*Ginkgo biloba*)

An isolated case describes fatal intracerebral bleeding in a patient taking ginkgo with ibuprofen, and another case describes prolonged bleeding and subdural haematomas in another patient taking ginkgo and rofecoxib. Studies with diclofenac and flurbiprofen showed that ginkgo had no effect on the pharmacokinetics of these drugs.

Clinical evidence

A case of fatal intracerebral bleeding has been reported in a 71-year-old patient taking a ginkgo supplement (*Gingium*) 4 weeks after he started to take **ibuprofen** 600 mg daily.[1] A 69-year-old man taking a ginkgo supplement and **rofecoxib** had a subdural haematoma after a head injury, then recurrent small spontaneous haematomas. He was subsequently found to have a prolonged bleeding time, which returned to normal one week after stopping the ginkgo supplement and **rofecoxib**, and remained normal after restarting low-dose **rofecoxib**.[2]

A placebo-controlled study in 11 healthy subjects who were given ginkgo leaf (*Ginkgold*) 120 mg twice daily for three doses, followed by a single 100-mg dose of **flurbiprofen**, found that the pharmacokinetics of flurbiprofen were unchanged.[3]

A study in 12 healthy subjects who were given **diclofenac** 50 mg twice daily for 14 days, with ginkgo extract (*Ginkgold*) 120 mg twice daily on days 8 to 15, found no alteration in the AUC or oral clearance of diclofenac.[4]

Mechanism

The reason for the bleeding is not known, but ginkgo extract contains ginkgolide B, a potent inhibitor of platelet-activating factor *in vitro*, which is needed for arachidonate-independent platelet aggregation. However, in one controlled study in healthy subjects, taking a ginkgo preparation alone for two weeks had no effect on platelet function.[5] Nevertheless, there are case reports of ginkgo supplements, on their own, being associated with prolonged bleeding times,[6,7] left and bilateral subdural haematomas,[6,8] a right parietal haematoma,[9] post-laparoscopic cholecystectomy bleeding,[10]

and subarachnoid haemorrhage.[7] Ibuprofen is an inhibitor of platelet aggregation, but selective inhibitors of COX-2 such as rofecoxib have no effect on platelets and would not be expected to potentiate any bleeding effect of ginkgo.

The pharmacokinetic studies involving diclofenac and flurbiprofen were designed to identify whether ginkgo exerted an inhibitory effect on the cytochrome P450 isoenzyme CYP2C9, which is involved in the metabolism of these NSAIDs.

Importance and management

The evidence from these reports is too slim to forbid patients to take NSAIDs and ginkgo concurrently, but some do recommend caution.[11] Medical professionals should be aware of the possibility of increased bleeding tendency with ginkgo, and report any suspected cases.[9] Consider also 'Antiplatelet drugs + Ginkgo (*Ginkgo biloba*)', p.816.

NSAIDs or Aspirin + Gold

Gold appears to increase the risk of aspirin-induced liver damage. The use of gold with fenoprofen seems to be safer with regard to liver toxicity. An isolated report suggested that naproxen may have contributed to gold-induced pneumonitis.

Clinical evidence, mechanism, importance and management

A study in patients with rheumatoid arthritis given aspirin 3.9 g or **fenoprofen** 2.4 g daily suggested that gold induction therapy (**sodium aurothiomalate**, by intramuscular injection, to a total dose of 985 mg over 6 months) increased aspirin-induced hepatotoxicity. Levels of AST, lactate dehydrogenase, and alkaline phosphatase were higher in those taking aspirin than in those taking **fenoprofen**. These indicators of liver impairment suggest that **fenoprofen** is safer than aspirin in this context. The concurrent use of gold and NSAIDs was more effective than the NSAIDs alone.[1]

A patient with rheumatoid arthritis taking gold (**sodium aurothiomalate**) developed pneumonitis soon after **naproxen** 500 mg twice daily was added. An *in vitro* study suggested the pneumonitis was due to hypersensitivity to gold. However, the patient's condition continued to deteriorate despite stopping the gold, then showed marked improvement when the **naproxen** was also stopped. The authors suggest that the **naproxen** may have altered the patient's immune system in some way to make them more sensitive to the gold.[2] This appears to be the only report of such an effect, and it is therefore unlikely to be of general relevance.

NSAIDs or Aspirin + H_2-receptor antagonists

The H_2-receptor antagonists have no effect or cause only modest and normally clinically unimportant changes in the serum levels of aspirin and NSAIDs. More importantly H_2-receptor antagonists may protect the gastric mucosa from the irritant effects of the NSAIDs.

Clinical evidence

(a) Aspirin

Cimetidine 300 mg, given one hour before a single 1.2-g dose of aspirin caused only a modest increase in the serum salicylate levels of 3 out of 6 healthy subjects.[1] When 13 patients with rheumatoid arthritis taking enteric-coated aspirin were given **cimetidine** 300 mg four times daily for 7 days the total amount of aspirin absorbed was unaltered, but aspirin levels were slightly raised, from 161 micrograms/mL to 180 micrograms/mL.[2] The pharmacokinetics of a single 1-g dose of aspirin were largely unchanged in 6 healthy subjects given **ranitidine** 150 mg twice daily for a week.[3] However, a study in 10 healthy subjects found that the antiplatelet effects of aspirin were reduced when it was given with **ranitidine**. This was unexpected as **ranitidine** alone may cause a modest decrease in platelet aggregation so it would be expected to enhance the marked antiplatelet effects of aspirin. The reduced effect was attributed to reduced blood levels of salicylate possibly due to changes in the absorption conditions of aspirin in the presence of **ranitidine**.[4] **Famotidine** has been found to cause some small changes in the pharmacokinetics of aspirin, but this is of doubtful clinical importance.[5]

(b) Azapropazone

A randomised, pharmacokinetic study in 12 healthy subjects found that **cimetidine** 300 mg every 6 hours for 6 days increased the AUC of a single 600-mg dose of azapropazone by 25%. The AUC of **cimetidine** was altered by less than 20%. No significant changes in laboratory values (blood counts, enzyme levels) were seen, and adverse effects were minor (headaches in 3 subjects).[6]

(c) Diclofenac

In 14 healthy subjects, **famotidine** 40 mg raised the peak plasma levels of enteric-coated diclofenac 100 mg from 5.84 mg/L to 7.04 mg/L. Peak plasma diclofenac levels also occurred more rapidly (2 hours versus 2.75 hours). The extent of diclofenac absorption was unchanged.[7] Diclofenac did not affect the pharmacokinetics of **ranitidine** nor its ability to suppress gastric pH.[8] Another study also found that the pharmacokinetics of diclofenac were unaffected by **ranitidine**.[9]

(d) Dipyrone (Metamizole)

In a study in 12 patients with confirmed duodenal ulcer, but no gastrointestinal bleeding, **cimetidine** 200 mg was given three times daily with another 400 mg at night for 20 days. A single 1.5-g or 750-mg dose of dipyrone was given on days 8 and 13. In the presence of **cimetidine**, the AUC of the active metabolite of dipyrone, 4-methyl-amino-antipyrine (4-MAA), was increased by 74%, with dipyrone doses of 1.5 g, but the renal clearance of 4-MAA remained unchanged.[10]

(e) Flurbiprofen

In 30 patients with rheumatoid arthritis, **cimetidine** 300 mg three times daily for 2 weeks increased the maximum serum level of flurbiprofen 150 to 300 mg daily, but **ranitidine** 150 mg twice daily had no effect. The efficacy of the flurbiprofen (assessed by Ritchie score, 50 foot walking time, grip strength) was not altered.[11] Another study in healthy subjects found that **cimetidine** 300 mg four times daily slightly increased the serum levels of a single 200-mg dose of flurbiprofen, and raised the flurbiprofen AUC by 13%.[12] No statistically significant interaction occurred with **ranitidine** 150 mg twice daily.[12] Although the activity of flurbiprofen is thought to be related to the *S*-enantiomer, neither **cimetidine** nor **ranitidine** were shown to interact preferentially with one enantiomer over the other.[13]

(f) Ibuprofen

Cimetidine 400 mg three times daily raised the peak serum levels and AUC of a 600-mg dose of ibuprofen by 14% and 6%, respectively. No changes were seen with **ranitidine** 300 mg daily.[14] Another study found that the AUC of *R*-ibuprofen and *S*-ibuprofen increased by 37% and 19%, respectively, but these changes were not statistically significant.[15] However, five other studies with ibuprofen found no interaction with **cimetidine** or **ranitidine**,[16-20] or **nizatidine**.[17] However, analysis of the results of one study showed that peak serum ibuprofen levels in black American subjects were 54% higher and occurred sooner, whereas in white American subjects they were 27% lower and delayed.[18,21]

(g) Indometacin

Cimetidine 1.2 g daily for 2 weeks was given to 10 patients with rheumatoid arthritis taking steady-state indometacin 100 to 200 mg daily. The plasma indometacin levels fell by 18%, but there was no significant

change in the clinical effectiveness of the anti-inflammatory treatment (as measured by articular index, pain, grip strength and erythrocyte sedimentation rate).[22] Another study found no changes in the pharmacokinetics of indometacin in healthy subjects given **ranitidine**.[23] In a single-dose study in healthy subjects, indometacin did not markedly affect the bioavailability of either **cimetidine** or **ranitidine**.[24]

(h) Ketoprofen

In a study in 12 healthy subjects, **cimetidine** 600 mg twice daily did not affect the pharmacokinetics of enteric-coated ketoprofen 100 mg twice daily.[25]

(i) Lornoxicam

In 12 healthy subjects, **cimetidine** 400 mg twice daily increased the maximum serum levels and AUC of lornoxicam 8 mg twice daily by 28% and 9%, respectively. **Ranitidine** 150 mg twice daily had no significant effect on lornoxicam pharmacokinetics in these same subjects, except that one subject had a very marked increase in serum lornoxicam levels while taking both drugs. He dropped out of the study after 6 days because of severe gastric irritation. It is not clear what part, if any, the **ranitidine** had to play in this effect.[26]

(j) Meloxicam

In a randomised, crossover study, a group of 9 healthy subjects was given meloxicam 30 mg either alone, or with **cimetidine** 200 mg four times daily for 5 days. **Cimetidine** had no significant effect on the pharmacokinetics of the meloxicam.[27]

(k) Naproxen

One study found no adverse interaction between naproxen and **cimetidine** and no alteration in the beneficial effects of **cimetidine** on gastric acid secretion,[28] but another study found that cimetidine caused a moderate 39 to 60% decrease in the half-life of naproxen,[29,30] and a 20% reduction in the AUC of naproxen.[30] In one of these studies the half-life of naproxen was reduced by about 40% by **ranitidine** and by 50% by **famotidine**.[30] A further study found that **nizatidine** does not affect the pharmacokinetics of naproxen.[31]

(l) Oxaprozin

In a study in 12 healthy subjects, peak plasma levels, time to peak level and elimination half-lives of a single 1.2-g dose of oxaprozin were not significantly affected by either **cimetidine** 300 mg four times daily or **ranitidine** 150 mg twice daily. Oxaprozin clearance was reduced by 20% by both **cimetidine** and **ranitidine**.[32]

(m) Piroxicam

In 10 healthy subjects, **cimetidine** 300 mg four times daily for 7 days slightly increased the half-life and the AUC of a single 20-mg dose of piroxicam, by 8% and 16%, respectively.[33] Another study found that **cimetidine** caused a 15% rise in the AUC of piroxicam.[34] In 12 healthy subjects the half-life and AUC of a single-dose of piroxicam were increased by 41% and 31%, respectively, by **cimetidine** 200 mg three times daily, and the plasma levels were raised accordingly.[35] For example, at 4 hours they were raised by almost 25%.[35] **Ranitidine** was not found to affect the pharmacokinetics of piroxicam.[36] No clinically significant changes occurred in the steady-state serum levels of piroxicam in a further study when either **cimetidine** or **nizatidine** were given.[37]

(n) Tenoxicam

The pharmacokinetics of a single 20-mg oral dose of tenoxicam was unaltered in 6 healthy subjects after they took **cimetidine** 200 mg three times daily and 400 mg at night for 7 days.[38]

Mechanism

Uncertain. Azapropazone, 4-MAA (the active metabolite of dipyrone), lornoxicam, and piroxicam serum levels are possibly increased because their metabolism via the cytochrome P450 system is reduced by cimetidine.[6,10,26,35] There may also be some effects on renal excretion.[6]

Importance and management

Most of the interactions between the NSAIDs and cimetidine, famotidine, nizatidine or ranitidine appear to be of no particular clinical importance. The general relevance of the isolated case of increased lornoxicam levels and severe gastric irritation with ranitidine is uncertain, but probably small. The H_2-receptor antagonists as a group may protect the gastric mucosa from the irritant effects of the NSAIDs and concurrent use may therefore be generally advantageous.

NSAIDs or Aspirin + Hormonal contraceptives or HRT

Oral hormonal contraceptives increase diflunisal clearance in women, but only to the level normally seen in men. One study found modestly reduced levels of ibuprofen with oral hormonal contraceptives, but another study did not. Oral hormonal contraceptives reduce the levels of aspirin, decrease the clearance of phenazone (antipyrine), but do not appear to affect the pharmacokinetics of phenylbutazone. Conjugated oestrogens have no clinically relevant effects on the pharmacokinetics of oxaprozin or phenazone (antipyrine).

Clinical evidence, mechanism, importance and management

(a) Aspirin

The AUCs of single 300- and 600-mg doses of aspirin were lower in 10 women after they started to take an oral combined hormonal contraceptive (**ethinylestradiol**/**norethisterone** 30 micrograms/1 mg). After the contraceptive had been discontinued, the pharmacokinetics of aspirin returned to baseline values.[1]

(b) Coxibs

For a report of pulmonary embolism in a patient taking valdecoxib with an oral combined hormonal contraceptive, and for the effects of coxibs on contraceptive metabolism, see 'Combined hormonal contraceptives + Coxibs', p.1181.

(c) Diflunisal

The clearance of a single 250-mg dose of diflunisal was 53% higher in 6 women taking oral hormonal contraceptives than in 6 control women, but was similar to the clearance in 6 men.[2] This difference is unlikely to be of clinical importance.

(d) Ibuprofen

In one study, the pharmacokinetics of *R*-ibuprofen did not differ between women taking oral combined hormonal contraceptives and two control groups (one women and one men).[3] However, in another study, the median $AUC_{0\text{-}12}$ of *S*-ibuprofen lysinate was 29% lower in users of oral contraceptives, and pain-intensity was higher (although this was possibly due to reduced pain tolerance).[4]

(e) Oxaprozin

There was no difference in the pharmacokinetics of a single 1.2-g dose of oxaprozin in 11 women taking **conjugated oestrogens** (*Premarin*) and in 11 women not taking oestrogens, except that the time to peak concentration was shorter (4 hours versus 8.9 hours).[5] This difference is unlikely to be of clinical importance.

(f) Phenazone (Antipyrine)

In a study, 12 healthy women taking an oral hormonal contraceptives were given a single 1-g intravenous dose of phenazone. When compared with 26 similar women not taking oral hormonal contraceptives, the clearance of phenazone was found to be 28% lower and its half-life was 3.4 hours greater, suggesting that oral hormonal contraceptives have modest effects on hepatic enzymes.[6] In another study in healthy women, the use of **conjugated oestrogens** for at least 3 months did not affect the clearance of single 1- to 1.2-g intravenous doses of phenazone.[7]

(g) Phenylbutazone

The pharmacokinetics of a single 400-mg dose of phenylbutazone did not change in 10 women after they started to take an oral combined hormonal contraceptive containing **ethinylestradiol**/**norethisterone** 30 micrograms/1 mg.[1]

NSAIDs or Salicylates + Mazindol

Mazindol does not appear to interact adversely with indometacin or salicylates.

Clinical evidence, mechanism, importance and management

In an 8-week, placebo-controlled study, mazindol was given to 26 patients with obesity and arthritis, 15 of whom were taking salicylates, 11 were taking **indometacin** and one was taking dextropropoxyphene (propoxyphene) with paracetamol (acetaminophen). Additional analgesic and anti-inflammatory drugs used were ibuprofen (4 patients), phenylbutazone (1), dextropropoxyphene (7) and paracetamol (3). No symptoms attributable to salicylism or **indometacin** toxicity (gastric intolerance, headache) were observed.[1]

NSAIDs or Aspirin + Metoclopramide

Metoclopramide increases the rate of absorption of aspirin and tolfenamic acid. Conversely, metoclopramide reduces the bioavailability of ketoprofen.

Clinical evidence

(a) Aspirin

In one study, intramuscular metoclopramide given before oral effervescent aspirin increased the rate of aspirin absorption during a migraine attack to that seen when aspirin was given alone to subjects who were headache free.[1] Similarly, in another study, intramuscular or oral metoclopramide 10 mg increased the rate of absorption of aspirin in patients with migraine.[2] However, in healthy subjects metoclopramide did not alter the pharmacokinetics of aspirin.[3] In addition, in one clinical study there was no difference in analgesic efficacy between aspirin with metoclopramide (*Migravess*) and aspirin alone (*Alka-Seltzer*) for migraine attacks.[4]

(b) Ketoprofen

In a single-dose study in 4 healthy subjects, metoclopramide 10 mg reduced the AUC of a 50-mg capsule of ketoprofen by 28%. The maximum plasma levels of ketoprofen were almost halved and the time to reach this maximum was prolonged by 30%.[5]

(c) Tolfenamic acid

Rectal metoclopramide 20 mg, given to 8 healthy subjects 30 minutes before oral tolfenamic acid 300 mg, caused a threefold increase in the serum tolfenamic acid levels at 45 minutes. However, there was no change in the maximum level or the AUC.[6] In another study, rectal metoclopramide similarly enhanced the rate of oral absorption of tolfenamic acid when it was given during a migraine attack.[7]

Mechanism

Metoclopramide speeds up gastric emptying. The relatively poorly soluble ketoprofen spends less time in the stomach where it dissolves, and as a result less is available for absorption in the small intestine. Conversely, the absorption rate of tolfenamic acid is increased, without a change in the extent of absorption.

Importance and management

The clinical importance of the reduction in ketoprofen levels is unknown, but the authors of the study recommend that ketoprofen (and possibly other NSAIDs that are poorly soluble) should be taken 1 to 2 hours before metoclopramide. Conversely, for aspirin, tolfenamic acid, and other NSAIDs, metoclopramide can be used to increase the rate of absorption,

and therefore possibly speed up the onset of analgesic effect in conditions such as migraine.

NSAIDs + NSAIDs

The concurrent use of two or more NSAIDs increases the risk of gastrointestinal damage. Diflunisal raises serum indometacin levels about twofold but does not affect naproxen levels. The concurrent use of indometacin and flurbiprofen does not appear to affect the pharmacokinetics of either drug. Floctafenine does not alter diclofenac levels. Indometacin caused renal impairment in a patient recovering from phenylbutazone-induced acute renal failure.

Clinical evidence

(a) Gastrointestinal effects

The risk of serious upper gastrointestinal bleeding was increased by the use of more than one NSAID in a meta-analysis of data from three case-controlled studies (odds ratio 4.9 with one NSAID and 10.7 with two NSAIDs).[1] Another study provided similar findings: the odds ratio was 7.1 with one NSAID and 12.3 with two or more NSAIDs.[2] Similar findings have been reported with aspirin and NSAIDs, see 'NSAIDs + Aspirin', p.158. Analysis of yellow card reports to the CSM in the UK, of gastrointestinal perforation, obstruction, ulceration or bleeding with **diclofenac**, **naproxen**, and **ibuprofen**, revealed that 6% of the patients were receiving another non-aspirin NSAID.[3]

One pharmacodynamic study in healthy subjects found that gastric instillation of a solution of **diflunisal** before an **indometacin** solution prevented the fall in transmucosal potential difference seen with **indometacin** alone. This was interpreted as evidence that **diflunisal** protects the human gastric mucosa against the damaging effects of **indometacin**.[4] However, the relevance of this test to the adverse effects of NSAIDs used clinically is unknown. Note that fatal gastrointestinal haemorrhage has been reported in a patient taking **diflunisal** and **indometacin**.[5]

(b) Pharmacokinetic studies

No clinically significant changes in the pharmacokinetics of either **indometacin** 75 mg daily or **flurbiprofen** 150 mg daily occurred when both drugs were given together.[6]

Diflunisal 250 mg twice daily had no effect on plasma levels or urinary excretion of **naproxen** 250 mg twice daily.[7]

A study in 16 healthy subjects found that **diflunisal** 500 mg twice daily raised the steady-state plasma levels and the AUC of **indometacin** 50 mg twice daily about twofold. Combined use was associated with more gastrointestinal and CNS adverse effects, but there was no clear effect on blood loss in the faeces.[8] Another study produced similar findings.[9]

No change in free **diclofenac** levels was seen when 6 healthy subjects were given **floctafenine** 400 mg with **diclofenac** 75 mg daily for a week.[10]

(c) Renal effects

An isolated report describes deterioration in renal function in a patient during recovery from **phenylbutazone**-induced renal failure when **indometacin** 25 mg three times a day was given. The **indometacin** was discontinued with improvement of renal function.[11]

Mechanism

The damaging effects of the NSAIDs on the gut appear to be additive. Diflunisal may inhibit the glucuronidation of indometacin, or could compete for renal clearance with unmetabolised indometacin.[9] All NSAIDs have the propensity to cause renal impairment.

Importance and management

The gastrointestinal toxicity of the NSAIDs is well documented, and it appears that combined use increases this risk. The CSM in the UK have suggested that the concurrent use of more than one NSAID should be avoided.[3,12] The marked rise in the plasma levels of indometacin with diflunisal gives an additional reason why this combination in particular should not be used. Some NSAIDs cause more gastrointestinal toxicity than others; a suggested broad 'rank order' of seven NSAIDs is as follows: highest risk (azapropazone); intermediate risk (diclofenac, indometacin, ketoprofen and naproxen, with piroxicam more risky); lowest risk (ibuprofen),[12] which has been borne out in another analysis.[3] The ranking was based on epidemiological studies and the yellow card database. **Ketorolac** may also be particularly associated with gastrointestinal bleeding, and concurrent use with other NSAIDs has been identified as a risk factor,[13] therefore the manufacturer of ketorolac specifically contraindicates its use with other NSAIDs.[14]

NSAIDs or Aspirin + Paracetamol (Acetaminophen)

Paracetamol levels are increased by diflunisal. Aspirin, diclofenac, nabumetone and sulindac pharmacokinetics do not appear to be affected by paracetamol. There is no pharmacokinetic interaction between ibuprofen and paracetamol. Propacetamol, and possibly paracetamol, increase the antiplatelet effects of diclofenac, although the evidence is limited and the clinical relevance of this is uncertain.

One epidemiological study found that paracetamol alone, and particularly when combined with NSAIDs, was associated with an increased risk of gastrointestinal bleeding, but other studies have not found such an effect. Case reports describe renal toxicity in patients taking ibuprofen or flurbiprofen in which paracetamol use was a theoretical contributing factor.

Clinical evidence, mechanism, importance and management

(a) Antiplatelet effects

In healthy subjects giving single doses of intravenous **propacetamol** 30 mg/kg and **diclofenac** 1.1 mg/kg augmented the platelet inhibitory effect of **diclofenac** by about one-third at 90 minutes post dose. At 5 minutes, the platelet inhibitory effect of both **diclofenac** alone and the combination was 100%, and by 22 to 24 hours, neither **diclofenac** alone nor the combination had any platelet inhibitory effect.[1] In a previous study, the authors had found that **propacetamol** (which is hydrolysed to

paracetamol) also inhibited platelet function, and they suggested that the effects of **diclofenac** and **propacetamol** were additive.[1] The clinical relevance of these findings is unclear, but the authors say it should be considered when assessing the risk of surgical bleeding.[1] Further study is needed.

An *in vitro* study suggested that high doses of paracetamol, and a combination of paracetamol and **diclofenac**, may cause platelet inhibition and may increase the risk of bleeding, particularly post-surgery.[2]

In 18 healthy subjects, intravenous **parecoxib** 40 mg given with intravenous paracetamol 1 g, was found not to alter platelet function when compared with paracetamol alone.[3]

(b) Gastrointestinal damage

In a case-control study of the UK General Practice Research Database from 1993 to 1998 the risk of upper gastrointestinal bleeding or perforation was slightly increased in those taking both aspirin and paracetamol (relative risk 3.3), when compared with aspirin alone (2.4), or paracetamol alone (2.4). Moreover, the risk was markedly increased in those taking NSAIDs and paracetamol (16.6), when compared with NSAIDs alone (3.6). The paracetamol doses used were at least 2 g daily. Paracetamol in doses of less than 2 g daily was not associated with an increased risk. Other drug doses and specific NSAIDs were not mentioned.[4] However, other epidemiological studies have not found any increased risk of upper gastrointestinal bleeding with paracetamol at any dose.[5] Paracetamol is usually considered not to increase the risk of upper gastrointestinal adverse effects, and the results of this case-control study are probably insufficient to change prescribing practice. Further studies are needed, controlled for the dose of the NSAID and indication for treatment.

(c) Pharmacokinetic studies

1. Aspirin. In a study in 6 healthy subjects, two doses of dextropropoxyphene with paracetamol 65 mg/650 mg, given one hour before and 3 hours after a single 1.2-g dose of soluble aspirin did not affect the plasma salicylate levels. A reduction in plasma salicylate levels was seen in one subject after a single 1.2-g dose of enteric-coated aspirin was taken with dextropropoxyphene and paracetamol, although the authors suggested that this was related to erratic absorption rather than a pharmacokinetic interaction.[6]

2. Diclofenac. In 6 healthy subjects, diclofenac 25 mg given with paracetamol 500 mg, both three times daily for 14 days, had no effect on the pharmacokinetics of diclofenac.[7]

3. Diflunisal. In a study in healthy subjects, diflunisal significantly raised serum paracetamol levels by 50% but the total bioavailability was unchanged; diflunisal levels were not affected.[8,9] This interaction has not been shown to be clinically important. Nevertheless, the manufacturer of diflunisal recommended that the combination should be used with caution, because of the association of high levels of paracetamol with hepatotoxicity.[9]

4. Ibuprofen. In a crossover study in 20 healthy subjects, ibuprofen 400 mg given with paracetamol 650 mg, both every 6 hours for 2 days, had no effect on the pharmacokinetics of either drug.[10]

5. Nabumetone. In a single-dose study, the absorption of nabumetone 1 g was not significantly altered by paracetamol 1.5 g.[11]

(d) Renal effects

Two children (aged 12 and 14 years) developed acute flank pain and reversible renal impairment during the short-term use of **flurbiprofen** or **ibuprofen**. They had also taken paracetamol.[12] Similarly, a 14-month-old infant with febrile status epilepticus was given an alternating regimen of paracetamol and **ibuprofen**, and subsequently developed acute renal failure.[13] NSAIDs can cause renal toxicity, whereas paracetamol is less likely to cause renal toxicity, except perhaps in overdose.[14] The authors of the first case report proposed that tubular toxicity of NSAIDs and paracetamol are theoretically synergistic.[12] This is because NSAIDs inhibit the production of glutathione (needed to prevent the accumulation of toxic metabolites of paracetamol) and renal ischaemia (possibly induced by NSAIDs, or by dehydration) might lead to the accumulation of paracetamol in the renal medulla.[12]

A review concluded that the available evidence does not support an increased risk of renal toxicity with the use of combination products of aspirin and paracetamol when compared with either drug alone.[15] Paracetamol is often combined with NSAIDs in the management of chronic pain. In addition, paracetamol and **ibuprofen** are often used concurrently (as alternating doses) in the management of fever, particularly in children. This latter practice has become controversial. Opponents cite the lack of efficacy data to support combined use (rather than appropriate doses of individual drugs), and the theoretical increased risk of overdose and renal toxicity.[16,17] Others consider that, in the absence of true safety issues, professional judgement should be used for recommending combined use.[18] Further study is clearly needed.

NSAIDs + Pentoxifylline

A review of bleeding events associated with the use of postoperative ketorolac revealed that a small number of patients were also taking pentoxifylline.[1] The UK manufacturer therefore, rather cautiously, contraindicates concurrent use,[2] whereas the US manufacturer[3] made no mention of this tentative interaction. The manufacturer of dexketoprofen similarly predicts that the concurrent use of pentoxifylline increases the risk of bleeding.[4] There seems to be no evidence regarding this interaction with other NSAIDs, but as non-selective NSAIDs have antiplatelet effects and pentoxifylline can cause bleeding events, it would be prudent to be alert for this possible interaction with any of the non-selective NSAIDs.

NSAIDs + Pesticides

Chronic exposure to lindane and other chlorinated pesticides can slightly increase the rate of metabolism of phenazone (antipyrine) and phenylbutazone.

Clinical evidence, mechanism, importance and management

(a) Phenazone (Antipyrine)

A study in 26 men occupationally exposed to a mixture of insecticides, predominantly **DDT** [**clofenotane**], **chlordane** and **lindane**, found that the half-life of phenazone 10 or 15 mg/kg was reduced from 13.1 hours, in a group of 33 unexposed subjects, to 7.7 hours in the exposed group.[1] The significance of this is unclear as changes in working practices have reduced occupational exposure to such chemicals.

(b) Phenylbutazone

The plasma half-life of phenylbutazone in a group of men who regularly used **chlorinated insecticide** sprays (mainly **lindane**) as part of their work, was found to be 20% shorter (51 hours) than in a control group (64 hours), due, it is believed, to the enzyme-inducing effects of the pesticides.[2] This modest increase in rate of metabolism is of doubtful direct clinical importance, but it illustrates the changed metabolism that can occur in those exposed to environmental chemical agents.

2. Kolmodin-Hedman B. Decreased plasma half-life of phenylbutazone in workers exposed to chlorinated pesticides. *Eur J Clin Pharmacol* (1973) 5, 195–8.

NSAIDs + Phenobarbital

Phenobarbital modestly decreases the AUC of fenoprofen and increases the clearance of phenylbutazone.

Clinical evidence, mechanism, importance and management

In 6 healthy subjects pretreatment with phenobarbital 15 or 60 mg every 6 hours for 10 days reduced the AUC of a single 200-mg dose of **fenoprofen** by 23% and 37%, respectively.[1]

In 5 healthy subjects the half-life of a single 6-mg/kg dose of **phenylbutazone** was reduced by 38% after pretreatment with phenobarbital 2 to 3 mg/kg daily for 3 weeks.[2] Other studies confirm that phenobarbital increases the clearance of **phenylbutazone**.[3,4]

The probable reason for the increased clearance or decreased exposure to these NSAIDs is that phenobarbital increases their metabolism by the liver. **Phenazone** is metabolised by mixed function oxidase enzymes in the liver, for which reason it is extensively used as a model drug for studying whether other drugs induce or inhibit liver enzymes. In one study phenobarbital caused about a 40% reduction in the half-life of **phenazone** thereby demonstrating that liver enzymes were being stimulated to metabolise **phenazone** more rapidly.[5]

The clinical importance of these interactions is uncertain, but given the magnitude of the effects it seems likely to be small. Nevertheless if the effects of these NSAIDs are reduced if phenobarbital is added it would seem prudent to consider an interaction as a possible cause.

NSAIDs + Probenecid

Probenecid reduces the clearance of dexketoprofen, diflunisal, indometacin (toxicity seen), ketoprofen, ketorolac, naproxen, meclofenamate, tenoxicam and tiaprofenic acid and raises their levels. The uricosuric effects of probenecid are not affected by indometacin but may be slightly reduced by sulindac.

Clinical evidence

(a) Diflunisal

In 8 healthy subjects probenecid 500 mg twice daily increased the steady-state plasma levels of diflunisal 250 mg twice daily by 65%, and reduced the clearances of its glucuronide metabolites.[1]

(b) Indometacin

A study in 28 patients with osteoarthritis, taking indometacin 50 to 150 mg daily orally or rectally, found that probenecid 500 mg to 1 g daily roughly doubled indometacin plasma levels and this paralleled increased effectiveness (relief of morning stiffness, joint tenderness and raised grip strength indices). However, 4 patients developed indometacin toxicity.[2]

Other studies have also found that probenecid causes a marked rise in plasma indometacin levels.[3-5] Clear signs of indometacin toxicity (nausea, headache, tinnitus, confusion and a rise in blood urea) occurred when a woman with stable mild renal impairment was given probenecid.[6] The uricosuric effects of probenecid were not altered.[3]

(c) Ketoprofen

In 6 healthy subjects probenecid 500 mg every 6 hours reduced the clearance of ketoprofen 50 mg every 6 hours by 67%.[7]

(d) Ketorolac

In a study in 8 subjects, probenecid 500 mg four times daily for 4 days increased the total AUC of a single 10-mg dose of ketorolac by more than threefold, increased its half-life from 6.6 hours to 15.1 hours, raised its maximum plasma levels by 24% and reduced its clearance by 67%.[8]

(e) Meclofenamate

Single-dose studies in 6 healthy subjects on the pharmacokinetics of sodium meclofenamate 100 mg found that pretreatment with probenecid (dosage unstated) increased its AUC and reduced its apparent plasma clearance by 60%, primarily due to a decrease in non-renal clearance.[9]

(f) Naproxen

In 12 healthy subjects, probenecid 500 mg twice daily increased the plasma levels of naproxen 250 mg twice daily by 50%.[10]

(g) Sulindac

The manufacturer of sulindac notes that probenecid increased plasma levels of sulindac and its sulfone metabolite, but had little effect on the active sulfide metabolite. Sulindac produced a modest reduction in the uricosuric action of probenecid,[11] which is said not to be clinically significant in most circumstances.[11]

(h) Tenoxicam

Probenecid 1 g twice daily for 4 days increased the maximum serum levels of a single 20-mg oral dose of tenoxicam by 25%. None of the other pharmacokinetic parameters was significantly altered.[12]

(i) Tiaprofenic acid

Probenecid appeared to reduce the urinary excretion of tiaprofenic acid in one healthy subject. The maximum urinary excretion rate was reduced by 66% and delayed by 2 hours.[13]

Mechanism

Probenecid is a known substrate for renal glucuronidation, and possibly competitively inhibits the renal glucuronidation of these NSAIDs.[14]

Importance and management

The interaction between indometacin and probenecid is established and adequately documented. Concurrent use should be well monitored because, while clinical improvement can undoubtedly occur, some patients may develop indometacin toxicity (headache, dizziness, light-headedness, nausea, etc.). This is particularly likely in those with some renal impairment. Reduce the indometacin dose as necessary. Information about other NSAIDs is not as well documented, but these interactions also appear to be established. The clinical importance of most of them is uncertain, but probably small. Reports of adverse effects seem to be lacking, but it would still be prudent to be alert for any evidence of increased adverse effects. Reduce the NSAID dose if necessary. The exception is ketorolac, which its manufacturer[15] contraindicates with probenecid.

NSAIDs or Aspirin + Prostaglandins

Misoprostol increases the incidence of abdominal pain and diarrhoea when used with diclofenac or indometacin. Isolated cases of neurological adverse effects have been seen when naproxen or phenylbutazone were given with misoprostol. However, no important pharmacokinetic interactions seem to occur between misoprostol and aspirin, diclofenac, ibuprofen or indometacin. NSAIDs are reported not to affect the abortive effects of intravaginal misoprostol.

Clinical evidence, mechanism, importance and management

A. Oral misoprostol

(a) Gastrointestinal adverse effects

A higher incidence of abdominal pain, diarrhoea, nausea and dyspepsia occurred when **diclofenac** was given with misoprostol.[1,2] Concurrent use of **indometacin** and misoprostol also resulted in an increase in the frequency and severity of abdominal symptoms, frequency of bowel movements, and a decrease in faecal consistency.[3] The most frequent adverse effect of misoprostol alone is diarrhoea, and this may limit the dose tolerated. When using misoprostol with NSAIDs, warn patients about the possibility of increased stomach pain and diarrhoea. However, note that preparations containing **diclofenac** or **naproxen** with misoprostol are available.

(b) Neurological adverse effects

A man with rheumatoid arthritis taking long-term **naproxen** developed ataxic symptoms a few hours after starting to take misoprostol. He said he felt drunk, staggering about and vomiting. He rapidly improved when he stopped the misoprostol but the adverse symptoms recurred on two further occasions when he restarted misoprostol.[4]

Adverse effects developed in 3 patients taking **phenylbutazone** 200 to 400 mg daily when they took misoprostol 400 to 800 micrograms daily.[5] One had headaches, dizziness and ambulatory instability that disappeared and then reappeared when the misoprostol was stopped and then restarted. No problems occurred when the **phenylbutazone** was replaced by **etodolac** 400 mg daily. The other 2 patients developed symptoms including headache, dizziness, hot flushes and transient diplopia.[5,6] No problems developed when one of them was given **naproxen** and misoprostol.[6] The reasons for this reaction are not understood but theoretically it could be due to a potentiation of the adverse effects of **phenylbutazone**. The general relevance of these few reports is unclear, but bear them in mind should unexpected neurological effects occur.

(c) Other studies

No clinically important pharmacokinetic interactions have been found to occur between **aspirin** 975 mg and misoprostol 200 micrograms,[7] or between **ibuprofen** and misoprostol.[8] One study found that misoprostol 800 micrograms daily decreased the AUC of a single 100-mg dose of **diclofenac** by a modest 20%.[2] However, other studies have found that misoprostol had no effect on steady-state **diclofenac** pharmacokinetics.[9] One study found that misoprostol 200 micrograms raised the steady-state levels of **indometacin** 50 mg three times daily by about 30%,[10] whereas another found that misoprostol 400 micrograms twice daily reduced the AUC of **indometacin** 50 mg twice daily by 13% after one dose and reduced the maximum steady-state plasma concentration by 24%.[3] These modest changes in **diclofenac** and **indometacin** levels are not expected to be clinically important.

Women undergoing second trimester medical terminations of pregnancy were given oral mifepristone 600 mg on day one, then 36 to 48 hours later, intravaginal misoprostol 800 micrograms. Starting 3 hours later, misoprostol 400 micrograms was given orally every 3 hours until expulsion, up to a maximum of nine oral doses of misoprostol. The women were randomised to receive a single dose of either paracetamol 1 g with dihydrocodeine 20 mg (n=38) or **diclofenac** 100 mg (n=36), given at the time of the intravaginal dose of misoprostol. The use of **diclofenac** did not increase either the time required for termination, or the amount of misoprostol needed.[11]

B. Vaginal prostaglandins

NSAIDs and aspirin are frequently avoided before the use of **prostaglandins** for induction of uterine contractions, because of the theoretical concern that they may inhibit efficacy.[12] For example, the UK manufacturer of **dinoprostone** says that NSAIDs including aspirin should be stopped before giving intravaginal **dinoprostone** for induction of labour.[13] However, a study involving 416 women given intravaginal **misoprostol** to induce early abortion found that the concurrent use of oral NSAIDs did not interfere with the efficacy of misoprostol,[12] and the US manufacturer of **dinoprostone** does not list NSAIDs or aspirin as possible interacting drugs.[14]

NSAIDs or Aspirin + Proton pump inhibitors

The antiplatelet activity and the pharmacokinetics of aspirin do not appear to be affected by omeprazole. There was no clinically relevant pharmacokinetic interaction between omeprazole and diclofenac, enteric-coated ketoprofen, naproxen, or piroxicam; or between pantoprazole and diclofenac or naproxen; or between esomeprazole and naproxen or rofecoxib.

Clinical evidence

(a) Aspirin

In a preliminary study in 11 healthy subjects, **omeprazole** 20 mg daily for 2 days reduced the serum levels of the salicylic acid metabolite of aspirin at 30 and 90 minutes after a single 650-mg dose of aspirin by 40% and 52%, respectively.[1] However, another study in 14 healthy subjects given **omeprazole** 20 mg daily for 4 days, with a final dose one hour before a single 125-mg dose of aspirin, found that **omeprazole** did not significant-

ly affect the plasma levels of either aspirin or salicylic acid. **Omeprazole** also did not affect the antiplatelet effects of aspirin.[2] Similarly, **omeprazole** had no effect on the bioavailability of aspirin (uncoated or enteric-coated tablets) in another study, although it increased the rate of absorption of aspirin from enteric-coated tablets.[3]

(b) Diclofenac

In a study in 13 healthy subjects, a single 105-mg dose of diclofenac potassium suspension (*Flogan*) was given during fasting and after gastric acid secretion blockade with **omeprazole**. The pharmacokinetics of the diclofenac were not changed to a clinically relevant extent by **omeprazole**.[4] Similarly, in 14 healthy subjects, the concurrent use of **omeprazole** 20 mg daily and diclofenac 50 mg twice daily for one week had no effect on the pharmacokinetics of either drug.[5]

In another study in 24 healthy subjects, the concurrent use of a single 40-mg oral dose of **pantoprazole** and diclofenac 100 mg (as enteric-coated *Voltarol*) did not affect the pharmacokinetics of either drug.[6]

(c) Ketoprofen

One study found that there were no significant changes in the pharmacokinetics of enteric-coated ketoprofen, given with or without **omeprazole**, although a trend towards higher plasma concentrations with omeprazole was noted, indicating the possibility of increased drug release in the stomach in the presence of an elevated pH.[7]

(d) Naproxen

Naproxen 250 mg twice daily, given to healthy subjects with **omeprazole** 20 mg daily,[5] **pantoprazole** 40 mg daily,[8] or **esomeprazole** 40 mg daily[9] for one week, had no effect on the pharmacokinetics of either naproxen or the proton pump inhibitor.

(e) Phenazone (Antipyrine)

In one study, the pharmacokinetics of **pantoprazole** 40 mg orally daily for 8 days was not altered to a clinically relevant extent by a single 5-mg/kg oral dose of phenazone given on day 8. **Pantoprazole** did not affect the pharmacokinetics of phenazone.[10]

(f) Piroxicam

In a study in 24 healthy subjects, the concurrent use of **omeprazole** 20 mg daily and piroxicam 10 mg daily for one week had no effect on the pharmacokinetics of either drug.[5]

(g) Rofecoxib

In a study in 30 healthy subjects, the concurrent use of **esomeprazole** 40 mg daily and rofecoxib 12.5 mg daily for one week had no effect on the pharmacokinetics of either drug, apart from a slight increase in the maximum level and AUC of rofecoxib, which was not thought to be clinically relevant.[9]

Mechanism

Data from *animal* studies suggest that the absorption and thus the effects of aspirin and NSAIDs can be reduced by omeprazole and H_2-receptor antagonists by a pH dependent mechanism.[11,12] However, note that clinical studies have not found H_2-receptor antagonists to have any important effect on the pharmacokinetics of aspirin or NSAIDs, see 'NSAIDs or Aspirin + H_2-receptor antagonists', p.165. It has been suggested that reducing gastric acidity with omeprazole results in the earlier disruption of enteric-coated tablets, and an increased absorption rate.[3]

Importance and management

The interaction between aspirin and omeprazole is not established. The balance of evidence suggests that omeprazole is unlikely to have an important effect on the pharmacokinetics and efficacy of aspirin. However, it would be of benefit to confirm this in further studies.[2,13]

No clinically significant pharmacokinetic interactions have been identified between any of the other NSAIDs and the proton pump inhibitors cited here, and no special precautions are needed during concurrent use. However, for mention that valdecoxib raises the plasma levels of omeprazole see 'NSAIDs; Parecoxib + Miscellaneous', p.177.

Note that omeprazole and other proton pump inhibitors are widely used in the management of the gastrointestinal complications of aspirin and NSAIDs.

NSAIDs + Rifampicin (Rifampin)

The plasma levels of celecoxib, diclofenac, and etoricoxib are reduced by rifampicin, but piroxicam does not appear to be affected. Dipyrone increased the maximum level of rifampicin in one study.

Clinical evidence

(a) Celecoxib

In 12 healthy subjects pretreatment with rifampicin 600 mg daily for 5 days reduced the AUC of a single 200-mg dose of celecoxib by 64% and increased its clearance by 185%.[1] A preliminary report of another study found broadly similar results.[2]

(b) Diclofenac

A study in 6 healthy subjects found that, after taking rifampicin 450 mg daily for 6 days, the maximum serum level of diclofenac, measured 8 hours after a single 100-mg dose of an enteric-coated tablet, was reduced by 43% and the AUC was reduced by 67%.[3]

(c) Dipyrone (Metamizole sodium)

A study in untreated patients with leprosy found that the pharmacokinetics of a single 600-mg dose of rifampicin were not markedly changed by 1 g of dipyrone, but peak serum rifampicin levels occurred sooner (at 3 instead of 4 hours) and were about 50% higher.[4]

(d) Etoricoxib

Rifampicin 600 mg daily for 12 days reduced the AUC of a single 60-mg dose of etoricoxib given on day 8 by 65%. The maximum plasma concentration of etoricoxib was reduced by 40%.[5]

(e) Phenazone (Antipyrine)

Rifampicin 600 mg daily for 13 days reduced the plasma concentrations of a single 1.2-g oral dose of phenazone. The mean AUC of phenazone was reduced by 59% and had not returned to the pre-rifampicin level 13 days after the final rifampicin dose.[6]

(f) Piroxicam

A study in 6 healthy subjects given a single 40-mg dose of piroxicam before and after a 7-day course of rifampicin 600 mg daily found that rifampicin did not significantly alter the pharmacokinetics of piroxicam.[7]

Mechanism

Rifampicin is a potent inducer of hepatic enzymes, and it is likely that it increased the metabolism of the affected NSAIDs.

Importance and management

Although information is limited, these pharmacokinetic interactions appear to be established. Their clinical relevance remains to be determined, but it seems likely that the efficacy of these NSAIDs will be reduced by rifampicin. Combined use should be well monitored, and the NSAID dosage increased if necessary, or an alternative analgesic considered. The clinical relevance of the increase in rifampicin maximum levels with metamizole is uncertain, but as it was only this pharmacokinetic parameter that was altered, it seems likely to be small.

NSAIDs + SSRIs

SSRIs may increase the risk of bleeding, including upper gastrointestinal bleeding, and the risk appears to be further increased by concurrent use of NSAIDs.

Clinical evidence

Studies and case reports have found that SSRIs alone increase the risk of upper (and lower[1]) gastrointestinal bleeding,[1-7] although some case control studies found this risk to be relatively small.[8-10] One review of studies concluded that the few epidemiological studies available provided weak evidence to support a link between SSRI use and upper gastrointestinal bleeding.[11] However, a retrospective study of the UK General Practice Research Database identified 1651 cases of upper gastrointestinal bleeding diagnosed between 1993 and 1997. The use of an SSRI increased the risk of bleeding threefold, when compared with 10 000 controls. In addition, the concurrent use of an SSRI with an NSAID greatly increased the risk of upper gastrointestinal bleeding (relative risk of bleeding compared with non-use of either drug: 15.6 for SSRIs with NSAIDs, 3.7 for NSAIDs alone, and 2.6 for SSRIs alone). Another study found a significant association between the degree of serotonin reuptake inhibition by antidepressants and risk of hospital admission for abnormal bleeding.[12] A retrospective cohort study in elderly patients taking antidepressants found a trend towards an increased risk of upper gastrointestinal bleeding for patients taking antidepressants with greater inhibition of serotonin reuptake. This association was statistically significant when controlled for previous upper gastrointestinal bleeding or age; and octogenarians, in particular, were at high risk.[13] and most of these studies found that gastrointestinal haemorrhage is potentiated by the concurrent use of NSAIDs.[1,2,7,11]

In contrast, some workers have disagreed with these results and found no evidence to suggest that SSRIs are more likely to cause gastrointestinal bleeding than other drugs.[14] One study reported that both SSRIs and NSAIDs were associated with a twofold increase in risk of gastrointestinal bleeding, but that the risk of bleeding was not substantially increased when both drugs were taken together (odds ratio for NSAIDs was 2.19, SSRIs was 2.63 and combined use was 2.93).[15] A further study found that the incidence of upper gastrointestinal bleeding in patients taking an SSRI and an NSAID was similar to that in those taking NSAIDs alone (odds ratio for NSAIDs was 7.82 and combined use was 8.32), with the SSRI alone having little risk.[9]

Mechanism

Serotonin is not synthesised by platelets but is taken up into platelets from the bloodstream. Serotonin released from platelets has an important role in regulating the haemostatic response to injury as it potentiates platelet aggregation. At therapeutic doses SSRIs can block this reuptake of serotonin by platelets leading to serotonin depletion, impairment of haemostatic function and so increase the risk of bleeding.[13,16-18]

Importance and management

Serotonin released by platelets plays an important role in haemostasis and there appears to be an association between the use of antidepressant drugs that interfere with serotonin reuptake and the occurrence of bleeding, including gastrointestinal bleeding. In addition, the concurrent use of an NSAID may potentiate the risk of bleeding. Therefore, the manufacturers of SSRIs advise caution in patients taking SSRIs with NSAIDs or other drugs that may affect coagulation or platelet function, such as 'aspirin', (p.817). Alternatives such as paracetamol (acetaminophen) or less gastrotoxic NSAIDs such as ibuprofen may be considered, but if the combination of an SSRI and NSAID cannot be avoided, prescribing of gastroprotective drugs such as proton pump inhibitors, H_2-receptor antagonists, or prostaglandin analogues should be considered, especially in elderly patients or those with a history of gastrointestinal bleeding. Patients, particularly those taking multiple drugs that may cause bleeding, should be advised to seek informed medical opinion before using non-prescription drugs such as ibuprofen on a regular basis.

NSAIDs or Aspirin + Sucralfate

Sucralfate appears not to have a clinically important effect on the pharmacokinetics of aspirin, choline-magnesium trisalicylate, diclofenac, ibuprofen, indometacin, ketoprofen, naproxen or piroxicam.

Clinical evidence, mechanism, importance and management

Sucralfate 2 g was given to 18 healthy subjects 30 minutes before single-doses of **ketoprofen** 50 mg, **indometacin** 50 mg, or **naproxen** 500 mg. Some statistically significant changes were seen (modestly reduced

maximum plasma levels of **ketoprofen**, **indometacin**, and **naproxen**, reduced the rate of absorption of **naproxen** and **indometacin**, and increased the time to achieve maximum plasma levels with **indometacin**) but no alterations in bioavailability occurred.[1] A delay, but no reduction in the total absorption of **naproxen** is described in two studies.[2,3] Sucralfate 1 g four times daily for 2 days was found not to decrease the rate of absorption of a single 400-mg dose of **ibuprofen**[4] or of a single 650-mg dose of **aspirin**.[5] Sucralfate 5 g in divided doses did not significantly alter the absorption of a single 600-mg dose of **ibuprofen**.[6] Similarly, another study also found that sucralfate had no important effect on the pharmacokinetics of **ibuprofen** enantiomers.[7] In one study, sucralfate 2 g was found not to affect significantly the pharmacokinetics of either **piroxicam** 20 mg or **diclofenac** 50 mg.[8] In another study, sucralfate 2 g twice daily modestly reduced the AUC_{0-8} and maximum serum levels of a single 105-mg dose of **diclofenac potassium** by 20% and 38%, respectively.[9] Sucralfate 1 g every 6 hours was found not to affect the pharmacokinetics of **choline-magnesium trisalicylate** 1.5 g every 12 hours.[10]

Single-dose studies do not necessarily reliably predict what will happen when patients take drugs regularly, but most of the evidence available suggests that the effects of sucralfate are modest at most, and it is therefore unlikely to have an adverse effect on treatment with these NSAIDs.

NSAIDs or Aspirin + *Tamarindus indica*

***Tamarindus indica* (tamarind) fruit extract markedly increases the absorption and plasma levels of aspirin and ibuprofen.**

Clinical evidence, mechanism, importance and management

(a) Aspirin

A study in 6 healthy subjects found that the bioavailability of a single 600-mg dose of aspirin was increased when it was taken with a millet meal containing *Tamarindus indica* (tamarind) fruit extract, compared with the millet meal alone or following overnight fasting. The aspirin AUC rose sixfold, the maximum plasma levels rose almost threefold (from about 10 micrograms/mL with the meal or fasting to about 29 micrograms/mL with the *Tamarindus indica* extract) and the half-life increased moderately (from about 1.04 to 1.5 hours).[1] The reasons are not known, nor has the clinical importance of these large increases been evaluated, but this interaction should be borne in mind if high (analgesic or anti-inflammatory) doses of aspirin are taken with this fruit extract. There would seem to be the possible risk of aspirin toxicity.

(b) Ibuprofen

A study in 6 healthy subjects found that the bioavailability of a single 400-mg dose of ibuprofen was increased when it was taken with a millet meal containing *Tamarindus indica* (tamarind) fruit extract compared with the millet meal alone, or following overnight fasting. The ibuprofen AUC rose approximately twofold and the maximum plasma levels rose from about 38 micrograms/mL to 45 micrograms/mL. There was also an increase in the plasma levels of the metabolites of ibuprofen. Ingestion of the meal containing *Tamarindus indica* was thought to favour the absorption of ibuprofen. This might result in an increased risk of toxicity.[2]

NSAIDs + Tobacco

The clearance of diflunisal, phenazone (antipyrine) and phenylbutazone is greater in smokers than in non-smokers.

Clinical evidence, mechanism, importance and management

(a) Diflunisal

The clearance of a single 250-mg dose of diflunisal was 35% higher in 6 women who smoked 10 to 20 cigarettes a day than in 6 non-smoking women.[1] This change does not appear to be large enough to be of clinical importance.

(b) Phenazone (Antipyrine)

When a single 1-g dose of phenazone was given intravenously, its clearance was increased by 63% and its half-life reduced from 13.2 hours to 8 hours in 10 healthy women who smoked cigarettes, when compared with a control group of 26 non-smoking women.[2] Similar results were reported in another study.[3] This is likely to be as a result of cigarette smoking causing induction of CYP1A2, the enzyme involved in the metabolism of phenazone.[2]

This suggests that smokers may need larger doses of phenazone to achieve the same effects as non-smokers.

(c) Phenylbutazone

The half-life of a single 6-mg/kg dose of phenylbutazone was 37 hours in a group of smokers (10 or more cigarettes daily for 2 years) compared with 64 hours in a group of non-smokers. The metabolic clearance was roughly doubled.[4] The conclusion to be drawn is that those who smoke may possibly need larger or more frequent doses of phenylbutazone to achieve the same therapeutic response, but this needs confirmation.

NSAIDs + Tricyclic antidepressants

An isolated report describes desipramine toxicity when ibuprofen was also given. The tricyclic antidepressants can delay the absorption of phenylbutazone and oxyphenbutazone from the gut.

Clinical evidence, mechanism, importance and management

(a) Ibuprofen

A 15-year-old patient with attention deficit disorder and depression treated with **desipramine**, which because of compliance problems was taken as a single 300-mg dose at bedtime, had **desipramine** levels of 164 nanograms/mL. The dose was increased to 375 mg at bedtime because of missed doses once or twice a week. He developed chest wall pain one week later, but an ECG at this time was normal. He was given ibuprofen 600 mg three times daily for the chest pain, but one week later developed blurred vision, clouding of consciousness and a grand mal seizure. He had a second seizure and ventricular tachycardia and was unresponsive until treated with physostigmine. Tricyclic toxicity was confirmed by a desipramine level of 657 nanograms/mL. This toxic level could have been due to the increase in **desipramine** dose, but as the ECG was normal one week after the increase and the fact that toxicity did not occur until 2 weeks after the dose increase and one week after starting ibuprofen, it was suggested that the toxicity might be due to inhibition of **desipramine** metabolism by ibuprofen.[1] This case is isolated and unconfirmed, and as such, no general recommendations can be made as a result of it.

(b) Oxyphenbutazone and Phenylbutazone

The absorption of a single 400-mg dose of phenylbutazone in 4 depressed women was considerably delayed (time to maximum level, 4 to 10 hours compared with 2 hours), but the total amount absorbed (measured by the urinary excretion of oxyphenbutazone) remained unchanged when they were pretreated with **desipramine** 75 mg daily for 7 days.[2] In another

5 depressed women the half-life of oxyphenbutazone was found to be unaltered by 75 mg of **desipramine** or **nortriptyline** daily.[3] *Animal* studies have confirmed that the absorption of phenylbutazone and oxyphenbutazone are delayed by the tricyclic antidepressants, probably because their antimuscarinic effects reduce gut motility,[4,5] but there seems to be no direct clinical evidence that the antirheumatic effects of either drug are reduced by this interaction. No particular precautions appear to be needed.

NSAIDs; Acemetacin + Miscellaneous

Acemetacin is a glycolic acid ester of indometacin, and its major metabolite is indometacin. Therefore acemetacin would be expected to interact in a similar way to indometacin.

NSAIDs; Azapropazone + Chloroquine

The plasma levels of azapropazone are not significantly altered by chloroquine.

Clinical evidence, mechanism, importance and management

A study in 12 subjects given azapropazone 300 mg three times daily found that the plasma levels of azapropazone, measured at 4 hours, were not affected by chloroquine 250 mg daily for 7 days.[1] No azapropazone dose adjustment would seem to be needed if these drugs are given together.

1. Faust-Tinnefeldt G, Geissler HE. Azapropazon und rheumatologische Basistherapie mit Chloroquin unter dem Aspekt der Arzneimittelinteraktion. *Arzneimittelforschung* (1977) 27, 2170–4.

NSAIDs; Celecoxib + Selenium

Selenium enriched baker's yeast does not appear to affect the pharmacokinetics of celecoxib.

Clinical evidence, mechanism, importance and management

In a study in 73 healthy subjects, celecoxib 400 mg was given daily for 2 weeks, then selenium enriched baker's yeast (*Saccharomyces cerevisiae*) 200 micrograms daily or matched placebo were added for 30 days. Following blood chemistry analysis (urea and electrolytes, full blood count etc), there were no clinically significant changes from baseline, nor were there any changes in celecoxib steady-state plasma levels.[1]

1. Frank DH, Roe DJ, Chow H-HS, Guillen JM, Choquette K, Gracie D, Francis J, Fish A, Alberts DS. Effects of a high-selenium yeast supplement on celecoxib plasma levels: a randomized phase II trial. *Cancer Epidemiol Biomarkers Prev* (2004) 13, 299–303.

NSAIDs; Diclofenac topical + Miscellaneous

Topical diclofenac intended for use on the skin is very unlikely to interact adversely with any of the drugs known to interact with diclofenac given orally.

Clinical evidence, mechanism, importance and management

The manufacturer of *Pennsaid* (a topical solution containing diclofenac 16 mg/mL in dimethyl sulfoxide) says that when the maximum dosage of 1 mL is used on the skin, the maximum plasma levels of diclofenac achieved are less than 10 nanograms/mL.[1] This is 50 times lower than the maximum plasma levels achieved with oral diclofenac 25 mg. Despite these very low concentrations, the manufacturer lists all the interactions that have been observed after systemic administration of diclofenac sodium (including **aspirin**, **digoxin**, **lithium**, **oral hypoglycaemic agents**, **diuretics**, **NSAIDs** including other **diclofenac** preparations, **methotrexate**, **ciclosporin**, **quinolones** and **antihypertensives**).[1] They note that the risk of these interactions in association with topical use is not known, but is probably low.[1] None of the drugs listed have yet been reported to interact with topical diclofenac.

The manufacturers of other topical preparations (*Solaraze* 3% w/w gel and *Voltarol* 1% w/w gel patch) state that interactions are not anticipated due to the low level of systemic absorption,[2,3] although one manufacturer still warns not to give, by either the topical or systemic route, any other medicinal product containing diclofenac or other NSAIDs.[3]

2. Solaraze 3% Gel (Diclofenac sodium). Almirall Ltd. UK Summary of product characteristics, February 2009.
3. Voltarol Gel Patch (Diclofenac epolamine). Novartis Consumer Health. UK Summary of product characteristics, November 2005.

NSAIDs; Etoricoxib + Miscellaneous

The manufacturer of etoricoxib recommends care when using etoricoxib with drugs that are metabolised by human sulfotransferases (they name oral salbutamol and minoxidil). This is because etoricoxib is an inhibitor of human sulfotransferase activity, and may increase the levels of these drugs. The increase in ethinylestradiol levels with etoricoxib is thought to occur as a result of this mechanism,[1] see 'Combined hormonal contraceptives + Coxibs', p.1181.

1. Arcoxia (Etoricoxib). Merck Sharp & Dohme Ltd. UK Summary of product characteristics, September 2009.

NSAIDs; Flurbiprofen + Cranberry juice

Limited evidence suggests that cranberry juice does not appear to affect the pharmacokinetics of flurbiprofen.

Clinical evidence

In a study in 14 healthy subjects, 230 mL of cranberry juice taken the night before, and 30 minutes before a single 100-mg dose of flurbiprofen, had no significant effect on the pharmacokinetics of flurbiprofen. Fluconazole, used as a positive control, increased the flurbiprofen AUC by about 80%.[1] In this study, the cranberry juice used was *Ocean Spray* cranberry juice cocktail from concentrate containing 27% cranberry juice.

Mechanism

Flurbiprofen is metabolised by the cytochrome P450 isoenzyme CYP2C9, and the clinical study appears to suggest that cranberry has no clinically relevant effect on this particular isoenzyme, despite the fact that it had some weak inhibitory effects *in vitro*.[1]

Importance and management

Evidence is limited, but what is known suggests that no pharmacokinetic interaction occurs between flurbiprofen and cranberry juice. Therefore no dose adjustment appears to be necessary if patients taking flurbiprofen wish to drink cranberry juice.

1. Greenblatt DJ, von Moltke LL, Perloff ES, Luo Y, Harmatz JS, Zinny MA. Interaction of flurbiprofen with cranberry juice, grape juice, tea, and fluconazole: in vitro and clinical studies. *Clin Pharmacol Ther* (2006) 79, 125–33.

NSAIDs; Ibuprofen + Moclobemide

Moclobemide did not alter the pharmacokinetics of ibuprofen, or ibuprofen-induced faecal blood loss in one study. Ibuprofen does not affect the pharmacokinetics of moclobemide.

Clinical evidence, mechanism, importance and management

A study in 24 healthy subjects found that moclobemide 150 mg three times daily for 7 days had no effect on the steady-state pharmacokinetics of ibuprofen 600 mg three times daily, and the amount of ibuprofen-induced faecal blood loss was unaffected.[1] Ibuprofen did not affect the pharmacokinetics of moclobemide. No special precautions appear to be required during concurrent use.

1. Güntert TW, Schmitt M, Dingemanse J, Jonkman JHG. Influence of moclobemide on ibuprofen-induced faecal blood loss. *Psychopharmacology (Berl)* (1992) 106, S40–S42.

NSAIDs; Ibuprofen + Nitric oxide

The manufacturer of ibuprofen injection, which is used to treat patent ductus arteriosus in preterm newborn infants, warns that its use with nitric oxide, which is used to treat hypoxic respiratory failure in neonates, may in theory increase the risk of bleeding as both drugs inhibit platelet function.[1] The clinical significance of this proposed interaction is unclear, but it may be prudent to be alert for any evidence of bruising or bleeding if both drugs are given.

1. Pedea Injection (Ibuprofen). Orphan Europe (UK) Ltd. UK Summary of product characteristics, July 2004.

NSAIDs; Ibuprofen + St John's wort (*Hypericum perforatum*)

St John's wort does not affect the pharmacokinetics of ibuprofen.

Clinical evidence

Eight healthy male subjects were given an oral dose of ibuprofen 400 mg before, and at the end of, a 21 day course of St John's wort 300 mg three times daily. The pharmacokinetics of ibuprofen were unaffected by St John's wort. The St John's wort extract was standardised to contain hypericin (probably 0.3%) and a minimum of 4% hyperforin.[1]

Mechanism

As ibuprofen is a substrate for the cytochrome P450 isoenzymes CYP2C9 and CYP2C8, the authors of the study suggest that the lack of interaction is evidence that St John's wort has no significant effects on these isoenzymes.[1]

Importance and management

St John's wort does not appear to interact with ibuprofen and therefore no special precautions seem necessary on concurrent use.

1. Bell EC, Ravis WR, Lloyd KB, Stokes TJ. Effects of St. John's wort supplementation on ibuprofen pharmacokinetics. *Ann Pharmacother* (2007) 41, 229–34.

NSAIDs; Indometacin + Cocaine

An isolated report describes marked oedema, anuria and haematemesis in a premature child attributed to an interaction between cocaine and indometacin, which were taken by the mother before the birth.

Clinical evidence, mechanism, importance and management

A woman who was a cocaine user and who was in premature labour was unsuccessfully treated with terbutaline and magnesium sulfate. Indometacin proved to be more effective, but after being given 400 mg over 2 days she gave birth to a boy estimated at 34 to 35 weeks. Before birth the child was noted to be anuric and at birth showed marked oedema, and later haematemesis.

It was suggested that the anuria and oedema were due to renal vascular constriction of the foetus caused by the cocaine combined with an adverse effect of indometacin on ADH-mediated water reabsorption. Both drugs can cause gastrointestinal bleeding, which would account for the haematemesis. The authors of this report point out that one of the adverse effects of cocaine is premature labour, and that the likelihood is high that indometacin may be used to control it. They advise screening likely addicts in premature labour for evidence of cocaine usage before indometacin is given.[1]

1. Carlan SJ, Stromquist C, Angel JL, Harris M, O'Brien WF. Cocaine and indomethacin: fetal anuria, neonatal edema and gastrointestinal bleeding. *Obstet Gynecol* (1991) 78, 501–3.

NSAIDs; Indometacin + Vaccines

Some very limited evidence suggests that the response to immunisation with live vaccines may be more severe than usual in the presence of indometacin.

Clinical evidence, mechanism, importance and management

A man with ankylosing spondylitis taking indometacin 25 mg three times daily had a strong primary-type reaction 12 days after **smallpox vaccination**. He experienced 3 days of severe malaise, headache and nausea, as well as enlarged lymph nodes. The scab that formed was unusually large (3 cm in diameter) but he suffered no long term ill-effects.[1] The suggestion was that indometacin alters the response of the body to viral infections, whether originating from vaccines or not.[1] This suggestion is supported by the case of a child taking indometacin who developed haemorrhagic chickenpox during a ward outbreak of the disease.[2] However, these appear to be isolated and relatively old reports, and are therefore probably of little general importance. Note that NSAIDs such as indometacin may mask some of the signs and symptoms of infection.

1. Maddocks AC. Indomethacin and vaccination. *Lancet* (1973) ii, 210–11.
2. Rodriguez RS, Barbabosa E. Hemorrhagic chickenpox after indomethacin. *N Engl J Med* (1971) 285, 690.

NSAIDs; Ketorolac + Vancomycin

An isolated report describes temporary acute renal failure and gastrointestinal bleeding following the use of ketorolac and vancomycin.

Clinical evidence, mechanism, importance and management

A previously healthy middle-aged man developed acute renal failure and subsequent gastrointestinal bleeding following uncomplicated surgery and treatment with ketorolac trometamol and vancomycin. The reason for the temporary renal failure is not known, but the authors of the report suggest that ketorolac inhibited the normal production of the vasodilatory renal prostaglandins so that renal blood flow was reduced. This would seem to have been additive with the nephrotoxic effects of vancomycin. Note that a vancomycin level taken on postoperative day 3 was found to be above the normal therapeutic range (although the timing of the sample was not stated).[1] Ketorolac alone can cause dose-related and transient renal impairment. The gastrointestinal bleeding appeared to be due to the direct irritant effects of the ketorolac, possibly made worse by the previous use of piroxicam[1] (see also 'NSAIDs + NSAIDs', p.168). The general importance of this interaction is uncertain. As renal function should be routinely monitored in patients given vancomycin no additional precautions seem necessary, but if renal impairment develops in a patient taking both drugs, consider an interaction as a possible cause.

1. Murray RP, Watson RC. Acute renal failure and gastrointestinal bleed associated with postoperative Toradol and vancomycin. *Orthopedics* (1993) 16, 1361–3.

NSAIDs; Naproxen + Diphenhydramine

No significant pharmacokinetic interaction appears to occur between diphenhydramine and naproxen.

Clinical evidence, mechanism, importance and management

In a study in 27 healthy subjects, diphenhydramine hydrochloride 50 mg had no clinically significant effect on the pharmacokinetics of a single 220-mg dose of naproxen sodium. The pharmacokinetics of diphenhy-

dramine were similarly unaffected by naproxen.[1] No dose adjustment of either drug appears to be necessary on concurrent use.

1. Toothaker RD, Barker SH, Gillen MV, Helsinger SA, Kindberg CG, Hunt TL, Powell JH. Absence of pharmacokinetic interaction between orally co-administered naproxen sodium and diphenhydramine hydrochloride. *Biopharm Drug Dispos* (2000) 21, 229–33.

NSAIDs; Naproxen + Sulglicotide

Sulglicotide does not affect the absorption of naproxen.

Clinical evidence, mechanism, importance and management

In a study in 12 healthy subjects, sulglicotide 200 mg had no significant effects on the pharmacokinetics of a single 500-mg dose of naproxen.[1] Sulglicotide may therefore be used to protect the gastric mucosa from possible injury by naproxen without altering its absorption.

1. Berté F, Feletti F, De Bernardi di Valserra M, Nazzari M, Cenedese A, Cornelli U. Lack of influence of sulglycotide on naproxen bioavailability in healthy volunteers. *Int J Clin Pharmacol Ther Toxicol* (1988) 26, 125–8.

NSAIDs; Naproxen + Zileuton

No clinically significant pharmacokinetic or pharmacodynamic interaction appears to occur between naproxen and zileuton.

Clinical evidence, mechanism, importance and management

In a randomised, placebo-controlled study, 24 healthy subjects were given zileuton 800 mg every 12 hours with naproxen 500 mg every 12 hours for 6 days. No clinically significant change was found in the pharmacokinetics of either drug. Naproxen did not affect the inhibitory effect of zileuton on leukotriene B_4 levels and similarly zileuton did not affect the inhibitory effect of naproxen on thromboxane B_2. The inhibition of the 5-lipoxygenase pathway by zileuton did not appear to worsen the gastrointestinal effects associated with naproxen. No special precautions would seem necessary if both drugs are given.[1]

1. Awni WM, Braeckman RA, Cavanaugh JH, Locke CS, Linnen PJ, Granneman GR, Dube LM. The pharmacokinetic and pharmacodynamic interactions between the 5-lipoxygenase inhibitor zileuton and the cyclo-oxygenase inhibitor naproxen in human volunteers. *Clin Pharmacokinet* (1995) 29 (Suppl 2) 112–24.

NSAIDs; Parecoxib + Miscellaneous

As parecoxib is rapidly metabolised to valdecoxib, the interactions are usually considered to be due to the effects of valdecoxib. The manufacturer of parecoxib cautions the concurrent use of carbamazepine, dexamethasone, phenytoin and rifampicin (rifampin). Valdecoxib increases the levels of dextromethorphan and omeprazole. Because of these interactions, caution is advised with drugs that are metabolised by the same isoenzymes.

Clinical evidence, mechanism, importance and management

Parecoxib is a parenteral drug that is rapidly metabolised in the liver to the active COX-2 inhibitor valdecoxib. Valdecoxib is predominantly metabolised by the cytochrome P450 isoenzymes CYP3A4 and CYP2C9. The interactions therefore are usually considered to be due to the effects of valdecoxib.

(a) CYP2C19 substrates

The manufacturers say that the AUC of **omeprazole** 40 mg was increased by 46% by valdecoxib 40 mg twice daily for a week. This indicates that valdecoxib is an inhibitor of CYP2C19, and although the manufacturers consider it to be a weak inhibitor,[1] they advise caution if valdecoxib is given with other drugs that are known to be metabolised by CYP2C19. They name **diazepam**, **imipramine** and **phenytoin**.[2] The implication is that the serum levels of these drugs and their effects may possibly be increased by the use of parecoxib.

(b) CYP2D6 substrates

The manufacturers say that valdecoxib 40 mg twice daily for a week caused a threefold increase in the serum levels of **dextromethorphan**. This indicates that valdecoxib is an inhibitor of CYP2D6, and therefore the manufacturers[1] suggest that caution should be observed with drugs that have a narrow therapeutic margin and are known to be predominantly metabolised by CYP2D6. They list **flecainide**, **metoprolol** and **propafenone**.[2] The implication is that the serum levels of these drugs and their effects may possibly be increased by the use of parecoxib; however, a study with metoprolol and valdecoxib did not find any clinically relevant interaction, see 'Beta blockers + Aspirin or NSAIDs', p.997.

(c) Enzyme inducers

The manufacturer of parecoxib[2] warns that, although they have not been studied, enzyme inducers (they name **carbamazepine**, **dexamethasone**, **phenytoin** and **rifampicin** (**rifampin**)) may increase the metabolism of valdecoxib. It may therefore be prudent to monitor the outcome of concurrent use for valdecoxib efficacy. However, note that dexamethasone does not usually appear to interact to a clinically relevant extent by this mechanism.

1. Pharmacia Ltd. Personal communication, May 2002.
2. Dynastat (Parecoxib sodium). Pfizer Ltd. UK Summary of product characteristics, July 2009.

NSAIDs; Phenylbutazone + Methylphenidate

Methylphenidate significantly increased the serum levels of phenylbutazone 200 to 400 mg daily in 5 out of 6 patients, due, it is suggested, to inhibition of liver metabolising enzymes.[1] The clinical importance of effect this is uncertain, especially as the report does not indicate the magnitude of the interaction.

1. Dayton PG, Perel JM, Israili ZH, Faraj BA, Rodewig K, Black N, Goldberg LI. Studies with methylphenidate: drug interactions and metabolism. In: Sellers EM ed. Clinical Pharmacology of Psychoactive Drugs. Ontario: Addiction Research Foundation, 1973. p183–202.

NSAIDs; Sulindac + Dimethyl sulfoxide (DMSO)

Isolated case reports describe serious peripheral neuropathy, which occurred when DMSO was applied to the skin of two patients taking sulindac.

Clinical evidence, mechanism, importance and management

A man with a long history of degenerative arthritis took sulindac 400 mg daily uneventfully for 6 months until, without his doctor's knowledge, he began regularly to apply a topical preparation containing DMSO 90% to his upper and lower extremities. Soon afterwards he began to experience pain, weakness in all his extremities, and difficulty in standing or walking. He was found to have both segmental demyelination and axonal neuropathy. He made a partial recovery but was unable to walk without an artificial aid.[1]

A second case describes a 68-year-old man with a history of mild osteoarthritis of the knees who was taking sulindac 150 mg twice daily. He later started to apply aqueous solutions of DMSO to his lower extremities, whilst continuing to take sulindac. Within 3 months he reported difficulty in climbing stairs, and myalgia of the thighs and legs. Over the next 5 months he experienced a progressive loss of gait, wasting of thigh and leg muscles, and more intense myalgia, cramps and fasciculations. Nerve conduction studies revealed damage to the nerves. During the year after discontinuing the DMSO, and supplementing his diet with vitamins B_6 and B_{12}, the patient had an improvement in the myalgia and physical disabilities, and a return to normal muscle strength. He continued to take the sulindac at a dose of 200 mg twice daily.[2]

The reason for this reaction is not known, but studies in *rats* have shown that DMSO can inhibit a reductase enzyme by which sulindac is metabolised,[3] and it may be that the high concentrations of unmetabolised sulindac increased the neurotoxic activity of the DMSO. Although there are only these two cases on record, its seriousness suggests that patients should not use sulindac and DMSO-containing preparations concurrently.

Opioids + Amfetamines and related drugs

Dexamfetamine and methylphenidate increase the analgesic effects of morphine and other opioids but reduce their sedative and respiratory depressant effects.

Clinical evidence, mechanism, importance and management

In studies during postoperative analgesia[1] and in healthy subjects,[2] **dexamfetamine** increased the analgesic effect of **morphine** and reduced its respiratory depressant effects to some extent. **Methylphenidate** 15 mg daily similarly increased the analgesic effects of various opioids (**morphine**, **hydromorphone**, **levorphanol**, **oxycodone**) and reduced the sedative effects in patients with chronic pain due to advanced cancer.[3] Similarly, two manufacturers of amfetamines advise that amfetamines potentiate the analgesic effects of **pethidine** (**meperidine**).[4,5] Therefore, the analgesic dose of an opioid may be lower than expected in patients taking amfetamines. The manufacturers also note that, in cases of **dextropropoxyphene** (**propoxyphene**) *overdose*, amfetamine CNS stimulation is potentiated and fatal convulsions can occur.[4,5]

Opioids + Antiemetics

Metoclopramide increases the rate of absorption of oral morphine and increases its rate of onset and sedative effects. Opioids may antagonise the effects of metoclopramide on gastric emptying. The use of droperidol with opioids can be beneficial, but an increase in sedation appears to occur.

Clinical evidence

(a) Alizapride

Intravenous alizapride 100 mg given to 60 women undergoing caesarean section under spinal anaesthesia, reduced **morphine**-induced pruritus, and the amount of sedation (8.3% both peri- and postoperatively) was less than with droperidol,[1] see below.

(b) Droperidol

1. Fentanyl. Epidural droperidol given with epidural fentanyl improved postsurgical analgesia following anorectal surgery and there was less nausea compared with fentanyl alone.[2]

2. Hydromorphone. Early respiratory depression has been reported when droperidol was given 10 minutes before epidural hydromorphone 1.25 mg; the patient became apnoeic 15 minutes after the epidural was given. Naloxone did not reverse the respiratory depression, but spontaneous ventilation resumed within 3 minutes of a 1-mg intravenous dose of physostigmine.[3]

3. Morphine. In a double-blind study in 179 patients following abdominal hysterectomy, droperidol 50 micrograms given with morphine 1 mg on demand via patient-controlled analgesia (PCA) provided a morphine-sparing effect and reduced the frequency of postoperative nausea and vomiting, when compared with morphine PCA alone.[4] However, in a study of 107 patients undergoing caesarean section, intravenous droperidol 2.5 mg given just after delivery reduced the incidence and severity of epidural morphine-induced pruritus, but the incidence of nausea and vomiting was not affected. Furthermore, somnolence was greater in the droperidol-treated patients (17% versus 2% in the control group) but it was never incapacitating.[5] Similar sedative effects were seen with spinal morphine and intravenous droperidol in another study.[1]

(c) Metoclopramide

1. Butorphanol. In a study in 24 healthy women, the pharmacokinetics of a single 1-mg intranasal dose of butorphanol were unaffected by a single 10-mg oral dose of metoclopramide. The pharmacokinetics of metoclopramide were also not affected, except for a delay in the time to reach maximum plasma levels (increased from one hour to 2 hours), which was probably due to reduction of gastrointestinal motility by butorphanol.[6] Metoclopramide reduced the nausea associated with butorphanol, probably by antagonism of central and peripheral dopamine receptors.[7]

2. Morphine. A single 10-mg dose of oral metoclopramide, given to 10 patients before surgery, markedly increased the extent and speed of sedation due to a 20-mg oral dose of modified-release morphine (*MST Continus Tablets*) in the first 1.5 hours after the dose. The time to peak plasma levels of morphine was almost halved, but peak plasma morphine levels and the total absorption remained unaltered.[7] A study involving 40 patients found that intravenous metoclopramide 10 mg antagonised the reduction in gastric emptying caused by premedication with intramuscular morphine 10 mg, given 20 minutes earlier. However, intramuscular metoclopramide given at the same time as the morphine had no effect on the reduced gastric emptying.[8]

Mechanism

Metoclopramide increases the rate of gastric emptying so that the rate of morphine absorption from the small intestine is increased. An alternative mechanism is that both drugs act additively on opiate receptors to increase sedation.[7] Droperidol may also enhance adverse effects such as sedation, and in some cases respiratory depression, possibly through opioid and other receptor sites in the CNS.[2] In one case, the respiratory depression was not reversed by naloxone, suggesting that droperidol was at least partially if not completely responsible.[3]

Importance and management

The effect of metoclopramide on oral morphine absorption is an established interaction that can be usefully exploited in anaesthetic practice, but the increased sedation may also present a problem if the morphine is being given long-term. The morphine-sparing effect of droperidol is also a useful interaction, but the increased sedation and possible respiratory depression and hypotension should be borne in mind. One manufacturer of fentanyl specifically warns that the concurrent use of droperidol can result in a higher incidence of hypotension.[9]

Morphine appears to antagonise the effects of metoclopramide on gastric emptying. As a reduction in gastric motility occurs with all opioids they would all be expected to interact with metoclopramide, and other motility stimulants such as **domperidone**. However, these drugs are commonly used together and the clinical significance of such effects is not clear.

Note that some sedating antihistamines, such as **cyclizine**, are also used as antiemetics, and additive sedation is likely to occur on concurrent use.

Opioids + Antiemetics; Ondansetron

Ondansetron reduces the analgesic efficacy of tramadol and at least doubled the tramadol dose required in one clinical study. This resulted in more vomiting despite the use of ondansetron. In

contrast, in studies in healthy subjects, ondansetron had no effect on the analgesic effects of morphine and alfentanil.

Clinical evidence

(a) Alfentanil

In a study in healthy subjects, single 8- or 16-mg doses of intravenous ondansetron were found to have no effect on the sedation or ventilatory depression due to alfentanil (a continuous infusion of 0.25 to 0.75 micrograms/kg following a 5-micrograms/kg bolus dose) and had no effect on the rate of recovery.[1] Similarly, in another study, intravenous ondansetron 8 mg did not oppose the analgesic effect of intramuscular alfentanil 30 micrograms/kg on experimentally-induced pain stimuli.[2]

(b) Morphine

A double-blind, placebo-controlled study in 12 healthy subjects found that a single 16-mg intravenous dose of ondansetron given 30 minutes after a single 10-mg intravenous dose of morphine did not alter the pharmacokinetics of morphine or its metabolites, morphine-3-glucuronide and morphine-6-glucuronide. The analgesic effect of morphine (as measured by a contact thermode system) was also unaffected by ondansetron.[3]

(c) Tramadol

Patients who were given a single 4-mg dose of ondansetron one minute before induction of anaesthesia required 26 to 35% more intravenous tramadol by patient controlled analgesia (PCA) from one to 4 hours postoperatively than those who received placebo.[4] Similarly, a 1-mg/hour ondansetron infusion increased the dose of postoperative intravenous tramadol given using a PCA pump by two- to threefold in 30 patients, when compared with 29 patients who received placebo. Moreover, in this study the group receiving ondansetron actually experienced more vomiting, probably because they used more tramadol, which caused an emetic effect not well controlled by the ondansetron.[5]

Mechanism

On theoretical grounds ondansetron (a 5-HT_3-receptor antagonist) might be expected to decrease the effects of drugs that reduce pain transmission because serotonin (5-HT) is thought to affect pain responses via presynaptic 5-HT_3 receptors in the spinal dorsal horn. This has been demonstrated for tramadol, which is not a pure opioid and also acts by enhancing the effects of serotonin and noradrenaline (norepinephrine). However, ondansetron had no effect on alfentanil or morphine analgesia in healthy subjects.

Importance and management

Although there is only data from two clinical studies, the interaction between ondansetron and tramadol appears to be established and of clinical importance. Ondansetron may double the dose requirement of tramadol, and so result in reduced pain control. The increase in dose requirements appears to increase nausea and vomiting which may not be sufficiently controlled by the ondansetron. Consequently ondansetron does not appear to be the best antiemetic to use with tramadol.[3] Although not tested, other 5-HT_3-receptor antagonists would be expected to interact similarly.

Ondansetron appears to have no effect on alfentanil or morphine.

Opioids + Antiepileptics; Enzyme-inducing

Patients taking enzyme-inducing antiepileptics appear to need more fentanyl than those not taking these antiepileptics. Similarly, the efficacy of buprenorphine may be reduced by carbamazepine, phenobarbital and phenytoin. Carbamazepine appears to increase the production of a more potent metabolite of codeine, normorphine. The plasma levels of tramadol are reduced by carbamazepine, and the analgesic efficacy would be expected to be reduced. There is also an increased risk of seizures with tramadol. A pharmacokinetic study confirms that phenytoin increases the production of the toxic metabolite of pethidine (meperidine). An isolated report describes pethidine toxicity in a man taking phenytoin.

Clinical evidence, mechanism, importance and management

(a) Buprenorphine

Although interaction studies have not been performed, the metabolism of buprenorphine is mediated by the cytochrome P450 isoenzyme CYP3A4 and therefore drugs that induce this isoenzyme such as **carbamazepine**, **phenobarbital** and **phenytoin** may induce the metabolism and increase the clearance of buprenorphine.[1,2] The manufacturers of buprenorphine state that inducers of CYP3A4 may reduce the efficacy of buprenorphine[1-3] and, if necessary, dose adjustments should be considered,[2] or the combination avoided.[1]

(b) Codeine

An experimental study in 7 patients with epilepsy, to find out if **carbamazepine** induces the enzymes concerned with the metabolism of codeine, found that it increased *N*-demethylation (to norcodeine and normorphine) by two- to threefold, but did not affect *O*-demethylation (to morphine). The patients were given a single 25-mg dose of codeine before and 3 weeks after starting to take **carbamazepine** 400 to 600 mg daily.[4] Similarly, an *in vitro* study found that **carbamazepine** and **phenytoin** did not alter the *O*-demethylation of codeine (methylmorphine) into morphine.[5]

Normorphine is an active metabolite, so that the authors of the first study suggest those taking both codeine and **carbamazepine** may possibly experience a stronger analgesic effect.[4] However, this needs further study. There would seem to be no reason for avoiding concurrent use.

(c) Dextropropoxyphene (Propoxyphene)

Dextropropoxyphene may increase the plasma levels of antiepileptics, particularly carbamazepine, see 'Carbamazepine or Oxcarbazepine + Dextropropoxyphene (Propoxyphene)', p.603.

(d) Fentanyl

Twenty-eight patients, undergoing craniotomy for seizure focus excision and receiving long-term treatment with antiepileptics in various combinations, needed 48 to 144% more fentanyl during anaesthesia than a control group of 22 patients who were not taking antiepileptics.[6] The fentanyl maintenance requirements were:

- 2.7 micrograms/kg per hour in the control group,
- 4 micrograms/kg per hour in patients taking **carbamazepine**,
- 4.7 micrograms/kg per hour in patients taking **carbamazepine** and **phenytoin** or **valproate**,
- 6.3 micrograms/kg per hour in patients taking **carbamazepine**, **valproate** and either **phenytoin** or **primidone**.

Similar results were reported by the same authors in a study involving 61 patients.[7] The increased opioid requirement probably occurs because these antiepileptics are potent enzyme inducers (with the exception of **valproate**), which increase the metabolism of fentanyl by the liver, so that its levels are reduced.[6] Changes in the state of opiate receptors induced by long-term antiepileptic exposure may also be involved.[7] A marked increase in the fentanyl requirements should therefore be anticipated in any patient receiving long-term treatment with **carbamazepine**, **primidone** or **phenytoin**. No fentanyl dose adjustment is expected to be needed with **valproate**.

(e) Methadone

Methadone levels can be reduced by carbamazepine, phenobarbital or phenytoin. See 'Opioids; Methadone + Antiepileptics', p.180.

(f) Pethidine (Meperidine)

A 61-year-old man who was addicted to pethidine, taking 5 to 10 g weekly, developed repeated seizures and myoclonus when he also took **phenytoin**. The problem resolved when both drugs were stopped.[8] It is known that **phenytoin** increases the metabolism of pethidine with increased production of norpethidine,[9] the metabolite of pethidine that is believed to be responsible for its neurotoxicity (seizures, myoclonus, tremors etc). A

study[10] in healthy subjects found that **phenytoin** 300 mg daily for 9 days decreased the elimination half-life of pethidine (100 mg orally and 50 mg intravenously) from 6.4 hours to 4.3 hours, and the systemic clearance increased by 27%. This seems to be the only report of an adverse interaction between **phenytoin** and pethidine so its general importance is uncertain.[8] As the study cited[10] found that pethidine given orally produced more of the toxic metabolite (norpethidine) than when given intravenously, it may be preferable to give pethidine intravenously in patients taking **phenytoin**, or use an alternative opioid. Consider also 'Opioids + Barbiturates', p.183, for the possible interaction between phenobarbital and pethidine.

(g) Tramadol

An unpublished study by the manufacturers found that the maximum plasma levels and the elimination half-life of a single 50-mg dose of tramadol were reduced by 50% by **carbamazepine** 400 mg twice daily for 9 days.[11] It is likely that **carbamazepine** increases the metabolism of tramadol. On the basis of this study the manufacturers say that the analgesic effectiveness of tramadol[12,13] and its duration of action would be expected to be reduced.[11,13] The US manufacturer recommends avoidance of concurrent use because of the increased metabolism and also the seizure risk associated with tramadol.[12] The UK manufacturer says that patients with a history of epilepsy or those susceptible to seizures should only be given tramadol if there are compelling reasons.[13] Monitor carefully if tramadol and antiepileptics, particularly **carbamazepine**, are required.

Opioids + Antiepileptics; Gabapentin

Morphine can increase the bioavailability of gabapentin. Gabapentin has been reported to enhance the analgesic effects of morphine and other opioids.

Clinical evidence, mechanism, importance and management

A single-dose, placebo-controlled study in 12 healthy subjects given controlled-release **morphine** 60 mg found that gabapentin 600 mg, given after an interval of 2 hours, had no effect on the pharmacokinetics of morphine, morphine-3- and morphine-6-glucuronides. In the presence of **morphine** the gabapentin AUC increased by 44% and its oral clearance and apparent renal clearance decreased by 23% and 16%, respectively. These changes may possibly be due to an increase in the absorption of gabapentin caused by reduced intestinal motility by morphine. The analgesic effect of **morphine** and gabapentin was evaluated by changes in the area under the curve of pain tolerance. Gabapentin with placebo had no significant analgesic effect, but a significant increase in the pain threshold and pain tolerance was found when gabapentin was given with morphine, when compared with placebo. The adverse effect profiles were similar for both the gabapentin with morphine and the morphine with placebo groups.[1] Other clinical studies have reported that gabapentin used in conjunction with opioids has an analgesic and opioid-sparing effect in acute postoperative pain management[2,3] and neuropathic pain.[4]

The modest changes in gabapentin pharmacokinetics seen in the study with morphine are unlikely to require a gabapentin dose adjustment. However, the manufacturer of gabapentin warns that patients should be carefully observed for signs of CNS depression (a pharmacodynamic effect), such as somnolence, and the dose of gabapentin or **morphine** should be reduced appropriately.[5]

Opioids; Methadone + Antiepileptics

Methadone levels can be reduced by carbamazepine, phenobarbital or phenytoin and opioid withdrawal symptoms may occur. Valproate does not appear to interact with methadone. An isolated report describes lamotrigine-associated rash and blood dyscrasias, which may have been associated with methadone use.

Clinical evidence

(a) Enzyme-inducing antiepileptics

A study in 37 patients taking methadone maintenance found that the 10 patients taking enzyme-inducing drugs (**carbamazepine**, **phenobarbital** or **phenytoin**) had low trough methadone levels of less than 100 nanograms/mL. One patient taking **carbamazepine** complained of daily withdrawal symptoms and had signs of opioid withdrawal.[1] Withdrawal symptoms have been seen in other patients taking **carbamazepine**,[2] **phenobarbital**,[3] and **phenytoin**.[1,2,4,5] Similarly, methadone withdrawal symptoms developed in 5 patients within 3 to 4 days of starting to take **phenytoin** 300 to 500 mg daily. Methadone plasma levels were reduced by about 60%. The withdrawal symptoms disappeared within 2 to 3 days of stopping **phenytoin** and the plasma methadone levels returned to their former values.[6] A further patient experienced methadone-induced respiratory depression after discontinuing **carbamazepine**.[7]

(b) Lamotrigine

Lamotrigine-associated rash and blood dyscrasias occurred in a 40-year-old opioid-dependent woman with hepatitis C. Lamotrigine was considered to be the causal factor as haematological values returned to normal 53 days after discontinuation. However, the woman was also receiving methadone maintenance and it was thought that the methadone, together with liver impairment, might possibly have caused elevated levels of lamotrigine (but note that these were not measured).[8]

(c) Valproate

Two patients who had methadone withdrawal symptoms while taking phenytoin 300 to 400 mg daily, and one of them later when taking carbamazepine 600 mg daily, became free from withdrawal symptoms when they were given valproate instead. It was also found possible to virtually halve their daily methadone dose.[2]

Mechanism

Not fully established, but carbamazepine, phenobarbital and phenytoin are recognised inducers of the cytochrome P450 isoenzyme CYP3A4, by which methadone is, in part, metabolised, and therefore increase methadone metabolism and its loss from the body. In one study it was found that phenytoin increased the urinary excretion of the main metabolite of methadone.[6]

Importance and management

Information is limited but the interaction between methadone and the enzyme-inducing antiepileptics, carbamazepine, phenobarbital and phenytoin, appears to be established and of clinical importance. Anticipate the need to increase the methadone dose in patients taking these antiepileptics. It may be necessary to give the methadone twice daily to prevent withdrawal symptoms appearing towards the end of the day. It seems probable that **primidone** and **fosphenytoin** will interact similarly because they are metabolised to phenobarbital and phenytoin, respectively. Also be aware of the need to reduce the methadone dose if any enzyme-inducing antiepileptic is stopped. Valproate appears not to interact.

It is unclear whether the methadone or the liver impairment contributed to the lamotrigine-associated rash and blood dyscrasias and therefore this isolated case is of unknown general significance.

Opioids + Antihistamines

Increased respiratory depression has been seen with hydroxyzine and opioids in one study,[1] but not in two others.[2,3] The US manufacturer of hydroxyzine warns that it may enhance the effects of pethidine (meperidine).[4] A reduction in dose may be necessary. All sedating antihistamines (see 'Table 15.1', (p.663)) would be expected to have additive CNS depressant effects with opioids. This may lead to increased sedation and respiratory depression, and therefore some caution is warranted when both drugs are given.

Opioids + Azoles

Several of the opioids (buprenorphine, hydromorphone, methadone) are metabolised by CYP3A, at least in part, and their metabolism is expected to be reduced by the azoles, which, to varying extents, inhibit CYP3A4. This has been seen when fluconazole and voriconazole are given with methadone, and when ketoconazole is given with buprenorphine. No interaction appears to occur between transdermal buprenorphine and ketoconazole. It has also been suggested that ketoconazole inhibits the metabolism of morphine and oxycodone, but evidence for this is sparse.

Clinical evidence

(a) Buprenorphine

Ketoconazole increased the AUC of buprenorphine by approximately 50% and increased its maximum level by approximately 70% in one study. The levels of the metabolite, norbuprenorphine, were also affected but to a lesser extent.[1] In contrast, a study in 20 healthy subjects reported no clinically significant change in the levels of transdermal buprenorphine 10 mg or its metabolites when it was given with oral ketoconazole 200 mg twice daily for 7 days.[2]

(b) Methadone

1. Fluconazole. A randomised, double-blind, placebo-controlled study in 25 patients taking maintenance methadone found that fluconazole 200 mg daily for 2 weeks increased the steady-state serum methadone levels and AUC by about 30%, but no signs of methadone overdose were seen and no changes in the methadone dose were needed.[3] However, a case report describes a man with advanced cancer who had received regular methadone 20 mg every 8 hours and one to three 5-mg rescue doses daily for 10 days, who rapidly developed respiratory depression of 4 breaths per minute and became unresponsive 4 days after starting fluconazole 100 mg daily, initially orally, then intravenously. Within a few minutes of receiving naloxone he regained consciousness and his respiratory rate increased.[4]

2. Ketoconazole. An *in vitro* study suggested that ketoconazole decreased the hepatic metabolism of methadone by about 50 to 70%.[5]

3. Voriconazole. In a double-blind, placebo-controlled study in 23 patients taking methadone, voriconazole 400 mg twice daily for one day then 200 mg twice daily for 4 days increased the AUC of *R*-methadone (active) by 47% and *S*-methadone (inactive) by 103%. Methadone appeared to have no effect on voriconazole pharmacokinetics when compared with a reference study in healthy subjects. There were no signs or symptoms of significant opioid withdrawal or overdose and the combination was generally well tolerated.[6]

Mechanism

As the metabolism of methadone is, in part, mediated by the cytochrome P450 isoenzyme CYP3A4,[7] methadone clearance can be decreased by drugs that inhibit CYP3A4 activity such as azole antifungals. Buprenorphine is also metabolised by CYP3A4[8] and may therefore be similarly affected. Most azoles inhibit CYP3A4 to a greater or lesser extent. Although ketoconazole may significantly inhibit the *N*-demethylation of **oxycodone** to noroxycodone by CYP3A4 *in vitro*,[9] as oxycodone metabolism also by CYP2D6, the overall effect would be expected to be less than that seen with opioids predominantly metabolised by CYP3A4. *In vitro* studies suggest that ketoconazole may inhibit **hydromorphone** metabolism by CYP3A4[10] and **morphine** glucuronidation.[11]

Importance and management

It has been suggested that although a statistically significant pharmacokinetic interaction occurs between **methadone** and fluconazole, it is unlikely to be clinically important.[3] However, the serious case report of respiratory depression with fluconazole and methadone introduces a note of caution. Caution is also advised if voriconazole is given with methadone, and a dose reduction of methadone may be required, although the combination was reported as being generally well tolerated.[6] Caution may also be warranted on the concurrent use of methadone and other azoles, as they all inhibit CYP3A4 to a greater or lesser extent.

Patients given ketoconazole with sublingual or intravenous buprenorphine should be closely monitored for an increase in buprenorphine adverse effects (such as drowsiness, nausea and vomiting) and a buprenorphine dose reduction considered as necessary; one manufacturer recommends that the dose of sublingual **buprenorphine** for treating opioid addiction should be halved when starting treatment with ketoconazole.[1] However, another manufacturer of both sublingual and intravenous preparations of buprenorphine suggests that, as the magnitude of the inhibitory effect is unknown, such drug combinations should be avoided.[12,13] Itraconazole, posaconazole and voriconazole would also be expected to interact similarly, as they are also potent inhibitors of CYP3A4. In contrast, based on the study reported above, one manufacturer of a transdermal buprenorphine product states that ketoconazole did not interact to a clinically relevant extent with buprenorphine,[14] therefore, no precaution appears to be necessary in patients using *transdermal* buprenorphine.

The clinical significance of the potential effects of azoles on other opioids, such as **hydromorphone**, and **morphine** is unclear. The UK manufacturer of oxycodone advises that inhibitors of CYP3A enzymes such as **ketoconazole** may inhibit the metabolism of oxycodone.[15]

Opioids; Fentanyl and related drugs + Azoles

Some patients may experience prolonged and increased alfentanil effects if they are given fluconazole or voriconazole; itraconazole and ketoconazole may interact similarly. Fluconazole and voriconazole inhibit the metabolism of fentanyl, and a fatality possibly due to the interaction with fluconazole and transdermal fentanyl has been reported. Itraconazole may interact similarly, but the evidence is conflicting.

Clinical evidence

(a) Alfentanil

A double-blind, randomised, crossover study in 9 healthy subjects given intravenous alfentanil 20 micrograms/kg after receiving **fluconazole** 400 mg, orally or by infusion, found that fluconazole reduced alfentanil clearance by about 60%. Both the alfentanil-induced ventilatory depression and its subjective effects were increased.[1]

A randomised, crossover study in 12 healthy subjects found that oral **voriconazole** (400 mg twice daily on the first day and 200 mg twice daily on the second day) caused an approximately fivefold increase in the mean AUC of intravenous alfentanil 20 micrograms/kg, given one hour after the last dose of the antifungal. The mean plasma clearance of alfentanil was decreased by 85% and its elimination half-life was prolonged from 1.5 hours to 6.6 hours. Visual adverse effects, nausea and vomiting occurred in 6, 5 and 4 subjects, respectively.[2]

In vitro data indicate that **ketoconazole** and **itraconazole** may interact in a similar way.[3-5]

(b) Fentanyl

In a crossover study in 10 healthy subjects the pharmacokinetics and pharmacodynamics of a single 3-micrograms/kg intravenous dose of fentanyl were not altered by **itraconazole** 200 mg daily for 4 days.[6] However, the manufacturer says that increased fentanyl plasma concentrations have been observed in individual subjects taking **itraconazole**,[7] and a case report describes a man with cancer and severe oropharyngeal candidiasis receiving *transdermal* fentanyl 50 micrograms/hour who developed signs of opioid toxicity (agitated delirium, bilateral myoclonus of muscles in the hand) the day after starting oral **itraconazole** 200 mg twice daily.[8]

A study in 12 healthy subjects reported that oral **voriconazole** (400 mg twice daily on day one followed by 200 mg twice daily on day 2) reduced the mean plasma clearance of a single intravenous dose of fentanyl 5 micrograms/kg by 23% and increased the AUC of fentanyl and its metabolite, norfentanyl, by 39% and 56%, respectively. The same study also found that oral **fluconazole** (400 mg on day one followed by 200 mg on day 2) reduced the clearance of the same dose of intravenous fentanyl by 16% and reduced the AUC of norfentanyl by 56%.[9] A patient receiving *transdermal* fentanyl 150 micrograms/hour for at least 3 weeks started taking oral **fluconazole** 50 mg daily but died 3 days later. Post-mortem analysis found a toxic level of fentanyl in the patient's blood and a high concentration of **fluconazole**, which the authors of this report attribute to an interaction between the fluconazole and fentanyl.[10]

Mechanism

Itraconazole, ketoconazole and voriconazole are potent inhibitors, and fluconazole is a moderate inhibitor, of the cytochrome P450 isoenzyme CYP3A4 in the liver, which is concerned with the metabolism of alfentanil and fentanyl. Other azoles also affect this isoenzyme. However, fentanyl has a high hepatic extraction, and so is more affected by changes in hepatic blood flow than changes in the isoenzymes responsible for its metabolism; it is therefore less affected by CYP3A inhibitors than alfentanil. **Sufentanil**, is similarly metabolised, but also has a high hepatic extraction and is therefore less likely to be affected by changes in liver metabolism.

Importance and management

The interaction of **alfentanil** with the azole antifungals appears to be established and clinically important. It is unlikely that a small, single dose of alfentanil will need adjustment.[2] Multiple doses or continuous infusions of alfentanil should be given with care to patients taking azole antifungals, as the clearance of alfentanil may be significantly reduced and its effects increased; it may be necessary to use a lower initial alfentanil dose.[2,4] Be alert for evidence of prolonged alfentanil effects, particularly respiratory depression, even after a single dose.

Although, itraconazole had no effect on the pharmacokinetics of intravenous **fentanyl** in one single-dose study, fluconazole and voriconazole have been reported to interact and the case reports involving *transdermal* fentanyl support the evidence for a possible clinically significant interaction. Caution should be used if azole antifungals are given concurrently with fentanyl, and a fentanyl dose adjustment should be considered, particularly in those patients with unstable advanced disease, or taking multiple medications that inhibit CYP3A4. Close monitoring is recommended. Although there is no specific information, this advice should probably also apply to all azoles (see *Mechanism*, above).

Opioids + Baclofen

The analgesic effects of fentanyl and morphine, but probably not pentazocine, may be increased by baclofen. Increased sedation may occur and the risk of respiratory depression may increase if opioids are given with baclofen.

Clinical evidence, mechanism, importance and management

A study in three groups of 10 patients found that pretreatment with baclofen 600 micrograms/kg, either in four intramuscular doses for 5 days, or intravenously in 100 mL of glucose 5%, 45 minutes before surgery, prolonged the duration of **fentanyl** analgesia from 18 minutes to 30 minutes. Baclofen also reduced the amount of **fentanyl** needed by 30 to 40%.[1]

In a placebo-controlled study in 69 patients undergoing surgery for the removal of third molar teeth, oral baclofen (5 mg three times daily for 3 days and then a 10-mg dose, 6 hours before surgery and again immediately before surgery) enhanced the postoperative analgesic effect of intravenous **morphine** 6 mg. However, analgesia due to intravenous **pentazocine** 30 mg was not enhanced.[2]

These limited reports suggest that baclofen may potentiate the effects of **fentanyl** and **morphine**. The reasons for this effect are not understood, but it may be connected in some way with the action of baclofen on GABA receptors, as the spinal cord circuits that are important in opioid analgesia contain GABAergic receptors.[1,2] It appears that baclofen enhances the analgesic effect of **fentanyl** and **morphine**, which are pure opioid agonists that act primarily through μ-opioid receptors, whereas it does not affect pentazocine, a predominantly κ-opioid analgesic.[2]

The manufacturer of baclofen warns that increased sedation may occur

if baclofen is taken with synthetic opioids and that the risk of respiratory depression is also increased. Careful monitoring of respiratory and cardiovascular functions is essential.[3]

Opioids + Barbiturates

A case of increased sedation with severe CNS toxicity has been reported with concurrent use of pethidine (meperidine) and phenobarbital. The analgesic effects of pethidine can be reduced by barbiturates. Secobarbital increases the respiratory depressant effects of morphine. Other barbiturates would also be expected to increase the CNS depressant effects of opioids.

Clinical evidence

(a) Codeine

A study in pain-free patients found that codeine 60 mg increased the hypnotic actions of **secobarbital** 100 mg resulting in synergism in the sedative effects.[1]

(b) Morphine

In a study in 30 healthy subjects, both intravenous **secobarbital** and intravenous morphine depressed respiration when given alone, and a much greater and more prolonged respiratory depression occurred when they were given together.[2]

(c) Pethidine (Meperidine)

1. Increased pethidine toxicity. A woman whose pain had been satisfactorily controlled with pethidine without particular CNS depression, had prolonged sedation with severe CNS toxicity when she was given pethidine after taking **phenobarbital** 30 mg four times daily for 2 weeks.[3]

2. Pethidine effects reduced. Studies in women undergoing dilatation and curettage found that **thiopental** and **pentobarbital** increased their sensitivity to pain, and opposed the analgesic effects of pethidine.[4] This confirmed the findings of previous studies.[5] A marked reduction in the analgesic effect of pethidine has been seen for up to 5 hours after high doses (6 to 10 mg/kg) of **thiopental**.[4] This reduction in efficacy also occurred with **phenobarbital**.[4]

Mechanism

Studies suggest that phenobarbital stimulates the liver enzymes concerned with the metabolism (*N*-demethylation) of pethidine (meperidine) so that the production of its more toxic metabolite (norpethidine) is increased. The toxicity seen appears to be the combined effects of this compound and the directly sedative effects of the barbiturate.[3,6]

Importance and management

Although phenobarbital has been seen to alter the metabolism of pethidine (meperidine) there is only one report of toxicity. The general clinical importance of this interaction is therefore uncertain. It has also been suggested that if pethidine is continued but phenobarbital is suddenly withdrawn, the toxic levels of norpethidine might lead to convulsions in the absence of an antiepileptic.[3] Note that the metabolite, norpethidine, is a less effective analgesic than pethidine and its increased production may increase the risk of CNS toxicity. Concurrent use should therefore be undertaken with care.

Both the barbiturates and the opioids have CNS depressant effects, which would be expected to be additive. The manufacturers of several opiates specifically mention that barbiturates can potentiate the adverse effects of opioids, such as sedation and respiratory depression. Care is therefore warranted on concurrent use. Note that most of the manufacturers of **methadone** also advise caution with other CNS depressants; however, one manufacturer suggests concurrent use is not advised.[7] For comment on the effect of phenobarbital on methadone metabolism, see 'Opioids; Methadone + Antiepileptics', p.180.

Be aware that the barbiturates may reduce the analgesic effects of the opioids, but the clinical relevance of this is unclear. Any effect is probably of most relevance in patients that have been titrated to stable doses of opioids.

For comment on the effect of phenobarbital on opioid metabolism, see 'Opioids + Antiepileptics; Enzyme-inducing', p.179.

Opioids + Benzodiazepines

In general the concurrent use of opioids and benzodiazepines results in both beneficial analgesic effects, and enhanced sedation and respiratory depression; however, in some cases benzodiazepines have antagonised the respiratory depressant effects of opioids, and, rarely, have antagonised their analgesic effects.

Clinical evidence, mechanism, importance and management

(a) Analgesia

In one study, low-dose **midazolam** (given to achieve levels of 50 nanograms/mL) reduced the dose of **morphine** required for postoperative analgesia in the first 12 hours.[1] However, in another study postoperative pain scores were higher in patients premedicated with oral **diazepam** 10 mg than with placebo, although **morphine** consumption did not differ.[2] Similarly, in another study, the benzodiazepine antagonist flumazenil enhanced **morphine** analgesia in patients who had been premedicated with **diazepam**.[3] It is suggested that benzodiazepines antagonise the analgesic effect of opioids via their effect on supraspinal GABA receptors. Why this has been shown in some studies, but not others, is unclear. Benzodiazepines and opioids are commonly used in surgical anaesthesia, and the relevance of these findings to clinical practice is uncertain.

(b) Overdose

Sudden deaths in patients who abuse opioids are frequently associated with ingestion of other CNS depressants, particularly benzodiazepines. One retrospective study found that 96 of 172 deaths related to **oxycodone** use were reported to have additionally used benzodiazepines (**alprazolam** or **diazepam** in 83 cases).[4] Cases have been reported with **buprenorphine**,[5,6] **oxycodone**,[7] and **tramadol**[8] taken with various benzodiazepines. It has not been established exactly why this occurs, but both pharmacodynamic and pharmacokinetic mechanisms are possible. The deleterious interaction of benzodiazepines and opioids on respiration is possibly due to central effects and/or additive actions on the different neuromuscular components of respiration.[9] For **buprenorphine**, it is considered most likely that excessive CNS depression is solely due to combined pharmacological effects, and not to any pharmacokinetic interaction with benzodiazepines.[10-12]

(c) Pharmacokinetics

A study involving 22 female patients given either intramuscular **pethidine** (**meperidine**) 100 mg or intramuscular **morphine** 10 mg found that the opioids delayed the absorption of oral **diazepam** 10 mg, taken 60 minutes after the opioids. Diazepam levels were found to be lower and peak levels were not reached in the 90-minute study period, when compared with the peak level at 60 minutes in the control group.[13] The underlying mechanism is that the opioid analgesics delay gastric emptying so that the rate of absorption of **diazepam** is reduced. The maximal effect of diazepam would be expected to be delayed in patients receiving these opioids.

Another study in healthy subjects found that **dextropropoxyphene** 65 mg every 6 hours prolonged the **alprazolam** half-life from 11.6 hours to 18.3 hours, and decreased its clearance by 38% (from 1.3 to 0.8 mL/minute per kg). The pharmacokinetics of single doses of **diazepam** and **lorazepam** were not significantly affected by **dextropropoxyphene**.[14] It would seem that **dextropropoxyphene** inhibits the hydroxylation of **alprazolam** by the liver, thereby reducing its clearance from the body, but has little or no effect on the *N*-demethylation or

glucuronidation of **diazepam** or **lorazepam**, respectively. The clinical importance of this is uncertain, but the inference to be drawn is that the CNS depressant effects of **alprazolam** will be increased, over and above the simple additive CNS depressant effects likely when other benzodiazepines and **dextropropoxyphene** are taken together. More study is needed.

Extended-release **oxymorphone** did not affect the metabolism of **midazolam** in healthy subjects.[15]

(d) Respiratory depression

A 14-year-old boy with staphylococcal pneumonia secondary to influenza developed adult respiratory distress syndrome. It was decided to suppress his voluntary breathing with opioids and use assisted ventilation and he was therefore given **phenoperidine** and **diazepam** for 11 days, and later **diamorphine** with **lorazepam**. Despite receiving **diamorphine** 19.2 mg in 24 hours his respiratory drive was not suppressed. On day 17, despite serum morphine and **lorazepam** levels of 320 micrograms/mL and 5.3 micrograms/mL, respectively, he remained conscious and his pupils were not constricted.[16] Later *animal* studies suggested that **lorazepam** opposed the respiratory depressant effects of morphine.[16]

In contrast, intravenous **diazepam** 150 micrograms/kg did not alter the respiratory depressant effect of intravenous **pethidine** (**meperidine**) 1.5 mg/kg in a study in healthy subjects[17] or in patients with chronic obstructive pulmonary disease.[18] Moreover, in the setting of overdose (see *Overdose*, above), benzodiazepines might increase the respiratory depressant effects of opioids.

(e) Sedation

The sedative effects of **midazolam** and **morphine** were additive in a study in patients given these drugs intravenously before surgery.[19] A prospective study in 80 patients undergoing elective endoscopy found that deep sedation occurred frequently (68% of patients) with **pethidine** (**meperidine**) and **midazolam** used with the intent of moderate sedation.[20] Another study found that single oral doses of **diazepam** 10 or 20 mg given to 8 patients taking **buprenorphine** increased subjective effects such as sedation and strength of drug effects, and also caused a deterioration in performance measures such as cancellation time, compared with placebo.[21] A further study by the same authors found similar effects when subjects stabilised taking **buprenorphine** were given a single 40-mg dose of oral diazepam.[22]

These additive adverse effects would be expected with concurrent use of benzodiazepines and opioids and the degree of impairment will depend on the individual patient. Warn all patients of the potential adverse effects on driving and other skilled tasks.

Opioids; Fentanyl and related drugs + Benzodiazepines

In general the concurrent use of benzodiazepines with alfentanil or fentanyl in anaesthesia is synergistic but may also result in additive adverse effects, such as respiratory depression and/or hypotension. A pharmacokinetic study found that fentanyl reduced the metabolism of midazolam. Retrospective evidence suggests that midazolam can increase the dose requirement of sufentanil, but midazolam did not alter the analgesic efficacy of fentanyl in healthy subjects.

Clinical evidence

(a) Anaesthetic induction

Giving **midazolam** with **alfentanil** or **fentanyl** for the induction of anaesthesia reduces the dose required of both the benzodiazepine and the opioid, when compared with either drug alone.[1-3] The interaction is synergistic.[2]

(b) Analgesic effects

An analysis of 43 patients who were mechanically ventilated following major trauma, and who were given infusions of **sufentanil** alone or **sufentanil** with **midazolam**, found that midazolam appeared to reduce the efficacy of sufentanil. The rate of sufentanil infusion in the group given both drugs (21 patients) was increased by more than 50%, when compared with the group given sufentanil alone (22 patients). It was found possible to reduce the sufentanil infusion in 8 of the patients given sufentanil alone, whereas this was possible in only one patient given both drugs.[4]

Conversely, in a study in healthy subjects, intravenous **midazolam** 500 micrograms to 2 mg per 70 kg did not affect the analgesia produced by intravenous **fentanyl** 100 micrograms per 70 kg in a cold pressor test.[5]

(c) Hypotension and respiratory depression

1. Neonates. Hypotension occurred in 6 neonates with respiratory distress who were given **midazolam** (a bolus of 200 micrograms/kg and/or an infusion of 60 micrograms/kg per hour) for sedation during the first 12 to 36 hours of life. Five of them were also given **fentanyl** either as an infusion (1 to 2 micrograms/kg per hour) or a bolus (1.5 to 2.5 micrograms/kg), or both. Blood pressures fell from an average of 55/40 mmHg to 36/24 mmHg in 5 of the neonates, and from 42/28 mmHg to less than 20 mmHg in the other neonate.[6] Another report describes respiratory arrest in a child of 14 months who was given both drugs.[7]

2. Adults. In a study in 12 healthy subjects, **midazolam** 50 micrograms/kg alone caused no episodes of apnoea or hypoxaemia, whereas **fentanyl** 2 micrograms/kg alone caused hypoxaemia in 6 subjects but no apnoea. When both drugs were given together 6 subjects had apnoea and 11 subjects had hypoxaemia.[8] Similarly, in a study in 12 healthy subjects, **fentanyl** with **diazepam** caused more respiratory depression than either drug alone.[9] Hypotension has also been seen in adults given fentanyl with **midazolam**[10] or **diazepam**.[11]

Acute hypotension occurred in a man receiving clonidine, captopril and furosemide who was premedicated with intramuscular **midazolam** 5 mg and anaesthetised with **sufentanil** 150 micrograms.[12] This is consistent with another report of sudden hypotension during anaesthetic induction in 4 patients given high-dose **sufentanil** who had been given **lorazepam** before induction.[13]

(d) Pharmacokinetics

A double-blind, placebo-controlled study in 30 patients undergoing orthopaedic surgery found that a single 200-microgram dose of **fentanyl** given one minute before intravenous **midazolam** 200 micrograms/kg decreased the systemic clearance of midazolam by 30%. The elimination half-life of midazolam was prolonged by about 50%.[14]

(e) Sedation

A study in patients undergoing an abdominal hysterectomy under **alfentanil** and **midazolam** anaesthesia found that although the pharmacokinet-

ics of midazolam were unchanged, postoperative sedation was more pronounced, when compared with a group of patients that did not receive alfentanil.[15]

Mechanism

Uncertain. The concurrent use of two or more CNS depressants may produce additive respiratory depressant and sedative effects. Reduced metabolism of midazolam might also enhance its effects. Why midazolam appeared to increase the analgesic dose requirement for sufentanil is unknown. An *in vitro* study found that fentanyl competitively inhibited the metabolism of **midazolam** by the cytochrome P450 isoenzyme CYP3A4.[16]

Importance and management

An interaction between alfentanil, fentanyl or sufentanil and the benzodiazepines would appear to be established. Not all pairs appear to have been studied, but they would all be expected to interact similarly, to a greater or lesser extent. Increased sedative and respiratory depressant effects are to be expected on concurrent use, and hypotension may also occur. The US manufacturer of transdermal fentanyl suggests that if benzodiazepines are also given the dose of one or both drugs should be significantly reduced.[17] It would therefore seem prudent to be alert for CNS depression and hypotension in all patients given alfentanil, fentanyl or sufentanil and a benzodiazepine, and adjust the dose according to effect.

What effect the use of midazolam has on the dose requirement of sufentanil and other opioids in the intensive care setting is unclear.

Opioids; Methadone + Benzodiazepines

Patients taking methadone who are given diazepam may experience increased drowsiness and possibly enhanced opioid effects, although not all studies have found this. Temazepam may have contributed to the sudden death of a patient taking methadone. An isolated case of ventricular arrhythmias has been reported with concurrent use of midazolam and high-dose methadone.

Clinical evidence and mechanism

(a) Diazepam

Four addicts, taking methadone for at least 6 months, were given diazepam 300 micrograms/kg for 9 days. The pharmacokinetics of methadone were unaltered and the opioid effects of methadone remained unchanged.[1] Analysis of blood samples from a study[2] confirmed that there is no pharmacokinetic interaction between methadone and diazepam.[3]

A study in patients taking methadone noted that diazepam abuse was prevalent, and that many patients reported that diazepam boosted the effects of methadone.[4] Another study suggested that the opioid effects of methadone (subjective effects and pupil constriction) may be enhanced by acute administration of diazepam and this was significant with high-dose methadone (150% of the maintenance dose) and diazepam 40 mg.[2] A further study in patients taking methadone found that single oral doses of diazepam 10 or 20 mg, which are within the usual therapeutic range, increased the subjective effects such as sedation, strength of drug effects and euphoria, and also caused a significant deterioration in performance measures such as reaction time, when compared with placebo.[5] A study in 4 patients stabilised on methadone found that diazepam 40 mg increased the intensity of subjective effects, such as sedation, and decreased psychological performance, such as reaction times and digit symbol substitution test (DSST), generally independent of the methadone dose administered. However, high-dose methadone was associated with a reduction in oxygen saturation levels.[6]

The absence of increased opioid effects reported in an earlier pharmacokinetic study[1] may possibly be explained by the relatively low regular daily doses of diazepam used, in contrast to the higher more intermittent doses used in the study above,[2] which is the pattern of dose reportedly used by patients.

(b) Midazolam

A case of ventricular arrhythmias has been associated with high-dose methadone given with CYP3A4 substrates including midazolam.[7] Note that high-dose methadone (more than 100 mg) alone may cause QT prolongation, see 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290.

(c) Temazepam

A 39-year-old man taking methadone 60 mg daily and temazepam 20 mg twice daily was found dead. Blood levels of methadone and temazepam were not particularly high, and revealed that amitriptyline had also been taken.[8] The cause of death was therefore considered to be accidental owing to methadone toxicity enhanced by the additive CNS depressant effects of both temazepam and amitriptyline.

Importance and management

The concurrent use of methadone with low-to-moderate doses of diazepam need not be avoided, but patients given both drugs are likely to experience increased drowsiness and reduced psychomotor performance, and should be warned against driving or operating machinery under these circumstances. With a high diazepam dose the possibility of opioid enhancement should be borne in mind. Bear in mind that the concurrent use of benzodiazepines appears to be a risk factor in sudden death in patients taking methadone.

Opioids + Calcium-channel blockers

Bradycardia and hypotension may be enhanced in patients taking opioids with calcium-channel blockers. The analgesic effects of morphine appear to be enhanced by some calcium-channel blockers, whereas nimodipine may increase morphine requirements. Diltiazem prolonged the effects of alfentanil in one study.

Clinical evidence and mechanism

(a) Delayed recovery from anaesthesia

In a study in 15 patients anaesthetised with midazolam, isoflurane, propofol and alfentanil (induced with 50 micrograms/kg, then maintained with 1 microgram/kg per minute) the AUC and half-life of **alfentanil** were increased by 24% and 50%, respectively, when they were given **diltiazem** 60 mg orally 2 hours before induction, then an infusion for 23 hours starting at induction. Tracheal extubation was performed on average 2.5 hours later in the patients receiving diltiazem than in a placebo group.[1] Diltiazem is a moderate inhibitor of the cytochrome P450 isoenzyme CYP3A4, which is responsible for the metabolism of alfentanil.[1]

(b) Effects on analgesia

A double-blind, placebo-controlled study in 26 patients undergoing surgery found that two doses of slow-release **nifedipine** 20 mg given on the day preceding surgery and a further dose given 60 to 90 minutes before surgery increased the analgesic effect of **morphine**.[2] In contrast, in a placebo-controlled study in 40 patients undergoing knee arthroplasty, 20 patients given oral **nimodipine** 90 mg one hour before surgery followed by 30 mg every 6 hours for 48 hours postoperatively, had increased intravenous **morphine** consumption via patient-controlled analgesia (PCA). No difference in pain scores was reported between the groups.[3]

Importance and management

Although information is limited, an interaction between alfentanil and diltiazem would appear to be established. Caution is required on concurrent use as there could be an increased risk of prolonged or delayed respiratory depression. The manufacturer says that the concurrent use of diltiazem and alfentanil requires special patient care and observation; it may be necessary to lower the dose of alfentanil.[4] Note that **verapamil** is also a moderate inhibitor of CYP3A4 and so might theoretically be expected to have a similar effect to diltiazem, although this needs confirmation.

The interaction between morphine and the other calcium-channel blockers is unclear, and the information conflicting, particularly that for nimodipine. It would seem prudent to bear the potential for an interaction in mind and adjust the opioid dose if necessary.

The manufacturer of **remifentanil** cautions that cardiovascular effects (bradycardia and hypotension) may be greater in patients also taking calcium-channel blockers,[5] and it would seem prudent to be alert for this effect with other related drugs (e.g. **sufentanil**).

Opioids + Cannabis

Low doses of cannabis enhanced the effect of morphine in three patients. *Animal* studies have shown that cannabinoids may enhance the potency of opioids. Additive sedation and CNS depression may occur with concurrent use of cannabis derivatives such as dronabinol with opioids.

Clinical evidence, mechanism, importance and management

A report of 3 patients with chronic pain (due to multiple sclerosis, HIV-related peripheral neuropathy, and lumbar spinal damage) found that small doses of smoked cannabis potentiated the antinociceptive effects of **morphine**. The patients were able to decrease the dose of opioid by 60 to 100%.[1] Studies in *animals* have shown that dronabinol (Δ^9-tetrahydrocannabinol), the major psychoactive constituent of cannabis, enhances the potency of opioids such as **morphine**, **codeine**, **hydromorphone**, **methadone**, **oxymorphone** and **pethidine** (**meperidine**).[2-4] It has been suggested that low doses of dronabinol given with low doses of **morphine** may increase opioid potency without increasing adverse effects.[5]

Cannabis use in **methadone**-maintained patients did not appear to affect treatment progress, although some psychological difficulties were slightly more prevalent.[6] However, other workers have suggested that heavy cannabis use is associated with a poorer progress when methadone is given in the treatment of opioid addiction.[7]

The manufacturer of a licensed buccal spray containing dronabinol and cannabidiol states that, as both of these drugs can inhibit the cytochrome P450 isoenzyme CYP3A4, they should be used with caution in patients taking other drugs metabolised by this isoenzyme (they name **alfentanil**, **fentanyl** and **sufentanil**).[8] In contrast, the manufacturer of oral dronabinol reports that no clinically relevant interactions were found in studies in patients taking various medications including opioids (not specified). However, both manufacturers advise that additive sedation and CNS depression may occur with concurrent use of these cannabinoids and opioids.[8,9]

Opioids + Carisoprodol

Carisoprodol may enhance the CNS depressant effects of the opioids.

Clinical evidence, mechanism, importance and management

A 49-year-old woman who had been taking **oxycodone** (*OxyContin*) 40 mg twice daily for more than one year was given carisoprodol 350 mg (one tablet) four times daily to treat muscle spasm and uncontrolled pain. After taking this regimen for one week without relief, she increased the dose to 8 to 10 tablets daily. She was found unconscious, was responsive only to painful stimuli, and her respiration was also depressed. She rapidly returned to full alertness when she was given naloxone 2 mg intravenously, although she had not taken any extra **oxycodone** tablets. The adverse effects were thought to be due to additive CNS depressant effects of both oxycodone and carisoprodol.[1]

In a retrospective review of deaths recorded in Jefferson County over a 12-year period, carisoprodol was present in the blood of 24 cases, but was never the sole drug detected; **dextropropoxyphene** (**propoxyphene**) was also present in 8 of the 24 cases. Respiratory depression was a major cause of death and as carisoprodol causes respiratory depression, it was considered to be probably responsible, in part, for these deaths.[2]

The manufacturer of carisoprodol reports that sedative effects can be additive with other CNS depressants such as the opioids and advises caution on concurrent use.[3]

Opioids + Chlorobutanol

Chlorobutanol, used as a preservative in methadone injection, may possibly have contributed to the QT prolongation seen with methadone in one study.
Somnolence in a patient given high-dose intravenous morphine was attributed to the associated high intake of chlorobutanol preservative in the morphine injection.

Clinical evidence, mechanism, importance and management

(a) Methadone

A study in patients receiving intravenous methadone found an approximately linear relationship between the log-dose of methadone and QTc measurements. In addition, methadone and chlorobutanol (a preservative used in intravenous methadone preparations) were both found to block cardiac potassium ion channels *in vitro*, and chlorobutanol potentiated this effect with methadone.[1] High doses of methadone have been reported to cause torsade de pointes, but chlorobutanol used as a preservative in methadone injection may possibly contribute to the QT prolongation.[1]

(b) Morphine

A report describes a 19-year-old woman who required increasing doses of intravenous morphine to control pain, reaching a peak of 275 mg/hour, which was maintained for 4 days. After palliative radiotherapy the rate was reduced to 100 to 150 mg/hour, but only partial pain relief was achieved; however the patient was somnolent, which was attributed to the chlorobutanol preservative content of the morphine injection (1 mg of chlorobutanol for every 3 mg of morphine). At doses of morphine 275 mg/hour, chlorobutanol intake was 90 mg/hour, which is in excess of the dose that has been used to aid sleep (150 mg); chlorobutanol accumulation may also have occurred as it has a long half-life.[2] This appears to be an isolated report, the general importance of which is unknown.

2. DeChristoforo R, Corden BJ, Hood JC, Narang PK, Magrath IT. High-dose morphine infusion complicated by chlorobutanol-induced somnolence. *Ann Intern Med* (1983) 98, 335–6.

Opioids + Cocaine

A case of cocaine-related torsade de pointes occurred in a patient taking methadone. Ventricular arrhythmias and increased cardiovascular effects have been reported when other patients taking methadone were given cocaine. The cardiovascular effects of cocaine and morphine appear to be similar to those seen with cocaine alone.

Clinical evidence, mechanism, importance and management

A 46-year-old woman who had been taking **methadone** 80 mg daily for over one year, started abusing cocaine by inhalation and injection and subsequently developed frequent self-limiting episodes of syncope. These syncopal events consistently occurred within an hour of cocaine use. She was admitted to hospital after collapsing and becoming comatose, and was found to have torsade de pointes. She developed irreversible anoxic brain injury secondary to cardiac arrest. Although **methadone** can cause QT prolongation, the serum methadone level was well within the therapeutic range and it was felt that several factors might have contributed to the arrhythmias including cocaine abuse.[1] Another patient taking **methadone** was withdrawn from a study due to the occurrence of premature ventricular contractions for several minutes after a single 32-mg/70 kg intravenous dose of cocaine.[2] Furthermore, increased cardiovascular effects (e.g. increased diastolic pressure and heart rate) have been reported when cocaine is given to patients taking **methadone**.[2] Both cocaine and **methadone** are considered to have effects on the QTc interval and both are potassium-channel blockers. The authors of one study suggested that the combination of these two drugs creates a potentially dangerous risk for torsade de pointes.[3]

A study in 9 healthy subjects found that although the combination of **morphine** and cocaine produced significant cardiovascular and subjective effects, for the most part, the cardiovascular effects were similar to those produced by cocaine alone. Neither cocaine nor **morphine** altered the plasma levels of the other drug.[4]

Opioids + Food

Food can delay the absorption of dextropropoxyphene (propoxyphene), but the total amount absorbed may be slightly increased. Food increases the bioavailability of oral morphine solution but delays the absorption of some controlled-release preparations of morphine. Food may increase the bioavailability of immediate-release hydromorphone and oxycodone solution, but sustained-release preparations of hydromorphone, oxycodone and tramadol appear not to be affected by food.

Clinical evidence, mechanism, importance and management

(a) Dextropropoxyphene (Propoxyphene)

A study in healthy subjects given a single 130-mg dose of dextropropoxyphene (as capsules) found that while fasting, peak plasma dextropropoxyphene levels were reached after about 2 hours. High-fat and high-carbohydrate meals delayed peak serum levels by about one hour, and high protein meals delayed the peak serum levels by about 2 hours. Both the protein and carbohydrate meals caused a small 25 to 30% increase in the total amount of dextropropoxyphene absorbed.[1] The delay in absorption probably occurs because food delays gastric emptying. Avoid food if rapid analgesic effects are needed.

(b) Hydromorphone

A crossover study in 24 healthy subjects found that food slightly reduced the peak plasma concentrations of a single 8-mg dose of immediate-release hydromorphone and increased its AUC by a modest 30%. However, these changes were not considered to be of clinical significance.[2]

A study in 24 healthy subjects found that food had no clinically significant effects on the pharmacokinetics of an extended-release once-daily hydromorphone capsule.[3] Similarly, another study in 27 healthy subjects found that food had no significant effect on the bioavailability of hydromorphone from a 24-hour controlled-release preparation (*OROS* osmotic pump delivery system).[4]

(c) Morphine

Twelve patients with chronic pain were given oral morphine hydrochloride 50 mg in 200 mL of water either while fasting or after a high-fat breakfast (fried eggs and bacon, toast with butter, and milk). The maximum blood morphine levels and the time to achieve these levels were not significantly altered by the presence of the food, but the AUC was increased by 34% and blood morphine levels were maintained at higher levels over the period from 4 to 10 hours after the morphine had been given.[5] The reasons for this effect are not understood. The inference to be drawn is that pain relief is likely to be increased if the morphine solution is given with food. This appears to be an advantageous interaction. More confirmatory study is needed.

Some differences in pharmacokinetic parameters have also been reported between the fed and fasted states for controlled-release formulations of morphine, but these are not necessarily translated into measurable differences in the pharmacodynamic effects of pain relief and adverse effects.[6] The effects also appear to vary by preparation. Studies have found that, compared with the fasting state, food increases the AUC and maximum plasma level of morphine from *MST Continus*[7] and *Oramorph SR*,[7] reduces the rate of absorption of morphine from *Kapanol*,[8] without affecting its bioavailability,[9] reduces the rate and extent of morphine absorption from *MXL* capsules[9] but does not affect the pharmacokinetics of morphine from *MS Contin* (Purdue Frederick Company, USA) between the fed and fasted states.[10] Most of these studies used single doses in healthy subjects and food was given in the form of a high-fat breakfast and although it appears that there might be some delay in the absorption of some sustained-release preparations of morphine with food, the overall effect is unlikely to be clinically significant.

Studies in *animals* suggest that ingestion of **sucrose** for a short duration may activate the endogenous opioid system and may modify morphine withdrawal.[11,12] Sucrose ingestion has also been shown to alleviate pain and distress in infants and adults.[11]

(d) Oxycodone

A study in 22 healthy subjects found that the bioavailability of oxycodone as an immediate-release solution was significantly altered by consumption of a high-fat meal: the AUC was increased by 20% and the maximum plasma level was decreased by 18%, when compared with the fasted state. A

study in healthy subjects using a preparation containing oxycodone 5 mg and ibuprofen 400 mg found no significant change in the rate of absorption of oxycodone between the fasted state and after a high-fat breakfast, and only a slight increase (of about 25%) in the AUC in the fed state.[13] However, there was no significant effect of food on the bioavailability of oxycodone given as a controlled-release tablet.[14]

(e) Tramadol

In an open, crossover study in 24 healthy subjects, tramadol sustained-release capsules were found to be bioequivalent with and without concurrent food intake (a high-fat breakfast).[15]

Opioids + Glutethimide

A study in *animals* suggested that glutethimide might potentiate and prolong the analgesic effect of codeine by increasing the plasma levels of its morphine metabolite.[1] Glutethimide combined with codeine can produce a euphoric state and may be addictive; seizures and psychosis have been reported.[2] Two studies have reported 21 deaths associated with concurrent use.[3,4] Given the wide availability of alternative hypno-sedatives, it may be prudent to choose a safer alternative.

Opioids + Grapefruit juice

Grapefruit juice may produce a modest increase in oral methadone bioavailability. The clearance of oral alfentanil may be reduced by grapefruit juice. Grapefruit juice does not appear to affect the bioavailability of intravenous alfentanil or transmucosal fentanyl to a clinically significant extent.

Clinical evidence, mechanism, importance and management

(a) Alfentanil

A study in 10 healthy subjects found that grapefruit juice had no effect on the bioavailability of *intravenous* alfentanil. However, the clearance of *oral* alfentanil was reduced by about 40% and the maximum plasma level and oral bioavailability were increased by about 40% and 60%, respectively. This was thought to be due to selective inhibition of intestinal CYP3A by grapefruit juice.[1] Therefore should alfentanil be given orally its effects would be expected to be increased and prolonged.

(b) Fentanyl

In a study in 12 healthy subjects, grapefruit juice had a minimal effect on the peak plasma levels or clinical effects of oral transmucosal fentanyl, despite a considerable proportion of the dose being swallowed and absorbed enterally.[2] There appears to be no further data on the effects of grapefruit on oral or oral transmucosal fentanyl. However, the manufacturer of fentanyl lozenges suggests that grapefruit juice may increase the bioavailability of swallowed fentanyl and therefore advises caution with concurrent use.[3] Note that *intravenous* and *transdermal* fentanyl are not expected to be affected to the same extent as oral fentanyl, as grapefruit juice mainly inhibits intestinal and not liver CYP3A4.

(c) Methadone

A study in 8 patients taking methadone found that 200 mL of grapefruit juice given 30 minutes before, and also with, their daily dose of methadone was associated with a modest increase in methadone bioavailability. The mean AUC and the maximum plasma levels increased by about 17%.[4] A study in healthy subjects found that grapefruit juice caused a similar modest increase in methadone bioavailability following oral methadone, but had no effect on intravenous methadone bioavailability.[5] The increase in methadone levels were not considered to be clinically significant in the patients studied.[4] On the basis of this evidence dose adjustments of methadone seem unlikely to be necessary in the presence of grapefruit juice.

Opioids + H_2-receptor antagonists

No clinically significant interaction appears to occur between cimetidine and butorphanol (intranasal), hydromorphone, morphine, pethidine (meperidine) or tramadol; between famotidine and hydromorphone; or between ranitidine and hydromorphone, morphine, or pethidine (meperidine). However, isolated reports describe adverse reactions in patients taking methadone, morphine or mixed opium alkaloids with cimetidine, or morphine with ranitidine.

Clinical evidence

(a) Butorphanol

In a study in 16 healthy subjects, the pharmacokinetics of intranasal butorphanol 1 mg every 6 hours and oral **cimetidine** 300 mg every 6 hours for 4 days were not significantly altered by concurrent use, except for a moderate increase in the elimination half-life of **cimetidine**.[1]

(b) Hydromorphone

The US manufacturer of hydromorphone says that the concurrent use of H_2-receptor antagonists (**cimetidine**, **famotidine**, **ranitidine**) had no significant effect on hydromorphone steady-state pharmacokinetics.[2]

(c) Methadone

An *in vitro* study briefly mentions an elderly patient receiving methadone 25 mg daily who developed apnoea 2 days after starting **cimetidine** 1.2 g daily.[3] Another elderly patient taking oral methadone 5 mg every 8 hours

and subcutaneous **morphine** 8 mg every 3 hours also developed apnoea (respiratory rate 2 breaths per minute) after receiving intravenous **cimetidine** 300 mg every 6 hours for 6 days. This was controlled with naloxone. It is unclear why the patient developed adverse effects on this occasion as no adverse effects occurred on the previous use of these drugs.[4]

(d) Morphine

1. Cimetidine. In another placebo-controlled study in 118 patients undergoing major abdominal surgery and given analgesia with morphine, preoperative or postoperative intravenous cimetidine 4 mg/kg did not affect postoperative pain intensity, sedation score, cumulative morphine consumption, or the incidence of adverse effects.[5] In a study in 7 healthy subjects, cimetidine 300 mg four times daily for 4 days had no effect on the pharmacokinetics of a single 10-mg dose of intravenous morphine. The extent and duration of the morphine-induced pupillary miosis were also unchanged.[6] In other healthy subjects, cimetidine 600 mg, given one hour before a 10-mg dose of intramuscular morphine prolonged the respiratory depression due to morphine, but the extent was small and not considered to be clinically significant.[7]

In contrast, an acutely ill patient with grand mal epilepsy, gastrointestinal bleeding and an intertrochanteric fracture, who was undergoing haemodialysis three times a week, was taking cimetidine 300 mg three times daily. After being given the sixth dose of intramuscular morphine (15 mg every 4 hours) he became apnoeic (three breaths per minute), which was managed with naloxone. He remained confused and agitated for the next 80 hours with muscular twitching and further periods of apnoea controlled with naloxone. He had received nine 10-mg intramuscular doses of morphine on a previous occasion in the absence of cimetidine without problems. About a month later he experienced the same adverse reactions when given opium alkaloids while still taking cimetidine (see below).[8] Apnoea has also been reported in a patient receiving morphine, methadone and cimetidine, see under *Methadone*, above.

2. Ranitidine. A study in 8 healthy subjects taking ranitidine 150 mg twice daily for 7 doses followed by a single 10-mg dose of oral morphine mixture suggested that ranitidine might slightly increase the bioavailability of morphine, although the increase was not statistically significant.[9] A man with terminal cancer receiving intravenous ranitidine 150 mg every 8 hours became confused, disorientated and agitated when given ranitidine after an intravenous infusion of morphine 50 mg daily was started. When the ranitidine was stopped his mental state improved but worsened when he was given ranitidine again 8 hours and 16 hours later. He again improved when the ranitidine was stopped.[10]

Similarly, another report describes hallucinations in a patient receiving ranitidine and sustained-release morphine followed by rectal **methadone**, but the author discounted the possibility of an interaction.[11]

(e) Opium alkaloids, mixed

A patient taking **cimetidine** 150 mg twice daily developed apnoea, confusion, and muscle twitching after receiving 7 doses of intramuscular *Pantopon* (hydrochlorides of mixed opium alkaloids) postoperatively. He required 4 doses of naloxone over the next 24 hours.[8]

(f) Pethidine (Meperidine)

In a study in 8 healthy subjects, **cimetidine** 600 mg twice daily for one week reduced the total body clearance of a single 70-mg intravenous dose of pethidine by a modest 22%.[12] In a similar study by the same research group, **ranitidine** 150 mg twice daily had no effect on pethidine pharmacokinetics.[13]

(g) Tramadol

In an unpublished study in healthy subjects on file with the manufacturers, **cimetidine** increased the AUC of tramadol by 15 to 27% and decreased the total body clearance by 14 to 22%.[14]

Mechanism

Cimetidine inhibits the activity of liver enzymes concerned with the *N*-demethylation of methadone[3] and the oxidation of pethidine (meperidine),[12,13] reducing their metabolism, so they could accumulate in the body, thereby exaggerating their respiratory depressant effects. A reduction in liver function might possibly have contributed towards, or even been largely responsible for the cases with methadone, because both patients were elderly. The manufacturers of methadone also suggest that H_2-receptor antagonists such as cimetidine can reduce the protein binding of methadone resulting in increased opiate action.[15,16]

The isolated case reports of possible interactions between morphine and H_2-receptor antagonists remain unexplained,[8,10] but both patients were seriously ill. *In vitro* studies have reported that the conjugation of morphine does not appear to be affected by cimetidine or ranitidine.[17]

Importance and management

The evidence generally suggests that morphine does not interact with cimetidine: those cases describing an interaction involved seriously ill patients. Concurrent use normally causes only a slight and normally unimportant prolongation of the respiratory depression due to morphine, but it might possibly have some importance in patients with pre-existing respiratory disorders. Several manufacturers note that cimetidine may inhibit the metabolism of morphine, although they do not give any specific advice regarding the management of this interaction. One US manufacturer warns that, because of the isolated report (see under *Morphine*, above), patients should be monitored for increased respiratory and CNS depression.[18] However, it should be noted that this patient was undergoing haemodialysis, and probably does not reflect the effects of this interaction in the general population. In contrast, one of the UK manufacturers gives no mention of a possible interaction with cimetidine.[19]

In vitro evidence suggests that ranitidine is unlikely to interact with morphine,[8] although one pharmacokinetic study indicated that ranitidine might cause a slight increase in morphine levels.[9] Again, the general significance of the case reports of an interaction is unclear.

Information about the interaction between **pethidine** (**meperidine**) and cimetidine is very limited. Its clinical importance is uncertain, but probably small given the minor changes seen in the pharmacokinetics of pethidine. However, some manufacturers warn that cimetidine may inhibit the metabolism of pethidine and the formation of the metabolite, norpethidine, and thus caution should be used with concurrent use.[20] Ranitidine has been shown not to affect the pharmacokinetics of pethidine.

It also seems doubtful if the interaction between **methadone** and cimetidine is of any general importance when the two isolated reports cited here are viewed against the background of the widespread use of both of these two drugs for a good number of years and the lack of other published adverse reports. However, some manufacturers warn that methadone clearance may be decreased, and the effects of methadone increased, when it is given with drugs that inhibit CYP3A4 activity including cimetidine.[15,16]

The UK manufacturer of **oxycodone** suggests that cimetidine, a non-specific inhibitor of CYP3A4, may affect its metabolism.[21] However, as CYP3A4 is only partly responsible for the metabolism of oxycodone, and cimetidine is not a potent inhibitor of this isoenzyme, any effects would be expected to be minimal. Nevertheless, until more is known, it may be prudent to be alert for increased oxycodone effects if cimetidine is given.

No clinically significant pharmacokinetic interaction appears to occur between intranasal **butorphanol** and oral cimetidine, or between **hydromorphone** and the H_2-receptor antagonists. Similarly, the minor changes in **tramadol** pharmacokinetics caused by cimetidine are unlikely to be of clinical significance.[22,23]

Opioids; Fentanyl and related drugs + H_2-receptor antagonists

Cimetidine, but not ranitidine, increases the plasma levels of alfentanil. Some preliminary observations suggest that the effects of fentanyl may be increased by cimetidine.

Clinical evidence, mechanism, importance and management

(a) Alfentanil

In a pharmacokinetic study in 19 intensive care patients, intravenous **cimetidine** 1.2 g daily for 2 days was given with a single 125-microgram/kg intravenous dose of alfentanil. When compared with either an aluminium/magnesium hydroxide antacid or intravenous **ranitidine** 300 mg daily, **cimetidine** increased the alfentanil half-life by 75% and 61%, respectively, and reduced the clearance by 64% and 54%, respectively. The alfentanil plasma levels were significantly raised by the **cimetidine**, probably because **cimetidine** inhibits the metabolism of the alfentanil.[1] Whether the effects of alfentanil are increased to a clinically important extent awaits assessment. However, be alert for increased alfentanil effects because pharmacokinetic changes of this size are known to be clinically important in some patients (see 'Opioids; Fentanyl and related drugs + Macrolides', p.192, and 'Opioids; Fentanyl and related drugs + Azoles', p.182). The UK manufacturer of alfentanil warns that alfentanil is metabolised mainly by CYP3A4, and therefore inhibitors of this isoenzyme, including **cimetidine**, could increase the risk of prolonged or delayed respiratory depression. The concurrent use of such drugs requires special patient care and observation; it may be necessary to lower the dose of alfentanil.[2] **Ranitidine** does not appear to interact.[1]

(b) Fentanyl

The terminal half-life of fentanyl 100 micrograms/kg was reported to be more than doubled, from 155 minutes to 340 minutes, by pretreatment with **cimetidine** (10 mg/kg the night before and 5 mg/kg 90 minutes before the fentanyl dose). This increase in half-life probably occurs because **cimetidine** inhibits the metabolism of fentanyl by the liver, thereby delaying its clearance from the body.[3] The clinical importance of this interaction has not been assessed, but if both drugs are used concurrently, be alert for increased and prolonged fentanyl effects.

Opioids + Haloperidol

A patient taking long-term haloperidol and morphine experienced extrapyramidal symptoms when naloxone was given. Haloperidol decreased the dose requirements of sufentanil for sedation in one study.

Clinical evidence, mechanism, importance and management

(a) Morphine

An 18-year-old woman with nasopharyngeal carcinoma who had been receiving long-term haloperidol and morphine developed profound extrapyramidal adverse effects during an attempt to reverse an intrathecal morphine overdose with naloxone. It was suggested that the long-term use of morphine might suppress haloperidol-induced extrapyramidal symptoms through its antimuscarinic and dopaminergic effects. Abrupt opioid withdrawal could be potentially hazardous in patients who are also taking haloperidol.[1]

See also 'Opioids; Morphine + Miscellaneous', p.210, for limited evidence that haloperidol may increase the risk of myoclonus with morphine.

(b) Sufentanil

A study involving 30 patients in an intensive care unit investigated the effects of adding haloperidol 3 mg/hour to a sufentanil infusion. The study found that haloperidol decreased the dose requirements of sufentanil when compared with sufentanil infusion alone. No differences in adverse effects were reported between the two groups.[2]

Opioids + Herbal medicines; Miscellaneous

Some herbal teas may contain opioids and may therefore cause additive CNS depression if taken with other opioids.

Clinical evidence, mechanism, importance and management

Some herbal preparations may actually contain opioids; the **morphine** content of two herbal teas containing *Papaveris fructus* was found to be 10.4 micrograms/mL and 31.5 micrograms/mL, respectively. Furthermore, **morphine** was detected in the urine of 5 healthy subjects one hour after drinking 2 cups of either of the herbal teas, and was maximal at 4 to 6 hours: positive urine samples were detected up to 6 to 9 hours after drinking the teas.[1] Therefore it may be expected that additive CNS depressant effects will occur if such teas are taken with other opioid preparations.

Opioids + Hormonal contraceptives

The clearance of morphine is roughly doubled by oral combined hormonal contraceptives. Oral combined hormonal contraceptives do not appear to alter the pharmacokinetics of pethidine (meperidine). Gestodene is predicted to increase the plasma levels of buprenorphine.

Clinical evidence, mechanism, importance and management

(a) Buprenorphine

An *in vitro* study reported that **gestodene** inhibited the metabolism of buprenorphine to norbuprenorphine by the cytochrome P450 isoenzyme CYP3A4 by about 60 to 70%.[1] Based on data from a study with the CYP3A4 inhibitor ketoconazole (see 'Opioids + Azoles', p.181) where the AUC of buprenorphine was increased by about 50%, the manufacturer predicts that other CYP3A4 inhibitors, such as **gestodene**, may also increase the exposure to buprenorphine. They advise that a buprenorphine dose reduction should be considered when initiating treatment.[2] Halving the starting dose of buprenorphine has been suggested for patients taking CYP3A4 inhibitors and receiving buprenorphine as a substitute for opioid dependence.[2] However, the same manufacturer suggests that, as the magnitude of an inhibitory effect is unknown, such drug combinations should be avoided when buprenorphine is used parenterally or sublingually as a strong analgesic.[3,4] However, note that there appear to be no clinical cases or studies reporting interactions where **gestodene** is acting as a clinically

relevant CYP3A4 inhibitor or has specifically affected the metabolism of buprenorphine or other opioids.

(b) Morphine

The clearance of intravenous morphine 1 mg and oral morphine 10 mg was increased by 75% and 120%, respectively, in 6 young women taking an oral combined hormonal contraceptive.[5] It was suggested that the oestrogen component of the contraceptive increases the activity of the liver enzyme (glucuronyltransferase) concerned with the metabolism of morphine, which results in an increased clearance. This implies that the dose of morphine would need to be increased to achieve the same degree of analgesia. Whether this is required in practice needs confirmation; however as the dose of morphine is usually titrated to effect, the clinical relevance of any effect seems likely to be small.

(c) Pethidine (Meperidine)

One early study suggested that 4 of 5 women taking an oral combined hormonal contraceptive (**mestranol** with **noretynodrel** or **norethisterone**) excreted more unchanged pethidine in the urine than a control group of 4 women not taking contraceptives, who were found to excrete more of the demethylated metabolite.[6] However a later, well-controlled, comparative study in 24 healthy subjects (8 women taking **ethinylestradiol/norgestrel** 50/500 micrograms, and 8 women and 8 men not taking contraceptives) found no differences between the plasma levels or excretion patterns of pethidine between the three groups.[7] No special precautions appear to be needed if pethidine is given to women taking combined hormonal contraceptives.

Opioids + Interferons

Peginterferon alfa-2a does not appear to affect the pharmacokinetics of methadone to a clinically relevant extent, but an isolated report describes a patient who relapsed to heroin use following treatment with peginterferon. Peginterferon alfa-2b may slightly increase the levels of methadone although this is not usually clinically significant. Methadone maintenance does not appear to affect the pharmacokinetics of peginterferon alfa-2a or the virological response to interferons. Similarly, buprenorphine does not appear to influence the effect of interferon.

Clinical evidence and mechanism

A study involving 22 patients with chronic hepatitis C who had been receiving **methadone** maintenance for at least 3 months found that subcutaneous peginterferon alfa-2a 180 micrograms once weekly for 4 weeks did not influence the pharmacokinetics of methadone to a clinically significant extent, although methadone exposure was slightly increased by 10 to 15%. The pharmacokinetics of peginterferon alfa-2a did not appear to be altered by **methadone** when compared with values from other patients.[1] However, a case report describes a patient who stopped taking **methadone** and then relapsed to heroin use approximately 5 months after completing treatment for chronic hepatitis C with peginterferon 180 micrograms per week and ribavirin.[2]

A non-randomised study in 9 patients with hepatitis C and HIV infections taking **methadone** 40 to 200 mg daily for at least 8 weeks, found that two doses of peginterferon alfa-2b 1.5 micrograms/kg given one week apart had no significant effects on the pharmacokinetics of methadone. Similarly, no evidence of opiate toxicity or withdrawal occurred during concurrent use. Subjects were not taking HIV medication known to interact with methadone such as ritonavir.[3] A study involving 20 patients with chronic hepatitis C and taking **methadone** for at least 3 months reported a small approximately 15% increase in the AUC and maximum concentration of methadone when peginterferon alfa-2b 1.5 micrograms/kg per week for 4 weeks was also given, when compared with methadone alone.[4]

Several studies suggest that the use of opioids (**buprenorphine**,[5] **methadone**[5-8]) has no effect on the outcome of treatment with interferon or peginterferon in patients with chronic hepatitis C, although opioids may possibly facilitate the outbreak of infections through immunomodulating effects on the immune response against a virus.[6]

Importance and management

Interferon does not appear to significantly affect the pharmacokinetics of methadone. Despite the minor changes reported, the manufacturers of peginterferon alfa-2a and alfa-2b advise monitoring for methadone toxicity, such as increased sedation and respiratory depression with concurrent use.[9,10] Note that patients taking methadone may experience increased cravings while receiving antiviral therapy as the adverse effects of interferons may mimic opioid withdrawal symptoms, and cravings may be secondary to mood changes caused by antiviral therapy, or be related to the use of needles used to deliver interferon.[2] It may, therefore, be necessary to increase the dose of methadone during interferon treatment.[2,5] Note that, as alfa interferons are associated with a risk of psychiatric disturbance and suicide, the US manufacturer of interferon alfa-2b advises that opioids should be used with caution.[11]

There appears to be no specific pharmacokinetic data relating to the use of other interferons with methadone or other opioids. It has been suggested that interferons (interferon beta and interferon gamma) may theoretically reduce the activity of the hepatic cytochrome P450. However, the general significance of this potential interaction is unknown. Further study is needed.

Opioids + Local anaesthetics

Chloroprocaine may reduce the efficacy of epidural morphine and fentanyl analgesia. Fentanyl and sufentanil may enhance the local anaesthetic effect of bupivacaine, but do not appear to affect respiratory depression. Similarly, extradural lidocaine does not appear to increase respiratory depression with extradural morphine. However, one case of respiratory depression has been reported with submucosal lidocaine and alphaprodine.

Clinical evidence, mechanism, importance and management

(a) Bupivacaine

A study in 50 elderly patients undergoing spinal anaesthesia, found that those given bupivacaine 7.5 mg and **sufentanil** 5 micrograms had a reduced incidence of hypotension requiring treatment with ephedrine, when compared with the patients who received bupivacaine 15 mg alone. None of the patients developed respiratory depression.[1] A study involving 40 elderly patients undergoing spinal anaesthesia found that bupivacaine

9 mg, with **fentanyl** 20 micrograms reduced the incidence of hypotension, when compared with bupivacaine 11 mg alone. Respiratory rates were not depressed in either group. The rate of failed spinal block and discomfort was similar in both groups. The addition of fentanyl allowed a reduction in the minimum dose of bupivacaine required to produce an adequate block, and consequently the incidence of hypotension was reduced.[2]

(b) Chloroprocaine

Two studies[3,4] have found that chloroprocaine decreases the duration of epidural **morphine** analgesia (16 hours when chloroprocaine was also given compared with 24 hours when lidocaine was also given).[3] Another study found that **morphine** requirements after caesarean section were much higher in women who had received chloroprocaine for epidural anaesthesia than in those receiving lidocaine.[5] The authors of one of the studies suggest that chloroprocaine should be avoided if epidural morphine is used.[3] However, another study found that following spinal anaesthesia with bupivacaine and fentanyl, chloroprocaine did not reduce the effectiveness or duration of postoperative analgesia when it was given 15 minutes before epidural **morphine**.[6] Epidural **fentanyl** also appears to be antagonised by chloroprocaine.[7]

(c) Lidocaine

In a study in 24 patients, giving extradural lidocaine with extradural **morphine** did not increase the risk of respiratory depression associated with morphine.[8] However, respiratory depression occurred in a 3-year-old boy given lidocaine with adrenaline (epinephrine) about 5 minutes after a submucosal injection of the narcotic **alphaprodine**. Naloxone reversed the respiratory depression.[9]

For further information on the interaction of opioids with *intravenous* lidocaine used to treat arrhythmias, see 'Lidocaine + Opioids', p.300.

Opioids + Macrolides

An isolated report describes a marked increase in the effects of dextromoramide, resulting in coma, in a man taking troleandomycin. Macrolides, including troleandomycin and erythromycin, are predicted to increase buprenorphine bioavailability, and similarly, troleandomycin may reduce the metabolism of hydromorphone. It has been suggested that the metabolism of methadone and oxycodone may be decreased by some macrolides, but there do not appear to be any clinical reports confirming this.

Clinical evidence, mechanism, importance and management

(a) Buprenorphine

Although no data from clinical studies are available, the manufacturers of buprenorphine predict that inhibitors of the cytochrome P450 isoenzyme CYP3A4 such as the macrolide antibacterials (including **erythromycin**[1] and **troleandomycin**[2-4]) may increase the levels of buprenorphine. Some manufacturers recommend close monitoring and possibly a dose reduction;[1] however, it has also been said that, because the magnitude of an inhibitory effect is unknown, such drug combinations should be avoided when buprenorphine is used parenterally or sublingually as an analgesic.[3,4] The manufacturer of buprenorphine licensed for the treatment of opioid addiction suggests using half the dose of buprenorphine if potent CYP3A4 inhibitors, such as some macrolides, are given.[2]

(b) Dextromoramide

A man taking dextromoramide developed signs of overdose (a morphine-like coma, mydriasis and depressed respiration) 3 days after he started to take **troleandomycin** for a dental infection. He recovered when given naloxone. A possible explanation for this effect is that the **troleandomycin** reduced the metabolism of the dextromoramide, thereby increasing its serum levels and effects.[5] The general importance of this interaction is uncertain but concurrent use should be well monitored.

(c) Hydromorphone

An *in vitro* study found that the cytochrome P450 subfamily CYP3A, and to a lesser extent the isoenzyme CYP2C9, catalyse hydromorphone *N*-demethylation to norhydromorphone. **Troleandomycin** (an inhibitor of CYP3A) reduced norhydromorphone formation by about 45%.[6] The clinical relevance of this is unknown.

(d) Methadone

A randomised, crossover study in 12 healthy subjects found that **troleandomycin** did not significantly affect oral or intravenous methadone bioavailability. **Troleandomycin** caused only a small reduction in methadone *N*-demethylation after oral methadone, suggesting only a small role for CYP3A4 in human methadone metabolism.[7] However, one manufacturer of methadone warns that its clearance may be decreased if it is given with drugs that inhibit CYP3A4 activity, such as some macrolide antibacterials.[8] Note that decreased methadone metabolism has been seen with some of the azoles (see 'Opioids + Azoles', p.181), which are known, potent CYP3A4 inhibitors.

(e) Oxycodone

The UK manufacturer of oxycodone suggests that inhibitors of CYP3A enzymes such as **erythromycin** may inhibit the metabolism of oxycodone,[9] although oxycodone is also metabolised by CYP2D6,[9] which would make a clinically significant interaction seem unlikely.

Opioids; Fentanyl and related drugs + Macrolides

Some patients may experience prolonged and increased alfentanil effects if they are given erythromycin or particularly troleandomycin. Troleandomycin also interacts with fentanyl but to a lesser extent. Erythromycin appears not to interact with sufentanil.

Clinical evidence

(a) Erythromycin

Erythromycin 500 mg twice daily for 7 days increased the mean half-life of **alfentanil** in 6 subjects from 84 minutes to 131 minutes and decreased its clearance by 26%. The two most sensitive subjects had considerable changes with only one day of erythromycin, and overall had a marked change. The other 4 subjects had only small or moderate changes.[1] A 32-year old man undergoing an exploratory laparotomy was given erythromycin 1 g and neomycin 1 g, both three times daily, on the day before surgery. During the induction and maintenance of anaesthesia he received a total of 20.9 mg of **alfentanil**. One hour after recovery he was found to be unrousable and with a respiratory rate of only 5 breaths per minute. He was successfully treated with naloxone.[2] Another patient given **alfentanil** and erythromycin is said to have developed respiratory arrest during recovery.[3]

In 6 healthy subjects erythromycin 500 mg twice daily for 7 days did not affect the pharmacokinetics of intravenous **sufentanil** 3 micrograms/kg in the 9 hours following administration.[4] Two of the subjects were the same as those who had an interaction with alfentanil and erythromycin, as cited above.

(b) Troleandomycin

A study in 9 healthy subjects given troleandomycin 500 mg orally found that the clearance of intravenous **alfentanil** 20 micrograms/kg was reduced by almost 70%, when compared with subjects given placebo.[5] Similar results were found in another study.[6] A further study found that oral troleandomycin (500 mg starting 105 minutes before an alfentanil infusion then 250 mg every 6 hours for 3 doses) reduced the clearance of **alfentanil** by 88%.[7] This study found that troleandomycin only reduced intravenous **fentanyl** clearance by 39%. In another study in 12 healthy subjects, peak **fentanyl** concentrations and maximum miosis following oral transmucosal fentanyl 10 micrograms/kg were minimally affected by oral troleandomycin (500 mg given about 3 hours before and 9 hours after the opioid), but fentanyl metabolism, elimination and duration of effects were significantly affected (fentanyl AUC increased by 77%; norfentanyl AUC decreased by 36%; AUC_{0-10} of miosis increased by 53%).[8]

Mechanism

Troleandomycin, and to a lesser extent erythromycin, inhibit the cytochrome P450 isoenzyme CYP3A4 in the liver, which is involved in the metabolism of alfentanil, fentanyl and sufentanil. Troleandomycin has also been reported to inhibit CYP3A5 and alfentanil appears to be metabolised by multiple CYP3A enzymes including CYP3A5.[9] Alfentanil is a low-extraction drug cleared mainly by hepatic metabolism,[6] whereas fentanyl and sufentanil are high extraction drugs (see 'Changes in first-pass metabolism', (p.4)) and are therefore less likely to be affected by changes in liver metabolism.[7,10] Alterations in intestinal or hepatic CYP3A activity also appear to have little influence on oral transmucosal fentanyl absorption and onset of effect, however, a significant proportion (approximately 75%) is swallowed and its systemic clearance may be decreased by CYP3A inhibitors.[8,11]

Importance and management

The interactions of **alfentanil** with erythromycin and troleandomycin appear to be established and clinically important. Clarithromycin and telithromycin (also CYP3A4 inhibitors, see *Mechanism*) would be expected to interact similarly. Alfentanil should be given in reduced amounts or avoided in those who are taking, or who have recently taken these drugs.[1] Be alert for evidence of prolonged alfentanil effects and respiratory depression. The interaction appears not to affect all patients given erythromycin. Alternatively, **sufentanil** in doses of 3 micrograms/kg or less may be used with erythromycin, but much larger doses of sufentanil should be given with caution.[4] Similar advice should probably apply to clarithromycin, telithromycin and particularly troleandomycin. Intravenous **fentanyl** may also be used with erythromycin, but should probably be used with caution with clarithromycin, telithromycin and troleandomycin. Caution is also advised if oral transmucosal fentanyl is given with these macrolides, as there may be increased bioavailability of swallowed fentanyl resulting in increased or prolonged opioid effects.[11] Similar advice is given for transdermal fentanyl: patients should be carefully monitored and fentanyl dose adjustments made if necessary.[12-14]

Opioids + Magnesium compounds

Magnesium compounds can potentiate opioid analgesia, although some studies have failed to find an effect. Magnesium sulfate may also reduce opioid requirements during anaesthesia. Magnesium can delay the onset of spinal anaesthesia in patients given fentanyl with bupivacaine.

Clinical evidence, mechanism, importance and management

Several clinical studies have found that magnesium enhances the analgesic effect of opioids, including intrathecal magnesium with intrathecal **fentanyl**,[1] and intravenous magnesium with intravenous **fentanyl**,[2] **remifentanil**,[3] or **tramadol**.[4] Magnesium sulfate infusion has also been reported to decrease **sufentanil** requirements for sedation.[5] In contrast, other studies have reported no beneficial effect with peri- or postoperative use of magnesium on postoperative **morphine** or **pethidine** (**meperidine**) requirements.[6,7]

Respiratory depression occurred in a patient with congenital myopathy following intramuscular administration of morphine for pain relief during labour and the subsequent administration of magnesium for hypertension and proteinuria. This was possibly due to an interaction between the magnesium and morphine; however, other factors may also have contributed.[8]

In general, no additional serious adverse effects were reported in these studies, although one study found that the perioperative use of intravenous magnesium sulfate appeared to increase intraoperative blood loss at caesarean delivery. However, as magnesium is a tocolytic and may cause uterine atony, an increase in bleeding would be expected.[6]

Intrathecal magnesium sulfate prolonged the period of spinal anaesthesia induced by bupivacaine and **fentanyl** without additional adverse effects, but the onset of anaesthesia was also significantly delayed.[9]

Divalent cations appear to be involved in the pain pathway and magnesium sulfate can potentiate the opioid analgesic effect,[5] possibly by antagonism of *N*-methyl-D-aspartate receptor ion channels.[4,5] It has been suggested that as magnesium ions do not easily cross the blood brain barrier, the intrathecal use of magnesium may modulate pain relief via central effects, whereas the intravenous route mainly only affects peripheral mechanisms.[3] If anything, these interactions appears to be generally beneficial, and no particular precautions seem necessary.

Opioids + NRTIs

Zidovudine had no effect on methadone levels in one study, but there is one report of a patient requiring a modest increase in

methadone dose after starting zidovudine. Similarly, case reports describe patients requiring a modest increase in their methadone dose after starting abacavir. Tenofovir, and a single dose of zidovudine with lamivudine had no effect on methadone pharmacokinetics.
Methadone can increase zidovudine levels, and reduce the levels of abacavir, stavudine, and didanosine from the tablet formulation, but not the enteric-coated capsule preparation.

Clinical evidence

(a) Abacavir

Eleven patients given **methadone** with abacavir had a 23% increase in the rate of methadone clearance but no change in the half-life or renal clearance. In addition, there was a delay, and a 34% decrease in the peak concentration of abacavir, but no change in abacavir clearance or half-life.[1] Of 3 patients taking **methadone** who started taking abacavir, lamivudine and zidovudine, 2 patients required methadone dose increases (31% and 46%, respectively). The abacavir was thought to be responsible for this effect.[2] A patient taking **methadone** experienced torsade de pointes when abacavir, lamivudine and zidovudine were also taken[3]

See also 'Opioids; Methadone + Protease inhibitors', p.200, for a report of a decrease in methadone levels in patients taking abacavir with amprenavir.

(b) Didanosine

A study in 17 subjects taking **methadone** found that the AUC and maximum levels of didanosine tablets were 57% and 66% lower, respectively, when compared with 10 control subjects. Trough levels of **methadone** did not differ from historical controls, suggesting that didanosine had no effect on methadone pharmacokinetics.[4] A later study found that there was no reduction in the AUC of didanosine given as enteric-coated capsules when **methadone** was also given.[5]

(c) Stavudine

A study in 17 subjects taking **methadone** found that the AUC and maximum levels of stavudine were 23% and 44% lower, respectively, when compared with 10 control subjects. Trough levels of **methadone** did not differ from historical controls suggesting that stavudine had no effect on methadone pharmacokinetics.[4]

(d) Tenofovir

In a study in 13 healthy subjects receiving **methadone**, tenofovir 300 mg daily for 2 weeks did not alter the pharmacokinetics of methadone, and no symptoms of opioid toxicity or opioid withdrawal were detected.[6]

(e) Zidovudine

1. Buprenorphine. In one study, there was no difference in the pharmacokinetics of oral zidovudine between patients receiving buprenorphine and control subjects.[7] Buprenorphine is not expected to cause zidovudine toxicity.

2. Methadone. A patient with AIDS needed an increase in his levomethadone (*R*-methadone) dose from 40 to 60 mg daily, within one month of starting to take zidovudine 1 g daily.[8] In contrast, a study found no evidence of any change in the pharmacokinetics of methadone in HIV-positive patients taking methadone 14 days after they started zidovudine 200 mg every 4 hours. No methadone withdrawal symptoms occurred.[9] Another study in 16 patients taking methadone found that a single-dose of a fixed combination of zidovudine 300 mg with lamivudine 150 mg *(Combivir)* had no effect on the pharmacokinetics of methadone, and there was no evidence of withdrawal or toxicity.[10]
The effect of methadone on the pharmacokinetics of zidovudine has also been studied. In one study the mean AUC of zidovudine was increased by 43% by methadone, and in 4 of 9 patients it was doubled.[9] Another study, in 8 HIV-positive patients starting methadone, found a 29% increase in the AUC of oral zidovudine and a 41% increase in the AUC of intravenous zidovudine. Three of the 8 patients stopped zidovudine because of adverse effects or haematological toxicity.[11] Decreased zidovudine clearance in patients taking methadone is described in another report.[12]

Mechanism

Uncertain. It appears that methadone reduces the bioavailability of didanosine, and to a lesser extent, stavudine, possibly because it delays gastric emptying. Thus, the enteric-coated didanosine preparation appears not to be affected.[4,5] Conversely, methadone apparently reduces the glucuronidation of zidovudine by the liver, resulting in an increase in its serum levels.[13] Methadone may also reduce the renal clearance of zidovudine.[11]

Importance and management

The increase in **zidovudine** levels with methadone is established, although the clinical relevance is uncertain. Be alert for any increase in zidovudine adverse effects. The balance of evidence suggests that zidovudine is unlikely to reduce methadone levels, and the one case reported remains unexplained, although note that some of the adverse effects of zidovudine may be mistaken for opioid withdrawal effects.

The reduction in **didanosine** levels with methadone may be clinically relevant, and the authors suggest increasing the dose of the tablet formulation. Monitor virological response. The enteric-coated didanosine preparation is not affected and it may therefore be worth considering using this preparation instead.

The reduction in **stavudine** levels with methadone is probably not clinically relevant, but again, further data are required. The changes in **abacavir** peak levels with methadone are not considered to be clinically relevant.[14] The reports suggest that it would be prudent to monitor for signs of opioid withdrawal and adjust the methadone dose if needed, when abacavir is also given.

Tenofovir does not appear to affect methadone levels.

Opioids; Buprenorphine + NNRTIs

Preliminary evidence suggests that buprenorphine does not affect the antiretroviral efficacy or pharmacokinetics of delavirdine and efavirenz. Delavirdine may increase buprenorphine plasma levels and efavirenz may decrease buprenorphine levels. Delavirdine given with buprenorphine and naloxone has been shown to slightly prolong the QT interval.

Clinical evidence

(a) Pharmacokinetic interactions

A study in 20 opioid-dependent subjects taking **buprenorphine** with naloxone found that **efavirenz** 600 mg daily for 15 days decreased the AUC of buprenorphine and its metabolite, norbuprenorphine, by about 50% and 71%, respectively. **Delavirdine** 600 mg twice daily for 7 days caused a greater than fourfold increase in the buprenorphine AUC, but the

norbuprenorphine AUC was decreased by about 60%.[1] In this study buprenorphine did not alter the pharmacokinetics of **delavirdine** or **efavirenz**.[1]

(b) QT interval prolongation

A study in 50 opioid-dependent patients given sublingual buprenorphine with naloxone alone for at least 2 weeks and then also given an antiretroviral (**delavirdine**, **efavirenz**, nelfinavir, ritonavir-boosted lopinavir, or ritonavir) for 5 to 15 days, investigated the effect of these drugs on the QT interval. Buprenorphine with naloxone alone did not significantly alter the QT interval; however, when delavirdine and efavirenz were given there was a statistically, but probably not clinically, significant increase in the QT interval. The greatest increase in the QTc interval was seen in patients taking **delavirdine** 600 mg twice daily.[2]

Mechanism

Buprenorphine is a substrate for the cytochrome P450 isoenzyme CYP3A4. Inducers of CYP3A subfamily, such as **efavirenz** and **nevirapine**, would be expected to increase buprenorphine clearance, whereas **delavirdine**, which is an inhibitor of CYP3A, would be expected to reduce the CYP3A-mediated metabolism of buprenorphine to norbuprenorphine.

Importance and management

Despite the magnitude of the changes in buprenorphine levels seen with efavirenz and delavirdine, clinically significant consequences of these interactions (opioid withdrawal symptoms, cognitive effects and adverse effects) were not seen in this particular study and it was suggested that dose adjustments were not likely to be necessary.[1] However, the study was in HIV-negative subjects, and it has been suggested that the interaction may be of significance in HIV-positive individuals.[3] More clinical studies in HIV-positive patients are needed. Until further data are available, it would seem sensible to monitor for a reduction in buprenorphine efficacy with efavirenz or nevirapine, and adjust the dose as necessary. With delavirdine, it would seem prudent to monitor for increased buprenorphine adverse effects (such as drowsiness, respiratory depression). For details on the manufacturers' warnings and dose recommendations for buprenorphine with CYP3A4 inhibitors, see under 'Opioids + Azoles', p.181.

The increase in the QT interval reported with the concurrent use of buprenorphine and delavirdine or efavirenz is not considered to be clinically significant.[2]

Opioids; Methadone + NNRTIs

Methadone plasma levels can be markedly reduced by efavirenz or nevirapine and withdrawal symptoms have been seen. No clinically significant interaction appears to occur between etravirine and methadone. In contrast, delavirdine slightly increased methadone levels in one study.

Clinical evidence

(a) Delavirdine

The pharmacokinetics of delavirdine 600 mg twice daily did not differ between 16 HIV-negative subjects taking methadone and 15 healthy control subjects.[1] In another study methadone did not affect delavirdine pharmacokinetics. However, delavirdine decreased methadone clearance and increased its AUC by 19%.[2]

(b) Efavirenz

An HIV-positive woman who had been taking methadone for over one year began to complain of discomfort within 4 weeks of having nelfinavir replaced by efavirenz 600 mg daily, and by 8 weeks typical methadone withdrawal symptoms were occurring late in the afternoon. It was found that the levels of *R*-methadone (the active enantiomer) had fallen from 168 nanograms/mL to 90 nanograms/mL, and those of the *S*-methadone from 100 nanograms/mL to 28 nanograms/mL. The methadone dose had to be increased from 100 mg to 180 mg daily before the symptoms disappeared.[3] A further case is reported in which a man taking methadone stopped taking efavirenz 600 mg daily because of the occurrence of withdrawal symptoms despite having has his methadone dose increased.[4] Another report describes a man who required a 133% increase in his methadone dose over 4 weeks after starting efavirenz, and mentions two other patients who complained of opioid withdrawal shortly after starting efavirenz. They also required methadone dose increases.[5]

In a pharmacokinetic study, 11 patients taking methadone 35 to 100 mg daily were given efavirenz with two nucleoside analogues. Nine of the patients developed methadone withdrawal symptoms and needed dose increases of 15 to 30 mg (mean 22%). A pharmacokinetic study of these patients found that 3 weeks after starting efavirenz their mean methadone AUCs were reduced by 57% and their maximum plasma levels by 48%.[6] Similar results were found in another study in 5 HIV-positive patients taking methadone: 4 patients experienced opioid withdrawal symptoms and a mean methadone dose increase of 52% was required.[7] In another retrospective study, 6 out of 7 patients needed methadone dose increases of 8% to 200% within 2 weeks to 8 months of starting an efavirenz-based regimen.[8] Another study in HIV patients also reported that 11 out of 18 patients taking efavirenz required a methadone dose increase (median 7.5 mg daily).[9]

(c) Etravirine

In a study, 16 subjects taking methadone for at least 14 days were also given etravirine 100 mg twice daily for 14 days. The pharmacokinetics of *R*-methadone were slightly increased (by about 10% by day 14) and those of *S*-methadone were slightly reduced (by about 11%) by etravirine. Similarly, methadone had no clinically significant effect on the pharmacokinetics of etravirine, when compared with historical controls. No relevant signs or symptoms of opioid withdrawal were reported.[10]

(d) Nevirapine

A retrospective review revealed 7 cases of patients taking methadone who developed withdrawal symptoms after starting regimens including nevirapine. The symptoms developed within 4 to 8 days, and methadone dose increases of 21 to 186% were required. Despite this, 3 patients did not respond. They elected to discontinue nevirapine, and in 2 patients somnolence developed within 2 weeks, so the methadone dose was reduced. Methadone plasma levels were available in 2 patients, and these suggested that nevirapine decreased methadone levels by about 90%.[11] In a pilot study of a once-daily nevirapine-containing regimen, 30% of patients required an increase in methadone dose.[12] A study in HIV-positive patients also reported that 32 out of 37 patients taking nevirapine required a methadone dose increase (median 20 mg daily).[9] In another study 4 of 5 patients taking methadone developed withdrawal symptoms on starting nevirapine-containing regimens and 2 patients refused further nevirapine, despite increasing their methadone dose. Another 2 patients were successfully treated with increases in their methadone doses of 33% and 100%.[13] Three other similar cases have been reported.[4,14,15]

In a pharmacokinetic study, 8 patients taking methadone 30 to 120 mg daily had methadone levels measured before and 14 days after starting an antiretroviral regimen including nevirapine 200 mg daily. The methadone AUC decreased by 52%, and the maximum level by 36%. Six patients complained of symptoms of methadone withdrawal, and required a mean increase in methadone dose of 16%.[16] Similarly, in 20 HIV-positive subjects stabilised on once-daily doses of racemic or *R*-methadone, the addition of nevirapine decreased the mean dose-adjusted AUC of methadone by 41%. This decrease resulted in symptoms of opioid withdrawal in 14 patients, which required additional doses of methadone.[17] Another pharmacokinetic study in 10 patients stabilised on methadone for at least 15 days found that nevirapine 200 mg daily reduced the AUC and maximum concentration of methadone by about 63% and 55%, respectively, but when the dose of nevirapine was increased to 400 mg daily there was no additional decrease in these pharmacokinetic parameters.[18]

Mechanism

Efavirenz and nevirapine induce the metabolism of methadone (possibly by the cytochrome P450 isoenzyme CYP3A4, or CYP2B6[19]), which results in reduced levels and effects. Etravirine also induces CYP3A4, but has only weak effects. In contrast, delavirdine is an *inhibitor* of various cytochrome P450 isoenzymes, and might therefore be expected to inhibit the metabolism of methadone, although the effects appear small.

Importance and management

The interaction between methadone and **efavirenz** or **nevirapine** is established and of clinical importance. Some authors have found that the dose increase required is much less than that predicted based on the reduction in methadone levels,[6,16] whereas others have questioned this.[5,20] It may be important not to confuse the adverse effects of the NNRTIs with opioid withdrawal symptoms.[6] It has been suggested that patients taking methadone who are given these drugs should be screened for opioid withdrawal beginning on the fourth day of the new medication. If symptoms develop, the methadone dose should be increased by 10 mg every 2 to 3 days until symptoms abate.[21] However, others have suggested dose increments should be made at one-week intervals to avoid overdose, as methadone has a long half-life (reported to range 13 to 47 hours).[22] Note that some patients may require an increase in methadone dose frequency to twice daily.[13] If efavirenz or nevirapine is stopped, the methadone dose should be gradually reduced to pretreatment levels over the course of one to 2 weeks.[21]

No dose adjustments of either **etravirine** or methadone are usually needed with concurrent use. However, despite this, the US manufacturer advises that patients are still monitored for signs of opioid withdrawal as the dose of maintenance methadone treatment may need to be altered in some patients.[23]

The US manufacturer of **delavirdine**[24] suggests that the methadone dose may need to be reduced; however, the effects in the study reported are small, and would not be expected to be of clinical significance.

Opioids + NSAIDs

In general, the concurrent use of NSAIDs and opioids is beneficial (improved pain relief, decreased adverse effects, reduced opioid requirements), and clinically relevant pharmacokinetic interactions are lacking. However, there is some conflicting evidence as to whether respiratory depression is increased or decreased in those given diclofenac and morphine. A single case report describes marked respiratory depression in a man given buprenorphine when ketorolac was added. An isolated report describes grand mal seizures in a patient given diclofenac and pentazocine.

Clinical evidence, mechanism, importance and management

NSAIDs are often given with opioids because they usually reduce the opioid requirements and some of the opioid-induced adverse effects.[1]

Enhanced pain relief has been reported with various combinations including **dextromethorphan** with **ketorolac**[2] or **tenoxicam**,[3] **oxycodone** with **ibuprofen**,[4] and **tramadol** with **ketorolac**[5] without increased adverse effects. Consider also 'Opioids + NSAIDs; Coxibs', p.197.

However, cases of respiratory depression have been reported, see *Morphine* below, and myoclonus has been reported with high doses of morphine given with NSAIDs, see 'Opioids; Morphine + Miscellaneous', p.210.

(a) Buprenorphine

A man underwent thoracotomy for carcinoma of the middle third of his oesophagus. One hour after transfer to the recovery ward he complained of severe pain at the operative site and was given epidural buprenorphine 150 micrograms (3 micrograms/kg), and 2 hours later intramuscular **ketorolac** 30 mg because of continued pain. During the next hour he became more drowsy, stopped obeying commands and his respiratory rate dropped to 6 breaths per minute. He recovered after 6 hours of mechanical ventilation. The authors of this report suggest that it may be necessary to use less buprenorphine in the presence of ketorolac to avoid the development of these respiratory depressant effects.[6] This appears to be the only report of this possible interaction, and, as with other opioids, NSAIDs such as **etodolac** have been used with buprenorphine to reduce the postoperative pain score without increasing adverse effects.[7]

(b) Codeine

A study in 12 healthy subjects found that a single 50-mg dose of **diclofenac** did not have a clinically important effect on the pharmacokinetics of a single 100-mg dose of codeine phosphate when compared with placebo. There was no effect on the metabolic clearance of morphine, and only a slight (about 5 to 10%) increase in the levels of glucuronide metabolites. In addition, **diclofenac** did not alter the analgesic effects of codeine as assessed in a cold pressor test (a test in which opioids, but not NSAIDs, are effective).[8] Although this interaction perhaps requires confirmation in a multiple-dose study in a clinical setting, the findings in healthy subjects suggest that no special precautions are required during the concurrent use of **diclofenac** and codeine.

Single oral-dose studies in 24 healthy subjects found that the bioavailability of both codeine phosphate 25 mg and **ibuprofen** 200 mg were unaffected by concurrent use.[9]

(c) Dextropropoxyphene (Propoxyphene)

In healthy subjects the concurrent use of dextropropoxyphene 260 mg daily and **sodium meclofenamate** 400 mg daily for one week was found to have no effect on the plasma levels of either drug.[10]

The manufacturer of **sulindac** notes that dextropropoxyphene had no effect on the plasma levels of sulindac or its sulfide metabolite.[11]

(d) Methadone

In a study in 16 patients with cancer-related pain, intramuscular **diclofenac** 75 mg twice daily given for 5 days with oral methadone solution every 8 hours had no effect on the AUC or maximum plasma levels of methadone.[12] Therefore, no methadone dose adjustments appear to be necessary during concurrent use.

(e) Morphine

In a study in 11 healthy subjects, an infusion of **ketoprofen** 1.5 mg/kg with morphine 100 micrograms/kg reduced the respiratory depression associated with morphine alone. There was no change in plasma morphine levels.[13] Another study in 6 patients found that intramuscular **diclofenac**

75 mg twice daily for 5 days did not affect the half-life and AUC of oral morphine solution.[14] Other studies have reported superior pain relief with morphine and NSAIDs, including **lornoxicam**,[2] **ketoprofen**,[15] and **ketorolac**,[16]with fewer adverse effects. Consider also 'Opioids + NSAIDs; Coxibs', below.

However, in contrast to these reports, a study in 7 patients on the first postoperative day after spinal surgery found that, although rectal **diclofenac** 100 mg reduced patient-controlled morphine consumption by 20%, respiratory rates were significantly lower after the **diclofenac**, and minimal at about 200 minutes. Levels of an active metabolite, morphine-6-glucuronide did not significantly decrease until 420 minutes post-dose.[17]

NSAIDs are frequently used with opioids because of their lack of respiratory depression and opioid-sparing effects. However, this study demonstrates that there may be a risk of respiratory depression and other adverse effects due to persistently high levels of morphine-6-glucuronide for a number of hours after receiving an NSAID. During this time period, patients should be more closely monitored.[17]

For mention of an increased incidence of myoclonus when high-dose morphine was given with NSAIDs, see 'Opioids; Morphine + Miscellaneous', p.210.

(f) Oxycodone

A study involving 23 healthy subjects found that the single-dose pharmacokinetics of **ibuprofen** 400 mg and oxycodone 5 mg were similar when given alone or in combination.[18]

(g) Pentazocine

A man with Buerger's disease had a grand mal seizure while watching television 2 hours after being given a single 50-mg suppository of **diclofenac**. He was also taking pentazocine 50 mg three times daily. He may possibly have had a previous seizure some months before after taking a single 100-mg slow-release **diclofenac** tablet.[8] The reasons for this reaction are not known, but on rare occasions **diclofenac** alone has been associated with seizures (incidence said to be 1 in 100 000) and seizures have also been seen with pentazocine alone. It is not clear what part the disease itself, or watching television, had in the development of this adverse reaction.[19] Therefore no interaction between **diclofenac** and pentazocine is established, but be aware of this case if concurrent use is being considered, particularly in patients who are known to be seizure-prone.

Opioids + NSAIDs; Coxibs

Parecoxib has no effect on the pharmacokinetics of alfentanil or fentanyl, and celecoxib and rofecoxib do not appear to affect the pharmacokinetics of tramadol. Coxibs can reduce the perioperative opioid requirement, but adverse effects are not necessarily reduced.

Clinical evidence, mechanism, importance and management

(a) Pharmacokinetic studies

In a crossover study in 12 healthy subjects, intravenous **parecoxib** 40 mg, given one hour before and 12 hours after an infusion of **alfentanil** 15 micrograms/kg or **fentanyl** 5 micrograms/kg, had no effect on the pharmacokinetics of these opioids.[1] Pupil diameter versus time curves were not affected by **parecoxib**. This interaction was investigated because both valdecoxib (the main metabolite of **parecoxib**) and **alfentanil** are substrates of the cytochrome P450 isoenzyme CYP3A4. The study suggests there should be no pharmacokinetic interaction during concurrent use.

In a study in patients receiving stable doses of **celecoxib** or **rofecoxib**, the pharmacokinetics of **tramadol** (given with paracetamol) did not appear to be affected by the coxibs. **Tramadol** is metabolised by CYP2D6 and CYP3A4, but there appeared to be no difference in the clearance of tramadol given with **celecoxib** (which is said to be a CYP2D6 inhibitor and is itself metabolised in part by CYP3A4) or **rofecoxib**.[2]

(b) Pharmacodynamic studies

Many studies have reported reduced opioid requirements and reduced opioid-related adverse effects when coxibs including **celecoxib**,[3] **parecoxib**,[4] and **rofecoxib**[5] are given perioperatively or postoperatively with various opioids including **hydrocodone**[3] and **morphine**.[5] The timing of the administration of the coxib appears to affect opioid-induced analgesia and post-infusion increases in sensitivity to pain. One study in healthy subjects found that pretreatment with **parecoxib** increased the analgesic effects of a **remifentanil** infusion and significantly diminished the increased sensitivity to pain after remifentanil was withdrawn. Giving parecoxib at the start of the remifentanil infusion did not alter its analgesic effects.[6] In another study, patients given preoperative and postoperative **rofecoxib**, or placebo, found that rofecoxib reduced **morphine** requirements and pain scores. In another group of patients given placebo preoperatively and **rofecoxib** postoperatively, rofecoxib did not significantly affect **morphine** requirements or pain scores at 24 hours after the operation compared to those given placebo pre-and postoperatively, but did show improvement at 48 hours and 72 hours after the operation. However, preoperative rofecoxib was considered to provide only moderate benefit and possibly offered little benefit over early postoperative administration.[5]

In a double-blind, placebo-controlled study in 72 patients undergoing laparoscopic cholecystectomy, oral **etoricoxib** 120 mg given 1.5 hours before surgery reduced the need for postoperative patient controlled analgesia (PCA) with **fentanyl**, but opioid-related adverse effects were not reduced.[7]

Opioids + Opioids

The concurrent use of two opioid agonists may have enhanced effects, although acute opioid tolerance may also occur. Opioids

with mixed agonist/antagonist properties (e.g. buprenorphine, butorphanol, nalbuphine, pentazocine) may precipitate opioid withdrawal symptoms in patients taking pure opioid agonists (e.g. fentanyl, methadone, morphine).

Clinical evidence, mechanism, importance and management

Many of the opioids used clinically act primarily at μ-opioid receptors including **codeine**, **diamorphine**, **fentanyl**, **methadone**, and **morphine**, but they often have pharmacological differences, and patients tolerant to one opioid can frequently be switched to another opioid (opioid rotation) at doses lower than predicted by relative potencies.[1] Studies in *animals* have found synergistic or additive effects between μ-opioids.[1] The majority of studies in patients have reported enhanced analgesic effects with opioid combinations,[2,3] although combined opioids are not always beneficial;[4] in some cases adverse effects were increased and acute opioid tolerance has also occurred.[3] For example, a study in 69 patients who had undergone abdominal surgery and were receiving **morphine** found that the addition of a **tramadol** infusion was associated with improved patient-controlled analgesia (PCA) and smaller **morphine** requirements with no increase in adverse effects.[2] However, another study found that the effects of this combination were less than additive.[5] Furthermore, the incidence of dry mouth occurred more frequently and it was concluded that the use of two μ-opioid agonists in combination might only increase the number of adverse effects.[5] Other studies have found that transdermal **fentanyl** reduced **morphine** requirements after hysterectomy[6,7] without affecting sedation scores.[6] However, the combination of **fentanyl** and **morphine** resulted in more pronounced respiratory depression than morphine alone.[6,7] In contrast, in a study of 49 patients undergoing major abdominal surgery, relatively large doses of intraoperative **remifentanil** (mean remifentanil infusion rate 300 nanograms/kg per minute) were reported to almost double **morphine** requirements in the first 24 hours postoperatively. The results suggested that **remifentanil** caused the development of acute opioid tolerance and excessive sensitivity to pain.[8] Therefore, although some opioid combinations are useful, clinical studies are needed to ascertain the benefits and safety of specific combinations.[4]

Opioids with mixed agonist/antagonist properties (e.g. **buprenorphine**, **butorphanol**, **nalbuphine**, **pentazocine**) may precipitate opioid withdrawal symptoms in patients taking pure opioid agonists such as **fentanyl**, **methadone** and **morphine** (see 'Table 6.1', (p.150), for a classification). An example of this occurred in a 60-year-old woman who was taking slow-release **morphine** 90 mg twice daily for cancer pain and was additionally given **nalbuphine** 30 mg intravenously in an ambulance following a fractured femur. She became agitated and experienced involuntary movements, tachycardia, hypertension and sweating (typical of opioid withdrawal). Her management was further complicated by resistance to intravenous **morphine**, necessitating a femoral nerve block. The agitation, which lasted for about 4 hours after she was given the **nalbuphine**, was controlled with lorazepam.[9]

Opioids + Phenothiazines

Chlorpromazine has been reported to increase the analgesic effect of pethidine (meperidine), but increased respiratory depression, sedation, CNS toxicity and hypotension can also occur. Other phenothiazines such as levomepromazine, promethazine, prochlorperazine, propiomazine and thioridazine may also interact with pethidine to cause some of these effects. Additive CNS depressant effects would be expected when opioids are given with phenothiazines.

Clinical evidence

(a) Pethidine (Meperidine)

In a single-dose study in healthy subjects, **chlorpromazine** had no effect on the pharmacokinetics of pethidine. However, the excretion of the metabolites of pethidine was increased, and symptoms of light-headedness, dry mouth and lethargy were significantly increased: 4 subjects experienced such marked debilitation that they required assistance to continue the study. Systolic and diastolic blood pressures were also reduced.[1]

Chlorpromazine 25 mg/70 kg given alone had no consistent effect on respiratory function in 6 healthy subjects but the respiratory depression produced by pethidine 100 mg/70 kg was exacerbated when the two drugs were given together. One subject had marked respiratory depression, beginning about 30 minutes after both drugs were given and lasting 2 hours.[2]

The respiratory depressant effects of pethidine can be increased by **promethazine** with pentobarbital,[3] **propiomazine**[4,5] and **levomepromazine**[6], but the effects of **prochlorperazine**[7] with pethidine on respiration were not statistically significant.

A 12-year-old patient taking long-term **thioridazine** 50 mg twice daily and given premedication with pethidine, diphenhydramine and glycopyrrolate, was very lethargic after surgery and stopped breathing. He responded to naloxone.[8] Promethazine may also decrease the dose requirements of pethidine during surgery, see under *Other opioids*, below.

(b) Other opioids

There have been conflicting data as to whether or not phenothiazines potentiate narcotic analgesia,[9] and it has been suggested that some patients treated with an opioid and a phenothiazine are merely too sedated to report pain.[10] However, some studies have found that **promethazine** reduces opioid requirements. The maintenance doses of a variety of opioid analgesics (**morphine**, **pethidine** (**meperidine**), **oxymorphone**, **hydromorphone**, **fentanyl**, **pentazocine**) required during surgical anaesthesia were reduced by 28 to 46% when 132 patients were premedicated with intramuscular **promethazine** 50 mg/70 kg, when compared with control patients. Similarly, on-demand **pentazocine** requirements post-caesarean section were reduced by 32% in women given **promethazine** as soon as the cord was clamped.[11] In a randomised, placebo-controlled study in 90 patients undergoing abdominal hysterectomy, the preoperative use of intravenous **promethazine** 100 micrograms/kg (given over 30 minutes, starting 30 minutes before induction), reduced the 24-hour postoperative **morphine** consumption by about 30%, when compared with placebo or postoperative **promethazine** use. Postoperative nausea and vomiting were reduced by both pre- and postoperative **promethazine**, when compared with placebo.[12]

Mechanism

There is evidence that chlorpromazine can increase the activity of liver microsomal enzymes so that the metabolism of pethidine (meperidine) to norpethidine and norpethidinic acid are increased. These metabolites probably account for the lethargy and hypotension seen in one study.[1] The effects of the phenothiazines on pethidine-induced respiratory depression may be related. Both the opioids and the phenothiazines are CNS depressants, and their effects may be additive.

Importance and management

Phenothiazines may enhance the hypotensive, sedative, and respiratory depressant effects of opioids. Patients should be monitored carefully on concurrent use, and opioid dose reductions made if necessary.

The manufacturers of **methadone** generally advise caution with other CNS depressants, however one manufacturer suggests that the concurrent use of other CNS depressants is not advised.[13]

Although lower analgesic doses of pethidine (meperidine) have been used with chlorpromazine,[14] a marked increase in respiratory depression can occur in some susceptible individuals[2] and the authors of one study[1] suggested that the risks of giving pethidine with chlorpromazine outweighed the advantages. Information about other adverse interactions between pethidine and the phenothiazines seems to be very limited: the interaction with thioridazine seems to be the only one reported. Increased

analgesia may occur but it may be accompanied by increased respiratory depression, which is undesirable in patients with existing respiratory insufficiency. The US manufacturer advises that concurrent use of pethidine with phenothiazines may also result in severe hypotension, profound sedation, or coma if usual doses of pethidine are used. They suggest that the dose of pethidine should be proportionally reduced (usually by 25 to 50%) when it is given with phenothiazines.[15]

For mention of myoclonus associated with high doses of morphine and chlorpromazine, see 'Opioids; Morphine + Miscellaneous', p.210.

Opioids + Protease inhibitors

Ritonavir decreases pethidine (meperidine) and increases norpethidine levels, which may possibly increase toxicity on long-term use. Similarly, ritonavir and other protease inhibitors increase buprenorphine levels. Ritonavir may increase the metabolism of morphine, and decrease the metabolism of dextropropoxyphene and tramadol.

Clinical evidence

(a) Buprenorphine

A study in 20 HIV-negative, opioid-dependent patients stable on a combination of sublingual buprenorphine with naloxone (ratio 4:1) found that **atazanavir** 400 mg daily for 5 days increased the AUC and maximum plasma concentration of buprenorphine by 93% and 64%, respectively. Similarly, **ritonavir**-boosted **atazanavir** 100 mg/300 mg daily for 5 days increased the AUC and maximum plasma concentration of buprenorphine (by 67% and 37%, respectively), although to a slightly lesser degree than atazanavir alone. The study also noted that the levels of buprenorphine metabolites were increased. Buprenorphine had no significant effects on the pharmacokinetics of atazanavir or ritonavir, when compared with healthy non-opioid-dependent controls. No additional increases in the cardiac PR interval or bilirubin levels associated with atazanavir were found with the buprenorphine-maintained group compared with the control group.[1] The manufacturer of ritonavir reports that, in a study, ritonavir 100 mg twice daily increased the AUC and maximum level of buprenorphine 16 mg daily (route not specified) by 57% and 77%, respectively.[2] In a study in opioid-dependent patients taking sublingual buprenorphine and naloxone, patients were given an antiretroviral (**nelfinavir**, **ritonavir**-boosted **lopinavir**, or **ritonavir**) for 5 to 15 days to investigate the effect of these drugs on the QT interval. Buprenorphine with naloxone alone did not significantly alter the QT interval, but when an antiretroviral was also given there was a statistically, but probably not clinically, significant increase in the QT interval. The greatest increase in QTc interval was seen in patients receiving buprenorphine with naloxone and **ritonavir** 100 mg twice daily (low booster dose).[3]

One report describes 3 HIV-positive patients who experienced increased buprenorphine adverse effects (e.g. daytime sleepiness, dizziness, and reduced mental function) within about 2 days of starting to take **ritonavir**-boosted **atazanavir**. When the dose of buprenorphine was reduced there was a reduction in sedative symptoms, although in one case this led to an increase in opioid cravings.[4]

(b) Fentanyl and related drugs

For the interactions of the protease inhibitors with alfentanil or fentanyl, see 'Opioids; Fentanyl and related drugs + Protease inhibitors', p.200.

(c) Methadone

For the interactions of the protease inhibitors with methadone, see 'Opioids; Methadone + Protease inhibitors', p.200.

(d) Pethidine (Meperidine)

In 8 healthy subjects, **ritonavir** 500 mg twice daily for 10 days decreased the AUC of a single 50-mg dose of oral pethidine by 62% and increased the AUC of the metabolite, norpethidine, by 47%.[2,5] Norpethidine is pharmacologically active, and is possibly less effective an analgesic than the parent compound, and more likely to cause CNS effects such as seizures.

Mechanism

In vitro and *in vivo* studies have demonstrated that ritonavir is a potent inhibitor of the cytochrome P450 isoenzyme CYP3A4 and to a lesser extent CYP2D6, and may also induce glucuronidation.[2] An *in vitro* study suggested that buprenorphine metabolism may be inhibited by ritonavir and to a lesser extent by **indinavir** and **saquinavir**,[6] which would be expected to lead to increased buprenorphine levels. **Dextropropoxyphene** (propoxyphene) is also metabolised by CYP3A4. Substrates of CYP2D6 include **codeine**, **dihydrocodeine**, **oxycodone**, and **tramadol**. **Morphine** undergoes glucuronidation, and the morphine metabolite [morphine-6 beta-glucuronide] is believed to contribute to the analgesic effects of morphine. Buprenorphine, and to some extent, **codeine** also undergo glucuronidation.[7] The exact mechanism for the unexpected increase in buprenorphine metabolite levels reported in one study is unclear, although the authors suggest that atazanavir alone or with ritonavir may increase the gastrointestinal bioavailability of swallowed buprenorphine, thereby leading to an apparent increase in metabolite levels.[1]

Importance and management

Most of these interactions remain theoretical, but they are consistent with the way the protease inhibitors and the opioids interact with other drugs. The consequences of inhibition of CYP2D6 are most pronounced for **codeine**, and CYP2D6 inhibition will lead to decreased levels of the morphine metabolite of codeine and therefore, perhaps contrary to expectation, a reduced effect. The levels of other CYP2D6 substrates **dihydrocodeine**, **oxycodone**, and **tramadol** would be expected to be raised, and dose reductions may be necessary. This has been suggested for tramadol.[8] It would seem prudent to monitor for adverse effects such as sedation. However, note that *low-dose* ritonavir (i.e. the dose used as a pharmacokinetic enhancer with other protease inhibitors) has a less potent effect on CYP2D6 and dose reductions of drugs metabolised by CYP2D6 would not generally be required if this dose of ritonavir is given concurrently.[9]

Ritonavir is a potent inhibitor of CYP3A4 and therefore the UK manufacturer of ritonavir contraindicates its use with **dextropropoxyphene** as raised dextropropoxyphene levels may occur, which would increase the risk of serious respiratory depression or other serious adverse events.[2] However, the US manufacturer only suggests that a dose decrease may be needed.[8]

The outcome of taking ritonavir with **morphine** is less clear, but it is expected that its levels will be decreased.[2,10] It would seem prudent to monitor closely to ensure morphine is effective in patients taking ritonavir. More study is needed.

It has been suggested[11] that the starting dose of **buprenorphine** should be halved in patients taking CYP3A4 inhibitors, such as the protease inhibitors, when it is used for opioid dependence, although this may not be of clinical significance in those patients given low-dose ritonavir alone with buprenorphine who are opioid-tolerant.[2] One manufacturer of sublingual and injectable buprenorphine states that as the magnitude of an inhibitory effect is unknown, such drug combinations should be avoided when buprenorphine is used by these routes.[12,13] There appears to be less likelihood of an interaction with CYP3A4 inhibitors if buprenorphine is used transdermally, see 'Opioids + Azoles', p.181.

The manufacturers contraindicate or advise against the concurrent use of **pethidine** (**meperidine**) with ritonavir because of the risk of norpethidine

toxicity (such as seizures).[2,8,14] The long-term use of pethidine with other protease inhibitors that are given with low-dose ritonavir is also not recommended.

Opioids; Fentanyl and related drugs + Protease inhibitors

Ritonavir increases the levels of alfentanil and fentanyl, and markedly increases alfentanil-induced miosis. Other protease inhibitors may have a similar effect.

Clinical evidence

(a) Alfentanil

A study in 11 healthy subjects found that steady-state **ritonavir** significantly reduced the clearance of both intravenous and oral alfentanil by about 3.7-fold and 10.5-fold, respectively. The oral bioavailability of alfentanil was increased from 37% to 95% by **ritonavir**. As a result of this, alfentanil-induced miosis was also significantly increased.[1] The same or a similar study has been reported elsewhere.[2]

(b) Fentanyl

In a study in healthy subjects, **ritonavir** 200 mg increased to 300 mg three times daily for a total of 7 doses increased the AUC of a single 5-mg/kg intravenous dose of fentanyl by 83%, decreased its clearance by 67%, and increased the elimination half-life twofold.[3]

Mechanism

Both fentanyl and alfentanil are metabolised by the cytochrome P450 isoenzyme CYP3A4. Ritonavir, and other protease inhibitors, are potent inhibitors of CYP3A4 and they therefore reduce the metabolism of these opioids, which results in increased levels and effects.

Importance and management

The evidence is limited, but is consistent with the way protease inhibitors and fentanyl or alfentanil are known to interact with other drugs. The UK manufacturer of alfentanil warns that potent CYP3A4 inhibitors such as ritonavir could increase the risk of prolonged or delayed respiratory depression, and says the combination should be used with special care, and that a reduced dose of alfentanil may be necessary.[4] Similarly, caution is required in patients taking ritonavir given fentanyl by any route (oral, parenteral, or transdermal). In particular, one UK manufacturer suggests avoiding the combination of ritonavir and transdermal fentanyl unless the patient can be closely monitored.[5] Fentanyl dose reductions may be needed with long-term treatment to avoid fentanyl accumulation.[5,6] Care should also be taken if low-dose ritonavir is used with other protease inhibitors as a pharmacokinetic enhancer.

The manufacturers also warn that other potent CYP3A4 inhibitors (they name **amprenavir**, **fosamprenavir**, and **nelfinavir**) may have a similar effect,[5,6] and it would seem prudent to be alert for an interaction with any protease inhibitor.

Opioids; Methadone + Protease inhibitors

Methadone levels can be reduced by amprenavir, nelfinavir, and high-dose ritonavir, as well as ritonavir-boosted lopinavir, saquinavir, and tipranavir, Ritonavir-boosted darunavir and fosamprenavir, and indinavir, and possibly unboosted atazanavir or saquinavir, do not appear to have clinically significant effects on methadone pharmacokinetics. In addition, amprenavir levels may be reduced by methadone. Cases of QT prolongation and torsade de pointes have been reported in patients taking protease inhibitors and methadone.

Clinical evidence

(a) Amprenavir

A study involving 16 opioid-dependent subjects found that amprenavir 1.2 g twice daily for 10 days decreased the AUCs for both *R*-methadone (active enantiomer) and *S*-methadone (inactive enantiomer) by 13% and 40%, respectively. No clinically significant changes were noted in opioid effects and there was no evidence of opioid withdrawal.[1] However, in another study, in 5 patients methadone levels were reduced by 35% (range 28 to 87%) within 17 days of starting to take amprenavir 1.2 g twice daily and abacavir 600 mg twice daily. Two patients reported nausea before their daily methadone dose, which can be a sign of opiate withdrawal.[2] Note that **abacavir** may modestly reduce methadone levels, and could therefore have contributed to this effect (see 'Opioids + NRTIs', p.193).

The first study also found that amprenavir and methadone resulted in a 30% decrease in the AUC of amprenavir compared with non-matched historical controls.[1]

(b) Atazanavir

In 16 patients treated for opiate addiction, atazanavir, given for 14 days, had little effect on the steady-state pharmacokinetics of methadone, and symptoms of opiate withdrawal or excess were not detected.[3] A case of torsade de pointes has been reported in a patient taking methadone and also taking ritonavir-boosted atazanavir 100/300 mg daily (although the patient admitted poor compliance). The protease inhibitors were withdrawn and the QT interval prolongation was reversed over the next 48 hours.[4]

(c) Darunavir

A study where subjects were given methadone 55 to 150 mg daily with ritonavir-boosted darunavir 100/600 mg twice daily found that the AUC and minimum levels of *R*-methadone were reduced by 16% and 15%, respectively.[5,6]

(d) Fosamprenavir

A study in 19 patients stable taking methadone found that the concurrent use of ritonavir-boosted fosamprenavir 100/700 mg twice daily for 14 days reduced the AUC and maximum concentration of *R*-methadone by 18% and 21%, respectively, and reduced the AUC and maximum concentration of *S*-methadone by 43%. These minor changes did not result in any serious adverse effects or any significant changes in cognitive performance. None of the patients experienced opioid withdrawal and no methadone dose adjustments were required. The levels of **amprenavir**, derived from fosamprenavir, were unaffected when compared with historical control data.[7]

(e) Indinavir

A randomised, crossover study in 12 patients taking methadone found that the pharmacokinetics of methadone were unchanged by indinavir 800 mg every 8 hours for 8 days. A small decrease in indinavir peak levels and a small increase in trough levels were noted, when compared with historical controls.[8] Another study in 6 HIV-positive patients taking methadone and two nucleoside analogues similarly found that methadone levels remained unchanged when indinavir was added.[9] Similar results have been reported elsewhere.[10]

There are also clinical reports about 2 patients whose methadone levels appeared to be unaltered while taking indinavir, but who later had reduced levels when taking nelfinavir, or saquinavir with ritonavir (see *Nelfinavir*, and *Saquinavir*, below).[11,12] This would seem to confirm that indinavir does not have a clinically relevant effect on methadone levels.

(f) Lopinavir

A study in healthy subjects found that ritonavir-boosted lopinavir 100/400 mg twice daily for 10 days reduced the AUC of a single 5-mg dose of methadone by about 50%.[13] Similarly, in 15 healthy subjects taking methadone, ritonavir-boosted lopinavir 100/400 mg twice daily for 7 days decreased the AUC of methadone by 26% and increased its clearance by 42%. Four of the subjects had clinically important increases in opioid-withdrawal scores, and were all found to have sub-therapeutic trough methadone levels.[14] [Note that the same dose of ritonavir alone had no effect on methadone levels, see *Ritonavir*, below]. In another study in 8 HIV-positive patients taking methadone, a lopinavir with ritonavir-based antiretroviral regimen reduced the AUC of methadone by 36%, after 14 days of treatment. However, none of these patients experienced methadone withdrawal during the study or during 6 weeks of follow-up.[15] In yet another study (that did not measure methadone levels), none of 18 patients experienced methadone withdrawal during the 28 days after starting ritonavir-boosted lopinavir.[16] In a further study, methadone appeared to have no effect on the pharmacokinetics of lopinavir or ritonavir (given as a combined preparation).[17] A case of prolonged QT interval associated with torsade de pointes has been reported in an HIV-positive patient taking long-term methadone when ritonavir-boosted lopinavir was *stopped*.[18]

(g) Nelfinavir

A pharmacokinetic study in 13 subjects stabilised on methadone maintenance for at least one month found that nelfinavir 1.25 g twice daily for 8 days decreased the $AUC_{0\text{-}24}$ of *R*-methadone and *S*-methadone by 43% and 51%, respectively, and decreased the maximum concentration of *R*-methadone and *S*-methadone by 43% and 50%, respectively. None of the subjects developed opioid withdrawal symptoms or required methadone dose alterations. The methadone concentrations increased during the 14-day period after nelfinavir was stopped, but to a slightly lower level than before nelfinavir was added. Nelfinavir pharmacokinetics were not affected by methadone, when compared with historical data.[19] In a study looking at the levels of nelfinavir and its active metabolite M8, methadone had no significant effect on the AUC of nelfinavir, but the $AUC_{0\text{–}12}$ of M8 was reduced by 48%.[20]

An HIV-positive man who had been taking methadone 100 mg daily for several years with indinavir 800 mg and zalcitabine 750 micrograms three times daily, developed opioid withdrawal symptoms within 6 weeks of starting to take stavudine and nelfinavir 750 mg three times daily. His methadone dose was increased to 285 mg daily before therapeutic serum levels were achieved. When his antiretroviral treatment was withdrawn, his methadone dose was successfully reduced to 125 mg daily.[12] Two other patients taking nucleoside analogues had a 40 to 50% fall in their serum methadone levels when nelfinavir was added.[9,10] Similarly, in another study, 4 of 6 patients developed symptoms of methadone withdrawal within 5 to 7 days of starting nelfinavir-based therapy. The mean AUC of methadone was reduced by 56% and the subjects required a mean increase in methadone dose of 15%.[21]

A retrospective study of HIV-positive patients taking methadone reported that 5 out of 30 patients (17%) required methadone adjustments (mean 26 mg). The use of nelfinavir with methadone was effective and well tolerated.[22] A further study by the same authors reported that the mean methadone dose was increased by 10.6 mg with concurrent nelfinavir, when compared with methadone doses before nelfinavir was started.[23] A patient receiving methadone experienced torsade de pointes after starting to take nelfinavir.[24]

(h) Ritonavir

A patient taking lamivudine and zidovudine had a marked decrease in methadone levels when ritonavir was added.[9,10] Another patient receiving methadone experienced an opioid withdrawal syndrome when ritonavir was added to a similar antiretroviral regimen.[25]

A study in healthy subjects given single doses of intravenous and oral methadone and taking ritonavir up to 400 mg twice daily found that short-term (3-day) and steady-state ritonavir, respectively, increased the systemic and apparent oral clearance of methadone by about 50% and 100%. This produced a significant reduction in both the *R*-methadone and *S*-methadone AUCs. Ritonavir also increased the renal clearance of methadone by 40 to 50% and stereoselectively increased hepatic *N*-demethylation of methadone to inactive metabolites (with a greater effect on *S*- than on *R*-metabolite formation clearance). This occurred despite more than 70% inhibition of CYP3A by ritonavir.[26] Ritonavir (dose not stated) was given to 11 healthy subjects for 14 days, with a single 5-mg dose of methadone on day 11. Ritonavir reduced the maximum serum levels of methadone by 38% and the AUC by 36%.[27] However, in another study in 15 healthy subjects receiving methadone, ritonavir 100 mg twice daily for 7 days had no significant effect on methadone pharmacokinetics.[14]

In a further study, methadone apparently increased ritonavir exposure by 60%, when given alone, but had no effect on ritonavir pharmacokinetics when it was given with lopinavir.[17]

In healthy subjects the miosis caused by oral and intravenous methadone was increased by the acute use of ritonavir for 3 days but returned to below baseline after longer-term use for 14 days. It appeared that acute ritonavir inhibited, but chronic ritonavir mildly increased methadone elimination.[28] A case of torsade de pointes has been reported in a patient taking methadone, atazanavir and ritonavir, see *Atazanavir* above.

(i) Saquinavir

A study in an HIV-positive patient taking methadone and two nucleoside analogues found that methadone serum levels remained unchanged when saquinavir was added.[9] Similar results have been reported elsewhere.[10] Other studies have been undertaken with ritonavir-boosted saquinavir. An HIV-positive patient taking methadone 90 mg daily with indinavir, lamivudine and zidovudine, developed withdrawal symptoms and was hospitalised within a week of stopping these HIV drugs and starting ritonavir 400 mg, saquinavir 400 mg and stavudine 40 mg twice daily. The patient was eventually re-stabilised taking methadone 130 mg daily.[11]

A later study in 12 HIV-positive subjects taking methadone maintenance found that giving ritonavir 400 mg twice daily with saquinavir 400 mg twice daily decreased the *S*-methadone AUC by 40% and the *R*-methadone AUC by 32%. However, when these decreases were corrected for changes in protein binding, the free *R*-methadone AUC was decreased by only 20%, and the free *S*-methadone AUC by 25%. None of the subjects experienced methadone withdrawal or required a change in their methadone dose.[29] Similarly, in another study ritonavir-boosted saquinavir 100/1600 mg daily for 14 days caused no clinically relevant changes in total or free levels of either enantiomer of methadone in 12 HIV-negative subjects taking methadone. None of the subjects experienced methadone withdrawal.[30]

(j) Tipranavir

The manufacturers of tipranavir state that use of methadone and ritonavir-boosted tipranavir can result in a decrease in methadone levels of about 50%.[31,32]

Mechanism

Not known. The findings are the opposite of those originally predicted based on *in vitro* data showing *inhibition* of methadone metabolism (principally mediated by the cytochrome P450 isoenzyme CYP3A).[33] A slight increase in methadone elimination has been reported with ritonavir,[26,28] but this does not appear to be mediated by CYP3A. It is possible that protease inhibitors induce the activity of other isoenzymes or act via other mechanisms (e.g. glucuronyltransferases). The reduction in methadone levels has not always correlated with clinical effects, and it has been suggested that this may be because the pharmacokinetics of the enantiomers (one of which is inactive) are affected differently, and/or altered protein binding occurs.[7,20,26]

Importance and management

Information is limited but the interactions of methadone with **amprenavir**, **nelfinavir**, **ritonavir** and ritonavir-boosted **lopinavir**, **saquinavir**, and **tipranavir** would appear to be established. However, the picture seems to be that not all patients experience withdrawal symptoms if given these drugs. Therefore, in methadone-maintained patients, care should be taken if any of these protease inhibitors is started or stopped. It has been suggested that patients taking methadone who are given a protease inhibitor should be screened for opioid withdrawal beginning on the fourth day of the new medication. If symptoms develop, the methadone dose should be increased by 10 mg every 2 to 3 days until symptoms abate.[34] However, others have suggested dose increments should be made at one-week intervals to avoid overdose, as methadone has a long half-life (reported to range from 13 to 47 hours).[24] If the protease inhibitor is stopped the methadone dose should be gradually reduced to pretreatment levels over the course of one to 2 weeks.[34]

Although the changes in methadone levels with ritonavir-boosted **darunavir** are minimal and no dose adjustment is initially needed, the manufacturers advise monitoring with longer-term use as ritonavir may induce the metabolism of methadone, requiring a dose adjustment in some patients.[5,6]

Similarly, the levels of methadone are minimally affected by ritonavir-boosted **fosamprenavir** and no withdrawal signs were reported in one study. However, despite noting that the interaction does not appear to be clinically relevant, the manufacturers still advise monitoring patients given both drugs for signs of opioid withdrawal, as a precaution,[35,36]

Note that **amprenavir** plasma levels may also be reduced by methadone. The US manufacturer noted that amprenavir may be less effective if taken concurrently with methadone and suggested that alternative antiretroviral therapy should be considered.[37] In contrast, amprenavir levels from ritonavir-boosted fosamprenavir were not affected by the concurrent use of methadone.[7]

Indinavir appears not to interact with methadone, and very limited evidence suggests that **atazanavir** and **saquinavir** alone do not interact either.

The protease inhibitors appear to have contributed to the cases of QT prolongation and torsade de pointes reported above, and a retrospective study in HIV-positive patients reported that nelfinavir and methadone were independently associated with an increased risk of QTc prolongation.[38] Patients taking methadone in doses greater than 100 mg and with additional risk factors for QT prolongation should be carefully monitored, see 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290.

Opioids + Quinidine

Quinidine appears to increase the *oral* absorption and effects of fentanyl, methadone, and morphine, but does not significantly alter the opioid-induced miosis when these opioids are given *intravenously*. Care should be taken if high-dose methadone is used with quinidine as cardiac conduction might possibly be affected. Quinidine may modestly increase the bioavailability of tramadol. No significant pharmacokinetic interaction appears to occur between quinidine and hydromorphone.

Clinical evidence

(a) Fentanyl

In a study in healthy subjects, quinidine sulfate 600 mg given one hour before an *intravenous* infusion of fentanyl 2.5 micrograms/kg did not alter fentanyl-induced miosis. However, the same dose of quinidine given before *oral* fentanyl 2.5 micrograms/kg (with ondansetron as an antiemetic) increased fentanyl-induced miosis. This increase was considered proportionate to the increase in the AUC of fentanyl (160%). There was no change in the elimination half-life of fentanyl.[1]

(b) Hydromorphone

An *in vitro* study suggested that quinidine did not significantly affect the metabolism of hydromorphone to norhydromorphone.[2]

(c) Methadone

In a study in healthy subjects, quinidine sulfate 600 mg, given one hour before *intravenous* methadone hydrochloride 10 mg, did not alter methadone-induced miosis. However, the same dose of quinidine given before *oral* methadone hydrochloride 10 mg (with ondansetron as an antiemetic) increased the peak methadone-induced miosis by 34%. The plasma levels of oral methadone in the absorption phase were increased, but the maximum plasma level or AUC of methadone were not affected.[3]

(d) Morphine

In a study in healthy subjects, quinidine sulfate 600 mg, given one hour before *intravenous* morphine sulfate 150 micrograms/kg, did not alter morphine-induced miosis. However, the same dose of quinidine given before *oral* morphine sulfate 30 mg (with ondansetron as an antiemetic) increased morphine-induced miosis by 56%. This increase was considered proportionate to the increase in morphine AUC (60%) and maximum level (88%). There was no change in the elimination half-life of morphine.[4] Similarly, in another study in healthy subjects, quinidine 800 mg given one hour before *intravenous* morphine 7.5 mg did not alter the respiratory depressant nor miotic effects of morphine, and there was no change in plasma morphine or morphine glucuronide levels.[5]

(e) Tramadol

A placebo-controlled study in 12 healthy subjects found that quinidine 50 mg had virtually no effect on the analgesic effect of tramadol 100 mg but it inhibited its effect on pupil size.[6] The US manufacturer reports that, in a single-dose study, quinidine 200 mg taken 2 hours before extended-release tramadol 100 mg increased the exposure to tramadol by 50 to 60%, and decreased the exposure to its M1 metabolite by a similar amount.[7]

Mechanism

Fentanyl and methadone are metabolised by the cytochrome P450 isoenzyme CYP3A4 and hydromorphone is demethylated by CYP3A4. Quinidine is also a substrate for CYP3A4 and inhibits CYP2D6, but does not appear to affect the metabolism of these opioids.[1-3] However, quinidine inhibits P-glycoprotein and this may affect fentanyl, methadone and morphine intestinal absorption.[1,3,4] The lack of effect on miosis indicate that quinidine does not appear to alter the brain distribution of fentanyl[1] or morphine.[4,5]

Tramadol is partially metabolised to the active metabolite *O*-desmethyltramadol (which affects opioid receptors), by the cytochrome P450 isoenzyme CYP2D6, which is inhibited by quinidine. However, this appears to have little effect on the analgesic efficacy of tramadol.[6]

Importance and management

The clinical significance of the increase in absorption of oral **fentanyl**, **morphine** and **methadone** caused by quinidine is unknown. However, note that both high doses of methadone and quinidine can affect the QT interval, see 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290. The clinical importance of a possible interaction with oral transmucosal fentanyl citrate (of which a significant proportion is swallowed) remains to be determined, but be aware that its effects may be increased.

Hydromorphone does not appear to be affected by quinidine although ideally this needs confirming in clinical studies.

The general significance of the interaction between quinidine and tramadol is unclear, although it would be prudent to bear the possibility of an interaction in mind should a patient taking both drugs develop an increase in tramadol adverse effects.

Opioids; Codeine and related drugs + Quinidine

The analgesic effects of codeine, and probably also hydrocodone, are reduced or abolished by quinidine. Quinidine alters the pharmacokinetics of dihydrocodeine and oxycodone, but this does not appear to alter their effects.

Clinical evidence

(a) Codeine

Codeine 100 mg was given to 16 CYP2D6 extensive metabolisers (that is, those with normal levels of this isoenzyme) with and without a single 200-mg dose of quinidine. The quinidine reduced the peak morphine levels by about 80% (from a mean of 18 nanomol/L to less than 4 nanomol/L). Codeine given alone increased the pain threshold (pinprick pain test using an argon laser) but no significant analgesic effects were detectable when quinidine was also present.[1] Another study found that the effects of codeine in CYP2D6 extensive metabolisers who were given quinidine, were virtually the same as codeine alone in CYP2D6 poor metabolisers (that is, those lacking or deficient in CYP2D6).[2] These studies confirm the preliminary findings of an earlier study using codeine 100 mg and quinidine 50 mg.[3] The quinidine reduced the peak morphine plasma levels by more than 90% (by 92% in 7 extensive metabolisers, and by 97% in one poor metaboliser) and similarly abolished its analgesic effects.[3]

(b) Dihydrocodeine

A study in which four CYP2D6 extensive metabolisers (that is, those with normal levels of this isoenzyme) were given dihydrocodeine 40 or 60 mg found that, when they were pretreated with quinidine 200 mg, almost none of the morphinoid metabolites of dihydrocodeine normally present in the serum could be detected.[4] The same authors found essentially similar results in a later study in ten CYP2D6 extensive metabolisers given dihydrocodeine 60 mg and quinidine 50 mg.[5] However, a single-dose study involving 10 healthy subjects who were CYP2D6 extensive metabolisers investigated the effect of quinidine on the visceral and somatic analgesic effects of dihydrocodeine and its metabolite, dihydromorphine. It was found that although quinidine reduced dihydromorphine plasma levels (by inhibition of CYP2D6 reducing the metabolism of dihydrocodeine to dihydromorphine), this did not result in diminished pain tolerance thresholds. This suggested that the metabolism of dihydrocodeine to dihydromorphine may not be clinically important for analgesia.[6]

(c) Hydrocodone

In a comparative study, 5 extensive metabolisers and 6 poor metabolisers of CYP2D6 (that is, those with normal levels of this enzyme, or those lacking or deficient in this isoenzyme, respectively) were given hydrocodone, and another four CYP2D6 extensive metabolisers were given hydrocodone after pretreatment with quinidine. The metabolism of the hydrocodone to its active metabolite, hydromorphone, was found to be high in the extensive metabolisers who described 'good opiate effects', but poor in the poor metabolisers and the extensive metabolisers pretreated with quinidine who described 'poor opiate effects'.[7] For the effect of quinidine on hydromorphone metabolism, see 'Opioids + Quinidine', p.202.

(d) Oxycodone

Quinidine given as 200 mg 3 hours before and 100 mg 6 hours after a single 20-mg dose of oxycodone almost completely inhibited the formation of the metabolite, oxymorphone in 10 healthy CYP2D6 extensive metabolisers (that is, those with normal levels of this isoenzyme). Despite this, the psychomotor and subjective effects of oxycodone were not altered (note that analgesia was not assessed). The AUC of the metabolite noroxycodone was increased about 85%, and the oxycodone AUC was slightly increased by 13%.[8] Similar results were found in the preliminary report of another study.[9]

Mechanism

The evidence available shows that the conversion of codeine, dihydrocodeine and hydrocodone to their active analgesic metabolites in the body (morphine, morphinoid metabolites and hydromorphone, respectively) probably depends upon the activity of the cytochrome P450 isoenzyme CYP2D6 in the liver. Inhibition of this conversion by quinidine means that analgesic effects may be reduced or lost. This interaction is only likely to

occur in extensive metabolisers, and not in poor metabolisers, who have minimal CYP2D6 activity and who therefore may only derive minimal benefit from analgesics such as codeine, whose principal pharmacological effect appears to depend on this metabolism.[2] However, one study in healthy subjects has suggested that the analgesic effect of dihydrocodeine does not necessarily depend on its systemic metabolism to dihydromorphine.[6] Similarly, although quinidine also blocks the conversion of oxycodone to oxymorphone, it appears that this is not important for the pharmacodynamic effects of this drug.

Importance and management

The interaction between **codeine** and quinidine is well established and clinically important. Codeine will be virtually ineffective as an analgesic in extensive metabolisers of CYP2D6 (the majority of patients) taking quinidine. An alternative analgesic should be used (possibly dihydrocodeine, see below, or tramadol, see 'Opioids + Quinidine', p.202). No interaction would be expected in poor metabolisers (about 7% of Caucasians), but codeine is probably unlikely to be effective in these patients in any case. Whether the antitussive effects of codeine are similarly affected is not established, but it seems likely. Note that this interaction has been used clinically in an attempt to treat codeine dependence.[10]

The interaction of **hydrocodone** is less well established, but the evidence suggests that the analgesic effect will similarly be reduced or lost if quinidine is given. Further study is needed.

The available evidence suggests that the efficacy of **dihydrocodeine** or **oxycodone** may not be significantly affected by quinidine, but this needs confirmation.

Opioids + Rifampicin (Rifampin)

Rifampicin markedly increases the metabolism of codeine and morphine, and reduces their effects. Rifampicin dramatically reduced the effects of oxycodone in one patient.

Clinical evidence, mechanism, importance and management

(a) Codeine

A study in 15 healthy subjects found that after taking rifampicin 600 mg daily for 3 weeks, the metabolism of a single 120-mg oral dose of codeine phosphate was markedly increased. The AUC of codeine was decreased by about 80% and both the *N*-demethylation and glucuronidation metabolic pathways were induced. Of the 15 subjects, 9 were extensive CYP2D6 metabolisers (that is, those with normal levels of this isoenzyme) and 6 were poor CYP2D6 metabolisers (those lacking or deficient in CYP2D6). The *O*-demethylation of codeine (mediated by CYP2D6) was induced only in the extensive metabolisers. In these subjects there was a 56% reduction in the AUC of morphine (the main active metabolite of codeine), and a 173% increase in the AUC of normorphine (another active metabolite). Note that morphine and its metabolites were not detected in poor metabolisers, either before or after rifampicin was given, because the pathway that leads to these metabolites is deficient or absent in these subjects. Rifampicin reduced the respiratory and psychomotor effects of codeine in extensive metabolisers, but not in poor metabolisers. In contrast, rifampicin decreased the pupillary effect of codeine in poor metabolisers, but it was not altered in extensive metabolisers, possibly due to the increase in the AUC of normorphine. The clinically more relevant question of whether, and to what extent, the analgesic effects of the codeine were reduced by this interaction was not addressed by this study.[1] However, some reduction in the effects of codeine might be expected. Therefore, if these drugs are used concurrently, be alert for the need to raise the codeine dose, or use an alternative analgesic. More study is needed.

(b) Fentanyl and related drugs

For the interactions of alfentanil and fentanyl with rifampicin, see 'Opioids; Fentanyl and related drugs + Rifampicin (Rifampin)', below.

(c) Methadone

For the interactions of methadone with rifabutin and rifampicin, see 'Opioids; Methadone + Rifamycins', p.205.

(d) Morphine

In a randomised study, 10 healthy subjects were given a single 10-mg oral dose of morphine sulfate with rifampicin 600 mg daily. It was found that rifampicin increased the clearance of the morphine by 49%, and its analgesic effects (using a modified cold pressor test) were abolished.[2] The mechanism of this interaction is uncertain as morphine is principally metabolised by glucuronidation but the findings of this study could not be attributed to rifampicin induction of glucuronosyltransferases.[2] Be alert for the need to use an increased dose of morphine in patients taking rifampicin. More study is needed.

(e) Oxycodone

A 60-year-old man who was taking rifampicin as well as oxycodone had three consecutive negative urine oxycodone screens in a 2-month period, which would normally suggest that he was not taking the oxycodone. However, oxycodone metabolites were found in his urine confirming compliance with his medication. An interaction between rifampicin and oxycodone was suspected and his oxycodone dose was increased to optimise his pain control.[3]

As oxycodone is metabolised by CYP2D6 and, to a lesser extent, CYP3A4, rifampicin, a known enzyme inducer, would be expected to increase its metabolism. The general significance of this isolated case is unclear, however be aware that the dose of oxycodone may need adjusting in patients taking rifampicin.

Opioids; Fentanyl and related drugs + Rifampicin (Rifampin)

The serum levels and effects of transdermal fentanyl were decreased in two patients when they took rifampicin. Studies in healthy subjects have found that the bioavailability of oral transmucosal fentanyl is reduced by rifampicin. The clearance of intravenous alfentanil is markedly increased by rifampicin.

Clinical evidence, mechanism, importance and management

(a) Alfentanil

A study in 9 healthy subjects found that when they were given intravenous alfentanil 20 micrograms/kg after taking rifampicin 600 mg orally for 5 days, alfentanil clearance was increased almost threefold.[1] Rifampicin is a known inducer of the cytochrome P450 isoenzyme CYP3A4 in the liver, which is concerned with the metabolism of alfentanil; concurrent use therefore leads to an increased clearance of alfentanil. This study was primarily designed to investigate the role of CYP3A4 in the metabolism of alfentanil, but it also provides good evidence that alfentanil is likely to be much less effective in patients taking rifampicin. A much larger dose of alfentanil will almost certainly be needed.

(b) Fentanyl

In a study in 12 healthy subjects, the peak levels and maximum miosis after oral transmucosal fentanyl 10 micrograms/kg were minimally affected by oral rifampicin 600 mg daily for 5 days, but the AUC of fentanyl was decreased by 63%; the AUC of its metabolite, norfentanyl, was increased by 73%, and the $AUC_{0–10}$ of miosis was decreased by 54%.[2]

A patient with lung metastases was given transdermal fentanyl (1.67 mg patch every 3 days). Serum fentanyl levels measured 48 and 72 hours after the first day of treatment were 0.9 nanograms/mL and 0.77 nanograms/mL, respectively (within the reported minimum effective therapeutic range of 0.2 to 1.2 nanograms/mL). On day 5, due to insufficient pain control, the fentanyl patch was increased to 2.5 mg every 3 days. However, on day 7, oral rifampicin 300 mg daily, isoniazid and ethambutol were started for pulmonary tuberculosis. The following day severe pain developed and the fentanyl serum levels 48 and 72 hours after treatment on day 8 were 0.53 nanograms/mL and 0.21 nanograms/mL, respectively, despite the significant increase in the fentanyl dose. Even after the dose was increased again up to 7.5 mg every 3 days, the patient still complained of moderate pain and the fentanyl serum level 72 hours after treatment was only 0.69 nanograms/mL, less than the level achieved with the 1.67 mg dose in the absence of rifampicin.[3] A patient with colon cancer taking rifampicin 450 mg daily, isoniazid 300 mg daily and ethambutol 750 mg daily was started on a transdermal fentanyl patch at a dose of 600 micrograms daily. However, this did not control his pain and neither did titration of the fentanyl dose up to 2.5 mg daily. The patient was changed to an equivalent dose of morphine, which provided effective pain relief, but he developed a disturbance in consciousness and so his treatment was changed to an NSAID.[4]

Fentanyl is metabolised by the cytochrome P450 isoenzyme CYP3A4 and rifampicin, a potent inducer of CYP3A4, appears to reduce its serum levels and analgesic effects. Thus an increase in fentanyl dose may be needed in patients taking rifampicin.[3]

Opioids; Methadone + Rifamycins

Serum methadone levels can be markedly reduced by rifampicin (rifampin), and withdrawal symptoms have occurred in some patients. Rifabutin appears to interact similarly, but to a lesser extent.

Clinical evidence

(a) Rifabutin

A study in 24 HIV-positive patients taking methadone found that rifabutin 300 mg daily for 13 days had only minimal effects on the pharmacokinetics of methadone. However, 75% of the patients reported at least one mild symptom of methadone withdrawal, but this was not enough for any of them to withdraw from the study. Only 3 of them asked for and received an increase in their methadone dose. The authors offered the opinion that over-reporting of withdrawal symptoms was likely to be due to the warnings that the patients had received.[1]

(b) Rifampicin (Rifampin)

The observation that former diamorphine (heroin) addicts taking methadone complained of withdrawal symptoms when given rifampicin, prompted a study[2] in 30 patients taking methadone. Withdrawal symptoms developed in 21 of the 30 patients within one to 33 days of starting rifampicin 600 to 900 mg daily and isoniazid daily. In 6 of the 7 patients most severely affected, the symptoms developed within one week, and their plasma methadone levels fell by 33 to 68%. Of 56 other patients taking methadone with other antitubercular treatment (which included isoniazid but not rifampicin), none developed withdrawal symptoms.[2-4] Other cases of this interaction have been reported.[5-9] Some patients needed two- to threefold increases in their methadone dose while taking rifampicin, in order to control the withdrawal symptoms.[6,7,9]

Mechanism

Rifampicin is a potent enzyme inducer, which increases the activity of the intestinal and liver cytochrome P450 isoenzymes concerned with the metabolism of methadone, resulting in a marked decrease in its levels.[10] In 4 patients in the study cited, the urinary excretion of the major metabolite of methadone rose by 150%.[2] Rifabutin has only a mild enzyme-inducing effect and therefore the effects are not as great.

Importance and management

The interaction between methadone and rifampicin is established, adequately documented and of clinical importance. The incidence is high: two-thirds (21) of the narcotic-dependent patients in one study[2] developed this interaction, 14 of whom were able to continue treatment. Withdrawal symptoms may develop within 24 hours. The analgesic effects of methadone would also be expected to be reduced. Concurrent use need not be avoided, but the effects should be monitored and appropriate methadone dose increases (as much as two to threefold) made where necessary.

Rifabutin appears to interact to a much lesser extent than rifampicin, so that fewer, if any, patients are likely to need a methadone dose increase.

Opioids + St John's wort (*Hypericum perforatum*)

St John's wort reduces the plasma concentrations of methadone and withdrawal symptoms may occur.

Clinical evidence

In a study in 4 patients taking **methadone**, St John's wort (Jarsin) 900 mg daily for 14 to 47 days decreased **methadone** plasma concentration-to-dose ratios (indicating decreased **methadone** levels) by 19 to 60%. Two patients reported symptoms that suggested a withdrawal syndrome.[1]

Mechanism

St John's wort is metabolised in the liver and induces the cytochrome P450 enzyme CYP3A4, and so could affect plasma levels of drugs metabolised in this way, such as methadone.[1]

Importance and management

St John's wort appears to reduce the plasma levels of methadone causing withdrawal symptoms in some patients. Therefore, concurrent use should be avoided. It may be prudent to follow the same advice for other opioids[2] that are mainly metabolised by CYP3A4, such as **buprenorphine**, **fentanyl** or **alfentanil**.

Opioids + Tobacco

Smokers who discontinue smoking appear to require more opioid analgesics for postoperative pain control than non-smokers; this

has been seen with both fentanyl and morphine patient-controlled analgesia. Atmospheric pollution and smoking has a similar effect on pentazocine. Codeine metabolism was not affected to a clinically relevant extent by smoking in one study.

Clinical evidence

A retrospective study of coronary artery bypass graft patients found that 20 patients who had abruptly discontinued smoking before surgery required more postoperative opioid analgesics than 69 non-smokers. The opioid analgesics included **dextropropoxyphene** (**propoxyphene**), **fentanyl**, **hydrocodone**, **oxycodone**, **morphine**, **nalbuphine** and **pethidine** (**meperidine**), but the most commonly used opioid was **fentanyl** (used in approximately two-thirds of the patients) given by patient-controlled analgesia (PCA). Smokers deprived of nicotine had an increase in opioid requirements (converted to morphine equivalents), during the first 48 hours after surgery, ranging from 29 to 33% (when normalised for body-weight or body mass index).[1] Similarly, another retrospective study in 171 women found that the average postoperative narcotic use over 12 hours (expressed as equivalent doses of morphine) was 10.9 mg for patients who had never smoked, 13 mg for former smokers, and 13.1 mg for current smokers.[2]

(a) Codeine

The metabolism of a single 25-mg dose of codeine did not differ between 9 heavy smokers (greater than 20 cigarettes daily) and 9 non-smoking control subjects, except that smokers had a slightly higher rate of codeine glucuronidation.[3] This is unlikely to be clinically important. Another study found no clinically important differences in the systemic availability of single 60-mg oral or intramuscular doses of codeine between 10 smokers and 12 non-smokers. There was no significant difference in the plasma half-life of codeine or in the conversion of codeine to morphine; however, there was a slightly higher plasma clearance of codeine in smokers than in non-smokers.[4] No differences in the efficacy of codeine are expected between smokers and non-smokers.

(b) Dextropropoxyphene (Propoxyphene)

A study in 835 patients who were given dextropropoxyphene for mild or moderate pain or headache found that its efficacy as an analgesic was decreased by smoking. The drug was rated as ineffective in about 10% of 335 non-smokers, 15% of 347 patients who smoked up to 20 cigarettes daily, and 20% of 153 patients who smoked more than 20 cigarettes daily.[5]

(c) Morphine

A study in 7 women during the acute post-caesarean recovery period found that intravenous morphine use over 24 hours (as patient-controlled analgesia; PCA) was significantly higher in smokers compared with non-smokers: weight-adjusted morphine use was 1.8 mg/kg compared with 0.64 mg/kg, respectively). It was suggested that a history of nicotine use and/or short-term nicotine abstinence could modulate morphine use and analgesia during postoperative recovery.[6] Similarly, another retrospective study found increased morphine PCA requirements in smokers compared with non-smokers.[7]

(d) Pentazocine

A study in which pentazocine was used to supplement nitrous oxide relaxant anaesthesia found that patients who came from an urban environment needed about 50% more pentazocine than those who lived in the country (3.6 micrograms/kg per minute compared with 2.4 micrograms/kg per minute). Roughly the same difference was seen between those who smoked and those who did not (3.8 micrograms/kg per minute compared with 2.5 micrograms/kg per minute).[8] In another study it was found that pentazocine metabolism was 40% higher in smokers than in non-smokers.[9]

Mechanism

It is thought that tobacco smoke contains compounds that increase the activity of the liver enzymes concerned with the metabolism of dextropropoxyphene, pentazocine and many other opioids, which increases their metabolism, decreases their levels and diminishes their effectiveness as analgesics.[2,5] However, former smokers have also been found to have increased opioid requirements and it has been suggested that smoking might have an effect on pain perception and/or opioid response, or that nicotine addiction and opioid requirements may be genetically linked.[2]

Importance and management

The interaction between tobacco smoking and opioids appears to be well established. Prescribers should be aware that smokers may require a greater amount of opioids postoperatively than non-smokers, although as pain control is tailored to requirement, this is unlikely to be clinically important. In contrast, codeine metabolism does not appear to be affected to a clinically relevant extent by smoking.

Opioids + Tricyclic and related antidepressants

In general, the concurrent use of most opioids and tricyclics is uneventful, although lethargy, sedation, and respiratory depression have been reported. Tramadol should be used with caution with tricyclic antidepressants because of the possible risk of seizures and serotonin syndrome. Dextropropoxyphene may cause moderate rises in the serum levels of amitriptyline, nortriptyline, and possibly doxepin, and methadone may moderately raise desipramine levels. The bioavailability and the degree of analgesia of oral morphine are increased by clomipramine, desipramine, and possibly amitriptyline.

Clinical evidence

(a) Buprenorphine

A study in 12 healthy subjects found that both sublingual buprenorphine 400 micrograms and oral **amitriptyline** 50 mg impaired the performance of a number of psychomotor tests (digit symbol substitution, flicker fusion, Maddox wing, hand-to-eye coordination, reactive skills), and the subjects felt drowsy, feeble, mentally slow and muzzy. When **amitriptyline** 30 mg, increased to 75 mg daily, was given for 4 days before a single dose of buprenorphine, the psychomotor effects were not significantly increased, but the respiratory depressant effects of buprenorphine were enhanced.[1]

(b) Dextropropoxyphene (Propoxyphene)

An elderly man taking **doxepin** 150 mg daily developed lethargy and daytime sedation when he started to take dextropropoxyphene 65 mg every 6 hours. His plasma **doxepin** levels rose by almost 150% (from 20 to 48.5 nanograms/mL) and desmethyldoxepin levels were similarly increased (from 8.8 to 20.7 nanograms/mL).[2]

The **amitriptyline** concentration to dose ratio in 12 patients given **amitriptyline** and dextropropoxyphene was raised by about 20% (suggesting raised amitriptyline levels), when compared with other patients taking **amitriptyline** alone. Similarly, the plasma level of the **amitriptyline** metabolite, nortriptyline, was raised by about 30% in 14 patients given dextropropoxyphene;[3] and in another study, **nortriptyline** plasma levels were raised by 16% by dextropropoxyphene.[3]

Fifteen patients with rheumatoid arthritis given a single 25-mg dose of **amitriptyline** and dextropropoxyphene (up to 65 mg three times daily) experienced some drowsiness and mental slowness. They complained of being clumsier and had more pain, but these effects were said to be mild.[4]

(c) Methadone

The mean serum levels of **desipramine** 2.5 mg/kg daily were approximately doubled in 5 men who took methadone 500 micrograms/kg daily for 2 weeks. Previous observations in patients given both drugs had shown that **desipramine** levels were higher than expected and adverse effects de-

veloped at relatively low doses.[5] Further evidence of an increase in plasma **desipramine** levels due to methadone is described in another study.[6]

(d) Morphine

In a study in 24 patients with cancer-related pain, **clomipramine** or **amitriptyline**, in doses of 20 or 50 mg daily, increased the AUC of oral morphine by 28 to 111%. The half-life of morphine was also prolonged.[7] A previous study[8] found that **desipramine**, but not **amitriptyline**, increased and prolonged morphine analgesia, and a later study by the same group confirmed this potentially beneficial effect of **desipramine**.[9] See also, 'Opioids; Morphine + Miscellaneous', p.210, for limited evidence that amitriptyline and **doxepin** may increase the risk of myoclonus with morphine.

(e) Oxycodone

In a study in 9 healthy subjects, pretreatment with **amitriptyline** 10 mg increased to 50 mg daily for 4 days caused no major changes in the psychomotor effects of a single 280-microgram/kg oral dose of oxycodone.[10] Respiratory effects were not assessed.

(f) Pentazocine

Both pentazocine and **amitriptyline** given alone caused 11 healthy subjects to feel drowsy, muzzy and clumsy, and reduced the performance of a number of psychomotor tests. However, when the same subjects were given intramuscular pentazocine 30 mg after taking **amitriptyline** 50 mg daily for one week, the combination of drugs appeared not to impair driving or occupational skills more than either drug given alone.[11] Respiratory depression was increased more by concurrent use than by either drug alone. **Amitriptyline** modestly decreased pentazocine plasma levels by about 20% at 1.5 hours and 3.5 hours post-dose.[11]

(g) Tramadol

The CSM in the UK has publicised 27 reports of convulsions and one of worsening epilepsy with tramadol, a reporting rate of 1 in 7000 patients. Some of the patients were given doses well in excess of those recommended, and 8 patients were also taking tricyclic antidepressants, which are known to reduce the convulsive threshold.[12] Similarly, the FDA in the US has received 124 reports of seizures associated with tramadol, 28 of which included the concurrent use of tricyclic antidepressants,[13] and the Australian Adverse Drug Reaction Advisory Committee (ADRAC) has received 26 cases of convulsions associated with tramadol, some of which included the concurrent use of tricyclic antidepressants.[14] ADRAC have also received reports of serotonin syndrome, which were associated with the use of tramadol and tricyclic antidepressants.[14] Furthermore, two case reports suggest that tramadol may have contributed to the development of serotonin syndrome, one report was of a patient abusing tramadol, moclobemide and **clomipramine**,[15] and the other was of a 79-year-old patient taking morphine *(MST),* co-proxamol (dextropropoxyphene with paracetamol (acetaminophen)) and **amitriptyline**, after she started to take tramadol.[16,17] In both of these cases the patient died.

Similarly, seizures and serotonin syndrome have been reported in a woman who took **mirtazapine** with tramadol, but this may have been due to over-use of the tramadol rather than an interaction.[18] Lethargy, confusion, hypotension, bronchospasm and hypoxia has also been seen following the use of tramadol and **mirtazapine**, which resolved within hours of both drugs being stopped.[19]

Mechanism

The CNS depressant effects of the opioids and the tricyclic antidepressants are expected to be additive. The reasons for the increased morphine levels and analgesic effects that occur with some tricyclics are not understood. However, it has been suggested that the increased analgesia may be due not only to the increased serum levels of morphine, but possibly also to some alteration in the way the morphine affects its receptors. Dextropropoxyphene probably inhibits the liver metabolism of some tricyclic antidepressants[3] by inhibiting the cytochrome P450 isoenzyme CYP2D6, and as a result the serum levels of the tricyclic antidepressants rise. It is suggested that methadone may possibly inhibit the hydroxylation of desipramine, thereby raising its levels.[6]

Importance and management

The majority of the evidence, and general clinical experience, suggests that in most cases, the use of opioids with tricyclic antidepressants is uneventful. Furthermore, limited evidence suggests that concurrent use may be beneficial in pain management. However, the CNS depressant effects of both these classes of drugs should be considered when prescribing the combination, especially as there is some evidence to suggest that the respiratory depressant effects are increased: this may be clinically important in patients with a restricted respiratory capacity.[11]

Certain opioids appear to have a greater propensity to interact. Both **tramadol** and the tricyclics can lower the seizure threshold and cause serotonin syndrome when used alone. Concurrent use may result in additive effects, and therefore particular caution is warranted with this combination, especially in patients with epilepsy or those taking other drugs that affect serotonin. Mirtazapine appears to interact with tramadol in the same way as the tricyclics. Be aware that **dextropropoxyphene** and **methadone** may raise tricyclic levels: however, the general clinical significance of these interactions is uncertain but be alert for any evidence of increased CNS depression and increased tricyclic antidepressant adverse effects (such as dry mouth, constipation, and urinary retention). In this context it is worth noting that one study reported that the incidence of hip fractures in the elderly was found to be increased by a factor of 1.6 in those taking dextropropoxyphene, and further increased to 2.6 when antidepressants, benzodiazepines or antipsychotics were added.[20]

Opioids + Urinary acidifiers or alkalinisers

Urinary methadone clearance is increased if the urine is made acid (e.g. by giving ammonium chloride) and reduced if it is made alkaline (e.g. by giving sodium bicarbonate). The urinary clearance of dextropropoxyphene (propoxyphene) and pethidine (meperidine) may also be increased by acidification of the urine.

Clinical evidence

(a) Dextropropoxyphene (Propoxyphene)

A study in 6 healthy subjects found that the cumulative 72-hour urinary excretion of unchanged dextropropoxyphene was increased sixfold by acidification of the urine with oral **ammonium chloride** and reduced by 95% by alkalinisation with **sodium bicarbonate**; the half-life of dextropropoxyphene was also shortened by ammonium chloride. The excretion of the active metabolite, norpropoxyphene, was much less dependent on urinary pH. However, the cumulative excretion of dextropropoxyphene

and norpropoxyphene, even into acidic urine, accounted for less than 25% of the dose during 72 hours.[1]

(b) Methadone

A study in patients taking methadone found that the urinary clearance in those with urinary pHs of less than 6 was greater than those with higher urinary pHs.[2] When the urinary pH of one subject was lowered from 6.2 to 5.5, the loss of unchanged methadone in the urine was nearly doubled.[3] A pharmacokinetic study in 5 healthy subjects given a 10-mg intramuscular dose of methadone found that the plasma half-life was 19.5 hours when the urine was made acidic (pH 5.2) with **ammonium chloride**, compared with 42.1 hours when the urine was made alkaline (pH 7.8) with **sodium bicarbonate**. The clearance of methadone fell from 134 mL/minute to 91.9 mL/minute when the urine was changed from acidic to alkaline.[4]

(c) Pethidine (Meperidine)

A study in 6 healthy subjects given intravenous pethidine 21.75 mg found that the 48-hour urinary recovery of pethidine and norpethidine was increased by urinary acidification with **ammonium chloride**, when compared with no urinary pH control. Recovery of pethidine increased from about 7% to 20%, and recovery of norpethidine increased from about 12% to 24%. Urinary alkalinisation reduced the urinary recovery of pethidine and norpethidine to less than 1% and 7%, respectively. These pronounced effects had negligible effects on the blood concentration/time profiles.[5] A study in 10 healthy Chinese subjects given intravenous pethidine 150 micrograms/kg found large variations in the 48-hour urinary recovery of pethidine and norpethidine depending on urinary pH; mean urinary recovery values under acidic conditions were 24% and 33%, respectively, and under alkaline conditions were 0.4% and 4%, respectively. The bioavailability was slightly lower under acidic urinary conditions due to the greater renal clearance of the drug.[6]

Mechanism

Methadone is eliminated from the body both by liver metabolism and excretion of unchanged methadone in the urine. Above pH 6 the urinary excretion is less important, but with urinary pH below 6 the half-life becomes dependent on both excretion (30%) and metabolism (70%).[3,4,7] Methadone is a weak base (pKa 8.4) so that in acidic urine little of the drug is in the un-ionised form and little is reabsorbed by simple passive diffusion. On the other hand, in alkaline solution most of the drug is in the un-ionised form, which is readily reabsorbed by the kidney tubules, and little is lost in the urine.

Acidification of the urine may also increase the renal clearance of unchanged pethidine (meperidine) and norpethidine, probably also due to reduced reabsorption in the renal tubule.[6] Dextropropoxyphene (propoxyphene) appears to be similarly affected, although this appears to be a minor route for dextropropoxyphene elimination.

Importance and management

The effect of urinary pH on the clearance of methadone is an established interaction, but of uncertain clinical importance. Be alert for any evidence of reduced methadone effects in patients whose urine becomes acidic because they are taking large doses of ammonium chloride. Lowering the urinary pH to 5 with ammonium chloride to increase the clearance can also be used to treat toxicity. Theoretically, urinary alkalinisers, such as sodium bicarbonate and **acetazolamide**, may increase the effect of methadone.

Similarly, the urinary clearance of dextropropoxyphene (propoxyphene) and pethidine (norpethidine) appear to be increased to some extent by acidification of the urine, although their bioavailabilities do not appear to be significantly affected and the clinical effect is probably small.

Opioids; Alfentanil + Reserpine

An isolated report describes ventricular arrhythmias when a patient taking reserpine was given alfentanil during anaesthesia.

Clinical evidence, mechanism, importance and management

A hypertensive woman taking reserpine 250 micrograms daily was given intravenous alfentanil 800 micrograms over 5 minutes, before anaesthesia with thiopental and suxamethonium (succinylcholine). During surgery she was given nine 100-microgram doses of alfentanil and 70% nitrous oxide/oxygen. Bradycardia developed and frequent unifocal premature ventricular contractions occurred throughout the surgery, but they disappeared 3 to 4 hours afterwards. The arrhythmia was attributed to an interaction between reserpine and alfentanil, but just why this should occur is not understood.[1] This is an isolated report and its general relevance is unclear.

1. Jahr JS, Weber S. Ventricular dysrhythmias following an alfentanil anesthetic in a patient on reserpine for hypertension. *Acta Anaesthesiol Scand* (1991) 35, 788–9.

Opioids; Alfentanil + Terbinafine

In a study, terbinafine 250 mg daily for 3 days had no statistically significant effect on alfentanil pharmacokinetics and no adverse effects were reported.[1] Therefore, no alfentanil dose adjustment appears to be necessary on concurrent use.

1. Saari TI, Laine K, Leino K, Valtonen M, Neuvonen PJ, Olkkola KT. Voriconazole, but not terbinafine, markedly reduces alfentanil clearance and prolongs its half-life. *Clin Pharmacol Ther* (2006) 80, 502–8.

Opioids; Codeine + Kaolin

An isolated report describes patients suffering from chronic diarrhoea, who were stabilised taking codeine phosphate, but who experienced a relapse when the codeine was added to *Kaolin Mixture*. An *in vitro* study suggested the bioavailability of codeine may be reduced by adsorption onto kaolin.[1] The general significance of this finding is unknown but bear this report in mind should a patient taking a kaolin-containing product report a reduced effect from codeine.

1. Yu SKS, Oppenheim RC, Stewart NF. Codeine phosphate adsorbed by kaolin. *Aust J Pharm* (1976) 57, 468.

Opioids; Codeine + Somatostatin analogues

Lanreotide and octreotide partially inhibit the metabolism of codeine, which may possibly reduce its analgesic effects.

Clinical evidence, mechanism, importance and management

A study in 6 patients with gastrointestinal carcinoid tumours found that **lanreotide** or **octreotide** 750 micrograms subcutaneously three times daily for 3 days decreased the partial metabolic clearance of codeine by *N*-demethylation (by the cytochrome P450 subfamily CYP3A) by an average of 44% and the *O*-demethylation (by CYP2D6) by 35%. However, the partial clearance by 6-glucuronidation and the total systemic clearance of codeine were not consistently changed. The effects of the somatostatins were thought to be mediated by a suppression of growth hormone secretion. The reduction in *O*-demethylation can reduce the active metabolite of codeine, morphine, which could reduce the analgesic effect of the

drug;[1] however, the clinical relevance of this does not appear to have been studied.

Opioids; Dextropropoxyphene (Propoxyphene) + Orphenadrine

An alleged adverse interaction between dextropropoxyphene and orphenadrine, which is said to cause mental confusion, anxiety, and tremors, seems to be very rare, if indeed it ever occurs.

Clinical evidence, mechanism, importance and management

The manufacturers of orphenadrine used to state in their package insert that mental confusion, anxiety and tremors have been reported in patients receiving both orphenadrine and dextropropoxyphene. The manufacturers of dextropropoxyphene issued a similar warning. However, in correspondence with both manufacturers, two investigators[1] of this interaction were told that the basis of these statements consisted of 6 anecdotal reports from clinicians to one manufacturer and 7 to the other (some could represent the same cases). Of the 7 cases to one manufacturer, 4 occurred where patients had received twice the recommended dose of orphenadrine. In every case the adverse reactions seen were similar to those reported with either drug alone. A brief study in 5 patients given both drugs to investigate this alleged interaction failed to reveal an adverse interaction.[2] One case has been reported separately.[3]

The documentation is therefore sparse, and no case of interaction has been firmly established. The investigators calculated that the two drugs were probably being used together on 300 000 prescriptions a year, and that these few cases would be less than significant.[1] There seems therefore little reason for avoiding concurrent use.

Opioids; Methadone + Disulfiram

No adverse interaction was seen when patients taking methadone were given disulfiram.

Clinical evidence, mechanism, importance and management

Seven opioid addicts, without chronic alcoholism or liver disease, and who were receiving methadone maintenance treatment (45 to 65 mg daily) had an increase in the urinary excretion of the major pyrrolidine metabolite of methadone (an indicator of increased *N*-demethylation) when given disulfiram 500 mg daily for 7 days. However, there was no effect on the degree of opioid intoxication, nor were opioid withdrawal symptoms experienced.[1] No special precautions would therefore seem to be necessary if both drugs are given.

1. Tong TG, Benowitz NL, Kreek MJ. Methadone-disulfiram interaction during methadone maintenance. *J Clin Pharmacol* (1980) 20, 506–13.

Opioids; Methadone + Fusidic acid

Fusidic acid may possibly affect the clearance of levomethadone (*R*-methadone), and a case of opioid withdrawal has been reported. However, another study found no evidence of an interaction.

Clinical evidence, mechanism, importance and management

A patient with AIDS needed an increase in his levomethadone (*R*-methadone) dose from 60 to 80 mg daily within 6 months of starting to take fusidic acid 1.5 g daily.[1] The patient had evidence of liver enzyme induction (using antipyrine as a marker), from which it was concluded that fusidic acid had increased the metabolism and loss of methadone from the body.[1] A subsequent study in 10 patients taking levomethadone confirmed that fusidic acid 500 mg daily for 28 days increased antipyrine clearance; some patients developed clinical signs of underdosage. In contrast, fusidic acid 500 mg daily for 14 days had no effect in another 10 patients taking levomethadone.[2]

Information appears to be limited to these reports. Bear them in mind in the event of any unexpected reduction in efficacy of levomethadone (and probably methadone) in a patient taking long-term fusidic acid.

Opioids; Methadone + Lofexidine

The concurrent use of methadone and low-dose lofexidine may cause significant hypotension and additional CNS depression.

Clinical evidence, mechanism, importance and management

A small study in 14 subjects taking stable doses of methadone 80 mg daily for 3 weeks found that the addition of lofexidine 400 micrograms daily had significant effects on blood pressure and cognitive function. Systolic and diastolic blood pressures were reduced by an average of 27 mmHg and 15 mmHg, respectively. Two female subjects reported drowsiness, with low blood pressure readings of 88/55 mmHg and 80/48 mmHg, respectively, which required discontinuation of lofexidine. Cognitive tests such as simple reaction times, memory tests and mathematical processing were also affected, although only the effect on mathematical processing reached statistical significance for overall dose effect. Two patients also developed asymptomatic, transient QTc prolongation after a single dose of lofexidine, which resolved when lofexidine was stopped.[1] Further study of the concurrent use of lofexidine and methadone in the management of opioid withdrawal is needed. Patients prescribed this combination should be closely monitored for adverse effects, in particular significant reductions in blood pressure and cognitive changes.

Note that the manufacturers advise avoiding other drugs that may cause QT prolongation as the clinical significance of the small QT changes reported with lofexidine are unclear.[2] Methadone usually only causes QT prolongation in doses of 100 mg or more daily.

2. BritLofex (Lofexidine hydrochloride). Britannia Pharmaceuticals Ltd. UK Summary of product characteristics, July 2006.

Opioids; Methadone + Quetiapine

Quetiapine modestly increased the levels of methadone but did not appear to result in a clinically significant increase in adverse effects in one study.

Clinical evidence

In a study, 14 patients taking methadone maintenance for at least one month were given an average dose of quetiapine of 138 mg daily for an average of 30 days. The addition of quetiapine increased the mean *R*-methadone plasma concentration to dose ratio by 21%, although there was significant interpatient variability (range 23% decrease to 85% increase). No significant effects on the *S*-methadone enantiomer were seen, and there were no reports of methadone overdose or toxicity in any of the patients. Some slight differences in the metabolism of *R*-methadone were seen when patients were assessed for difference in the expression of the cytochrome P450 isoenzyme CYP2D6 and P-glycoprotein, but these were not statistically significant. However, because some changes were seen, the authors suggest that one or both of these mechanisms may possibly be responsible for the interaction seen.[1]

Evidence appears to be limited to this study, in which only small, clinically unimportant increases in methadone levels were seen. However, as

the dose of quetiapine was relatively low, and the patient numbers were small, further study is needed to establish these findings.

1. Uehlinger C, Crettol S, Chassot P, Brocard M, Koeb L, Brawand-Amey M, Eap CB. Increased (*R*)-methadone plasma concentrations by quetiapine in cytochrome P450s and *ABCB1* genotyped patients. *J Clin Psychopharmacol* (2007) 27, 273–8.

Opioids; Morphine + Miscellaneous

Some limited evidence suggests that antidepressants, antipsychotics, NSAIDs and thiethylperazine may increase the myoclonus caused by high doses of morphine.

Clinical evidence, mechanism, importance and management

In 19 patients with malignant disease taking high doses of morphine (daily doses of 500 mg or more orally or 250 mg or more parenterally), an analysis was made of the relationship between myoclonus and the use of supplemental drugs. In the 12 patients with myoclonus, 8 patients were taking antidepressants (**amitriptyline**, **doxepin**) or antipsychotics (**chlorpromazine**, **haloperidol**) compared with none of 6 patients without myoclonus. In addition, there was a higher use of NSAIDs (**indometacin**, **naproxen**, **piroxicam**, **aspirin**) and an antiemetic (**thiethylperazine**).[1] The reasons are not understood, and the findings of this paper have been questioned.[2]

2. Quinn N. Myoclonus associated with high doses of morphine. *BMJ* (1989) 299, 683–4.

Opioids; Pethidine (Meperidine) + Aciclovir

An isolated report describes pethidine toxicity associated with the use of high-dose aciclovir.

Clinical evidence, mechanism, importance and management

A man with Hodgkin's disease was treated with high-dose intravenous aciclovir for localised herpes zoster, and with intramuscular pethidine, oral methadone and levodopa with carbidopa. On the second day he experienced nausea, vomiting and confusion, and later dysarthria, lethargy and ataxia. Despite vigorous treatment he later died. It was concluded that some of the adverse effects were due to pethidine toxicity arising from norpethidine accumulation, associated with renal impairment caused by the aciclovir.[1] The US manufacturer of pethidine says that plasma concentrations of pethidine, and its metabolite norpethidine, may be increased by aciclovir, thus caution should be used if both drugs are given.[2]

2. Demerol (Meperidine hydrochloride). Sanofi-Aventis US LLC. US Prescribing information, October 2008.

Opioids; Tramadol + Pseudoephedrine

An isolated report describes ischaemic colitis when a patient taking tramadol took a decongestant containing pseudoephedrine.

Clinical evidence, mechanism, importance and management

Acute, self-limiting ischaemic colitis occurred in a 46-year-old patient taking regular tramadol, celecoxib and diazepam for back pain, who had self-medicated with an oral decongestant containing pseudoephedrine. He had taken the maximum recommended dose of pseudoephedrine (240 mg daily) for 7 days. A similar, but milder abdominal discomfort had occurred 3 months earlier when he had used the same medication for one week. The colitis was thought to be due to pseudoephedrine, but the concurrent use of tramadol might possibly have contributed by increasing adrenergic vasoconstriction.[1] Note also that celecoxib alone has, rarely, been reported to cause colitis,[2] although the bearing of this effect on this case is unknown. The general significance of this isolated case is unclear.

Paracetamol (Acetaminophen) + Amantadine

Amantadine had no clinically significant effect on the pharmacokinetics of a single dose of paracetamol in one study.

Clinical evidence, mechanism, importance and management

A single 650-mg dose of paracetamol was given to 5 healthy subjects who had taken amantadine 200 mg daily for 42 days, and also after a single dose of amantadine. Although the apparent volume of distribution of paracetamol was very slightly larger following long-term amantadine use, no other pharmacokinetic parameters were altered. Therefore, from this limited information, it appears that no change in the dose of paracetamol is necessary if these two drugs are given together.[1]

1. Aoki FY, Sitar DS. Effects of chronic amantadine hydrochloride ingestion on its and acetaminophen pharmacokinetics in young adults. *J Clin Pharmacol* (1992) 32, 24–7.

Paracetamol (Acetaminophen) + Antiepileptics

The metabolism of paracetamol is increased in patients taking enzyme-inducing antiepileptics (carbamazepine, phenytoin, phenobarbital, primidone). Isolated reports describe unexpected hepatotoxicity in patients taking phenobarbital, phenytoin, or carbamazepine after taking paracetamol. Valproate does not appear to affect paracetamol metabolism.
Paracetamol modestly reduces the AUC of lamotrigine but does not appear to affect the levels of phenytoin or carbamazepine.

Clinical evidence

(a) Enzyme-inducing antiepileptics

The AUC of oral paracetamol 1 g was found to be 40% lower (and when given intravenously, 31% lower) in 6 patients with epilepsy than in 6 healthy subjects. Five of the patients were taking at least two antiepileptics (combinations of **carbamazepine**, **phenobarbital**, **primidone**, and **phenytoin**), and one was taking **phenytoin** alone.[1] Similar findings (a 38% decrease in AUC) were reported in another study in 13 patients taking enzyme-inducing antiepileptics and 2 patients taking rifampicin (rifampin). In these patients, the amount of glucuronide, but not sulfate, metabolites of paracetamol were higher than the controls, but the amount of the potentially hepatotoxic metabolite (assessed by mercapturic acid and cysteine conjugates) was not raised.[2] Similar changes in paracetamol metabolites were reported in Chinese patients taking **phenytoin** alone. However, in those taking **carbamazepine** alone there was no change in the paracetamol metabolites, when compared with control subjects.[3] Other studies have also reported a greater rate of paracetamol glucuronidation and unchanged paracetamol sulfation in patients taking **phenytoin** alone[4] and patients taking **phenytoin** and/or **carbamazepine**.[5] The latter study found an increase in the clearance of the glutathione-derived conjugates (mercapturic and cysteine conjugates), which may indicate an increased risk of paracetamol hepatotoxicity.[5]

An woman with epilepsy taking **phenobarbital** 100 mg daily developed hepatitis after taking paracetamol 1 g daily for 3 months for headaches. Within 2 weeks of stopping paracetamol her serum transaminase levels had fallen to within the reference range, which implied drug-induced liver damage.[6] Another patient taking **phenobarbital** developed liver and kidney toxicity after taking only 9 g of paracetamol over 48 hours.[7] **Phenobarbital** also appeared to have increased the toxic effects of paracetamol in an adolescent who took an overdose of both drugs, which resulted in fatal hepatic encephalopathy.[8]

Other case reports describe unexpected paracetamol hepatotoxicity in three patients taking **phenytoin**,[9-11] three patients taking **carbamazepine**,[12-14] and a patient taking **phenytoin** and **primidone**.[15] Another analysis of patients with paracetamol-induced fulminant hepatic failure suggested that mortality was higher in the group of patients receiving antiepileptics (including **phenytoin**, **phenobarbital**, **carbamazepine**, **primidone** and **valproate** alone or in combination).[16]

In a study in 10 epileptics, paracetamol 1.5 g daily, taken for 3 days, had no significant effect on the serum levels of **phenytoin** and **carbamazepine**.[17]

(b) Lamotrigine

A study in 8 healthy subjects found that paracetamol 2.7 g daily modestly reduced the AUC of a 300-mg dose of lamotrigine by 20% and reduced its half-life by 15%.[18]

(c) Valproate

Valproate is extensively metabolised in man and a significant proportion of the metabolism occurs via glucuronide conjugation. A study designed to determine whether valproate affected the disposition of drugs that are largely dependent on conjugation found that it did not affect the pharmacokinetics of paracetamol in 3 patients with epilepsy.[19]

Mechanism

The increased paracetamol clearance with carbamazepine, phenobarbital, primidone, and phenytoin is due to the well-recognised enzyme-inducing effects of these antiepileptics, which increase its metabolism (glucuronidation and oxidation) and clearance from the body. It has been suggested that this could result in an increase in the production of the hepatotoxic oxidative metabolite of paracetamol, *N*-acetyl-*p*-benzoquinone imine. If this toxic metabolite then exceeds the normal glutathione binding capacity, liver damage may occur (see 'paracetamol', (p.149)). The production of the toxic metabolite *in vitro* in *animals* and humans seems to depend on several isoenzymes, but the available evidence indicates that the cytochrome P450 isoenzyme CYP2E1 is the primary isoenzyme involved in humans.[20] Therefore, because these enzyme-inducing antiepileptics do not induce this isoenzyme, some consider the few possible cases described merely represent idiosyncratic effects.[20] However, others have suggested that, when several drugs, including phenobarbital or phenytoin are taken, inhibition of glucuronosyltransferases by one of these drugs can lead to decreased glucuronidation, increased systemic exposure, and paracetamol toxicity.[21]

Importance and management

Information is limited. The clinical importance of these interactions is not established and further study is needed. Paracetamol is possibly a less effective analgesic in patients taking enzyme-inducing antiepileptics (carbamazepine, phenobarbital, primidone, and phenytoin) as plasma-paracetamol levels may be reduced. However, levels of the potentially hepatotoxic metabolites may be increased. Some believe that the evidence indicates that the risk of liver damage after paracetamol overdose is increased, and they suggest that patients taking enzyme-inducing antiepileptics should be treated with antidotes at lower plasma levels of paracetamol.[9,11,12,15] In addition, some suggest that therapeutic doses of paracetamol should be used with caution in patients receiving these drugs.[10,11,16] Conversely, others consider that therapeutic doses of paracetamol are not associated with an increased risk of toxicity when used with enzyme-inducers. Moreover, phenytoin, by increasing glucuronidation, may actually have some hepato-protective effects.[20,22] The differences stem from different understandings of which mechanism and isoenzyme(s) are important in the production of the hepatotoxic metabolite of paracetamol[10,20] (see *Mechanism*, above). Note that, there appears to be no evidence regarding **fosphenytoin**, but as it is a prodrug of phenytoin, it would be expected to interact in much the same way.

It is unlikely that the interaction between lamotrigine and paracetamol is of practical importance, but this needs confirmation.

Paracetamol (Acetaminophen) + Antimuscarinics

Propantheline reduced the rate, but not the extent, of paracetamol absorption. Other antimuscarinic drugs that delay gastric emptying would be expected to interact similarly. However, one study found that diphenhydramine did not appear to affect the absorption of paracetamol, although one case reports that an effect may occur in overdose.

Clinical evidence, mechanism, importance and management

One study in 10 healthy subjects reported that **diphenhydramine** 250 mg, taken with paracetamol 5 g (simulated paracetamol overdose) had little effect on the absorption of paracetamol.[1] However, a case has been described where the **diphenhydramine** component of a paracetamol product (*Tylenol PM*) taken in overdose (paracetamol 7.5 g and **diphenhydramine** 375 mg) delayed the absorption of paracetamol, so that the peak serum-paracetamol level did not occur until 8 hours after ingestion (usual maximum is 2 hours).[2] In this situation there is a danger that early paracetamol levels could be incorrectly assessed. Therefore, when assessing paracetamol overdoses, it is important to consider whether any concurrent drugs could delay the absorption of paracetamol.

In a study in 6 convalescent patients, **propantheline** 30 mg given intravenously delayed the peak serum levels of paracetamol 1.5 g from about one hour to 3 hours. The peak levels of paracetamol were lowered by about one-third, but the total amount absorbed was unchanged.[3] This effect occurs because **propantheline** is an antimuscarinic drug that slows the rate at which the stomach empties, so that the rate of absorption of paracetamol in the gut is reduced. The practical consequence of this is likely to be that rapid pain relief with single doses of paracetamol may be delayed and reduced by antimuscarinics but this needs clinical confirmation. If the paracetamol is being taken in repeated doses over extended periods this seems unlikely to be an important interaction because the total amount absorbed is unchanged. See 'Table 18.2', (p.786), for a list of drugs with known antimuscarinic effects.

Paracetamol (Acetaminophen) + Caffeine

Caffeine appears to increase the rate of absorption of paracetamol. Caffeine has been reported to increase or decrease the bioavailability of paracetamol.

Clinical evidence, mechanism, importance and management

In a study in 10 healthy subjects, caffeine citrate 120 mg increased the AUC of a single 500-mg dose of paracetamol by 29%, increased the maximum plasma levels by 15% and decreased the total body clearance by 32%. The decrease in time to maximum level and increase in absorption rate did not reach statistical significance.[1] A randomised, crossover study in 24 healthy subjects compared the effects of a single 1-g dose of paracetamol alone and with caffeine 130 mg. The overall bioavailability was the same between the combination and paracetamol alone, but the combination had a faster rate of absorption shown by the increase in the AUC over the first 20 minutes and early plasma concentrations.[2] There was also an increase in analgesic effects (using a pain model) throughout the observation period from about one to 3.5 hours.[2] In another study, although caffeine slightly increased the rate of absorption of paracetamol, it had no effect on the extent of absorption.[3] However, a further study states that caffeine decreased plasma paracetamol levels and its AUC, and increased paracetamol elimination in healthy men.[4]

Caffeine is commonly included in paracetamol preparations as an analgesic adjuvant, although its potential benefits and the exact mechanism for its action is still unclear. However, note that if paracetamol formulated with caffeine is given there is the potential for additive caffeine adverse effects (such as headache, jitteriness, restlessness, and insomnia). Caffeine intake should be reduced if this occurs.

Paracetamol (Acetaminophen) + Chloroquine

Chloroquine modestly increases the levels of paracetamol, whereas chloroquine levels are minimally affected by paracetamol.

Clinical evidence, mechanism, importance and management

In a single-dose study, intravenous chloroquine increased the peak plasma levels and AUC of paracetamol by 47% and 22%, respectively.[1] Another single-dose study, in 8 healthy subjects, found that paracetamol 500 mg increased the maximum plasma level and AUC of chloroquine 600 mg by 17% and 24%, respectively.[2] These changes were thought unlikely to be clinically significant.[1] A further study, in 5 healthy subjects, found that the pharmacokinetics of a single 300-mg dose of chloroquine were not affected by a single 1-g dose of paracetamol.[3] This evidence therefore suggests that no dose adjustments would be expected to be necessary when paracetamol is given with chloroquine.

Paracetamol (Acetaminophen) + Colestyramine

The absorption of paracetamol may be reduced if colestyramine is given at the same time, but the reduction in absorption is small if colestyramine is given an hour later.

Clinical evidence

When 4 healthy subjects took colestyramine 12 g and paracetamol 2 g together, the absorption of the paracetamol was reduced by 60% (range 30 to 98%) at 2 hours, but the results were said not to be statistically significant. When the colestyramine was given one hour after the paracetamol, the absorption was reduced by only 16%.[1]

Mechanism

Colestyramine reduces absorption, presumably because it binds with the paracetamol in the gut. Separating the doses minimises mixing in the gut.

Importance and management

Although information is limited, it suggests that colestyramine should not be given within one hour of paracetamol if maximal analgesia is to be achieved. It is normally recommended that other drugs are given one hour before or 4 to 6 hours after colestyramine.

Paracetamol (Acetaminophen) + Disulfiram

Disulfiram had no important effect on the metabolism of paracetamol in one study, but decreased the production of the glutathione (hepatotoxic) metabolites of paracetamol in another.

Clinical evidence, mechanism, importance and management

In a study in 5 healthy subjects without liver disease and 5 others with alcoholic liver cirrhosis, the clearance of a single 500-mg intravenous dose of paracetamol was slightly reduced (by about 10%) and the fractional clearance of paracetamol to its glucuronide, sulfate and glutathione metabolites was not altered by disulfiram 200 mg daily for 5 days.[1] In contrast, another study found that pretreatment of healthy subjects with a single 500-mg dose of disulfiram 10 hours before a single 500-mg oral dose of paracetamol reduced the recovery of glutathione metabolites (a measure of the production of the hepatotoxic metabolite, see 'paracetamol', (p.149)) by 69%.[2]

Disulfiram is an inhibitor of the cytochrome P450 isoenzyme CYP2E1, which is involved in the metabolism of paracetamol. Previously, the authors of the first study[1] had shown that in *rats,* high doses of disulfiram protected against the hepatotoxicity of paracetamol. Therefore, it was suggested that disulfiram might be useful in reducing the risks of paracetamol overdose. However, the authors of the first study concluded that disulfiram, at doses used clinically, is unlikely to have any beneficial (or adverse) effect on paracetamol metabolism.[1] In contrast, the authors of the second study consider that disulfiram may be useful in reducing the formation of the hepatotoxic metabolite of paracetamol in some situations.[2] Further study is needed.

Paracetamol (Acetaminophen) + Domperidone or Metoclopramide

Metoclopramide increases the rate of absorption of paracetamol and raises its maximum plasma levels. Similarly, domperidone may increase the rate of absorption of paracetamol.

Clinical evidence, mechanism, importance and management

In a study in 5 healthy subjects (slow absorbers of paracetamol), intravenous metoclopramide 10 mg increased the peak plasma levels of a single 1.5-g dose of paracetamol by 64% and increased its rate of absorption (peak levels reached in 48 minutes instead of 120 minutes), but the total amount absorbed remained virtually unaltered.[1] Oral metoclopramide also increases the rate of paracetamol absorption,[2] probably because the rate of gastric emptying is increased. Similarly, the speed of absorption of paracetamol may also be increased by domperidone.[3] This interaction is exploited in *Paramax* (a proprietary oral preparation containing both paracetamol and metoclopramide) to increase the effectiveness and onset of analgesia for the treatment of migraine. This is obviously an advantageous interaction in this situation.

Paracetamol (Acetaminophen) + Erythromycin

Erythromycin increases the rate of gastric emptying and may increase paracetamol absorption.

Clinical evidence, mechanism, importance and management

In a study in healthy subjects, intravenous erythromycin 0.75 to 3 mg/kg accelerated gastric emptying in a dose-dependent manner and increased paracetamol absorption.[1] However, a study in 7 healthy subjects found that a single 250-mg dose of intravenous erythromycin promoted gastric emptying of solids during acute pain, but had no significant effect on the pharmacokinetics of paracetamol 1 g in 150 mL of water.[2] Another study found that erythromycin 200 mg intravenously, given to promote gastrointestinal motility, did not alter the pharmacokinetics of an oral dose of extended-release paracetamol.[3] A further study in 7 healthy subjects reported that the pharmacokinetics of a single 1-g oral dose of paracetamol were not significantly affected by pretreatment with oral erythromycin 250 mg four times daily for 7 days.[4] It was suggested that the concurrent use of erythromycin and paracetamol is unlikely to result in a clinically significant interaction.[4]

Paracetamol (Acetaminophen) + Food

Food slows the rate of absorption of paracetamol, but the overall bioavailability is not usually affected. However, in some individuals food may delay and reduce peak paracetamol-plasma levels, and a high-fat meal may slightly reduce the extent of paracetamol absorption. Certain foods, such as cabbage and brussels sprouts, may affect the metabolism of paracetamol.

Clinical evidence, mechanism, importance and management

(a) Absorption of paracetamol

Several studies have demonstrated that food slows the rate of absorption of paracetamol, but the overall bioavailability is not affected[1-5] and some studies have also reported that food has no effect on the analgesic efficacy of paracetamol[6] or its onset.[7] The absorption of paracetamol is affected by the rate of gastric emptying and most foods delay this. Carbohydrate,[2] fat,[2] **guar gum** and **pectin**,[5] protein,[1] and particularly **fibre**,[2,4] may delay the absorption of paracetamol. Furthermore, the rate and extent of absorption, and the peak plasma levels of a single dose of paracetamol have been found to be impaired in vegetarians compared with non-vegetarians.[8] A high-fat diet has also been reported to slightly reduce the extent of absorption.[2]

Although overall bioavailability is not usually affected by food, there may be a delay in reaching therapeutic plasma paracetamol levels, particularly following a single dose of paracetamol. A reduction in the maximum plasma paracetamol level has been reported when it is given after food, when compared with the fasted state;[3,9] in one study the maximum plasma paracetamol level in some individuals did not reach the level reported to be required for effective analgesia.[9] The dosage form will also affect the absorption; many of the studies have used conventional paracetamol tablets, but some formulations (for example paracetamol with sodium bicarbonate)[3,7] are more rapidly absorbed and, although food may reduce the rate of absorption,[3,4] one study found that there was no difference in the onset of analgesia between the fed and fasted states.[7] Another study found that diet composition did not affect the systemic availability of paracetamol in a liquid dosage form, whereas absorption of the tablet form was delayed by a **fibre**-enriched diet.[4]

The clinical importance of these findings is uncertain. It appears that rapid pain relief with single doses of paracetamol tablets may possibly be delayed and reduced by food in some individuals, but liquid or rapidly absorbed preparations are less likely to be affected. If paracetamol is taken in repeated doses, the interaction with food is unlikely to be clinically important as the total amount absorbed is usually unchanged.

(b) Metabolism of paracetamol

In a crossover study in 10 healthy subjects, a 10-day balanced diet including cabbage 100 g and brussels sprouts 150 g at lunch and dinner was found to stimulate the metabolism of paracetamol, at least in part by enhanced glucuronidation. Compared with a control diet (which included instead, lettuce, cucumber, green beans and peas), cabbage and brussels sprouts induced a 16% decrease in the mean AUC of paracetamol, a 17% increase in the mean metabolic clearance rate, and an 8% increase in the mean 24-hour urinary recovery of the glucuronide metabolite.[10] Consumption of watercress caused a decrease in the levels of plasma and urinary oxidative metabolites of paracetamol, but the urinary excretion of paracetamol, or its glucuronide and sulfate were not significantly altered.[11] However, charcoal-broiled beef (which accelerates the oxidative metabolism of some drugs) did not affect paracetamol metabolism.[12] It seems unlikely that these foods would have a significant clinical effect, except perhaps cabbage and brussels sprouts if eaten to excess.

(c) Toxicity of paracetamol

A prospective study found that, of 49 patients with paracetamol hepatotoxicity, all had taken more than the recommended limit of 4 g of paracetamol daily. Paracetamol hepatotoxicity after a dose of 4 to 10 g daily was associated with fasting, and less commonly with alcohol use, and it was suggested that paracetamol hepatotoxicity after an overdose appears to be enhanced by fasting in addition to alcohol ingestion.[13] The metabolism of a lower 2-g dose of paracetamol was not, however, affected by food restriction in obese patients.[14] Fasting may possibly contribute to paracetamol toxicity by shunting paracetamol detoxification from the conjugative to the potentially toxic oxidative pathways.[14] Consider also, the food preservative sodium nitrate, see 'Paracetamol (Acetaminophen) + Sodium nitrate', p.217, and 'Alcohol + Paracetamol (Acetaminophen)', p.80.

Paracetamol (Acetaminophen) + Garlic

A study in healthy subjects found that garlic did not affect the pharmacokinetics of single-dose paracetamol to a clinically relevant extent.

Clinical evidence

A study in 16 healthy subjects found that the use of an aged garlic extract (approximately equivalent to 6 to 7 cloves of garlic daily) for 3 months had little effect on the metabolism of a single 1-g oral dose of paracetamol.[1]

Mechanism

There was a very slight increase in glucuronidation of a therapeutic dose of paracetamol after the long-term use of garlic in the clinical study, and some evidence that sulfate conjugation was enhanced, but no effect on oxidative metabolism.

Importance and management

The evidence regarding an interaction between paracetamol and garlic is limited, but what is known suggests that no clinically significant interaction would be expected if paracetamol is taken with garlic. *Animal* data suggest that it is possible that some garlic constituents, or substances derived from them, might prove to protect against the hepatotoxicity from higher than therapeutic doses of paracetamol,[2] but this requires further study.

Paracetamol (Acetaminophen) + H_2-receptor antagonists

Cimetidine, nizatidine, and ranitidine do not appear to alter the pharmacokinetics of paracetamol to a clinically relevant extent.

Clinical evidence

(a) Cimetidine

In a study in 4 healthy subjects, cimetidine (given as a single 200-mg dose or as 1 g daily in divided doses for 7 days) had no statistically significant effect on the pharmacokinetics of a single 750-mg dose of paracetamol.[1] Similarly, in another study in 10 healthy subjects, a single 800-mg dose of cimetidine given one hour before paracetamol 1 g had no effect on the paracetamol half-life or plasma clearance, and no effect on the urinary excretion of its principal metabolites (glucuronide, sulfate, mercapturate).[2] Furthermore, a study in 10 patients found that the pharmacokinetics of a single 1-g dose of paracetamol were not altered by 2 months of treatment with cimetidine 400 mg twice daily. The only difference in urinary metabolites was a modest 37% decrease in paracetamol mercapturate (indicating a reduction in the hepatotoxic metabolite).[2] Other studies have found that cimetidine does not alter the clearance[3-5] or metabolic pathways of paracetamol.[3,5]

In contrast, one study reported that cimetidine 300 mg every 6 hours decreased the fractional clearance of the oxidised metabolites (mercapturate and cysteine conjugates) of paracetamol in healthy subjects.[6] Another study found that a single 400-mg dose of cimetidine given one hour before paracetamol 1 g in fasting subjects delayed the absorption of paracetamol (for instance, there was a 37% reduction in peak salivary level and a 63% increase in time to peak level). This effect was not seen when the two drugs were given simultaneously.[7]

(b) Nizatidine

In a study in 5 healthy subjects, nizatidine 300 mg taken with paracetamol 1 g modestly increased the AUC of paracetamol in the first 3 hours by 25%. Over this time period, there was also a 4% reduction in the formation of paracetamol glucuronide, but this did reach statistical significance at 30 minutes and 45 minutes. Nizatidine 150 mg had a similar, but smaller, effect.[8]

(c) Ranitidine

In a study in 8 healthy subjects, ranitidine 300 mg twice daily for 4 days had no effect on the clearance and half-life of single 1-g intravenous and oral doses of paracetamol, given one hour after the ranitidine dose. In addition, there was no difference in the urinary excretion of the paracetamol metabolites.[9,10] Another study reported similar findings when ranitidine 300 mg was given one hour before paracetamol 1 g. However, when the two drugs were given simultaneously, the AUC_{0-3} of paracetamol was increased by 63%, and there was a 35% decrease in the AUC_{0-3} of paracetamol glucuronide, but no change occurred in sulfate levels.[11] An isolated case describes a man who noted his urine was dark 3 weeks after starting to take ranitidine 150 mg twice daily and paracetamol 1.3 to 2 g daily. He was found to have raised liver enzyme levels (alkaline phosphatase 708 units/L; AST 196 mIU/mL), which returned to normal on discontinuing ranitidine.[12]

Mechanism

Cimetidine may inhibit the oxidative metabolism of paracetamol by cytochrome P450 isoenzymes, resulting in a reduction in the hepatotoxic metabolite, see 'paracetamol', (p.149). It was suggested that cimetidine delayed paracetamol absorption by reducing gastric emptying.[7] Nizatidine may cause a minor inhibition of glucuronyltransferases.[8] Ranitidine may also inhibit paracetamol glucuronyltransferases when given simultaneously, but this was not seen when the drugs were given one hour apart.

Importance and management

Any changes in the pharmacokinetics of paracetamol with these H_2-receptor antagonists appear to be clinically unimportant. Thus, no special precaution would seem to be necessary when paracetamol is used with cimetidine, nizatidine or ranitidine. The effect of cimetidine on the oxidative metabolism of paracetamol has been investigated as a means of reducing paracetamol hepatotoxicity. However, it appears that cimetidine is not effective for this purpose.[13]

Paracetamol (Acetaminophen) + Herbal medicines; Miscellaneous

Hibiscus extract does not appear to affect the pharmacokinetics of single-dose paracetamol to a clinically relevant extent. Kakkonto extract does not appear to affect the pharmacokinetics of a single dose of paracetamol, although *animal* studies reported an increase in paracetamol levels.

Clinical evidence, mechanism, importance and management

(a) Hibiscus

A study in 6 healthy subjects found that **Zobo** drink (***Hibiscus sabdariffa*** water extract) given 78 minutes before a single 1-g dose of paracetamol did not affect the absorption or AUC of paracetamol, but the total body clearance increased by 12%.[1] This is not expected to be clinically significant.

(b) Kakkonto

A study in 6 healthy subjects found that 5 g of Kakkonto extract, a Chinese herbal medicine containing extracts of *Puerariae*, *Ephedrae*, *Zingiberis*, *Cinnamomi*, *Glycyrrhizae*, *Paeoniae* and *Zizphi* spp. had no effects on the pharmacokinetics of a single 12-mg/kg dose of paracetamol. A further study in 19 healthy subjects found that 1.25 g of Kakkonto had no effect on the pharmacokinetics of paracetamol 150 mg (from a preparation also containing salicylamide, caffeine and promethazine methylene disalicylate). Because in *animal* studies high doses of Kakkonto for 7 days were found to significantly increase serum levels of paracetamol, the authors concluded that further investigations were required to assess safety and efficacy of concurrent use.[2]

Paracetamol (Acetaminophen) + Hormonal contraceptives or HRT

Paracetamol clearance is increased in women taking oral hormonal contraceptives. Paracetamol also slightly increases the absorption of ethinylestradiol from the gut. HRT does not appear to interact with paracetamol.

Clinical evidence

(a) Effect of contraceptives or HRT on paracetamol

In 7 healthy women taking oral combined hormonal contraceptives (containing **ethinylestradiol**), the plasma clearance of a single 1.5-g dose of paracetamol was 64% higher and the elimination half-life 30% lower, when compared with 7 healthy women not taking oral hormonal contraceptives. The fractional clearance by glucuronidation and of the cysteine conjugate increased, but that of sulfation and the mercapturic acid conjugate were unchanged.[1] Similarly, other studies have found higher paracetamol clearances of 30 to 49%, and corresponding lower paracetamol half-lives, in women taking oral hormonal contraceptives, when compared with control subjects.[2-4]

One study found that the pharmacokinetics of a single 650-mg intravenous dose of paracetamol did not differ between women who had taken **conjugated oestrogens** for at least 3 months and control subjects.[5]

(b) Effect of paracetamol on oral contraceptives

In a study in 6 healthy women, a single 1-g oral dose of paracetamol increased the AUC of **ethinylestradiol** by 22%, and decreased the AUC of ethinylestradiol sulfate by 41%. The plasma levels of **levonorgestrel** were not affected.[6]

Mechanism

The evidence suggests that oral hormonal contraceptives increase the metabolism (both oxidation and glucuronidation) of paracetamol by the liver so that it is cleared from the body more quickly.[3] The increased absorption of the ethinylestradiol probably occurs because paracetamol reduces its metabolism by the gut wall during absorption.[6] It has been suggested that the differences between the effects of oral hormonal contraceptives and conjugated oestrogens on paracetamol may be attributable to the influence of progestogens on glucuronide and sulfate conjugation.[5] This needs confirmation.

Importance and management

The modest pharmacokinetic interaction between the oral hormonal contraceptives and paracetamol appears to be established, but its clinical importance has not been directly studied. The clinical importance of the modest increase in ethinylestradiol absorption is also uncertain, but it is likely to be minor. HRT appears not to interact with paracetamol.

Paracetamol (Acetaminophen) + 5-HT$_3$-receptor antagonists

Tropisetron and granisetron may block the analgesic effects of paracetamol.

Clinical evidence, mechanism, importance and management

A placebo-controlled, crossover study in 26 healthy subjects found that both intravenous granisetron 3 mg and tropisetron 5 mg blocked the analgesic effect of a single 1-g oral dose of paracetamol given 90 minutes later. The pharmacokinetics of paracetamol were unaffected by the two drugs. The interaction was thought to involve the serotonergic system,[1] see *Mechanism*, under 'Opioids + Antiemetics; Ondansetron', p.178, for further explanation of this effect. It may be prudent to consider the use of other analgesics in patients given these antiemetics.

Paracetamol (Acetaminophen) + Isoniazid

A number of reports suggest that the toxicity of paracetamol may be increased by isoniazid so that normal analgesic doses (4 g daily) may not be safe in some individuals. Pharmacokinetic studies suggest that isoniazid usually inhibits the metabolism of paracetamol, but that metabolism to toxic metabolites may be induced shortly after stopping isoniazid, or late in the isoniazid dose-interval in fast acetylators of isoniazid.

Clinical evidence

A 21-year-old woman who had been taking isoniazid 300 mg for 6 months developed marked evidence of liver damage (prolonged prothrombin time, elevated ammonia, transaminases, hyperbilirubinaemia) within about 6 hours of taking 3.25 g of paracetamol for abdominal cramping.[1]

A young woman taking isoniazid who had taken up to 11.5 g of paracetamol in a suicide attempt, developed life-threatening hepatic and renal toxicity despite the fact that her serum paracetamol levels were only 15 micromol/L 13 hours after ingestion (toxicity normally associated with levels above 26 micromol/L).[2]

Three other similar cases have been reported in patients taking isoniazid, rifampicin and pyrazinamide who had taken only 2 to 6 g of paracetamol daily.[3] Three other possible cases of this toxic interaction have also been described.[4]

However, in a pharmacokinetic study in 10 healthy subjects (including both slow and fast acetylators of isoniazid), isoniazid 300 mg daily for 7 days modestly decreased the total clearance of a single 500-mg dose of paracetamol by 15%. Moreover, the clearance of paracetamol to oxidative metabolites was *decreased*.[5] Similarly, in a further study in 10 healthy slow acetylators of isoniazid, the formation of paracetamol thioether metabolites and oxidative metabolites was reduced by 63% and 49%, respectively, by isoniazid 300 mg daily. However, one day after stopping isoniazid, the formation of thioether metabolites was *increased* by 56%, and this returned to pretreatment values 3 days after the discontinuation of isoniazid.[6] In yet another study in 10 healthy subjects taking isoniazid as prophylaxis, the formation clearance of paracetamol to *N*-acetyl-*p*-benzoquinone imine (NAPQI) was inhibited by 56% when paracetamol was given simultaneously with the daily isoniazid dose, but when the paracetamol was taken 12 hours after the isoniazid, there was no difference in NAPQI formation clearance, compared with the control phase (one to 2 weeks after isoniazid had been discontinued). However, when the results were analysed by isoniazid acetylator status, it appeared that the NAPQI

formation clearance was *increased* in fast acetylators taking paracetamol 12 hours after the isoniazid dose.[7]

Mechanism

Not established. A possible reason for the altered paracetamol metabolism is that isoniazid induces the cytochrome P450 isoenzyme CYP2E1 by stabilisation.[8] This means that while the isoniazid is still present, the metabolism of substrates such as paracetamol is inhibited. However, when isoniazid levels drop sufficiently (as may be the case late in the dosing interval in fast acetylators), metabolism may be induced resulting in a greater proportion of paracetamol being converted into toxic metabolites than would normally occur.[7]

Importance and management

Information is limited, but it would now seem prudent to consider warning patients taking isoniazid to limit their use of paracetamol because it seems that some individuals risk possible paracetamol-induced liver toxicity, even with normal recommended doses of paracetamol. Pharmacokinetic studies suggest that it is possible that the risk is greatest shortly after stopping isoniazid. The risk may also be higher if paracetamol is taken late in the isoniazid dosing interval, particularly in fast acetylators of isoniazid. More study is needed to clarify the situation.

Paracetamol (Acetaminophen) + Opioids

Diamorphine, morphine, oxycodone, pentazocine and pethidine (meperidine) delay gastric emptying so that the rate of absorption of oral paracetamol is reduced. No pharmacokinetic interaction occurs between codeine and paracetamol, but the combination may not always result in increased analgesia.

Clinical evidence

(a) Codeine

A study in 6 healthy subjects found that paracetamol 1 g every 8 hours for 7 doses had no effect on the pharmacokinetics of a single 30-mg oral dose of codeine, or its metabolites.[1] Similarly in other studies, codeine had no effect on the pharmacokinetics of paracetamol.[2,3] Paracetamol and codeine are often given together because the combination is more effective than either drug given alone. However, note that not all studies have found this. For example, in one clinical study of surgical removal of impacted third molar teeth, there was no difference in analgesic efficacy between patients given paracetamol alone (800 mg given 3, 6, and 9 hours after surgery, then 400 mg four times daily for 2 days) and those given the same dose of paracetamol with the addition of codeine phosphate 30 mg. Moreover, patients given codeine experienced more adverse effects (nausea, dizziness, drowsiness).[4]

(b) Diamorphine, Pethidine (Meperidine) and Pentazocine

A study in 8 healthy subjects reported that the absorption of a single 20-mg/kg oral dose of paracetamol solution given 30 minutes after an intramuscular injection of either pethidine 150 mg or diamorphine 10 mg was markedly delayed and reduced. Peak plasma paracetamol levels were reduced by 31% and 74%, respectively, and delayed from 22 minutes, to 114 minutes and 142 minutes, respectively.[5] This interaction was also observed, by the same study group, in women in labour who had been given paracetamol tablets after receiving pethidine, diamorphine or pentazocine.[6]

(c) Fentanyl

An *in vitro* study found that paracetamol inhibited the oxidation of fentanyl to norfentanyl, but the concentrations of paracetamol used were greater than those found therapeutically. A potential interaction was thought possible because fentanyl is metabolised by the cytochrome P450 isoenzyme CYP3A4 and paracetamol is also partially metabolised by the CYP3A family.[7]

(d) Morphine

A study in healthy subjects, who remained in the supine position, investigated the effect of morphine syrup (4 doses of 10 mg given every 4 hours) on the absorption of paracetamol. The time to the maximum plasma paracetamol level, for conventional tablets, was increased from 51 minutes to 160 minutes by morphine, whereas the time to the maximum plasma paracetamol level for dispersible tablets was only increased from 14 minutes to 15 minutes.[8]

(e) Oxycodone

A crossover study in 10 healthy subjects investigated the effect of oxycodone 500 micrograms/kg on the absorption kinetics of a simulated paracetamol overdose (5 g). The maximum serum paracetamol level was reduced by 40%, the time to maximum level was increased by 68%, and the $AUC_{0–8}$ was 27% lower, when compared with paracetamol alone.[9]

Mechanism, importance and management

The underlying mechanism of these interactions is that the opioid analgesics delay gastric emptying so that the rate of absorption of paracetamol is reduced, but the total amount absorbed is not affected. These were largely investigational studies in healthy subjects, where paracetamol was used as a measure of gastric emptying, and any clinical relevance has not been determined. Reducing the rate of paracetamol absorption would be expected to reduce the onset of analgesic effect, but this is probably not relevant in patients who are receiving regular doses of paracetamol. However, if speed of onset of action is important, one study[8] suggested that the use of dispersible paracetamol might help to reduce the delay in reaching therapeutic plasma levels.

In paracetamol overdose, it has been suggested that when an opioid is present there may be a potential role for the use of activated charcoal beyond one-hour post-ingestion, because of the delay in the absorption of paracetamol.[9] When assessing treatment options it is also worth noting that maximum plasma levels may be delayed.

Paracetamol (Acetaminophen) + Probenecid

Probenecid reduces the clearance of paracetamol.

Clinical evidence, mechanism, importance and management

A metabolic study in 10 healthy subjects found that the clearance of paracetamol 1.5 g was almost halved (from 6.23 to 3.42 mL/minute per kg) when it was taken one hour after a 1-g dose of probenecid. The amount of unchanged paracetamol in the urine stayed the same, but the glucuronide metabolite fell sharply.[1] Another study in 11 subjects also found that probenecid 500 mg every 6 hours almost halved (from 329 to

178 mL/minute) the clearance of a 650-mg intravenous dose of paracetamol. The urinary excretion of the glucuronide metabolite was decreased by 68% and the excretion of the sulfate metabolite was increased by 49%.[2] These studies suggest that probenecid inhibits paracetamol glucuronidation, possibly by inhibiting glucuronyltransferases. The practical consequences of this interaction are uncertain but there seem to be no adverse reports.

Paracetamol (Acetaminophen) + Propranolol

Propranolol may slightly increase the bioavailability of paracetamol.

Clinical evidence, mechanism, importance and management

In a study in 10 healthy subjects, propranolol 80 mg twice daily for 4 days increased the half-life of a single 1.5-g dose of paracetamol by 25% and lowered its clearance by 14%. The partial clearance of paracetamol to its cysteine and mercapturate derivatives was decreased by 16% and 32%, respectively, and the clearance to the glucuronide conjugate was decreased by 27%, but the sulfate was not significantly affected.[1] Similarly, an earlier study found that propranolol 40 mg four times daily for one week increased the maximum plasma level of a single 1.5-g dose of paracetamol and reduced the time to peak plasma level. However, the increased rate of absorption of paracetamol was not thought to be clinically important.[2] In contrast, a study in 6 subjects found that a relatively small dose of propranolol (80 mg daily for 6 days) did not affect the pharmacokinetics of paracetamol.[3] Another study found that long-term propranolol use in patients with chronic liver disease did not influence the clearance of total or unconjugated paracetamol.[4] The changes described here appear to be small, and are therefore unlikely to be clinically significant.

Paracetamol (Acetaminophen) + Proton pump inhibitors

Lansoprazole modestly increased the rate, but not the extent, of absorption of a paracetamol solution. Omeprazole does not appear to have any effect on the metabolism of phenacetin (which is metabolised to paracetamol) or paracetamol.

Clinical evidence

(a) Lansoprazole

In a study in 6 healthy subjects, lansoprazole 30 mg daily for 3 days increased the peak level of paracetamol (given as a single 1-g dose in solution) by 43%, and decreased the time to peak paracetamol levels by half (from about 35 to 17.5 minutes). However, lansoprazole had no effect on the AUC and elimination half-life of paracetamol.[1]

(b) Omeprazole

In 10 healthy subjects omeprazole 20 mg daily for 8 days had no effect on the pharmacokinetics of **phenacetin**, or paracetamol derived from **phenacetin**, except that the peak plasma level of **phenacetin** was higher. There was no change in the metabolism (oxidative and conjugative) of **phenacetin** or derived paracetamol.[2] In another study in 10 subjects, omeprazole 40 mg daily for 7 days had no effect on the formation of thioether metabolites of paracetamol.[3]

Mechanism

Lansoprazole may increase the absorption of paracetamol by indirectly increasing the rate of gastric emptying.[1] Phenacetin is metabolised to paracetamol by the cytochrome P450 isoenzyme CYP1A2, and it has been suggested that omeprazole can induce CYP1A2, and possibly increase the formation of hepatotoxic metabolites of paracetamol. However, the findings here suggest that omeprazole has no important effect on CYP1A2, or on phenacetin or paracetamol metabolism.

Importance and management

The findings from these studies suggest that neither lansoprazole nor omeprazole cause any clinically important changes in the pharmacokinetics of paracetamol. No paracetamol dose adjustment appears to be needed on the concurrent use of either omeprazole or lansoprazole. Other proton pump inhibitors would also not be expected to interact, but this needs confirmation.

Paracetamol (Acetaminophen) + Rifampicin (Rifampin)

Rifampicin increases the metabolism of paracetamol. An isolated report describes liver failure, which may have been due to an interaction between paracetamol and rifampicin.

Clinical evidence, mechanism, importance and management

In 10 patients taking rifampicin 600 mg daily, the metabolite to paracetamol ratio for glucuronides was twice as high than in 14 healthy control subjects. In contrast the ratio for sulfates did not differ between the two groups.[1] In a crossover study in healthy subjects, rifampicin 600 mg daily for one week, given before paracetamol 500 mg, had no effect on the formation of *N*-acetyl-*p*-benzoquinone imine (NAPQI) or the recovery of thiol metabolites formed by conjugation of NAPQI with glutathione.[2] The clinical importance of these studies awaits further clarification, but they suggest that rifampicin may reduce the efficacy of paracetamol. These studies suggest that rifampicin induces the glucuronidation of paracetamol, but that it does not increase the formation of hepatotoxic metabolites of 'paracetamol', (p.149). However, a 32-year-old woman, who had taken paracetamol 2 to 4 g daily for several weeks, and who had not responded to doxycycline or clarithromycin for suspected cat scratch fever, became confused and agitated 2 days after starting to take rifampicin 600 mg twice daily. Her INR increased from 1.1 to 5.2 and her liver enzymes became raised. Rifampicin and paracetamol were stopped, and she was treated with vitamin K and acetylcysteine, and liver function returned to normal. Paracetamol hepatotoxicity, in doses not normally associated with such effects, occurred only after the addition of rifampicin. It was suggested that rifampicin, which alone may cause hepatitis, had in this case induced the metabolism of paracetamol to hepatotoxic metabolites.[3] The general significance of this is unknown.

Paracetamol (Acetaminophen) + Sodium nitrate

An isolated report describes severe methaemoglobinaemia in a patient who had taken paracetamol after a meal consisting of 'yuke' (raw beef preserved with sodium nitrate). Both paracetamol and sodium nitrate may cause methaemoglobinaemia, so an

interaction resulting in additive effects may have occurred, but a genetic cause was also considered to be a possibility.[1] This is an isolated report and its general relevance is unknown.

Paracetamol (Acetaminophen) + Sucralfate

In 6 healthy subjects, the bioavailability of paracetamol 1 g (using salivary paracetamol levels over 4 hours as a measure of paracetamol absorption) was found to be unchanged by sucralfate 1 g.[1] This suggests that paracetamol absorption is unlikely to be affected by sucralfate. No special precautions appear to be necessary if both drugs are given.

1. Kamali F, Fry JR, Smart HL, Bell GD. A double-blind placebo-controlled study to examine effects of sucralfate on paracetamol absorption. *Br J Clin Pharmacol* (1985) 19, 113–14.

Paracetamol (Acetaminophen) + Sulfinpyrazone

Sulfinpyrazone modestly increases the clearance of paracetamol.

Clinical evidence, mechanism, importance and management

In a study in 12 healthy subjects, sulfinpyrazone 200 mg given every 6 hours for one week increased the clearance of a single 1-g dose of paracetamol by 23%. There was a 26% increase in metabolic clearance of the glucuronide conjugate of paracetamol, and a 43% increase in the glutathione-derived conjugates (indicating an increased production of the hepatotoxic metabolite), but no change in sulfation.[1] It has therefore been suggested that, in patients taking sulfinpyrazone, the risk of liver damage may be increased after paracetamol overdose and perhaps during prolonged consumption,[1] but there seem to be no adverse reports. The clinical importance of these findings awaits further study.

Paracetamol (Acetaminophen) + Tobacco

Heavy, but not moderate, smoking may increase the metabolism of paracetamol. The clearance of phenacetin (which is metabolised to paracetamol) is also increased in smokers. There is some evidence that smokers are at risk of a poorer outcome after paracetamol overdose.

Clinical evidence, mechanism, importance and management

There was no difference in the clearance of a single 1-g dose of paracetamol or its metabolites in 6 otherwise healthy smokers (more than 15 cigarettes per day) and 6 healthy non-smokers in one study.[1] Similarly, another study found no difference in the pharmacokinetics of a single 650-mg intravenous dose of paracetamol in 14 otherwise healthy smokers (range 8 to 35 cigarettes per day) and 15 non-smokers.[2] In contrast, in another study, the glucuronide metabolite to paracetamol ratio was 83% higher in 9 heavy smokers (about 40 cigarettes daily), suggesting increased paracetamol metabolism, than in 14 healthy non-smokers. However, it was not higher in moderate smokers (about 10 cigarettes daily).[3] A retrospective study of patients treated for paracetamol poisoning found that there was a much higher proportion of smokers than in the general population (70% versus 31%). Moreover, smoking was independently associated with an increased risk of hepatic encephalopathy (odds ratio 2.68) and death (odds ratio 3.64) following paracetamol overdose.[4]

A study in 36 healthy Chinese subjects given a single 900-mg dose of **phenacetin** (which is metabolised to paracetamol) found that subjects who smoked cigarettes (7 to 40 daily; mean 20) had a 2.5-fold higher phenacetin apparent oral clearance, when compared with non-smokers. Paracetamol plasma levels were also moderately lower in the smokers.[5]

Cigarette smoke appears to induce the metabolism of **phenacetin** by the cytochrome P450 isoenzyme CYP1A2, and also appears to increase the metabolism of paracetamol either by stimulating a minor pathway involving CYP1A2 oxidation or by stimulating the conversion of phenacetin to compounds other than paracetamol.[5]

No interaction is established, but the above studies suggest that heavy smoking may increase the metabolism of paracetamol. The retrospective study also suggests that smoking is associated with a poorer outcome after paracetamol overdose. Further study is needed.

Ziconotide + Miscellaneous

The use of ziconotide with intrathecal morphine increases the risk of neuropsychiatric adverse effects. Additive CNS depression may occur if ziconotide is given with other CNS depressants: ziconotide may increase the risk of somnolence in patients also taking baclofen, clonidine, propofol or bupivacaine. No interaction appears to occur between ziconotide and ACE inhibitors or protease inhibitors.

Clinical evidence, mechanism, importance and management

(a) Opioids

Intrathecal ziconotide appears to increase the incidence of neuropsychiatric adverse effects (confusion, paranoia, hallucinations, abnormal gait) as well as vomiting, anorexia and peripheral oedema in patients receiving *intrathecal* **morphine**.[1] Intrathecal **morphine** given to patients established on ziconotide may be better tolerated, although pruritus has been reported.[1] If an opioid and ziconotide are needed, patients should be closely monitored for adverse effects. If adverse effects occur, consideration should be given to discontinuing one or both drugs, or decreasing their doses. The US manufacturer advises against the use of *intrathecal* opiates with ziconotide as this has not been fully studied in placebo-controlled clinical studies.[2]

The UK manufacturer notes that there is no data on concurrent use of partial opioid agonists such as **buprenorphine** with ziconotide.[1]

(b) CNS depressants

The use of ziconotide may increase the risk of CNS adverse effects, including confusion and dizziness, if it is given with other CNS depressant drugs.[2] Note that respiratory depression does not appear to occur with ziconotide.[1,2] As ziconotide may cause loss of consciousness or stupor, the manufacturers recommend that, should this occur, the concurrent use of other CNS depressants should be reviewed and ziconotide discontinued until the patient regains full consciousness.[1,2] The US manufacturer notes that patients also taking antiepileptics, sedatives or diuretics are at higher risk of this loss of consciousness occurring.[2] Note that increased somnolence has been seen in patients given ziconotide with systemic **baclofen**, **clonidine**, **propofol** or **bupivacaine**.[1] See also *Opioids*, above.

(c) Miscellaneous

The manufacturers of ziconotide note that, based on limited data, ACE inhibitors (**benazepril**, **lisinopril** and **moexipril** specifically named) and protease inhibitors (**ritonavir**, **saquinavir** and **indinavir** specifically named) are not expected to affect plasma levels of ziconotide.[1]

Note that ziconotide is given intrathecally, and is therefore contraindicated with intrathecal chemotherapy. The UK manufacturers also note that only a small number of patients have received systemic chemotherapy and intrathecal ziconotide, and therefore caution is advised on concurrent use.[1]

Anorectics and Stimulants

This section covers the drugs used in the management of obesity (such as orlistat, rimonabant and sibutramine) as well as the older drugs, such as the amfetamines, which are now no longer widely indicated for this condition and are now more generally considered as drugs of abuse. However, it should not be forgotten that the amfetamines (largely dexamfetamine) still have a limited therapeutic role in the management of narcolepsy and refractory attention deficit hyperactivity disorder (ADHD).

Ecstasy (MDMA, methylenedioxymethamfetamine), a drug of abuse that is structurally related to amfetamine, is also included in this section. The amfetamines are sympathomimetics, a diverse group, which have a number of interactions not necessarily shared by all members of the class. The mechanism of action and classification of sympathomimetics is discussed in 'Cardiovascular drugs, miscellaneous', (p.1047). Other stimulant drugs such as atomoxetine or methylphenidate (another sympathomimetic), that have a role in ADHD, and modafinil, used in narcolepsy, are also discussed in this section.

Amfetamines + Caffeine

A man who took a mixture of amfetamines and caffeine intranasally had an ischaemic stroke, and a girl receiving dexamfetamine experienced acute onset myoclonus after taking a caffeine-containing preparation.

Clinical evidence, mechanism, importance and management

A 37-year-old man experienced an ischaemic stroke after the nasal use of amfetamines and caffeine. Three hours after he took the mixture, his blood pressure was 230/130 mmHg and pulse rate 120 bpm, but there was no neurological deficit. However, 6 hours later he had developed motor aphasia, right hemiplegia and right facial nerve palsy, and his blood pressure was 200/100 mmHg. It was thought that the nasal use of a mixture of amfetamines and caffeine caused the stroke, probably through the rapid rise in blood pressure combined with cerebral vasoconstriction.[1]

A 16-year-old girl with attention deficit hyperactivity disorder (ADHD) well controlled with **dexamfetamine** 10 mg daily, experienced a severe headache and then, on the following day, palpitations and acute onset myoclonus, which ceased spontaneously within 4 to 5 hours. The patient then revealed that she had taken *Excedrin* (paracetamol (acetaminophen), aspirin and caffeine) for headaches, both the day before and on the day of the abnormal movements; the last dose had been taken about 30 minutes before the jerking movements began. The combination of the CNS stimulant caffeine and **dexamfetamine** was thought to have caused the CNS toxicity.[2]

These appear to be the only documented cases of an interaction and so their clinical relevance is unclear. However, given the severity of the outcome, it may be prudent to consider potential caffeine intake in anyone receiving amfetamines.

Amfetamines + Calcium-channel blockers

Diltiazem attenuated the increase in blood pressure caused by dexamfetamine, and isradipine had similar effects with metamfetamine. The subjective changes or changes in reaction time associated with dexamfetamine were not affected by diltiazem. However, isradipine, both alone and with metamfetamine, tended to modestly decrease cognitive performance.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study in 10 healthy subjects, pretreatment with a single 60-mg dose of **diltiazem** significantly attenuated the increase in diastolic blood pressure caused by a single oral 20-mg dose of **dexamfetamine**. The increase in systolic blood pressure was also attenuated, but the effect of diltiazem wore off over the 4-hour study period. The subjective changes or changes in reaction time associated with **dexamfetamine** were not affected by **diltiazem**.[1] A placebo-controlled study in 19 **metamfetamine**-dependent subjects found that pretreatment with **isradipine** reduced intravenous metamfetamine-associated increases in all measures of blood pressure except pulse pressure, but tended to enhance the effect of metamfetamine on heart rate.[2] Furthermore, another study found that **isradipine** tended to modestly decrease cognitive performance both with and without **metamfetamine**.[3]

The clinical relevance of these effects is unclear; the interaction between dexamfetamine and diltiazem may be beneficial, but the effects of isradipine on metamfetamine may be detrimental in some subjects. More study is needed.

Amfetamines + Cannabis

Cannabis opposes the stimulant and hyperthermic effects of ecstasy, but long-term users of both drugs may potentially experience cumulative CNS impairment. A report describes severe arterial ischaemia in a patient who regularly abused amfetamines and cannabis.

Clinical evidence

A 22-year-old woman who smoked cigarettes and had regularly abused amfetamine derivatives such as **metamfetamine** ("crystal speed") and **ecstasy** (MDMA, methylenedioxymethamfetamine) together with cannabis, experienced severe arterial ischaemia leading to claudication and ulceration of the feet.[1]

A study in 18 cannabis users, 11 cannabis and **ecstasy** users, and 31 subjects who had used neither drug, found that cannabis and cannabis/ecstasy users performed similarly in most CNS tests. However, both groups combined performed less well than non-drug users on tests of memory, learning, word fluency, speed of processing and manual dexterity. Furthermore, the deficits were more closely related to cannabis than **ecstasy** usage.[2] Similar results were reported in another study.[3] A further self-rated study found that moderate cannabis use might help to improve or mask **ecstasy**-induced aggression and somatic symptoms (e.g. headache, chronic tiredness). However, heavy cannabis and **ecstasy** use appeared to be associated with problems such as paranoia or cognitive disorders, which might emerge after a period of abstinence from both drugs.[4]

Mechanism

It was suggested that the amfetamine derivatives might have induced vasculitis of the arteries with cannabis possibly adding to the effect on the microcirculation.[1] Both drugs may cause additive CNS impairment.

Importance and management

The majority of recreational **ecstasy** users also take cannabis and this combined-drug usage appears to reflect the opposing effects of the two drugs: ecstasy is a powerful stimulant whereas cannabis is a relaxant, ecstasy is hyperthermic whereas cannabis is hypothermic and ecstasy increases oxidative stress whereas cannabinoids are antioxidant. Therefore cannabis may modulate the acute reactions to **ecstasy**.[5] However, the chronic effects of each drug may be functionally damaging, so that using both drugs may be associated with a variety of psychological problems.[5,6] Furthermore, regular cannabis use seems to be necessary for the development and maintenance of symptoms of mental illness in ecstasy users.[6]

Amfetamines + Cocaine

An ischaemic stroke occurred in a patient who was abusing amfetamine and cocaine. Convulsions and cardiovascular adverse effects occurred in an infant exposed to an amfetamine and cocaine. *In vitro*, cocaine inhibits the metabolism of ecstasy, but the clinical significance of this is unknown.

Clinical evidence, mechanism, importance and management

A 16-year-old boy developed unsteadiness and double vision 5 minutes after intranasal inhalation of a small amount of **amfetamine** 'cut' with cocaine. Cranial magnetic resonance imaging revealed a mesencephalic

lesion that was seen to have decreased 12 days later, and he became symptom-free after 3 weeks. The ischaemic lesion was thought to be due to vasospasm caused by synergistic stimulation of the sympathetic nervous system: amfetamine causes the release of adrenaline (epinephrine) and noradrenaline (norepinephrine), while cocaine prevents their reuptake.[1] An 11-month-old infant experienced apparent generalised convulsions and cardiovascular adverse effects after accidental ingestion of **ecstasy** (MDMA, methylenedioxymethamfetamine) and chronic exposure to cocaine. It was suggested that, as both drugs are neurotoxic and have similar mechanisms of action, the combination could increase the risk of serious medical consequences.[2]

An *in vitro* study showed that cocaine (a potent inhibitor of the cytochrome P450 isoenzyme CYP2D6) inhibited the CYP2D6-mediated demethylenation of **ecstasy**. Therefore, theoretically, the use of cocaine would be expected to increase plasma and CNS **ecstasy** levels[3] but it is not known if this is significant in practice.

Evidence is currently limited, but it would appear that the concurrent use of amfetamines and cocaine may have adverse CNS consequences. The clinical relevance of these reports is unclear.

Amfetamines and related drugs + Lithium

The stimulant and/or cardiovascular effects of the amfetamines have been shown to be opposed by lithium in some, but not all studies.

Clinical evidence, mechanism, importance and management

Two depressed patients stopped abusing **metamfetamine** and cannabis, or **phenmetrazine** and 'other diet pills' because, while taking lithium carbonate, they were unable to get 'high'. Another patient complained that she felt no effects from amfetamines taken for weight reduction, including no decrease in appetite, until lithium carbonate was withdrawn.[1] A controlled study in 9 depressed patients confirmed that lithium carbonate taken for 10 days attenuated the subjective stimulant effects of **dexamfetamine** or **levamfetamine**.[2] Another study found similar results with **dexamfetamine** in schizophrenic patients.[3] However, in a further study, the stimulant effects of **amfetamine** were attenuated in only 4 of 8 subjects given lithium. However, lithium attenuated the increase in systolic blood pressure caused by amfetamine (from an average increase of 31/15 mmHg down to 20/9 mmHg).[4]

In contrast, in a placebo-controlled study in healthy subjects, lithium 1.2 g daily for 7 days did not alter the subjective or cardiovascular effects of a single 20-mg dose of **dexamfetamine**.[5] In another controlled study, in 9 subjects, the only significant effect of pretreatment with lithium 900 mg for 14 days was to attenuate the feeling of happiness induced by **dexamfetamine**.[6]

The reasons for these reactions, when they occur, are not known. One study found that pretreatment of healthy subjects with lithium for 14 days attenuated **dexamfetamine**-induced regional decreases in brain activation when performing cognitive tasks.[7] It has been suggested that amfetamines and lithium have mutually opposing pharmacological actions on dopamine and noradrenaline (norepinephrine) release and uptake at adrenergic neurones,[1,7] possibly partially due to opposing effects on the phosphoinositol second messenger system (PI-cycle).[7]

Information is contradictory, and therefore an interaction is not fully established. Nevertheless, it may be prudent to be alert for evidence of reduced amfetamine effects in the presence of lithium.

Amfetamines + Miscellaneous

The use of amfetamines and beta blockers may have undesirable effects on blood pressure. Delavirdine and disulfiram are predicted to inhibit the metabolism of amphetamines, and drugs that increase gastrointestinal acidity are predicted to decrease the absorption of amfetamines.

Clinical evidence, mechanism, importance and management

(a) Beta blockers

The US manufacturers of some amfetamines give general warnings that the effects of adrenergic blockers are inhibited by amfetamines[1,2] and that amfetamines may antagonise the hypotensive effects of antihypertensives.[1-3] However, the UK manufacturer of **dexamfetamine** warns that the concurrent use of beta blockers may result in severe hypertension and that adrenoreceptor blocking drugs such as **propranolol** may antagonise the effects of **dexamfetamine** (a sympathomimetic).[4] This is similar to the effects seen with vasopressor sympathomimetics, see 'Beta blockers + Inotropes and Vasopressors', p.1011.

(b) Delavirdine

The NNRTI, delavirdine, is an inhibitor of CYP3A and other isoenzymes including CYP2D6 by which amfetamines are metabolised. The manufacturer suggests caution if delavirdine is used with amfetamines because the amfetamine levels may be increased.[5]

(c) Disulfiram

Studies in *animals* have indicated that disulfiram may inhibit the metabolism of amfetamines.[6] The UK manufacturer of **dexamfetamine** says that disulfiram may inhibit the metabolism and excretion of **dexamfetamine**. In addition, they contraindicate the use of **dexamfetamine** in patients with a history of alcohol abuse.[4]

(d) Drugs that affect gastric acidity

The manufacturers note that drugs or substances that increase gastrointestinal acidity (**glutamic acid hydrochloride**, **ascorbic acid**, **fruit juices** etc.) could lower the absorption of amfetamines and might therefore lower their blood levels and efficacy.[1,2]

Amfetamines + Ondansetron

Ondansetron appears to attenuate the effects of amfetamine and dexamfetamine on subjective feelings such as light-headedness, but not the effects of amfetamine on psychomotor tests. One study found that ondansetron did not affect most physiological responses to dexamfetamine, but might attenuate blood pressure increases, although another study found ondansetron had no effect on amfetamine-induced increases in blood pressure.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study, when 9 healthy subjects were given **amfetamine** 15 mg, they reported an increase in subjective feelings such as light-headedness or "high" and a decrease in hunger. The use of **amfetamine** also caused an increase in systolic blood pressure and a decrease in the mean time to complete psychomotor tests. When ondansetron 4 mg was given every 12 hours for 3 doses, with the last dose 30 minutes before the amfetamine, the effects of **amfetamine** on hunger and subjective state

were diminished, but its effects on blood pressure and psychomotor performance tests were not altered.[1] These findings have also been published elsewhere.[2] In another placebo-controlled study, in 10 healthy subjects, pretreatment with ondansetron 150, 50 or 15 micrograms/kg reduced the increases in prolactin associated with intravenous **dexamfetamine** 500 micrograms/kg, but did not affect other neuroendocrine responses (increased plasma levels of cortisol and growth hormone) or most physiological responses (elevated pulse and temperature). However, the lower doses of ondansetron attenuated amfetamine-induced increases in diastolic blood pressure. Mild/moderate euphoria/activation induced by **dexamfetamine** was only minimally affected by pretreatment with ondansetron, but ondansetron did attenuate the responses in subjects with robust euphoria/activation.[3]

It is suggested that ondansetron may attenuate some catecholamine-mediated effects of **amfetamine**, but a pharmacokinetic interaction has not yet been excluded.[1,2] However, analysis of the plasma levels in 4 subjects found that ondansetron did not significantly alter mean **dexamfetamine** levels, or the time taken to reach peak dexamfetamine levels.[3]

These studies were mainly designed to establish whether or not ondansetron altered the responses to amphetamines. They suggest that no clinically relevant adverse interaction occurs, but more study is needed to establish the absence of a pharmacokinetic interaction.

Amfetamines and related drugs + Phenothiazines

The appetite suppressant and other effects of amfetamines, chlorphentermine and phenmetrazine are opposed by chlorpromazine. It seems possible that other phenothiazines will interact similarly. The antipsychotic effects of chlorpromazine can be opposed by dexamfetamine. Dexamfetamine can oppose the antipsychotic effects of chlorpromazine, and in one case dexamfetamine exacerbated a perphenazine-related withdrawal dyskinesia.

Clinical evidence

In a placebo-controlled study, 10 obese schizophrenic patients who were taking drugs including **chlorpromazine**, **thioridazine**, imipramine and chlordiazepoxide did not respond to treatment with **dexamfetamine** for obesity. The expected sleep disturbance in response to **dexamfetamine** was also not seen.[1] In a double-blind, placebo-controlled study in 76 patients, **chlorpromazine** was found to diminish the weight-reducing effect of **phenmetrazine**,[2] and, in another study, patients taking **chlorpromazine** did not experience the expected weight loss when they were given **phenmetrazine** or **chlorphentermine**.[3] Similarly, antagonism of the effects of **amfetamines** by **chlorpromazine** has been described in other reports,[4,5] and this interaction has been deliberately exploited, with success, in the treatment of 22 children poisoned with various amfetamines or related compounds (**amfetamine**, **dexamfetamine**, **metamfetamine**, **phenmetrazine**).[4]

A study in 462 patients taking **chlorpromazine** 200 to 600 mg daily found that the addition of **dexamfetamine** 10 to 60 mg daily had a detrimental effect on the control of their schizophrenic symptoms.[6]

A 9-year-old boy taking **perphenazine**, **dexamfetamine**, fluoxetine and diphenhydramine had his **perphenazine** dose tapered and then discontinued, followed by discontinuation of the fluoxetine and diphenhydramine. Two days after the perphenazine was stopped the patient began to have repeated tongue protrusions, which progressed to abnormal involuntary movements involving his upper and lower extremities. It was suspected that **dexamfetamine** was aggravating the movement disorder and so it was tapered over 2 days and stopped, resulting in an immediate and dramatic improvement.[7]

Mechanism

Not fully understood. It is known that chlorpromazine can inhibit adrenergic and dopaminergic activity, which could explain some part of the antagonism of the amfetamines, the euphoriant effects of which are said to be mediated by central dopamine receptors.

The severe extrapyramidal movement disorder might have occurred due to the patient developing dopamine supersensitivity as a result of long-term antipsychotic therapy. On antipsychotic withdrawal, an increased number of postsynaptic dopamine receptors were available to the dopamine agonist effects of continued amfetamine treatment, resulting in the extrapyramidal movement disorder, which did not subside until the dopamine agonist was withdrawn.[7]

Importance and management

Established interactions. These reports suggest that it is not beneficial to attempt to treat patients taking chlorpromazine with amfetamines, such as dexamfetamine, or other central stimulants such as phenmetrazine. Although in one study, thioridazine also appeared to interact it is not clear whether this interaction takes place with antipsychotics other than chlorpromazine. However, it seems possible that this interaction may occur with all phenothiazines, especially if the suggested mechanism is correct. Note that central stimulants are no longer recommended for the treatment of obesity.

The case of dyskinesia suggests that central stimulants may exacerbate symptoms caused by antipsychotic withdrawal. See also 'Methylphenidate + Risperidone', p.228.

Amfetamines + Pimozide

Two studies suggest that pimozide attenuates the stimulant effects of amfetamine or dexamfetamine, but in two other studies the effects were inconsistent.

Clinical evidence, mechanism, importance and management

Pimozide, a dopamine antagonist, given in single oral doses of 5, 10 or 20 mg, or repeated doses of 5 mg daily, reduced the euphoriant effects of large (200-mg) intravenous doses of **amfetamine** in subjects with a history of amfetamine abuse. The blood pressure response to amfetamine was also reduced.[1] Similarly, a placebo-controlled study in 8 healthy subjects found that pimozide 2 mg attenuated the stimulant action of **dexamfetamine** 10 mg, but had no effect on dexamfetamine-induced anorexia.[2]

In contrast, in a placebo-controlled study, 10 healthy subjects were given either **dexamfetamine** 10 mg or 20 mg 2 hours after pimozide 1 mg or 2 mg. Pimozide was found to be inconsistent in antagonising the subjective responses to **dexamfetamine**.[3] In a further study by the same authors, pimozide 8 mg did not consistently antagonise the effects of **dexamfetamine**, although pimozide 8 mg alone did produce effects opposite to those of dexamfetamine.[4]

The results are inconsistent, and therefore more study would be beneficial to establish an interaction, and its clinical relevance.

Amfetamines and related drugs + Protease inhibitors

A man taking ritonavir suffered a fatal serotonergic reaction after taking ecstasy (MDMA, methylenedioxymethamfetamine). A similar fatal reaction has occurred with metamfetamine and ritonavir. An isolated case of haemolytic anaemia has been reported in a patient taking indinavir and ecstasy. The effectiveness of antiretroviral therapy has been found to be reduced in users of metamfetamine.

Clinical evidence

(a) Ecstasy (MDMA, Methylenedioxymethamfetamine)

An HIV-positive man taking lamivudine and zidovudine was also given **ritonavir** 600 mg twice daily. About 2 weeks later he went to a club and took ecstasy, in a dose estimated to be about 180 mg. He soon became unwell, and when seen by a nurse in the club, was hypertonic, tachypnoeic (45 breaths per minute), tachycardic (more than 140 bpm), cyanosed and diaphoretic. He had a tonic-clonic seizure, his pulse rose to 200 bpm, he then vomited, had a cardiorespiratory arrest and died. A post mortem showed blood-alcohol levels of 24 mg% and an ecstasy level of 4.56 micrograms/mL, which was almost 10 times greater than might have been expected from the dose he had taken. The authors say that death was consistent with a severe serotonergic reaction.[1] Another report verifies that high ecstasy levels (4.05 micrograms/mL) may result in these life-threatening symptoms.[2]

A patient with AIDS, taking **ritonavir** and **saquinavir**, experienced agitation that lasted for over a day, following a small dose of ecstasy. He then experienced a nearly fatal reaction to a small dose of **sodium oxybate** (**GHB**, **gamma-hydroxybutyrate**, **γ-hydroxybutyrate**), becoming unresponsive within 20 minutes of ingestion of the drug and exhibiting a brief episode of repetitive clonic contractions.[3]

Another HIV-positive man who was well established on HAART (zidovudine, lamivudine and **indinavir**) experienced transient haemolytic anaemia thought to be a toxic reaction to taking three ecstasy tablets, the effects of which may have been potentiated by the indinavir.[4]

(b) Metamfetamine

A 49-year-old HIV-positive man taking protease inhibitors was found dead after injecting himself twice with metamfetamine as well as sniffing **amyl nitrate**. He had been taking an antiretroviral regimen of **ritonavir** 400 mg twice daily, soft gel **saquinavir** 400 mg twice daily and stavudine 40 mg twice daily for 4 months and it was considered that the protease inhibitors may have interacted with the recreational drugs. Toxicology detected metamfetamine 500 nanograms/mL in the blood (considered to be in the fatal range, especially when used with other drugs [unnamed]). Cannabinoids and traces of diazepam and nordiazepam were also found in this patient.[5]

An analysis of 133 patients who were receiving HAART, found that HAART effectively lowered viral loads in *former* metamfetamine users, but not in *active* metamfetamine users.[6]

Mechanism

Ritonavir inhibits the cytochrome P450 isoenzyme CYP2D6, which is responsible for the demethylenation of ecstasy, so concurrent use leads to a sharp rise in ecstasy plasma levels. Metamfetamine is also metabolised by CYP2D6 and its levels would therefore similarly be raised by ritonavir. Poor liver function (due to alcoholism) may have been a contributory factor in one patient,[1] and further inhibition of cytochrome P450 by nitric oxide (the metabolite of amyl nitrate) may have contributed to another case.[5] An additional factor is that ecstasy may show non-linear pharmacokinetics.[7]

It was suggested that the increase in virus load in metamfetamine users receiving HAART might be due to poor adherence or altered metabolism of the antiretroviral medications.[6] Another possible mechanism might be that metamfetamine induces increases in extracellular dopamine, which in turn might activate HIV replication.[8] In addition, metamfetamine use can undermine the general health of the user.[9]

Importance and management

Although there are few reported cases of interactions between amfetamines or related drugs and protease inhibitors, what happens is consistent with the known toxic effects and pharmacology of the drugs concerned. In addition, protease inhibitors may, theoretically, inhibit the metabolism of ecstasy via other isoenzymes (CYP3A4, CYP2B6), which could therefore also lead to increased levels.

It has been suggested that patients who are prescribed any protease inhibitor should be made aware of the potential risks of using any form of recreational drugs metabolised by CYP2D6.[5] In particular, some authors recommend that patients taking ritonavir should avoid using ecstasy and other amfetamines particularly metamfetamine.[10] Open discussions of illicit drug use would enable carers to warn patients that the use of these drugs may be even more dangerous while taking protease inhibitors. Appropriate precautions, apart from avoidance, include a reduction of the usual dose of ecstasy to about 25%, taking breaks from dancing, checking that a medical team are on site, maintaining adequate hydration by avoiding alcohol, and replenishing fluids regularly.[10]

Amfetamines and related drugs + SSRIs

The psychological effects of ecstasy (MDMA, methylenedioxymethamfetamine) may be reduced if citalopram, fluoxetine or paroxetine have previously been given; some physiological effects such as increased heart rate may also be reduced. It seems likely that other SSRIs will also reduce or block some of the effects of ecstasy. There may be an increased risk of serotonin effects and neurotoxic reactions if amfetamines or related drugs are given with SSRIs. Fluoxetine and paroxetine may decrease the metabolism of amfetamines and ecstasy; amfetamine toxicity and phentermine toxicity have been reported.

Clinical evidence

(a) Amfetamines (unspecified or related drugs)

A man who had taken a small, unspecified, but previously tolerated dose of amfetamines developed signs of amfetamine overdosage (restlessness, agitation, hyperventilation, etc.) while taking **fluoxetine** 60 mg daily. Another man taking **fluoxetine** 20 mg daily developed symptoms of schizophrenia after taking two unspecified doses of amfetamines.[1]

A 22-year-old woman who had successfully and uneventfully taken **fluoxetine** 20 mg daily for 3 months, stopped the fluoxetine and then 8 days later took a single 30-mg tablet of **phentermine**. Within a few hours she experienced racing thoughts, stomach cramps, palpitations (pulse 84 bpm), tremors, dry eyes and diffuse hyper-reflexia. The problems had all resolved the following day after she took lorazepam 1.5 mg. The authors of this report suggested that the residual inhibitory effects of the **fluoxetine** on liver cytochrome P450 enzymes led to decreased **phentermine** metabolism, resulting in increased **phentermine** levels and sympathetic hyperstimulation. It is known that **fluoxetine** and its active metabolite have a long half-life and can persist for weeks. The authors also

alternatively wondered whether some of the symptoms might have fitted those of the serotonin syndrome.[2]

(b) Dexamfetamine

A patient who developed serotonin syndrome while taking 'venlafaxine', (p.1478), with dexamfetamine had a second episode when **citalopram** was taken with dexamfetamine.[3]

(c) Ecstasy (MDMA, Methylenedioxymethamfetamine)

A placebo-controlled psychometric study in 16 healthy subjects found that oral ecstasy 1.5 mg/kg produced an emotional state with heightened mood, increased self-confidence and extroversion, moderate derealisation and an intensification of sensory perception. Most of these effects were found to be markedly reduced by pretreatment with intravenous **citalopram** 40 mg, although their duration was prolonged by up to 2 hours.[4] Similarly, a study in 8 ecstasy users found that **fluoxetine** 20 mg daily for at least 5 days attenuated most of the positive subjective effects (e.g. arousal, elation, positive mood, vigour etc.) associated with ecstasy. In addition, heart rate but not blood pressure increases were reduced.[5] Another study found that pretreatment with oral **paroxetine** 20 mg daily for 3 days decreased both the physiological and subjective effects of a single 100-mg oral dose of ecstasy.[6]

A case report describes 2 patients taking **citalopram** 20 mg daily or **paroxetine** 20 mg daily who did not experience any effects from ecstasy after starting the SSRI. One of these patients continued to experience a 'high' from **amfetamines** whilst taking **paroxetine**.[7] However, an account of 4 ecstasy users who had taken **fluoxetine** 20 mg before taking ecstasy 100 to 250 mg, reported that they still experienced the subjective effects of euphoria, but one commented that the overall acute experience was "slightly calmer". Some of the adverse effects such as jaw clenching and insomnia were also attenuated and recovery was more rapid.[8]

When a man taking **citalopram** 60 mg daily also took unknown amounts of ecstasy he became aggressive, agitated, severely grandiose, restless and performed compulsive movements in a peculiar and joyless dance-like manner. He lacked normal movement control and said he could see little bugs. He was treated with haloperidol and chlordiazepoxide, and improved within 2 days of replacing the **citalopram** with promazine.[9]

In a placebo-controlled, randomised study, 7 healthy subjects were given ecstasy 100 mg on the last day of taking **paroxetine** 20 mg daily for 3 days. **Paroxetine** raised the maximum serum levels and AUC of ecstasy by 17% and 27%, respectively.[10] Another study also found that pretreatment with **paroxetine** resulted in similar increases in the maximum plasma levels and AUC of ecstasy (16% and 22%, respectively), and reductions in those of the metabolite, 3-methoxy-4-hydroxymethamfetamine (49% and 38%, respectively).[6]

Mechanism

Complex. It has been suggested that the psychological and neurotoxic effects of ecstasy may be caused by serotonin release in the brain.[8,11] This could potentially be blocked by serotonin reuptake inhibitors (such as citalopram) resulting in reduced ecstasy effects. However, ecstasy is also thought to inhibit serotonin reuptake,[11] so its use with the SSRIs could increase serotonin effects, which could result in neurotoxicity.[12] Other amfetamines also affect catecholamines such as dopamine, noradrenaline and serotonin in the brain, so they have the potential to interact with SSRIs, although they differ in their affinity for these neurotransmitters (for example metamfetamine primarily affects dopamine).[13]

In addition, some SSRIs (to varying degrees) inhibit the cytochrome P450 isoenzyme CYP2D6, by which amfetamine, metamfetamine and ecstasy are metabolised, so concurrent use could result in increased levels of the amfetamine.

Importance and management

The available evidence suggests that patients already taking citalopram, fluoxetine or paroxetine may not be able to get as 'high' on usual doses of ecstasy, and some adverse effects may also be reduced. Furthermore, if the proposed mechanism of interaction is correct, the same is also likely to be true if they are taking any SSRI. Also be aware of possible pharmacokinetic interactions with some SSRIs that are CYP2D6 inhibitors (e.g. fluoxetine, paroxetine), which may increase the levels of ecstasy or possibly other amfetamines. Marked decreases in the effects of these drugs could lead users to take higher doses, which might produce potentially life-threatening toxic effects, especially if plasma levels are raised due to a pharmacokinetic interaction. This interaction has been investigated for its potential to aid amfetamine abstinence,[14,15] but the results have not been promising, and the incidence of adverse effects may be increased.

There may be a risk of increased serotonergic activity with SSRIs and amfetamines, consider *Serotonin syndrome*, under 'Additive or synergistic interactions', (p.9), for further information.

The neurotoxic reactions cited seem to be isolated cases but they illustrate some of the risks attached to using anorectic, stimulant or 'recreational' drugs by patients already taking other medications, particularly antidepressant and psychotropic drugs that affect the same receptors in the CNS. Furthermore, as with the other interactions discussed here, toxic reactions may be more likely if the plasma levels of the amfetamine are increased by the SSRI.

Amfetamines + Topiramate

Topiramate does not affect the haemodynamic response to metamfetamine, although some aspects of metamfetamine-induced positive cognitive performance may be increased and there may be a trend towards increased plasma levels of metamfetamine.

Clinical evidence, mechanism, importance and management

A placebo-controlled study in 10 metamfetamine-dependent subjects found that intravenous **metamfetamine** 15 or 30 mg was associated with increased psychomotor performance and attention. Pretreatment with topiramate 100 or 200 mg orally in two divided doses tended to enhance **metamfetamine**-induced increases in attention and concentration, but decreased perceptual motor function.[1] A further study in the same subjects found that **metamfetamine**-associated increases in haemodynamic response (blood pressure, heart rate) were not significantly affected by pretreatment with topiramate. However, there was a non-significant trend for topiramate to increase plasma **metamfetamine** levels, possibly due to alkalinisation of the urine by topiramate.[2]

These studies were primarily designed to assess the potential use of topiramate in amphetamine abuse. However, they indicate that a clinically significant pharmacokinetic interaction seems unlikely, and that concurrent use does not appear to be associated with any particular adverse effects.

Amfetamines + Urinary acidifiers or alkalinisers

The urinary excretion of amfetamines is increased by urinary acidifiers (ammonium chloride) and reduced by urinary alkalinisers (sodium bicarbonate).

Clinical evidence

A study in 6 healthy subjects given **dexamfetamine** 10 to 15 mg found that when the urine was made alkaline (pH of about 8) by giving **sodium bicarbonate**, only 3% of the original dose of amfetamine was excreted over a 16-hour period, compared with 55% when the urine was made acidic (pH of about 5) by taking **ammonium chloride**.[1] Similar results have been reported elsewhere for **amfetamine**, **dexamfetamine** and **metamfetamine**.[2-5] A further study found that the effects of **amfetamine** were increased and prolonged in subjects with alkaline urine,[6] and psychoses resulting from **amfetamine** retention in patients with alkaline urine have been described.[7]

Mechanism

Amfetamines are bases, which are excreted by the kidneys. If the urine is alkaline most of the drug exists in the unionised form, which is readily reabsorbed by the kidney tubules, so that little is lost. In acid urine, little of the drug is in the unionised form so that little can be reabsorbed and much of it is lost. For more detail on this mechanism, see 'Changes in urinary pH', (p.7).

Importance and management

A well established and well understood interaction but reports of problems in practice seem rare. Nevertheless, there is still the possibility that therapeutic doses of amfetamines may be excreted too rapidly if urinary acidifying agents are given. This interaction has been exploited to increase the clearance of amfetamines in cases of overdose, but although amfetamine excretion is increased, acidification of the urine is believed to increase the risk of acute renal failure if myoglobinuria is present.[8-10]

Care is needed to ensure that amfetamine toxicity does not develop if the urine is made alkaline with sodium bicarbonate or another urinary alkaliniser such as **acetazolamide**, or **sodium phosphate**.[8,10]. Note that sodium bicarbonate may also increase the absorption of amfetamines, by decreasing gastrointestinal acidity, and one manufacturer says that gastrointestinal alkalinising agents such as **antacids** should be avoided with amfetamines.[8]

Amfetamines + Valproate

Valproate appears to attenuate the effects of dexamfetamine on mood changes and blood pressure.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study, healthy subjects were given sodium valproate 500 mg daily for 3 days, then 1 g daily for 11 days followed by a single 25-mg dose of **dexamfetamine**. Pretreatment with valproate was found to significantly attenuate the effects of **dexamfetamine** on mood (happiness, energy, alertness) and attenuated the increases in diastolic blood pressure associated with **dexamfetamine**. The mechanism is uncertain, but may be partly due to the action of valproate on phosphoinositol cycle activity.[1]

The clinical significance of these changes is unclear, but the effects on blood pressure are, if anything, likely to be beneficial. It is unclear whether other amfetamines are affected similarly.

Atomoxetine + Amfetamines

The use of atomoxetine in patients taking amfetamines may lead to adverse effects, such as psychosis and movement disorders.

Clinical evidence, mechanism, importance and management

A 9-year-old boy with attention deficit hyperactivity disorder (ADHD) who had been taking clonidine and amphetamine with dexamfetamine (*Adderall XR*) for several years, developed psychosis, abnormal involuntary movements and insomnia when atomoxetine was added to his treatment.[1]

The authors of the report suggested that the addition of atomoxetine to stable but moderately high doses of stimulant and alpha$_2$-adrenergic agonist medication triggered the symptoms through additive effects on noradrenaline and possibly dopamine. In addition, a pharmacokinetic interaction might have occurred as the cytochrome P450 isoenzyme CYP2D6 is involved in the metabolism of both drugs.[1]

Evidence for an interaction appears to be limited to this isolated case. However, the manufacturer recommends caution when atomoxetine is given concurrently with other drugs that affect noradrenaline, because of the potential for additive or synergistic pharmacological effects.[2] If both drugs are given, be aware that adverse CNS effects may develop, and consider reducing the doses or stopping one of the drugs should this occur.

2. Strattera (Atomoxetine hydrochloride). Eli Lilly and Company Ltd. UK Summary of product characteristics, May 2009.

Atomoxetine + CYP2D6 inhibitors

Paroxetine markedly increases atomoxetine levels in extensive metabolisers of CYP2D6. Fluoxetine also raises atomoxetine levels; there is a possibility that this may increase adverse effects.

Clinical evidence

In one study, 22 healthy subjects who were extensive metabolisers of the cytochrome P450 isoenzyme CYP2D6 (most common phenotype) were given **paroxetine** 20 mg daily for 17 days, with atomoxetine 20 mg twice daily on the last 5 days. **Paroxetine** increased the AUC of atomoxetine 6.5-fold, increased its maximum plasma level by 3.5-fold, and increased its elimination half-life by 2.5-fold, when compared with atomoxetine alone. No changes in paroxetine pharmacokinetics were seen.[1] The pharmacokinetics of atomoxetine with **paroxetine** in these subjects was similar to that previously seen with atomoxetine alone in poor metaboliser subjects.[1,2]

Following a small-scale study in which atomoxetine was given with **fluoxetine** without any adverse effects, 127 children with attention deficit hyperactivity disorder were randomised to receive **fluoxetine** 20 mg daily and 46 to receive placebo. After 3 weeks atomoxetine (starting at 0.5 mg/kg daily, increasing over 5 weeks to a maximum of 1.8 mg/kg daily) was also given to both groups. The **fluoxetine** group had 3.3-fold higher peak atomoxetine levels than the placebo group. However, despite a trend towards a greater incidence of decreased appetite with the combination (20% versus 6.8%), there was no significant difference in adverse events between the two groups.[3]

Mechanism

Atomoxetine is extensively metabolised by the cytochrome P450 isoenzyme CYP2D6,[4] an isoenzyme that shows polymorphism, with up to 10%

of the population lacking an active form (poor metabolisers). Paroxetine inhibits CYP2D6, and thereby increases atomoxetine levels in those with an extensive metaboliser phenotype. It would not be expected to have any effect in poor metabolisers. Fluoxetine can similarly inhibit CYP2D6.

Importance and management

An established pharmacokinetic interaction. Paroxetine effectively changes patients from an extensive metaboliser phenotype to a poor metaboliser phenotype, markedly raising atomoxetine levels. Although the clinical relevance of this effect has not been directly assessed, the manufacturer notes that some adverse effects of atomoxetine were up to twice as frequent in poor metaboliser patients in clinical studies.[2] Both manufacturers suggest that, in patients already taking CYP2D6 inhibitors, dose adjustment and slower titration of atomoxetine may be necessary,[2,5] with the dose increased only if symptoms fail to improve and if the initial dose is well tolerated.[2] This seems a sensible precaution. Note that in the fluoxetine study, which found that the concurrent use of atomoxetine was generally well tolerated, dosage increases were made on a weekly basis, from 0.5 mg/kg to 0.8 mg/kg and then 1.2 mg/kg daily at the start of the third week.[3] The US manufacturer suggests a starting dose of atomoxetine 0.5 mg/kg daily (40 mg per day in those over 70 kg) and only increasing the dose to 1.2 mg/kg daily (or 80 mg per day) if symptoms fail to improve after 4 weeks and the initial dose is well tolerated.[2] The UK manufacturers say that the initial dose should be maintained for a minimum of 7 days before increasing it, if necessary.[5]

It would also seem prudent to be alert to the possibility of an increase in adverse effects if CYP2D6 inhibitors are added to established atomoxetine treatment, and the manufacturers specifically name fluoxetine, paroxetine, **quinidine**,[2,5] and **terbinafine**.[5] If one of these drugs is given they suggest that the clinical response and tolerability should be re-evaluated and a dose adjustment may be necessary.[5] For a list of inhibitors of CYP2D6, see 'Table 1.3', (p.6).

Extra caution may be prudent with this combination in those with epilepsy, as both atomoxetine and SSRIs may lower the seizure threshold, and this risk appears to be increased by higher atomoxetine levels.[2] Patients may also be more at risk of QT interval prolongation when atomoxetine is given with CYP2D6 inhibitors, see *Drugs that prolong the QT interval*, under 'Atomoxetine + Miscellaneous', below.

Atomoxetine + Miscellaneous

The manufacturer of atomoxetine contraindicates the concurrent use of MAOIs. Atomoxetine is predicted to have additive effects with pressor drugs and other sympathomimetics and has been seen to potentiate the increase in heart rate and blood pressure caused by intravenous salbutamol. However, no increase in cardiovascular effects was seen when atomoxetine was given with methylphenidate. Atomoxetine also has the potential for an interaction with drugs that prolong the QT interval and drugs that lower the seizure threshold.

Atomoxetine does not alter desipramine or midazolam pharmacokinetics and would therefore not be expected to affect other substrates of CYP2D6 or CYP3A4. Antacids and omeprazole do not alter atomoxetine bioavailability.

Clinical evidence, mechanism, importance and management

(a) Antacids or Omeprazole

In a study in 20 subjects, **aluminium**/**magnesium hydroxide** (*Maalox*) and omeprazole did not affect the bioavailability of atomoxetine 40 mg.[1] No special precautions appear to be necessary on concurrent use.

(b) CYP2D6 substrates

In a study[2] in 21 subjects who were extensive metabolisers of CYP2D6 (most common phenotype), atomoxetine 40 or 60 mg twice daily for 13 days had no effect on the pharmacokinetics of a single 50-mg dose of **desipramine** given on day 4.

Desipramine is extensively metabolised by CYP2D6, and can be used as a probe drug for the assessment of the effect of drugs on this isoenzyme in extensive metabolisers (see 'Genetic factors', (p.4)). It was concluded that atomoxetine, even at the maximum recommended dose, does not cause clinically relevant inhibition of CYP2D6 *in vivo*, and so will not affect the pharmacokinetics of other CYP2D6 substrates.[2] For a list of CYP2D6 substrates, see 'Table 1.3', (p.6).

(c) CYP3A4 substrates

Atomoxetine 60 mg twice daily for 12 days was given to 6 subjects who were poor metabolisers of CYP2D6, with a single 5-mg oral dose of **midazolam** on days 6 and 12. Atomoxetine increased the maximum level and AUC of midazolam by about 16%, which was not statistically or clinically significant.[2]

Midazolam is extensively metabolised by CYP3A4, and can be used as a probe drug for assessment of the effect of drugs on this isoenzyme. Poor metabolisers of CYP2D6 were chosen for this study, because they have much higher levels of atomoxetine than extensive metabolisers of CYP2D6. It was concluded that atomoxetine, even at the maximum recommended dose, does not cause clinically relevant inhibition of CYP3A4 *in vivo*, and so will not affect the pharmacokinetics of other CYP3A4 substrates.[2] For a list of CYP3A4 substrates, see 'Table 1.4', (p.6).

(d) Drugs that lower the seizure threshold

Seizures are a potential risk with atomoxetine and caution is advised if drugs that lower the seizure threshold (such as **antidepressants**, **antipsychotics**, **mefloquine**, **bupropion**, or **tramadol**) are given concurrently.[3]

(e) Drugs that prolong the QT interval

There is potential for an increased risk of QT interval prolongation[3] when atomoxetine is given with other QT prolonging drugs (such as **antipsychotics**, class Ia and class III **antiarrhythmics**, **moxifloxacin**, **erythromycin**, **methadone**, **mefloquine**, **tricyclic antidepressants**, **lithium** or **cisapride**), drugs that cause electrolyte imbalance (such as **thiazide diuretics**), and drugs that inhibit CYP2D6 (see 'Atomoxetine + CYP2D6 inhibitors', p.225).

(f) MAOIs

The manufacturer contraindicates the concurrent use of atomoxetine with MAOIs, or within 2 weeks of stopping an MAOI,[3,4] because other drugs that affect brain monoamine levels have caused serious reactions (including symptoms of serotonin syndrome or symptoms similar to neuroleptic malignant syndrome) when taken with MAOIs.[4]

(g) Methylphenidate

In a placebo-controlled, crossover study, 12 healthy subjects were given atomoxetine 60 mg twice daily or methylphenidate 60 mg daily for 5 days, with the other drug added for the final 2 days. No additional changes in blood pressure or heart rate were seen when the drugs were given together, and concurrent use did not increase the frequency of adverse effects.[5]

(h) Pressor drugs

Atomoxetine is a sympathomimetic that acts as a noradrenaline reuptake inhibitor. As such, it causes a modest increase in pulse and/or blood pressure in many patients.[3,4] The manufacturer recommends caution if atomoxetine is given concurrently with pressor drugs (e.g. **dopamine**, **dobutamine**)[4] because of the possible additive effects on blood pressure.[3,4]

(i) Salbutamol (Albuterol)

The manufacturer notes that atomoxetine 60 mg twice daily for 5 days potentiated the increase in heart rate and blood pressure caused by an infusion of salbutamol 600 micrograms, given over 2 hours.[4] Because of this, they recommend caution when atomoxetine is used in patients receiving intravenous or oral salbutamol or other beta$_2$ agonists[3,4] (for a list, see 'Table 34.1', (p.1414)). The UK manufacturer also extends this precaution to high-dose nebulised salbutamol.[3] However, the effects on heart rate and blood pressure were not seen in another study when 21 healthy Asian subjects, who were extensive CYP2D6 metabolisers, were given salbutamol 200 to 800 micrograms daily with atomoxetine 80 mg daily, for 5 days.[4]

(j) Miscellaneous

The manufacturer recommends caution when atomoxetine is given concurrently with other drugs that affect noradrenaline, because of the potential for additive or synergistic pharmacological effects. They name antidepressants such as **imipramine**, **mirtazapine** and venlafaxine, and the decongestants **pseudoephedrine** or **phenylephrine**.[3] This would seem a sensible precaution, particularly as neurological complications have been reported in one patient given atomoxetine and 'venlafaxine', (p.1477) and a child given atomoxetine and 'dexamfetamine', (p.225).

Dexfenfluramine or Fenfluramine + Anorectics

Fenfluramine and dexfenfluramine have generally been withdrawn worldwide because of the occurrence of serious and sometimes fatal valvular heart disease and pulmonary hypertension, which occurred when they were taken alone and when combined with phentermine. Some herbal preparations may, however, still contain fenfluramine and related drugs. There is an isolated case of cardiomyopathy attributed to the use of fenfluramine with mazindol.

Clinical evidence, mechanism, importance and management

Fenfluramine and dexfenfluramine have generally been withdrawn worldwide because of the occurrence of serious and sometimes fatal valvular heart disease (aortic, mitral, tricuspid or mixed valve disease). Pulmonary hypertension has also sometimes been seen. These serious adverse effects occurred when these drugs were taken alone, and when combined with phentermine as *Fen-phen* and *Dexfen-phen*, but not with phentermine alone.[1-6] There is also an isolated case of cardiomyopathy attributed to the use of fenfluramine with mazindol.[7] Before the withdrawal of the drug from the market, the manufacturer of fenfluramine recommended that concurrent use with other centrally-acting anorectics should be avoided.[8]

Note that some unlicensed traditional Chinese medicines have been found to contain **nitrosofenfluramine** (known to be toxic to the liver) and fenfluramine. Reports suggest that other products for weight loss may also contain undeclared fenfluramine and nitrosofenfluramine.[9]
